The region of major interest with regard to solute penetration into the phreatic aquifer is the capillary fringe, which incorporates water subject to pressure below the atmospheric pressure. Due to the capillary forces, water in the capillary fringe is almost stagnant, and does not take part in groundwater horizontal flow. The groundwater table is defined as the level of atmospheric pressure. Therefore, as shown in Figure 5, the water level in a well represents the groundwater table. The contaminant usually migrates as a solute with water that infiltrates, as a wetting front through the vadoze zone. During this process, and mainly in the capillary fringe, where water residual saturation is comparatively high, the infiltrating water is subject to mixing with the residual water saturation and redistribution of contaminant concentrations takes place. This mixing is associated with local reduction of the capillary effect and migration of water with pollutants into the aquifer. However, all these processes may significantly increase the pollutant concentration in the capillary fringe. Here, the effect of groundwater table fluctuation may play an important role in preserving the contamination of the capillary fringe at levels similar to those of the aquifer. However, if such fluctuations are minor, then the capillary fringe may be subject to significantly higher pollutant concentrations than those typical of the aquifer.

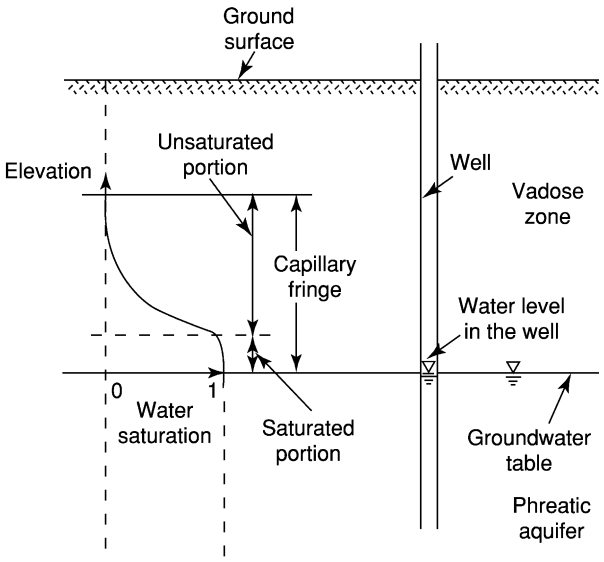

Figure 5 Water saturation distribution in the phreatic aquifer and the vadose zone.

Pollutant Transport in the Aquifer

Pollutants that penetrate through the capillary fringe, due to a wetting-front movement or due to groundwater table fluctuations, are subject to transport in the aquifer. The evaluation of pollutant transport in groundwater incorporates at least two basic differential equations, the equation of groundwater flow, namely Darcy law, and the diffusion–advection equation:

$$\mathbf{q} = \mathbf{K} \cdot \mathbf{J} \qquad [3]$$

$$\frac{\partial C}{\partial t} + \mathbf{V} \cdot \nabla C = \nabla \cdot (\mathbf{D_h} \cdot \nabla C) - R \qquad [4]$$

where $\mathbf{q}$ is the specific discharge vector (Darcy velocity), $\mathbf{K}$ is the hydraulic conductivity tensor (which depends on the permeability and kinematic viscosity of the fluid, namely water), $\mathbf{J}$ is the gradient of the piezometric head, C is the pollutant concentration, $\mathbf{V}$ is the interstitial velocity (the specific discharge divided by the effective porosity), $\mathbf{D_h}$ is the hydrodynamic dispersion tensor (it incorporates effects of diffusion and tortuosity of streamlines), which depends on $\mathbf{V}$ and properties of the permeable domain, and R represents possible chemical reactions (such as adsorption and decay).

In cases of isotropic porous media and fluid of constant density (no density stratification is significant), the hydraulic conductivity is a scalar quantity. Then eqn [3] represents the specific discharge as a vector originating from the gradient of the piezometric head, which is a scalar quantity. Therefore, all approaches and techniques used for the solution of potential flow problems are also applicable to the description of flow phenomena taking place in the aquifer. However, usually in groundwater flow, the streamlines are almost horizontal, and in such cases the Dupuit approximation can be applied.

According to the Dupuit approximation, lines of constant piezometric head (equipotential lines) are vertical. If pollutants have minor effect on the fluid density, the solution of eqns [3] and [4] can be done in a series. This means that after solving the flow with eqn [3] and obtaining a complete description of the streamlines and velocity distribution in the domain, these results are used as an input for the solution of eqn [4]. If the pollutant concentration is comparatively high, then density stratification might be significant, and therefore the velocity and pollutant distributions in the domain should be obtained simultaneously by the simultaneous solution of eqns [3] and [4]. Such cases are typical of saltwater intrusion into aquifers. The solution of eqn [3] is often obtained by analytical means, provided that density stratifications are minor. On the other hand, in most practical cases the solution of eqn [4], under all types of fluid-density distribution in the domain, usually requires the employment of numerical approaches. Only a limited number of analytical solutions to this equation have been developed. However, various methods can be used to obtain approximate first-order descriptions of pollutant transport in the aquifer. **Figure 6** provides a schematic description of the buildup of the contaminant plume at the pollutant penetration site. In some cases, the buildup of this plume can be evaluated by using the approximate approach of boundary layer methods.

It should be noted eqns [3] and [4] refer to an unconsolidated permeable material and a single type of pollutant. If several pollutants are involved, then each pollutant has to be referred to by a particular use of its contaminant transport equation, subject to its particular set of initial and boundary conditions. In some cases also considerations of possible chemical reactions that might occur between the different pollutants have to be taken into account.

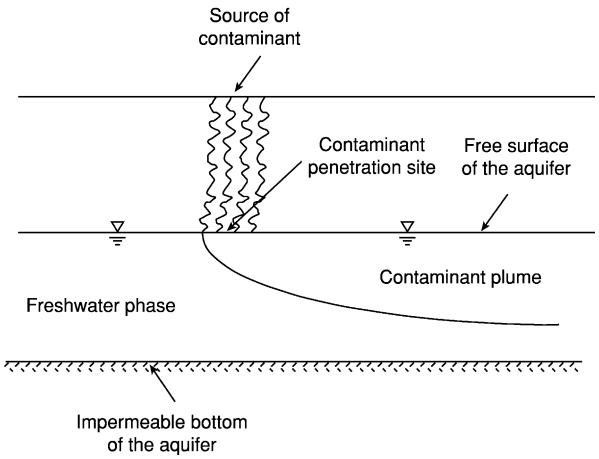

Figure 6 Buildup of a contaminant plume at a contaminant penetration site. Reproduced from Rubin H and Buddemeier RW (2002) Groundwater contamination downstream of a contaminant penetration site. 1. Extension-expansion of the contaminant plume. *Journal of Environmental Science and Health* A37(10): 1781–1812.

Two major issues that are intimately connected should be noted in connection with the appropriate evaluation of pollutant transport in aquifers: (1) upscaling, namely the relevance of phenomena observed on a small scale, such as in a laboratory, to those predicted at the large field scale; and (2) the effect of the aquifer formation heterogeneity on pollutant transport. Physical quantities characterizing groundwater flow through the aquifer are very little affected by the formation heterogeneity, and flow calculations can be done by using the continuum approach, which leads to eqn [3]. With regard to pollutant transport in groundwater, issues of upscaling and aquifer heterogeneity may impose very serious problems on the simple use of the continuum approach, which leads to eqn [4]. Therefore, a variety of approaches, such as double porosity approximation, and statistical presentation of the medium characteristics and transport parameters are very often used by scientists and engineers.

Contamination of Groundwater by NAPLS

Since the mid-1980s, much attention has been directed toward the evaluation of groundwater contamination by nonaqueous-phase liquids (NAPLs). This high level of attention has originated from the realization of how common cases of groundwater contamination by NAPLs are, and how many risks to human health and the environment are associated with such a contamination. The term 'NAPL' has substituted the previous term 'immiscible fluids.' This change indicates that, although the miscibility of these fluids in water is very low (in the order of magnitude of parts per million, ppm), such concentrations in water avoid its safe use by human populations, and they also introduce high risks to the environment. 'NAPL' usually represents an organic liquid-phase material. Such a liquid is very often comprised of a mixture of many organic compounds used for a specific task, e.g., fossil fuels that are employed in driving internal combustion engines, or creosote that is used for treating wood in the wood industry. Various types of chlorinated hydrocarbons are NAPLs used for medical purposes, e.g., chloroform, or for degreasing purposes by the steel industry, e.g., trichloroethylene.

Generally, two types of NAPLs are identified: (1) light NAPLs (LNAPLs), whose density is lower than that of water; and (2) dense NAPLs (DNAPLs),

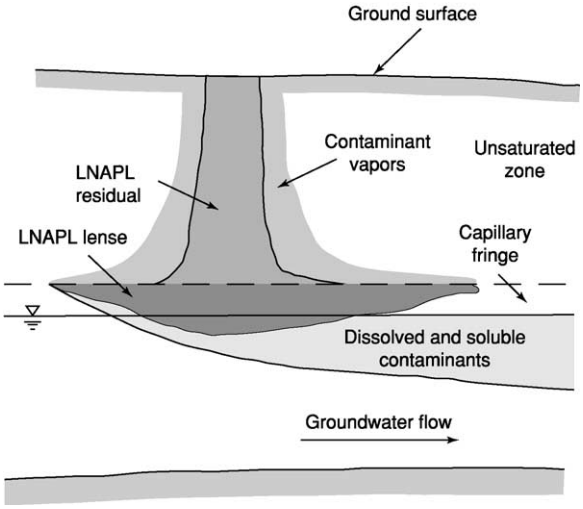

Figure 7 Contamination of the vadose zone and the phreatic aquifer by light nonaqueous-phase liquids (LNAPL). Reproduced with permission from Rubin H, Narkis N, Carberry JB (1998) Overview of NAPL contamination and reclamation. Springer-Verlag: Berlin, Heidelberg, New York. © Springer-Verlag.

whose density is higher than that of water. This classification is extremely important for the evaluation of NAPL penetration into the aquifer, and its migration with the flowing groundwater. Figures 7 and 8 provide schematic descriptions referring to LNAPL and DNAPL contamination, respectively.

After the release of the NAPL (LNAPL or DNAPL) at the ground surface, it migrates downward within the vadose zone with limited lateral expansion. During the downward migration, the NAPL plume is subject to partial entrapment and the release of some vapors of volatile compounds into the gaseous phase of the vadose zone. Differences between LNAPL and DNAPL contamination take place after the arrival of the contaminant plume at the capillary fringe and the groundwater table.

As shown in Figure 7, at the groundwater table, the LNAPL plume spreads horizontally and creates a lens that floats on top of the groundwater table. If the LNAPL plume originates from the release of a limited and small quantity of NAPL, then possibly the entire mass of NAPL is completely entrapped in the vadose zone without its arrival at the groundwater table. If the released quantity is limited but incorporates a significant volume, then the scenario of migrating LNAPL ends with its complete entrapment within the vadose zone and the floating LNAPL lens on top of the groundwater table.

As shown in Figure 8, after its arrival at the groundwater table, the DNAPL plume penetrates into the aquifer and keeps its downward migration. This process is associated with DNAPL entrapment within the phreatic aquifer. If quantities of released DNAPL are large, then the scenario of DNAPL migration ends with complete entrapment of the released DNAPL in the vadose zone, in the phreatic aquifer, and even possible accumulation of the DNAPL in a pool, at the bottom of the aquifer (or on top of impermeable soil lenses that might be located within the phreatic aquifer).

Scenarios of the NAPL migration in the vadose zone and the phreatic aquifer can be evaluated by using numerical models originating from reference to multiphase flow in porous media. Such models have been used for many years by the oil industry, and have been adapted for the quantification of the environmental issues represented by Figures 7 and 8. In the vadose zone, calculations refer to the solid phase and three fluid phases (gaseous, water, and NAPL). In the aquifer, reference is made to the solid phase and two fluid phases (water and NAPL). The mathematical model of multiphase flow in porous media is generally formulated as:

$$\epsilon_\alpha \rho^\alpha \frac{\partial \omega_{\mathrm{i}}^\alpha}{\partial t} + \rho^\alpha \mathbf{q}^\alpha \nabla \omega_{\mathrm{i}}^\alpha - \nabla \cdot (\epsilon_\alpha \rho^\alpha \mathbf{D}_{\mathrm{h_i}}^\alpha \cdot \nabla \omega_{\mathrm{i}}^\alpha) = \sum_{\beta \neq \alpha} E_{\mathrm{i}}^{\alpha\beta} - \omega_{\mathrm{i}}^\alpha E^\alpha \qquad [5]$$

which is subject to the two following constraints:

$$\sum_{i} \omega_i^{\alpha} = 1; \quad \sum_{\alpha} \epsilon_{\alpha} = 1 \qquad [6]$$

where ϵ_α is the volume fraction of the α phase, ω_i^α is the mass fraction of component i in the α phase, $\mathbf{D}_{h_i}^{\alpha}$ is the hydrodynamic dispersion tensor of the α phase, $\mathbf{q}^\alpha$ is the specific discharge of the α phase, ρ^α is the density of the α phase, and $E_i^{\alpha\beta}$ represents exchange of mass of component i between the α and β phases.

Equation [5] refers to each component i (of the total number of relevant compounds), that may comprise portions of the α and β phases (solid skeleton, water, gaseous phase, and NAPL). Besides eqns [5] and [6], some constitutive relationships should be applied to calculate the propagation of each fluid phase and specific species in the domain.

However, as implied by preceding paragraphs, scenarios of multiphase flow involved in contamination of the vadose zone and the phreatic aquifer usually take place for a limited time, until all quantities of the NAPL are entrapped within the porous medium; then the only mobile fluid phase present in the aquifer is water. Under such conditions the effect of the immobile, entrapped NAPL on flow parameters of groundwater are represented by the decrease in the water saturation and the reduced permeability of the formation. These effects lead to the following modified Darcy law:

$$\mathbf{q} = \nabla \cdot \left[g\left(\mathbf{k} \frac{k_{rw}}{\nu} \right) \cdot \mathbf{J} \right] \qquad [7]$$

where g is the gravitational acceleration, $\mathbf{k}$ is the permeability tensor, k_{rw} is the relative water permeability (which depends on the water saturation), and ν is the kinematic viscosity of the water.

The modified diffusion–advection equation, which is applied to simulation of dissolved constituents transport with the flowing groundwater, is given by:

$$\phi S_w \frac{\partial C}{\partial t} + \mathbf{q} \cdot \nabla C = \nabla \cdot (\phi S_w \mathbf{D}_h \cdot \nabla C) + R + E^{wn} \qquad [8]$$

where ϕ is the porosity, S_w is the water saturation and E^{wn} represents interphase mass transfer, namely mass transfer from the entrapped NAPL into the flowing water phase, due to NAPL dissolution.

The chemical reaction term, R, of eqn [8] is mainly attributed to adsorption and desorption, as well as biological degradation of the organic compound that is used as a substrate for the development of the biomass. The interphase mass transfer term, E^{wn}, of eqn [8] is considered as the major contributor to groundwater contamination due to the presence of the entrapped NAPL in the aquifer. It can also be useful for aquifer cleanup procedures such as pump-and-treat.

Most cases of NAPL contamination in aquifers are attributed to petroleum hydrocarbons, namely fossil fuels. Obviously this phenomenon originates from the widespread use of these types of NAPLs. However, most types of olefins that incorporate the major compounds of fossil fuels do not impose high risks on the environment. Fossil fuel compounds of high risks include various fuel additives and BTEX (benzene, toluene, ethylbenzene, and xylene). Due to the widespread use of fossil fuels, entrapment of LNAPL in the vadose zone and aquifers is a quite common phenomenon. Usually, such an entrapment with comparatively high residual NAPL saturation is limited to the top layers of the aquifer and regions of the capillary fringe. Therefore, the entrapped LNAPL supplies dissolve constituents into the flowing groundwater, as well as volatile organic compounds into the gaseous phase of the vadose zone.

DNAPL contamination of groundwater is less common than LNAPL contamination, and entrapment of DNAPL in aquifers is quite rare. However, the constituents of DNAPLs are usually chlorinated hydrocarbons, which pose a high risk to human health and the environment. Their threshold concentrations are of minute values, of the order of magnitude of several parts per billion. Therefore, the penetration of water solution, which incorporates several parts per million of these compounds, into groundwater may cause a very significant contamination of the aquifer. Furthermore, the chlorinated hydrocarbons are volatile organic compounds (VOCs). The migration of such compounds with groundwater may be associated with the release of poisonous vapors into the vadose zone. Such a phenomenon is somehow mitigated by the immobile water saturation of the capillary fringe. But intensive fluctuations of the groundwater table may significantly reduce the efficiency of this vapor barrier.

Summary

There is an intimate connection between the pollution of groundwater and the vadose zone. Special attention is given here to calculations of overall mass budgets and flux balance of pollutants for the evaluation of phreatic aquifer contamination due to its use as a source of water for human populations. When water shortage becomes a significant barrier for the development of various societies, it is appropriate to evaluate efficient approaches of increasing the number of water resources and avoiding the deterioration of groundwater quality.

Various methods and means are used for the evaluation of the fate of constituents that are dissolved in water and subject to transport with the water cycle, leading to groundwater pollution. The classification of NAPLs to LNAPLs and DNAPLs is extremely important, as these two types of NAPL have different phenomenological effects on the pollutant penetration into the aquifer. There are also significant differences between their potential risk to human health and the environment, their physical properties, rate of biodegradation, and the possible source of organic contaminants in the liquid and vapor phase in the vadose zone.

List of Technical Nomenclature

α, β	indices referring to the particular fluid phase (water, gas, NAPL)
ΔC	difference between final and initial concentration ($kg\,m^{-3}$)
ΔC_0	pollutant accumulated within Q_{nr} in the natural environment ($kg\,m^{-3}$)
ΔC_1	pollutant accumulated within infiltrating water in the vadose zone ($kg\,m^{-3}$)
ΔC_2	pollutant accumulated within complete water-recycling ($kg\,m^{-3}$)
ΔC_3	pollutant accumulated within Q_{nr} by activities of the human population ($kg\,m^{-3}$)
ΔC_4	pollutant accumulated within wastewater released into seas and oceans ($kg\,m^{-3}$)
ϵ	volume fraction
ν	kinematic viscosity ($m^2\,s^{-1}$)
ρ	density ($kg\,m^{-3}$)
φ	porosity
ω	mass fraction
C	pollutant concentration ($kg\,m^{-3}$)
C_0	initial pollutant concentration ($kg\,m^{-3}$)
C_∞	final pollutant concentration ($kg\,m^{-3}$)
E	rate of pollutant interphase transfer ($kg\,m^{-3}\,s^{-1}$)
$\mathbf{D_h}$	hydrodynamic dispersion tensor ($m^2\,s^{-1}$)
$\mathbf{K}$	hydraulic conductivity tensor ($m\,s^{-1}$)
$\mathbf{k}$	permeability tensor (m^2)
k_{rw}	relative soil permeability for water
Q_{ev}	rate of evapotranspiration involved with all types of irrigation ($m^3\,s^{-1}$)
Q_{ev1}	rate of evapotranspiration involved with regular irrigation ($m^3\,s^{-1}$)
Q_{ev2}	rate of evapotranspiration involved with wastewater-recycling irrigation ($m^3\,s^{-1}$)
Q_{hs}	rate of water consumption by the human population ($m^3\,s^{-1}$)
Q_{ir}	rate of water used for regular irrigation ($m^3\,s^{-1}$)
Q_{nr}	rate of water supply into the aquifer by natural recharge ($m^3\,s^{-1}$)
Q_{rc}	rate of water used for irrigation with recycled wastewater ($m^3\,s^{-1}$)
Q_{so}	rate of water supplied by the aquifer into seas and oceans ($m^3\,s^{-1}$)
R	rate of pollutant formation and/or disappearance by chemical reactions ($kg\,m^{-3}\,s^{-1}$)
S_w	water saturation
t	time (s)
W	volume of the aquifer (m^3)

Introduction

The term 'pollution' is often used, but seldom defined. A search of the literature reveals that it is often used synonymously with the term 'contamination.' Is there a distinction between pollutants and contaminants? For example, the US Environmental Protection Agency (EPA) defines pollution as "Generally, the presence of a substance in the environment that because of its chemical composition or quantity prevents the functioning of natural processes and produces undesirable environmental and health effects." Under the US Clean Water Act, pollution has been defined as the man-made or man-induced alteration of the physical, biological, chemical, and radiological integrity of water and other media. The word 'integrity' again seems to infer some harm has occurred. However, the US EPA also gives a definition of the term 'contamination' as "Introduction of microorganisms, chemicals, toxic substances, wastes, or wastewater in a concentration that makes the medium unfit for its next intended use." Once more, some damage is inferred, but here microorganisms are specified in addition to chemicals. It would be useful if microorganisms or presence and absence of harm gave a distinction between these terms, but many of the published definitions and recent usage show they are in fact considered synonymous. So although a few authors have tried to distinguish between pollution and contamination, here, the focus will be on the addition of chemical substances to soil that affect its use or affect other parts of the environment through soil.

Time and rate of addition of a substance to soil are important, as substances can be degraded, leached, or volatilized, thereby being removed from soils. Soils can immobilize pollutants, and it is only when the inputs far outweigh these loss pathways that the soil itself will become polluted. Of course, soils may in turn become the source of a pollutant rather than a sink when losses to water or volatilization take place. Another important concept relating to which chemicals become pollutants in soil is the idea of residence time. Because some potential pollutants arriving in soils can be rapidly degraded, leached, or volatilized, they may never become a serious problem. Examples would be some of the easily degraded organic compounds, which disappear quickly, but on the other hand some recalcitrant organic and inorganic pollutants build up in soil because there is little loss by any pathway.

The importance or magnitude of pollution depends on factors such as the rate of addition of the pollutants per unit area. Each route or pathway that pollutants follow to reach a site needs to be summed. Pathways may include wastewater from industry, solid wastes, emission to the air and subsequent deposition, and leaks and spills (Figure 1). Concentrations and total loads in the pathways minus the loss rates due to the processes mentioned above and

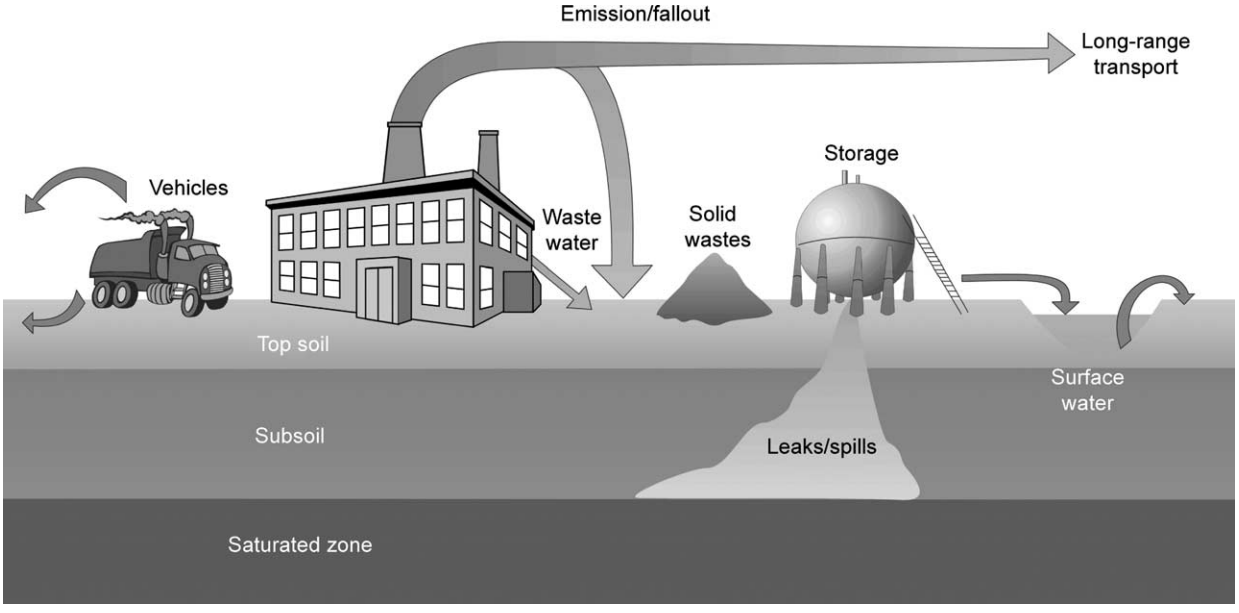

Figure 1 Pathways of industrial pollutants in the soil environment.

Table 1 Estimated number of contaminated sites in Europe and the United States

Country	*Contaminated sites (estimate of total)*	*Contaminated sites (in critical condition)*
Austria	3300	–
Belgium	8300	2000
Denmark	20 000	3600
Germany	>100 000	10 000
Italy	5600	2600
Netherlands	110 000	4000
European Union	1500 000	300 000
Norway	25 000	–
United Kingdom	100 000	–
United States	37 600[a]	>1300[b]

[a]Reported to the US EPA in 1993.
[b]National priority list ('Superfund sites').

time of exposure all affect the buildup of the pollution and hence its importance.

Because of the difficulty of determining whether sites are polluted, there are only estimates in relatively few countries of the extent of what is normally referred to as 'contaminated land' (Table 1). For example, in the UK it is estimated that 300 000 ha of land are affected to some extent by contamination left by industrial activities. In the European Union 300 000 sites have already been identified as potentially or definitely contaminated, and the best estimate is that there are 1.5 million contaminated areas.

Excluding pesticides and radionuclides, the most common pollutants found at US Superfund sites include: acetone, arsenic, barium, benzene, 2-butanone, cadmium, carbon tetrachloride, chloroform, chromium, cyanide, 1,1-dichloroethene, 1,2-dichloroethane, lead, mercury, methylene chloride, napthalene, nickel, pentachlorophenol, polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons, tetrachloroethylene, toluene, trichloroethylene, vinyl chloride, xylene, and zinc. Common radionuclides at Superfund sites are: americium-241, cesium-137, cobalt-60, iodine, plutonium, radium, radon, strontium, technetium-99, thorium, tritium, and uranium.

Origins of Industrial Pollution

Many different industries and processes emit pollutants into the environment. Use of agricultural chemicals, such as nitrate, and pesticides will not be discussed here. Activities that are nonprimary or 'commercial' also result in emissions and pollution of soil, examples being transport and dredging of waterways, where pollutants are often deposited on the sides and banks of roads or along the banks of rivers. Industrial emissions may also move through air or water to sewage-treatment facilities, where they are often concentrated in the sewage sludge solids that are frequently utilized on land (*See* **Waste Disposal on Land:** Municipal). However, there are also domestic inputs of some pollutants to sewage.

The European Environment Agency considers that most cases of soil contamination arise from the following industries: chemicals, metals, energy, mining, oil, electronics, glass, ceramics, stone, textile, leather, wood, paper, food, trade, and traffic. Some of the activities likely to cause pollution of soils are shown in Table 2. Some of these arise from point sources such as factories, smelters, waste pipes, ditches, or mines. These are stationary sources and may be small or large. One feature of point sources is that the concentrations of pollutants can be high and may build up rapidly. They may also fall off rapidly with distance from the source. Nonpoint sources of pollution are not easily associated with or as regulated as point sources and normally originate from such activities as agricultural practices, urban runoff, and transportation.

Types of Pollutant

Many thousands of pollutants have been dispersed in the environment by human activities, some for a long time. They are broadly classified as inorganic and organic pollutants. However, depending on the source and other local emissions, multiple or 'copollution' of soils may occur. An example would be the land around a factory that used multiple chemicals in its processes or land that has been used by different industries over time.

Table 2 Activities likely to cause pollution in soils

Activity	*Examples*	*Likely inorganic pollutants*	*Likely organic pollutants*
Mineral extraction/processing			
Coal	Deep or open cast mines, crushing	Acidity, pyrites, sulfur	Dust
Metals	Ferrous and nonferrous, deep or open cast, crushing, waste lagoons	All metals and associated anions	
Other minerals	Asbestos, chalk, china clay, gypsum	Sulfides, sulfates	
Waste disposal			
Municipal	Domestic waste, sewage sludge	Many, including leachates	Many, including leachates
Industrial	Unused raw materials, by-products, spent catalysts	Many, including leachates	Many, including leachates
Industries			
Brick works		Fluoride, sulfur dioxide	
Chemical works	Battery, electronics, and pigments manufacture, electroplating	Acidity, alkalinity, As, asbestos, Cd, Cr, Cu, cyanide, Pb, Hg, Ni, sulfate, Zn	Dioxins, halogenated hydrocarbons, pesticides, phenols, PCBs, solvents
Gasworks	Coal gasification	Sulfur, cyanides	Phenols, tar, PAHs
Iron and steel	Blast furnaces	Metal wastes, iron and steel slag	
Nonferrous smelting/ processing	Lead, zinc, copper smelters	Pb, Zn, Cu, Hg, Cd, Ni, acidity	
Oil refineries	Petroleum production	Lead compounds	Tar, oils, phenols, sulfate
Power generation	Coal, gas, nuclear plant	Fuel ash, fly ash, various radionuclides	PCBs, PAHs
Recycling/scrap	Batteries, cars, domestic appliances	Acidity, asbestos, Pb, Ni, Cd	Oils, paint, phenols, PCBs
Sewage treatment	Various processes	Metals, phosphate	Various
Tanneries		Chromium	Dyes
Military bases			
Air/army/navy bases	Munitions, anticorrosion or antifouling chemicals, preservatives	Various	Various, fuels
Defense establishments		Various	Various
Firing ranges		Pb, various	Various
Transportation			
Airports	Runoff, workshops		Fuel, oil, deicing compounds
Canals, waterways, docks	Dredged sediments, dumped waste	Acidity, alkalinity, antifouling compounds, metal wastes	Contaminated sediments
Railways	Railways, borders and sidings/yards	Metal wastes, asbestos	Oil, paint
Roads	Borders, central reservation, runoff areas	Pb, Cd, Zn	PAHs
Energy supply			
Pipelines	Oil pipelines		Oil leaks
Electricity supply network	Cables and towers, substations, transformers	Zn, Cu	PCBs
Oil/petroleum storage		Pb	Tar, petroleum, oils, phenols

PCBs, polychlorinated biphenyls; PAHs, polycyclic aromatic hydrocarbons.

Inorganic Pollutants

Materials that are not based on carbon compounds are termed 'inorganic pollutants.' It is important to realize that some elements are in fact essential nutrients required by organisms, and that they can be deficient in some soils or diets; examples include Zn, B, Cu, Se. A consequence of this is that additions of nutrients will at first be beneficial for the growth and reproduction of organisms. It is only when they become excessive that negative impacts will occur.

This typically occurs because the soil's ability to hold these substances is overwhelmed, along with the ability of the organisms in the ecosystem to cope with the oversupply.

Organic Pollutants

Organic molecules in the environment are usually classified depending on whether they are persistent. For example, solvents may almost completely sterilize the soil if added in large quantities, but they typically volatilize in a relatively short time and the soil may then recover. Some compounds used in industry, such as surfactants and plasticizers, can have disruptive effects on the endocrine system. However, these normally act through the water pathway or directly in packaged and processed food and are not thought to persist in soils. The term 'persistent organic pollutants' (POPs) refers to those which do not degrade, leach out, or volatilize from soils readily. This group can, therefore, build up to concentrations in soil that may inhibit biological processes. Characteristics that make a compound persistent in soil include its low aqueous solubility, low vapor pressure, and a high octanol to water partition coefficient (*See* **Pollutants:** Persistent Organic (POPs)). These characteristics usually mean that only small amounts of POPs are taken up by plant roots because of their low solubility and tendency to bind to organic matter in soil. However, grazing animals and some invertebrates such as earthworms may mobilize POPs from soils in their digestive systems when they ingest soil.

Examples of Pollutants

Many industrial and commercial sources emit pollutants to air and water or direct to soil. Some are short-lived because they are degraded and others leach rapidly in environments with excess rainfall over evapotranspiration. However, others bind to organic matter, clay, and oxides or form insoluble compounds in surface soils and so tend to remain and accumulate in soil with time. Those that have this tendency are metals, metalloids, persistent organic compounds, asbestos, coal tar, fuel ash, and some radionuclides (*See* **Pollutants:** Persistent Organic (POPs)). Some of the industrial sources of these pollutants are shown in Table 3. It is important that any 'new' substances being used in industrial processes or mobilized in the environment are considered also for their persistence and effects in soil.

Legislative Controls on Pollution

The ultimate environmental control method is to prevent the dispersion of pollutants in the environment. This has resulted in complete bans on the production of some compounds perceived to be very harmful. For example, manufacture of PCBs in the USA was banned by the EPA in 1977, though it continued under considerable restrictions in other countries until the mid-1980s. Even after production of any substance ceases, it will continue to be present in products, and thus present a disposal hazard, for a considerable period, e.g., PCBs in the insulation of electrical transformers. Legislation needs to be coordinated such that removing a toxic pollutant from air (e.g., by stopping incineration of certain materials) does not lead to transfer of the pollutants to soil or water. On the other hand, legislation for some classes of pollutants is based on containment or controls on the rate of emission to air or water, or on the purposeful additions of materials to land.

Source–Pathway–Receptor Principle

As mentioned in the Introduction, the term 'pollution' infers that some harm has already been done or will take place. Recent legislation and schemes to determine whether land is polluted or contaminated take a risk assessment approach to evaluate potential harm. The source–pathway–receptor principle requires that all three aspects are established at a site and that there is significant harm. Source is an origin of pollution, which could be wastewater or contaminated soil in the present context. The pathway is a means by which the pollutant can reach and affect a receptor. A receptor is an organism or group of organisms, an ecological system, or a piece of property which is being or could be harmed by a pollutant. A 'pollutant linkage' has to be established, which means the relationship between the pollutant, pathway, and receptor. In some cases there may be more than one pathway (for example, dust and water contamination). Another valuable aspect of the pollutant linkage idea is that the breaking of this linkage can be a very important way of stopping pollution or remediating contaminated sites. Prevention can be brought about by stopping the source or putting a barrier in the pathway to the receptor (*See* **Remediation of Polluted Soils**).

Also, the bioavailability of the pollutant to an organism is an important consideration in the pathway: because a pollutant is present in soil (or another medium) does not necessarily mean that it is likely to transfer and affect an organism. In soils, binding of pollutants by organic matter or soil minerals may render them sparingly or nonbioavailable (*See* **Pollutants:** Persistent Organic (POPs)). An example is chromium; two forms occur in the environment, with valency states III and VI. In soils however,

Table 3 Pollutants likely to occur in soils in contaminated environments

Pollutants	*Industrial sources*
Metals/metalloids	
Antimony	Electronics, metal smelting
Arsenic	Insecticide manufacture and use, wood preservation
Beryllium	Nuclear, munitions, and electronics
Cadmium	Pigments, alloys, electroplating, batteries, mining, and smelting industries
Chromium	Plating, tanning, inks, wood treatment, pigments, and dyes
Copper	Mining and smelting, wood treatment, electronics, plumbing, copper and brass manufacture
Lead	Batteries, tetraethyl lead production, mining, smelting, plumbing
Mercury	Chemical plant, mining and smelting, refining gold and silver, electrolysis industry, chlor-alkali plant, paper mills
Nickel	Plating and metal works, batteries, iron and steel industries, electronics
Selenium	Smelting, paint, pigment, electronics
Silver	Mining, photographic, electroplating, silver manufacture
Thallium	Cement industry, electronics
Zinc	Mining and smelting, plating, galvanizing, runoff from galvanized surfaces, print and paper
Other inorganic pollutants	
Fluoride	Cement and brick production, aluminum smelting, phosphate fertilizer manufacture
Cyanides	Coal gasification, metallurgical processes, solvent/separation of gold
Sulfur	Sulfides, residues from coal processing
Organic pollutants	
Aromatic compounds	
Benzene	Tar, gas, or coke works, petroleum refineries
Ethyl benzene	Tar, gas, or coke works, petroleum refineries
Toluene	Tar, gas, or coke works, petroleum refineries
Xylene	Tar, gas, or coke works, petroleum refineries
Phenols	Tar, gas, or coke works, petroleum refineries
Polycyclic aromatic hydrocarbons (PAHs)	Combustion of coal hydrocarbons and wastes
Chlorinated organic compounds[a]	Pesticide manufacture, deodorants, timber and textile peservatives, transformer insulation
Dioxins and furans	Sewage sludge application, waste disposal, waste incineration
Other pollutants	
Asbestos	Insulation in buildings, boats, other transportation, power stations
Coal tar	Tar, gas, or coke works, petroleum refineries
Fuel ash	Coal-fired power generation
Protons	Oxidation of sulfur dioxide and metal sulfides
Radionuclides	Power generation, weapons production, phosphate manufacture

[a]Aliphatic chlorinated compounds, chlorobenzenes, chlorophenols, polychlorinated biphenyls.

chromium is usually reduced to chromium III, which is insoluble, and as a result little is bioavailable. In some circumstances in aquatic systems, chromium VI may occur, which is bioavailable and very toxic.

Persistent, Bioaccumulative, and Toxic Pollutants

One way of prioritizing pollutants is to choose those that are known to be persistent, bioaccumulative, and toxic (PBT). These are substances that can build up in the soil and the food chain to levels that are harmful to human and ecosystem health. Other features related to their chemical characteristics are that they may travel long distances, and transfer easily between air, water, and soil, and therefore reside for a long time in the environment. In addition to some pesticides, the US EPA's first priority list of PBT pollutants includes the following industrial pollutants: benzoapyrene, hexachlorobenzene, alkyl lead, mercury and its compounds, octachlorostyrene, PCBs, dioxins, and furans. Because of their properties, PBTs have attracted many voluntary or legal controls on their production, use, and entry into the marketplace to decrease their emission in the environment.

Statistics show that the production of some potential pollutants (for example, nonferrous metals) has increased continually over the last decade. However, due to the legislative controls discussed above, and because of controls on emissions of chemicals to the environment, the point and nonpoint (diffuse) sources of pollution are decreasing in the developed countries. However, it should be remembered that, in many rapidly developing countries without strong environmental controls, pollution is actually increasing.

POLYMERS AND MICROORGANISMS

M C Rillig, University of Montana, Missoula, MT, USA

Introduction

Extracellular polymers, organic macromolecules found outside the cell or hyphal wall, are a common feature in eukaryotic and prokaryotic soil microbes. This summary deals with four main groups of extracellular microbial polymers, believed to be of particular significance in soil biology and the interaction of soil microbes with their environment: exopolysaccharides (EPS), hydrophobins (a group of small fungal proteins), glomalin (a glycoproteinaceous substance produced by arbuscular mycorrhizal fungi, AMF), and extracellular lipid compounds (for example, glycolipids such as rhamnolipids). Extracellular polymers are present in the soil in complex mixtures (spatially and temporally), being produced by a variety of microbes and being subject to modifications after entering the soil environment. They fulfill a range of functions in soil, from biofilm formation and modification of the habitat to increasing solubility of carbon substrates. In addition to the groups discussed here, extracellular enzymes are clearly a crucial component of the soil environment for microbes with absorptive nutrition (such as soil fungi and bacteria), but these are examined in detail elsewhere (*See* **Enzymes in Soils**). Polymeric compounds secreted by microbes in soil are also pertinent in the context of formation and composition of organic matter (*See* **Organic Matter:** Principles and Processes), and in the process of soil aggregation (*See* **Aggregation:** Microbial Aspects).

Extracellular Polymers: Definition and Overview

Commonly microbes in soil are embedded in a matrix of extracellular polymeric substances; the production of these substances is a common feature of archaea, Eubacteria, and eukaryotic microorganisms (e.g., algae, fungi). As a result of the production of these substances, biofilms are formed. Biofilms are mostly discussed in the aquatic microbial ecology literature, because they are uniquely suited to the challenges of inhabiting an aquatic habitat. Clearly, biofilms with their exopolymer matrix occur in soil as well, and can be seen by electron microscopical techniques (see Figure 1). Biofilms are accumulations of microbes (can be mixed communities), extracellular polymeric substances, multivalent cations, and various biogenic particles, as well as dissolved compounds.

Extracellular polymeric substances have been defined as "substances of biological origin that participate in the formation of microbial aggregates." Other definitions highlight the role these substances play in cohesion of microbes and adhesion (binding to the substratum). However, these more structural roles are not the only functions of extracellular polymers (see Table 1).

Extracellular polymers include organic macromolecules (formed by polymerization of similar or identical building blocks) such as polysaccharides, proteins, nucleic acids, and lipids. These polymers may contain nonpolymeric substituents (which can sometimes greatly influence the properties of the polymer). For example, proteins can be glycosylated or there can be acetyl or succinyl groups in polysaccharides.

These polymers are found by definition outside the cell wall, where they may have arrived through active

Table 1 Examples of the variety of functions of microbial exopolymers in soil

Exopolymer	*Function*
Exo- and ectoenzymes	Crucial component of absorptive nutrition of microbes
Hydrophobins	Lowering water surface tension, allowing hyphal emergence into air
Hydrophobins, some exopolysaccharides	Microbial attachment/adhesion to surfaces
Glomalin, many other exopolymers	Stabilization/formation of soil aggregates: involvement in the modification of the 'macro'-environment; importance in soil carbon storage via stabilization of labile carbon inside aggregates
Some rhamnolipids	Biocidal (antiviral, antibacterial, antifungal) activity
Exopolysaccharides, many other exopolymers	Biofilm formation: aggregation of microbes (increases potential for communication, synergism, gene transfer); leading to enhanced sorption of nutrients (inorganic, organic); retention of exoenzymes
Exopolysaccharides	Enhanced desiccation resistance
Some rhamnolipids	Surfactant activity (enhanced degradation of hydrocarbons; biosurfactants)
Some exopolysaccharides	Symbiotic signal (e.g., *Rhizobium*); also pathogen recognition
Attached exopolymers	Modification of microbial cell/hyphal wall properties (e.g., hydrophobicity, charge) with potential consequences for microbial transport, nutrient absorption
Exopolysaccharides, other exopolymers	Protection from toxic compounds, e.g., metals, biocides
Attached expolymers	Food web processes: protection from grazers, predation (e.g., amebae)

secretion processes (for example, through the vesicle-mediated pathway at the growing tip of fungal hyphae), sloughing off of cell-surface material, or lysis of microbial cells. Additionally, organic compounds from the environment (e.g., from lysis and hydrolysis) can become part of the polymer matrix.

Once extracellular, polymers are subject to various modifications by enzymatic processes. Various polymer-degrading enzymes such as hydrolases can be present in the matrix. Polymer-breakdown products can sometimes be reutilized by microbes. Due to these processes within a biofilm, the composition of extracellular polymers can be variable both spatially and temporally.

Extracellular polymers can also be broadly distinguished into those that are attached (bound) and nonattached. Bound polymers include capsules and sheaths of bacteria, and loosely bound polymers, while soluble polymers include slime and colloids, as well as other water-soluble macromolecules.

Historically, extracellular polymers were studied by extraction methods. Fractions were defined operationally using the extraction method of choice, e.g., centrifugation, boiling, ultrasonication, filtration, or solubility in various solvents (e.g., NaCl, NaOH, organic solvents). This work was mostly performed using laboratory pure cultures of microbes. In addition, there are now available techniques for the *in situ*, nondestructive study of these polymers, including infrared spectroscopy (e.g., attenuated total reflectance/Fourier transform infrared spectroscopy (ATR/FT-IR), detects signals of surface chemical groups), nuclear magnetic resonance (NMR), and confocal laser scanning microscopy (CLSM). These methods have greatly increased the understanding of the three-dimensional structure and composition of extracellular polymer matrices.

In summary, extracellular polymers occur in complex mixtures of compounds in the environment (to which frequently more than one species or group of microbes can contribute); they can arrive at a certain location by a variety of different mechanisms and may not have been formed where they are found; these mixtures are then subject to processing and modification in the environment as a function of time and space, and the structure of the polymer matrix can also change in response to environmental conditions. It is very important to keep this complexity in mind in the following discussion of selected components of these extracellular polymer mixtures.

Hydrophobins: Secreted Fungal Proteins

Structure and Properties

Hydrophobins are relatively recently discovered, small (ca. 100 amino acids), secreted, moderately hydrophobic proteins produced by fungi in the *Ascomycota* and *Basidiomycota*. Their occurrence in other Eumycotan phyla (*Chytridiomycota*, *Zygomycota*) is not yet clearly established. Based on hydropathy patterns (hydropathy is a measure of the hydrophobic character of an amino acid) and solubility characteristics, hydrophobins have been divided into class I and class II (the latter having been found only in the *Ascomycota* so far). Sequence homology of hydrophobins is very low (especially among class I hydrophobins), but all proteins share eight conserved cysteine residues; these cysteine residues form intramolecular disulfide bridges. Some hydrophobins, like the intensively studied SC3 (isolated from *Schizophyllum commune*, a basidiomycete fungus), are glycosylated. Several fungi have more than one hydrophobin gene. For example, *S. commune* contains at least four hydrophobin genes, which are expressed at different fungal life-history stages (e.g., monokaryotic versus dikaryotic mycelium). Six hydrophobin genes have been identified in *Cladosporium fulvum*. Complementation studies showed that some hydrophobins could only partially substitute for each other, suggesting that hydrophobins may have evolved to fulfill different functions.

All hydrophobins so far studied self-assemble at hydrophilic–hydrophobic interfaces, such as a water–air boundary. This self-assembly is accompanied by conformational changes of hydrophobin monomers that form the amphipathic film or membrane.

Virtually all studies performed with hydrophobins appear to have been conducted under *in vitro* conditions to study molecular and biochemical aspects of their production; hence there is little information about the amount and behavior of hydrophobins found in soils or their persistence in the soil environment.

Functions

Hydrophobins are believed to be essential in several functions in the fungal life-cycle and development. These proteins, by virtue of their ability to self-assemble into amphipathic membranes, allow hyphae to break the water–air barrier (overcoming surface tension), coat air-exposed fungal structures with a hydrophobic film, and allow hyphae to attach to hydrophobic surfaces. Hydrophobins have also been found to alter hyphal wall composition.

Hydrophobins allow fungi to escape their aqueous environment This is a necessary step for the formation of fungal fruiting bodies. However, mycelium growth in soil is also confronted with air–water boundaries as hyphae cross pore spaces between aggregates. The importance of secreted hydrophobins such as SC3 in hyphal growth across a water–air barrier lies in the lowering of water surface tension (Figure 2). A strain of *S. commune* with the *SC3* gene disrupted produces few aerial hyphae, but by adding SC3 protein to the culture medium, water surface tension is decreased to wild-type levels, and formation of aerial hyphae is possible. The time course of decrease in water surface tension of a culture of *S. commune* also correlates with the production and secretion of SC3 into the medium. The mechanistic details of emergence of hyphae as mediated by a hydrophobin-membrane are not known.

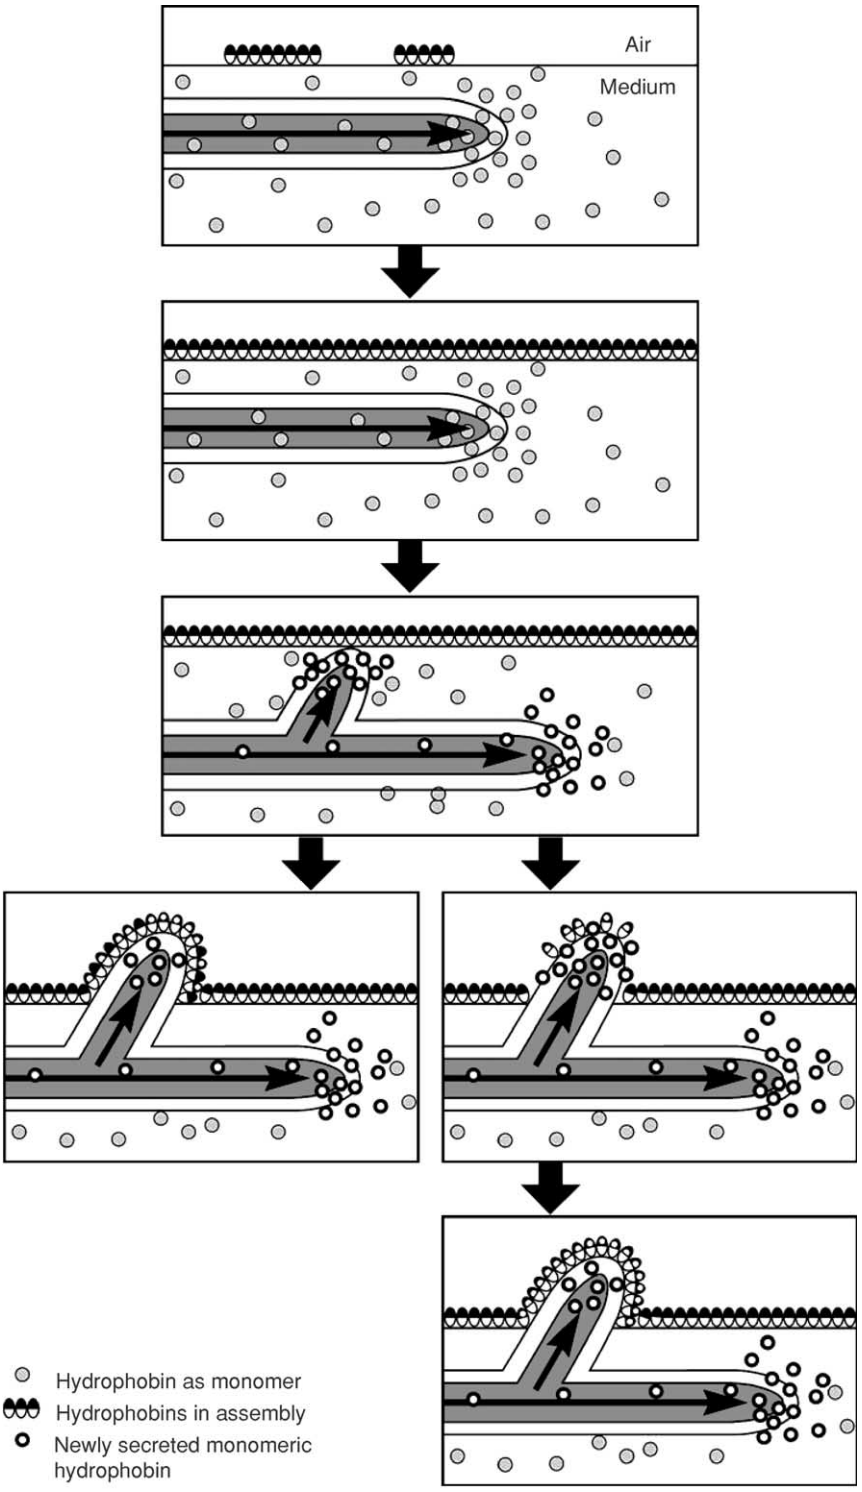

Figure 2 Functioning of fungal hydrophobins at the air–water interface. Monomeric hydrophobins are secreted into the aqueous medium. These spontaneously assemble at the air–water interface, where they greatly decrease the surface tension, allowing hyphae to emerge. In the process of emergence, it is unclear whether hyphae just stretch the hydrophobin film that has formed at the interface (bottom left) or if the film is ruptured as the hypha emerges (bottom right). Hydrophobins coat the hypha exposed to the air. Reproduced from Wösten HAB (2001) Hydrophobins: multipurpose proteins. *Annual Reviews of Microbiology* 55: 625–646. Glomalin: An Abundant Glycoproteinaceous Substance Produced by Arbuscular Mycorrhizal Fungi

Properties

Glomalin is a relatively recently discovered glycoproteinaceous substance (of as yet unknown amino acid sequence and structure) produced apparently only by AMF. AMF are obligate biotrophs (in the phylum *Glomeromycota*) living in symbiosis with the roots of ca. two-thirds of higher plants; they are ubiquitous in soils of terrestrial ecosystems (*See* **Mycorrhizal Fungi**).

Glomalin is, like many substances found in soil (e.g., humic acid), operationally defined, and hence definitions are subject to change once structural details become known. Glomalin is the protein (or the proteins, since it is somewhat unlikely that all AMF species produce exactly the same substance) that reacts with a monoclonal antibody (MAb32B11) raised against crushed spores of the AMF species *Glomus intraradices*, and as the protein (as determined with a Bradford assay) that is extracted with 50 mmol l^{-1} sodium citrate (pH 8.0) in successive cycles of autoclaving (121°C) until the supernatant is clear. Several fractions of glomalin are distinguished, based on their immunoreactivity (i.e., if the protein can be detected using an enzyme-linked immunosorbent assay (ELISA) with MAb32B11) and ease of extraction from soil (easily extractable glomalin is extracted in an initial round of autoclaving for only 30 min with 20 mmol l^{-1} sodium citrate, pH 7.0).

Defined in this way, glomalin occurs in very large amounts in soil, typically in the range of several to 10 mg g^{-1} soil (in one case 60 mg cm^{-3} soil was found). Glomalin decomposes slower than the AMF hyphae producing it, and the estimated turnover time for glomalin in soil is on the order of several decades (derived from chronosequence studies and C-14 carbon dating). Glomalin is also produced in sterile *in vitro* cultures of AMF, but most of the work has been done in pot cultures or soil.

Glomalin appears to have N-linked oligosaccharide side chains, and the extract also contains Fe in variable percentages (it is not known in what way Fe is bound in the molecule). In its native state, glomalin is assumed to be insoluble and hydrophobic. Evidence (e.g., from NMR studies) is mounting that glomalin is a compound distinct from humic acid; its ^{1}H NMR spectrum is also distinctly different from tannic acid. The pathway of release of glomalin into soil is not clear; glomalin could be actively secreted at the hyphal tip, or it could be sloughed off hyphae as they grow through soil.

It is not known what factors control glomalin production. However, in an experiment with AMF *in vitro* cultures, glomalin concentrations were significantly higher when AMF hyphal growth was reduced compared with control, perhaps suggesting that glomalin is not constitutively produced but that its production is subject to environmental controls. There is also evidence that AMF species differ in glomalin production rates. Glomalin concentrations in soil are responsive to several disturbances, including various agricultural practices (e.g., crop rotations, tillage, etc.), and factors of global change (e.g., elevated atmospheric CO_2, warming).

Functions

Soil aggregation Possibly the most important function of glomalin from the ecosystem perspective, and the best-documented overall, relates to its role in soil aggregation. While the mechanisms are not clearly understood, there is a strong and consistent correlation of glomalin concentrations in soil (or soil aggregates) with soil-aggregate water stability (a measure of resistance of aggregates to disintegration when sieved in water). The correlation is frequently strongest using the immunoreactive easily extractable glomalin (IR-EEG) fraction of glomalin. The relationship of glomalin concentration with soil aggregate water stability is curvilinear such that at higher glomalin concentrations no additional aggregate stability is achieved (Figure 3). Microscopic observation shows that aggregates are irregularly coated with glomalin (as identified with MAb32B11; see Figure 4), suggesting that a possible mode of action involves sealing off

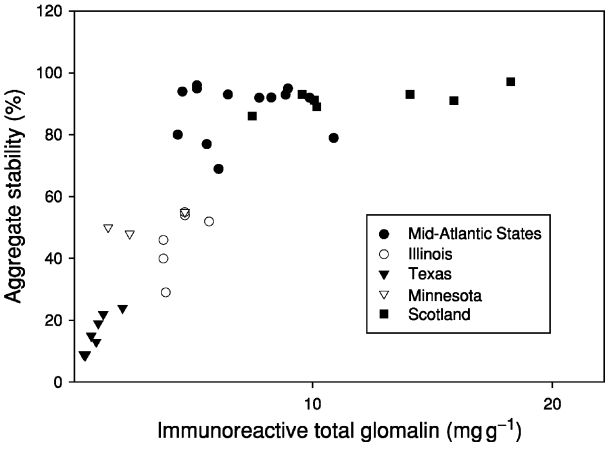

Figure 3 Curvilinear relationship of glomalin concentrations with soil aggregate water stability (1- to 2-mm aggregates) across a variety of soils. Reproduced with permission from Wright SF and Upadhyaya A (1998) A survey of soil for aggregate stability and glomalin, a glycoprotein produced by hyphae of arbuscular mycorrhizal fungi. *Plant and Soil* 198: 97–107 (Figure 3). With kind permission of Kluwer Academic Publishers.

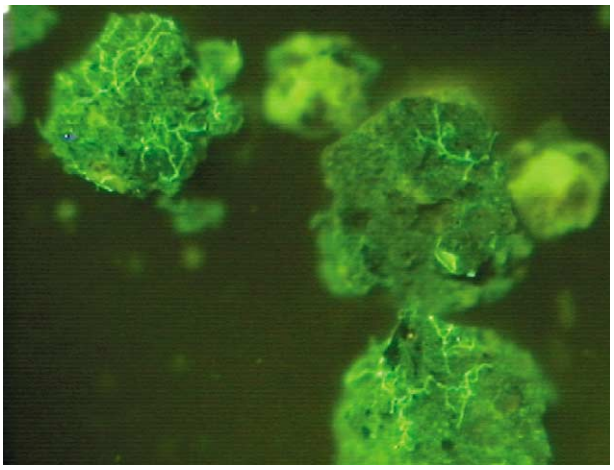

Figure 4 Glomalin (visualized as immunofluorescence using MAb32B11) on the surface of arbuscular mycorrhizal fungal hyphae on soil aggregates (1–2 mm diameter). Reproduced with permission from Wright SF (unpublished).

aggregates to prevent intrusion of water into the aggregate interior. Additionally, glomalin may make AMF hyphae 'sticky' so that the enmeshment mechanism of hyphae could be more efficient. Importantly, the relatively slow turnover of glomalin in soil may explain why aggregates formed by AMF are typically stable for a longer period than aggregates formed by other fungi, for example saprobes.

Role in the biology of AMF and symbiosis It is remarkable that plants and their AMF symbionts invest a significant amount of carbon into glomalin, begging the question what might be physiological roles of the protein. AMF hyphae are less palatable to grazing collembolans than hyphae of other, for example, saprobic fungi; it is hypothesized that glomalin may play a role in the decreased palatability of AMF hyphae in soil. The growth of AMF may be enhanced in aggregated soil compared with soil with no macropore spaces, although this is difficult to show experimentally (due to the presence of confounding factors when comparing aggregated and nonaggregated soil). The investment into glomalin may then serve to increase hyphal growth rate via the effect of the substance on soil aggregation. Results consistent with this idea have been obtained in an artificial bead-culture system. Other hypothesized functions include the adsorption of metals to the protein, and a role in the Fe economy of the rhizosphere.

Exopolysaccharides

EPS are extracellular polysaccharides that occur widely among prokaryotes; bacterial EPS have been studied in greatest detail. Also most microalgae and many filamentous fungi have EPS. EPS are abundant extracellular products that either accumulate on the surface of the cell (for example as a capsule) or that are released into the cell's surroundings. EPS originate from cytoplasmic sugars, and in some cases (e.g., succinoglycan in *Rhizobium*; alginate in *Pseudomonas*) details of the mechanisms of assembly, polymerization, and export are known. In *Rhizobium*, over 20 genes are known to be involved in EPS synthesis.

Structure

EPS are primarily composed of carbohydrates, but, in addition to sugars, there may be organic and inorganic components. Many or most are polyanionic in nature. Organic substituents include various organic acids (acetate, pyruvate, etc.) and amino acids. Inorganic substituents include sulfate, phosphate, and also cations (due to the polyanionic nature). For example, some alginates bind Ca^{2+}. Hetero- and homopolysaccharides are distinguished, depending on whether the monomers in the polymer are different or all the same. EPS can also be further distinguished based on linkage types and branching.

Functions

EPS mediate attachment to roots Work with associative diazotrophs (N-fixing bacteria), for example *Alcaligenes*, has shown that EPS are important in attachment of bacteria to roots. Mutant strains of *Alcaligenes faecalis* that produce either no or reduced levels of EPS, or that strongly overproduce EPS are not able to attach to rice roots as well as wild-type bacteria (the difference being several orders of magnitude of cells per grams of root).

EPS as symbiotic signals: *Rhizobium* EPS are known to play a role in the development of root nodule symbioses between *Rhizobium* and legumes. A mutant of *R. meliloti* that is defective in the production of the EPS succinoglycan (a heteropolysaccharide) is defective in nodule colonization, although (noninfected) pseudonodules are formed. This indicates that succinoglycan is not the initiating signal, but that it is required for successful nodule invasion. Invasion is blocked where the infection thread (which normally carries rhizobia into the nodule cells of the plant) penetrates beyond the epidermal cell layer.

Desiccation resistance Bacteria in soil generally exist within a matrix mainly composed of EPS. This EPS matrix may protect bacteria from drying and from fluctuations in water potential. EPS production may hence serve to alter their microenvironment to

enhance survival of desiccation in soils that experience drought conditions (complementing other mechanisms, such as synthesis of compatible solutes or uptake of inorganic solutes such as K^+). Slowing the rate of drying within the microbe's microenvironment may increase the time for adjustment of metabolism. Additionally, increased water retention and diffusion rates in EPS may help soil bacteria to maintain physiological functions at low water potentials. At various soil water potentials, glucose diffuses faster in EPS or in EPS-amended clay than in pure clay, due to the higher volumetric water content of EPS and their water-saturated porosity.

In experiments using a sand matrix, EPS produced by a soil *Pseudomonas* species has held several times its weight in water at low water potentials (e.g., between 3 and 10 g water per gram of solid EPS at −3 MPa), suggesting that EPS may serve as a water reservoir for cells in the vicinity. EPS-amended sand also holds more water at all water potentials than unamended sand, and the presence of EPS slows the drying rate of the sand. Cultures of the bacteria exposed to desiccation while growing in sand contain more EPS, suggesting that resources are allocated to EPS production during drought. Also, the structure of the bacterial EPS is altered in response to desiccation (as shown by cryoscanning electron microscopy), such that the EPS structures appear less porous and more massive under desiccation.

Soil aggregation Numerous products and activities of microbes in soil contribute to the complex process of soil aggregation (*See* **Aggregation:** Microbial Aspects). Organic binding agents that are involved in stabilizing aggregates can be categorized into transient, temporary, and persistent binding agents based on their persistence in soil. Transient binding agents are decomposed rapidly (and produced rapidly) by microorganisms in soil; the most important of these are polysaccharides, including EPS of microbial origin. Evidence for the involvement of polysaccharides in soil aggregation comes from many sources, spanning the spectrum of soil ecological approaches. Correlative studies have related the concentration of certain fractions of extracted polysaccharide (e.g., NaOH or hot water extraction) with aggregate stability; however, as is the case with many other soil extractions, large amounts of other components of soil organic matter may be coextracted (for example humic acid). Some studies have used the ratio of the monosaccharides mannose to xylose (M/X) to assess the relative origin of carbohydrates in soil (after hydrolysis). The proportion of carbohydrates of microbial origin is assumed to increase with increasing M/X ratios. Other approaches include selective oxidation of polysaccharides (using periodate), electron-microscopical observations of aggregates (showing attachment of clay particles to EPS material), and controlled environment studies with defined microbial EPS and clays.

Alginate: a model system for EPS biology The acidic EPS alginate has been shown to be involved in biofilm formation of the Gram bacterium *Pseudomonas aeruginosa*. Alginate biosynthesis has become a model system in the study of EPS production (perhaps not least due to the biomedical context of cystic fibrosis research). Alginate is composed of β-1,4-linked D-mannuronic acid and α-L-guluronic acid. The monomers can be arranged in a homopolymeric or heteropolymeric fashion. In addition bacterial alginates are frequently O-acetylated to different degrees. The polymeric structure and O-acetylation determine the physicochemical properties of this EPS; for example, increased O-acetylation increases the water-binding capacity of alginate. Bacterial alginate has a high molecular mass and is negatively charged (as a consequence it is hydrated and viscous). Alginate is produced in the environment, in human infections, and industrial systems. It also functions as a virulence factor of plant pathogenic *Pseudomonas* spp., and is involved in the encystment process of *Azotobacter* spp.

A considerable amount of detail is available for the biosynthesis pathway of alginate. More than 20 genes are involved in alginate biosynthesis in *P. aeruginosa* (all located on the bacterial chromosome). Biosynthesis starts with fructose-6-phosphate and proceeds through the phases of activation of precursor, oxidation of precursor (to guanosine diphosphate (GDP)-mannuronate), polymerization, modification (epimerization, O-acetylation), and export. The initial steps in the pathway are common in general carbohydrate metabolism; a critical shunt and kinetic control point in alginate synthesis is GDP-mannose dehydrogenase (*algD*), the *algD* gene being tightly controlled. The export mechanism of alginate is not clearly established yet, but modification of alginate takes place in the periplasmic space: O-acetylation and epimerization. It is not clear how these reactions are controlled, but their rates are important in determining the properties of alginate.

Alginate biosynthesis is triggered by a variety of environmental factors. These include high osmolarity, nutrient limitation, presence of toxic compounds (e.g., copper), and attachment of bacteria to a solid surface. High osmolarity and ethanol (dehydrating agent) enhance transcription of alginate biosynthesis genes (and to a limited extent, alginate production) in *P. aeruginosa* and *P. syringae*. AlgU, a regulatory

element (sigma factor) involved in the regulation of biosynthesis of the EPS alginate in *P. fluorescens*, is essential in providing desiccation tolerance *in vitro* and in soil. ATR/FT-IR and CLSM were used to study the role of alginate and alginate structure in biofilm formation by *P. aeruginosa* on surfaces. Alginate appears to be required for formation of thicker, three-dimensional biofilms.

Extracellular Lipid Compounds

Lipids are typically discussed in the context of membrane composition (e.g., phospholipids) or intracellular storage compounds; however, extracellular lipids are produced by both prokaryotes and eukaryotes. Simple extracellular lipids (e.g., free fatty acids, and various oxidation products of microbes utilizing alkanes) are not discussed here; the focus is on complex extracellular lipids. These contain long-chain acyl moieties attached to a nonlipid component; the latter is frequently a carbohydrate, a protein, or a peptide.

The combination of lipid and nonlipid components in the molecule confers hydrophilic and hydrophobic properties, and hence some of these compounds can be active as surfactants (also referred to as biosurfactants). The emulsifying ability of some complex extracellular lipids explains probably most of their biological role; however, some of these lipid compounds also alter the hydrophobicity of the microbial cell, which also influences (positively or negatively) uptake of, for example, hydrocarbons. Microbially produced surfactants offer the advantage of being potentially less toxic and more biodegradable than some synthetic surfactants, explaining the heightened interest in this compound in biotechnology. The efficiency of biosurfactants in soil remediation has been studied in the case of soil contamination by metals (e.g., Cd^{2+}, Zn^{2+}, Pb^{2+}), polychlorinated biphenyls (PCBs), phenantrene, and polyaromatic hydrocarbons (PAHs).

Glycolipids are lipids with a sugar moiety; the most common groups are sophorolipids (glycolipids containing the disaccharide sophorose; e.g., in *Candida* yeasts), trehaloselipids (containing the disaccharide trehalose; e.g., in *Arthrobacter*, *Rhodococcus*), and rhamnolipids (containing the sugar rhamnose). Rhamnolipids have been extensively studied with respect to their surfactant ability (mostly in the context of bioremediation of metal or hydrocarbon contaminated soils and subsoils), for example in strains of the soil bacterium *P. aeruginosa*.

In addition to having surfactant function (allowing the bacteria to grow on hydrocarbons), rhamnolipids have some bactericidal (against Gram-negative) and antiviral activity. Rhamnolipid from *P. aeruginosa* has zoosporicidal activity against phytophathogenic fungal species such as *Pythium*, *Phytophthora*, and *Plasmopara*. Proposed mechanisms of action include disruption of the fungal plasma membrane by the rhamnolipid. This points to a potential use of glycolipids in biological control of agricultural pests.

POROSITY AND PORE-SIZE DISTRIBUTION

J R Nimmo, US Geological Survey, Menlo Park, CA, USA

Published by Elsevier Ltd.

A soil's porosity and pore-size distribution characterize its pore space, that portion of the soil's volume that is not occupied by solid material. The basic character of the pore space governs critical aspects of almost everything that occurs in the soil: the movement of water, air, and other fluids; the transport and the reaction of chemicals; and the residence of roots and other biota. By convention the definition of pore space excludes fluid pockets that are totally enclosed within solid material – vesicles or vugs, for example, that have no exchange with the pore space that has continuity to the boundaries of the medium. Thus we consider a single, contiguous pore space within the body of soil. In general it has fluid pathways that are tortuous, variably constricted, and usually highly connected among themselves. Figure 1 shows an example of a two-dimensional cross section of soil pore space.

The pore space is often considered in terms of individual pores – an artificial concept that makes possible many quantifications of its essential character. Though many alternatives could serve as a basis for the definition of pores and their sizes, in soil science and hydrology these are best conceptualized, measured, and applied with respect to the fluids that occupy and move within the pore space.

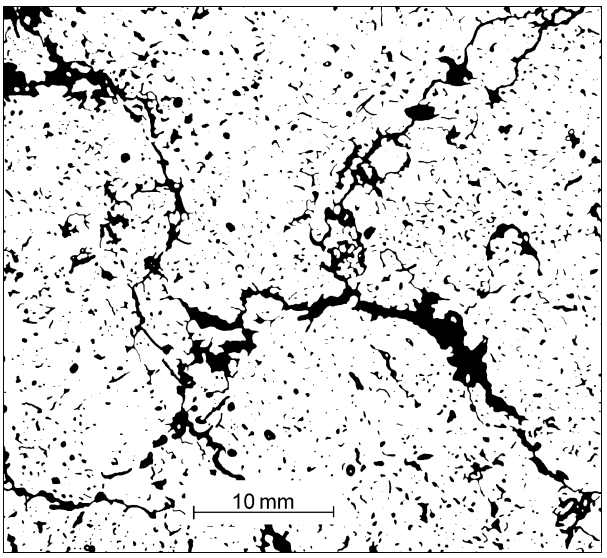

Figure 1 Cross section of a typical soil with pore space in black. Study of this figure would lead to an underestimate of porosity, because pores smaller than about 0.1 mm do not appear. (Adapted from Lafeber D (1965) The graphical representation of planar pore patterns in soils. *Australian Journal of Soil Research* 3: 143–164, with permission.)

Porosity

Porosity, ϕ, is the fraction of the total soil volume that is not occupied by solid material. Thus it is a single-number quantification of the amount of space available to fluid within a specific body of soil. With the assumption that soil is a continuum, porosity can be considered as a function of position. Being simply a fraction of total volume, ϕ can range from 0 to 1, typically falling between 0.3 and 0.7 for soils.

Porosity in Natural Soils

The porosity of a soil depends on several factors, including: (1) packing (bulk) density, (2) the breadth of the particle-size distribution (polydisperse versus monodisperse), (3) the shape of particles, and (4) cementing materials. Mathematically considering an idealized soil of packed uniform spheres, ϕ must fall between 0.26 and 0.48, depending on the packing. Spheres randomly thrown together will have ϕ near the middle of this range, typically 0.30–0.35. A sand with grains nearly uniform in size (monodisperse) packs to about the same porosity as spheres. In a polydisperse sand, the fitting of small grains within the pores between large ones can reduce ϕ, conceivably below the 0.26 uniform-sphere minimum. Figure 2 illustrates this concept. The particular sort of arrangement required to reduce ϕ to 0.26 or less is highly improbable, however, so ϕ also typically falls within 0.30–0.35 for polydisperse sands. Particles more irregular in shape tend to have larger gaps between their nontouching surfaces, thus forming media of greater porosity. In porous rock such as sandstone, cementation or welding of particles not only creates pores that are different in shape from those of particulate media, but also reduces the porosity as solid material takes up space that would otherwise be pore space. Porosity in such a case can easily be less than 0.3, even approaching 0. Cementing material can also have the opposite effect. In many soils, clay and organic substances cement particles together into aggregates. An individual aggregate might have a 0.35 porosity within it, but the medium as a whole has additional pore space in the form of gaps between aggregates, so that ϕ can be 0.5 or greater. Observed porosities can be as great as 0.8–0.9 in a peat soil (extremely high in organic matter).

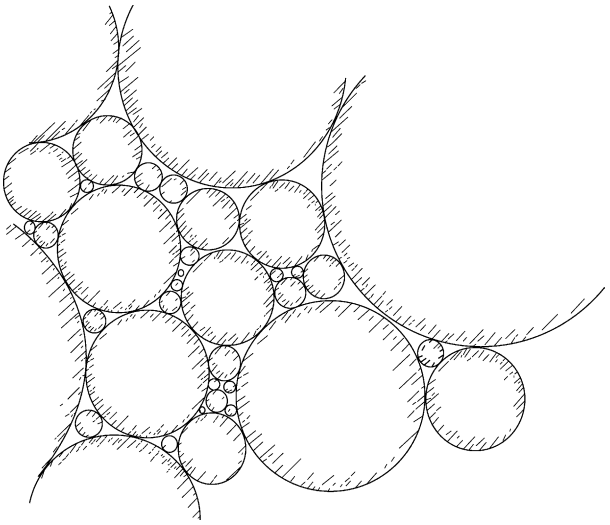

Figure 2 Dense packing of polydisperse spheres. (Adapted from Hillel D (1980) *Fundamentals of Soil Physics*. San Diego: Academic Press, with permission.)

Porosity is often considered to partition into two components, most commonly called textural and structural porosity. The textural component is the value the porosity would be deduced to have if the arrangement of the particles were random, as described above for granular material without cementing. That is, the textural porosity might be approximately 0.3 in a granular medium. (The low end of the 0.30–0.35 range is preferred, because the high end probably reflects nonrandom structural influences in real sands.) The structural component, often considered to represent macropores, is arithmetically the difference between the textural porosity and the total porosity.

The texture of the medium relates in a general way to the pore-size distribution, as large particles give rise to large pores between them, and therefore is a major influence on the retention curve. Additionally, the structure of the medium, especially the degree to which it has aggregation, shrinkage cracks, wormholes, etc., substantially influences the retention curve.

Measurement of Porosity

The technology of thin sections or of tomographic imaging can produce a visualization of pore space and solid material in a cross-sectional plane, as in Figure 1. The summed area of pore space divided by total area gives the areal porosity over that plane. An analogous procedure can be followed along a line through the sample, to yield a linear porosity. If the medium is isotropic, either of these would numerically equal the volumetric porosity as defined above, which is more usually of interest.

The volume of water contained in a saturated sample of known volume can indicate porosity. The mass of saturated material less the oven-dry mass of the solids, divided by the density of water, gives the volume of water. This divided by the original sample volume gives porosity.

An analogous method is to determine the volume of gas in the pore space of a completely dry sample. Of course not only the sampling but also the drying of the soil must be done so as not to compress the soil or otherwise alter its porosity. A pycnometer can measure the air volume in the pore space. A gas-tight chamber encloses the sample so that the internal gas-occupied volume can be perturbed by a known amount while the gas pressure is measured. This is typically done with a small piston attached by a tube connection. The Boyle law indicates the total gas volume from the change in pressure resulting from the volume change. This total gas volume minus the volume within the piston, connectors, gaps at the chamber walls, and any other space not occupied by soil gives the total pore volume to be divided by the sample volume.

To avoid the need to saturate with water or air, measurements of particle density, ρ_p, and bulk density, ρ_b, are used. From the definitions of ρ_b as the solid mass per volume of soil and ρ_p as the solid mass per solid volume, their ratio ρ_b/ρ_p is the complement of ϕ, so that:

$$\phi = 1 - \rho_b/\rho_p \qquad [1]$$

Often the critical source of error is in the determination of soil bulk volume, measured on an uncompacted sample or from the volume of the excavation from which the soil sample originated.

Pores and Pore-Size Distribution

The Nature of a Pore

That soil has pores is obvious, but the precise delineation of an individual pore readily leads to ambiguity and contradiction. Pore space can be partitioned into individual pores only by an arbitrary criterion, which often is not explicitly stated when pores or their sizes are discussed. Because of this inherent arbitrariness, some scientists argue that the concepts of pore and pore size should be avoided. Much valuable theory of the behavior of the soil–water–air system, however, has been built on these concepts, defined using widely, if not universally, accepted criteria.

A particularly useful criterion considers the pore space as a collection of channels through which fluid can flow. The effective width of such a channel varies

along its length. Wide portions can be considered individual pore bodies, and narrow portions can be considered the pore openings that separate them. These are often described with anatomical metaphors, the wide part being the 'belly' or 'waist', and the constrictive part being the 'neck' or 'throat.' In a medium dominated by textural pore space such as sand, pore bodies are the intergranular spaces of dimensions typically slightly less than those of the adjacent particles. At another extreme, a wormhole, if it is essentially uniform in diameter along its length, might be considered a single pore. The boundaries of such a pore are of three types: (1) interface with solid, (2) constriction – a plane through the locally narrowest portion of pore space, or (3) interface with another pore (e.g., a crack or wormhole) or a hydraulically distinct region of space (e.g., the land surface).

Pores conceptualized by this cellular approach are especially relevant to hydraulic behavior, as has been recognized for more than 70 years. The initial application was to Haines jumps, shown in Figure 3, still considered the basic phenomena of capillary hysteresis. The pore openings, which control the matric pressure P at which pores empty, are smaller than the pore bodies, which control the P at which pores fill. As the medium dries and P decreases, water retreats gradually as the air–water interface becomes more curved. At the narrowest part of the pore opening, this interface can no longer increase curvature by gradual amounts, so it retreats suddenly to narrower channels elsewhere. An analogous phenomenon occurs during wetting, when the decreasing interface curvature cannot be supported by the diameter of the pore at its maximum width. The volume that empties and fills in this way is essentially an individual pore. Not all pore space is subject to Haines jumps – water remains in crevices and in films (not seen in Figure 3) coating solid surfaces. Various models and theories treat this space in different ways. By the definition above it is part of a pore in addition to the volume affected by the Haines jump.

Pores can be classified according to their origin, function, or other attributes. A textural/structural

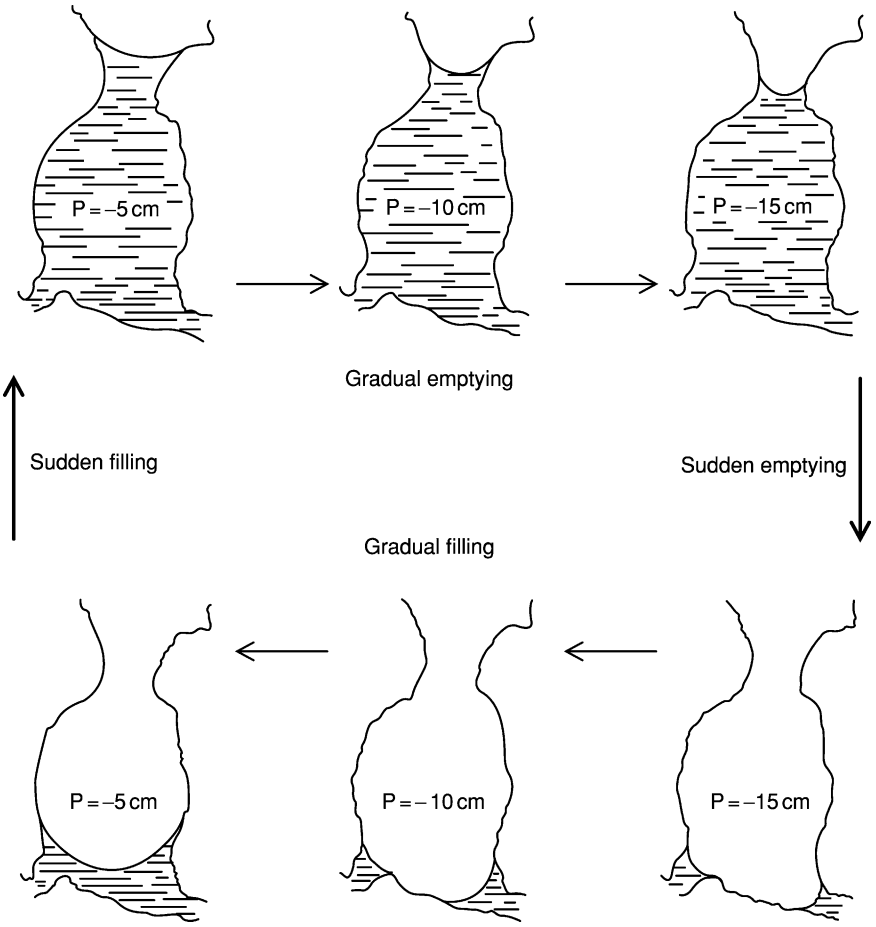

Figure 3 Dynamics of a Haines jump. (Adapted from Miller EE and Miller RD (1956) Physical theory for capillary flow phenomena. *Journal of Applied Physics* 27: 324–332, with permission.)

distinction is possible, analogous to porosity. Hierarchical classifications are also possible. Intragranular or dead-end pores (if not entirely enclosed within solid) might empty or fill with water, but without contributing directly to fluid movement through the medium. Intergranular pores are the major portion of textural porosity, as discussed above. Intraaggregate pores may be essentially equivalent to intergranular pores within an aggregate. Interaggregate pores, including shrink–swell cracks, are common types of macropores. Biogenic pores, for example the channels left by decayed roots and the tunnels made by burrowing animals, are another common type of macropore in soils.

Specific pore sizes are usually specified by an effective radius of the pore body or neck. This relates to the radii of curvature of the air–water interface at which Haines jumps occur, and by capillarity, to the matric pressures at which these occur. Alternative indicators of size include the cross-sectional area or the volume of a pore, and the hydraulic radius, the ratio of the cross-sectional area to circumference, or of pore volume to specific surface.

The pore-size distribution is the relative abundance of each pore size in a representative volume of soil This can be symbolized with a function $f(r)$, proportional to the combined volume of pores of effective radius r. Figure 4 shows examples. As with porosity, the continuum assumption makes valid the concept that $f(r)$ varies from point to point within a body of soil. Also like porosity, $f(r)$ may be taken to comprise textural and structural components.

Measurement

The most obvious and straightforward measurements of pore size are with geometric analysis of images of individual pores. This can be done using various types of microscopy on thin sections or other flat soil surfaces, or tomographs. Dimensions of pore bodies and necks can be measured manually or by computer analysis of digitized images. The lengths of segments of solid or pore along one-dimensional transects can serve similar purposes. As in the case of porosity, isotropy is required for assuming the equality of lineal, areal, and volumetric pore size distribution. For pore size, however, a more important problem is that, when working with fewer than three dimensions, one doesn't know what *part* of pore the selected slice intersects; because it does not in general go through the widest part, it underestimates the pore diameter. Correction techniques are necessary to estimate true pore body and opening sizes.

Three-dimensional analysis is possible with impregnation techniques. In these, the soil pore space is filled with a resin or other liquid that solidifies. After it has done so, the medium is broken up and individual blobs of solid resin, actually casts of the pores, are analyzed as particles.

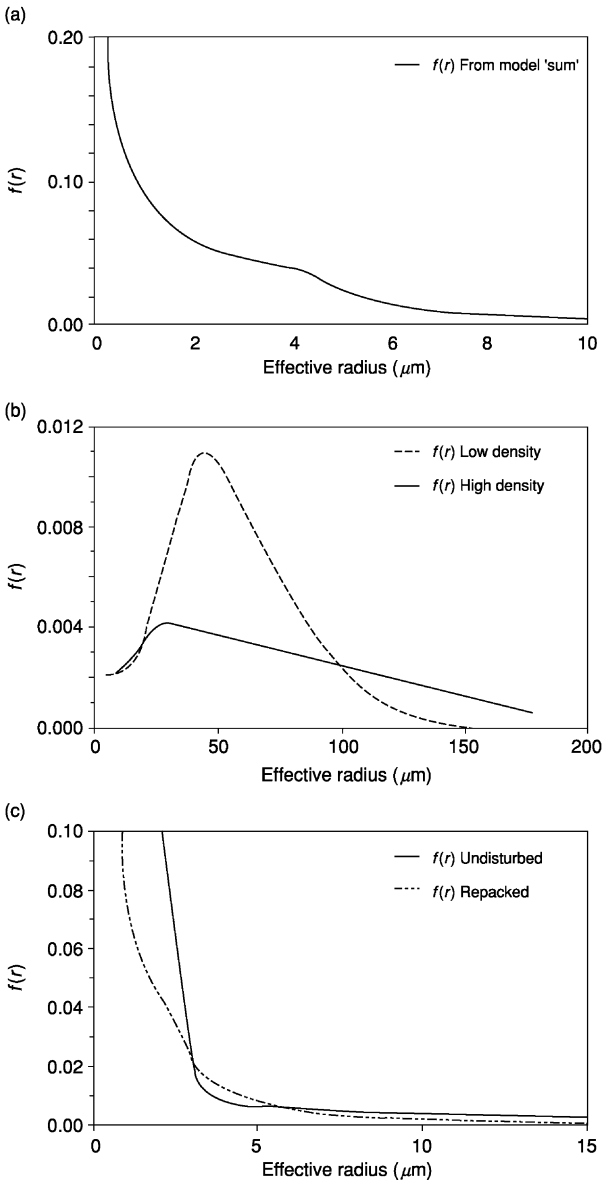

Figure 4 Pore-size distributions based on measured water retention. (a) Loamy soil. (Reproduced with permission from Schofield (1935).) (b) Silty sand at two packing densities. (Data from Croney D and Coleman JD (1954) Soil structure in relation to soil suction (pF). *Journal of Soil Science* 5: 75–84.) (c) Paleosol of sandy loam texture from 42 m depth, as a minimally disturbed core sample, and after disaggregation and repacking to the original density. (Data from Perkins KS (2003) Measurement of sedimentary interbed hydraulic properties and their hydrologic influence near the Idaho Nuclear Technology and Engineering Center at the Idaho National Engineering and Environmental Laboratory. *Water-Resources Investigations Report* 03-4048. Idaho Falls, Idaho: US Geological Survey; and Schofield RK (2002) The pF of the water in soil. *Transactions of the Third International Congress of Soil Science*, pp. 38–48. London: T Murby.)

Image-based techniques can be prohibitively tedious because enough pores must be analyzed to give an adequate statistical representation. They can give a wealth of information, however, on related aspects such as pore shape and connectivity.

More common than imaging methods are those based on effective capillary size. These use data from fluid behavior in an unsaturated medium, usually the emptying or filling of pores during soil drying or wetting (Figure 3), that is, the water-retention curve $\theta(P)$, where θ is the volumetric water content. Because large pores fill or empty at P near 0, a medium that has many large pores will have a retention curve that drops rapidly to low θ at high matric potentials. Conversely, one with very fine pores will retain much water even at highly negative P, thus having a flatter retention curve. By the capillary hypothesis, the P at which a pore empties (or fills) corresponds to the pore opening (or body) size according to:

$$r = \frac{-2\sigma\cos\alpha}{P} \qquad [2]$$

where σ is the surface tension and α is the contact angle. This formula can convert a measured $\theta(P)$ into an equivalent $\theta(r)$ curve. This curve is actually a cumulative pore-size distribution; the water content on a drying $\theta(r)$ indicates the combined volume of all pores with opening radius less than r. Applying the fundamental theorem of calculus, the direct pore-size distribution is simply the derivative:

$$f(r) = \frac{\mathrm{d}\theta}{\mathrm{d}r} \qquad [3]$$

Mercury porosimetry is analogous to the water retention-based method, but uses air as the wetting fluid, corresponding to the water, and mercury as the nonwetting fluid, corresponding to the air in the water–air system. Mercury is forced into the pores of dry soil incrementally, so that the relation between mercury content and mercury pressure is obtained. Applying eqn [2] with the appropriate values of surface tension and contact angle for mercury leads to a pore-size distribution estimate as for the extraction of water from a water–air system.

The different measurement techniques do not give exactly the same results. Emptying and filling depend on more than capillarity – different methods are affected differently by unintended influences. Contact angles, for example, are dynamic, are not likely to be at handbook values in soil, and may deviate quite differently for water and for mercury. The swelling of clays can be a major influence on a water-retention curve, but should have no effect with mercury.

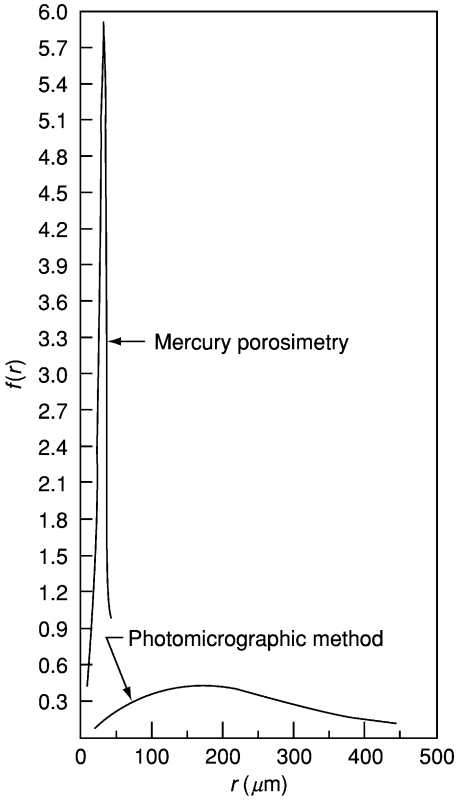

Figure 5 Pore-size distributions obtained for an artificial medium using an imaging method and mercury intrusion. (Reproduced with permission from Dullien FAL and Batra VK (1970) Determination of the structure of porous media. *Industrial Engineering Chemistry* 62: 25–53.)

Imaging techniques are subject to some entirely different influences, such as the chance and subjectivity involved in assessing pore bodies and openings. Figure 5 shows an example of substantially different results from different methods. In soil environmental applications, use of the water-retention curve is most common. Data are more commonly available for this than for any other method. One can also expect a water-based method to give better results for a water-based application (e.g., hydraulic conductivity).

Representation

The basic representation of pore-size distribution is as the function $f(r)$ (Figure 4). Corresponding graphs of the cumulative size distribution can be used equivalently. Often a specific functional form or other representational model of pore-size distribution is useful. A normal or lognormal can be fitted to the data, for example. Structural features may give the soil a bimodal pore-size distribution, leading to several distinctive effects on water flow. Bimodal, trimodal, or other multimodal forms are possible, and can be

represented by superpositions of the normal or lognormal forms. Self-similar or fractal forms of the distribution function are also used, giving a power-law form of the cumulative pore-size distribution.

Typical Features of a Pore-Size Distribution

With the equivalent-capillary concept taken as broadly as possible, the smallest possible pore is limited to the order of a few molecular diameters, approximately 1 nm. Fluid behavior is then likely to be dominated by interaction with the solid material and is not necessarily describable by capillary laws or even standard thermodynamics. The smallest pores measured by water retention or mercury intrusion are typically 50 or 100 times larger than this, though with greater cost and effort, greater magnitudes of pressure and hence smaller measured r can be achieved. As the imputed pore size approaches zero, in effect thin films are associated with effective radii of filled pores. Because r relates inversely to P, the whole dry portion of the retention curve is contained in a very small region near $r = 0$, where the apparent number of pores becomes large. In the extreme case, when θ is held to remain artificially finite at an assumed residual water content as P goes to negative infinity, $f(r)$ at $r = 0$ is a delta function.

There is no real upper limit to pore size, though instability will cause the capillary hypothesis to break down for r of a few millimeters. The experimental limit is typically approximately 0.5 mm.

At either extreme, where capillary phenomena lose dominance, eqn [2] no longer applies, though it still can give r-values corresponding to P. These may be useful for translating one property to another (discussed below) even though they are invalid in terms of the capillary analog.

At intermediate values of r, sometimes $f(r)$ has a pronounced peak, as in **Figures 4b** and 5. Such a peak is assumed to exist in many applications and interpretations of pore-size distributions, for example normal or lognormal representations, though it does not always exist in the measurable range of r. A peak in $f(r)$ corresponds to an inflection point in $\theta(r)$. The inverse relation of r to P means that $\theta(P)$ is much more likely to have an inflection point than $\theta(r)$; if $\theta(r)$ has an inflection point, then $\theta(P)$ is mathematically required to have an inflection point, but the converse is not true. The common case of an S-shaped retention curve (with inflection point in the measured range, and normally a distinct air-entry effect) will have a defined peak in the pore-size distribution only if the middle portion of the retention curve has a slope that differs markedly from that of the two end segments. This is frequently true for monodisperse media and for repacked samples, in which pores larger than a certain r have been destroyed. For many soils, perhaps most, $f(r)$ does not have a peak except at $r = 0$ or so close to 0 that it cannot be measured. This is especially likely for media that are macroporous, polydisperse, or that show an air-entry effect at essentially $P = 0$. Retention curves represented by a fractal or power-law model are also in this category. Lognormal models or other representations that have a defined peak can often still be applied but with the peak outside the measurable range. Some models (e.g., of hysteresis and hydraulic conductivity) may be unaffected by the lack of a measurable peak even though they were derived assuming the pore-size distribution resembles some form of normal distribution.

Significance to Soil and Water Behavior

Significance of Porosity

One obvious significance of porosity is that it is an upper limit of volumetric water content. It is similarly essential to the definition of degree of saturation, θ divided by porosity. Another significance is that, within the pore space, the complement to θ is gas content. That is, volumetric gas content equals the difference between θ and porosity.

The magnitude of porosity roughly indicates complexity of structure, being greater for greater complexity, as noted above for aggregated soil. The spatial variability of porosity is also important, greater variability correlating with greater heterogeneity of the soil. Significant spatial variability on a small scale also implies greater structural complexity, independent of the magnitude of porosity.

Significance of Pore-Size Distribution

A major importance of a soil's pore-size distribution is that it relates to other soil properties in a complex and useful way, as discussed below. It indicates complexity of structure in far more detail than porosity alone. The spatial variation of pore size is an important characteristic of the medium. The pore-size distribution of different parts of soil is the fundamental basis for the concept of aggregates, for example. By some definitions, pore size can permit essential distinctions between micropores and macropores (and mesopores, where that term is used for intermediate-size pores).

The relation of pore-size to particle-size distribution in a randomly structured medium is likely to be monotone: bigger pores are associated with bigger particles. With the nonrandom structure of most soils, the relation to particle size is complex. Bigger pores can be associated with bigger particles, but

also with smaller particles such as clays that promote aggregation and hence the existence of large interaggregate pores.

With more intricate conceptualizations, subdivisions of a pore-size distribution can represent more detailed properties of soils, for example the hysteresis of soil water retention. Figure 6 shows an example in which one graph represents pore-opening and pore-body size distributions. The added information of what fraction of pores with a given opening size have a particular range of body sizes is taken to represent the essential quantitative basis of soil water hysteresis.

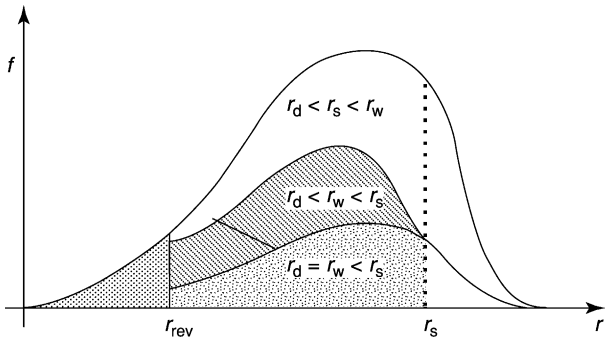

Figure 6 Hypothetical pore-size distribution with subregions distinguished on the basis of pore body and opening radii and drying–wetting history. (Adapted from Nimmo JR (1992) Semiempirical model of soil water hysteresis. *Soil Science Society of America Journal* 56: 1723–1730.)

Pore Dynamics

Natural and artificial soil processes create and destroy pores, and induce changes in their size and other attributes. Table 1 lists some of the common effects on pore-size distribution caused by routine processes. In general, if the soil is compacted by uniform stress, such as a weight imposed at the land surface, it normally loses large pores and gains small pores. Figure 4b shows results of this type. Disturbance from irregular stresses, as during digging or repacking, has a variety of effects on pore size, often with the net effect of a decrease in the number of large pores and an increase in the number of small pores, as shown in Figure 4c. Several types of process can create pores. Though small intergranular pores are seldom completely closed, some processes can close macropores, in effect destroying them.

Applications to Soil Transport Properties

Because the pores it characterizes are conduits and repositories for water, the pore-size distribution relates directly to soil hydraulic properties. In addition to water retention, as described above, because the characterized pores are also fluid conduits, it connects with predictions of hydraulic conductivity

Table 1 Possible effects of routine soil processes on pore-size distribution

Soil process	*Effect*
Shrinkage	Enlarged macropores
	New macropores created
	Within an aggregate, intraaggregate pores decrease in size, or increase in size if clay particles shrink
Swelling	Decrease in the size of macropores
	Closed macropores
	Within an aggregate, intraaggregate pores increase in size, or decrease in size if clay particles expand
Mechanical compression	Decrease in the size of macropores
	Closed macropores
	Aggregates break up, reducing the number of intraaggregate pores, thereby reducing the fraction of the pore space represented by the smallest pores
Disturbance from digging or plowing	Existing macropores destroyed
	Interclod macropores created
	Aggregates break up, reducing the number of intraaggregate pores, also the fraction of the pore space represented by the smallest pores
Biological activity	New macropores created
	Enlarged macropores, as by ongoing traffic of ants or burrowing mammals
	Decrease in the size of macropores, e.g., if they are affected by compression resulting from the expansion of a nearby root
	Increased aggregation, promoting the creation of interaggregate macropores, and possibly smaller intergranular pores within aggregates
	Constricted or obstructed pores, e.g., through growth of microorganisms
Chemical activity	Constricted or obstructed pores through formation of precipitates
	Enlarged pores through dissolution of precipitates
	Increased or decreased interparticle cohesion, with complex effects on pore size and structure

K. The same principles can be applied to the transport of fluids other than water, including gases, though water flow is the most common application.

By analogy to laminar flow in tubes as quantified by the Poiseuille law, the conductance of a single pore can be inferred to be proportional to the fourth power of its effective radius. This makes its hydraulic conductivity proportional to the square of its effective radius. An estimated $f(r)$ distribution tells the relative abundance of each conduit size, thus providing the ingredients needed to predict K.

A K prediction based on the capillary hypothesis assumes pores are filled if smaller than a certain radius determined by θ. The portion of $f(r)$ representing the filled pores is relevant to unsaturated K. The simplest possibility is to integrate $f(r)$ weighted by r^2 over the domain represented by filled pores, giving a number proportional to K for the corresponding θ. Multiplying this integration by a separately determined matching factor gives the actual predicted K.

Many specific models in the published literature are based on these ideas. They differ in how they treat matters such as pore length, connectedness, tortuosity, and the distinction between pore opening and body dimensions. Popular models include those of Mualem and Burdine, which have been analytically combined with widely used empirical formulas for retention curves.

Considering solute transport, the pore-size distribution affects advection as it does hydraulic conductivity. Additionally it is important to dispersion, expected to be greater for a broader pore-size distribution. Adsorptive reactions with other soil constituents are related in a complex way. The smaller pores are associated with longer residence times and greater relative surface area, but most solutes may go quickly through the large pores with minimal opportunity to react. Interchange between fast-transporting and slow-transporting portions of the pore space is a vital and much-investigated aspect of solute transport in soils. Sometimes the terms 'mobile' and 'immobile' are used in this context, but of course the distinction is not as sharp as these terms imply.

For particle transport, many aspects are essentially the same as for K and solute transport. Additionally, the phenomenon of straining depends critically on the proportion of pores smaller than a given particle size. This is the dominant factor in some particle-transport applications.

Pore-size distribution relates indirectly to heat transport. It correlates in some way with the degree of aggregation, the moisture relations, the number of points of particle contact, and other factors affecting thermal conductivity.

Summary

The characterization of pore space is a vital and fruitful aspect of soil investigation. Liquid, solid, and gas constituents of the soil govern the form and development of pores, whose character in turn profoundly influences the nature and behavior of the soil.

Soil porosity is fairly well standardized in definition and measurement techniques. Pore size, however, is not obviously definable, much less measurable. Yet it is central to topics such as macropores, aggregation, fractures, soil matrix, and solute mobility. Pore size plays a key role in various proposed means of quantifying soil structure. It also has a major practical role in the prediction of hydraulic properties. New pore-size concepts, measurement techniques, and relations to transport phenomena are likely to remain a major emphasis in the study of soil.

Introduction

Potassium (K) is a major constituent of soils and plants. The common range of K content in the soil is 0.4–30 g K kg^{-1}. Of the major nutrient elements, K is generally the most abundant in the soil. Of this total K content, 98% is bound in the mineral form, whereas 2% is in soil solution and exchangeable phases.

Among the mineral cations essential for plants, K is the largest in size. Therefore, the number of oxygen ions coordinating K in mineral structure is high. The strength of each K-O is, thus, relatively weak. Potassium has a polarizability of 0.088 nm^3, which is higher than for Ca^{2+}, Li^+, Mg^{2+}, and Na^+, but lower than for Ba^{2+}, Cs^+, NH_4^+, and Rb^+ ions. Ions with higher polarizability are preferentially selected in ion exchange reactions.

The vitality of K in plant growth and yield formation has been known since the work of von Liebig, published in 1840. The availability of K to plants is related in many ways to the structural and surface chemistry of soil minerals. The large amount of K in soil minerals, fixation of applied K, and ion selectivity and dynamics of soil K have led researchers to study the relationships between K uptake by plants and the chemistry of soil K for decades.

Forms of Soil Potassium

Soil K exists in four forms in soils: solution, exchangeable, fixed, and structural (Figure 1). Solution and exchangeable K generally account for relatively small proportions of the total K in soils. Potassium-bearing micas and feldspars are the major K reserves of the soil. Upon reaction with weathered micas, vermiculites, allophane, and zeolites, K is also present in fixed form in soils. In the immediate vicinity of the fertilizer zone, K can react with aluminum hydroxides and acid phosphate solution to form taranakite. However, the nucleation and crystallization of taranakite can be perturbed in soils with high Fe content, especially under reduced and acidic conditions. In acid soils, K could also be coprecipitated with Al and sulfate to form alunite. The order of the soil K forms in terms of bioavailability is: solution > exchangeable > fixed > structural.

Solution K

Plants and microorganisms directly take up soil solution K. This form of K is also most subject to leaching in soils. The concentration of soil solution K varies from 2 to 5 mg K l^- for normal agricultural soils of humid regions and is an order of magnitude higher in arid-region soils. The amount of soil solution K is generally too low to meet the requirement of K by a crop during a growing season. Soil solution K is in dynamic equilibrium with other forms of soil K and is influenced by the soil moisture content, the concentrations of cations in the solution and on the exchanger phase, and the concentration of solution inorganic and organic ligands.

Exchangeable K

Exchangeable K is the portion of soil K that is electrostatically bound as an outer-sphere complex to the surfaces of soil minerals and organic matter. It is readily exchanged with other cations and bioavailable. The replenishment of a K-depleted soil solution is affected by the release of exchangeable K from soils.

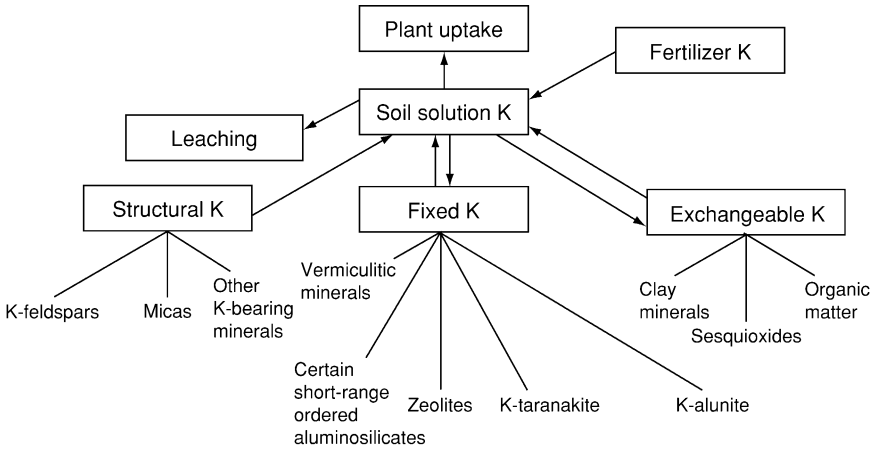

Figure 1 Interrelationship of various forms of soil K. Reproduced with permission from Sparks DL and Huang PM (1985) Physical chemistry of soil potassium. In: Munson RD (ed.) *Potassium in Agriculture*. Madison, WI: American Society of Agronomy, Crop Science Society of America, and Soil Science Society of America.

Fixed K

Fixed K (nonexchangeable K) is different from structural K in that it is not bound within the crystal structures of soil minerals. It is held in the interlayer space of weathered micas, vermiculites, and hydroxy-interlayered vermiculites. Potassium becomes fixed because the binding forces between K and the mineral surfaces are greater than the hydration forces between individual K ions. This results in a partial collapse of the crystal structures and the K ions are physically trapped to varying degrees, making K release a slow, diffusion-controlled process. Fixed K can be found in a series of soil components and is also present in wedge zones of weathered micas and vermiculites. Cations with a size similar to K^+, e.g., NH_4^+ and H_3O^+, can exchange K from wedge zones of interlayers. Large hydrated cations, such as Ca^{2+} and Mg^{2+}, cannot fit into the wedge zones and, thus, cannot release fixed K. Fixed K is moderately to sparingly available to plants. Release of fixed K to the exchangeable form can take place when levels of exchangeable and solution K are decreased by plant removal, microbial activity, and leaching. The ability of plants to take up nonexchangeable K appears to be related to the plant species.

Structural K

Most of the total soil K is in the form of structural K, mainly as K-bearing primary minerals such as feldspars and micas. The total soil K is present in a series of particle-size fractions. The distribution of K in feldspars and micas in a wide range of particle-size fractions of moderately weathered soil profiles is illustrated in Table 1. The K-feldspars and K-micas of soils serve as an important reserve of available K, although structural K is generally assumed to be only slowly available to plants. The availability of structural K depends on the dynamics of K release from micas and K-feldspars, which are, in turn, related to the crystal structure and atomic bonding of these K-bearing primary minerals, the degree of weathering of these minerals, and the level of K in other forms. A substantial amount of K is released from the sand fractions of Delaware soils that are high in K-feldspars. This, along with the large quantities of mineral K in these and other Atlantic coastal plain soils, helps to explain the often observed lack of crop response to K fertilization on these soils.

Ion Selectivity and Fixation of Potassium in Soils

Ion Selectivity

Potassium selectivity of soils is affected by their mineralogical and chemical properties.

Mineralogical properties The layer charge, particle size, configuration of interlayers and wedge zones, position of wedge zones in interlayers, hydroxy interlayers, and variable-charge minerals are important mineralogical properties that affect K ion selectivity of soils.

The site of negative charge and the charge density of minerals may affect K^+ selectivity. The high K^+ selectivity of clay-size muscovite is attributed to the negative charge arising in the tetrahedral sheet. The K^+/Ca^{2+} cation exchange selectivity (CES) values, expressed as the equivalent ratio of exchangeable K^+ to Ca^{2+}, range from 0.1 for montmorillonite to 1.7 for muscovite. This corresponds to the order of

Table 1 Distribution of feldspar K in various size fractions of a Haverhill soil profile (Aridic Haploboroll) in Saskatchewan, Canada

increasing layer charge and surface charge density of the minerals.

Potassium selectivity of soils varies with particle size. It increases with particle size in some soils. Potassium selectivity may decrease with particle size at later stages of weathering. Much of the K selectivity apparently occurs in the interlayer regions.

Potassium selectivity is influenced by the configuration of interlayers and the position of the wedge zone in the interlayer. Instead of large hydrated ions such as Ca^{2+} and Mg^{2+}, K^{+} is selected due to the space limitations for diffusion of these large hydrated cations in the wedge zones. If the wedge zone is near the edge of the particle, it can be effective in only a small amount of K selection. If the wedge zone is deep within the particle, much more K can be selected. Wedge zones increase as more interlayers are opened and decrease as the interlayers are opened all the way through the particle.

Potassium selectivity is enhanced by the presence of hydroxy-Al and hydroxy-Fe(III) polymers in the interlayer space. These interlayer materials act as props to hinder the collapse of the layers about the K ions. Potassium ions are able to move more easily in propped-open interlayer spaces than in collapsed interlayers (Figure 2). Besides the propping effect, the preferential occupation by the hydroxy-Al polymers of the interlayer exchange sites that would normally adsorb Ca may also affect K selectivity. Due to their size, the polymers would not be adsorbed at wedge zones but rather in a more expanded interlayer position (Figure 3). Consequently, sites that would normally adsorb Ca^{2+} ions would be occupied by Al polymers, whereas wedge sites would be relatively unaffected by the adsorption of hydroxy-Al

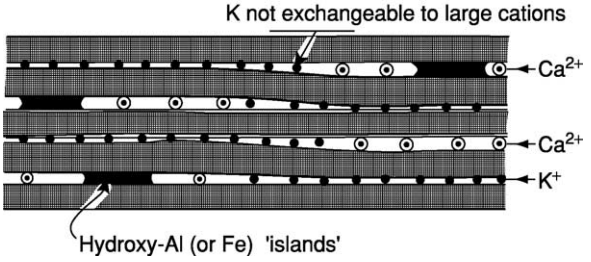

Figure 2 Proposed model of an expandable layer silicate with interlayers indicating effect on K fixation. Reproduced with permission from Rich CI (1968) Mineralogy of soil potassium. polymers. Hydroxy-Al interlayers may also exert a retarding effect on the entry of the more hydrated Ca^{2+} ions. This would result in the increase of the selectivity toward the less hydrated K ions.

Besides layer silicates, variable-charge minerals also contribute to adsorption and selectivity of K ions. The contribution of these minerals to K selectivity is pH-dependent. Further, both cationic and anionic environments have a profound influence on the adsorption of K^+ and Ca^{2+} in metal oxides such as birnessite (Mn oxide). This is of significance in understanding the chemistry of K in variable-charge soils.

Chemical properties Besides mineralogical properties, chemical properties also affect K selectivity of soils. The hydrated ion size and valence greatly influence K selectivity. In soils containing partially weathered micas and vermiculites where wedge zones exist, NH_4OAc removes more exchangeable K than does $Mg(OAc)_2$, although Mg^{2+} is usually a better replacer of K^+ than NH_4^+. The wedge zones exclude the hydrated Mg^{2+} due to steric hindrance and preferentially adsorb cations that can fit into the wedge sites. $MgCl_2$ can remove more K^+ than can $Mg(OAc)_2$ because of the depression effect of soil pH by $MgCl_2$ and the formation of H_3O^+ by exchange or hydrolysis of exchangeable and polymeric Al. The H_3O^+ ion is similar in size to K and is thus able to fit into the wedge zone and exchange K^+. A combination of NH_4OAc and $MgCl_2$ is more effective in removing exchangeable K^+ than either electrolyte alone. This is attributable to Mg^{2+} opening up the interlayer space and facilitating the exchange of K^+ by NH_4^+.

Ions do not migrate rapidly enough to account for the reaction rate involving H_3O^+ ions. The lifetime of an individual H_3O^+ is exceedingly short, $\sim 10^{-13}$ s, since all of the protons are undergoing rapid exchange. As long as there is a continuous film of H_3O^+ to a K^+ ion, the exchange of H_3O^+ for K could proceed rapidly. Potassium exchange of soils is enhanced by low pH. The effect of pH on ion selectivity varies with the associated cations. pH has little effect for NH_4^+. NH_4^+-saturation collapses the interlayer structure and, thus, excludes H_2O which is the medium for transport of protons to and from the exchange sites. By contrast, the effect of pH for Li^+ and Mg^{2+} is pronounced. The increased efficiency of Li^+ and Mg^{2+} with a decrease in pH is attributed to an expansion of the interlayer structure, which facilitates the entry of water and protons and the exchange of H_3O^+ for K.

Potassium selection in the wedge zones is influenced by the concentration of K^+ in the soil solution. There is K selection at the wedge sites at low K concentration. As the K^+ concentration increases, the silicate layer collapses at the wedge sites, resulting in an entrapment of ions deeper in the interlayer space. A high K^+ concentration is necessary to initiate collapse of the interlayer space of vermiculite and to enhance K selectivity in the absence of wedge zones.

Temperature also affects K selectivity of soils. A rise in temperature decreases K selectivity of Delaware soils (loamy sand, Typic Quartipsamments; sandy loam, Typic Hapludults; silt loam, Typic Hapludults; clay minerals include vermiculite, chloritized vermiculite, mica, kaolinite, chlorite, and quartz). This indicates that K sorption decreases with increasing temperature. The Delaware soils contain wedge zones that would selectively exclude large hydrated cations such as Ca^{2+} and Mg^{2+} and preferentially select smaller cations such as NH_4^+ and K^+. As the temperature increases, the hydration of Ca^{2+} and Mg^{2+} is decreased relative to that of K^+. Therefore, the size is not as important in K^+ selectivity. Furthermore, increased temperature could collapse the interlayer space of hydroxy-interlayered vermiculite and, thus, decrease K^+ selectivity of the soils.

Fixation of Potassium

Potassium fixation in soils has been extensively studied. The extent of K fixation is related to the type of clay minerals and their charge density, the degree of hydroxy interlayering, the concentration of K^+ ions and competing ions such as NH_4^+, the moisture content, and solution pH. The expansible 2:1 layer silicates such as weathered micas, vermiculites, and smectites are the major clay minerals responsible for K fixation in soils. Weathered micas and vermiculites

fix K under moist as well as dry conditions, whereas smectites fix K only under dry conditions. The amount of K fixation by smectites is very small unless their charge density is high. Some soil smectites have a higher charge density and likely have wedge sites near mica-like zones where K selectivity is high and K fixation can take place.

The principal mineral responsible for K fixation in acid soil is probably dioctahedral vermiculite. Counteracting the effect of high-charge density on K fixation in many acid soils is the presence of hydroxy-Al and –Fe(III) polymers in the interlayer space. The polymers act as props between the unit silicate layers and inhibit collapse of the layers about the K ions. The presence of hydroxy-interlayer polymers in vermiculite increases the Gapon coefficient K_G (K/Ca) from 5.7×10^{-2} to 11.1×10^{-2} l(mmol)$^{1/2}$. On the other hand, K fixation is reduced markedly.

Since the pioneer research on the effect of freezing and thawing on K fixation and release, the significance of wetting and drying and freezing and thawing has been recognized by numerous researchers. The degree of K fixation or release on wetting or drying depends on the type of colloids and the level of K^+ in the soil solution.

Potassium fixation in soil and clay systems is influenced by pH. The pH effect on K fixation is related to: (1) the concentration of H_3O^+ and the competing cations and (2) the extent of interlaying and the resultant charge neutralization and propping effect. A marked increase in K fixation in soils was observed when pH was raised to about 9 or 10 with Na_2CO_3. There was no fixation at pH values up to 2.5; the amount of K fixation increased very rapidly between pH 2.5 and 5.5. Fixation of K increased more slowly above pH 5.5. At low pH, the lack of K fixation is attributed to a high concentration of H_3O^+ and its ability to replace K^+. At pH >5.5, Al^{3+} cations precipitate as hydroxy polycations, which increase in the number of OH groups as pH increases until a discrete gibbsite phase is formed. At pH about 8, Al^{3+} does not neutralize the negative charge on the clay and cannot prevent K fixation. The increase in K fixation between pH 5.5 and 7.0 is attributed to the decreased number of hydroxy-interlayer material that decreases K fixation.

Potassium Release from Soils

Primary Minerals

Micas and feldspars are the main K reserves of soils (Figure 1). The release of K from micas and feldspars replenishes the K in the labile pool. Therefore, these K-bearing primary minerals have a significant impact on long-term soil K fertility.

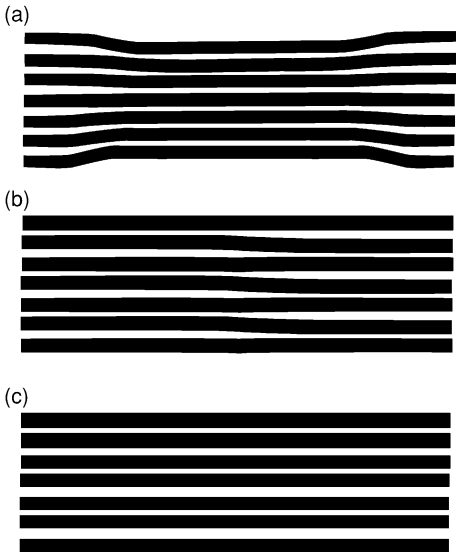

Figure 4 Diagram of a weathered mica particle containing about 50% expanded (vermiculite) layer. (a) 'Frayed edge' and mica core; (b) alternate layers open halfway through interlayer; and (c) regularly interstratified mica-vermiculite (no wedge zone). Reproduced from Rich CI (1972) Potassium in soil minerals. *Proceedings of the 9th Colloquium of the International Potash Institute* 9: 15–31.

Micas Potassium release from micas may proceed by two processes: the transformation of micas to expansible 2:1 layer silicates by exchanging the K^+ with hydrated cations and the dissolution of micas resulting in the formation of weathering products. Both types of reaction occur in soil environments.

The transformation of micas to 2:1 expansible layer silicates through K^+ release proceeds by first, edge weathering and second, layer weathering. These weathering mechanisms are depicted in Figure 4. In models (a) and (b), the expanded interlayers are not continuous but have internal terminations forming 'wedge zones.' In model (c), interlayer spaces are either expanded all the way through the particle or nonexpanded uniformly through each layer. Edge weathering is most common in larger mica particles; in contrast, layer weathering is most common in smaller particles.

The mineralogical factors influence the release of K^+ from micas by both cation exchange and dissolution reactions. These include tetrahedral rotation and cell dimensions, tetrahedral tilting, hydroxyl orientation, chemical composition, particle size, structural imperfections, and layer charge alterations and related reactions. Ionic factors also substantially influence the release of K from micas. The hydronium ion, H_3O^+, is one of the dominant ions in acidic soil solutions. Reaction rates involving the H^+ ion are not restricted by diffusion rates of H_3O^+. Therefore,

proton transfer may be rapid to the wedge zone at the junction of 'open' to 'closed micas.' The rate of H_3O^+–K^+ exchange may be limited by the rate of K^+ diffusion.

The sources of H_3O^+ in soils include water through its dissociation, the dissolution of CO_2 from the air and soil atmosphere, strong mineral acids originated from weathering reactions, and low-molecular-weight organic acids. Hydronium ions are probably the cause of major release of structural K^+ by weathering reactions. This mechanism is especially important in the soil rhizosphere, which is the most important plant feeding zone. Therefore, the extraction of soils with boiling 1 mol l^{-1} HNO_3, dilute HCl solutions, and other acid dissolution techniques have been proposed for measuring the K-supplying power of soils.

The activity of K^+ ions in the soil solution greatly influences the release of K^+ from micas by cation exchange. Therefore, the K release can be greatly driven by K^+ leaching and especially by cropping without K^+ fertilizer application. When the K level is less than the critical value, K^+ is released from the interlayer by other cations from the solution. On the other hand, when the K level is higher than the critical level, the mica-expansible 2:1 phyllosilicates adsorb K^+ from the solution. The critical K level is highly mineral-dependent, being much lower for muscovite than for trioctahedral micas. The nature and concentration of the replacing cations also influence the critical K level in the solution. For example, the critical K levels decrease in the order $Ba^{2+} > Mg^{2+} > Ca^{2+} \cong Sr^{2+}$ for the same concentration of these ions and with a constant mica particle.

Many organic and inorganic ligands in the soil solution also affect K release from minerals. The kinetics of K release from muscovite and biotite is greatly influenced by the nature of organic acids which are common in soil environments, especially in localized zones where biological activity is intense, such as in the rhizosphere and near decomposing plant residues. Besides organic ligands, some strong complexing inorganic ligands such as phosphate can influence the kinetics of K release from micas. In the immediate vicinity of the phosphate fertilizer zone, the concentration of phosphate can be as high as 2.9–4.5 mol l^{-1}. The rates of K release from muscovite, biotite, and illite are significantly enhanced by 1 mol l^{-1} $NH_4H_2PO_4$ (pH 4.0).

Redox potential of soils influences the K^+ release from micas because the interlayer K is more tenaciously held after oxidation of the structural Fe(II). Other factors being equal, the extent of K^+ release from micas appears to be less in oxidized soil environments then in reduced soil environments.

Potassium-bearing feldspars The release of K from feldspars through weathering reactions is an important process in replenishing the labile pool of soil K. The weathering rate of K-bearing feldspars appears to be affected by their structural properties which include the chemical composition, principally the inclusion of Na in the structure, the order of Si and Al in the structure, crystal and particle size, crystallization of more than one mineral within one particle, and the nature of twinning. The rate of weathering reactions of K-bearing feldspars probably increased with Si/A1 disorder and Na content. A perthitic feldspar would likely weather more rapidly than a homogeneous particle. Albite would be weathered more rapidly in perthitic structures than the K-feldspar. Weathering is also likely more rapid at the junction of twins because of disorder at these planes.

Hydronium ions are an important chemical weathering agent of K-bearing feldspars. The initial weathering of K-bearing feldspars proceeds by surface reactions in which K^+ is displaced by H_3O^+. The substitution of K^+ by H_3O^+ weakens the feldspar structure. The kinetics of dissolution of K^+ from K-bearing minerals by 1 mol l^{-1} HNO_3 indicates that, for the temperature range studied, the rates of K^+ release from muscovite, phlogopite, and biotite are about 2, 9–12, and 118 to 190 times, respectively, greater than the rate of K^+ release from microcline (Table 2). The release of K^+ from a tectosilicate is more difficult than from the interlayers of micas. The Arrhenius heat of activation for the release of K^+ from microcline is greater than for the micas. The heat of activation is interpreted as the energy level the structural K must acquire to be able to react. As the heat of activation increases, the rate constant decreases, since the mineral with higher heat of activation for the release of K^+ would release less K per unit time. The Arrhenius heat of activation and apparent rate constant for K^+ release from the K-bearing minerals (Table 2) are fundamental to understanding the availability of K^+ in feldspars and

Table 2 Apparent rate constants and Arrhenius heats of activation for the release of structural K from K minerals

	Rate constant		*Arrhenius heat of activation*
Mineral	*301 K (h^{-1})*	*311 K (h^{-1})*	*(kJ mol^{-1})*
Biotite	1.46×10^{-2}	3.09×10^{-2}	58.66
Phlogopite	9.01×10^{-4}	2.44×10^{-3}	77.81
Muscovite	1.39×10^{-4}	4.15×10^{-4}	85.52
Microcline	7.67×10^{-5}	2.63×10^{-4}	96.24

micas to plants. Although the release of K^+ from K-feldspars is generally more hindered than from micas, the K-feldspars are the largest natural reserves of K in many soils. Therefore, the role of K-feldspars in supplying K to plants cannot be ignored.

Besides H_3O^+ ions in soil solutions, complexing organic and inorganic ligands have significant roles in the release of K from the feldspar structure. Low-molecular-weight organic acids are very effective in releasing K^+ from K-bearing feldspars. Root growth and root length along with organic acids in the soil rhizosphere, thus, merit attention. In the immediate vicinity of the phosphate fertilizer zone, high concentrations of phosphate in the soil solution may also induce K release from K-feldspars.

Climate, topography, and the degree of leaching also influence the stability of K-bearing feldspars in soils. All experimental evidence shows that chemical breakdown of K-feldspars accelerates with raising temperature. Warm climate and high precipitation in tropical soils may have depleted all of their K-feldspars. However, these minerals may persist in temperate soils, especially in sand and silt fractions.

Natural Soils

Chemical methods have been used to extract nonexchangeable K of soils. These include boiling HNO_3, H_2SO_4, hot HCl, electroultrafiltration, Na tetraphenylboron with ethylenediaminetetraacetic acid (EDTA), and ion exchange resins such as H- and Ca-saturated resins.

Soil K released to Ca-resin can be divided into three simultaneous rates of K release from the surface of the soil complex, the weathered periphery, and the micaceous matrix. The diffusion coefficient (3×10^{-19} $cm^2\,s^{-1}$) calculated for the slowest process, which is suggested to be from the mineral matrix, is of the same magnitude as that for illitic clay minerals. Comparing the values of rate constants for K release from the soils with those for K release from minerals, the rate constants of K release from the soils are within the range expected for K release from the mixtures of micas and K-feldspars. The rate constants of K release from six Great Plain soils by successive extraction with Ca-saturated cation exchange resin are highly correlated with mica contents of the soils, cumulative K uptake, and cumulative alfalfa yield.

The release of nonexchangeable K from soils is not only from clay-size K-bearing minerals but also from micas and feldspars in silt and sand fractions. The release of K^+ by the H^+-saturated ion exchanger from these size fractions as a function of time is demonstrated in Figure 5, based on the Elovich equation. The variation in the slope of the Elovich equation correlates significantly with the concentration of micaceous minerals in the sand, silt, and clay fractions, and may have an important impact on K for plant uptake.

Few studies have investigated the effect of anions on the kinetics of K^+ release from soils. The amounts of K^+ released from the Oxisol, Alfisol, and Entisol in $1\,mol\,l^{-1}$ $NH_4H_2PO_4$ (pH 4.0) for 4 weeks are 4.77, 114.0, and $207.8\,mg\,kg^{-1}$, respectively (Figure 6). The results clearly indicate that the K release in $1\,mol\,l^{-1}$ $NH_4H_2PO_4$ at pH 4.0 from the three soils is 2.3–2.9 times higher than that in $1\,mol\,l^{-1}$ NH_4Cl at the same initial pH. Compared with the NH_4Cl systems, the excess K released from the soils in the $NH_4H_2PO_4$ systems is attributed to the phosphate-induced alteration of K-bearing minerals of the soils, since $1\,mol\,l^{-1}$ $NH_4H_2PO_4$ induces alteration of micas and feldspars and the subsequent K release. The amount of the $NH_4H_2PO_4$-induced K^+ release is related to the degree of weathering of the soils, namely, Oxisol < Alfisol < Entisol. The combined effect of phosphate and proton on the alteration of K-bearing minerals and the formation of NH_4-taranakite are the major mechanisms of the $NH_4H_2PO_4$-induced K^+ release from the soils. In the immediate vicinity of the fertilizer zone, the P concentration is very high and the pH is quite low. Therefore, application of $NH_4H_2PO_4$ fertilizer to soils would promote dissolution of K-bearing minerals from the soils, thus enhancing their K-supplying rate.

Availability of Soil Potassium

Quantity/Intensity Relationships

The ratio of the activity of cations such as K^+ and Ca^{2+} is defined by the relation $a_K/(a_{Ca})^{1/2}$ where a is the ion activity. The concepts of quantity (Q) and intensity (I) have been applied to the mineral nutrient status of soils. Based on the ratio law, the I of K in a soil at equilibrium with its solution could best be defined by the ratio $a_k/(a_{Ca} + a_{Mg})^{1/2}$ of the soil solution. This equilibrium activity ratio for K is referred to as AR^K and has often been used as a measure of K^+ availability. However, it has been proposed that the activity of K in the soil solution is of primary importance as it is relevant for K^+ diffusion and K translocation in soils by mass flow to roots.

Soils showing the same value of AR^K may not possess the same capacity for maintaining AR^K while K is removed by plant uptake. Therefore, one must include not only the current potential of K in the labile pool but also the way in which the potential depends on quantity of labile K present. These findings brought about the classic Q/I relationships where the activity ratio AR^K value is related to the change in

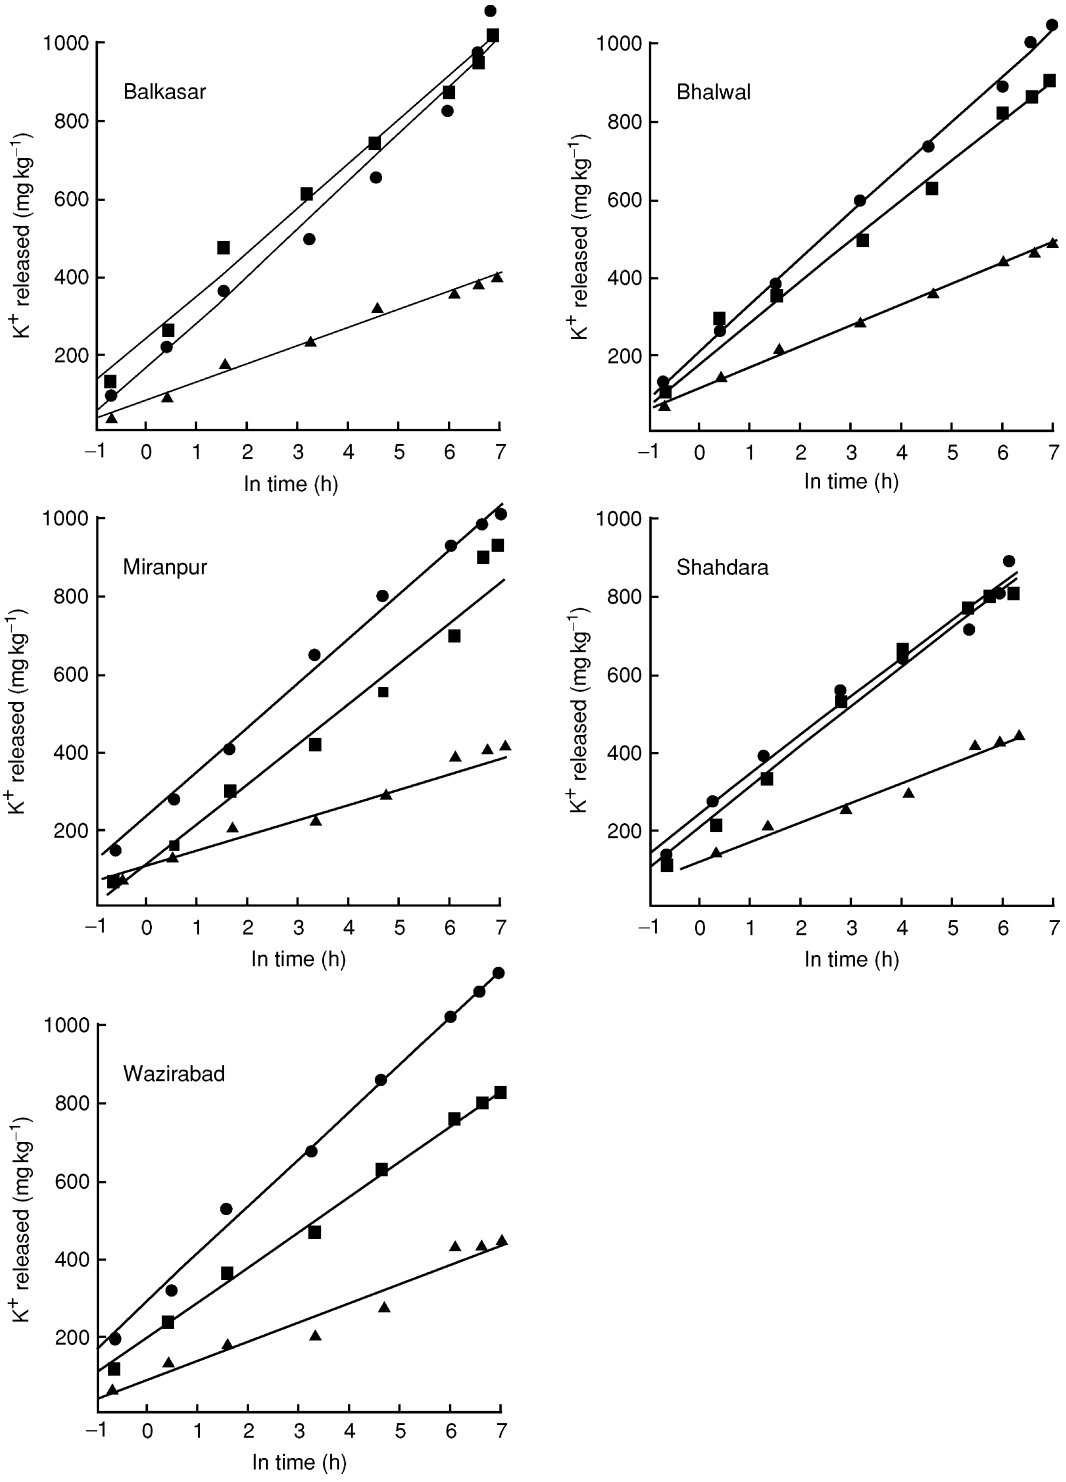

Figure 5 Release of nonexchangeable K^+ from sand (triangles), silt (squares), and clay (circles) fractions. Reproduced with permission from Rahmatullah and Mengel K (2000). Potassium release from mineral structure by H^+ ion resin. *Geoderma* 96: 291–305.

exchangeable K to obtain the effect of quantity of labile K (exchangeable K) on intensity of labile K (AR^K). The *Q/I* concept has been widely disseminated in the soil literature in understanding soil K status.

The method used for constructing a typical *Q/I* curve involves equilibrating a soil with solutions containing a constant amount of $CaCl_2$ and increasing the amount of KCl. The soil gains or loses K to achieve the characteristic AR^K of the soil or remains

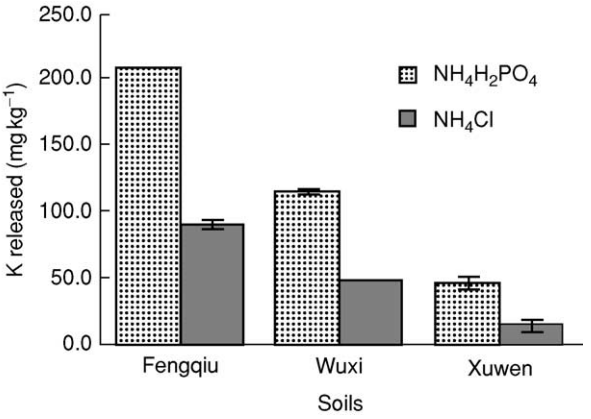

Figure 6 Potassium released from the soil in 1 mol l^{-1} $NH_4H_2PO_4$ and 1 mol l^{-1} NH_4Cl solutions (pH 4.0) at 25°C in 4 weeks. The Fenqiu, Wuxi, and Xuwen soils are Entisol, Alfisol, and Oxisol, respectively. The standard errors of the K release in $NH_4H_2PO_4$-Fengqiu and NH_4Cl-Wuxi soil systems were too small to be shown in the figure. Figure 7 Typical quantity/intensity (*Q/I*) plot. Reproduced with permission from Sparks DL and Huang PM (1985) Physical chemistry of soil potassium. In: Munson RD (ed.) *Potassium in Agriculture*. Madison, WI: American Society of Agronomy, Crop Science Society of America, and Soil Science Society of America.

unchanged if its AR^K is the same as the equilibrating solution. The AR^K values are calculated from the measured concentrations of K^+, Ca^{2+}, and Mg^{2+} converted to their ionic activities by application of the extended Debye–Hückel equation. The AR^K values are then plotted versus the gain or loss of K to form the characteristic *Q/I* curve (Figure 7). Several parameters can be obtained from the *Q/I* plot to characterize soil K status. The value of AR^K when the *Q* factor (ΔK) equals zero is a measure of the degree of K availability at equilibrium or AR^K_e. The value of ΔK when AR^K equals zero is a measure of labile or exchangeable K in soils or $\Delta K°$. The slope of the linear portion of the curve gives the potential buffering capacity of K (PBC^K) and is proportional to the cation exchange capacity of the soil. The number of specific sites for K (K_x) is the difference between the intercept of the curve and the linear portion of the *Q/I* plot at AR^K equals 0. Advances in ion-selective electrode (ISE) technology have allowed for more rapid *Q/I* analysis.

Soils which have the same AR^K_e may not have the same capacity for maintaining AR^K_e while K is being uptaken by plant roots. Soils can have the same AR^K_e but contain different amounts of labile K. K fertilization, liming, and cropping can change AR^K_e values.

The $\Delta K°$ values are a better estimate of soil labile K than normal exchangeable K. Higher values of labile K ($-\Delta K°$) indicate a greater K^+ release into the soil solution, resulting in a larger pool of labile K. The $\Delta K°$ becomes more negative or the labile K pool increases with K fertilization and liming on cropped soil.

The PBC^K indicates the ability of a soil to maintain the intensity of K^+ in the soil solution. A high PBC^K value is indicative of constant availability of K^+ in the soil over a long period. By contrast, a low PBC^K value would indicate the need for frequent K fertilization. However, the lack of response of a Kalmia soil in the Delaware coastal plain in USA, which had a low PCB^K value, to applied K was observed. This was attributed to the presence of the large amount of K-bearing minerals in the soil that with time could release K^+ to exchangeable and to solution form. Cropping and liming can change the PBC^K values of soils.

The Rhizosphere Chemistry and Labile Pool of Soil Potassium

The soil rhizosphere is the narrow zone of soil influenced by the root and exudates. The extent of the rhizosphere may vary with soil type, plant species, age, and many other factors, but it is usually considered to extend from the root surface out into the soil for a few millimeters. Microbial population in the rhizosphere can be 10–100 times larger than the populations in bulk soil. The rhizosphere is, thus, bathed in root exudates and microbial metabolites. Therefore, chemistry and bioavailability of soil K in the rhizosphere should differ from those in bulk soil.

A wide variety and considerable amount of organic compounds are released from plant roots in the rhizosphere. On average, between 30 and 60% of the net photosynthetic C is allocated to the roots in annual species; an appreciable portion (4–70%) of this C is released as organic compounds into the rhizosphere. The major components of rhizodeposition

are sloughed-off cells and their lysates, mucilage, and low-molecular-weight organic compounds. Both the amount and proportion of the various organic compounds of root exudates vary substantially with plant species and cultivars. Moreover, the same plant cultivar grown in different soils varies in the kind and amount of low-molecular-weight organic acids present in the rhizosphere. Biological activity promotes K^+ release from micas. Besides the depletion of the K of the soil solution by plant roots, the overall action of biological activity is more complex when organic acids are produced. Organic acids substantially influence the dynamics of K^+ release from K-bearing minerals. The effect of organic acids in enhancing the release of K is attributed to the dissociated H^+ ions and complexing organic ligands. The weakening of the metal–O bonds by protonation of surface OH groups and the formation of inner-sphere surface complexes with organic ligands certainly enhance mineral dissolution and K release.

In view of the impact of plant species and cultivars and their interactions with soil properties on the formation of the kind and amount of organic acids and the influence of organic acids on the dynamics of K^+ release from the K-bearing minerals common in soils, the role of organic acids in the rhizosphere in affecting the labile pool of soil K merits close attention.

Assessing Potassium Availability by Soil Tests

Most soils have a relatively large quantity of total K but relatively small amounts of plant-available K. Potassium soluble in water plus K adsorbed to exchange sites largely accounts for the labile pool of soil K. The exchangeable K is readily released to solution by the equilibrium process. During the course of a growing season, some initially nonexchangeable K may become water-soluble or exchangeable, and thus be plant-available.

The soil test methods for plant-available K are generally those that measure the soluble and exchangeable K or some parameter that relates to their equilibrium state. Soil test extractants for K are used to measure K easily and rapidly in soils and to estimate K availability. Based on the amounts of extractable K, recommendations based on field test calibrations can then be made on the amount of K required to obtain maximum yields.

Although soil tests for K usually measure the quantity of solution and exchangeable K, acids are usually used as extractants. Therefore, some nonexchangeable and structural K is also extracted. There are a number of soil test methods that are used to evaluate K availability of soils. The suitability of these soil test methods varies with soil types. The $1\,mol\,l^{-1}$ NH_4OAc at pH 7 procedure is probably the most widely used of all soil test methods for measuring so-called plant-available K on a global scale. Water-soluble K^+ or soil solution K^+ is such a small fraction of the total extracted by this method that it is not measured separately but is included along with that extracted (soluble and exchangeable). Both the K^+ in solution and that in the nonexchangeable form are in dynamic equilibrium with the exchangeable form. Therefore, the exchangeable K is sometimes referred to as a moving target.

Several other methods of determining exchangeable K^+ in soils have been developed for various soil conditions or for various methodological expediences. The Mehlich no. 1 (double acid) method ($0.05\,mol\,l^{-1}$ HCl in $0.025\,mol\,l^{-1}$ H_2SO_4) is considered best for sandy, acid, low CEC soils. The Mehlich no. 2 method ($0.2\,mol\,l^{-1}$ HOAc in $0.015\,mol\,l^{-1}$ NH_4F in $0.2\,mol\,l^{-1}$ NH_4Cl in $0.012\,mol\,l^{-1}$ HCl) is considered good for a wide range of soil conditions. The ammonium bicarbonate-diethylenetriamine pentaacetic acid (AB-DTPA) method is considered best for alkaline conditions. The Bray P-1 extractant is also used in some soil-testing laboratories to measure exchangeable K^+.

The soil test methods currently used in the USA are Mehlich no. 1 and Mehlich no. 3 procedures in the north-eastern and south-eastern regions, the Morgan and modified Morgan procedures in parts of the north-eastern region, and the $1\,mol\,l^{-1}$ NH_4OAc at pH 7 procedure in the western region.

For the interpretation of soil tests, it would be useful to know which K^+ quantity originates from the hydrated K^+ fraction and which from the nonhydrated K^+ fraction. The routine method which distinguishes between these two fractions is electroultrafiltration (EUF), which is used in Germany and Austria on a broad scale for K^+ fertilizer recommendation.

Soils which have long-term K-supplying power are attributed to the presence of sufficient K-bearing minerals (micas and K-feldspars). There are soils in the Punjab and Europe which hardly respond to K fertilization in long-term fertilizer trials. These soils release much K^+ from the silt fraction (Figure 5). Such soils differ much from sandy soils in their K fertilizer strategy.

Plant Analysis for Potassium

Plant K analysis is an approach to assess soil K status. This method is based on the principle that if an element such as K is deficient in a plant, growth rates and yields will be decreased. If increasing amounts of K are added, the K concentration in the plant or plant part increases until an optimum level is

Table 3 Critical K concentrations in agronomic crops

Crop	*Time of sampling*	*Plant part*	*Critical concentration*[a] *(g kg^{-1})*
Sugarbeet		Blade	10
Cotton		Leaves	<9–15
Wheat	Jointing (GS6)	Total tops	20–25
	Early boot (GS9)	Total tops	15–20
Rice	Flag leaf to mid-tillering		10–14
Corn	At tassel	Ear leaf	19
	At tassel	Leaves	17–27
	At silk	Sixth leaf from base	13
	At silk	Leaf opposite and just below ear shoot	20
Grain sorghum	Full heading	Second blade below apex	18
Alfalfa		Whole top	8–22
Red clover		Tops	15–22.5
Bermudagrass		Tops	13–15
Orchardgrass		Tops	23–25
Tall fescue		Tops	24–38
Kentucky bluegrass		Tops	16–20

[a]Critical concentration is that nutrient concentration at which plant growth begins to decrease in comparison with plants above the critical concentration. After Westerman RL (1990). Reproduced from Sparks DL (2000) Bioavailability of soil potassium. In: Sumner ME (ed.) *Handbook of Soil Science*. Boca Raton, FL: CRC Press.

attained. This approach is used to express growth and yield as a percentage of the maximum. The zone between the deficient and optimum concentration is referred to as the transition zone. The transition zone is the zone between nutrient concentrations that cause a 20% reduction in growth or yield and those that produce optimum or 100% in the maximum yield. This latter zone is referred to as the critical range where researchers select the yield reduction and nutrient concentrations that are acceptable. The critical K concentrations for various agronomic crops are shown in Table 3. These critical K concentrations are determined by relating yield (percentage of maximum yield or growth rate) to K concentration ($g\,kg^{-1}$) for a specific plant part sampled at a given stage of development.

PRECIPITATION, WATERSHED ANALYSIS

J V Bonta, USDA Agricultural Research Service, Coshocton, OH, USA

Published by Elsevier Ltd.

Introduction

Variability in current and historic weather and long-term climate, acting on spatially variable watershed characteristics, is the driving force that causes observed variability in stream flows, sediment transport, and water quality. Watershed characteristics such as spatial distribution of soil-water storage, hydraulic conductivity, tension characteristics, subsurface flow, and drainage affect flow, erosion, and water-quality sources and transport in a watershed. Weather varies significantly with time at a point on the landscape. Climate and weather also vary spatially over a watershed from one area to another and with elevation, and temporally from season to season.

The most obvious component of weather that affects watershed variability is precipitation, which has both deterministic and random components. Errors in measurement of precipitation, streamflow and other environmental variables, temporal and spatial variability and inadequate quantification of processes of water, sediment, and chemical movement in watersheds cause uncertainties in estimating the impacts of land-management changes on hydrology and water quality. This article summarizes current understanding of watershed processes, precipitation characterization and measurement, and watershed, weather, and precipitation modeling.

Measurement of Precipitation

Precipitation measurements and characterization have inherent inaccuracies that must be recognized before they are used in computer models and in other analyses. Accurate precipitation measurement is complicated because of its significant spatial and temporal variability, and because of its different forms (liquid, solid, mixture). There are three components to precipitation measurement – sensing, representativeness, and resolution. Precipitation sensing involves using a sensor to measure a control volume of atmospheric particles presented to the sensor. Representativeness refers to how accurately the sensed particles represent the volume of precipitation actually reaching the ground, which is important to evaluating a watershed's response to precipitation. Resolution refers to how often (time resolution – minute, hourly, daily) precipitation is measured, and to the depth increment measured (depth resolution – 0.1 mm, 1.0 mm, etc.).

Precipitation measurements must be accurate and representative because watershed model studies have shown that small changes in precipitation can cause large changes in watershed response, highlighting the nonlinearity of watershed systems. Few multidecadal records of representative short-time increment precipitation data with good spatial coverage exist. Synthesized precipitation data are often unrepresentative because precipitation 'data' synthesized by precipitation models are parameterized using the nonrepresentative raw precipitation data. Much has been learned from precipitation-measurement studies that can provide guidance for future precipitation measurements.

Precipitation Sensing and Resolution

A storage gauge is typically a cylindrical container with the orifice about 1 m off the ground. The depth of precipitation is often recorded every 24 h.

A recording weighing gauge (Figure 1a) weighs the precipitation that enters the orifice, and records the weight with a strip chart or data logger. The weighing gauge gives the best measurement of precipitation because the data can be collected at any time or depth resolution (e.g., 1 min and 0.25 mm); there is no limit on high intensities. Also, beginning and ending times of bursts of precipitation can be determined.

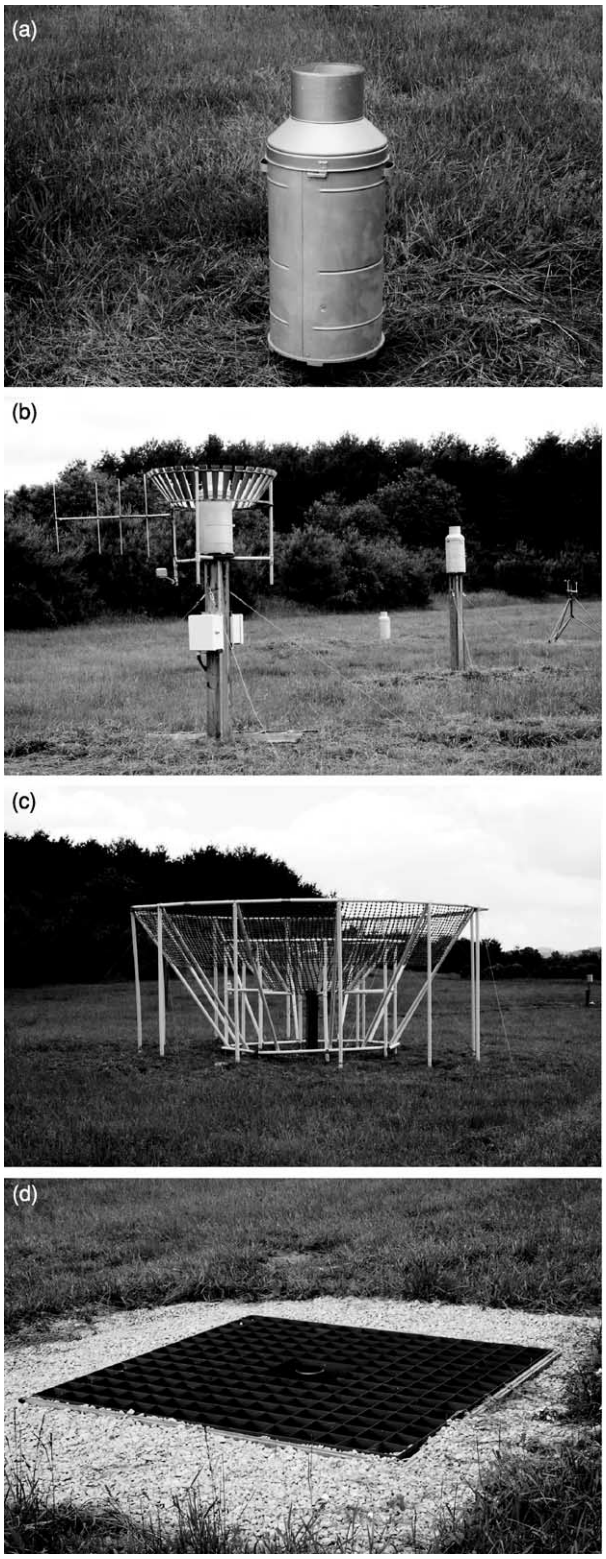

Figure 1 Types of precipitation gauges and shield configurations at the North Appalachian Experimental Watershed at Coshocton, Ohio: (a) standard gauge; (b) dual-gauge system; (c) Wyoming shield; and (d) pit gauge.

In tipping-bucket gauges, water from the orifice is funneled to a small hole where it drops into one side of a small 'bucket' that fills to a known volume before it empties its contents (e.g., 0.1 mm). This device is often used because tips are easily recorded as pulses with a data logger. However, the gauge must be calibrated, because at large rainfall intensities the system becomes overwhelmed and the volume of water from each tip of the bucket is less than the volume of a bucket. Therefore, long-term precipitation records can become truncated at larger intensities, often the ones of interest in watershed studies. Ponding above the buckets under high rainfall rates, and snow measurements can be problems. If heaters are used to melt frozen precipitation, they cause lower measurements because of evaporation and convection currents. Accurate beginning and ending times of storms are unknown with these gauges because water must accumulate in a bucket before it tips.

Precipitation-Measurement Representativeness

Standard precipitation gauges (Figure 1a) typically underestimate true ground-level precipitation, the measurement of interest in watershed modeling and analysis. This is because wind diverts many smaller-diameter rain drops over the top of the gauge orifice. Light-density snow flakes are particularly vulnerable to transport by the wind, bypassing the orifice. Lysimeters (large isolated blocks of soil that act as a ground-level gauge) at the North Appalachian Experimental Watershed (NAEW) at Coshocton, OH, on average measured 9% more annual precipitation and 27% more snow and mixed precipitation than an adjacent recording gauge. Other studies of wind effects on precipitation-gauge catch found that a standard gauge can measure as much as 60% less snowfall than measured at ground level on windy days.

Many studies have shown that shielding gauge orifices increases the precipitation catch. A ring of freely hanging baffles surrounding a gauge orifice (Alter shield) has been shown to be about 75% effective in measuring ground-level precipitation (depending on wind speed). A Wyoming gauge shield (Figure 1c) composed of a standard gauge at the center of two concentric wind shields made of snow fence, and a dual-gauge system (Figure 1b) composed of two elevated standard gauges (one shielded and one unshielded) have been shown to give representative ground-level precipitation measurements.

A pit gauge (Figure 1d) is considered to be the standard measurement system for rainfall. A coniferous forest opening is considered the best place to measure snow. A Tretyakov gauge composed

of dual concentric octagonal snow fences surrounding a gauge is an alternative standard for measuring snow because forest openings are often not available. A round inverted bell-shaped shield (Nipher shield) that surrounds a gauge gives good measurements of snowfall.

Representativeness is also affected by terrain slope. Horizontal orifice measurements can be much different compared with measurements from orifices parallel to the slope. Another factor affecting representativeness is obstacles in the vicinity of precipitation gauges.

Representativeness is also important over large areas as discussed later.

Characterization of Precipitation

Even though precipitation is highly variable across both small and large areas, from season to season, and from storm to storm, hydrologists have developed methods to quantify precipitation for use in models for watershed analysis. Characterization of precipitation involves spatial and temporal components important for watershed evaluations. Recent research has focused on stochastic simulation methods to generate long records of precipitation with similar statistical characteristics for the location of interest. Practical characterization of spatial variability for modeling purposes is a current research topic.

Four elements of a precipitation record require characterization for different purposes: (1) dry time between storms (TBS); (2) storm duration; (3) storm depth; and (4) within-storm intensity variation and corresponding mass curves.

Dry Times Between Storms

In any precipitation record (Figure 2), bursts (B_i) of varying intensities of precipitation are surrounded by dry periods (D_i). These TBS periods can range from a minute to months. A question facing an analyst is: what is the minimum dry-period duration (MDPD) for which $D_i > \text{MDPD}$ separates storms, and $D_i < \text{MDPD}$ is included in a storm. Intuitively, a 5-min period of no rain most likely will be included in the same storm, but a 5-month period would not. Quantification of MDPD is the first step in analyzing a record of precipitation data because storms can be identified, providing a data set for analysis of the other three elements. MDPD can be found by analyzing precipitation data independent of, or dependent on, watershed characteristics.

Arbitrary fixed-storm separation techniques are often used to identify storms. However, a fixed MDPD does not capture the spatial and monthly characterization of dry periods required for some

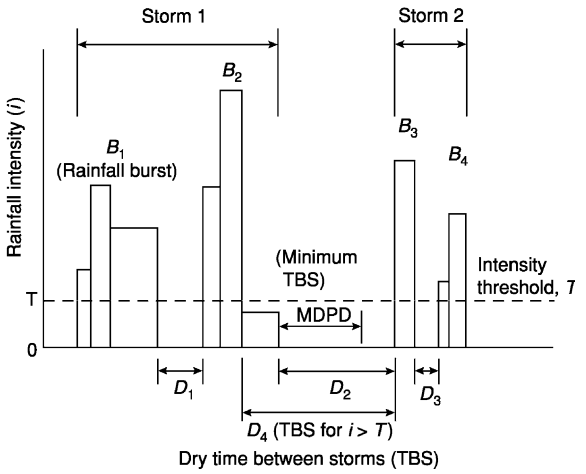

Figure 2 Definition sketch for identifying storms in a precipitation record. See text for details

analyses. Other specific storm-identification methods can be assigned, such as used in determining the 'R factor' (rainfall-runoff erosivity factor) of the Revised Universal Soil Loss Equation (RUSLE), a model used extensively for estimating soil loss on hill slopes (*See* **Erosion:** Water-Induced).

Rank correlation uses equally spaced time intervals of rainfall intensities that are lagged by increasing time intervals until time intervals are not correlated. The rank correlation method uses the rainfall intensity data to determine the dry time between storms instead of using the dry periods. Autocorrelation analysis has also been applied but the procedure does not always give well-defined estimates of MDPD.

Another method of determining MDPD is to assign a fixed time period for rainfall intensities greater than a threshold intensity, such as T in Figure 2. In this case, D_2 would be replaced by D_4. T represents an unknown parameter that is likely to be seasonally and spatially dependent, and interpretation must be qualified.

Another technique is called the 'exponential method.' In this method, MDPD is obtained by approximating groups of bursts of rainfall and dry periods (storms) as a Poisson process. Under this assumption, storms are considered statistically independent 'events' and the interarrival times of events are described by the exponential frequency distribution. In this method, dry periods greater than MDPD form an exponential distribution, and dry periods less than MDPD are included in storms. The exponential distribution is a good method to represent TBS, as it characterizes seasonal variation of TBS. Examples of best-fit exponential frequency distributions for several months at Bridgeport, NE, are shown in Figure 3.

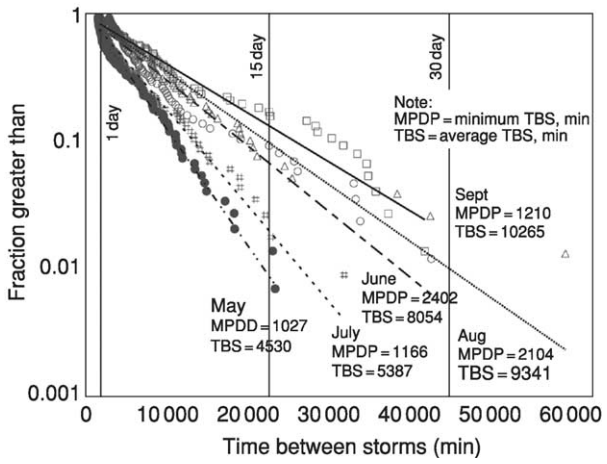

Figure 3 Seasonal variation of exponential frequency distributions of times between storms (TBS) for Bridgeport, Nebraska, USA. —●· May; —○— June; - # - July; ···△··· August; —□— September.

The average TBS is the parameter of the exponential distribution.

Finally, some precipitation analyses have not used the concept of an MDPD value, but used only daily precipitation totals. For example, during the development of the watershed curve number (CN) technique, used worldwide for estimating watershed runoff potential, daily (and not storm) precipitation was used because these were the most common data available from a storage-gauge network. Recent investigations of the CN technique now match actual storms with observed runoff data for curve-number development.

Most methods of determining MDPD assume that storms occur independently from the watershed. However, as in the case of determining precipitation that causes observed runoff hydrographs used in determining a watershed CN, identifying storms that incorporate watershed characteristics will give different results. This is because identifying precipitation that causes runoff events includes watershed storage that attenuates watershed response to rainfall intensities. Increasing watershed size increases storage effects, and spatial variability of precipitation also becomes more important. One or more storms (or partial storms) identified using the exponential method may comprise the causal storm for a watershed hydrograph. The method used for identifying causal precipitation for CN analysis incorporates the threshold T value in Figure 2.

Stochastic simulation of the occurrence of individual storms (alternative to using 24-h total precipitation) is possible by sampling the appropriate monthly exponential frequency distribution of TBS (Figure 3) using the Monte Carlo technique.

Storm Depths and Durations

Storm depths and durations are usually analyzed together. Often daily total precipitation has been used, such as in the development of the CN method, and individual storm durations are ignored. However, times of observation of 24-h totals may be inconsistent, because precipitation may not necessarily have been recorded over the same 24-h period. Yet precipitation analyses often assume 24-h totals at midnight. This inconsistency has led to the approach of identifying individual storms using the exponential method.

One form of depth and duration data characterization is through intensity–duration–frequency curves (IDFs). IDFs summarize the return periods of different intensity rainfalls for a given duration (e.g., 5-year, 30-min intensity). IDFs are widely used in engineering design of culverts and sewerage systems through peak-runoff estimation methods. They are also used in engineering design with synthetic mass curves of rainfall. IDFs represent only the maximum intensities in a storm, with no information on time distribution of rainfall. Maps of isopleths of IDF curves are often available. An assumption made when using IDF curves is that the return periods of precipitation and peak-runoff rate are the same.

Newer precipitation-analysis approaches eliminate the 24-h constraint and use storms as described above using the exponential method. Storm durations can range from a few minutes to several days. Once storms have been identified by monthly MDPD values, storm depth and durations can be analyzed for particular purposes. Storm depths and durations are typically correlated (Figure 4); however, there is much scatter. Storm simulation involves sampling from graphs like Figure 4, using the Monte Carlo method.

Within-Storm Intensities and Mass Curves

There is an infinite number of ways that a storm total can be distributed, as evidenced by the sample of 181 storm mass curves at Coshocton, OH (Figure 5). Historically, the use of only daily precipitation totals has led to simple methods for disaggregating the 24-h or IDF total to determine the time distribution of precipitation. Fixed patterns of rainfall intensities ('design storms') have been used to distribute the total in time (Figure 6). The USDA Natural Resources Conservation Service often uses design storms for determining peak flow rates in design (type I, II, etc. curves). However, fixed patterns do not describe the variability found in nature (Figure 5).

The most satisfactory mass-curve representation has been found to be Huff curves (Figure 6d) because the wide variability of curves is similar to that

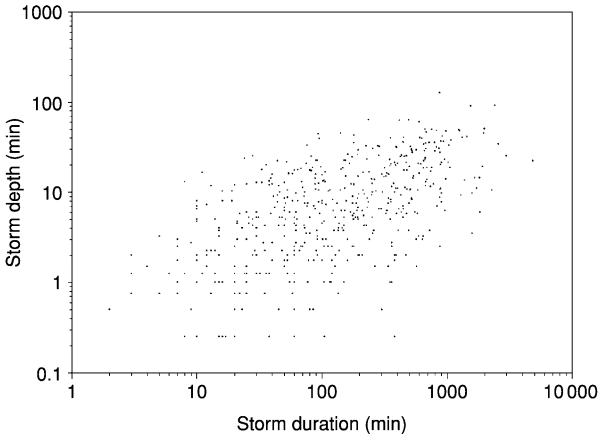

Figure 4 Example of the correlation between storm depths and durations for July at the North Appalachian Experimental Watershed at Coshocton, Ohio, USA.

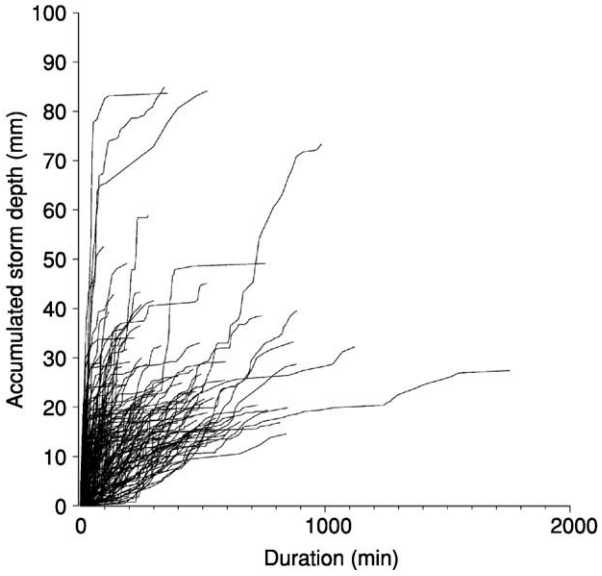

Figure 5 Example of the wide variability in mass curves at the North Appalachian Experimental Watershed at Coshocton, Ohio, USA.

observed in natural precipitation. These are isopleths of the frequency of occurrence of dimensionless accumulated depths for given dimensionless elapsed times in a storm. There are several curves that can be used, compared with a single mass curve of precipitation in a design storm. Documented methods to use the information contained in Huff curves in watershed analysis are an unresolved issue.

Spatial Variability

Spatial variability of storm depth and duration are often linked by snapshots of storm mass curves at the same time by using maps showing isopleths of

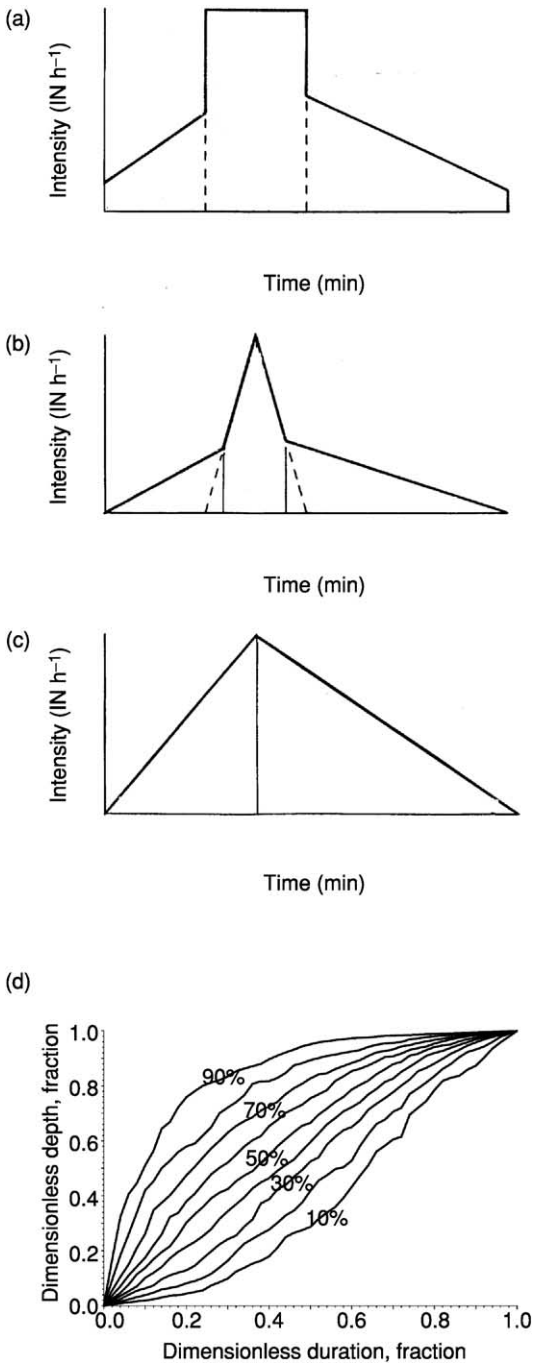

Figure 6 Design storms used for distributing total precipitation (a) mixed trapezoids (Sifalda V (1973) Entwicklung eines Berechnungsregens für die Bemessung von Kanalnetzen. *Wasser Abwasser* 114: 435–440); (b) mixed triangles (Desbordes M and Raous P 1976) Un exemple de l'intérêt des études de sensibilité des modèles hydrologiques. *La Houille Blanche* 1: 37–43); (c) triangular (Yen BC and Chow VT (1980) Design hyetographs for small drainage-structures. *Journal of Hydraulics Division* 106: 1055–1076); and (d) Huff curves at a point (Bonta JV (1997) Proposed use of Huff curves for hyetograph characterization. In: Richardson CW *et al.* (eds). *Proceedings of Workshop on Climate and Weather Research*, pp. 111–124. USDA–Agricultural Research Service 1996–03.

precipitation depth from several rain gauges during the storm (isohyetal maps). Isohyet interpolation can be by linear interpolation between known precipitation amounts, inverse-squared mapping, kriging, and by other methods. Average precipitation is computed by weighting isohyets by the area between isohyets. Thiessen polygons have also been used to capture the spatial variability of precipitation. These are polygons surrounding rain gauges such that the area enclosed by the polygons is closer to the enclosed rain gauge than to adjacent rain gauges. Polygon boundaries are the perpendicular bisectors between adjacent gauges. The polygons provide area-based weights for measured precipitation amounts.

Mapping of precipitation only grossly characterizes the spatial variability of precipitation. This is because precipitation distribution over an area can vary rapidly over time and with elevation in unknown ways over rolling hills and large mountains. Furthermore, precipitation depths can vary on the windward and leeward sides of mountains (i.e., 'rain shadow' effect). The effects of these factors can change monthly. Objective forms of mapping by interpolation do not consider orographic influences, and in mountainous areas, isohyets must often be adjusted manually.

One method of spatial characterization of precipitation that overcomes the problems of spatial variation with elevation is the use of conditional regression. This method of mapping utilizes regression relationships developed from precipitation data, and accounts for elevational, coastal, and other factors known to affect precipitation. Average monthly and annual precipitation have been mapped on a 4-km^2 grid across the USA. These maps are useful for general characterization, exploring relationships between average monthly weather elements and other variables (e.g., TBS), and mapping parameters for weather simulation models.

Watershed Response to Precipitation due to Physical Characteristics

Precipitation and Soil Variability

Watersheds that have similar appearance and land use respond differently to precipitation because of spatial and temporal variability of soil characteristics. Even watersheds having soils mapped in the same soil-map unit from an available soil survey and with the same land management can have significant differences in annual runoff. This is caused by natural spatial variability of soils and complex interactions between precipitation and surface–subsurface water. Studies in experimental watersheds attribute runoff differences to factors such as heavier-textured soil in different parts of the watershed, small seeps on the hillslope due to geologic clay layers that drain perched water to the seeps, and persistently high soil moisture in different areas. Heavier-textured soils and wetter watershed surfaces tend to run off sooner during the higher-intensity parts of storms than coarser-textured and drier areas, and runoff generation during a storm is nonuniform in the watershed. A local soil-survey map cannot necessarily be used to characterize small watersheds adequately because these factors are not typically mapped.

Watersheds exhibit complex interactions between surface and subsurface flow paths. Spatial and temporal variability of precipitation superimposed on watershed variability is an important factor to consider in understanding and modeling watershed hydrology. As watersheds become larger, more diversity in watershed characteristics can be expected.

Watershed Processes

Infiltration at the land surface significantly affects the timing and amounts of high and low watershed flows. Infiltration during rainfall events is affected by soil type, porosity, texture, vegetative cover, land management, preferential flow in soil and bedrock due to roots, cracks, and soil fauna. Macropores in natural systems can contribute significant amounts of infiltrated water and pollutants quickly to shallow and deep waters under high-intensity rainfalls. Advanced infiltration models require short-time increment precipitation to simulate matrix and macropore flow.

Land management can significantly affect infiltration. For example, rainfall on a field plowed with a moldboard plow tends to cause development of a relatively impervious surface due to crusting, whereas surface residue protects the soil surface from crusting with no-till cropping.

Infiltration is also affected by the degree of saturation since the last rainfall event (TBS, described above) as influenced by evapotranspiration (ET) and drainage rates. ET and drainage between storm events vary with soil type, vegetative cover, position on the landscape, aspect, geology, land use, climate, and time and weather since the last rainfall (TBS). The rate of water loss in the soil affects the storage available for water at the beginning of the next rainfall event ('antecedent soil water conditions').

In some watersheds, water moves horizontally near the surface as 'interflow.' The interflow process stores storm water for slow release either during a storm or after a storm has ended. It can also contribute to wetter antecedent conditions. Its effect on runoff, water quality, and erosion depends on the time until rainfall starts

again (TBS) and drainage and ET rates. In addition, interflow can re-emerge at the land surface, causing localized seeps (this is known as 'exfiltration') that immediately generates runoff during a storm.

Interflow, groundwater flow, and spatial variability of soil characteristics affect antecedent water conditions nonuniformly on a watershed surface. Typically, higher soil-water levels can be found in concave parts of the hillslope and along the periphery of stream channels. This is because soil water accumulates by gravity in these low areas during and between storm events. This leads to areas of watersheds that are wetter than others and that can run off sooner in a storm compared with drier areas. However, runoff can be randomly generated from any part of the landscape due to local factors. The nonuniformity of antecedent conditions leads to areas of the watershed that expand as areas become wetter during a storm, leading to a 'variable source area' of runoff generation. Runoff from these varying areas is sensitive to changing rainfall intensities during storms, affecting timing and amounts of runoff, chemicals, and sediment transported.

Watershed and Weather Modeling

Watershed–Precipitation Interactions

Watershed models are one tool for investigating the impacts of alternative land-management practices on hydrology, water quality, and sediment transport. Lack of data and simplifications of watershed processes are necessary. Often some processes are eliminated in modeling because of lack of understanding of these processes.

Few models adequately include the important processes of preferential movement of water as infiltration, subsurface flow, and interflow. The observed effects of scale of watershed on water yield must include a subsurface component to link upland and lowland areas quantitatively. Inadequate modeling of these processes and surface–subsurface precipitation interactions lead to errors in hydrology, erosion, and water-quality modeling.

Few models include spatial variability of infiltration and soil-water storage, except through land-surface discretization methods. These methods include representations of the land surface as square grids, triangles, and irregularly shaped areas. All these methods typically assume uniformity within the discretized element. Even within very small watersheds, however, there is significant variability in the distribution of soil characteristics. When small watersheds are subjected to precipitation, the spatial variability of characteristics can have significant effects on watershed hydrology and water quality. Sometimes a small area of a watershed may contribute a large fraction of sediment or chemicals downstream because it is wetter and tends to runoff sooner under rainfall, or it may receive anthropogenic inputs (e.g., fertilizer, vulnerable land-management practices). Another method for characterizing watershed elements is by using frequency distributions of infiltration characteristics within a 'uniform' element. Knowledge of the spatial variability of infiltration, runoff-producing areas, and antecedent conditions can be useful for developing management practices that minimize the effects of chemicals and eroded sediment.

Watershed Models

Although understanding of natural watershed processes is deficient, there have been many attempts to model watershed hydrology and water quality. The CN model mentioned earlier is widely used for estimating runoff volumes from watersheds, and is often a component of more complex models. Models that measure responses to precipitation have been developed for field-level investigations of surface runoff, sediment, pesticides, subsurface water, leachate and water quality, and erosion on hillslopes.

Weather and Precipitation Modeling

Weather and precipitation provide the deterministic and random driving forces in watersheds, and affect quantities and timing of runoff, sediment, and chemicals. Often measured weather and precipitation data are used as inputs to watershed modeling. Unfortunately, records are often not long, and short time-increment precipitation data exist only at points on a landscape. Furthermore, if several precipitation-gauge records are required, the periods of records may not overlap, the gauges may have had different sampling intervals (15-min vs 24-h), or the gauges inadequately characterize spatial variability of precipitation over watersheds. Consequently, weather and precipitation models have been developed. These models stochastically simulate weather for the long periods needed for analyzing modeled watershed outputs using frequency distributions. Stochastic simulation involves analyzing historic weather data to develop parameters that describe the frequency distributions of measured data. The models are designed so that the long records of weather and precipitation data have the same statistical characteristics as the measured data for a given location.

Two better-known weather models are CLIGEN and GEM (Generation of Weather Elements for Multiple Applications). Both models synthesize daily values of solar radiation, maximum and minimum

air temperature, and precipitation, wind speed, wind direction, and dew point. Both models simulate daily precipitation that depends on whether there was precipitation during the previous day. Both models are 'point' models, meaning that simulated precipitation is modeled at a point and not over an area.

GEM additionally generates weather elements that are dependent on whether a day has precipitation ('wet' or 'dry' days). Intuitively, for example, on a day with rain, the sky is cloudy, and there is less likelihood of a large daily solar radiation value. Consequently, the frequency distribution describing solar radiation is different for dry and wet days. Furthermore, an advanced version of the GEM model incorporates spatially dependent weather elements. Extensive databases for CLIGEN have been created by developing parameters at individual gauges, requiring extrapolation to ungauged areas. GEM databases have been interpolated for many areas in the USA on a 4-km^2 grid.

Spatial Variability of Weather and Precipitation

Under ideal conditions, weather inputs should be spatially available for watershed models at appropriate time steps, particularly for large areas. Often weather elements such as solar radiation and temperature do not vary greatly over large areas (except for variations in elevation), and a daily time resolution is adequate. However, precipitation intensities can vary greatly over small areas and characterization for both spatial and temporal variability for small areas and short time steps are required. Precipitation falling on areas of a watershed with potentially high runoff-generating potential (soil near saturation, feedlots, mined and urban areas, etc.), if not properly characterized in time and space, will result in inadequately modeled volume and timing of runoff. The spatial variability and uncertainties in precipitation, weather, and watershed modeling require watershed data and model outputs to be analyzed in terms of probabilities and frequency distributions (e.g., chemical loads, peak flows, runoff volumes).

Summary

Precipitation characterization for analyzing watersheds depends on data that are representative of ground-level precipitation. Precipitation is characterized in terms of times between storms, storm durations and depths, within-storm intensities, and spatial variation of these storm elements. Spatial and temporal characterization of precipitation is important because watershed landscapes also have significant spatial variability in characteristics that affect runoff generation. Water-movement processes on watershed surfaces are inadequately understood and quantified. However, scientists and engineers have developed many methods and computer models for characterizing natural variability in storms and watersheds to solve practical runoff and water-quality problems.

Much remains to be learned regarding the interactions between precipitation and watershed characterizations. Factors that affect parameterization of weather and precipitation models are weather modification, changing climate, and persistence in weather caused by large-scale atmospheric forcings (e.g., El Niño Southern Oscillation). Atmospheric forcings cause persistent dry or wet periods lasting years in different parts of the world. Unless data are categorized to include these persistent periods, this effect will not be considered. Parameterization to reflect weather modification is lacking. Data sets from which parameters are developed may be changing because of potential changes in climate ('nonstationarity' data). Therefore, long periods of synthesized weather data for watershed modeling may not be representative of future conditions.

PRECIPITATION–DISSOLUTION PROCESSES

W P Robarge, North Carolina State University, Raleigh, NC, USA

Introduction

Precipitation and dissolution reactions in soils and the underlying strata have long been of interest to soil scientists and soil chemists, because primary and secondary minerals are inherently part of many soil processes, e.g., chemical weathering, soil genesis, and nutrient availability (which can impact human and animal nutrition). More recently, the importance of precipitation and dissolution in soils has been emphasized because of environmental issues, e.g., mineral dissolution reactions as a buffering mechanism against inputs of acidic deposition, and formation of new solid phases as a means of remediation for trace metal contamination. Indeed, it is a mistake to attempt to limit the importance of precipitation and dissolution reactions in soils to mineral-weathering reactions or formation of secondary precipitates around fertilizer granules. Rather, it is necessary to acknowledge that precipitation–dissolution reactions span a range in physical scales that extends from the atomic and submicron through laboratory, watershed, and even continental processes.

Understanding precipitation and dissolution reactions in soils requires knowledge of the chemical and physical laws assumed to govern these processes. These laws are derived from consideration of either macroscale or microscale reactions. Macroscale processes are based on the science of thermodynamics and allow prediction of precipitation or dissolution under equilibrium conditions. The power of this approach is that it is possible to make predictions of precipitation or dissolution without any knowledge of the actual reactions that occur at mineral surfaces or during the formation of nuclei that lead to the formation of stable precipitates. The disadvantage of this approach is that it cannot easily predict the rate at which reactions will occur. Theories that focus on microscale reactions assume that specific chemical-reaction mechanisms occur at mineral surfaces and are more successful in predicting the rate of mineral dissolution due to changes in the composition of the surrounding soil solution. Unfortunately, equations predicting rates for microscale processes tend to be empirical in nature and require information specific to a given set of conditions that can usually be generated only within the laboratory. Most of the time, laboratory conditions only approximate the actual weathering environment in the soil. A knowledge of both macroscale and microscale processes is important in understanding precipitation and dissolution reactions in soils.

Macroscale Processes

The dissolution of a mineral is a chemical reaction. Thermodynamics predicts that a chemical reaction will proceed when energy can be released. A simple chemical reaction can be written as follows:

$$A + B \Leftrightarrow C + D \qquad [1]$$

where chemical species A and B react to form chemical species C and D. The symbol $\Leftrightarrow$ means that the chemical reaction has reached equilibrium and that there is essentially no net change in the concentrations of A, B, C, or D. Thermodynamics allows eqn [1] to be written in the following format:

$$K = \frac{(C)(D)}{(A)(B)} \quad [2]$$

where K is termed the equilibrium constant and parentheses refer to the activity of the chemical species in solution. The activity of a chemical species is a function of its concentration in solution. The equilibrium constant is related to the energy of the chemical reaction through the expression:

$$\Delta G_r = -RT \ln K \quad [3]$$

where in thermodynamics ΔG_r is termed the standard Gibbs energy change, R is the molar gas constant, T is absolute temperature, and K is the equilibrium constant when all the reactants and products are in their standard states. For sparingly soluble compounds, K is written as K_{so} and defined as the solubility product when the chemical reaction is written as a dissolution reaction. Most secondary minerals found in soils can be considered sparingly soluble in the presence of water: dissolution does not noticeably change the total mass of the solid phase present. Standard state assumptions concerning the solid phase are thus applicable, and the solubility of the mineral can be described by a solubility product. The solubility product of a mineral, therefore, is a relative index of its potential stability (whether it will dissolve, remain stable, or conditions are favorable for its formation) in the soil environment.

Representative values of $\log K_{so}$ calculated from standard Gibbs free energies are listed in Table 1. Negative values of $\log K_{so}$ indicate low solubility in the presence of water. Positive values of $\log K_{so}$ suggest that the corresponding mineral phases are not stable and would not attain equilibrium in the typical aqueous soil environment. This comparison is only qualitative, however, as the dissolution reaction for most silicates and phyllosilicates requires the presence of H^+ as well as water, thus the dissolution reaction (and therefore mineral stability) is also a function of pH. Calculated values of K_{so} are also dependent on the degree of uncertainty associated with the standard Gibbs free energies for each of the constituents in the reaction and variations in calculated $\log K_{so}$ values of several whole numbers or more are not uncommon.

Ion Activity Products

The dissolution of a mineral can be written as the transition from one solid phase to another:

$$\text{mineral A} + \text{water} \Leftrightarrow \text{mineral B} + \text{solution species C} \quad [4]$$

or the destruction of the original mineral with the stoichiometric (in proportion to the atomic structure of the mineral) release of the constituent ions to solution. The dissolution reaction for the secondary mineral kaolinite can be written as:

$$Al_2Si_2O_5(OH)_4(s) + 6H^+(aq) \Leftrightarrow 2Al^{3+}(aq) + 2H_4SiO_4^0(aq) + H_2O(l) \quad [5]$$

where the subscript '(s)' refers to the solid phase, '(aq)' to the ion in solution, and '(l)' for the bulk aqueous phase. The calculated $\log K_{so}$ for this reaction is 5.4 (Table 1). Solving for K_{so} yields the following equation:

$$K_{so} = \frac{(Al^{3+}(aq))(H_4SiO_4^0(aq))^2(H^+(aq))^{-6}(H_2O(l))}{(Al_2Si_2O_5(OH)_4(s))} \quad [6]$$

Under standard conditions, the expressions for the solid-phase kaolinite and the bulk liquid-phase water are defined as being equal to a value of 1, leaving the numerator as an ion activity product (IAP) for the constituent ions in solution:

$$IAP = (Al^{3+}(aq))(H_4SiO_4^0(aq))^2(H^+(aq))^{-6} \quad [7]$$

When the IAP $> K_{so}$, the solution is said to be supersaturated with respect to the solid phase (conditions favor the precipitation of kaolinite). When the IAP $< K_{so}$, the solution is undersaturated with respect to kaolinite (conditions favor the dissolution of kaolinite). When IAP $= K_{so}$, the solution is considered saturated and at equilibrium (kaolinite should neither dissolve nor precipitate). With tabulated values of solubility products (Table 1) and measurements of the dissolved concentrations of ions in soil solutions or streams, soil scientists can predict the possible absence or presence of minerals by calculating IAPs.

Activity Diagrams

The IAP provides a numerical way to estimate the stability of a mineral in a given soil environment. A visual representation of the relative stability of a mineral can be obtained using an activity diagram. Activity diagrams vary in complexity, depending on the number of mineral phases involved. They are all, however, based on rearrangement of dissolution reactions (e.g., eqn [5]) into a linear form where the y- and x-axes are represented by constituent ions common to all the mineral phases being addressed. This rearrangement often involves the introduction of H^+ into the dissolution reaction by adding the hydrolysis reaction of water. The resulting K values are sometimes designated as K_{diss} (where 'diss' is 'dissolution') in contrast to K_{so} to reflect the mathematical convenience of incorporating H^+ into the dissolution reaction.

Table 1 Calculated solubility products for selected minerals using standard Gibbs free energies of formation[a]

Name	*Chemical formula*	*Dissolution reaction*	*log K_{SO}*
Carbonates			
Calcite	$CaCO_3$	$Ca^{2+} + CO_3^{2-}$	−8.3
Dolomite	$MgCa(CO_3)_2$	$Mg^{2+} + Ca^{2+} + 2CO_3^{2-}$	−17.6
Siderite	$FeCO_3$	$Fe^{2+} + CO_3^{2-}$	−10.1
Rhodochrosite	$MnCO_3$	$Mn^{2+} + CO_3^{2-}$	−9.9
Sulfates			
Gypsum	$CaSO_4 \cdot 2H_2O$	$Ca^{2+} + SO_4^{2-} + 2H_2O$	−4.6
Jarosite	$KFe_3(SO_4)_2(OH)_6$	$K^+ + 3Fe^{3+} + 2SO_4^{2-} + 6OH^-$	−95.3
Alunite	$KAl_3(SO_4)_2(OH)_6$	$K^+ + 3Al^{3+} + 2SO_4^{2-} + 6OH^-$	−79.9
Phosphates			
Variscite	$AlPO_4 \cdot 2H_2O$	$Al^{3+} + PO_4^{3-} + 2H_2O$	−21.8
Strengite	$FePO_4 \cdot 2H_2O$	$Fe^{3+} + PO_4^{3-} + 2H_2O$	−26.1
Vivianite	$Fe_3(PO_4)_2 \cdot 8H_2O$	$3Fe^{2+} + 2PO_4^{3-} + 8H_2O$	−35.5
K-Taranakite	$H_6K_3Al_5(PO_4)_8 \cdot 18H_2O$	$6H^+ + 3K^+ + 5Al^{3+} + 8PO_4^{3-} + 18H_2O$	−176.5
Octacalcium phosphate	$Ca_8H_2(PO_4)_6 \cdot 5H_2O$	$8Ca^{2+} + 2H^+ + 6PO_4^{3-} + 5H_2O$	−92.6
Hydroxyapatite	$Ca_{10}(OH)_2(PO_4)_6$	$10Ca^{2+} + 2OH^- + 6PO_4^{3-}$	−114.9
Fluorapatite	$Ca_{10}F_2(PO_4)_6$	$10Ca^{2+} + 2F^- + 6PO_4^{3-}$	−314.3
Sulfides			
Alabanite	MnS	$Mn^{2+} + S^{2-}$	−12.7
Sphalerite	α-ZnS	$Zn^{2+} + S^{2-}$	−24.4
Pyrite	FeS_2	$Fe^{2+} + S_2^{2-}$	−26.6
Covellite	CuS	$Cu^{2+} + S^{2-}$	−35.6
Black-metacinnibar	β-HgS	$Hg^{2+} + S^{2-}$	−51.0
Oxides/hydrous oxides			
Quartz	α-SiO_2[a]	$H_4SiO_4^0$	−4.0
Quartz (amorphous phase)	SiO_2[a]	$H_4SiO_4^0$	−2.7
Gibbsite	γ-$Al(OH)_3$	$Al^{3+} + 3OH^-$	−33.5
Gibbsite (amorphous phase)	$Al(OH)_3$	$Al^{3+} + 3OH^-$	−31.9
Boehmite	γ-AlOOH[b]	$Al^{3+} + 3OH^-$	−33.4
Amorphous iron hydroxide	$Fe(OH)_3$	$Fe^{3+} + 3OH^-$	−37.9
Hematite	α-Fe_2O_3[b]	$Fe^{3+} + 3OH^-$	−41.4
Goethite	α-FeOOH[b]	$Fe^{3+} + 3OH^-$	−41.5
Silicates[c]			
Olivine	$Mg_{1.6}Fe_{0.4}SiO_4$	$1.6Mg^{2+} + 0.4Fe^{2+} + H_4SiO_4^0$	25.8
Diopside	$CaMg(SiO_3)_2$	$Mg^{2+} + Ca^{2+} + 2H_4SiO_4^0$	20.9
Pyroxene	$CaAl_2SiO_6$	$Ca^{2+} + 2Al^{3+} + H_4SiO_4^0 + 2H_2O$	34.8
Albite	$NaAl_2Si_3O_8$	$Na^+ + Al^{2+} + 3H_4SiO_4^0$	3.6
Microcline	$KAlSi_3O_8$	$K^+ + 2Al^{3+} + 3H_4SiO_4^0$	1.0
Anorthite	$CaAl_2Si_2O_8$	$Ca^{2+} + 2Al^{3+} + 2H_4SiO_4^0$	23.0
Phyllosilicates[c]			
Muscovite	$KAl_2(AlSi_3O_{10})(OH)_2$	$K^+ + 3Al^{3+} + 3H_4SiO_4^0$	13.3
Vermiculite	(see below)[d]	$2.71Mg^{2+} + 0.02Fe^{2+} + 0.46Fe^{3+} + 0.06Ca^{2+} + 0.1K^+ + 1.14Al^{3+} + 2.91H_4SiO_4 + 0.36H_2O$	38.1
Montmorillonite	(see below)[e]	$0.49Mg^{2+} + 1.71Al^{3+} + 0.22Fe^{3+} + 3.81H_4SiO_4^0$	2.7
Kaolinite	$Al_2Si_2O_5(OH)_4$	$2Al^{3+} + 2H_4SiO_4^0 + H_2O$	5.4

[b]Water added as a reactant (e.g., $SiO_2 + 2H_2O = H_4SiO_4^0$).
[c]Water and H^+ added as reactants.
[d]$Mg_{2.71}Fe(II)_{0.02}Fe(III)_{0.46}Ca_{0.06}K_{0.1}(Si_{2.91}Al_{1.14})O_{10}(OH)_2$.
[e]$Mg_{0.2}(Si_{3.81}Al_{1.71}Fe(III)_{0.22}Mg_{0.29})O_{10}(OH)_2$.

Simple activity diagrams usually include a series of linear lines, reflecting differences in the solid phase under consideration (Figure 1). These differences are often associated with variations in solubility due to assumed crystallinity or size of the solid phase. Experimental data points plotted on such graphs which fall along the linear lines are taken to reflect equilibrium with the solid phase. Data points falling above or below the line indicate undersaturation or supersaturation of the soil solution with respect to the mineral phase (Figure 1). More detailed activity diagrams can also be used to delineate regions of stability among several mineral phases (Figure 2). Experimental data can be plotted on such plots, but the intersection of the

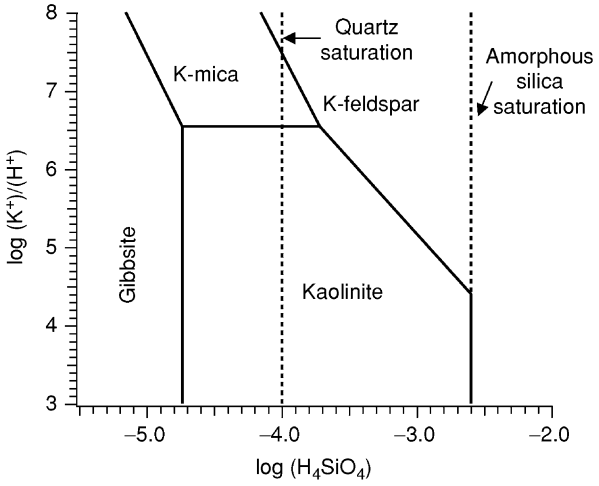

Figure 3 Phase diagram for gibbsite, kaolinite, K-feldspar, K-mica, silica mineral assemblage. Adapted from Garrels RM and Christ CL (1965) *Solutions, Minerals and Equilibria*. New York: Harper and Row, with permission.

various linear representations of mineral solubility also provide predictive information concerning the stability of minerals in soil systems. For example, kaolinite is the most stable phase compared with gibbsite in soil environments where the log ($H_4SiO_4^0$) in soil solution is more than −4.5. The region of stability is increased if the activity of $H_4SiO_4^0$ in solution is controlled by amorphous silica in contrast to quartz (Figure 2).

Dissolution reactions as depicted in eqn [4] can also be displayed visually through a variation in activity plots known as a phase diagram (also known as an activity–activity diagram) (Figure 3). Linear lines in such plots represent equilibrium between two solid phases. Departure away from the linear lines indicates that only one of the mineral phases in question would be stable for the values of the constituent ions plotted along the axes.

Understanding the dissolution of minerals as a macroscale process relies on the assumptions inherent in thermodynamics and congruent dissolution of the solid phase. Congruent dissolution requires that the rates of release of the chemical species represented by the formula weight for a mineral are equal. In other words, it is assumed that the various chemical species that comprise a mineral enter the surrounding soil solution at the same time during the dissolution reaction. For many carbonate, sulfate, phosphate, sulfide, and even silicate-based minerals, this assumption is probably valid. With increasing complexity in mineral structure, however, the assumption of congruent dissolution becomes questionable. For example, the congruent dissolution of montmorillonite or muscovite (Table 1) involves the concurrent

release to soil solution of up to five different ionic species. Given the differences in chemical bonding between these constituent species within the mineral structure, it is highly unlikely that dissolution of these minerals proceeds in a congruent fashion. It is more likely that the dissolution reaction is incongruent: the ratio of ions released to solution is not the same as that found in the bulk phase of the mineral. The extent to which incongruent dissolution invalidates the macroscale approach to understanding mineral solubility in soil systems is not easily determined. In general the macroscale approach is valid for predicting long-term, steady-state conditions or delineating boundaries for possible reactions.

There are also limits to using the condition of $IAP > K_{so}$ (supersaturation) to predict precipitation reactions in the soil environment. Minerals (including soil clay minerals) represent the selective accumulation of two or more constituent ions into an organized solid matrix. This can occur on the bulk soil solution (homogeneous precipitation) or on the surfaces of other soil solids that act as a catalyst to promote the growth of a new solid phase (heterogeneous precipitation). It is possible for many solids with relatively simple structures (carbonates, sulfates, sulfides, and some phosphates and oxides) to form in soils over relatively short time periods. For example, soil horizons that experience periodic wetting and drying due to a variable water table lose and gain color due to the dissolution and then subsequent precipitation of iron oxides. In more arid climates, it is not uncommon to find layers of carbonates and even sulfates that precipitate from the soil solution as the wetting front from a rain event slows and finally stops as it moves through the soil. Formation of more complex solids, especially silicates, phyllosilicates (which include most soil clay minerals) and apatites, however, should not be assumed to occur readily in the bulk soil environment. These solids generally require unique conditions within the soil that favor their formation, or occur as heterogeneous precipitation reactions on the surfaces of or near other minerals that are undergoing dissolution. Even when such solids form, they are often amorphous in nature, meaning that they have the expected chemical composition for the solid phase, but require more time to mature and develop the internal crystalline, well-ordered structure characteristic of a given mineral. Amorphous phases of a mineral are more soluble than its crystalline counterpart and may not survive long enough to develop into a stable separate phase within the soil. As with dissolution reactions, predicting the rates of precipitation in specific soil environments is best viewed as a microscale process.

Microscale Processes

Precipitation

Formation of a new solid phase when viewed as a microscale process requires a series of steps that must occur before a new solid can survive and be characterized as having a specific K_{so} value. The first requirement is that supersaturation ($IAP > K_{so}$) conditions must exist whether the reaction results in homogeneous or heterogeneous precipitation. Supersaturation conditions are necessary because they promote the formation of nuclei as a result of the collisions in solution (or on a foreign surface) of the constituent ions that eventually could become the new solid phase. Once formed, the nuclei must resist the tendency to dissolve and must strive to grow in size by accumulating other constituent ions and transforming into crystallites. The formation of crystallites is a critical step, because they are large enough in size to begin to lower the supersaturation of the solution and lower the chances of other nuclei forming. This effectively promotes their own survival, because it lowers the competition for the remaining constituent ions in solution. The final step is the growth of the crystallites into crystals through the process called Ostwald ripening: an increase in the size of a selected number of crystallites to form crystals by the net transfer of material from smaller nuclei and crystallites via dissolution and precipitation. The larger crystals being formed in fact can be defined by an IAP and continue to grow until ideally $IAP = K_{so}$ (saturation).

Which crystallites survive the transformation into crystals and the eventual formation of a new solid phase can be predicted by consideration of two sources of energy which influence the growth of crystals in solution or on the surface of a foreign particle. The first source of energy is the formation of the chemical bond between the constituent ions that will compose the solid (here designated as ΔG_{bulk}). The second energy term is related to the amount of work for the nuclei actually to be present within the solution (here designated as ΔG_s). In other words, the act of forming nuclei must result in the displacement of the surrounding water molecules to create a volume in solution where the nuclei can physically exist. How well a nucleus or crystallite can do this is related to its size and its ability to interact with the surrounding water molecules. This latter ability is referred to as interfacial tension. The summation of the two energy terms equals to amount of energy available for the formation of a stable nuclei in solution (or on a foreign surface):

$$\Delta G^0_{r(nucleus)} = \Delta G_{bulk} + \Delta G_s \qquad [8]$$

For any nucleus, ΔG_{bulk} is related to the number of molecular units in the nuclei or crystallites and the degree of supersaturation in solution. As long as IAP $> K_{so}$, ΔG_{bulk} is negative, which promotes nuclei or crystallite growth. ΔG_s is a function of the interfacial tension between the surrounding water molecules and the surface area of the nuclei or crystallites. This term is often positive in value, meaning that it requires energy to make room for the particles to grow in solution.

Mathematical expressions for the two energy terms in eqn [8] can be derived but are a function of the geometry selected for the nuclei and will not be discussed here. Equation [8] does, however, provide a qualitative explanation for the results of precipitation and dissolution reactions often observed in the soil environment. For example, inclusion of ΔG_s illustrates why dissolution rates are often a function of particle size, i.e., smaller particles dissolve faster than larger particles. Small particles, typically less than 1 μm in size, have significant positive ΔG_s values because of the combination of their relatively large surface area to volume ratios and interfacial tension. Small particles therefore exhibit a different K_{so} value than their larger counterparts, such that a solution may appear supersaturated with respect to a solid phase when in fact that solid may actually be present but as very small particles. The presence of the ΔG_s in eqn [8] also explains why amorphous phases may be present in soils even though they are more soluble than their more crystalline counterparts (e.g., compare K_{so} values for amorphous silica with quartz in **Table 1**). For two solids having the same chemical composition, the solid that is more crystalline in nature should have a larger negative ΔG_{bulk} value. However, if the amorphous-phase nuclei have a lower interfacial tension than the crystalline phase, ΔG_s will have smaller positive value such that the sum of the two terms actually results in a $\Delta G^0_{r(nucleus)}$ value that favors formation of the amorphous phase. Experimental evidence suggests that formation of amorphous phases is almost always preferred over crystalline phases under most conditions that favor precipitation. More crystalline phases usually develop later either through internal rearrangement of the amorphous-phase solid, or through the dissolution of the amorphous phase and subsequent growth of the crystalline phase. In either case, it should not always be assumed that the crystalline phases of minerals will dominate soil environments simply because of differences in K_{so} values.

Lastly, the role of interfacial tension also offers an explanation of why heterogeneous precipitation occurs in the presence of foreign surfaces, often at supersaturated conditions below those necessary to promote homogeneous precipitation. If the interfacial tension between the constituent ions of a nuclei or crystallite is lower when interacting with a surface than with bulk water, the formation of a nucleus on the surface of a foreign particle would reduce the surface area exposed to solution, in effect lowering the value of ΔG_s in eqn [8]. This yields a $\Delta G^0_{r(nucleus)}$ value that favors nuclei attempting to grow on the surface of a foreign particle in contrast to those attempting to survive in the bulk solution. Thus solid phases that nucleate and grow on a foreign surface perform less work in order to survive. Depending on the surface of the foreign particle (i.e., the interfacial tension between the foreign particle and the nuclei of the new solid phase), the growth of the nuclei into crystallites may actually proceed along the surface of the foreign particle before developing as a separate, three-dimensional phase extending away from the foreign surface. This affords one explanation for the development of coatings, such as iron oxide coatings on clay minerals, which are often observed in soils.

Dissolution

The dissolution of a mineral can be defined as the detachment of constituent ions from the surface of a mineral and their subsequent transport to the bulk solution. It is now generally accepted that the rate of dissolution of minerals in soils is controlled by chemical reactions along the mineral surfaces at distinct surface features that can include dislocations, etch pits, and micropores. Dislocations represent areas in the mineral structure where the normal growth of the mineral has been disrupted or caused to alter in some fashion. Etch pits and micropores form in the surface of minerals and are visible as holes in the mineral surface when viewed using devices such as a scanning electron microscope. The presence of surface features such as dislocations, etch pits, and micropores is taken as an indication of a population of surface reactive sites where dissolution reactions are favored above those possible along the total surface area of a mineral.

The dissolution reaction at the surface reactive sites is considered a two-step process. The first step involves the relatively rapid formation of a surface species as the result of the reaction with entities in soil solution such H^+, OH^-, H_2O molecules, and inorganic and organic ligands. The second step, and the one that is considered rate-limiting, involves the transformation of the surface species into an activated complex with the eventual release of constituent ions to the bulk solution. Dissolution at the microscale therefore can be considered a function of the reactive surface area of the mineral, the nature of the inherent chemical bonding structure that comprises the

mineral, and the presence of various chemical species in the soil solution. Thus the dissolution rate of a mineral is not a fixed quantity but dependent upon a number of variables, which may change with time due to changes in the physical size of the mineral itself, as well as changes in the surrounding soil solution.

Rate law A general form of a rate law for chemical dissolution at heterogeneous mineral surfaces has been formulated to account for the various factors important in the solubility of minerals. A simplified version of this rate law can be expressed as:

$$\text{Rate} = k_o \cdot S_{min} \cdot \exp^{(-E_a/RT)} \cdot \int\left(\text{pH} \cdot a_i^{N_i}\right) \cdot \int(\text{IAP}) \quad [9]$$

where k_o is the intensive rate constant (moles per meter squared per second), S_{min} is the reactive surface area of the mineral, and E_a is the overall activation energy for the reaction. The possible effects of pH, ionic strength, and other ligands, reductants, oxidants, or sorbed ions ($\int(\text{pH} \cdot a_i^{N_i})$) are written as products to emphasize that these effects can be studied separately or in concert with one another, but that one cannot ignore the influence of any of these variables on the rate of dissolution. The final term, $\int(\text{IAP})$, is added to account for the fact that rate of dissolution is also a function of the degree of supersaturation or undersaturation of the soil solution. Technically eqn [9] can represent the rate of dissolution or precipitation, with rate = 0 at saturation (IAP = K_{so}).

The range in dissolution rates possible for various minerals, primarily from laboratory dissolution experiments, is shown in Table 2. Among the silicates and the phyllosilicates, those minerals referred to as framework silicates (quartz, albite, microcline, anorthite) and the sheet silicates (kaolinite, montmorillonite, muscovite) are more insoluble than the chain silicates (diopside) or the ring and orthosilicates (olivine). Assuming a mineral particle with an initial radius of 1 mm, minerals with log rate values of less than −13 could have lifetimes of more than 1 000 000 years, while log rate values of −8 to −5 would have lifetimes of less than one hundred to several thousands of years. Such predictions are generally valid as compared to actual field observations across many different types of geologic and hydrological systems. However, dissolution rates and mineral stability within specific local environments are dictated by the variables included in eqn [9]. Laboratory dissolution rates for calcite and dolomite (Table 2) suggest that these minerals are not stable across geologic time spans, yet under proper conditions these minerals are found naturally in soils.

Table 2 Rates of dissolution for selected minerals

Mineral	*Log rate* ($mol\,m^{-2}\,s^{-1}$)	*Conditions*
Silicates		
Quartz	−13.2	40°C, $I = 0$[a]
	−11.2	25°C, pH 5
	−10.7	70°C, pH 5.4, 0.25 mol l^{-1} Na^+
	−9.9	70°C, pH 6, $I = 0.35$
Microcline	−12.5	25°C, pH 5
	−11.8	25°C, pH 3, $I = 0$
	−11.1	25°C, pH 3.1, 1 mmol l^{-1} oxalic acid
Diopside	−11.3	25°C, pH 3.6
	−10.2	25°C, pH 5
Albite	−12.3	25°C, pH 5
	−11.3	25°C, pH 5, oxalic acid
	−11.6	25°C, pH 3, oxalic acid
Anorthite	−12.0	25°C, pH 6.2, $I = 0$
	−8.6	25°C, pH 5
Olivine	−5.7	25°C, pH 3–5
Phyllosilicates		
Kaolinite	−13.8	25°C, pH 5
	−13.0	25°C, pH 8
Montmorillonite	−14.1	20°C, pH 8
	−13.4	25°C, pH 5
	−12.5	25°C, pH 3
Muscovite	−13.0	25°C, pH 5
	−12.5	25°C, pH 3
Other		
Gibbsite	−12.5	25°C, pH 5
	−11.3	25°C, pH 3.1, $I = 0.0001$
Calcite	−5.6	pH 5, low P_{CO_2}
	−4.5	pH 3, low P_{CO_2}
Dolomite	−6.5	pH 5
	−5.0	pH 3

Summary

The dissolution of minerals is a vital geochemical process that has led to the development of life on Earth as we know it. The presence of minerals in soils and underlying soil parent material is critical to the sustainability of soils, especially forest soils, where fertilization to replace mineral elements such as calcium or magnesium lost by timber harvesting or enhanced leaching due to acidic deposition is currently cost-prohibitive. Intensive investigation into the solubility of minerals continues using both the macroscale and microscale approaches. New efforts are now being directed at incorporating *ab initio* quantum-mechanical calculations of mineral surface reactions to gain a better understanding of heterogeneous kinetics. This work is made possible by the

rapid changes in computer technology, hardware, and software that have occurred since the 1980s. Just how molecular modeling will impact our understanding of the solubility of minerals and the precipitation of new solid phases, especially for larger and more complex chemical systems, is uncertain, but the merger of computational and experimental science has begun and will continue for the foreseeable future.

PRODUCTIVITY

Introduction

Soil productivity is defined as the capacity of a soil to produce a certain yield of agricultural crops or other plants using a defined set of management practices. It encompasses soil fertility plus all of the other factors affecting plant growth and development, even though it is impossible to explain all of the potential interactions. Soil productivity is most accurately defined in terms of a specific kind of soil, for a specific crop or crop sequence, and with regard to a specific set of management practices. As a result of all these constraints, the concept is perhaps more accurately defined as an economic relationship than one of soil science.

Soil productivity is generally measured by comparing inputs with outputs. For agronomic situations, 'output' generally means crop yield, while 'inputs' usually refer to water, plant nutrients, genetic resources, pest control, or labor. Therefore, for a specific input (e.g., water or plant nutrients) productivity is sometimes calculated as efficiency (i.e., water-use efficiency or nutrient-use efficiency). With regard to sustainability, unintended off-site effects such as runoff, erosion, or leaching losses are also recognized as cropping system outputs that must be considered when evaluating productivity with regard to the social acceptability. The relationships between productivity and economic return are very evident at the farm level, while, from a global perspective, productivity is strongly associated with food sufficiency and sustainable food, feed, and fiber production systems. These multiple scales at which productivity can be evaluated mean that economically beneficial inputs at the field scale may or may not be environmentally and socially acceptable when evaluated at the whole-farm, watershed, regional, national, or international scale.

Productivity is also dependent upon the physical, chemical, and biological characteristics that for each soil reflect numerous interactions among the five basic soil-forming factors (parent material, climate – especially moisture and temperature effects – macro- and microorganism species and populations, topography, and time). Therefore, even though soil productivity *per se* is not an inherent soil characteristic, it will be different for every soil and is therefore one of the many characteristics used to classify more than 18 000 soil series in the USA alone.

Productivity is also affected by what some refer to as a sixth soil-forming factor – humankind. Others prefer to classify this response as 'dynamic soil properties,' since the changes are often controllable and reflect the soil-management decisions or practices that are imposed by humankind on the soil resource. Processes affecting the dynamic soil properties include erosion, nutrient mining (where removal is greater than the inputs), loss of organic matter, acidification, salinization, water logging, and compaction. Productive soils generally exhibit resistance or resilience, two properties that enable the resource to withstand degradation by natural (e.g., drought or flooding) or human-induced (e.g., tillage) stress without losing their ability to provide critical functions.

Productivity Effects of the Inherent Soil-Forming Factors

The specific effect of each soil-forming factor on productivity will differ among soils, but for high agronomic productivity the soil must provide physical support, plant-available water, air for respiration, and the essential nutrients (C, H, O, N, P, K, Ca, Mg, S, B, Cu, Fe, Mn, and Zn). Parent material influences the availability of essential plant nutrients (those required to complete the life cycle) through its mineral composition and predominant particle size (i.e., sand, silt, or clay). Particle size is important because it influences soil texture as well as the type and rate of chemical reactions that occur within a specific soil. The process through which parent material was derived (e.g., volcanic activity, sedimentation, residual weathering of rocks) or transported to various sites (e.g., water, wind, or glaciers) affects productivity, primarily through soil texture and landscape topography. Climate, especially precipitation and temperature, influences inherent soil productivity through its effect on weathering of the primary minerals, erosion by wind or water, and the native vegetation (i.e., forest versus prairie). Chemical reaction rates for processes such as solution, hydration, and leaching are also regulated by water and temperature regimes. The primary type and quantity of vegetation found at various landscape positions, the type and amount of microbial growth, the type of enzymes produced, the number and type of soil animals (e.g., grazers versus burrowers), the predominant soil biota, and amount of organic material added to the

soil from above- and belowground plant parts each year are also influenced by climate.

Topography influences soil productivity primarily through its effects on soil water, temperature, and erosion. Soils on sloping land, especially those with a medium or fine texture, will almost always capture less precipitation, irrigation, or runoff water and are more likely to be degraded through erosion than soils with similar vegetation on more level areas. Soils in low-lying or depression areas can be highly productive if rainfall or irrigation is evenly distributed, but they can be nonproductive if water accumulates, creating aeration problems or increasing leaching. Slope orientation and elevation affect productivity primarily through their effects on soil-forming processes as related to soil temperature and water content. Time of formation exerts its influence through the degree of soil development by processes of eluviation (loss of material) and illuviation (accumulation of material) at different positions within the soil profile.

Vegetation influences productivity through photosynthesis, which determines the quantity, quality, and spatial distribution (above- or belowground) of carbon input each year. This annual carbon input as soil organic matter affects nutrient cycling, soil aggregation, and soil structure. In this context, vegetation quality generally refers to carbon-to-nitrogen (C:N) or lignin-to-nitrogen ratios. These quality factors affect the food source for soil biota and hence nutrient cycling. Aggregation, the process through which primary soil particles (sand, silt, and clay) are bound together by natural forces and organic compounds derived from root exudates and microbial processes is important because, if soil aggregates are stable, rainfall or irrigation water are more likely to enter (infiltrate) the soil than to runoff. Aggregates also provide the building blocks for soil structure which influences productivity through its effect on root proliferation, aeration, and the volume of soil available for water retention. Vegetation also provides the fuel for naturally occurring and intentional fires, a natural ecosystem process that plays an exceptionally important role in nutrient cycling and reseeding of grasslands and coniferous forests. Periodic fires also prevent encroachment of trees into grassland areas, and also, in arid areas, they prevent shrubs or other woody species such as honey mesquite (*Prosopis glandulosa*) from becoming established.

Humankind's Impact on Productivity

Humankind can have a tremendous impact on soil productivity, because with external inputs distinctly different soils can have very similar outputs. For example, two soils that respond similarly with low input (e.g., simply tilling, planting, and harvesting) may respond in very different ways if the inputs include fertilizer, lime, animal manure, or rotations with deeply rooted legumes. These differences illustrate the impact of humankind on dynamic soil properties through their land use and other decision-making processes.

For comparative purposes, the US Department of Agriculture (USDA)–Natural Resources Conservation Service (NRCS) soil survey program defines soil productivity assuming some specified level of management. A productive soil is generally defined as one that will produce good yields of adapted crops in relation to the level of labor, nutrient, and energy inputs. This interpretation of inherent soil productivity provides a basis for comparing crop yield per unit area among soil map units throughout the USA. The caveat for each comparison is that the reported yields are those that can be expected under a high level of management, but the specific management practices are not defined. Also, when a yield is not given for a specific soil map unit within a survey report, it implies that either the soil is not suited for that particular crop or the crop is generally not grown on that particular soil.

Long-term soil management through its effect on the dynamic soil properties has created some general expectations regarding soil productivity when evaluated at regional or major land resource area (MLRA) scales. Soils formed under grassland in humid regions often have higher organic matter content, an increased percentage of water-stable aggregates, and a structure that accommodates rapid plant growth, unlimited root proliferation, and thus increased productivity (i.e., crop yield). These soil characteristics generally occur because grasses in these regions replace most of their roots and top growth each year. As the aboveground plant dies, it falls on the soil surface, where it is decomposed or mixed into the upper part of the soil. Earthworms and other soil organisms incorporate a large portion of this material into the soil. The dead plant material serves as a food source for fungal and bacterial decomposition processes, leading to the formation of soil aggregates, and modifies effects of soil texture with regard to water and air relationships and root penetration. The increased water-stable aggregation, annual proliferation of plant roots, and associated wetting and drying cycles gradually develop a soil structure that is stable and, with good management, generally resists degradation (Figure 1).

Grassland soils are often less acid than those developed under forest vegetation. This occurs because grassland soils were generally formed with less annual precipitation which can cause greater leaching

Figure 1 A well-structured grassland soil showing characteristics associated with productivity.

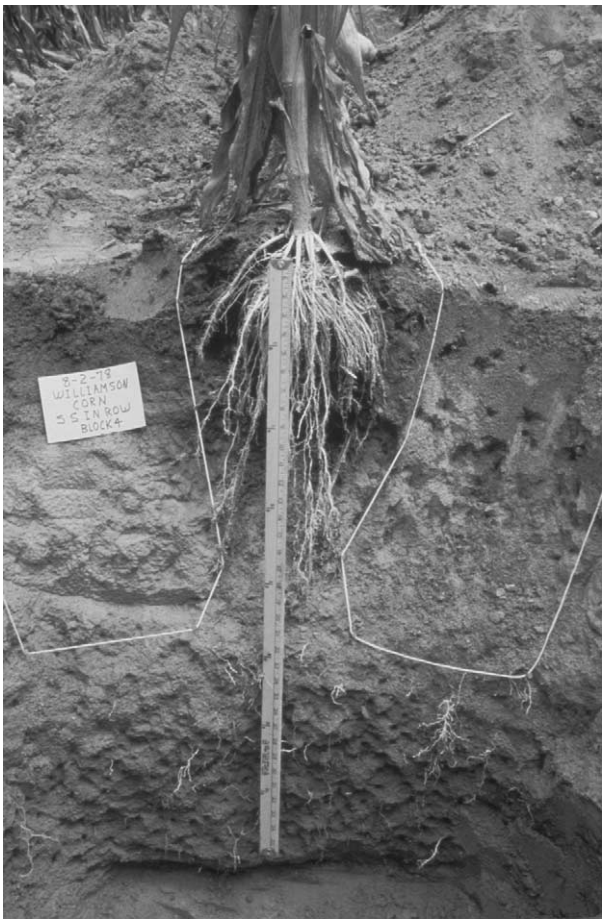

Figure 2 Corn root proliferation restricted to the area where in-row subsoiling (deep tillage) disrupted the eluviated layer in a southeastern Coastal Plain soil.

of soluble elements such as K, Ca, Mg, and NO_3-N. Grassland soils also tend to have a darker color and organic matter accumulation to a greater depth than soils developed under forest. This occurs because trees have larger and longer-living roots than grasses, thus reducing the amount of new organic matter added to the soil each year. Furthermore, most organic matter under forest vegetation is concentrated in the litter layer and remains in the upper few inches of the surface or A horizon. Below that relatively shallow zone in forest-derived soils, the soil organic matter is often more eluviated (leached) than under grassland. The increased amount of organic matter and prolific plant root systems in grassland soils also enable them to be more effective at recycling leached nutrients than forest-derived soils. Nutrient recycling occurs when plant roots absorb ions from the soil solution and transport these materials to aboveground to leaves and other plant parts, which then die and return the nutrients to the soil through litter and root decomposition. As a result of these soil-formation processes, grassland soils (Mollisols) are often considered to have a higher inherent productivity for commonly grown crops than forest soils (Alfisols or Ultisols). The increased aggregation and desirable soil structure enhance air exchange, water entry and retention, and nutrient cycling for subsequent crops.

The eluviated soil layers typically found within forest-derived soils are often more dense and subject to compaction when tilled. This subsurface compaction reduces inherent productivity by decreasing the volume of soil that is available for water retention, air exchange, and plant root development. In the US southeastern Coastal Plain, eluviated horizons are dominated by sand-sized particles (0.05–2.0 mm) and generally have less than 10% by weight of highly weathered kaolinite or similar clay minerals. This results in low plant-available water content, nutrient retention, and organic matter, and thus reduces the absorption of water and nutrients by plants. The most common soil-management practice to enhance the productivity of these soils would be to use some type of deep tillage or mechanical disruption such as in-row subsoiling to loosen the very dense, root-restrictive eluviated soil layers (Figure 2). The short-term benefit of deep tillage on several of the dynamic soil properties is often positive. However, tillage also enhances oxidation of the already low levels of soil organic matter and, in the long term, results in even greater compaction due to the wheel traffic.

Soil Productivity Comparisons

To illustrate soil productivity, selected chemical and physical characteristics, as well as the resultant corn and soybean productivity ratings, for a midwestern Mollisol representing the northern US Corn and Soybean Belt (Nicollet) and an Ultisol from the southeastern Coastal Plain (Norfolk) can be compared (Table 1). The soils differ in their productivity ratings for soybean and corn by 290 kg ha^{-1} and 375 kg ha^{-1} when given a high degree of management. Several factors contribute to crop yield differences, but a comparison of the soil-forming factors, dynamic soil properties resulting from management decisions, and the subtle interactions provide a better understanding of soil productivity.

The cation exchange capacity (CEC) for the two soils reflects inherent differences in clay mineralogy and the amount of organic matter. This impacts productivity by influencing the total amount of cations (primarily Al^{3+}, Ca^{2+}, H^{+}, Mg^{2+}, K^{+}, and Na^{+}) that the soil can retain. However, the specific effect of these differences on nutrient availability (*See* **Nutrient Availability**) and crop yield will depend on the total nutrient management program (*See* **Nutrient Management**). The lower pH within the Norfolk soil (i.e., more acid), coupled with the lower CEC, means that smaller but more frequent lime applications may be needed to optimize productivity. The lower amount of organic matter in the Norfolk soil will affect both soil structure and water-retention characteristics. The lower plant-available water capacity (AWC) means that plants growing on the Norfolk soil must receive rainfall or irrigation water more frequently during the growing season than those growing on Nicollet soil. Fortunately, annual rainfall in the southeastern Coastal Plain is greater, but so is the average temperature. Also, because of the restricted rooting associated with compaction, the volume of soil available for each plant to obtain water and nutrients effectively is generally less for the Norfolk soil than for the Nicollet. The effects of compaction and the lower nutrient and water retention can be partially compensated for by including deep tillage as part of the high-level management plan for Norfolk soils. However, use of a subsoiler/ripper requires approximately 16 l ha^{-1} of diesel fuel,

Table 1 The soil-forming factors, resultant chemical and physical properties, and productivity ratings for a US Midwestern Mollisol and a southeastern Coastal Plain Ultisol

	Nicollet	*Norfolk*
Soil-forming factor		
Parent material	Loamy glacial till, calcareous	Loamy marine sediments, acid
Time	Deposited during late Pleistocene	Deposited during Pliocene/Miocene
Climate	Mean annual temperature 8°C (mean winter −7°C, summer 22°C); annual precipitation 864 mm	Mean annual temperature 17°C (mean winter 7°C, summer 26°C); annual precipitation 1162 mm
Topography	Nearly level to gently sloping glacial till plains and moraines, 1–3% slope	Nearly level to sloping marine terrace uplands, 0–2% slope
Natural vegetation	Prairie vegetation characterized by Indian grass, little bluestem, switchgrass, needlegrass, blue grama, sideoats grama, and scattered trees and shrubs of bur oak, juniper, and sumac	Mixed pine and oak forest vegetation characterized by loblolly, longleaf, slash, and shortleaf pines; yellow poplar; sweetgum; and red and white oaks as overstory, and dogwood and farkleberry as understory
Resultant properties		
Mineralogy	A mixture of minerals in the sand, silt, and clay fractions	Dominated by resistant sand grains and low-activity clays
Drainage	Moderately permeable but somewhat poorly drained, seasonal high-water-table 60–100 cm	Moderately permeable but well-drained, seasonal high-water-table 100–180 cm
Texture	Loam, clay loam, silty clay loam	Loamy sand, sandy loam
Organic matter (g kg^{-1})	40–80	5–20
CEC (cmol kg^{-1})	25–40	1–5
pH	5.6–7.8	4.0–5.5
AWC (cm cm^{-1})	0.17–0.22	0.06–0.11
Productivity ratings		
Corn	7275 kg ha^{-1}	6900 kg ha^{-1}
Soybean	2960 kg ha^{-1}	2690 kg ha^{-1}

CEC, cation exchange capacity. A measure of the ability of the soil to retain positively charged ions such as potassium (K), calcium (Ca), or magnesium (Mg) that are essential for plant growth and development.
AWC, available water capacity. The amount of plant-available water that a soil can retain.

increasing the annual costs of production on that soil and further decreasing economic productivity when computed using output per unit input.

Productivity Ratings

As illustrated by the comparison of Norfolk and Nicollet soils under natural or nonirrigated conditions, the critical functions that strongly influence the relative productivity rating of a soil for crop production are those needed to provide a nonlimiting rooting environment. For maximum productivity, this environment must be capable of meeting the plant's water and nutrient requirements throughout the growing season. The suitability of a soil for plant root proliferation thus provides a scientific basis for several soil productivity indices. One of the most common is:

$$\mathrm{PI} = \sum_{\mathrm{i}=1}^{r} (A_{\mathrm{i}} * C_{\mathrm{i}} * D_{\mathrm{i}} * \mathrm{WF})$$

where PI is the relative productivity index (0–1), A_{i} is the sufficiency of AWC, C_{i} is the sufficiency of bulk density, D_{i} is the sufficiency of pH, WF is a weighting factor representing an idealized plant root distribution, and r is the number of horizons in the rooting depth. Within this index, sufficiency is defined as the pH, D_{i}, and C_{i} levels that do not restrict plant growth or development throughout the life cycle of the species for which the assessment is being made.

This approach for evaluating productivity uses readily available information, assumes a high level of management, assesses only those changes associated with nonreplaceable inputs, and assesses long-term productive potential without annual fluctuations in crop yield. It was used extensively during the 1980s to project the potential effects of soil erosion and demonstrate the usefulness of soils databases, especially the SOILS-5 and the National Resources Inventory (NRI). One conclusion drawn from a study designed to predict the effects of soil erosion in the US Corn and Soybean Belt was that the nonreplaceable productivity would decline by an average of less than 8% during the next 100 years. The rationale for such a small decline was that the soils in that region are typically deep and fertile, and the cropland tends to be on level-to-gently-rolling terrain. However, for soils in landscape positions where the slope exceeds 6%, the decline in long-term productivity could be much greater. Also, for soils with unfavorable subsoil material (e.g., bedrock or gravel), the loss of productivity could be much greater if erosion was allowed to continue.

Processes Reducing Soil Productivity and Practices for Restoring It

Soil erosion, nutrient mining (removal or output greater than input), loss of organic matter, acidification, salinization, water logging, and compaction are among the most common causes for reduced soil productivity. As shown by the productivity index, reductions in plant-available water, nutrient retention, and the creation of a less-favorable environment for plant growth are the primary reasons for loss of soil productivity via erosion.

Erosion primarily removes surface soil, which often has the highest biological activity and greatest amount of soil organic matter. This results in an economic loss of essential plant nutrients and a potential environmental loss if those nutrients are transported to water resources, where they can create problems such as algal blooms and eutrophication. Visual indicators that suggest soil erosion may be reducing productivity include changes in soil color, decreasing soil horizon depth, deposition at field boundaries, or, in desert soils, the presence of moss and algal (crypotogam) crusts. The erosion processes occur not only through the effects of wind and water, but also through mechanical processes such as the removal of soil through the harvest of root crops or tillage and cultivation practices that move soil downslope. Management practices that can help minimize erosion and the subsequent productivity loss include modifying the landscape to control runoff amounts and rates (e.g., terracing, shortening slope length and steepness, strip-cropping, planting shelterbelts) or maintaining a protective cover on the soil (e.g., protecting the surface with crop residue with no-tillage, growing cover crops, improving aggregate stability, increasing water infiltration).

Loss of organic matter decreases productivity by reducing air and water movement within the soil, decreasing cation and anion exchange sites, increasing the potential for crusting and subsequent runoff, and reducing the availability of N, P, and S. Soil organic matter can be lost through erosion or decomposition processes. When soils are tilled, organic matter decomposes faster than under no-till conditions because of changes in water, aeration, and temperature. Although the actual amount of organic matter lost after clearing a wooded area or tilling native grassland will vary, a large amount (e.g., 30–50%) will often be lost within the first 10 years.

Practices that hasten the loss of soil organic matter and potentially decrease productivity include: (1) decreasing the production of plant materials (e.g., replacing perennial vegetation with short-season vegetation, replacing mixed vegetation with

monoculture cropping, using cultivars with high harvest indices, increasing the use of bare fallow, or introducing more-aggressive but less-productive plant species); (2) decreasing the supply of organic materials by burning forest, range, or crop residue or through excessive grazing; and (3) increasing the rate of organic matter decomposition through tillage, drainage, or excessive N fertilization. Strategies to enhance soil productivity by increasing soil organic matter include: (1) increasing plant material production with irrigation, optimum fertilization, use of cover crops, reforestation, or restoration of grassland; (2) increasing organic matter supply by protecting from fire (provided the area is not degraded grassland, where fire actually improves productivity by preventing encroachment of shrubs and other woody plant species), applying animal manure or other carbon-rich materials, and controlling insects and rodents; or (3) decreasing rates of decomposition by reducing or eliminating tillage, preventing excessive drainage, or reducing soil temperature by preserving surface vegetative cover.

Acidification or decreases in soil pH often occur because of the excessive application of nitrogen fertilizers. Acidity reduces productivity by decreasing the availability of essential plant nutrients such as Ca, Mg, or P; decreasing CEC through accelerated mineral weathering; and increasing the solubility of Al, which can interfere with plant root development. Acidity also affects the activity of many microorganisms responsible for organic matter decomposition and chemical transformations within the soil. A soil pH between 6.6 and 7.3 is favorable for microbial activities that contribute to the availability of N, S, and P in soils.

Salinization decreases soil productivity by limiting the ability of plants to take up water. It occurs in response to any practice that affects the soil–water balance and allows water-soluble salts to accumulate in the soil. Irrigation, drainage, changes in plant community composition that alter soil cover or rooting characteristics, and summer fallow are some agricultural management practices that can result in salinization if the climate and hydrology conditions are favorable. The process can occur on the soil surface whenever the following conditions occur together: soluble salts, such as sulfates (SO_4^{-2}) of Na, Ca, or Mg are present in the soil, the water table is near the soil surface, evaporation rates are high, or annual rainfall is low. In semiarid areas, this process often results in saline seeps on the rims of depressions and edges of drainage-ways, at the base of hill-slopes, and in flat, low-lying areas surrounding sloughs or shallow bodies of water.

Early signs of salinization include: (1) increased soil wetness in semiarid and arid areas to the point that the soil does not support agricultural equipment, (2) growth of salt-tolerant weeds, and (3) irregular patterns of crop growth and lack of plant vigor. Advanced signs include a white crusting on the surface, a broken ring pattern of salts adjacent to a body of water, white spots and streaks in the soil (even where no surface crusting is visible), or the presence of weeds or other naturally growing, salt-tolerant vegetation.

Restoring soil productivity in saline areas is done primarily through water management. Sufficient irrigation water should be applied to leach salts below the root zone, but care should be taken not to overirrigate, especially in areas that do not have adequate natural drainage. It is very important to provide suitable drainage water outlets that do not degrade water bodies or other natural resources into which the drainage water flows. The use of cropping and tillage systems that promote adequate infiltration and permeability can also help restore productivity. This includes building soil organic matter for better soil aggregation and avoiding compaction. Planting salt-tolerant crops that use available soil moisture, removing excess water from recharge areas with actively growing, deep-rooted plant species such as alfalfa, and reducing summer fallow by continuous cropping are among the most effective cropping practices for controlling salinization, restoring productivity, and minimizing negative impacts on the environment.

Soil compaction reduces productivity by restricting rooting depth and the uptake of water and nutrients. Compaction occurs when soil particles are pressed together, increasing the weight of solids per unit volume of soil (bulk density). This reduces pore size and volume, increasing the proportion of water-filled to air-filled pore space. Although in some soils compaction can increase thermal conductivity, causing the soil temperature to be higher than under noncompacted conditions, soils in humid regions with a high water content often have a lower soil temperature, which suppresses the activity of many thermophilic and mesophilic microorganisms that drive soil organic matter decomposition and the subsequent release of nutrients. Compaction also decreases infiltration, increasing the potential for runoff and erosion.

Tilling, harvesting, or grazing when soils are too wet are some of the primary causes for soil compaction. The depth at which compaction occurs, the shrink–swell potential of soil (which is determined by the clay mineralogy), and climate are critical factors determining the persistence of problems and overall impact on productivity. Subsoiling or deep tillage may be necessary to break up compacted layers in some soils. Applying animal manure, compost,

newspaper, or woodchips with an appropriate C:N ratio, or municipal sludge that does not contain toxic compounds can help restore productivity by improving soil structure and biological activity. The negative effects of compaction on soil productivity can also be minimized by reducing wheel traffic, the pressure or weight of equipment, and maintaining or increasing soil organic matter.

Summary

Soil productivity encompasses soil fertility plus the inherent and management-related factors affecting plant growth and development. It is generally measured in terms of inputs versus outputs, which for agronomic situations generally refers to water and/or nutrient input versus crop yield. The critical soil functions influencing productivity within any soil are those that provide physical support, a rooting medium with plant-available water, air for respiration, and essential nutrients. Humankind can also have a tremendous impact on soil productivity through its effects on the dynamic soil properties. Agricultural management decisions regarding tillage, fertilization, crop rotation, irrigation, and drainage are among the practices that can significantly affect soil productivity.

PROTOZOA

W Foissner, Universität Salzburg, Salzburg, Austria

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Protozoa are unicellular, heterotrophic, eukaryotic organisms comprising four organization types: amebae, flagellates, ciliates, and parasitic sporozoans. About 1600 species, of which some are restricted to certain geographic regions, are known to live in terrestrial habitats; however, at least the same number is still undiscovered. Small body size and the ability to produce protective resting cysts are the main adaptations of protozoa to the peculiarities of the soil environment. Many soil protozoa feed, more or less selectively, on bacteria, while others are omnivorous or highly specialized fungal feeders. Protozoa (active and cystic) inhabit the soil in great numbers, that is, some 10 000–1 000 000 individuals per gram dry mass, and produce many generations annually. They significantly enhance the flow of nutrients and growth of plants and earthworms. Accordingly, they are important soil inhabitants, and studies on their dynamics and community structures thus provide a powerful means for assessing and monitoring changes in biotic and abiotic soil conditions. Unfortunately, methodological and taxonomical problems still limit the use of protozoa as bioindicators in terrestrial environments.

This article covers the diversity, ecology, and bioindicative value of soil protozoa. The knowledge on autotrophic soil protists, which mainly live on the soil surface because they depend on light, is still in its infancy. However, they play an important role, especially as a symbiotic partner of lichens in the crust soils of extreme regions, such as desert and high mountain areas.

A Brief History of Soil Protozoology

Although there were predecessors, such as Ehrenberg, Goodey, and Russel and Hutchinson, soil protozoology as a science was established by the Austrian–Hungarian naturalist H.R. Francé and the English microbiologist D.W. Cutler in the 1920s. Their monographs showed that unicellular organisms inhabitate the soil in great number and diversity, and thus contribute significantly to soil fertility and sustainability. Francé's booklet saw many editions, the latest in the 1960s.

This first bloom of soil protozoology followed a long period where a few specialists added significantly to the knowledge available, mainly J.F. Darbyshire in the UK, L. Bonnet in France, J.D. Stout in New Zealand, S.S. Bamforth in the USA, and V.F. Nikolyuk in Russia. It was only in the last two decades of the twentieth century that soil protozoology was rejuvenated by the studies and reviews of W. Schönborn in Germany, F. Ekelund and R. Rønn in Denmark, W. Foissner in Austria, and J.F. Darbyshire, who edited the first book devoted entirely to the biology and ecology of soil protozoa. Today, the field is well established but still a domain of a limited number of specialists, while general soil ecologists have problems to incorporate the new knowledge appropriately, in contrast to marine and limnetic plankton researchers, where the 'microbial loop,' that is, the intimate connection of dissolved organic matter, bacteria, and protists, greatly changed views and research strategies.

Diversity and Biology

Diversity and Geographic Distribution

About 23 000 free-living, extant protozoa are known. Of these, roughly 1600 were originally described or later reported from terrestrial habitats (Table 1). For a long time, the soil protozoan community was considered as an ubiquitous part of limnetic species and some even suggested that nearly the same species of protozoa occur in soil, sewage, and activated sludge. However, more detailed research disproved these findings and showed that they were based on misidentification of species. Today it is widely accepted that the main part (>70%) of the soil protozoan species evolved in and are restricted to terrestrial environments. Refined morphological methods and gene sequence data indicate that a considerable portion of soil and freshwater protists have a restricted geographical distribution (Figures 1 and 2), disproving the old hypothesis that, in microorganisms, 'everything is everywhere, the environment selects.' This matter, however, is still under discussion.

Table 1 Known and proposed diversity of soil protozoa

Taxa	*Known species*	*Proposed species*
Naked amebae[a]	60	600
Testate amebae	300	500
Flagellates	270	600
Ciliates	1000	2000
Microsporidia and sporozoans	3	?

[a]Without several hundreds of slime molds.

Table 1 shows the known and proposed soil protozoan diversity. While numbers of testate amebae and ciliates are supported by detailed data, those of the other groups are very speculative. Likewise, little is known of protozoan parasites. But even the known soil protozoan diversity is high and a major problem in basic and applied soil biology because comprehensive identification literature is lacking and few taxonomic specialists are available. The decreasing interest of the public and science in classical taxonomy, will soon dramatically increase our ignorance. Although molecular methods likely can solve some of the problems, nobody will be available to add names to the sequences. Thus, great efforts are necessary to educate young scientists in classical alpha-taxonomy.

Morphological and Physiological Adaptations

The soil is a very special environment for protozoa. Three factors are most important for their existence and activity: (1) the structure of the porous space; (2) the astatic water supply; and (3) intraspecific and interspecific interactions. These factors caused two basic adaptations: small body size and the universal capability to produce protective resting cysts. These and some other important adaptations will be briefly described.

Morphological adaptations Mean body length, mean body width, and mean biomass are significantly smaller in soil ciliates and testate amebae than in ciliates and testaceans from fresh water. The small size, and volume, is achieved either by an overall reduction in size or by reduction of body width. Many soil ciliates are thigmotactic creepers with a reduced ciliature and a flattened and/or worm-like

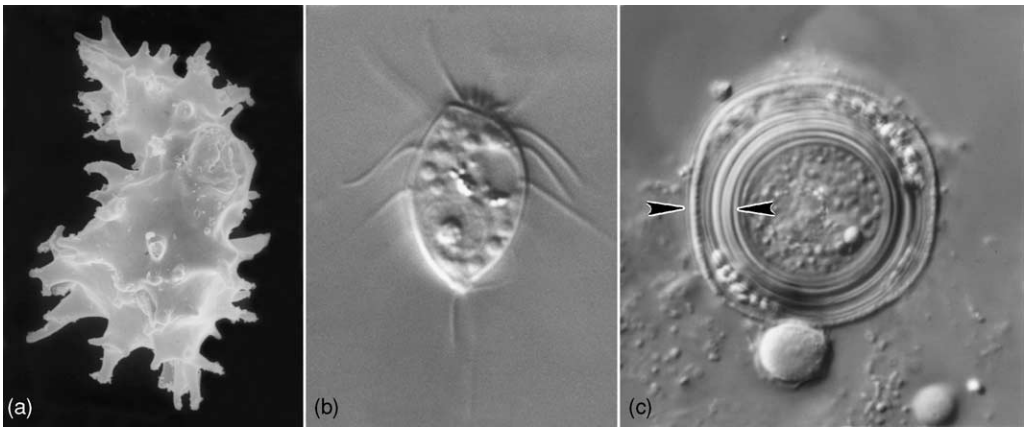

Figure 1 Small-sized and cystic soil protozoa. (a) A naked ameba about 30 μm long with many tiny pseudopodia which can exploit even minute soil pores for food. (b) A 15 μm long soil flagellate, *Hemimastix amphikineta*, which only occurs in southern terrestrial environments, that is, in Gondwana. Note the two rows of flagella which make the organism look like a ciliate. (c) Resting cyst (diameter about 35 μm) of the ciliate *Exocolpoda augustini*. This ciliate occurs mainly in hot and dry soils, e.g., the Namib desert, and thus has a very thick cyst wall (arrowheads) composed of many membranes. The organism can remain viable in this condition for years.

body (Figure 3b). These features and several physiological peculiarities produced a soil ciliate community of unique structure, characterized by a high proportion of colpodids (Figure 3a and 3b) and hypotrichs and a strong underrepresentation of sessile peritrichs and suctorians compared with fresh water ciliate communities. The soil testacean community is characterized by having a high proportion of species with reduced pseudostome size (opening of the shell), a flattened ventral side, and a globular shape (Figure 2). Soil naked amebae and flagellates have similar adaptations as ciliates and testate amebae (Figure 1a and 1b): most are very small and the amebae, for instance, can exploit with their tiny and flexible pseudopodia micropores which have a diameter of only 1 μm.

Physiological adaptations Few physiological adaptations have been investigated in detail; it is probable that several are still to be discovered. Some physiological adaptations cause conspicuous morphological specializations.

Food and feeding Many soil protozoa, especially most naked amebae and flagellates, entirely or partially feed on bacteria, skimming off the dense bacterial standing crop provided by many soils. However, under natural conditions soil protozoa cannot significantly reduce bacterial abundance, and the absolute amount of organic matter consumed by the testacean community is small – 234 mg m^{-2} during a 3-month period.

In soil ciliates, 39% feed mainly on bacteria, 34% are mainly predaceous, and 20% are omnivorous. Some are strictly mycophagous and the most characteristic species of the soil ciliate community. They have reduced the classical ciliate mouth almost completely and evolved a minute feeding tube producing discrete holes in the hyphae and spores of fungi and yeasts (Figure 3b–e). This type of feeding has been termed 'perforation lysis' and is also found in several naked amebae. There is evidence from pot experiments that such activities can reduce the inoculum level of plant pathogenic fungi in soils and can reduce the severity of take-all disease of wheat by the fungus *Gaeumannomyces graminis* var. *tritici*. Some flagellates are also strictly mycophagous, but take up the fungi by an ordinary cytostome. Many soil testaceans seem to feed on humus particles and/or fungal hyphae and spores, but other materials such as algae, protozoa, and bacteria are also ingested; some are polyphagous. A Gondwanan species, *Apodera vas*, can even feed on nematodes (Figure 2b). In some other species, *Difflugia lucida* and *Schoenbornia humicola*, a remarkable specialization has been described: they collect and store humus particles around the pseudostome during optimal periods and transport them into the cytoplasm during suboptimal environmental conditions (Figure 2c).

r/K-*selection* Field data and laboratory experiments show that colpodid ciliates are more *r*- than *K*-selected. Thus, they are particularly diverse and frequent in unpredictable and extreme habitats, such as leaf surfaces, lichens, and alpine and desert soils. In contrast, polyhymenophoran ciliates (mainly hypotrichs) are more *K*-selected and thus particularly diverse and frequent in predictable habitats (Figure 4). The ratio of these ciliate groups proved to be a sensitive indicator for biotope stability and can thus be used in studies on human-influenced soils.

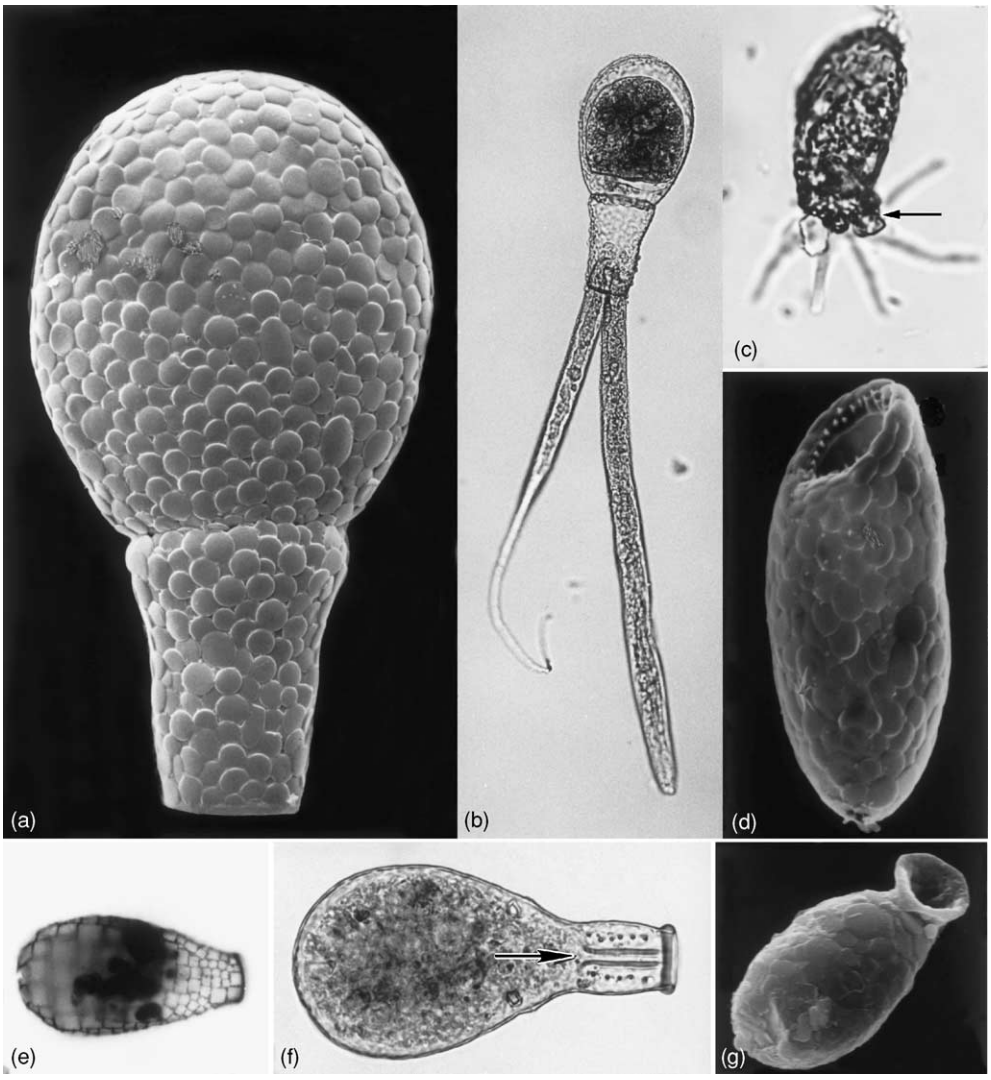

Figure 2 Soil testate amebae. (a, b) *Apodera vas* is about 170 μm long and only occurs in the southern hemisphere, i.e., in Gondwana. It can feed on nematodes (b) and build its shell of platelets taken from the shell of another prey organism, the testate ameba *Trinema lineare* (d). (c) *Difflugia lucida* is about 60 μm long and produces food-bundles (arrow) around the shell opening under optimal environmental conditions. These food accumulations are ingested and digested when conditions are less favorable. (d) *Trinema lineare* is about 35 μm long and one of the most common soil testate amebae globally. Its shell is made of silicium platelets, which *A. vas* uses for building its own shell (a). (e) *Quadrulella* makes the test of quadrangular silicium platelets. (f) *Nebela certesi* is about 150 μm long and only occurs in the southern hemisphere (Gondwana). Note the oral tube (arrow) surrounded by minute teeth. (g) *Edaphonobiotus campascoides*, a soil testate ameba about 35 μm long has, as yet, been found only in central Europe (Laurasia). Its shell is highly similar to that of some marine sand testaceans.

Testate amebae are, in general, on the *r* side within the *r/K*-continuum, when compared with ciliates, naked amebae, and flagellates. However, a more fine-scaled rating suggests that autochthones are more *K*-selected than allochthones.

Cysts All soil protozoa survive detrimental environmental conditions in a dormant stage, termed 'protective resting cyst.' When encysting, the cell rounds up, loses water, and secretes a thick wall (Figure 1c). In encysted condition, protozoa can withstand, for instance, decades of drought and food depletion, liquid nitrogen, and strong acids. When conditions become favorable again, the cell excysts and commences feeding and reproduction. The receptors indicating favorable conditions to the encysted cell are still not known. Likewise, few reliable data are available on the factors stimulating excystment, but substances secreted by potential food organisms and CO_2 might be important. A slight increase in the CO_2 level to 0.5–0.8% enhanced excystment of soil amebae, but a further increase inhibited it.

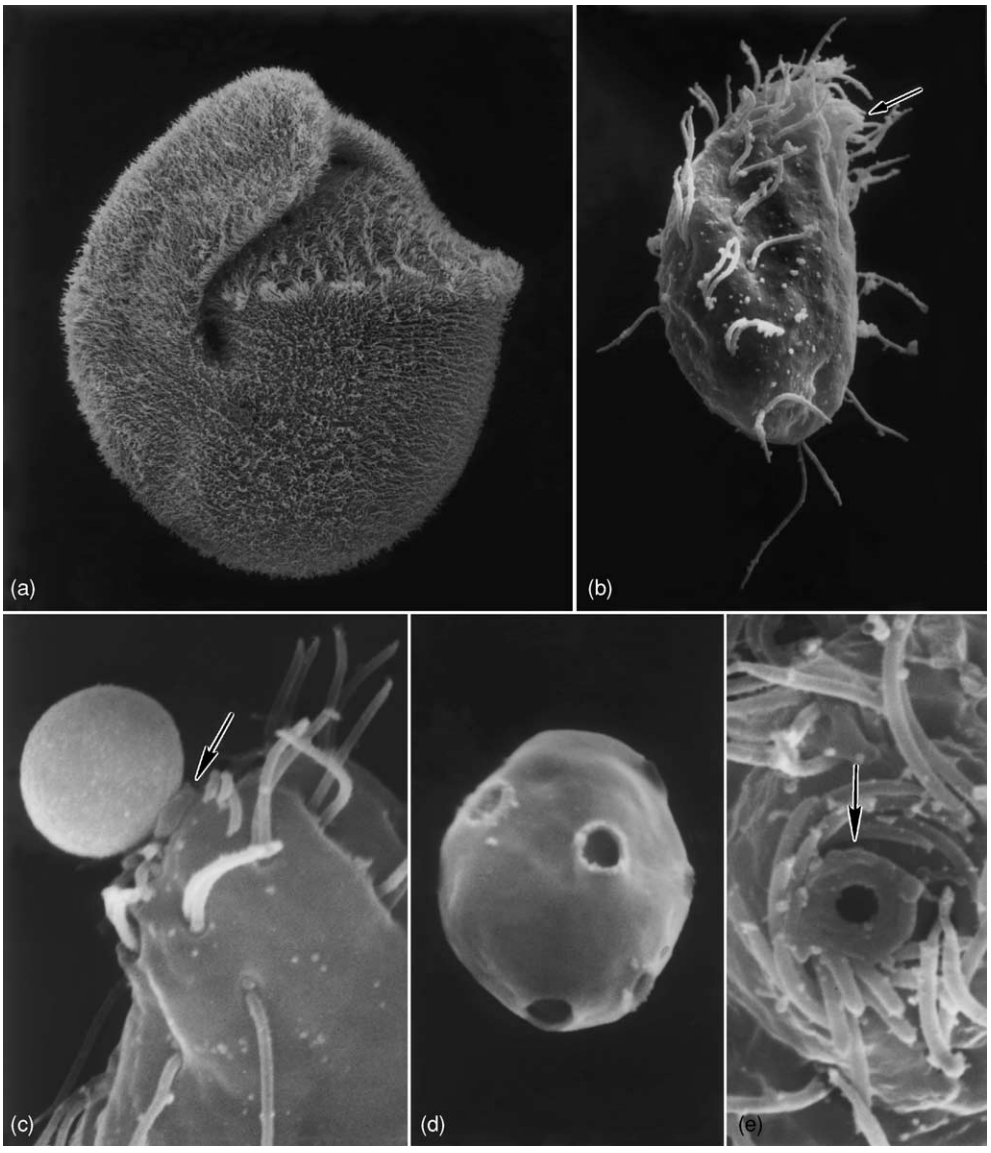

Figure 3 (a) *Bresslauides discoideus* is a colpodid ciliate up to 600 μm large and likely restricted to the northern hemisphere. It is a predator with a large mouth and one of the largest ciliates occurring in soil. (b–e) *Pseudoplatyophrya nana* is a minute species about 25 μm long that feeds only on yeasts and fungi. It feeds by perforation lysis, that is, has a minute oral tube (arrows) that enzymatically produces small holes in the yeast's cell wall (c, d).

There is evidence that cysts are adapted to the overall environmental conditions in which the trophic cells live. Cysts formed, for instance, in arid environments can survive desiccation for decades, while those produced in rainforests survive drought for only a few weeks or months. The same is true for temperature. In experimental microcosms, diversity of soil ciliates and reproduction are highest at or near the mean annual temperature of the habitat, that is, around 20°C for soils from the region of Bonn, Germany, and 25–30°C for those from an African savannah. These data show the existence of many local physiological races adapted to the specific conditions of the habitat.

There are further cyst variations in soil protozoa. Testate amebae can produce a so-called 'precystic stage' for bridging short unfavorable periods, an adaptation to the often quickly changing soil environment. When forming this stage, the organism produces a thin membrane (epiphragm) closing the shell opening (pseudostome), and rounds up, but does not form a thick cyst wall. During excystment, the epiphragm is lysed or digested. Another spectacular cyst is produced by the epiphytic, colpodid ciliate genus *Sorogena*. Under favorable conditions, it multiplies rapidly, aggregates, encysts, and produces noncellular stalked aerial sori which look highly similar to those

of cellular slime moulds. The sorogenesis requires alternate light and dark conditions, just as in the pink slime mold *Acrasia rosea*.

Anabiosis Anabiosis (cryptobiosis, anhydrobiosis) is the property of organisms to resist desiccation without marked morphological changes, such as the production of a special cyst or membrane. It is common in some groups of soil- and moss-inhabiting animals, such as rotifers, tardigrades, and nematodes, but is very restricted among soil protozoa, where it likely occurs in a few naked amebae and in a suctorian ciliate, as I myself have observed.

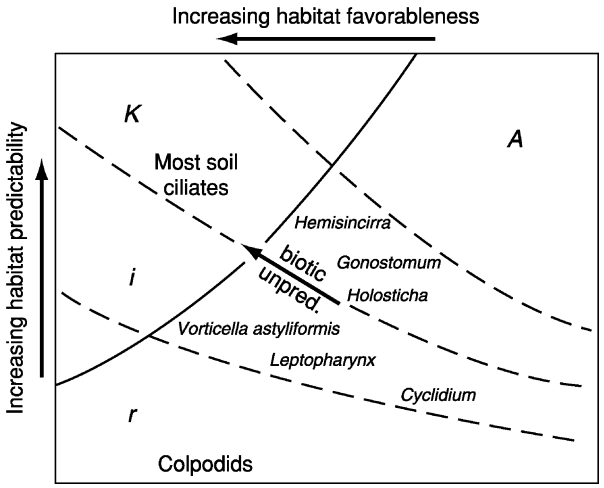

Figure 4 Ordination of soil ciliate taxa on a two-dimensional template. Colonizing *r*-organisms, colpodids, characterize ephemeral habitats of low resources (lower left to lower right of diagram). A few intermediate *K*-selected species (e.g., *Cyclidium* and *Holosticha*) can adapt to harsh conditions. Species diversity increases towards the upper left corner of the diagram where the abiotic factors of the habitat improve, enabling more biotically unpredictable interactions due to competition and predation. *A*, adversity selection; *i*, intermediates. Reproduced with permission from Bamforth SS (2001) Proportions of active ciliate taxa in soils. *Biology and Fertility of Soils* 33: 197–203.

Number and Biomass

In soil, protozoa are present as active (trophic) and inactive (encysted, dormant) cells. It is likely that many soil protozoan species are encysted most of their life. Thus, the encysted portion of the total number is usually much larger than the active. There is currently no reliable method available for separating active and dormant specimens. Furthermore, most counts rely on culture techniques followed by a most probable number (MPN) calculation of protozoan abundance. However, only few of the many protozoan species present excyst and grow to detectable numbers under the limited conditions of such cultures. All these methodological shortcomings mean that many of the quantitative data available in the literature are doubtful, especially as concerns the active and thus ecologically relevant portion. Only numbers obtained by direct microscopic counts in soil suspensions are reliable (Table 2). Unfortunately, naked amebae and flagellates can hardly be counted with direct methods because they strongly adhere to the soil particles and thus cannot be seen. Accordingly, all numbers on active naked amebae and flagellates are highly questionable.

In spite of these problems, it is clear that protozoa inhabit soil in great numbers, that is, some 10 000–1 000 000 individuals per gram dry mass (Tables 2–4, Figure 5). Biomass tends to correlate with abundances, and values between 0.1 g and 5 g m^{-2} are frequent. Naked amebae and flagellates (active plus cystic) usually show numbers between 2000 and 1 000 000 g $^{-1}$ dry mass of soil. Standing crop numbers of active testate amebae are moderately high i.e. 100–1000 individuals per gram dry mass in arable land and mineral soils, 1000–10 000 in meadow and grassland topsoils, and 10 000–100 000 in forest leaf litter and upper humus horizons. However, as many testate amebae are rather voluminous, their standing crop and production biomass often surpasses that

Table 2 Mean numbers of active ciliates per gram dry meadow soil (0–5 cm), spruce litter (0–2 cm), and beech litter (0–2 cm)

of all other protozoans (Table 4). Thus, their omission in many recent studies is an unfortunate mistake. Abundances of active ciliates are low in evolved soils (humus and mineral horizons), usually <100 cells g^{-1} (Tables 2 and 3). However, up to 10 000 individuals per gram dry mass can be reached in developing soils and leaf litter (Table 2), showing that ciliates are important during the early stages of soil formation.

Vertical and Horizontal Distribution

Like as many soil organisms, protozoa are usually most abundant and diverse in the upper 0–10 (30) cm soil layer, where food is concentrated in the form of leaf litter and the rhizosphere. However, there is a distinct, not yet fully understood, niche separation of ciliates and testate amebae. While active ciliates occur mainly in the uppermost (fresh) leaf litter layer, where abundances of up to 10 000 individuals per gram dry mass are reached, testate amebae peak underneath, that is, in the evolving humus horizon ('fermentation layer'; Table 3). Thus, habitats such as meadow topsoils and arable lands contain very few active ciliates, usually $<100\ g^{-1}$ dry mass, although a lot of viable resting cysts are present. The inability to excyst (germ) in evolved soils has been termed ciliatostasis,

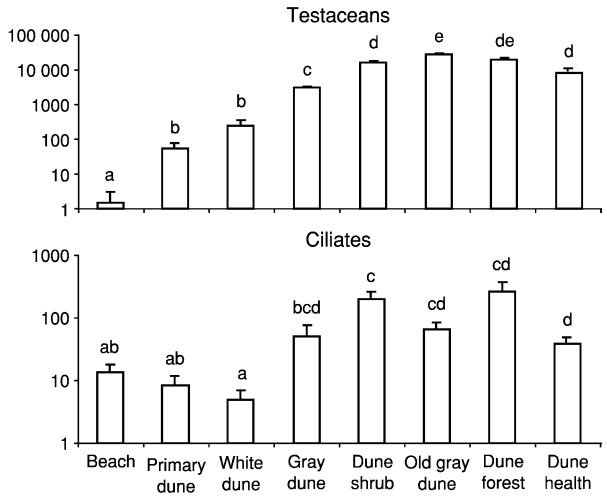

Figure 5 Abundance (individuals g^{-1} dry mass of soil) of active testate amebae and ciliates in dune soils along a series of soil (dune) development. Significant differences ($P < 0.05$) are indicated by different letters. Reproduced from Verhoeven R (2002) The structure of the microtrophic system in a development series of dune soils. *Pedobiologia* 46: 75–89.

in analogy to fungistasis. The reasons for ciliatostasis are not yet clear, but enrichment of certain detrimental substances during humification, density-dependent processes, and general food depletion are discussed.

Little is known about the horizontal distribution of soil protozoa. However, a very clumped distribution is evident from several faunistic and 'hot spot' investigations. Recent data suggest that spatial organization of protozoan communities occurs at scales below 10 cm.

The 'Water Paradox'

Protozoa are aquatic organisms, and free water is thus indispensable for their life. Accordingly, it appears reasonable to assume that water is the key factor for soil protozoan abundance and diversity. Surprisingly, carefully designed field and laboratory studies do not support this assumption, but over the years have provided many conflicting results. Two examples from recent studies should demonstrate the 'water paradox.'

In one study, aspen woodland plots were irrigated during the seasonal dry period every 3 days with 3.78 l m^{-2} and testate amebae were sampled on three occasions. The general effect of adding water to the soil was to increase significantly the number of active testaceans and to decrease the number of encysted specimens. Numbers of active testaceans and of total living testaceans (active plus encysted) showed a significant, positive correlation with soil moisture content. At higher soil moisture levels, the larger (>60 μm) species present tended to have a larger proportion of living individuals as cysts than did the smaller forms which numerically dominated the population. Generation times were shorter and secondary production higher in the watered plots.

In the other study, spruce forest plots were irrigated during the seasonal dry period every 4 days with 25 l m^{-2} (Table 3). This caused a marked decrease ($P \leq 0.05$) in the abundance of the active ciliates in the litter layer; species richness, in contrast, increased in both ciliates and testate amebae, while testacean abundance did not increase significantly. The nematode numbers increased dramatically by about 45%, while rotifer abundance did not change significantly.

As yet, there is no convincing explanation for these and many other contrasting results. However, most soil protozoologists agree on the basic assumption that water is a key factor for protozoan life, not only because they basically depend on water but also due to several morphological peculiarities most meaningfully explained as adaptations to the astatic water regime of the soil environment in general. I suggest, very briefly, two hypotheses for explaining the 'water paradox':

1. Water correlates with other, not yet recognized factors, especially the presence or growth of appropriate food organisms. This hypothesis is supported by the observation that laboratory microcosms, where food has been tested to be edible for the protozoans under investigation, show more consistent results, that is, increasing protozoan abundance and biomass with increasing soil moisture.
2. Protozoa can tolerate a wide range of soil moisture; only under extreme conditions do communities react. This hypothesis is supported by the occurrence of local, physiological races and the ability of many protozoan species to live in very thin films of water covering the soil pores and soil particles. In the spruce forest experiment described above, the litter of the control plot was hand-dry; most of the water present was a constituent of the needles (Table 3).

Ecological Significance

Standing Crop, Respiration, and Annual Production

Several ecosystem studies show consistently that the microflora (bacteria and fungi) accounts for about 90% of the heterotrophic soil respiration. Only about 10% of the total comes from the 'animals,' and about 70% of the 'animal' respiration is due to the protozoa, although their contribution to the standing crop is 'only' approximately 30% (Figure 6). This is due to their small size and fast reproduction. However, in earthworm-rich soils the proportion of

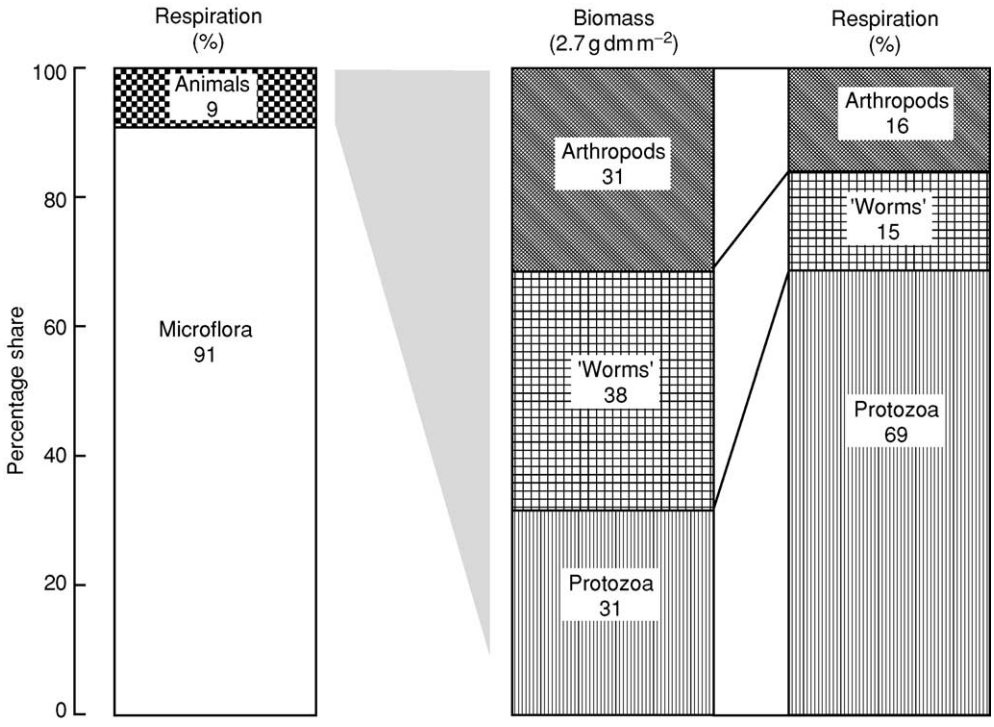

Figure 6 Contribution of protozoa to dry biomass (dm) and respiration of soil organisms. The graphs show the mean of 14 ecosystem studies from various sites of the world. Reproduced with permission from Foissner W (1987) Soil protozoa: fundamental problems, ecological significance, adaptations in ciliates and testaceans, bioindicators, and guide to the literature. *Progress in Protistology* 2: 69–212.

protozoa to the total biomass is considerably lower than stated above, while it is higher in extreme regions, where earthworms are few or lacking, for instance, in coniferous forests, deserts, and high mountains.

Field studies of production of soil protozoa are mostly restricted to testate amebae, the shells of which can be used to estimate their mortality. The annual production is in the same order of magnitude as that of the earthworms, especially when productions of naked amebae and flagellates are added (Table 4). The high contribution of the protozoa to the total annual animal production is due to the many generations produced and shows that protozoa play an important role in the energy flux of the soil ecosystem.

Mineralization and Plant Growth

Considering the fast growth of protozoa and their high annual production (Table 4), it is not surprising that they enhance flows of nutrients in soil to the benefit of plants and microorganisms. Experiments suggest that a complex 'microbial food-web' is operating rather than a simple 'microbial loop' during decomposition and growth. Convincing evidence is available that protozoa enhance plant growth significantly ($\geq$20%) either directly by increasing the availability of nitrogen in soil and leaching water and/or indirectly by nonnutritional effects, such as selective grazing on microbial populations, modification in the concentrations of plant hormones in the rhizosphere, or suppression of pathogenic bacteria. This matter is still under discussion. About 40% of the ingested microbial biomass N will be excreted by protozoa, leading to a constant release of nutrients available for plant uptake. Protozoa are not only responsible for respiring about 10% of the total carbon input but also for 20–40% of net N mineralization in the field. Furthermore, protozoa enhance growth of the plant root system and thus nutrient uptake (Figure 7).

Protozoa also cause a strong decrease in phosphate leaching. Phosphate is one of the most immobile nutrient ions in soil and continuous microdisturbance by protozoa and other microfaunal organisms (e.g., nematodes) is likely particularly important for microbial phosphate availability.

Earthworm Growth

Early reports that earthworms feed on protozoa and are an essential constituent in the diet of the compost worm *Eisenia fetida* to reach sexual maturity were recently confirmed and extended by carefully designed experiments. These showed that *Aporrectodea caliginosa* actively searchs for places with high

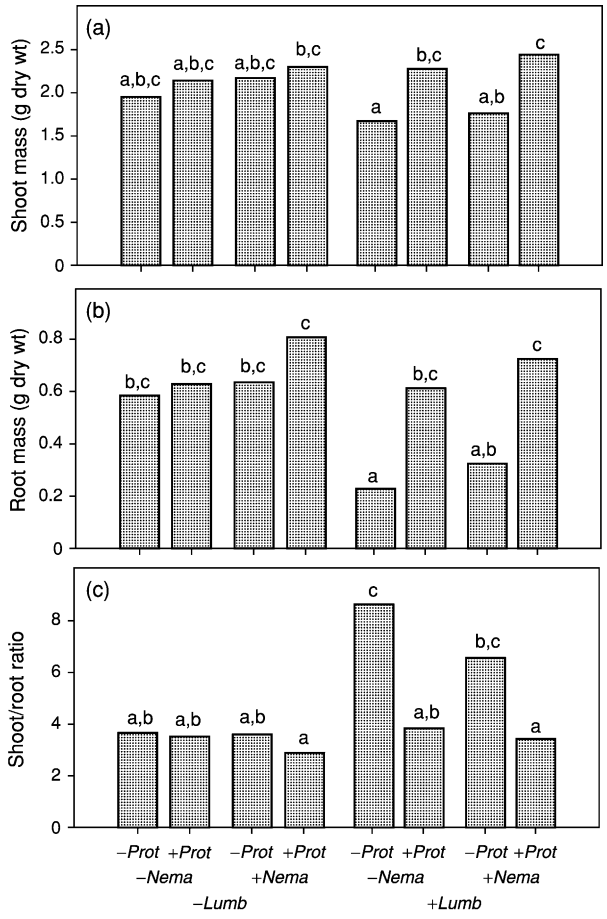

Figure 7 Effects of protozoa (−*Prot* without protozoa, +*Prot* with protozoa), nematodes (−*Nema* without nematodes, +*Nema* with nematodes) and earthworms (−*Lumb* without earthworms, +*Lumb* with earthworms) on (a) shoot biomass; (b) root biomass; and (c) shoot/root ratio of *Hordelymus europaeus*, a grass, in experimental chambers at the end of the experiment (112 days). Bars sharing the same letter are not significantly different. $P > 0.05$ (three-way ANOVA). protozoan densities and feeds on them. The weight gain of young *A. caliginosa* in soil with naked amebae was twice that in soil without amebae.

Protozoa as Bioindicators in Terrestrial Environments

There is considerable literature on the use of protozoa as bioindicators in terrestrial environments, and recently appropriate soil protozoan bioassays became available. Previous reviews summarized data obtained until 1998 and discuss general problems and methodology of bioindication. It has been shown that the full power of bioindication needs identification of species and/or functional groups because the information content of individual numbers and biomasses is often rather limited. Here, some recent studies are reviewed to demonstrate the great potential of protozoa in the investigation of natural and human-influenced soil ecosystems.

Compared to the soil meso- and macrofauna, protozoa have several specific features making them especially useful for bioindication:

1. Protozoa are an essential component of terrestrial ecosystems, because of their large standing crop and production and their high food consumption and respiration per mass unit (Figure 6, Table 4). Thus, changes in their numbers and diversity influence the rate and kind of soil formation and soil fertility.
2. Protozoa, with their rapid growth, short lifetime, and delicate external membranes, can react more quickly to environmental changes than any other eukaryotic organism and can thus serve as an early warning system and excellent tool in bioassays. Results are obtained within a few days, faster than with any other eukaryotic test system.
3. The genome of the protozoa is similar to that of the metazoa. Their reactions to environmental changes can thus be related to higher organisms more convincingly than those of the prokaryotes.
4. Morphologic and genetic differentiation among globally distributed protozoan species is rather low, suggesting that many indicator species can be used worldwide.
5. Protozoa inhabit and are particularly abundant in those soil ecosystems that almost or entirely lack higher organisms, especially earthworms, due to extreme environmental conditions.
6. Protozoa are not readily dislodged in soil. The difficult problem of horizontal migration, especially with the epigaeon, does not affect the investigations.

Protozoa also pose problems when used as bioindicators; specifically, counting methods are time-consuming and species identification is troublesome due to the lack of comprehensive identification literature. There are indications that molecular methods and taxonomic reviews can partially solve these drawbacks.

Soil Protozoa as Indicators in Natural Ecosystems

The main humus types, mull, moder, and mor, can be finely discriminated by certain protozoan species, especially testate amebae. Further, some ciliates are excellent indicators for periodic or sporadic oxygen depletion, which is often difficult to recognize and

measure with physicochemical methods. Of course, protozoa can also be used to characterize certain habitats and soil development, for instance, in coastal dunes of Germany (Figure 5). This study shows, *inter alia*, that the content of organic matter is a key factor for the abundance and diversity of the microfauna, and testate amebae are the most important group, reaching up to 50 000 individuals per gram dry mass. Further, active ciliates are comparatively abundant. These data are in accordance with niche separation of testate amebae and ciliates and the concept of ciliatostasis reported in the section on vertical distribution.

Protozoa as Indicators in Reclaimed Open-Cast Coal Mining Areas

Topsoil removal, as occurs in open-cast mining areas and during the preparation and use of high-mountain ski slopes, heavily impoverishes protozoa and soil life in general (Figure 8). However, colonization occurs within a few months. Abundances and biomasses in 2- up to 46-year-old afforested mine soils are in the same order as in undisturbed forest soils, but typical humus-inhabiting, large-sized testacean species are lacking or occur rarely, showing that reclamation was only partially successful. Six ubiquists out of 48 taxa contributed 61–87% to the overall abundance. Generally, all test sites had a distinct testacean community, whose structure depended on age, substrate, and stocking.

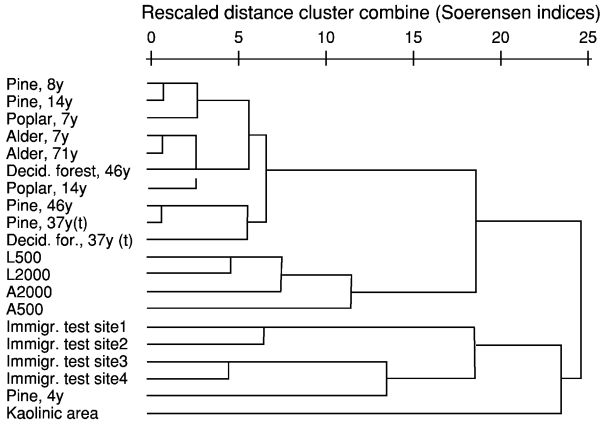

Figure 8 Cluster based on similarity (Soerensen index, UPGMA-linkage) of numbers and species of testate amoebae in various immigration test sites, minicontainers (sites L, A), and recultivated forests. The distances are rescaled to fall in the range of 1–25. Quality and development of the substrates exposed for different time intervals were more important for immigration and colonization success than the adjacent source habitats. Reproduced with permission from Wanner M and Dunger W (2001) Biological activity of soils from reclaimed open-cast coal mining areas in Upper Lusatia using testate amoebae (protists) as indicators. *Ecological Engineering* 17: 323–330.

Protozoa as Indicators of Soil Decontamination

Decontamination of polluted soils is a current challenge for scientists from various fields. Few data are available as concerns the soil fauna, and only one study included protozoa (Figure 9). Immediately after decontamination, active protozoa, nematodes, and collembola were not detected in treated soil. However, protozoan cysts survived treatment (5700 ± 4200 cysts per g dry soil). Following 1 week of exposure, no active protozoa were found. From the second sampling date onwards (after 3 weeks), protozoa were observed with significantly increasing biomass until the end of the experiment 12 weeks after exposition.

Effects of Biocides

A considerable amount of literature is available on the effects of biocides on soil protozoa. Several reviews showed that: (1) the general reaction of soil protozoa to biocide stress matches that of other organisms; (2) many protozoan species seem to be just as sensitive to pesticides as other more commonly used test organisms; (3) insecticides are usually more toxic than herbicides; (4) insecticides disturb soil protozoa critically, i.e., populations often do not fully recover within 60 days; and (5) investigations should be performed at species and/or functional group level because the simple measure 'total protozoan abundance' is often too insensitive. This is also obvious from a recent study, where the effects of the fungicide fenpropimorph have been investigated in laboratory microcosms and field experiments. While the microcosms showed that bacterivorous protozoa were affected by fenpropimorph at concentrations

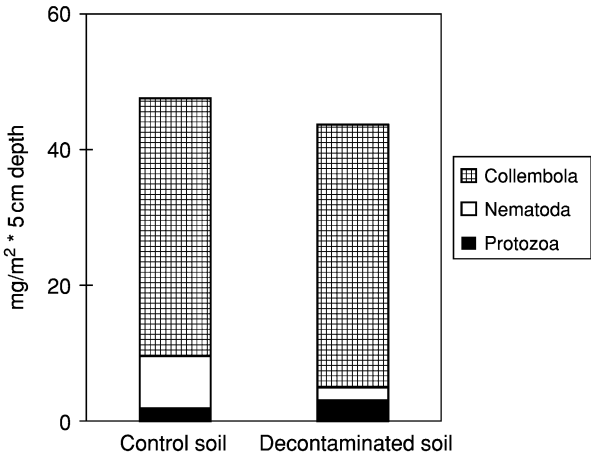

Figure 9 Biomass of Collembola, Nematoda and Protozoa in control and decontaminated soil after 12 weeks of exposure in an arable field. Q

QUALITY OF SOIL

B J Wienhold, G E Varvel, and J W Doran, USDA Agricultural Research Service, Lincoln, NE, USA

Published by Elsevier Ltd.

Introduction

Soil forms a thin layer over the surface of the earth that performs many functions essential to life. It serves as a substrate to support plant growth, a reservoir for many nutrients essential for plant growth, a filter to maintain air quality through interactions with the atmosphere, and a storage and purification medium for water. Soil also supports biological activity involved in the decomposition and recycling of animal and plant products; and it has been identified as having a major role in carbon sequestration and mitigation of climate change associated with anthropogenic emissions of carbon dioxide and other greenhouse gases. Maintaining these soil functions in natural and managed systems is essential for environmental quality, system productivity and biodiversity. Human activity has affected soil functions in many natural and managed systems. Management practices have been developed to manipulate the soil and its functions, to facilitate planting and harvesting of food, forage, and fiber, and to improve productivity. Commonly used management practices include grazing systems, prescribed fire, forest management, tillage, fertilization, crop rotation, water management, liming, and cover crops.

'Soil quality' refers to the capacity of a soil to sustain biological productivity, maintain environmental quality, and promote plant and animal health. Land-management practices influence soil quality to varying degrees, and this influence can be positive or negative. Any management practice misapplied can result in soil degradation, and this has been the case with many traditional practices. As our understanding of how management practices affect soil quality improves, new practices are developed that maintain or improve soil quality. Monitoring soil quality allows those managing the land to assess the impact their decisions are having on the soil and the functioning of that resource. Hence, soil quality serves as a tool for monitoring soil function and system sustainability. Soils are not managed for soil quality per se; rather, soils are managed to optimize inputs to maintain soil functions and generate an acceptable rate of return on investment. In managed systems, soils are managed to produce food, forage, and fiber needed by society. In addition, producers and other land managers may use soil-quality indicators to focus on the intended result of soil management, i.e., improvement of the fitness of a soil for a particular use, not merely the characterization of the soil material itself. Soil quality is a tool that managers can use to identify problems in the short term and to develop management practices that are sustainable over the long term.

Management Systems

Soil-quality and land management have the dual goals of meeting the needs of society and conserving essential soil, water, and air resources for future generations. Rangelands are managed for forage production, water harvesting, recreation, and wildlife production. On rangelands, management is heavily focused on vegetation. In these systems, animal stocking rates are managed to maintain vegetation composition and productivity, while water-source and mineral-supplement locations are used to improve animal distribution and avoid overgrazing and compaction of the soil. Avoiding compaction and maintaining vegetative cover reduces the potential for erosion and maintains water quality in rangeland watersheds. Prescribed fire, fertilization, and seeding are other management practices that can be used to improve degraded rangelands and maintain critical soil functions.

In forests, soils are managed for wood and fiber production and other multiple uses such as water harvesting, recreation, and wildlife. During timber-harvesting operations, soil quality is maintained by using practices that minimize the potential for erosion and

restore vegetative cover as quickly as possible. Prescribed fire, fertilization, and seeding (or seedling transplants) can be used to improve site productivity and maintain critical soil functions.

In agriculture, soils are managed primarily for the production of food and fiber. Historically, tillage has been used to prepare a seedbed, incorporate residue, control weeds, and distribute agricultural chemicals. Inorganic fertilizer, animal manure, or other organic by-products are applied to provide nutrients needed by the crop but not supplied in sufficient quantities by the soil or to replace nutrients removed by the harvested crop. Lime is applied to increase soil pH. Crop sequences and crop rotations are used to break disease cycles, diversify crop production, and provide additional marketing options. Soil quality monitoring allows agricultural managers to make assessments of the effects of various combinations of these management factors in the overall system.

Soil Quality Assessment

Soil quality is an effective tool for monitoring soil function. Assessing soil quality involves measuring physical, chemical, and biological soil properties and using these measured values to identify properties of the soil that may be inhibiting soil function or to monitor how changes in management are affecting soil functions.

The initial steps in this assessment are to identify the management goals (e.g., food or fiber production, environmental protection) and to determine the soil functions that contribute toward accomplishing them. For a soil managed for food production, functions such as providing a suitable plant substrate and serving as a nutrient reservoir are important. For a soil managed for environmental protection, key functions are storage and purification of water, and interactions with the atmosphere.

Once soil functions important to a management goal are identified, soil properties influencing those functions can be selected for measurement (Table 1), depending on location and soil type. For example, soil properties important for a soil being managed for irrigated crop production in an arid environment (e.g., sodicity, depth to water table) will be different from those for a soil in a rain-fed environment (e.g., infiltration rate, potentially mineralizable N, extractable P). Selection of soil properties for soil quality assessment also needs to take into account the expertise and resources available to the person doing the assessment. Some soil properties are better indicators of soil quality than others, but special facilities or equipment may be required to quantify the property; in which case they are often of little practical use.

A one-time measure of these soil properties may identify properties that fall outside an acceptable range of values for that soil. Once soil properties exhibiting an unacceptable value are identified, management practices can be implemented to improve them and restore the associated soil function. If multiple management practices are being used on a single soil type, a one-time comparison of soil properties among the practices can be used to determine the effect the various practices have on soil quality. Such one-time assessments are termed 'comparative soil quality assessments.' A more effective approach is to sample the soil repeatedly (e.g., two or three times each year or at the same time of year for several years) and assess management effects on soil properties over time (i.e., during the year or from year to year). Repeated measurement of soil properties is termed

Table 1 Potential soil properties for assessing soil functions

Soil function	*Physical properties*	*Chemical properties*	*Biological properties*
Substrate for plant growth	Bulk density Aggregate stability Soil depth	Electrical conductivity Sodium adsorption ratio	
Nutrient reservoir		Inorganic N content Extractable P pH	Potential mineralization
Atmospheric interactions	Water-filled pore space	CO_2 flux NO_x flux Methane flux NH_4 flux	
Storage and purification of water	Infiltration rate Water-holding capacity	NO_3-N concentration Extractable P	
Biological activity	Water-filled pore space		Microbial biomass Soil respiration Potential mineralization Earthworm population

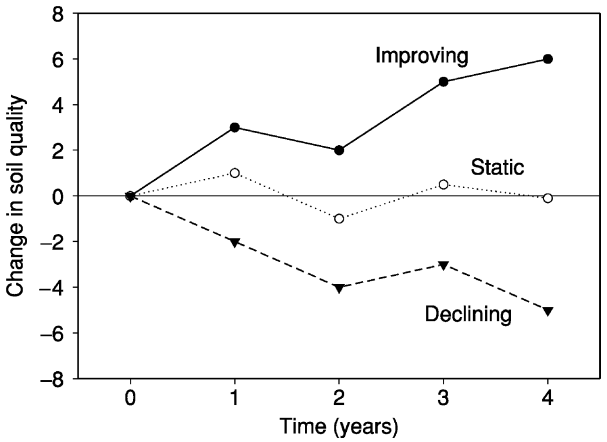

Figure 1 Hypothetical outcomes for a dynamic soil quality assessment.

'dynamic soil-quality assessment.' By repeatedly measuring a soil property, the direction and magnitude of change can be assessed and management practices can be adjusted (Figure 1).

Soil Function–Soil Indicator Relationships

Relationships exist between soil properties and soil functions, which may take the form of: (1) lower or decreasing in value is better, (2) higher or increasing in value is better, or (3) an optimum range (Figure 2). As soil functions are identified, appropriate soil properties are selected to assess those functions. Identifying critical soil functions and selecting soil properties to be measured for assessing soil-quality management goals are decisions that are best made on a case-by-case basis.

Evaluation of soils functioning as a substrate for plant growth includes measurement of soil properties such as bulk density, soil depth, and electrical conductivity. These properties affect the rooting activity of plants and influence the ability of the plant to acquire water and nutrients. The relationship between bulk density and rooting activity takes the form of 'less is better', with rooting activity being depressed when the bulk density exceeds a certain value. The value at which bulk density restricts rooting activity varies with soil texture and ranges from $1.4\,g\,cm^{-3}$ for a clay soil to $1.7\,g\,cm^{-3}$ for a sandy soil. The relationship between soil depth and rooting activity takes the form of 'more is better', with the relationship leveling off when soil depths exceed the rooting depth of the crop. The relationship between rooting activity and electrical conductivity takes the form of 'less is better'. As electrical conductivity increases, the effect on rooting activity and subsequent plant growth is dependent on plant species. Crops such as bean (*Phaseolus vulgaris* L.), with a threshold of $1.0\,dS\,m^{-1}$, are much more sensitive to electrical conductivity (salinity) than others such as barley (*Hordeum vulgare* L.), with a threshold of $8.0\,dS\,m^{-1}$.

Evaluation of soils functioning as nutrient reservoirs includes measurement of soil properties such as the concentration of nutrients essential to plant growth and pH. These properties are measures of the soil's ability to provide nutrients needed by the plant. The relationship between nutrient concentration and ability to meet plant demand takes the form of 'more is better' for most nutrients. For some nutrients the relationship takes the form of 'more is better' at low concentrations and 'less is better' at high concentrations, due to negative effects on crop quality. The range of concentrations needed to meet crop needs varies among crops and soils. Values needed to develop these relationships are available in the soil nutrient-testing literature. The relationship between plant growth and pH is of the form of an optimum range. The availability of many nutrients essential to plant growth are highest at pH values between 5.5 and 7.5. At higher pH values, nutrient availability is reduced; at lower pH values, nutrient availability is reduced and availability of toxic elements such as aluminum increases.

Evaluation of soil interactions with the atmosphere includes measurement of soil properties such as respiration and flux of greenhouse gases. These properties provide a measure of whether the soil is serving as a source or sink for greenhouse gases – carbon dioxide, (CO_2), methane (CH_4), and nitrogen oxides (NO_x). The relationship between respiration and atmospheric interactions takes the form of an optimum range with lower values than optimum suggesting that beneficial

microbial activity is too low (e.g., suboptimal release of nutrients from organic matter, low N-fixation rates, poor development of soil structure) and high values suggesting that microbial activity is too high (e.g., degradation of soil organic matter and release of nutrients in amounts exceeding what plants can utilize). Optimum value is determined by comparing organic matter inputs (crop residue and animal manure) with net respiration. The relationship between greenhouse gas fluxes and the atmosphere takes the form of 'less is better'. Low gas fluxes are a consequence of the activity of microorganisms naturally present in the soil. High gas fluxes represent the presence of labile C and nutrient substrates (e.g., nitrogenous fertilizers) under conditions (e.g., water-filled pore space of ~80%) that stimulate microorganisms that produce greenhouse gases as products of their metabolism (Figure 3).

Evaluation of soils as a medium for the storage and purification of water includes measurement of properties such as infiltration rate and nutrient concentrations. These properties provide a measure of the potential for contamination of surface-water and groundwater resources. The relationship between infiltration rate and storage and purification of water takes the form of 'more is better' and differs among soils as a function of soil texture. Low infiltration rates contribute to runoff and erosion losses of nutrients to surface water. The relationship between soil nutrient concentrations and storage and purification of water takes the form of 'less is better'. High nutrient concentrations in surface soils can contribute to contamination of surface waters when they are transported in runoff and erosion sediments. High nutrient concentrations in subsurface soils can contribute to groundwater contamination when they are leached from the root zone.

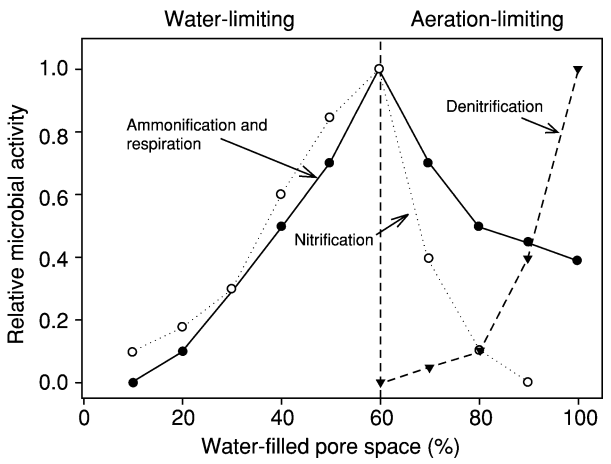

Figure 3 Hypothetical relationship between soil water-filled pore space and microbial activity associated with respiration, nitrification, and denitrification. (Source: Linn DM and Doran JW (1984) Effects of water-filled pore space on carbon dioxide and nitrous oxide production in tilled and non-tilled soils. *Soil Science Society of America Journal* 48: 1267.)

Evaluation of the biological activity of a soil includes measurements of soil properties such as water-filled pore space and microbial biomass. These properties provide a measure of the soil's ability to decompose added material and to recycle nutrients contained in that material. Including physical soil properties in the evaluation of biological activity provides information about whether the products resulting from biological activity are from aerobic metabolic pathways (e.g., carbon dioxide, nitrate, sulfate) or from anaerobic metabolic pathways (e.g., methane, oxides of nitrogen, hydrogen sulfide). The relationship between water-filled pore space and biological activity takes the form of an optimum range. The optimum range corresponds to a moist, well-aerated soil. Microbial activity is greatest at 60% of water-filled pore space and declines linearly as the soil dries (Figure 3). When water-filled pore space reaches 80%, anaerobic processes such as denitrification increase. Microbial biomass responds more quickly to management than does soil organic carbon. Increases in microbial biomass are usually associated with improved management and an increase in soil quality.

For each soil function, soil quality is the integrated total of the selected set of properties i.e., the integration of soil physical, chemical, and biological processes specific to a particular soil and environment. Because it is location-specific, care must be taken when making soil-quality comparisons between soils. A soil that has been poorly managed for a long period of time may have a relatively low soil quality as compared to a similar, yet well-managed soil. Improved management is likely to have a much greater effect on the soil quality of the poorly managed soil.

Summary

Since soil quality is assessed in terms of the fitness of a soil for its intended use, conflicts can arise when there are multiple uses and management goals for a soil. The quality of an agricultural soil may be quite different if the management goal being assessed is crop production than if the management goal being assessed is environmental services. A manager may incorporate residue using tillage to produce a seedbed and promote mineralization of nutrients. Fertilizers may also be used to provide adequate amounts of nutrients needed by the crop. Assessing the crop-production management goal for a given field may reveal that soil properties such as nutrient concentration, potentially mineralizable

N, and soil respiration are within the optimum range. Assessing the environmental-services goal for the same field may reveal that nutrient concentrations may be near levels with potential for leaching losses to groundwater, that denitrification rates are high following precipitation or irrigation, or that decomposition of the incorporated residue results in high carbon dioxide fluxes. Conflicting assessment outcomes are not a failure of the soil-quality concept. Knowledge of the soil-quality status for multiple management goals provides the potential for making adjustments in management practices to minimize negative aspects while maintaining positive aspects. The goal is that such assessment of management goals and adjustment of management practices will improve the sustainability of the system.

Concerns regarding the soil quality concept include the need to test underlying concepts in more soils and production systems and to develop procedures for addressing the potential for conflicting outcomes. Soil quality assessment is a management tool that is being improved to include more management goals, soil functions, and soil properties. The concept is being used in a wider range of soils and production systems. The utility of the soil quality concept improves as our understanding of the soil resource improves. Proponents and sceptics of the soil quality concept share a common goal: to improve management of the soil resources to maintain critical soil functions.

List of Technical Nomenclature

Ammonification	Biological process leading to ammonium formation from nitrogen-containing organic compounds
Denitrification	Biological reduction of nitrate and nitrite to nitrogen and nitrogen oxides
Labile carbon	Carbon-containing compounds that can be readily metabolized by microorganisms
Nitrification	Biological oxidation of ammonium to nitrate and nitrate
Respiration	Oxidative reactions providing energy to an organism

RADIATION BALANCE

J L Hatfield, T J Sauer, and J H Prueger,
National Soil Tilth Laboratory, Ames, IA, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Life on Earth depends upon the flow of energy. Living objects balance their energy inputs with outputs to create a comfortable environment. Humans have an advantage because they create clothing and shelter to help modify their environment. Plants and soil also have inputs of energy, but have limited controls on the dissipation of energy and even less control on the energy inputs into the system. When we begin to think about the balance of energy in the soil or plant system we can begin to understand some of the remarkable balances that exist within the natural environment. Understanding the surface radiation and energy balances provides an opportunity to explore the role of different components, e.g., crop residue, tillage, cover crops, on soils and the environment.

The balance of radiation is similar to a checkbook or savings account. How much money is in it at any one time depends upon how much has been put into the account and how much has been taken out. This balance can be expressed very simply in word form. Net radiation is the difference between the gains (incoming solar radiation and absorbed longwave radiation) and losses (reflected and transmitted solar radiation and emitted longwave radiation). This 'budget' can be expressed mathematically as:

$$R_n = (1 - \alpha)S_t + L_d - \epsilon\sigma T_s^4 \qquad [1]$$

where R_n is the net radiation at the surface expressed as the amount of energy (joules) per unit area (meters squared) per unit time (seconds) or watts per meter squared. All of the radiation terms (S_t, L_d, and $\epsilon\sigma T_s^4$) in eqn 1 must have the same units to avoid problems. As we expand these terms, S_t is the solar radiation input, α the albedo or reflectance of the surface, L_d the input of longwave radiation, $\epsilon\sigma T_s^4$ is the energy lost as longwave radiation from the surface. Shortwave radiation represents the energy in the 0.3- to 3-μm range, while longwave radiation is derived from wavelengths of more than 3 μm. Another way to consider this difference is that shortwave originates from the sun, with a surface temperature near 6000 K, while longwave is derived from objects with temperatures near 300 K. A representation of the radiation balance for two different days is shown in Figure 1. Radiation balance values throughout the day do not always produce a smooth curve because of the presence of clouds. Nighttime values are zero or below because the Earth's surface tends to lose more energy than it receives. Energy available as net radiation is further divided into other components. We express the energy balance as:

$$R_n = \mathrm{LE} + H + G \qquad [2]$$

where LE represents the energy used to evaporate water, H the energy to heat the air, and G the amount stored in the soil volume. The more energy input to the surface the greater the potential magnitude of these components. (*See* **Energy Balance**.)

Incoming Solar Radiation

Solar radiation originates at the Sun and travels through space and the atmosphere before it reaches the Earth's surface. Solar radiation consists of two

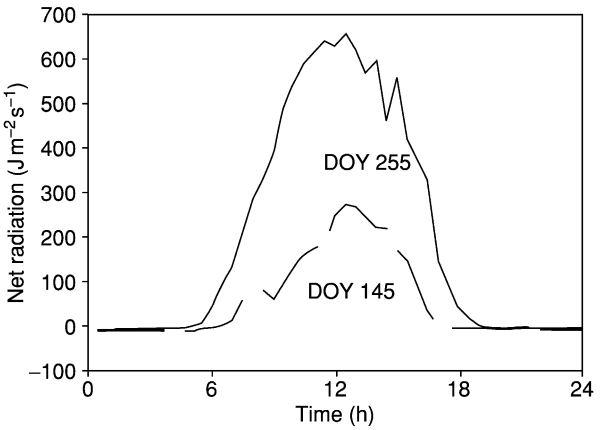

Figure 1 Net radiation balance for 2 days (days 145 and 255) during the midsummer growing season in central Iowa.

components, the direct component (S_b) and the diffuse (S_d) component. Diffuse radiation comes from all angles, while the direct beam follows the path of the Sun throughout the day. Diffuse radiation is formed by the scattering of the direct beam by particles in the atmosphere. Physically, we can observe the effect of direct and diffuse radiation by sharpness of shadows. On a clear day, the outlines of the shadows are clearly defined, while on a cloudy day there are no shadows yet we still can see. Mathematically, we represent incoming solar radiation as:

$$S_t = S_b \sin\beta + S_d \quad [3]$$

The angle of the Sun's beam above a horizontal surface, β, distributes the energy in the beam over a different area than if the surface were perpendicular to the beam. The magnitude of direct and diffuse radiation depends upon the solar elevation, the angle of the Sun's beam above the horizon, the amount of scattering and adsorption by atmospheric gases and aerosols, and the amount of scattering and adsorption by water droplets and ice particles in the clouds. The effect of clouds is easy to understand; however, particles in the atmosphere have a large impact, because they scatter radiation back to space and some toward the Earth's surface. The portion of diffuse radiation increases as the number of particles in the atmosphere increases.

There is large variation in the incident solar radiation at many locations throughout the year because of the changing angle of inclination of the Earth with respect to the Sun. At the equator there is little difference; however, at the midlatitudes there are large differences between summer and winter. Clear-sky solar radiation incident on the Earth at midday is approximately $26\,J\,m^{-2}$ per day during summer, but approximately $9\,J\,m^{-2}$ per day during winter at 42° N latitude. Clouds affect these totals and need to be considered. There are tables of clear-sky solar radiation incident on the Earth's surface for any location: these tables have been assembled through measurements and empirical calculations.

The slope of the surface is a critical factor in the radiation balance. If there is a south-facing slope in the northern hemisphere then more energy is going to be absorbed than if there is a north-facing slope. More subtle differences exist if the slope of the soil surface is changed with tillage implements. The creation of a furrow with a tillage tool that runs east to west across the field creates a surface in which one part will receive more direct solar radiation than the other. This will cause the soil surface and soil temperatures to be warmer on the south side and cooler on the north side in the northern hemisphere. Temperatures for bare soil at the surface under these conditions may be 10–20°C different at midday. This same furrow shape placed in a north–south direction will have differences in surface temperatures from morning to afternoon. The geometry of the surface plays a critical role in the radiation balance through the effect of direct-beam solar radiation. Manipulation of the soil surface through tillage implements can create a specific microclimate at the soil surface that influences temperature-dependent processes within the soil.

Albedo

Albedo of a surface is the ratio of amount of solar radiation reflected back to the atmosphere to the amount of incoming solar radiation (S_r:S_t). We see a highly reflective surface as white, and a low-reflectance surface as black. A dark surface will absorb more radiation than a light-colored surface. The range of albedo values for different surfaces is shown in Table 1.

Albedo is more complex than assuming a single constant value for a surface. Albedo values for a soil surface change with soil water content, type of soil, tillage, amount and type of crop-residue cover, and age of residue. Starting with a smooth soil surface with an albedo of 0.15, the addition of water to wet the soil surface decreases the albedo to 0.10, and then there is a slow return to the original value as the surface dries. If the same surface is roughened, there is a further decrease in the albedo of a dry surface to near 0.10. This decrease is due to the change in the soil surface that traps more direct- and diffuse-beam solar radiation. Wetting this surface further decreases the albedo. Adding a fresh crop residue increases the albedo because of the highly reflective nature of the crop residue; however, as the residue ages, the albedo decreases and may be only slightly different from the soil surface in the spring. Soil surfaces are continually undergoing changes that affect their albedo. This will impact the radiation balance and ultimately the evaporation of water from the surface, heating the air, and warming the soil.

Table 1 Albedo values for different natural surfaces

Surface	*Albedo*
Bare soil, dry	0.20
Bare soil, wet	0.15
Bare soil, fresh corn residue	0.35
Bare soil, weathered corn residue	0.22
Corn canopy	0.22
Wheat canopy	0.26
Rice canopy	0.24
Deciduous forest with leaves	0.18
Coniferous forest	0.16

The albedo values shown in Table 1 represent an integrated value over the shortwave wavelengths and are determined by measured the incoming solar radiation with a pyranometer and reflected radiation with an inverted pyranometer of the same type. Within the solar radiation spectrum, there are differences in reflectance, as shown in Figure 2 for a corn leaf. There is a dramatic change in the reflectance between the visible and near-infrared wavelengths from 0.6 to 0.7 μm. The difference in reflectance spectra across the wavelengths in plant material shows low reflectance values in the blue and red portions of the spectrum, an increase in the green wavelengths, and then a sharp increase in the near-infrared wavelengths. Reflectance values for a bare soil across the solar radiation wavelengths show a different pattern from a leaf and tend to increase linearly with wavelength, not showing the large differences among portions of the spectrum (Figure 3). Tilling the soil to change the roughness and increase the water content changes the reflectance of the soil. There is a decrease in the reflectance values for all wavelengths (Figure 3). Adding crop residue to the soil surface also changes the reflectance of the surface and changes the energy-balance components.

When solar radiation impinges on a leaf or any other object, the radiation may be reflected, absorbed, or transmitted. If we imagine ourselves underneath a thin layer of white cloth, from the upper side we would see the white color owing to reflection of all wavelengths; however, underneath the cloth we would still see owing to light being passed through (transmitted). Some of the light would be absorbed by the cloth. Under a 10-cm layer of soil, there would be no transmitted light and there would be no shortwave radiation, therefore no visibility. This same principle applies when layers of material are added to the soil surface. A layer with a high light transmittance allows solar radiation to reach the soil surface and warm the soil, evaporate water, or warm the air next to the soil surface. When a highly reflective and low-transmittance material is placed on the soil surface, there is little change in the temperature of the soil surface with varying solar radiation; hence snow affects the radiation balance. Transmittance values for different materials vary widely, as shown in Table 2 for both the shortwave and longwave regions of the spectrum. Transmittance of solar radiation through materials, especially plant material, has a large effect on the radiation balance at the soil surface. Very dense canopies transmit some light through all of the layers of leaves to the soil surface. Humans are able to see in this region; however, a leaf receives little energy. Plants grown under other canopy layers often have very large leaves with less chlorophyll (more yellow) than the same plant grown in full sunlight. The radiation balance of these plants and the soil under dense canopies is much different from the environment without this canopy.

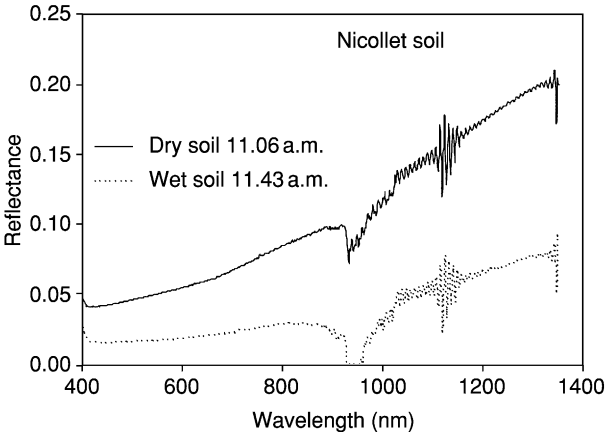

Figure 3 Reflectance of solar radiation across visible and near-infrared wavelengths for a smooth, tilled, Nicollet soil when wet and dry.

Table 2 Transmittance values for different natural surfaces

Surface	*Transmittance*
Corn leaves, visible	0.08
Corn canopy, visible	0.05
Wheat leaves, visible	0.07
Wheat canopy, visible	0.06
Fresh corn residue, visible	0.05
Weathered corn residue, visible	0.04
White plastic, visible	0.95
Black plastic, visible	0.0

Incoming Longwave Radiation

All objects with an absolute temperature of more than 0 K emit energy. Objects in our atmosphere such as gases, particles, ice crystals, or water droplets have temperatures above absolute zero and emit energy. The energy emitted is equivalent to the 4th power of their temperature as described by the Stefan law, $E = es\ T^4$. The Stefan constant, s, is $5.67 \times 10^{-8}\,\mathrm{W\,m^{-2}\,K^{-1}}$. The amount of energy emitted by an object greatly increases as the temperature increases. The emissivity term can be considered an efficiency factor. The higher the emissivity of an object the more effective the emission of longwave radiation away from the object. Longwave radiation is measured with radiometers designed to capture only these wavelengths; however, there are relatively few of those instruments located around the world. Incoming longwave radiation is generally estimated from mathematical equations in which the emissivity of the atmosphere, e_a, is estimated through a combination of water vapor or temperature measurements to modify the energy relationship to $e_a s T_a^4$. In one of the original relationships for this estimation, it was proposed that $e_a = 0.51 + 0.66 e_0^{1/2}$, where e_0 is the water vapor pressure of the atmosphere. There have been several attempts to refine this relationship, for example, where e_a is estimated by $0.575 e_0^{1/7}$ and e_a is best represented by $0.70 + 5.95 \times 10^{-5} e_0 \exp(1500/T_0)$, with T_0 the air temperature in degrees Kelvin. Both e_0 and T_0 are obtained from meteorological station data at a height of 2 m above the surface and are available every hour throughout the day. A comparison of all of these different methods with data collected across the USA has found that there is little difference among the methods and all predicted longwave radiation to within 5% of the measured values. Emissivity values for clear skies can range from 0.6 to 0.75, and these equations apply to the clear-sky condition. When there are clouds, the e_a term can be considered to be near 1. Consider what happens to air temperature on a clear versus a cloudy night. On the clear night there is a rapid drop in air temperature because the atmosphere is contributing little energy to the Earth's surface. On a cloudy night or an extremely humid night there is little change in air temperature because the longwave radiation lost from the Earth is captured by the clouds or water vapor and reemitted back to Earth's surface.

Terrestrial Longwave Radiation

Objects on the Earth's surface have a temperature and emit energy in relationship to their temperature as discussed for longwave energy emitted from the atmosphere. The same principle applies to the soil surface or objects on the Earth's surface. The last term in eqn 1, $e_s s T_s^4$, represents the loss of energy away from the surface into the atmosphere. Emissivity values for objects on Earth are close to 1; however, there is variation, as shown in Table 3. The variation is small and often the assumption is that 0.95 or 0.97 are adequate mean values that can be used. The T_s term in the relationship represents the surface temperature of the object. This would be the temperature at the outer surface of an object or at the very top layer of the soil surface. There are large gradients of temperature in the soil, and for a dry soil the surface temperature at midday may exceed 50°C while at 10 mm below the surface the temperature is less than 40°C. In the estimation of the longwave energy lost from the surface, a longwave radiometer can be inverted over the surface to measure the amount of energy escaping or estimated using measurements of surface temperature obtained from infrared thermometers combined with an estimate of emissivity for the surface. The latter approach works quite well for smooth or uniform surfaces; however, for rough or undulating surfaces or surfaces comprised of a combination of plants and soil, there is a large variation in surface temperature and measurements would have to be made that would represent the average value for the entire surface area. The magnitude of the energy lost from surfaces with different temperatures is shown by Figure 4. As the surface temperature increases, the energy emitted increases rapidly, because emission is a function of the 4th power of surface temperature.

Table 3 Emissivity values for different natural surfaces

Surface	*Emissivity*
Bare soil, dry	0.97
Bare soil, wet	0.99
Bare soil, fresh corn residue	0.97
Bare soil, weathered corn residue	0.98
Corn canopy	0.94
Wheat canopy	0.96
Deciduous forest, foliage present	0.99
Coniferous forest	0.99

Radiation Balance

Each of the terms in eqn [1] has been discussed separately in order to develop an appreciation for the variation within each component and the factors that affect the magnitude of the energy within each term. As these components are reassembled into the radiation balance for a surface it is possible to see how soil-management factors might affect the

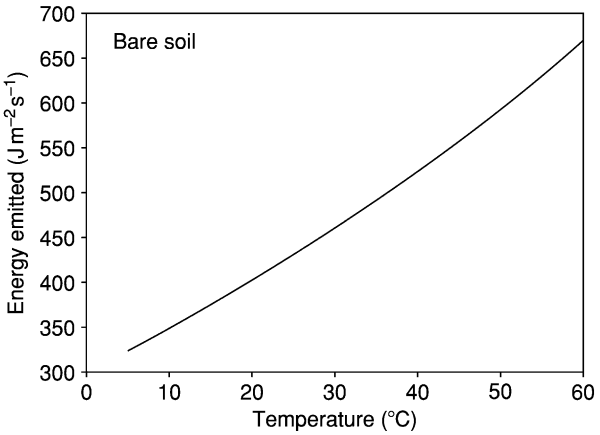

Figure 4 Energy emitted from a soil surface under different surface temperatures.

radiation balance. There are changes throughout the day as shown in Figure 1. If the radiation balance is expanded into the components for each hour throughout the day, the differences that each component adds to the balance can be seen. The largest factor is the solar radiation term, and the difference between the two days is a direct result of the incoming solar radiation. The least amount of variation among days is introduced by the incoming longwave radiation, L_d, since this factor is primarily affected by air temperature. Longwave loss is actually highest during the day when the surface temperatures are highest. As these relationships are expanded into annual radiation balances, surface temperature and air temperature variations among days across the seasons have a large impact. If the annual radiation balance over the year is computed, the sum of the inputs and losses is nearly zero.

On a daily interval, changing the soil surface through tillage or crop-residue management has a large impact on the radiation balance. If a smooth, dry soil is tilled, there are several changes in the radiation balance components. Incoming solar and longwave radiation do not change. The albedo decreases so there is a greater adsorption of solar radiation leading to a greater amount of energy available at the soil surface. However, evaporation of soil water from the wet, rough surface decreases the surface temperature, creating a situation in which the surface emits less energy. The end result is a surface that has an increased amount of energy available than did the surface before tillage. This effect lasts only as long as there is soil water to evaporate, but there is some effect of the rough surface on reducing the albedo of a dry soil; however, this effect is small compared with the initial period with a wet soil surface.

The final example is the soil surface to which crop residue has been added. In the case of fresh crop residue there is an increase in the albedo of the surface and a reduction in net radiation. Weathered residue decreases the albedo and allows the surface to have an increased net radiation loading. Wetting and drying of the crop residue has some effect on the radiation balance because of the effect of water on both the albedo and emissivity of the surface. Soil-management practices have a large impact on the radiation balance, so understanding which factor is affected by management will help provide an improved understanding of the consequences of management decisions.

Implications

The radiation balance of a surface represents the balance of shortwave gains and losses and longwave gains and losses. The radiation balance changes throughout the day and year owing to incoming solar radiation, which has the largest effect on the radiation balance, followed in importance by the cloud cover. The next major factor is the slope of the surface, which affects the amount of solar radiation absorbed. The slope factor can be both a large-scale (slope of hills and mountains) and microscale factor (creation of furrows and ridges with tillage implements). Humans have a large impact on the radiation balance and can manipulate the energy balance through all of the components in the radiation balance.

RANGE MANAGEMENT

G L Anderson, USDA Agricultural Research Service, Sidney, MT, USA

Published by Elsevier Ltd.

Introduction

Proper rangeland management includes good stewardship of the rangeland biological components to preserve soil health and soil conservation. Certain management practices can also contribute to a host of soil-related problems (e.g., excessive wind and water erosion, nutrient loading, and increased sedimentation in reservoirs), ultimately leading to a general reduction in the land's ability to sustain healthy rangeland systems. Many of these problems can be avoided by the proper management of the aboveground or biological component of the range. While the concept of managing a healthy rangeland may seem simple and straightforward, different definitions of what constitutes a healthy rangeland result in divergent management approaches.

What are Rangelands?

The natural evolution of different types of rangeland occurs under varying conditions and disturbances. Environmental factors such as drought, wind, and temperature affect the different types of plants that make up the rangeland plant communities found around the world. Other disturbances that influence the development of specific range types include: grazing (native animals and livestock), fire, weeds, and diseases. These disturbances have always been an important part of rangeland development and health.

In the USA a general example of these varying rangeland types includes: the presence of tall-grass prairies in the eastern Central Plains, mid-grass prairies in the Central Plains and Midwest, and short-grass prairies in the Midwest and West. Environmental conditions also result in varying amounts of shrubs, forbs, and trees. Rangeland in south Texas is dominated by trees, shrubs, and forbs; sagebrush dominates prairies in the west; and grasses dominate the northern and middle portions of the country.

Internationally, rangelands are divided into six broad categories: nonwoody grasslands, open shrublands, closed shrublands, savannas, woody savannas, and tundra. Africa is dominated by savannas with some open shrublands and closed shrublands, Australia is largely savannas along the coast and open shrublands in the interior, and Eurasia is dominated by nonwoody grasslands and open shrublands. All categories of rangeland are found in South America, except tundra, with the most diverse mixture of the different classes occurring along the lengthy western coast. Tundra is primarily limited to the extreme northern latitudes.

How Much Area is Covered by Rangelands?

Worldwide, approximately 40.5% of terrestrial area is grasslands. This means that rangelands comprise more than 52.5 million km^2. This area can be further broken down into the different types of rangeland. Approximately 13.8% of terrestrial rangelands are woody savanna, 12.7% are open and closed shrublands, 8.3% are nonweedy grasslands, and 5.7% are tundra.

What Determines How Rangelands are Managed?

Widely different environmental conditions and impacts of multiple disturbances make rangeland health difficult to define. One of the most influential factors behind range-management decisions is the manager's understanding of what comprises a healthy

rangeland. There are essentially three major rangeland models or concepts that influence a rangeland manager's understanding and actions.

The climax model evaluates range condition and trend based on vegetation composition, plant production, ground cover, and soil erosion. By measuring and monitoring existing conditions, proponents of this approach hope to develop a meaningful index of rangeland health. The underlying assumption of this model is that a definable mixture of plant species composes the 'climax' or 'healthiest' vegetation type for a given ecosystem. Plant communities, over long periods of time, come to an equilibrium of predictable species based on the impact of human use, soil condition, geographic position, plant competition, animal use, microbial activity, burning, and climatic factors. Areas with minimal or no discernible impact by humans are often referred to as 'pristine' rangelands or rangelands that exemplify the purest, uncorrupted mixture of soils, microbes, plants, and naturally occurring animals, diseases, and pests.

While the climax model considers human use as a component associated with rangeland health, many people now view human activities (e.g., livestock grazing) as the primary cause of rangeland degradation. Therefore, any departure from the climax state is often attributed to misuse of the land by humans. An example of this type of thought underlies the beliefs of those proposing the development of 'buffalo commons,' which involve returning vast areas of US rangelands to a more 'natural' state, devoid of domestic grazing and other human uses. A synopsis of the climax model is: (1) We know what the composition of native plant and animal species should be, and (2) by limiting human influence the climax state can be maintained, and, given enough time, degraded ecosystems will ultimately return to a predetermined state of equilibrium.

A similar ecologic model of a healthy rangeland ecosystem also presumes a climax state exists, but that this state is rarely, if ever, achieved, because of natural and human impacts. The basic difference between this model and the previous one is the belief that nature often has as great, or greater, an impact on rangelands as do humans. In this model, plant community equilibrium is prevented by discrete occurrences of drought, fire, disease, pests, weeds, or human influences. But the basic idea that an ultimate climax state exists, remains. A synopsis of the ecologic model disturbance is: We know what the composition of native plant and animal species should be, but due to natural and human disturbance, this ideal state is rarely, if ever, achieved. However, the closer the system is to the expected equilibrium the healthier it is perceived to be.

The above two models presuppose that we know the basic combination of biotic and abiotic conditions that should exist in a given area. In reality we rarely, if ever, can know with any degree of certainty what a climax community should look like or even if climax in a grassland ever existed. This uncertainty has led to the development of the state and transition model, which presupposes that an ecologic system can transition (change) into several states (multiple types of vegetation communities), dependent on changing conditions that occur at critical junctures in a rangelands development. According to this model, the biological composition of rangelands can transition over time into a variety of different plant communities. Each transition can happen relatively quickly (e.g., from a grassland to a pine–juniper savanna) if the right environmental conditions occur, but once the change occurs it is very difficult to reverse. This means that some changes are ultimately permanent. Thus, this model recognizes that rangeland ecosystems are dynamic and changing, and that there is no 'one' combination of plants that is ecologically the 'right or ultimate' state.

An illustration can be found in an article written by Dr. Donald Jameson, who found that the combination of overgrazing followed by at least three wet years could result in the establishment of pines on rangelands previously devoid of the tree and that this change could ultimately be permanent and progressive without further human intervention. A synopsis of the state and disturbance model is: Many types of rangeland plant communities can develop in an area over time, and each can be 'healthy' and stable for long periods of time. However, the model takes into account that rangeland ecosystems can, and do, change when conditions are right.

In our brief discussion of what constitutes a healthy rangeland ecosystem, we have traversed from an absolute model (climax) to a more relative model of multiple steady states. How range managers approach their job is directly influenced by which concepts they use. As one progresses from one end of the ecologic spectrum to the other, a divergence of management approaches occurs. In the first instance (climax), managers view an ecologically defined set of specific plants as a healthy rangeland ecosystem, while at the other end (the transition model), managers expect to see any number of ecologic states where rangeland 'health' is not dependent on the existence of a specific type of plant community. In the former case, climax theory leaves the manager striving to achieve something that probably never existed on rangelands, while in the latter case the transition model incorporates change as a component of ecologic health. Under this conceptual model a

range manager strives to achieve or maintain rangeland health; however, the ecologic definition of health depends on relatively 'recent' environmental conditions and the current mix of plants in the community.

Biological Diversity

While divergent opinions on how best to manage rangelands often result in different impacts to the rangeland ecosystem, agreement generally exists on one key component: a healthy rangeland must maintain a mix of desirable (preferably native) plants that are self-sustaining. Biological diversity (or the number of different types of plants and organisms in the system) is an important consideration, because it provides food and habitat needs for different native and domestic grazers, birds, and the living microbial component of the soil.

The health of the belowground component of the plant and soil interface also depends on diversity (e.g., different plants using and influencing different portions of the ecosystem), a sustained rate of returning dead plant and animal material back into usable nutrients, maintenance of soil porosity (the rate at which water enters the soil), and water-holding capacity (the amount of water that the soil will retain for future use). For example, in the Northern Great Plains of the USA, most native rangeland plant species have fairly shallow roots, capable of capturing the limited amount of precipitation that occurs during the growing season. This shallow root mass is one of the primary zones of competition between plants, and it is the part of the biological component that minimizes soil loss. To a large degree, it is the soil–root interface that ultimately determines the stability and sustainability of the rangeland ecosystem. Therefore, it is here that changes in the aboveground plant community can have the greatest impact.

A common idiom in ecology is that 'nature abhors a vacuum.' When applied to this discussion, it simply means there are many environmental and soil conditions that exist across a rangeland, with different plants living and utilizing the resources in each of these areas or niches. If a specific plant group is missing (the vacuum), something will move in to take its place, and it is the range manager's job to ensure the niche is filled with the proper plant type. Unfortunately, more often than not, invading undesirable plants (weeds) exploit these areas and establish before management steps can successfully close the empty niches. Thus, the introduction of invasive weeds into the system can have a devastating impact on the soil–root interface, plant biodiversity, soil health, and finally the economic worth of rangelands.

Introduction of Undesirable Plant Species

The impact of weeds on rangelands and range ecology is dramatic: First, native plants disappear, wind and water erosion are accelerated, and eventually the seedbank is altered to the point where there is no natural way for the system to recuperate. Second, weeds can also alter the soil chemistry so that little else is capable of growing in that location, and, finally, they often use excessive amounts of 'deep' water that give them a jumpstart in the early spring before native species begin their annual growth cycle.

The preponderance of weeds (undesirable plant species) that are proliferating across all types of rangelands is perhaps the single greatest biological threat to the maintenance of rangeland health today. Many of these undesirable plants have been introduced through several pathways: as contaminated seeds or plants used in landscaping, uncertified hay and landfill, and as unwelcome residents of improperly disposed waste material. While there are natural checks and balances for many of the native weeds present on rangelands, newly introduced species often propagate and disperse like a highly virulent disease, because existing natural control mechanisms are lacking. Consequently, many of these highly invasive species can establish in even the healthiest rangelands and quickly dominate the landscape.

One such plant is leafy spurge. Leafy spurge was introduced into the USA in 1827. The weed out-competes native vegetation for water in early spring and readily establishes in a wide range of climatic types. Figure 1 shows leafy spurge stands dominating the riparian habitat in and around Devils Tower, Wyoming. The inset shows leafy spurge's ability to survive even in the harshest of areas (in this case growing out of a crack in a sandstone rock). Most invasive weeds are not used by domestic or native grazers. Limited grazing pressure increases a weed's ability to out-compete and native plants can result in monocultures that exist for decades.

Weeds impact most ecosystems; however, their impact on rangelands is usually much more pronounced for several reasons. First, the large area covered by rangelands, and their remoteness, may mean that invasive weeds are not discovered until they are well-established. Second, the individual cost to landowners, for combating weed infestations, is usually several times the economic return of the land. Finally, a failure to respond rapidly and aggressively to a weed infestation (either using herbicides or other control methods) leads to extensive problems that even most state and federal governments are financially unable to combat.

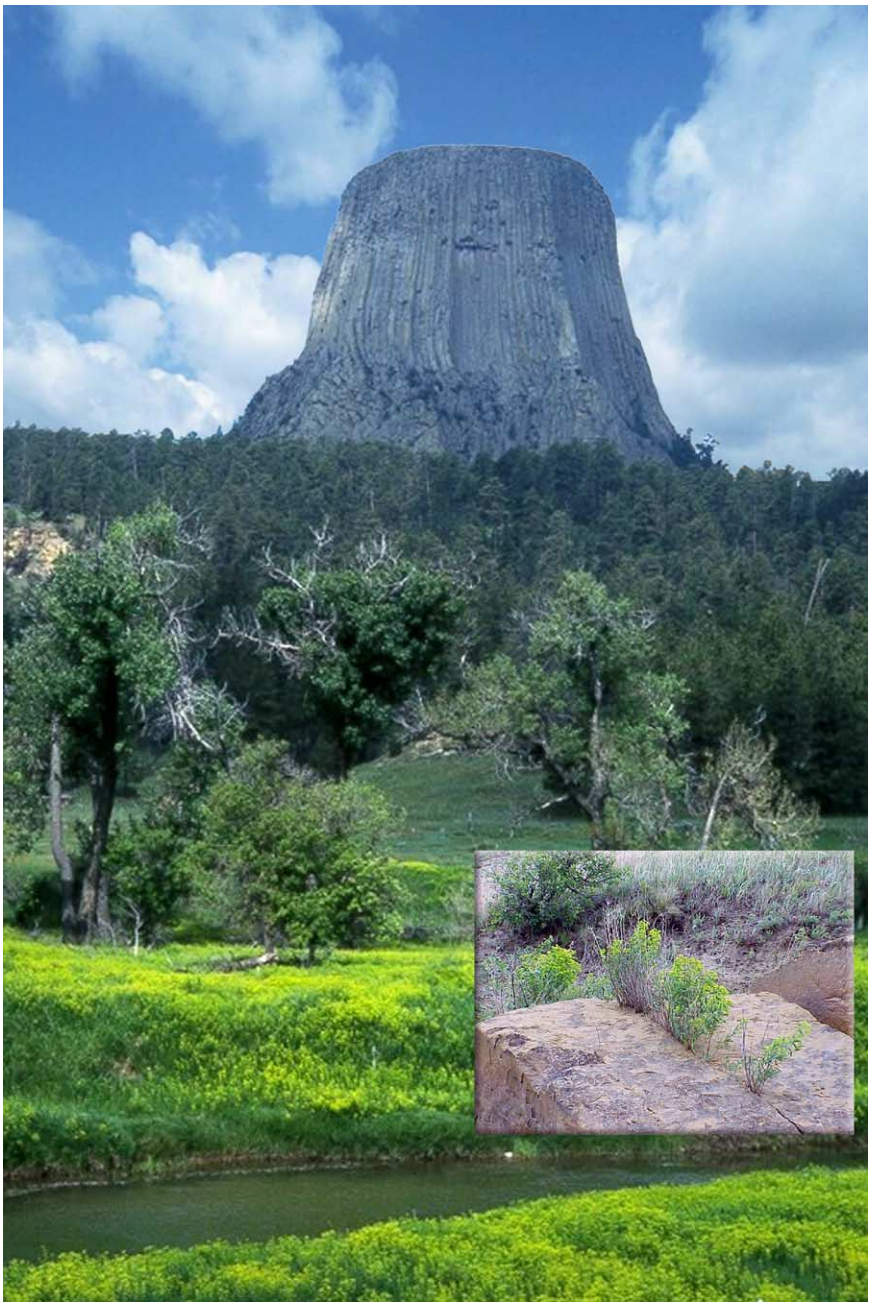

Figure 1 Leafy spurge invasion near Devils Tower, Wyoming, USA. The yellow-green weed dominates the riparian flood zone and can even establish in the harshest of areas (inset, leafy spurge growing out of a sandstone rock).

Invasive and noxious weeds are expected to infest 57 million hectares of rangeland in the USA by the year 2010. When combined with the impact of other invasive species (not restricted to rangeland), the cost to the USA is estimated to be $137 billion per year. Given the rangeland's economic disadvantages and remoteness, range managers must prioritize the set of weeds they will attempt to manage and develop new approaches that are economically and ecologically sustainable. One innovative control method, refined since the mid-1990s, is to find natural enemies that occur where the weed originated (e.g., Europe, Asia, or the Middle East), ensure the natural enemy affects only the target plant, and establish and spread these populations across areas in North America infested by the weed. Secondly, managers need to look at additional control approaches (e.g., cultural, mechanical, and chemical) to aid the natural enemy and diminish further weed establishment. The scientific term for this type of control is 'biologically based

integrated pest management,' because it combines natural enemies with other control options to provide affordable, ecologically sound, and sustainable weed control.

The Role of Disturbance in Rangeland and Soil Health

Rangelands develop under conditions of periodic disturbance (e.g., drought, fire, grazing by domesticated animals and native wildlife, weed incursions, outbreaks of insect pests, disease, and human activities). These disturbances often help maintain rangeland ecosystem biological diversity and soil health over long periods of time. If the magnitude of the disturbance(s) is too great, the results can be devastating to the resource and result in permanent ecologic changes that are undesirable and frequently destabilizing to the point that the system may not recover.

Given that excessive disturbance can have an adverse effect on the rangeland ecosystem, managers generally accept that healthy rangelands depend on a certain amount of disturbance. However, the beneficial effects of certain disturbances are subject to debate, with livestock grazing being one of the most contentious. Many in the general public and some range managers believe rangeland health has been substantially degraded by livestock grazing. The idea is that healthier rangeland ecosystems will result from the elimination of livestock grazing. This was the rationale used to eliminate livestock grazing on many hectares of rangeland in the 1990s. But, the question remains: Is this policy effective in improving rangeland and soil health?

Livestock Grazing

No Domestic Grazing

Since some individuals attribute changes in rangelands to human influences, such as grazing, one solution often proposed is to do away with domestic grazing. While this may seem reasonable to those unfamiliar with the complexities and history of the rangeland ecosystem, the results are typically more detrimental to the resource than livestock grazing.

Grazing, even overgrazing for limited periods, has always been a part of rangeland ecosystems. The vast herds of buffalo and other native grazers migrating across the landscape no longer exist and the reestablishment of the dynamic interactions of native species that existed 100–200 years ago is difficult, if not impossible. While different native grazers may be introduced, historical movement of the herds throughout the landscape (typically memorized by the oldest member of the herd) has been lost. Physical boundaries, such as roads and fences, also preclude movement of larger native grazers and would concentrate native grazing much the same as they do for domestic livestock. Therefore, the reestablishment of native grazers is seldom effective over large areas and the cost–benefit ratio often precludes introduction altogether. The net result is the elimination or reduction of rangeland grazing pressure that was typical 200 years ago.

Given the limitations of reestablishing a natural symbiotic plant–animal interaction, several things happen to the rangeland resource if livestock grazing is entirely removed. One is the reduction in the turnover rate of nutrients from aboveground plants to the soil. This often stresses existing plants that grow in the nutrient-poor soil. As plants become stressed, they begin to lose root biomass. Soil compaction typically follows (reducing the ability of the soil to take up water) and dead, aboveground plant tissue can block incoming sunlight from living plants. There also tends to be an overall loss of biodiversity. The ultimate result is usually the dieback of a portion of the root system, an increased susceptibility to disease, and an increased amount of bare soil that results in unprotected areas (gaps) where weeds can readily establish and insect populations (e.g., grasshoppers that feed on the remaining plants) can reach high levels. While this situation may occur when the range is utilized for domestic grazing, it is nearly inevitable when rangelands are not managed at all.

Therefore, the removal of grazing or human management of native rangeland does not always result in a more natural or healthier rangeland. In fact, reduced human management often results in declining range health and a rapidly changing plant component that requires an inordinate amount of resources to maintain.

Domestic Grazing

Grazing livestock on rangelands can have a negative impact when not managed properly. The existing body of scientific literature indicates that proper grazing is an important part of maintaining healthy rangelands. When rangelands are grazed using a proper grazing system (individual pastures are grazed at different times of the year to prevent overutilization of plants that prosper at different times of the year) and by only removing aboveground plant material to acceptable levels (leaving approximately 25% of the produced plant material), there is a positive impact on the soil–root interface. Roots continue to receive the photosynthetic materials needed to flourish and maintain a healthy mixture, many of the nutrients needed for plant growth are recycled

quickly by the cattle and soil microbes back to the soil, and the stress of aboveground plant removal does not favor any single plant component (warm-season or cool-season plants). Rangelands flourish under proper grazing management. Rooting systems and species composition are maintained, soil structure and composition are protected from wind and water erosion, and the health of the system is more resilient to weed, insect, and disease impacts.

Overgrazing

In this instance, the overutilization of the range due to excessive use or during periods of extended drought can worsen and ultimately cause increased soil erosion, soil compaction, and the permanent alteration of the soil seedbank and the rangeland plant community.

In any management application, there is always the possibility that the rangeland resource can be overutilized. However, the overwhelming majority of ranchers are good stewards of the range, more so because they choose to ranch as a lifestyle rather than for the earning potential of the job. To do that on an often limited income, they must maintain the quality of the rangeland needed for their livestock.

There are, however, times when even the best management plans can be taxed. Balancing grazing pressure during periods of drought, disease, or pest infestation is difficult. It is hard to predict how long adverse situations will last or how extensive problems will become. Therefore, there is often a lag-time between management changes and negative environmental impact. The result is, during periods of extended adverse conditions, management responses may not come quickly enough to prevent some damage to the rangeland resource.

What happens to rangelands when they are overgrazed for long periods or when improper management strategies are applied? Perhaps the most predominant impact of long-term overgrazing (or drought coupled with grazing) is the removal of more plant material than is recommended. For example, in the US Great Plains, the removal of more than 75% of aboveground production is considered detrimental to rangeland health. At this point there is not enough photosynthetically active plant material to provide the roots with the nutrients needed to maintain a healthy balance. The result is host dieback, and associated susceptibility to disease, repeated weeds and insect infestations.

Summary

Maintaining or improving rangeland health is the primary concern of most range managers regardless of the ecologic concept they espouse. But the approaches they use to achieve that goal often diverge, particularly when a single rangeland concept or model is overemphasized. This is particularly true when the impact of periodic disturbances is considered.

Rangelands are dynamic and complex. Therefore our understanding and management strategies must also be dynamic to account for new knowledge. This is important for ensuring that rangeland health and soil health can be maintained for generations to come.

REDOX POTENTIAL

Introduction

Geochemists, soil scientists, and limnologists have used redox potential (E_h) measurements to characterize oxidation–reduction status of surface environments. The redox potential of soil, water, and marine systems is a measure of electrochemical potential or electron availability within these systems. Electrons are essential to all inorganic and organic chemical reactions. Redox potential measurements allow for rapid characterization of the degree of reduction and for predicting stability of various compounds that regulate nutrients and metal availability in soil and sediment. Redox potential is diagnostic for determining whether an area is functioning as wetland or nonwetland.

Oxidation and reduction reactions regulate many of the biogeochemical reactions in surface environments. Redox potential (E_h) is determined from the concentration of oxidants and reductants in the environment. The inorganic oxidants include oxygen, nitrate, nitrite, manganese, iron, sulfate, and CO_2, while the reductants include various organic substrates and reduced inorganic compounds.

Theoretical Relationships

Oxidation and reduction reactions involve transfer of electrons from one compound to another and play a major role in regulating many reactions in biological systems. Oxidation–reduction reactions are coupled reactions.

Oxidation is defined as removal of electrons from a compound. Such a compound is usually referred to as 'electron donor' or 'reductant.' During this process it is oxidized and increases its oxidation number:

$$\text{Reductant} = \text{Oxidant} + e^-$$

Reduction is defined as the addition of electrons to a compound.

A compound that accepts electrons is usually referred to as 'electron acceptor' or 'oxidant.' During this process the compound is reduced and its oxidation number is decreased:

$$\text{Oxidant} = \text{Reductant} + e^-$$

The tendency of compounds to accept or donate electrons is expressed as 'reduction potential' or 'redox potential.' The redox potential of a substance depends upon:

- Affinity of molecules for electrons;
- Concentration of reductants and oxidants (referred to as redox pair);

Reductants (electron donors) in wetland soils are:

- Organic matter and various organic compounds;
- Reduced inorganic compounds such as NH_4^+, Fe^{2+}, Mn^{2+}, S^{2-}, CH_4, and H_2.

Oxidants (electron acceptors) are inorganic compounds such as O_2, NO_3^-, MnO_2, FeOOH, SO_4^{2-}, and HCO_3^-.

Anaerobic environments such as wetland soils are usually limited by electron acceptors and have an abundant supply of electron donors. Aerated soils are usually limited by electron donors and have an abundant supply of electron acceptors (primarily O_2).

Redox–pH Relationships

Redox reaction in surface environments can be represented by the following half-cell reduction equation:

$$\text{Ox} + m\text{H}^+ + ne^- \rightarrow \text{Rd} \qquad [1]$$

where Ox is the oxidized component or electron acceptor, Rd is the reduced component or electron donor, m is the number of hydrogen ions involved in the reaction, and n is the number of electrons involved in the reaction. The electrons used in eqn [1] must be supplied by an accompanying half-cell oxidation reaction. In soils, organic matter (CH_2O) is the primary source of electrons. The oxidation reaction balances the reduction reaction. This is illustrated below with the reduction of $Fe(OH)_3$:

$$4Fe(OH)_3 + 12H^+ + 4e^- \rightarrow 4Fe^{2+} + 12H_2O \text{(reduction)}$$
$$CH_2O + H_2O \rightarrow CO_2 + 4H^+ + 4e^- \text{(oxidation)}$$
$$4Fe(OH)_3 + CH_2O + 8H^+ \rightarrow 4Fe^{2+} + CO_2 + 11H_2O$$

The reduction reaction can be defined quantitatively through the change in Gibbs free energy (ΔG):

$$\Delta G = \Delta G^0 + RT \ln\left(\frac{\text{Rd}}{(\text{Ox})(\text{H}^+)^m}\right) \qquad [2]$$

where ΔG^0 is the standard free energy change, R is the gas constant, and T is absolute temperature. The Nernst equation expresses the reduction reaction in terms of electrochemical energy (millivolts) using the relationship $\Delta G = -nEF$

$$E_h = E^0 - \frac{RT}{NF}\ln\left(\frac{(Rd)}{(Ox)}\right) - \frac{mRT}{nF}\ln(H^+) \qquad [3]$$

where E_h is the electrode potential, E^0 is the standard half-cell potential, F is the Faraday constant, n is the number of electrons exchanged in the half-cell reaction, m is the number of protons exchanged, and the activities of the various oxidized and reduced components are shown in parentheses. Substituting values of $8.31\,J\,K^{-1}\,mol^{-1}$ for R, $9.65 \times 10^4\,C\,mol^{-1}$ for F, and 298 K for T, and using the relationship $\ln(x) = 2.303\log(x)$, eqn [3] simplifies to:

$$E_h(mV) = E^0 - \frac{59}{n}\log\left(\frac{(Rd)}{(Ox)}\right) + 59\frac{m}{n}pH \qquad [4]$$

Inspection of eqns [3] and [4] reveals that redox potential (E_h) increases with increasing activity of the oxidized component, decreases with increasing activity of the reduced component, and increases with an increase in H^+ activity (or a decrease in pH).

Equation 4 shows the importance of pH in redox reactions. When the ratio of protons to electrons (m/n) is equal, there is a predicted 59 mV change in E_h per pH unit. The E_h/pH slope can vary depending on the oxidants and reductants involved.

The E_h/pH slope predicted from the Nernst equation assumes that the redox couple controls the pH of the system. This is only true for pure chemical solutions. Measured slopes in natural systems due to mixed potential or various redox couples deviate from the predicted values. Applying the 59 mV correction factor cannot be used under those conditions.

The reduction reaction in eqn [1] can also be defined by an equilibrium constant:

$$K = \frac{(Rd)}{(Ox)(e^-)^n(H^+)^m} \qquad [5]$$

which can be rewritten in log form:

$$\log K = \log(Rd) - \log(Ox) - n\log(e^-) - m\log(H^+) \qquad [6]$$

The $-\log(e^-)$ term in eqn [6] can be defined as pE (relative electron activity) in the same way pH is defined as $-\log(H^+)$. Rearranging eqn [5] yields:

$$pE + pH = \log K - \log(Rd) + \log(Ox) \qquad [7]$$

Equation [7] can be used for plotting equilibrium solubility diagrams, because the pE + pH sum can be used as one axis and species activity as the other axis. E_h is the more-common expression of soil redox potential, since it is readily determined with a platinum electrode. Soil pE can be calculated from E_h using eqn [8]:

$$pE = \frac{E_h(mV)}{59} \qquad [8]$$

Normal Limits of pH and Redox Potential (E_h) in the Environment

Carbon dioxide from the atmosphere and organic acids formed by decaying organic matter are the two sources of acidity in most near-surface environments, resulting in acid pHs in the range 5–6. Lower pHs are found in acid sulfate soils, where values as low as 4.0 are sometimes recorded. As a result, a pH of 4 can be selected as the usual lower limit of pHs in natural environments (**Figure 1**).

The upper end of the pH limits is associated with CO_2-free water in contact with carbonate rocks and can acquire a pH of 10 and, in contact with some silicates, a pH up to nearly 11. But since most surface waters emit CO_2 to the atmosphere, such alkalinities are not attained. A reasonable upper limit of pH in most near-surface environments is near 9.0.

Oxygen is the strongest oxidizing agent commonly found in nature. Stronger agents than this cannot persist, because they react with water to liberate oxygen. Thus the upper limit of redox potentials is defined by the reaction:

$$H_2O \Leftrightarrow \frac{1}{2}O_2 + 2H^+ + 2e^- \qquad E^0 = +1.23\,V$$

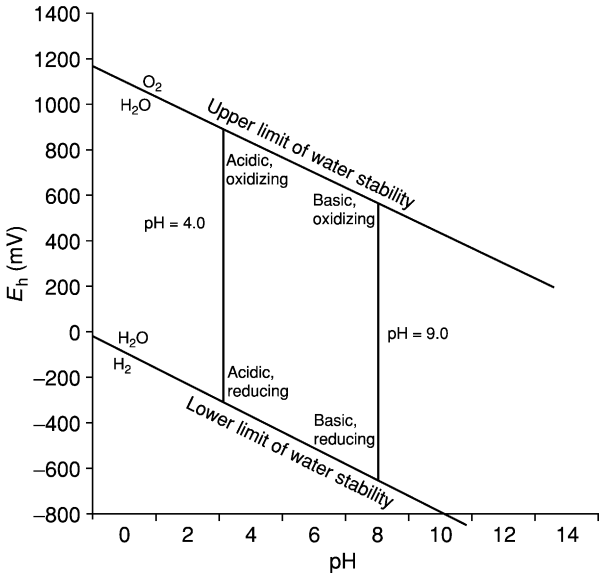

Figure 1 The E_h–pH range found in soil surface environments. Adapted from Krauskoft KB (1967) *Introduction to Geochemistry*. New York, NY: McGraw Hill.

The potential of this half-reaction, which reflects the upper limitations of water stability, clearly depends on the pH, as shown by the equation:

$$E = +1.23 + 0.03\log[O_2]^{1/2}[H^+]^2$$

The lower limit of redox potential is that of the hydrogen reaction,

$$H_2 \Leftrightarrow 2H^+ + 2e^- \qquad E^0 = 0.00\,V$$

For which

$$E = 0.00 + 0.03\log[H^+]^2 - 0.03\log[H_2]$$
$$= -0.059\,pH - 0.03\log[H_2]$$

Since the pressure of hydrogen in surface environments could not exceed 101 kPa, the maximum possible reducing potential in the presence of water would be:

$$E_h = -0.059\,pH - 0.03\log(1) = -0.059\,pH$$

Aerobic and/or Anaerobic Redox Potential Range in the Environment

The E_h scale used to quantify reduction intensity (or oxidation intensity) in chemical and biological systems is shown in Figure 2. The scale is in electromotive force units or volts (or millivolts) and can be divided into zones ranging from oxidized (where the aerobes function) to highly reduced (where the methane producers and sulfate reducers function).

Typically in wetland soils, E_h values range from −300 to 700 mV, with a total range of approximately 1000 mV. In aerobic soils where the O_2/H_2O redox couple functions, the E_h range is between 300 and 700 mV.

Redox Couples in Wetlands

Although several redox couples function in wetlands soils, the following are the most common reduction reactions involving a specific redox couple:

$$O_2 + 4e^- + 4H^+ \rightarrow 2H_2O$$
$$2NO_3^- + 10e^- + 12H^+ \rightarrow N_2 + 6H_2O$$
$$MnO_2 + 2e^- + 4H^+ \rightarrow Mn^{2+} + 2H_2O$$
$$Fe(OH)_3 + e^- + 3H^+ \rightarrow Fe^{+2} + 3H_2O$$
$$SO_4^{2-} + 8e^- + 8H^+ \rightarrow S^{2-} + 4H_2O$$
$$CO_2 + 8e^- + 8H^+ \rightarrow CH_4 + 2H_2O$$

The various inorganic redox systems found in soil and sediment become unstable at critical redox potentials (Figure 3). Sequentially following flooding, oxygen is reduced first, followed by nitrate and oxidized manganese compounds, and then ferric iron compounds. After the reduction of ferric iron, the next redox compound to become unstable is sulfate, followed by the reduction of carbon dioxide to methane.

Soil redox potential represents an indication of the oxidation–reduction status of the various redox couples. For example, a redox potential of 0 mV indicates that oxygen and nitrate are not likely to be present and that the bioreducible iron and manganese compounds are in a reduced state. At this same potential, however, sulfate is stable in the soil with no production of sulfide, which is toxic to plants. A redox potential of +400 mV indicates that oxygen may be present even though there may be excess water.

Redox potential measurements in pure systems can be used to predict the ionic distribution between chemical species which may interact with the transfer of electrons, such as ferrous and ferric iron or nitrite and nitrate nitrogen. However, in natural systems, there are many redox couples present, and not all redox couples are chemically interactive with others. Unless the concentration of a given redox couple is relatively high, inert electrodes (generally platinum) used for redox measurements are not specific for a specific redox couple. The redox electrode responds to the collective electrochemical potentials of all redox couples present.

The measured redox potential in soil is generally a mixed potential which reflects a weighted average of the potentials contributed by each of the redox couples present. As a result of the continuous

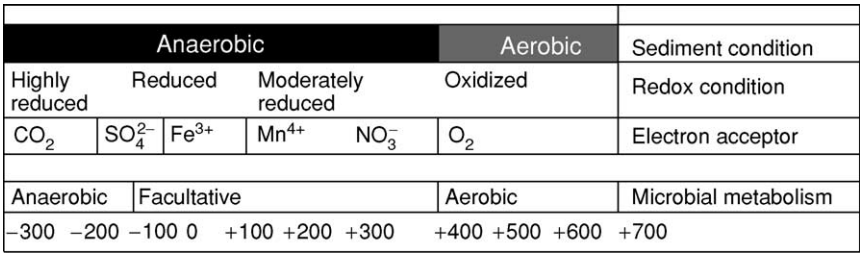

Figure 2 Redox potential range in soil and sediment, showing the microbial metabolism process and electron acceptor.

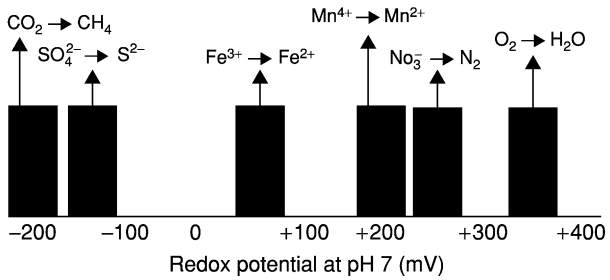

Figure 3 Critical redox potential for the transformation of redox couples.

addition of organic matter, which oxidizes and serves as an electron donor, a redox equilibrium is almost never attained in a natural system.

With the theoretical limitations involved in the use of redox potentials to quantitatively describe a specific ionic distribution in a mixed system, redox measurements can be successfully applied to characterize the oxidation–reduction transformations of many elements, including heavy metals and plant nutrients in soil.

Predicting Mineral Stability

E_h and pH can also be used for plotting stability fields for specific minerals. For example, the E_h–pH stability field for iron in Figure 4 can be interpreted that hematite (Fe_2O_3) is a stable iron mineral under oxidizing environments. Under reducing environments, a stable mineral may be pyrite. If dissolved sulfur is low, siderite ($FeCO_3$) may be the predominant mineral under reducing conditions.

Intensity and Capacity of Reduction

Redox potential measurement is only one measure of intensity of reduction in soils and sediment, as described below.

Intensity

The ease of reduction is represented by the free energy of reduction or equivalent electromotive forces of the reaction (oxidation–reduction potential or redox potential).

The reduction processes that take place in a soil as a result of the oxidation of organic matter utilizing alternate electron acceptors of nitrate, manganic manganese, ferric iron, sulfate, and carbon dioxide do not proceed together. As indicated previously, nitrate is utilized first after oxygen disappears, followed by manganic manganese, ferric iron, sulfate, and finally carbon dioxide. For this reason the soil must be considerably more reduced for sulfate to be

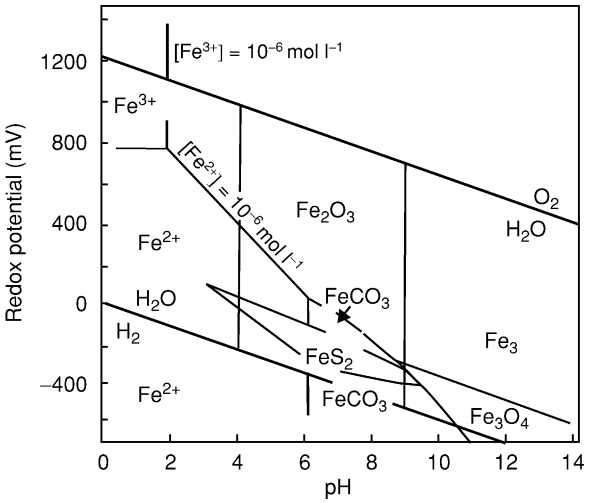

Figure 4 Redox–pH effect on stability of iron minerals. Adapted from Krauskoft KB (1967) *Introduction to Geochemistry*. New York, NY: McGraw Hill.

reduced than for nitrate to be reduced. If nitrate and sulfate and a suitable organic substrate are all present in a flooded, oxygen-deficient soil at the same time, the denitrifiers will reduce all of the nitrate before any of the sulfate is reduced by the sulfate reducers. The intensity of reduction is different for the two reduction processes. The soil is not very reduced (low reduction intensity or low electron pressure) for the reduction of nitrate, while it is very reduced during the reduction of sulfate (high reduction intensity or high electron pressure).

This intensity of reduction can be thought of in terms of the pressure of the electrons that the microorganisms need to dispense with as they carry out oxidation of the energy source. It does not require much electron pressure for the nitrate to accept electrons (and even less electron pressure for oxygen, if it is present, to acceptor electrons). This is why a large energy yield can be obtained from the oxidation of the energy source, since not so much of the possible energy from the oxidation process is utilized in forcing the electron acceptor to accept the electrons from the organic matter oxidation.

Electron acceptors that are difficult to reduce require more electron pressure to force the electrons to move to the electron acceptor. For example, sulfate reducers in soil and sediment can oxidize organic substrates, but a great deal of the energy derived from the oxidation is required to force the sulfate ion to accept the electrons and be converted to sulfide. This leaves less energy than the microorganism derives from the reaction that it can use for its energy needs. A great intensity of reduction is required for

sulfate to accept the electrons produced during the oxidation of the energy source.

This approach to determine the intensity of reduction is called the oxidation–reduction or redox potential of the soil. Measurement of redox potential is conducted by placing a platinum electrode in the soil, connecting it to a suitable circuit that balances and measures the electron pressure from the reduction processes.

Reduction capacity described below differs from intensity of reduction.

Capacity

The total amount of electrons accepted by oxidants or number and redox system undergoing reduction is the 'capacity.' The capacity can be best described in terms of its O_2 equivalent (not redox potential measurement).

The capacity factor of the various redox systems varies from one soil to another. The amount of oxygen present in the soil at the time of flooding is usually low. The amount of NO_3^- present in the soil is dependent on soil organic matter and can be variable. Biologically reducible Mn can be present in soils at varying levels (less than 100 to 1000 mg kg^{-1}), while reducible Fe can be in the range of 500–3000 mg kg^{-1} of soil.

Although the critical redox potential at which the inorganic redox systems become unstable provides valuable information, it does not provide any indication of the total capacity of the system to accept electrons or support microbial respiration. Capacity factor is equivalent to the total amount of electrons accepted by the oxidants in support of microbial respiratory activity. The redox couple present in lowest quantity has the smallest capacity for supporting microbial respiration. In mineral-flooded soils, reducible Mn and Fe primarily support the organic matter decomposition. In estuarine areas that receive sea water containing large amounts of SO_4^{2-}, the reduction of SO_4^{2-} to S^{2-} supports the microbial respiratory activities.

Redox Condition and Metal/Metalloid Chemistry

Redox conditions of soil and sediment deposits also govern heavy metal chemistry (Figure 5). For example, chromium can exist in several oxidation states from Cr(0), the metallic form, to Cr^{6+}. The most stable oxidation states of chromium in the environment are Cr^{3+} and Cr^{6+}. Besides the elemental metallic form, which is extensively used in alloys,

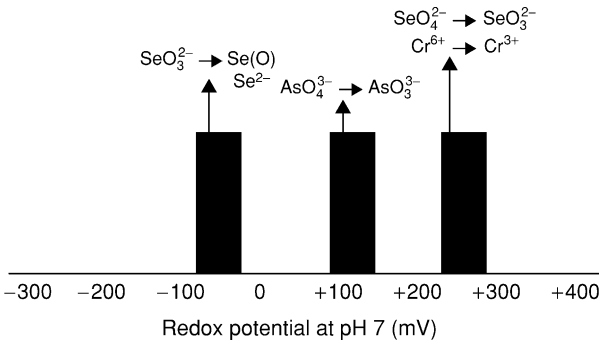

Figure 5 Redox potential as related to metal and/or metalloid chemistry or transformation.

chromium has three important valence forms: Cr^{2+}, Cr^{3+}, and Cr^{6+}.

The trivalent chromic Cr^{3+} and the tetravalent dichromate Cr^{6+} are the most important forms in the environmental chemistry of waters and sediments. The presence of chromium Cr^{6+} is of particular importance, because in this oxidation state Cr is water-soluble and extremely toxic. They are also the only forms that undergo valence changes in the E_h–pH ranges encountered in natural systems. The solubility and potential toxicity of the chromium that enters into aquatic or sediment columns are governed to a large extent by oxidation–reduction reactions. Cr^{6+} reduces to Cr^{3+} at approximately +300 mV (Figure 5).

Oxidation–reduction processes also play a role in arsenic (As) and selenium (Se) chemistry (Figure 5). For the pH and redox conditions in most soils and sediments, As exists as an oxyanion in the arsenate ($H_2AsO_4^-$, and $HAsO_4^{2-}$, As^{5+}) or arsenite [H_3AsO_3; As^{3+}] form. Monomethylarsenic acid (MMAA) and dimethylarsenic acid (DMAA) are important organoarsenic chemical species. Se occurs as selenate (SeO_4^{2-}, Se^{6+}), selenite ($HSeO_3^-$ and SeO_3^{2-}; Se^{6+}), and elemental selenium (Se(0)), but selenide (DMSe) is the most important. At higher soil redox levels (+200 to +500 mV), As^{5+} is the predominant As species present. The reduction of As^{5+} to As^{3+} occurs at redox levels corresponding within the nitrate-reducing zone of soils characterized by a soil redox level of approximately +300 mV. When Fe reduction starts and soil redox levels drop below +50 mV, selenite is reduced to elemental Se or metal selenides. Reoxidation of reduced As and Se species occurs at similar soil redox levels to those identified for reduction reactions. Both microbial-mediated and chemical-oxidation processes are thought to be involved in the oxidation of reduced As and Se species.

Measurement of Redox Potential

Inert metal electrodes (usually platinum) are widely used to measure the oxidation–reduction potentials of chemical systems. The inert metal electrode is used in conjunction with a reference electrode to form a complete cell. The most widely used reference electrodes for redox potential measurement are the calomel (mercury–mercurous chloride) and the silver/chloride electrode. The redox potential (E_h) is obtained from the potential of the cell (E) by adding the appropriate value for the reference electrode potential corrected for liquid junction effects. The potential measured with the platinum electrode and the secondary reference electrode must be corrected to give true E_h or redox potential.

The platinum electrode referenced to a saturated calomel electrode will give E_h or millivolt readings, provided corrections are made for the potential of the calomel electrode.

Performance of the platinum electrodes is checked by immersing the platinum electrode along with the reference calomel electrode in pH 4.00 and pH 7.00 buffer to which a small amount of quinhydrone has been added. The reading on the E_h meter in millivolts should agree with that shown in Table 1. The meter reading is corrected relative to hydrogen by adding the calomel potential (Table 1). This value is the quinhydrone E_h in millivolts relative to hydrogen. For example, a meter reading of 218 mV at 25°C for quinhydrone in pH 4.00 buffer gives an E_h of 462.3 mV:

$$E_h = \text{meter reading} + \text{calomel potential}$$
$$E_h = 218.0 + 244.3 = 462.3\ \text{mV}$$

An electrode is considered satisfactory if it does not deviate from the above values by more than 5 mV.

When making soil E_h measurements, the calomel potential must be added to the meter reading (millivolts). The procedure is as follows:

The potential is measured by inserting the electrodes in the substance to be measured and reading the millivolt scale on the pH meter. Since the calomel electrode is used as a reference, +244.3 mV is added to the recorded potential for reference to the hydrogen electrode.

Table 1 Effect of temperature on the standard potential of a calomel half-cell and platinum electrode

Temperature (°C)	Calomel potential (mV)	Meter reading[a]	
		pH 4 (mV)	pH 7 (mV)
5	257.0	236.0	66.5
10	253.9	231.6	60.1
15	250.8	227.3	53.7
20	247.3	222.7	47.3
25	244.3	218.0	40.8
30	240.9	213.4	34.3
35	237.5	208.5	27.7
40	234.1	203.5	21.0
45	230.6	198.4	14.2

Oxidation and reduction (redox) reactions constitute a diverse, complex, and extremely important class of reactions in soils. Redox reactions influence properties, such as solubility and reactivity, of both organic and inorganic species/phases. For example, the two environmentally important oxidation states of Cr, Cr(III) and Cr(VI), have dramatically different properties. Cr(III) is sparingly soluble, tending to precipitate as Cr or Fe/Cr oxyhydroxides, while Cr(VI) exists as the soluble and quite mobile CrO_4^{2-} oxyanion. Similarly, properties of fulvic and humic acids, including their contrasting solubilities and sorption behavior, are fundamentally a consequence of their oxidation state. Moreover, all biological life is dependent on redox reactions proceeding at disequilibrium.

Because of the dramatic effect that oxidation state can have on the properties of important compounds, soil chemists are often interested in being able to understand, model, and predict the redox behavior of a certain species under various conditions. We therefore need two kinds of information: thermodynamic and kinetic. Thermodynamics describes the overall path and time-independent energetics of a reaction. Kinetics describes the time-dependent behavior of a reaction. Thermodynamic data are generally more accessible; they answer unequivocally whether a reaction is 'favored' (i.e., possible) under certain conditions. However, reaction kinetics dictate the rate at which a reaction will proceed; reactions that do not proceed 'instantaneously' are often termed 'kinetically controlled.' For example, the oxidation of carbon as diamond to CO_2 by atmospheric O_2 is thermodynamically favored (by $\sim$400 kJ/mol^{-1}) but proceeds appreciably only on geologic time scales. As we study kinetics, it is crucial to keep in mind that thermodynamic driving forces do not dictate reaction kinetics.

The vast majority of the redox reactions of interest to the soil chemist are kinetically controlled, and all life depends on kinetic constraints maintaining disequilibrium. Because of this, the study of redox kinetics is of central importance to understanding almost any soils system. Kinetic data are usually combined into a mathematical description of the reaction kinetics known as the kinetic rate law. A complete rate law contains terms for all the variables in a system that affect the time-course of the reaction. These factors include the chemical species involved in the reaction as well as other factors such as temperature, pressure, or ionic strength. The rate law also contains a constant that is an indication of the reaction's relative speed, known as the rate constant. The initial form and some of the important terms in a rate law can occasionally be deduced from equilibrium data or from a theoretical description of the reaction, but complete rate laws, other than the simplest gas phase reactions, are experimentally determined. Rate laws are essential for a variety of purposes, including modeling experimental data, understanding the detailed molecular steps involved in the reaction (the reaction mechanism) or, most importantly, to model and predict actual field behavior.

Kinetic Rate Laws

We mathematically define the rate of a reaction in terms of how quickly a given reactant is consumed or product is formed. In order to do this we must already have good equilibrium data on the reaction that tells us the reactants, the products, and the stoichiometric relationships between these species. For example, a reaction like that described in eqn [1], where the reactants A and B combine to form products C and D, and the stoichiomteric coefficients of each reactant or product, are given by a, b, c, or d respectively.

$$aA + bB \rightleftarrows cC + dD \qquad [1]$$

The rate can be defined based on any of the reactants or products as follows, where square brackets denote the concentration (and not activities) of a species.

$$\text{Rate} = -\frac{1}{a}\frac{d[A]}{dt} = -\frac{1}{b}\frac{d[B]}{dt} = \frac{1}{c}\frac{d[C]}{dt} = \frac{1}{d}\frac{d[D]}{dt} \qquad [2]$$

Eqn [2] is valid as long as the stoichiometric coefficients in eqn [1] are accurate under the given conditions (i.e., there are no side reactions that consume or produce species within the reaction). For cases involving side reactions, the proportionality of the reaction/products would not depend solely on the coefficients in eqn [1].

The rate as defined in eqn [2] is the difference between the rate of the forward reaction (eqn [1] read from left to right, which will be a function of, among other things, the concentration of A and B) and the reverse reaction (eqn [1] read from right to left, which will be a function of the concentrations of C and D).

$$\text{Rate}_{net} = \text{Rate}_{forward}([A],[B]) - \text{Rate}_{reverse}([C],[D]) \qquad [3]$$

Equilibrium is the point where the concentrations of reactions and products remain constant, or, in

other words, that Rate_{net} is zero. We can see from eqn [3] that equilibrium does not mean that eqn [1] has ceased to occur but simply that the $\text{Rate}_{\text{forward}}$ is equal to the $\text{Rate}_{\text{reverse}}$. As long as eqn [1] is far from equilibrium, we can neglect the rate of the reverse reaction and concentrate solely on the forward reaction. As stated already, the $\text{Rate}_{\text{forward}}$ will be a function of the concentrations of A and B, known as the rate law. The exact nature of this function must be determined experimentally, but for many reactions the rate law takes the form shown in eqn [4], where $[A]$ and $[B]$ are the concentrations of reactants A and B; concentration units of molarity (M or mol l^{-1}) are usually used for dissolved species. Solid species can also be reported in terms of molarity or in mass (mg l^{-1}) or surface area (m^2l^{-1}) concentrations. The constant k is an experimentally determined proportionality factor known as the rate constant. The constants α and β are also experimentally determined and are denoted as the reaction order. If α is equal to 1 and β is equal to 2, then the reaction is said to be first-order in A, second-order in B, and third-order overall. The units of k are dictated by the reaction order such that the units of the rate will come out appropriately; usually rates are reported in units of concentration per time, such as $\text{mol l}^{-1}\,\text{s}^{-1}$.

$$\text{Rate}_{\text{forward}} = k[A]^{\alpha}[B]^{\beta} \qquad [4]$$

If eqn [1] was an elementary reaction, the coefficients in eqn [1] (a and b) would be equal to the α and β of eqn [4]. Unfortunately, most soil systems are sufficiently complex that we must deal in overall reactions, meaning reactions whose reactants, products, and stoichiometry have been determined macroscopically. In this case, there is no theoretical link between the coefficients in eqn [1] and the exponents in eqn [4]. In fact, the exponents in eqn [4] need not even be whole numbers.

Integrated Rate Laws

Remember that eqn [4] is in fact a differential equation of the form shown in eqn [5]. If we were able to integrate eqn [5] we would be able to calculate the concentrations of A or B at any given time.

$$\text{Rate}_{\text{forward}} = -\frac{1}{a}\frac{d[A]}{dt} = -\frac{1}{b}\frac{d[B]}{dt} = k[A]^{\alpha}[B]^{\beta} \qquad [5]$$

The integration of a general equation like eqn [5] is not trivial. For this reason, let us first consider a simpler system. Eqn [6] shows the rate law for a reaction that depends only on the concentration of A and is first-order in A.

$$\text{Rate} = -\frac{d[A]}{dT} = k[A] \qquad [6]$$

Eqn [6] is easily integrated to yield eqn [7], where $[A]_0$ is the initial concentration of A, $[A]_t$ is the concentration of A at any time t, and k is the first-order rate constant.

$$[A]_t = [A]_0 e^{-kt} \qquad [7]$$

The integrated rate laws for zero- and second-order, single-species rate laws are shown in **Table 1**.

Table 1 Integrated rate law expressions

Reaction order	*Rate law*	*Integrated rate law*	*Units of* k	*Linear plot*
0	$-\frac{d[A]}{dt} = k$ [8]	$[A]_t = [A]_0 - kt$ [9]	$\text{mol l}^{-1}\,\text{s}^{-1}$	$[A]_t$ versus t
1	$-\frac{d[A]}{dt} = k[A]$ [10]	$[A]_t = [A]_0 e^{-kt}$ [11]	s^{-1}	$\ln[A]_t$ versus t
2	$-\frac{d[A]}{dt} = k[A]^2$ [12]	$\frac{1}{[A]_t} = \frac{1}{[A]_0} + kt$ [13]	$\text{mol}^{-1}\,\text{l}\,\text{s}^{-1}$	$\frac{1}{[A]_t}$ versus t
2	$-\frac{d[A]}{dt} = k[A][B]$ [14]	$\frac{1}{[B]_0 - [A]_0}\ln\frac{[A]_0[B]_t}{[B]_0[A]_t} = kt$ [15] $\frac{1}{[A]_t} = \frac{1}{[A]_0} + bkt$ [16]	$\text{mol}^{-1}\,\text{l}\,\text{s}^{-1}$	
$\alpha+\beta+\chi$	$-\frac{1}{a}\frac{d[A]}{dt} = k[A]^{\alpha}[B]^{\beta}[C]^{\chi}$ [17]	None	$\text{mol}^{-(\alpha+\beta+\chi-1)}\text{l}^{(\alpha+\beta+\chi-1)}\text{S}^{-1}$	

Reactions whose rates are controlled solely by one species and are exactly zero; first-, or second-order do exist, and sometimes the order of a reaction can be identified solely by collecting concentration data over time for a single reactant and comparing to one of the simple rate laws. As seen in **Table 1**, if the reaction is first-order in A then a plot of the $\ln[A]_t$ versus t should be a straight line. Similarly, if the reaction is second-order in $[A]$, then a plot of $[A]_t^{-1}$ versus t should be a straight line.

Unfortunately, the majority of reactions of interest do not fall neatly into one of the easily integrateable rate laws, and it is more common that we must use mathematics or experimental design to simplify a more complex rate law, like eqn [17]. The most common of these techniques are discussed below, but a clever experimentalist or mathematician can always devise new approaches.

Initial Rates

The technique of initial rates can be used to determine the order of an individual reactant within a complex rate expression. The initial rate is the linear reaction rate at the beginning of a reaction before a significant amount (<10%) of any of the reactants has been consumed and before there is any appreciable reverse reaction. This is expressed mathematically in eqn [18].

$$\text{Rate}_{\text{initial}} = -\frac{1}{a}\frac{d[A]}{dt} \approx -\frac{1}{a}\frac{\Delta[A]}{\Delta t} \approx k[A]^{\alpha}[B]^{\beta}[C]^{\chi} \quad [18]$$

For example, if we wanted to determine α, the order of A in eqn [17], we need only to measure the initial rate at two different A concentrations. We can then take the ratio of these two rates as shown in eqn [19].

$$\frac{\text{Rate}_1}{\text{Rate}_2} = \frac{k[A_1]^{\alpha}[B]^{\beta}[C]^{\chi}}{k[A_2]^{\alpha}[B]^{\beta}[C]^{\chi}} \quad [19]$$

Since the rate constant, k, and the concentration of B and C should be equal in both equations, eqn [19] reduces to eqn [20].

$$\frac{\text{Rate}_1}{\text{Rate}_2} = \frac{[A_1]^{\alpha}}{[A_2]^{\alpha}} = \left(\frac{[A_1]}{[A_2]}\right)^{\alpha} \quad [20]$$

α can be determined by taking the log of both sides and rearranging, to give eqn [21].

$$\alpha = \frac{\text{Log}\left(\frac{[\text{Rate}_1]}{[\text{Rate}_2]}\right)}{\text{Log}\left(\frac{[A_1]}{[A_2]}\right)} \quad [21]$$

This process can be repeated to determine the order of any number of reactants. Because these are reaction orders for a complex overall reaction, α, β, and χ need not be whole numbers.

Although it is true that in theory one needs only to determine the initial rate at two different concentrations of A, it is good practice to employ several different concentrations to make sure that the orders calculated with any pair of A concentrations are the same (i.e., the reaction rate is determined at varying concentrations of A while all other concentrations are maintained at the same value). In fact, one can rearrange eqn [18] to give eqn [22]. Using this equation a plot of $\log(\text{Rate}_{\text{initial}})$ versus $\log[A_{\text{initial}}]$ should give a straight line with slope α. The analogous equation can be used to determine the remaining reaction orders.

$$\text{Log}(\text{Rate}_{\text{initial}}) = \alpha\log[A_{\text{initial}}] + \log(k[B]^{\beta}[C]^{\chi}) \quad [22]$$

Once the orders of all the various reactants have been determined, the rate constant can be calculated simply by rearranging any of the expressions of the form of eqn [17] into eqn [23].

$$k = \frac{\text{Rate}_{\text{initial}}}{[A]^{\alpha}[B]^{\beta}[C]^{\chi}} \quad [23]$$

The rate constant should be the same, or very similar. The rate constants should also be equal (within experimental error) or the reaction is incorrectly modeled and the calculated orders are not valid.

The initial rate approach was used to determine the orders for the reactants involved in the reduction of birnessite ($MnO_{1.7}$) to Mn(II) by catechol ($C_6H_6(OH)_2$). According to the overall reaction equation (eqn [24]), the general rate expression should contain three factors, birnessite, catechol, and H^+, according to eqn [25].

$$MnO_{1.7(s)} + 0.7C_6H_6(OH)_{2(aq)} + 2H^+ \rightarrow Mn(II)_{(aq)} + 0.7C_6H_4O_{2(aq)} + 1.7H_2O \quad [24]$$

$$\frac{d[Mn(II)]}{dt} = k[MnO_{1.7}]^{\alpha}[C_6H_6(OH)_2]^{\beta}[H^+]^{\chi} \quad [25]$$

Each reactant was varied independently and the initial rates were measured. Plots of initial rates versus $\log[C_6H_6(OH)_2]$ or $\log[MnO_{1.7}]$ were linear, with slopes equal to one indicating that the reaction was first-order in both catechol and birnessite. On the other hand, plots of initial rates versus $\log[H^+]$ were flat, i.e., slope of zero, indicating a zero-order dependence on H^+ concentration. This information allowed the rate law for this reaction to be simplified to eqn [26].

$$\frac{d[Mn(II)]}{dt} = k[MnO_{1.7}][C_6H_6(OH)_2] \quad [26]$$

Pseudo *n*th-Order Reactions

Some reactions are so rapid as to preclude the collection of initial rate data. In these situations, we can reduce higher-order reactions to 'pseudo' lower-order reactions by adjusting the concentrations of the various reactants; this is often referred to as the method of isolation. Returning to eqn [17], if we set the concentration of B and C such that they are much greater than the concentration of A, we can assume, after taking into account appropriate stoichiometries, that A can be entirely consumed without significantly altering the concentration of B or C. Thus, eqn [17] reduces to eqn [27], where k' is the 'pseudo α order rate constant.' (k' is also frequently denoted k_{obs} because it is the observed (measured) rate constant for the specific experimental conditions employed.)

$$-\frac{1}{a}\frac{d[A]}{dt} = k'[A]^{\alpha} \quad [27]$$

Using this approach, we can reduce a rate expression of any order into one with only one or two reactants of concern and determine if it conforms to one of the simple rate expressions in **Table 1**, in other words that α is $\cong 0$, 1, or 2. This was the case for the reduction of carbamate pesticides by Fe(II). The initially postulated rate expression for this process was eqn [28], but by monitoring the reduction of the carbamate pesticide in the presence of large excesses of Fe(II), eqn [28] simplifies to eqn [29].

$$-\frac{d[\text{pesticide}]}{dt} = k[Fe(II)][\text{pesticide}] \quad [28]$$

$$-\frac{d[[\text{pesticide}]}{dt} = k_{obs}[\text{pesticide}] \quad [29]$$

Plots of ln[pesticide] versus time were found to be linear, indicating that eqns [29] and [28] are indeed first-order with respect to pesticide concentration.

Second-Order, Two-Reactant Rate Laws

If we suspect that we a have a rate law in the form of eqn [14], we can model the data and determine the rate constant, k, in one of two ways. If it is relatively simple to measure both A and B during the course of reaction, it is possible to fit the data to eqn [15] using k as a fitting parameter. Alternatively, if it is difficult to measure A and B simultaneously, but we know the stoichiometric relationship between A and B, we can use that relationship to simplify eqn [15]. We can substitute an expression of the form $[B]_t = [B]_0 - ab^{-1}[A]_t$ into eqn [15], where a and b are the stoichiometric coefficients for A and B analogous to those in eqn [1]. Or, more elegantly, we can design our reaction such that A and B are initially present in their stoichiometric ratios according to eqn [30].

$$\frac{[A_0]}{[B_0]} = \frac{a}{b} \quad [30]$$

When eqn [30] is valid, then the integrated form of eqn [14] is simply eqn [16]. This expression is similar to eqn [13] except for the stoichimetric factor b.

This approach was employed to determine the rate constant for the reduction of Cr(VI) by Fe(II). The rate expression for this reaction was postulated to be first-order in each reactant and second-order overall (eqn [31]). Three Fe(II) ions are necessary to provide the three electrons needed to reduce one Cr(VI) to Cr(III). This leads to an Fe(II) to Cr(VI) stoichiometry of 1:3, respectively. By controlling the initial reaction conditions such that $[Fe(II)_0] = 3[Cr(VI)_0]$, the researchers were able to use eqn [32] to fit their data and obtain a value for k.

$$-\frac{d[Cr(VI)]}{dt} = k[Fe(II)][Cr(VI)] \quad [31]$$

$$\frac{1}{[Cr(VI)]_t} = \frac{1}{[Cr(VI)]_0} + 3kt \quad [32]$$

Reaction Diagrams and Activation Energies

The progress of a reaction can be represented as in **Figure 1**, in which the y-axis represents energy and the x-axis is what is known as the reaction coordinate, and is simply a way of showing the progress of the reaction from reactants to products. **Figure 1** represents what is known as a reaction diagram; this can be a very effective and concise way of summarizing the energetics of a reaction. For a reaction to be thermodynamically favored, the total energy of the products must be less than the total energy of the reactants, or, in other words, the products must be more stable than the reactants. The energy barrier shown between the reactants and the products is known as the activation energy (E_a). The magnitude of this barrier (as represented by its height in **Figure 1**) determines the rate of the reaction. Reactions with smaller activation

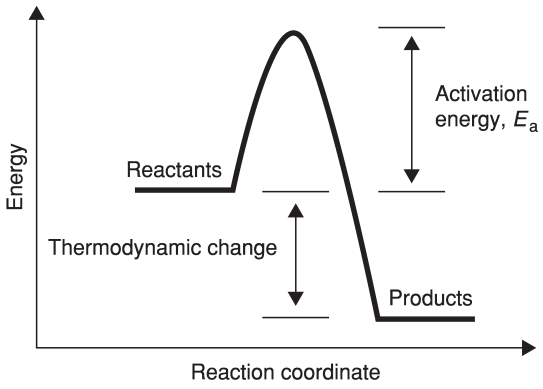

Figure 1 Reaction diagram for generalized thermodynamically favored but activation energy-limited reaction.

energies will proceed rapidly from reactants to products as compared with those with larger activation energies. This is the reason why reactions can be thermodynamically favored but kinetically unimportant (owing to huge activation energies).

Reactants gain the energy necessary to overcome the activation energy by colliding with each other. For reactions with very small activation energies, reactants will form products virtually every time there is a collision. These reactions are known as diffusion- or transport-controlled reactions because the rate of reaction is only limited by how quickly the reactants can approach one another through diffusion. At normal temperatures, homogeneous aqueous diffusion-controlled reactions are too rapid to be of much interest to soil chemists. On the other hand, for heterogeneous reactions, in which reactants must diffuse toward a surface or into and out of pore spaces, rates of diffusion are much slower. Under these conditions it is possible to have a relatively slow, but diffusion-controlled reaction. Diffusion-controlled reactions generally obey rate laws of a different form than the ones discussed here.

For reactions with larger activation energies, only a small percentage of collisions will have enough energy to push the reactants over the activation energy barrier. For these reactions, it is the activation energy that determines the magnitude of the rate constant, k. The mathematical relationship between the activation energy and the rate constant was developed by Savante Arrhenius and is known as the Arrhenius equation (eqn [33]), where E_a is the molar activation energy in $\mathrm{J\,mol^{-1}}$, R is the universal gas constant ($8.3145\,\mathrm{J\,K^{-1}\,mol^{-1}}$), T is temperature in K, and A is a proportionality constant known as the preexponential factor.

$$k = Ae^{\frac{-E_a}{RT}} \qquad [33]$$

Many people are qualitatively familiar with the observation that most reactions tend to proceed more rapidly at higher temperatures, but it is the Arrhenius equation that allows this temperature dependence to be quantified.

The activation energy of a reaction can be determined by measuring k at several different temperatures and using the Arrhenius equation. A plot of $\ln(k)$ versus T^{-1} should yield a straight line with slope, $-E_a R^{-1}$ according to eqn [34], which is obtained simply by taking the natural log of both sides of eqn [33] and rearranging.

$$\mathrm{Ln}(k) = \mathrm{Ln}(A) - \frac{E_a}{\mathrm{RT}} \qquad [34]$$

Similarly, two temperature points can be used to calculate E_a according to eqn [35].

$$E_a = \frac{\mathrm{Ln}(k_1) - \mathrm{Ln}(k_2)}{\left(\frac{1}{T_2} - \frac{1}{T_1}\right)} \qquad [35]$$

Because both of these approaches are simple rearrangements of the Arrhenius equation, they are theoretically equivalent. Once the activation energy has been determined we can model and predict the temperature dependence of a reaction. The magnitude of E_a can help determine whether the reaction is diffusion-controlled or activation energy-controlled. Diffusion-controlled reactions tend to have an E_a less than $\sim 40\,\mathrm{kJ\,mol^{-1}}$.

Reaction Mechanism (Rate-Limiting Step and Preequilibria)

Understanding reaction kinetics has additional benefits beyond simply being able to model the time-dependent progress of a given reaction. The kinetics of a reaction can often be used to make conclusions regarding the mechanism of that reaction, although this must be done with caution. The mechanism of a reaction is the series of elementary reactions that combine to give the complete reaction. With complex soil chemical reactions, it is rarely, if ever, possible to break a reaction mechanism into all of its elementary reactions. This being said, all metal redox reaction must progress through three stages: (1) formation of a prereaction complex; (2) electron transfer; and (3) separation of postreaction complex. In organic redox reactions, the second step often involves the transfer of an entire atom or group of atoms instead of simply an electron, but the fundamental process is similar.

The individual steps that make up a reaction mechanism usually have different activation energies and

therefore different rates. It is unlikely that for a given redox reaction each of the three stages outlined above will have the same rate constant. In fact, it is often the case that the activation energy of one of the steps will be much greater than that of the others and therefore will be much slower. The slowest step is known as the rate-limiting or rate-determining step (it is the 'bottle-neck' in the reaction progression). If the rate-determining step is the first step in a reaction mechanism, none of the following reactions or intermediate species will appear in the rate law. This effect can be seen in the reduction of carbon tetrachloride (CCl_4) by surface-absorbed Fe(II); the overall reaction is as seen in eqn [36].

$$CCl_4 + 2Fe(II) + H^+ \rightarrow CHCl_3 + Cl^- + 2Fe(III) \quad [36]$$

$$\frac{d[CHCl_3]}{dt} = k[CCl_4][Fe(II)] \quad [37]$$

The experimentally determined rate expression for this reaction was found to be first-order in carbon tetrachloride, second-order in Fe(II), and zero-order in H^+ (eqn [37]). The absence of H^+ in the rate law can be explained by postulating the following mechanism, in which eqn [38] is assumed to be the rate-limiting step.

$$CCl_{4(sorbed)} + 2Fe(II)_{(sorbed)} \rightarrow CCl^-_{3:(aq)} + Cl^- + 2Fe(III)_{(sorbed)} \quad [38]$$

$$CCl^-_{3:(aq)} + H^+_{(aq)} \rightarrow CHCl_{3(aq)} \quad [39]$$

However, if there are fast reactions before the rate-determining step, then these reactions will appear in the rate law. Because these early reactions are so much faster – both forward and reverse reactions – than the rate-limiting step, we can assume that they always remain at equilibrium throughout the course of the reaction. Acid–base reactions and metal speciation reactions are generally rapid and are frequently treated as preequilibria. Similarly, surface absorption can sometimes be treated as a preequilibrium, as was done in the case of the oxidation of fulvic acid by an Mn-oxide. The proposed reaction mechanism involved rapid absorption of the fulvic acid on to the Mn-oxide followed by a slow electron transfer step (eqns [40] and [41]), where Mn≡ denotes a Mn-oxide surface site.

$$Fulvic_{(aq)} + Mn{\equiv}OH \rightleftarrows Mn{\equiv}Fulvic (rapid) \quad [40]$$

$$Mn{\equiv}Fulvic \rightarrow Mn(II) + oxidized\ Fulvic\ (slow) \quad [41]$$

If eqn [41] is the rate-limiting step then the rate equation for this process should be like that seen in eqns [42], and [40] can be treated as an equilibrium expression (eqn [43]).

$$\frac{d[Mn(II)]}{dt} = k_{41}[Mn{\equiv}Fulvic] \quad [42]$$

$$K_{40} = \frac{[Mn{\equiv}Fulvic]}{[Fulvic][Mn{\equiv}OH]} \quad [43]$$

Combining eqns [42] and [43] and the equality that the total oxide surface sites must be equal to the free sites plus the fulvic occupied sites, $[Mn{\equiv}_{tot}] = [Mn{\equiv}OH] + [Mn{\equiv}fulvic]$, it was possible to obtain a rate expression that matched the data (eqn [44]).

$$\frac{d[Mn(II)]}{dt} = k_{41}K_{40}[Mn{\equiv}_{tot}]\frac{[Fulvic]}{1 + K_{abc}[Fulvic]} \quad [44]$$

Although this equation may initially seem more complicated, it is practically speaking much simpler because it is based on total reactant concentrations that are much easier to measure.

Biologically Controlled Redox Reactions

Many important redox transformations in soils are controlled by enzymes produced by microorganisms. Enzymatically controlled reactions are frequently modeled using either Michaelis–Menten kinetics or a derivative of Michaelis–Menten kinetics known as Monod kinetics. The proposed enzyme-controlled reaction mechanism used to develop Michaelis–Menten kinetics is shown in eqns [45] and [46], where E is the enzyme, S is the metal or organic molecule of interest known as the substrate, ES is the enzyme substrate complex, and P is the product.

$$E + S \rightleftarrows ES \quad [45]$$

$$ES \rightarrow P \text{ and } E \quad [46]$$

To convert this qualitative mechanism into a quantitative rate law, we must make an assumption known as the steady-state assumption. This assumption is similar but not identical to the preequilibrium situation described above. In the steady-state assumption, we assume that certain species are present at relatively constant values throughout the course of the reaction, although not necessarily their equilibrium values. To develop a steady-state situation we must assume that the substrate binds rapidly and

reversibly to the enzyme – eqn [45] is rapid in both the forward and reverse directions. Next it is assumed that the transformation of the enzyme substrate complex into the product (eqn [46]) is a first-order process and is the rate-limiting step in the overall reaction (eqn [48]). These assumptions allow us to assume that ES is present in a steady state or, in other words, that the rate of ES formation is equal to the rate of ES destruction. Eqn [47] shows this mathematically where the equation for ES formation is shown on the left and is set equal to the sum of the equations for ES destruction.

$$k_{45}[E][S] = k_{-45}[ES] + k_{46}[ES] \quad [47]$$

$$\text{Rate} = \frac{d[P]}{dt} = k_{46}[ES] \quad [48]$$

If we mathematically combine these two assumptions by substituting in for ES, we derive the basic Michaelis–Menten equation (eqn [49]).

$$\text{Rate} = \frac{k_{222}[E]_{tot}[S]_{tot}}{K_m + [S]_{tot}} \quad [49]$$

K_m is called the Michaelis–Menten or the Michaelis constant and $[E]_{tot}$ and $[S]_{tot}$ are the total enzyme and substrate concentrations, respectively.

The development of Monod kinetics is similar to that for Michaelis–Menten, with the insertion of X as the total cell concentration and K_s as the half saturation constant.

$$\text{Rate} = \frac{k[X][S]_{tot}}{K_s + [S]_{tot}} \quad [50]$$

Because it is frequently more feasible to control/measure cell concentration than enzyme concentration, Monod kinetics often have a practical advantage over Michaelis–Menten kinetics.

Conclusion

It is important to remind ourselves of primary assumptions made throughout this chapter. First, we have almost exclusively dealt with reactions that are far from equilibrium and were therefore able to ignore reverse reactions. For systems closer to equilibrium these reactions must be included. Although this complicates the mathematics, the general approach for developing the rate laws remains the same. Second, because these rate laws are empirically derived relationships, they are only rigorously applicable to systems with reactant concentrations, temperatures, ionic strengths, and other variables within the ranges used experimentally to develop the rate laws. They can sometimes be applied to slightly different systems, but this must always be done with caution. Lastly, there are many more detailed and complex rate laws that have been developed for both abiotic and biotic redox reactions, but they are beyond the scope of this chapter. The interested reader is referred to the further reading as a place to start.

REMEDIATION OF POLLUTED SOILS

E Lombi and R E Hamon, CSIRO Land and Water, Glen Osmond, SA, Australia

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Public concern about environmental pollution has increased substantially since the beginning of the twentieth century with growing awareness of the stresses being placed on the environment due to activities arising from both industrial activity and intensive agriculture, and as a consequence of high-profile incidents that have highlighted the risks of pollution for human health. Examples of such incidents include industrial pollution at Love Canal, USA, the chemical factory explosion at Bhopal, India, and the nuclear near-accident at Three Mile Island, USA. Pollutants tend to have longer residence times in soil than in water or air. The soil acts as a sink or a filter in which pollutants are accumulated rapidly but are depleted slowly. The decontamination of polluted soils is becoming an issue of societal and political interest, because of its importance for environmental protection and human health, and its economical relevance. New technologies based on physical, chemical, and biological processes to reclaim polluted soils have been developed during the last decades. This article briefly describes the available technologies for the remediation of organic and inorganic contaminants in soils. A synopsis of these technologies is depicted in Figure 1.

Containment Versus Clean-Up Strategies

In terms of managing soil pollution, there are two types of strategy. The first, which at the beginning of the twenty-first century is the preferred option for many regulatory agencies, has the remediation goal expressed as a maximum allowable total concentration of pollutant in the soil. To comply with this approach, the total concentration of pollutant in soil must be lowered and this can be achieved using the group of technologies termed 'clean-up' technologies (Figure 1). The second strategy does not require a reduction in the total concentration of a pollutant in soil, but aims to manage exposure to the pollutant, and hence environmental and health risks, through technologies that lower pollutant mobility and bioavailability. These are termed 'containment' technologies (Figure 1).

In Situ Versus *Ex Situ* Strategies

In situ remediation refers to a soil-treatment regime in which the soil remains confined to its original location throughout the remediation process. Some earth-moving activities may be required in order to ensure complete exposure of the soil to the remedial treatment. Protocols that minimize off-site transport of dusts, vapors, or contaminated liquors are critical. *In situ* strategies have advantages in that costs, and environmental and health risks associated with excavation and off-site transport of polluted soil are reduced. However *ex situ* strategies (transport of

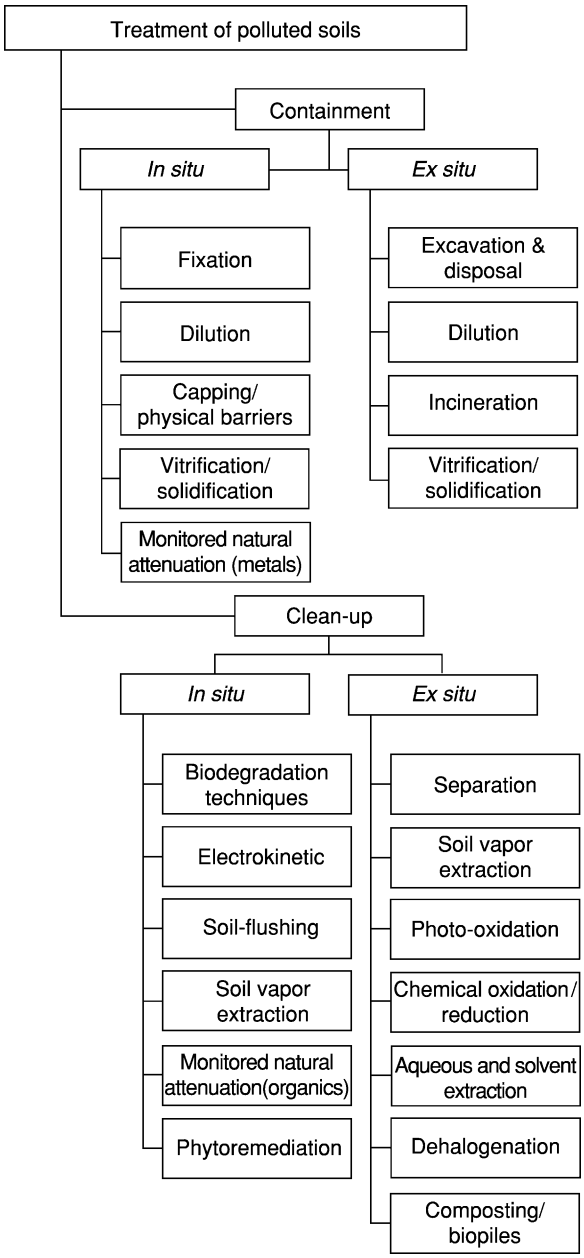

Figure 1 Decision tree of the alternatives available to treat polluted soils.

polluted soils to an external location) may be unavoidable because of impracticalities in establishing essential treatment infrastructure at the polluted site, or due to the site being positioned in a high-risk area.

Physical Treatment Technologies

Excavation and Off-site Disposal (*Ex Situ*, Requires Ongoing Monitoring)

Applicable to both inorganic and organic pollutants, excavation and off-site disposal entails removing the polluted soil from a high-value or vulnerable site to a disposal facility where potential pollutant exposure routes can be more effectively managed. Some pretreatment of the soil may be required to reduce the concentration of readily mobile pollutants in order to meet disposal-facility restrictions. Precautions associated with the excavation and transport of polluted soils need to be taken. This is a rapid method for managing polluted sites which has been widely employed in the past but potentially just relocates the problem and hence is not a remediation treatment *per se*. With landfill space at a premium, leading to rapidly rising disposal costs, this strategy is becoming less acceptable to industry, regulatory bodies, and the public. Ongoing monitoring of the disposal facility to ensure no off-site movement of contaminants is essential.

Dilution (*In Situ* or *Ex Situ*)

Applicable to both inorganic pollutants, including nutrients, and organic pollutants, dilution of soil pollution can be achieved through soil-mixing, deep tillage, or fracturing. It may be effective in reducing the potential contaminant exposure dose at sites in which pollutants are present in low levels or in which contamination is present in small, dispersed 'hot spots.' This method increases the volume of contaminated soil but may be appropriate for management of soils that have been polluted by nutrient oversupply (e.g., soils receiving dairy/piggery effluents). However, dilution is unlikely to meet with regulatory or community acceptance with respect to other types of pollutants.

Capping and Encapsulation (*In Situ*, Requires Ongoing Monitoring)

Applicable to both inorganic and organic pollutants, containment technologies aim to eliminate exposure of humans and the environment to the polluted soil. Lateral or vertical movement of the contaminant (due to water percolation, erosion, or plant root acquisition) is eliminated through the construction of highly reactive and/or impermeable subsurface barriers and surface caps. Both inorganic and organic pollutants may be managed using the monitored natural attenuation strategy. However, as with excavation and off-site disposal, the soil is not cleaned of pollutants, so this is not a permanent remediation solution. Barriers may fail as a result of weathering and/or chemical degradation, settlement, cracking, erosion, poor drainage away from the surface cap, or penetration by deep-rooted vegetation. There is therefore a need for ongoing monitoring of the site to ensure that the barriers and caps have not been breached. Introduction of barriers constructed of materials that either sorb the contaminant or chemically react with it can provide an extra degree of protection against inadvertent contaminant migration. Mobile contaminants, which might otherwise escape through ruptures in the barrier, may instead diffuse toward it and be chemically immobilized.

Separation–Fractionation (*Ex Situ*)

Applicable to both inorganic pollutants, including radionuclides, and organic pollutants, separation and fractionation is based on the principle that contaminants are frequently associated with specific particle-size fractions within soils and uses sieving or sedimentation to separate and remove the contaminated fraction from excavated soils. For example, the most reactive components of soils are generally found within the clay-size fraction ($<2\ \mu$m) due to the high relative surface area of this fraction. Contaminants entering the soil in soluble forms therefore typically partition to, and hence are concentrated in, the clay fraction. Separation of this fraction from the soil produces a highly polluted residue which requires further treatment (e.g., see Incineration, below) or disposal. However, the benefit is that the mass of material requiring further treatment is significantly reduced compared with the original soil. Contaminants may also be present in the form of discrete particles (e.g., lead (Pb) pellets from firing ranges), allowing for removal from the soil using physical sieving techniques. Immiscible organic pollutants may also be isolated from the soil using gravity separation methods.

Electrokinetic Separation (*In Situ*)

Applicable to both inorganic and polar organic pollutants, electrokinetic technology uses the generation of a low-intensity current between electrodes placed in the soil to mobilize and concentrate anionic and cationic pollutants toward the anode and cathode, respectively. The contaminants are then recovered through processes such as electroplating, precipitation, and coprecipitation at the electrode, concentration on ion-exchange resins or physical extraction of the aqueous phase. Soil types amenable to this treatment are those of low permeability (high clay content)

which are poorly drained. This is a new technology, but limited pilot trials show promising results as of 2003.

Soil-Flushing (*In Situ*)

Applicable to both inorganic pollutants, including radionuclides, and organic pollutants, in soil-flushing an aqueous solution (water or water containing contaminant-solubilizing additives) is circulated through the contaminated soil. The pollutant is desorbed from the soil and retrieved from the fluid. The operation usually takes the form of a continuous cycle, with the purified fluid being reinjected back into the contaminated soil, circulated, reextracted, and repurified. This technology performs poorly in soils with low permeability and with pollutants that partition strongly to the soil surface. For soils in which the pollutant has been present for an extended period of time, natural attenuation processes can also markedly reduce pollutant mobility, requiring many flushing cycles to be completed before pollutant concentrations are significantly reduced. These factors can make application of this technology impractical in terms of the timescales needed to complete remediation and associated costs.

Vitrification (*In Situ* or *Ex Situ*, Requires Ongoing Monitoring)

Applicable primarily to inorganic pollutants, especially radionuclides, in vitrification an electric current is used to melt the soil at temperatures up to 2000°C. The melted soil cools to form a chemically stable, leach-resistant, glass-like solid which encases and entraps inorganic pollutants. Organic pollutants are destroyed through pyrolysis at the high temperatures attained. However, this procedure destroys the soil, thereby limiting future site use. Adoption of this method is likely to be limited to inorganic contaminants under extreme cases where pollutant risks are very high, such as may be the case for radionuclide-polluted soils. Given its use for high-risk pollutants, it is important to institute an ongoing monitoring protocol for the solidified mass to ensure that contaminants are not lost over time through leaching or chemical weathering processes.

Solidification (*In Situ* or *Ex Situ*, Requires Ongoing Monitoring)

Applicable primarily to inorganic pollutants, including radionuclides, solidification involves introduction to the polluted soil of a leach- or weathering-resistant material through either mixing or injection which is then allowed to cure to form a solid product. The material acts to prevent pollutant exposure and migration by physically encapsulating the pollutants within a nontoxic, impermeable coating. A wide range of materials have been used in solidification technologies, including: cement, fly ash, bitumen, emulsified asphalt, and polyethylene. The resulting product is not soil but can often be used as a building or construction material. Ongoing monitoring of the final product is necessary to assess contaminant leakage.

Incineration (*Ex Situ*)

Applicable primarily to organic pollutants and pathogens, excavated soil is transferred to a contained facility and heated under controlled conditions in an incinerator. Organic pollutants are vaporized and collected, or destroyed through pyrolysis. Some volatile metals (e.g., mercury (Hg), cadmium (Cd), Pb) may also be released and captured from the exhaust gases. For soils or residues generated from separation–fractionation treatments containing very high concentrations of inorganic pollutants, it may be economically viable to roast or smelt the soil and recover the metal or nutrient for reuse.

Soil Vapor Extraction (*In situ* or *Ex situ*)

Applicable to organic pollutants, in soil vapor extraction, volatile organic contaminants (VOCs) are mobilized and removed from soils through application of a pressure–concentration gradient using a vacuum. Extraction wells are drilled into the soil (*in situ*) or the soil is excavated and placed over a network of perforated pipes (*ex situ*) and the organic pollutants contained within gases extracted following application of the vacuum are collected and destroyed by processes such as pyrolysis or photo-oxidation. Volatilization of the organic contaminants from the soil can be thermally enhanced by steam or hot-air injection, or electrical or electromagnetic heating techniques.

Photo-oxidation (*Ex Situ*)

Applicable to organic pollutants, vacuum-extracted organic pollutants (see Soil vapor extraction, above) are condensed, mixed with catalyst, and fed into a reactor in photo-oxidation. Ultraviolet light (sunlight or artificial) activates the catalyst, causing oxidation of the organic compounds into simple inorganic products, mainly carbon dioxide and water.

Chemical Treatment Technologies

Monitored Natural Attenuation (*In Situ*, Requires Ongoing Monitoring)

Both inorganic and organic pollutants can be managed by a monitoring natural attenuation strategy. The mobility and biological availability of pollutants can decrease with time of contact of pollutants with

soils due to chemical reactions and/or sorption which occur over the long term. The rates of these reactions depend upon the chemical characteristics of both the soil and the pollutant. The rates are difficult to predict, but are possible to measure. For low-risk polluted soils in which there is evidence that natural attenuation is occurring at a satisfactory rate, it may be appropriate to rank these soils as lower priority in terms of requirement for other remedial treatments. Even if contaminant solubility is not of immediate concern, action to reduce movement of polluted soil through erosion needs to be considered to prevent physical transport of contaminants off-site. Factors affecting the potential reversibility of the natural attenuation process are also unclear, so there is an ongoing requirement for monitoring of any site for which natural attenuation is enlisted as the primary 'treatment' strategy.

Fixation–Stabilization (*In Situ* or *Ex Situ*, Requires Ongoing Monitoring)

Applicable primarily to inorganic pollutants, including nutrients. The availability or toxicity of a pollutant is not necessarily related to its total concentration in the soil. This is because contaminants can exist in different chemical forms in soils, and it is primarily the aqueous and easily exchangeable forms which are both mobile and biologically available. Fixation–stabilization technologies aim to decrease the concentration of the aqueous and exchangeable forms of pollutants in soils through the application of nontoxic reactive agents. Agents that have been tested for this purpose include: lime, soluble phosphate compounds, fly ash, clays such as zeolite and also those rich in iron and aluminum oxides (e.g., red mud, steel shots, red gypsum, etc.), as well as mixtures of these materials. Many such agents are by-products from processing industries and so are inexpensive. The agents act either by encouraging the formation of insoluble precipitates of inorganic pollutants or by increasing the amount of pollutant sorbed to the solid phase, thereby decreasing the aqueous concentration of the pollutant. An advantage of this method is that, providing pollutant mobility and availability can be decreased to a satisfactory level, the soil can retain many components of its original functionality. Limitations to use of this technology include soils contaminated with mixed pollutants for which a chemical strategy to manage one of the pollutants is incompatible with the chemistry required to manage another. For example, increasing soil pH can significantly reduce the mobility of metals such as Pb, zinc (Zn), and nickel (Ni) but could result in an increase in the mobility of other co-contaminants such as arsenic (As) and cyanide. Moreover, as with the natural attenuation strategy, care is needed to prevent physical transport of polluted soil offsite, and an ongoing monitoring program may be necessary to assess the continued stability of the fixation treatment.

Chemical Oxidation–Reduction (*Ex Situ*, may Require Monitoring (Inorganics))

Applicable to some inorganic and organic pollutants, chemical oxidation–reduction uses the addition of oxidizing or reducing agents to convert pollutants to less toxic or inert compounds. For example, both Cr and As exist in more than one valence state. Cr(VI) is more toxic and mobile in soils than Cr(III), and As(III) is more toxic and mobile than As(V). Chemical reduction of Cr and oxidation of As can therefore decrease the pollutant toxicity. However, depending on conditions, there is always a risk of reconversion back to the more toxic valence state. Hence it is necessary to institute an ongoing monitoring program to detect this. Biological degradation processes are usually more cost-effective for organic pollutants than chemical oxidation methods and hence tend to be preferred.

Aqueous and Solvent Extraction (*Ex Situ*)

Applicable to inorganic and organic pollutants, in the process of aqueous and solvent extraction, excavated soil is placed in a pile and leached with an extraction fluid, or soil and extraction fluid are mixed in a reactor vessel. The extraction fluid dissolves the pollutants and the fluid is collected and then treated to remove the pollutants. The excavated soil is often pretreated using physical separation techniques to minimize the volume of material required to be extracted. For inorganic pollutants, an acidic aqueous solution which may contain surfactants is typically used as the extraction fluid. Soil pH is neutralized with base following removal of the pollutant. For organic pollutants, the extraction fluid is likely to be an organic solvent. Traces of the solvent may remain in the soil following extraction, so toxicity of the solvent is an important consideration. Low extraction efficiencies for pollutants that are highly attenuated (see Monitored Natural Attenuation, above) can severely limit the performance of this technology.

Dehalogenation (*Ex Situ*)

Applicable to halogenated organic pollutants, dehalogenation, the removal of halogen groups from organic pollutants, generally renders such compounds less toxic or nontoxic. Reagents that catalyze the removal of halogen groups are mixed with polluted soils, and the mixture is heat treated in a reactor

vessel to facilitate the reaction. Due to the cost of reagents, this technology is generally uneconomical for highly polluted soils or large volumes of polluted soil.

Biological Treatment Technologies

Biodegradation Techniques (*In Situ*)

Applicable to organic pollutants, biodegradation techniques are bioremediation clean-up techniques which aim to decrease the total concentration of pollutant in soil through the degradation of organic compounds by microorganisms. The microorganisms involved, also called degraders, are stimulated to use the pollutants as a source of nutrients and energy (enhanced biodegradation). Generally, this is achieved by optimizing the environmental conditions in terms of oxygen, nutrients, and moisture, and controlling the temperature and pH. For instance, the technology known as bioventing aims to stimulate pollutant biodegradation in unsaturated soils by increasing the soil oxygen content. This is achieved by forcing air through the soil by either extraction (vacuum) or injection methods. Specific strains of degraders can also be introduced to the soil to enhance the degradation process in a technology known as bioaugmentation. Typically for this application, microorganisms from the site under remediation are collected and those that preferentially feed on the contaminants at the site are isolated, cultured, and reintroduced to the site as a means of rapidly increasing the population of degraders. Remediation trials have also been conducted using nonindigenous strains of degraders introduced to a polluted site. However, so far there is no conclusive evidence to indicate that the use of non-native microorganisms has been beneficial in the situations tested.

One of the advantages of biodegradation technologies is that they can typically be implemented at a low cost. However the process may require more time than other available treatments. The degradation rate is controlled by both environmental conditions and by the nature of the pollutant. For example, biological treatment of polyaromatic hydrocarbons (PAHs) is selective, and the less-degradable PAHs (of high molecular weight) may remain unchanged. Furthermore, some compounds may be broken down into more toxic by-products during the bioremediation process (e.g., trichloroethylene (TCE) to vinyl chloride). Therefore, continuous monitoring and additional precautions have to be implemented in these cases. Although not all organic compounds are amenable to biodegradation, bioremediation techniques have been used successfully to treat soils polluted by petroleum hydrocarbons, solvents, pesticides, wood preservatives, and other organic chemicals.

Composting and Biopiles, and Slurry-Phase Biological Treatment (*Ex Situ*)

Applicable to organic pollutants, in this suite of technologies, the soil is excavated and mixed with appropriate amendments in order to stimulate microbial degradation of the pollutants. During composting, the microbial activity induces an increase in temperature that allows a faster degradation rate and can also be effective in reducing pathogen numbers. Piles of the material to be remediated can be aerated with blowers or vacuum pumps (aerated static-pile composting), or through periodic mixing with mobile equipment (windrow composting). Alternatively, the compost is placed in a reactor vessel where it is mixed and aerated (mechanically agitated in-vessel composting).

In the slurry-phase biological treatment, the excavated soil is mixed with water and various additives. The slurry is stirred to keep solids suspended and microorganisms in contact with the soil contaminants.

Limitation to this technology can be due to the large area needed for composting, the necessity to control release of VOCs, and the presence of toxic metals, which may impair microbial activity. However, this type of biological treatment has been used successfully to remediate soil contaminated by explosives and PAHs.

Phytoremediation (*In Situ*)

Applicable to both inorganic pollutants, including radionuclides, and organic pollutants, phytoremediation refers to a group of technologies that use green or higher terrestrial plants for treating chemically or radioactively polluted soils. There are five fundamental processes by which plants can be used to remediate soil contaminated with organic or inorganic pollutants. These processes result in the plant-based containment or removal of the soil pollutant. Phytoimmobilization processes prevent the movement and transport of dissolved contaminants by using plants to decrease the mobility of pollutants in soils. Phytostabilization as defined here is the use of pollutant-tolerant plants to mechanically stabilize polluted soils to prevent bulk erosion and airborne transport of pollutants to other environments. In addition, leaching of pollutants may be reduced due to higher evapotranspiration rates relative to bare soils. Phytovolatilization relies on the joint effect of plants and microbes which, acting in concert, are able to convert some metals and organic pollutants to volatile or more available forms. Examples include removal of Se or volatile organic pollutants from soils. In a

different approach, plant biochemistry has been modified by the insertion of bacterial genes that make the transformed plants able to volatilize Hg. Phytoextraction can be used to remediate both metallic and organic constituents from soil by direct uptake into plants and translocation to aboveground biomass. Two phytoextraction approaches are being developed, both aiming to extract toxic metals from soil. The first makes use of hyperaccumulator plants with exceptional metal-accumulating capacity (natural phytoextraction). The second uses high-biomass crops that are induced to take up large amounts of metals by enhancing the mobility of metals in soil with chemical treatments (chemically assisted phytoextraction). This latter method has recently been criticized because enhancing mobilization of toxic metals, to increase plant uptake, is also likely to increase the risk of leaching to groundwater. Phytodegradation refers to enhanced degradation of organic pollutants in soil induced by the action of rhizosphere microorganisms and by plant-derived enzymes. Furthermore, some organic compounds, depending on their chemical and physical characteristics, can be taken up by plants and partially or totally degraded by plant enzymes or endophytic microorganisms. Phytodegradation is also defined as plant-assisted biodegradation, because plant roots supply nutrients to microorganisms, which enhances their biological activities.

This group of technologies have a series of limitations as follows: the depth of the treatment zone is limited by the depth of the root system, high concentrations of the pollutants may be toxic to plants, the process may be seasonal, it is not effective for strongly sorbed contaminants, and may require long times to complete. On the other hand, these technologies are low-cost, environmentally friendly, and thought to be well accepted by the public.

Selection of Remediation Technologies and Future Directions

Once a need for soil remediation is recognized, the best available technology is selected according to the nature, toxicity, and origin of the contaminant, the present and potential hazard related to the degree of contamination, the chemical and physical characteristics of the soil, the land use, the time available for remediation, the community acceptance, and a cost-benefit analysis. These different criteria vary widely in the technologies described above. For instance, the average cost of remediation with different technologies can differ by a factor of greater than 25 (Figure 2). The development of low-cost, low-input technologies, driven in industrialized countries by economic benefits, is also essential to tackle remediation of polluted soils in developing countries.

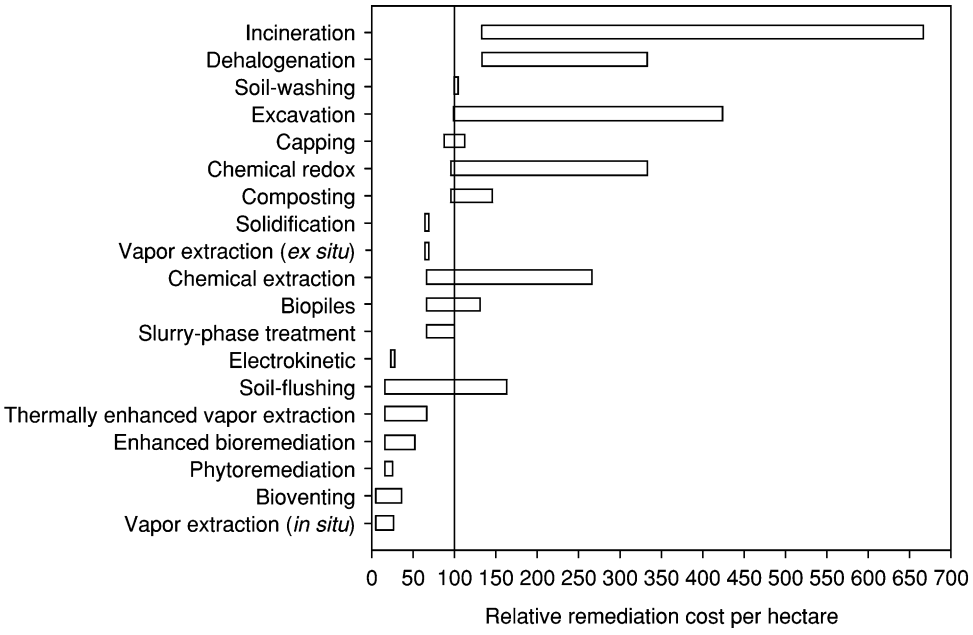

Figure 2 Range of relative remediation costs for different technologies, expressed as a percentage of the cost for capping. Costs are calculated on the basis of the 1 ha area, 0.25 m soil depth, and soil density of 1.2 g cm^{-3}.

Some of the technologies described in this article are well established, whereas others are still being developed. Due to ever-increasing public concern for the risks posed by soil pollution, it is expected that a larger number of technologies will be available in the future. For example, rapid progress in the field of molecular biology will allow a better understanding of the mechanisms involved in bio- and phytoremediation. This knowledge is of fundamental importance in order to optimize these processes. A new field of investigation may also be opened by recent concerns related to the possibility of pathogen-contaminated soils.

Introduction

Remote sensing is the collection and interpretation of data obtained from an object at a remote vantage point without making physical contact with the object or subject. Electromagnetic energy, as shown in Figure 1, may be recorded by a variety of remote-sensing methods. The most common include color and color infrared photography, aerial and satellite imaging, and radar sensing.

Aerial photography records energy in the ultraviolet part of the spectrum (which is not used for agricultural analysis because it is absorbed by the atmosphere), the part visible to humans, and a portion of the near-infrared (NIR) spectrum. Optical sensors record energy in a digital format from the visible, reflective infrared, and thermal infrared spectra from both aerial and satellite platforms within the Earth's atmosphere. Microwave wavelengths are another form of energy important to remote sensing. Microwave energy is received on Earth and the responses recorded by a digital instrument. This is known as 'passive energy,' compared with energy from portions of the spectrum that are measured directly and thus called 'active energy.'

For more than three decades, remote sensing has been envisioned as a useful source of data for inventorying and monitoring the Earth's surface for many purposes. One can apply the use of remote sensing to disciplines in agriculture, hydrology, forestry, oceanography, weather, land use, environmental concerns, security purposes, and military operations.

In the 1950s it was demonstrated that infrared aerial photography could be used to detect vegetation stress. This led to a host of applications and, by the 1960s, the US Weather Bureau was launching satellites to observe cloud patterns around the globe. Weather satellites today are used to monitor not only clouds, but also changes in precipitation patterns by radar, lightning strikes through brightness sensors, and vegetation density changes. They also contribute to predictions of where and when hurricanes are expected to strike land areas.

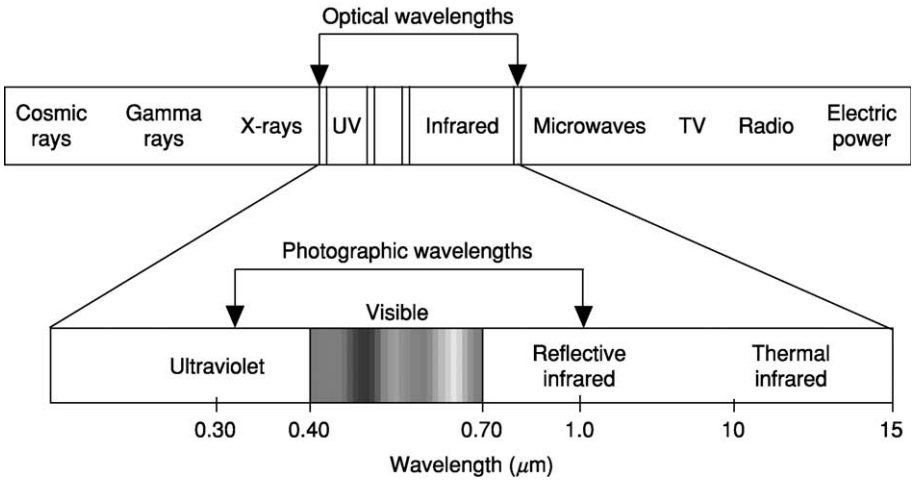

Figure 1 The electromagnetic spectrum showing the wavelengths of energy that are important to remote sensing applications. These include energy measurements from the visible, reflective infrared, thermal infrared, and microwave regions. (Reproduced with permission from Landgrebe DA (2003) *Signal Theory Methods in Multispectral Remote Sensing*. New Jersey: John Wiley.)

However, until recently, satellite data have not been available at a satisfactory temporal frequency for agricultural purposes; that is, they have not had the ability to provide repetitive coverage on a daily basis or 5- to 10-day intervals. The necessary spatial resolution, which is the ability to identify the detail of the measurement at a meter or less, has been provided by commercial satellites only since 1999. Critical needs for remote sensing in agriculture are to provide spatial resolutions of 5–20 m, frequent coverage of 2–5 days, and rapid data delivery to the user.

Aircraft platforms help in rectifying some of the problems associated with satellite acquisition in that spatial resolution can be acquired in the 1- to 5-m range because of smaller sensor viewing areas. Further, aircraft or aerial data collection is not limited to a fixed schedule and/or orbit as is satellite data acquisition. Satellite data are obtained from fixed orbits, provide no data during cloud cover, and have higher cost considerations, all of which users need to consider when acquiring data within a narrow, specific timeframe.

Current trends in the use of remote sensing data in agriculture are driven by goals similar to those of site-specific crop management. The delineation of suitable management units is an important aspect of remote sensing relating to site-specific crop management practices, and remote sensing has great potential to provide soil and crop information for this purpose. One of the most useful aspects of remote sensing is its ability to generate images that show the spatial variation in fields caused by natural and cultural factors without having to depend on costly sampling intervals or geostatistical interpolations. A major challenge is the development of robust image-analysis techniques for delineating soil conditions; another is to provide the proper training to data providers and farmers/producers in the use of this new information.

Early remote sensing research used primarily two approaches: the first was the traditional photointerpretation or visual approach, in which the actual image or photograph was analyzed subjectively by human interpretation. Although this method gave users an overall impression of within-field variation, it also had two crucial shortcomings: first, visual interpretation of black-white or color paper prints depends largely on the interpreter's personal experience and his or her knowledge of field conditions. This leads to the possibility that the results will vary among analysts and over time. Second, the speed of visual interpretation may pose a problem because of the time required to do an exhaustive analysis of the image.

The second approach in the early days of remote sensing, which is more standardized and less labor-intensive than the visual approach, used computer-implemented pattern recognition techniques applied to an image to classify surface soil patterns into different groups or classes. Advances in computer and information technology have overcome concerns related to the large data volume that needs to be analyzed for a successful application.

Mapping of Soils

There are many different soil classification systems used around the world and each is a product of the needs of people, the amount of data available, training, and the technology that was used. Remote sensing techniques are only beginning to show a

positive influence on the way soils are mapped on the Earth's surface. A unified global effort in soil survey and mapping was the FAO/UNESCO Soil Map of the World produced in the late 1960s, with a revised legend in 1988. This effort produced a map at a scale of 1:5 000 000, but did not make use of spatial technologies.

The US Department of Agriculture (USDA) National Resources Conservation Service (NRCS), a partnership of the National Cooperative Soil Survey (NCSS) with local and state agencies and land grant universities within the USA, are generating soil maps and interpretations using Soil Taxonomy. For modern farming practices, these soil surveys typically do not have sufficient resolution to capture natural soil variability in enough detail to support 'precision farming' recommendations, which use technologies such as remote sensing, geographic information systems, and global positioning systems. With the increasing availability of both very high spatial and spectral resolution remote sensing data, the opportunity to redefine soil survey maps is an important benefit.

Another pressing problem related to the use of soil maps, yield-monitoring, or soil samples is that the data are collected at different spatial scales and therefore need to be adjusted in order to make relevant management decisions. Producers have long known that soil variability influences the productive potential of their fields. Because of labor and analysis costs, some highly commercialized producers use a system of soil sampling in small blocks (i.e., grids). These blocks are commonly 0.4 ha (1 acre) to 1 ha (2.5 acres) in size and can be either square or rectangular in shape. This type of sampling scheme requires that soil samples acquired at coarse and/or variant resolutions be interpolated to obtain average soil characterization values at a given finer resolution.

Since natural soil boundaries do not follow straight lines found within the grid system, a producer makes decisions as to which soil is most represented within the grid (Figure 2). Generally, geostatistical analysis is used for this interpolation, based on kriging or inverse-distance weighting. The drawbacks of geostatistical analysis include the need for a large number of samples at close sampling intervals and the assumption of stationary data variation, which is often not the case for soil properties. Remote sensing offers the potential to overcome these drawbacks.

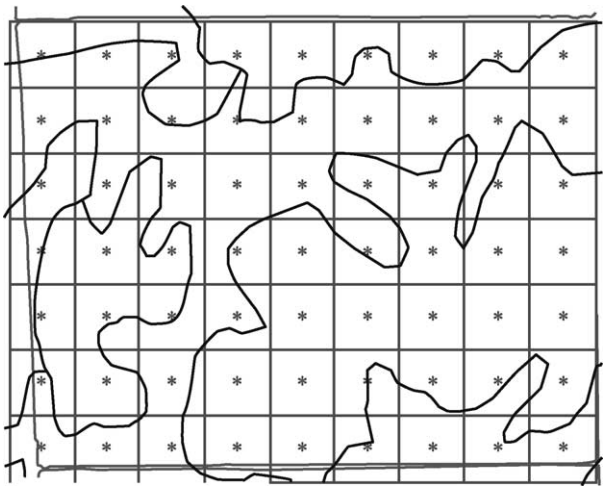

Figure 2 A gridded soil-sampling pattern overlaid on a soil map to illustrate the difficulty in representing the natural soil patterns with this approach.

Remote Sensing for Soil Mapping

Soil scientists have used photography in producing soil maps since the early 1930s. During the first 50 years, much of the interest in photography was related to having a reliable local-to-regional base map. During the 1960s, multispectral remote sensing data were considered of limited use because the evaluated results were compared with existing soil maps generated by conventional methods. The low accuracy attributed to remotely sensed data when compared with existing soil maps was the result of the assumptions that (1) the conventionally prepared soil map is 100% correct, and (2) that the spectral response of the soil surface is determined by the same morphological features used to derive the soil survey maps.

Soil survey mapping units are defined by the soil properties throughout the soil profile that affect management practices, such as drainage, and erosion control; whereas maps of spectral responses are based directly on the spectral properties of only the portion of the soil profile that is exposed at the surface. In laboratory studies, soil reflectance has been successfully correlated with soil properties such as organic carbon, moisture, and total nitrogen under controlled conditions.

With the more recent emphasis on intensive, precision farming, producers have been requesting more detailed field-level soil maps. Current attention is focused on the resolution to be mapped and the soil categories or soil management zones that a producer can use effectively in making management decisions.

We know that (1) soil properties such as organic matter and iron oxides are measured by reflectance or image response, (2) soil surface conditions such as surface roughness influence the response, and (3) remotely sensed imagery of different wavelengths enhances soil patterns so they can be more easily mapped. In summary, the responses of images can be related to soil properties such as organic matter

content, since dark soils (higher organic matter) are less reflective in contrast with light-colored soils (lower organic matter). The vegetation spectral response can also be used to infer various soil conditions such as water-holding capacity, eroded locations, and nutrient differences.

With advances in remote sensing technologies (e.g., digital imaging), such information can now be directly integrated into a geographic information system. The approach commonly taken in studying the feasibility of using imaging devices for soil mapping has been the acquisition and analysis of imagery or other remotely sensed data over a specific area that is then supplemented by limited ground reference data.

There must be an awareness of changes in remote sensing imagery due to surface reflectance, sensor sensitivity, and spectral composition of the sunlight on the area being sensed. For example, if images are obtained over an area every hour throughout the day, the soil surface will have a different soil reflectance during each acquisition caused by the sun's angle. If the surface soil is moist and it is a windy day, the surface soil reflectance will change owing to the drying action (Figure 3).

Automatic pattern-recognition techniques used on aerial sensing data show that different classes of soil surface conditions can be mapped with reasonable accuracy. Since the launch of the Landsat 1 satellite in 1972, much attention has been directed to the relationship of soils and land use. 'Agrophysical units' are defined as geographic areas having definable or comparable agronomic and physical parameters such as soils, which reflect a range in agricultural use and management.

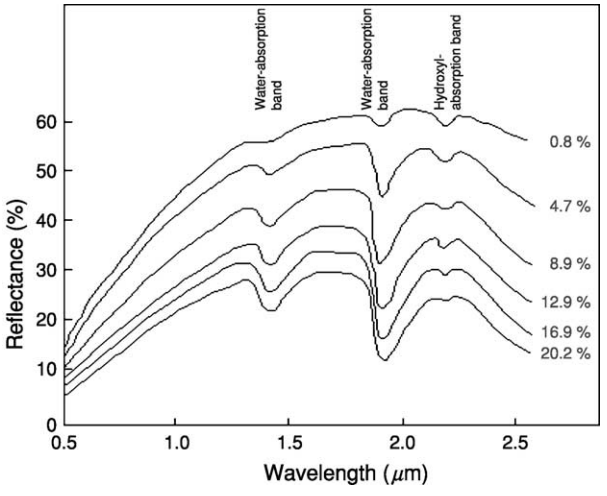

Figure 3 Laboratory spectra of a silt loam soil under different moisture conditions. Soil reflectance decreases in the visible and near infrared region with an increase in soil moisture. This silt loam soil was dried in the laboratory to demonstrate the reflectance change from 0.5 to 2.5 μm. (Adapted from Bowers SA and Hanks RJ (1965) Reflection of radiant energy from soil. *Soil Science* 100: 130–138.)

Early work using visual interpretation of Landsat images provided overlays with acetate transparencies of soil map sheets to investigate relationships of Landsat multispectral data to soil patterns. Although the results vary by geographic regions, there is agreement that the use of satellite or airborne imagery decreases the time required in the soil survey and mapping period and therefore reduces costs. Spectral classification alone cannot distinguish between widely differing soils exhibiting similar spectral responses. By adding ancillary data, a more detailed delineation of soils can be provided as compared to information derived solely from Landsat data. However, these comparisons also reveal some discrepancies between spectral soil maps produced from Landsat data and conventional soil survey maps. One important soil property that has received much focus is soil organic matter.

Organic Matter Detection

Quantitative relationships between soil color and organic matter content are not well quantified because of differences in soil moisture, iron oxides, and other soil properties. However, these relationships are of considerable practical importance in mapping and classifying soils, interpreting soil properties, and designing sensors that can detect soil properties.

Soils of higher organic matter content are generally less reflective or darker in color than those soils with lower organic matter content; therefore, soil color has long been associated with native soil fertility. Soils with thick, dark surface horizons are often separated from other soils in many soil classification systems, which emphasize the importance of these soils both as a medium for plant growth and also as an indicator of land value for agricultural and urban uses.

Accurate and timely information about soil organic matter is essential for agricultural production and environmental research. During the past three decades, high-altitude remote sensing coupled with laboratory-based reflectance spectroscopy has emerged as an important technology for monitoring the Earth's agricultural resources.

Although data from currently operational reflectance sensors such as Landsat, SPOT, and a host of other public and private sensors (Table 1) have proven useful for crop identification and wetland inventory, attempts to characterize soils have attained only limited success. The major difficulty in deriving soil information from remotely sensed data is the

complex nature of relationships between soil parameters and reflectance. Organic matter, moisture, texture, cation exchange capacity (CEC), mineral oxides, and surface conditions such as residue cover and soil crusting have demonstrated unique influences on soil reflectance. These relationships are wavelength-dependent; therefore, the soil parameters may affect reflectance differently in different regions of the spectrum.

In glaciated soil regions, high organic soils can be readily differentiated in high-resolution satellite images from soils formed under prairie grass vegetation and soils formed under forest vegetation (Figure 4).

Several problems have been encountered when viewing the soil with an electro-optic sensor. These problems can be reduced if one has collected reference information on ground conditions. Bare soil areas with high-residue content from the previous crop may mask soil spectral responses (Figure 5). The use of high spatial digital terrain models

Figure 4 Soil patterns as seen on an Ikonos color infrared image (24 May 2000) of the Purdue University Agronomy Center for Research and Education (ACRE, W. Lafayette, Indiana, USA) and surrounding area. The dark soils (Mollisols) are higher in organic matter and derived under grassland vegetation, while the lighter soils (Alfisols) have low surface soil organic matter and are derived under forest vegetation. Red shows healthy vegetation; white, streets, roadways, and buildings; dark green to black, areas of high organic matter and high surface moisture of soils; light-green areas, low surface soil organic matter, some of which are muted by high surface residues from the previous crop. © Space Imaging 2000.

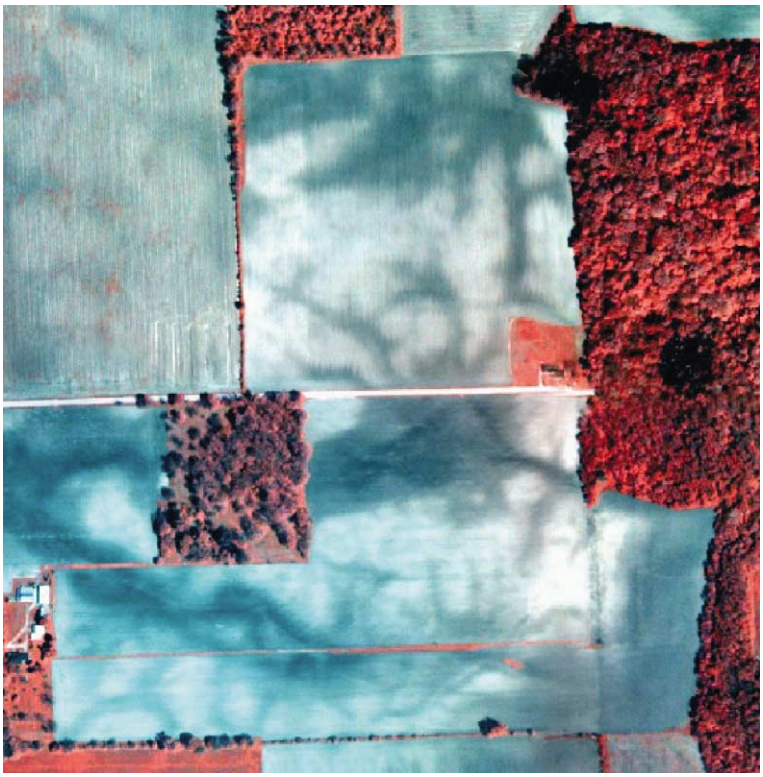

Figure 5 Aerial color infrared image showing soil patterns over an eastern Indiana farming area. The darker areas are higher in organic matter content and were previously wetland areas. The field in the upper left does not have the same soil patterns, since residues from the previous year cover it. Red shows healthy vegetation such as grasses and bushes; maroon, trees (the color resulting from the leaves, branch spacing, and shadows); white, roads and buildings; dark green to black, areas of high organic matter; light green, low surface soil organic matter content. Muted lined patterns masking the normal colors are corn residues from the previous crop. Courtesy of Emerge.

(DEM) produced by remote microwave or laser techniques can provide a better understanding of soil formation and surface moisture movement and aid in interpreting surface soil organic matter content.

Sensing soil organic matter from airborne or satellite platforms requires reference data. Soil types whose classifications are driven by soil color and all of the previously mentioned parameters may have as much variation in soil properties from within a given soil type as they do between different soil types. Many different methods have been developed for the calibration of soil organic matter sensors. Most involve a given sequence of soils of about the same age, related parent material, and similar climatic conditions, but characterized by variations in topography and drainage. Laboratory studies have measured soil reflectance, attempting to quantify the relationship between soil color and organic matter content by comparing the soil spectra with soil Munsell values.

Most studies have concluded that NIR predictions of organic matter and soil moisture become less accurate as one considers soil samples from a wider geographic range. Low correlations between reflectance and organic carbon content have been attributed to the confounding effects of texture, mineralogy, and soil moisture. It is expected that high-resolution (temporal, spatial, and spectral) reflectance data will lead to a better understanding of the relationships between these and other soil properties and reflectance.

Investigations have attempted to link reflectance to specific organic matter components. Typically these studies fractionate organic matter into pools such as humic acid, fulvic acid, and the remaining mineral components; then each fraction is analyzed using a spectrophotometer. It has been shown that even small amounts of organic material may be particularly effective in masking mineral features in the shorter wavelengths. It appears that unfractionated soils and their mineral components are important influences on reflectance with regard to examining organic carbon content in relation to other soil properties.

Table 2 Importance of spectral bands based on response of soil reflectance to organic carbon (OC) content, parent material, and other soil properties

Soils within similar parent materials (northern soils)			*Soils across different parent materials (all soils)*

Source: Henderson TL, Baumgardner MF, Franzmeier DP, Stott DE, and Coster DC (1992) High dimensional reflectance analysis of soil organic matter. *Soil Science Society of America Journal* 56: 865–872, with permission.

To examine specific effects of organic carbon on soil reflectance, researchers have tested differing spectral response in separable bands in terms of observable soil properties such as sand, silt, clay, iron oxides, magnesium oxides, and organic carbon. The separable bands of the inorganic fractions (in which the extractable organic matter and humic acid have been removed) are compared with the separable bands from the soils that are unfractionated. There is a direct relationship between organic carbon and soil reflectance in the set of bands in question: as soil organic carbon increases reflectance decreases. The organic matter contained within the soil is the physical factor responsible for spectral differences in this set of bands (Table 2).

In Table 2, the first column lists the bands that respond to organic carbon content only. In these bands, higher organic carbon content causes a decreased measure of reflectance. The first three of the 12 optimal bands are in the NIR portion of the spectrum (700–1300 nm), with the others in the middle-infrared (MIR) region (1300–2500 nm). The second column lists bands in which soil reflectance responds to both organic carbon and other soil properties. These bands include the entire visible range of the spectrum (400–700 nm) and some in the NIR and MIR region; they are useful because the organic carbon content masks the effect of the mineral soil properties. The wavelengths in column 3 should be avoided when classifying organic carbon content. Although the soil curves are separable in the bands listed, the spectral response in these bands is unrelated to organic carbon content, since no direct relationship between organic carbon content and the magnitude of the spectral response in those wavelengths exists.

The Future

The hyperspectral format contains up to several hundred wavelength bands and provides the potential for differentiating more specific soil properties. Note that current studies have used only three to four bands of data, which are very broad bands. The hyperspectral bands would be very narrow in terms of the wavelengths covered. The spectral mapping of specific soil properties will provide further assistance to soil pedologists in the development of soil surveys.

Recent advances in precision farming technologies require an accurate representation of yield-limiting variables, which include soil properties. Producers have used soil type maps, as they are related to soil organic matter, to help in management practices such as fertility application, herbicide placement, and seed spacing. When coupled with the adoption of global positioning satellites and geographic information system technologies, accurate soil organic matter maps allow for greater precision in performing management practices.

Advances in remote sensing technology are providing a new way to 'see' soil properties and agricultural fields. The provision of geographically accurate soils data assists producers to adjust their application rates of fertilizers and pesticides according to soil properties. This helps producers to increase profits

and to provide environmentally safer approaches to producing food.

Soil Moisture

T J Jackson, USDA Agricultural Research Service, Beltsville, MD, USA

Soil moisture mapping using remote sensing is becoming a reality. Soil moisture has been difficult to measure and map using conventional ground-based technologies. Microwave remote sensing-based soil-moisture retrieval has been demonstrated using tower and aircraft instruments; however, the implementation of this approach on satellites has been limited by both technology and availability. Developments in both science and associated technologies now make the exploitation of the microwave region for soil moisture mapping feasible. A review of the basic principles, operational retrieval algorithms, aircraft applications, and current and future satellite missions is presented.

Microwave Remote Sensing of Surface Soil Moisture

Microwave sensors, especially those operating at lower microwave frequencies (<6 GHz), are of particular value in soil moisture measurement because they respond to the amount of water in the soil. When this technique is used in a remote sensing instrument, the surface layer of soil contributes to the microwave sensor measurement.

Microwave remote sensing can provide a direct measurement of the surface soil moisture for a range of vegetation-cover conditions within reasonable error bounds. Two basic approaches are used, passive and active. In passive methods, the natural thermal emission of the land surface (or brightness temperature) is measured at microwave wavelengths, using very sensitive detectors. In active methods or radar, a microwave pulse is sent and received. The power of the received signal is compared to that which was sent to determine the backscattering coefficient.

The microwave region of the electromagnetic spectrum consists of frequencies of 0.3–30 GHz. This region is subdivided into bands, which are often

referred to by a lettering system. Some of the relevant bands that are used in Earth remote sensing are: K (18–27 GHz), X (8–12 GHz), C (4–8 GHz), and L (1–2 GHz). Within these bands, only small ranges are protected for scientific applications, such as radioastronomy and passive sensing of the Earth's surface. Communications and other uses can contaminate the unprotected regions of this electromagnetic region. This contamination is called radiofrequency interference and it is becoming a greater problem each year.

A general advantage of microwave sensors (in contrast to visible and infrared) is that observations can be made through cloud cover, because the atmosphere is nearly transparent, particularly at frequencies <10 GHz. In addition, these measurements are not dependent on solar illumination and can be made at any time of the day or night. Instruments can be mounted on trucks, aircraft, and spacecraft for repetitive large-area observations.

Microwave sensors operating at very low microwave frequencies (<6 GHz) provide the best soil moisture information. At low frequencies, attenuation and scattering problems associated with the atmosphere and vegetation are less significant, the instruments respond to a deeper soil layer, and a higher sensitivity to soil water content is present.

As noted above, there are two microwave remote sensing approaches, passive and active. Each has unique capabilities and limitations that must be matched with specific types of applications. Currently, passive microwave remote sensing offers more robust and well-validated retrieval algorithms. However, it is limited by spatial resolution at satellite altitudes. Very large antenna sizes are required to achieve high spatial resolutions. Getting these into space at a reasonable cost has been a limitation for quite some time. Currently, products are limited to 50 km resolution; however, future systems will provide 10 km products. Passive systems can provide daily global coverage. Active microwave techniques can provide very high spatial resolution data from space (10–20 m) but suffer from weak soil moisture algorithms. The temporal repeat of these systems is also very limited, typically over 30 days.

Reflectivity and Soil Moisture

Active and passive sensors provide different types of measurements, which are determined by various physical phenomena. However, both types of sensor provide information on the surface reflectivity. The essential relationship needed to utilize microwave remote sensing is a link between reflectivity and soil moisture.

Assuming that the Earth is a plane surface with surface geometric variations and volume discontinuities much less than the wavelength, only refraction and absorption of the media need to be considered. This situation permits the use of the Fresnel reflection equations as a model of the system. These equations predict the surface reflectivity (r) as a function of dielectric constant (k) and the viewing angle (θ), based on the polarization of the sensor (horizontal-H or vertical-V).

$$r^{\mathrm{H}} = \left| \frac{\cos\theta - \sqrt{\mathrm{k} - \sin^2\theta}}{\cos\theta + \sqrt{\mathrm{k} - \sin^2\theta}} \right|^2 \qquad [1]$$

$$r^{\mathrm{V}} = \left| \frac{\mathrm{k}\cos\theta - \sqrt{\mathrm{k} - \sin^2\theta}}{\mathrm{k}\cos\theta + \sqrt{\mathrm{k} - \sin^2\theta}} \right|^2 \qquad [2]$$

The Fresnel equations apply when the two media at the interface each have uniform dielectric properties. From the reflectivity, the dielectric constant of the soil can be estimated. The dielectric constant of soil is a composite of the values of its components: air, soil, and water. Although the dielectric constant is a complex number, for soil mixtures the imaginary part is small and can be ignored for computational purposes without introducing significant error. Values of the real part of the dielectric constant for air and dry soil particles are 1 and 5, respectively. Therefore, a very dry soil has a dielectric constant of about 3. Water has a value of about 80 at low frequencies. The basic reason microwave remote sensing is capable of providing soil moisture information is this large difference between the dielectric constants of water and the other components. Because the dielectric constant is a volume property, the volumetric fraction of each component is involved in the computation of the mixture dielectric constant. The computation of the mixture dielectric constant (soil, air, and water) has been the subject of several studies, and different theories exist as to the exact form of the mixing equation.

The dielectric constant of water referred to above is that of free water, in which the molecules are able to rotate and align with an electrical field. However, not all the water in soil satisfies this condition. Some water in the soil has different properties. The initial water added to dry soil below a 'transition' water content is held more tightly by the soil particles and has the dielectric properties of frozen water (~3).

Based upon the discussion above, four components must be considered in computing the dielectric constant of soil: air, soil particles, bound water, and free

water. Thus, in order to interpret the data correctly, some knowledge of the soil texture is needed. All dielectric mixing models incorporate this information. Based on an estimate of the mixture dielectric constant derived from the Fresnel equations and information on the soil texture, volumetric soil moisture can be estimated using an inversion of the model.

Various theories describe the reflection resulting from a soil profile with uniform or varying properties. The computations involve a nonlinear weighting that decays with depth. Some modeling studies suggest that this dominant depth is one-tenth the wavelength. Field experiments suggest that the contributing depth is about one-quarter the wavelength. At a frequency of 6 GHz this depth would be about 1.5 cm and at 1.4 GHz about 5 cm.

Passive Microwave Techniques

Passive microwave remote sensing utilizes radiometers that measure the natural thermal radio emission within a narrow band centered on a particular frequency. The measurement provided is the brightness temperature in degrees Kelvin, T_B, which includes contributions from the atmosphere, reflected sky radiation, and the land surface. Atmospheric contributions are negligible at frequencies <10 GHz, and the following section assumes this to be the case. Galactic and cosmic radiation contribute to sky radiation and have a known value that varies very little in the frequency range used for observations of soil water content (T_{sky} ~4 K). The observed brightness temperature of a surface is equal to its emissivity (e_{obs}) multiplied by its physical temperature (T). The observed emissivity is equal to 1 minus the reflectivity, which provides the link to the Fresnel equations and soil moisture for passive microwave remote sensing.

Based upon the above and neglecting atmospheric contributions, for a specific frequency (f), polarization (p), and viewing angle (θ) the equation for T_B is:

$$T_{B_{fp\theta}} = e_{\mathrm{obs}_{fp\theta}} T + (1 - e_{\mathrm{obs}_{fp\theta}}) T_{sky} \qquad [3]$$

The second term of eqn [3] is about 2 K. A typical range of response for a soil is 60 K; therefore, the reflected sky contribution can be dropped for computational purposes. Eqn [3] can be rearranged as follows:

$$e_{\mathrm{obs}_{fp\theta}} = T_{B_{fp\theta}} / T \qquad [4]$$

If the physical temperature is estimated independently, the emissivity can be determined from T_B. The physical temperature can be estimated using surrogates based on satellite surface temperature, air-temperature observations, or forecast model predictions. As noted above, the derived emissivity is for a specific instrument configuration (frequency, polarization, and viewing angle).

For natural conditions, varying degrees of vegetation type and density are likely to be encountered. The presence of vegetation has a major impact on the microwave measurement. Vegetation reduces the sensitivity of the retrieval algorithm to changes in soil water content by attenuating the soil signal and by adding a microwave emission of its own to the microwave measurement. This attenuation increases with increasing microwave frequency, which is another important reason for using lower frequencies. Attenuation is characterized by the optical depth of the vegetation canopy. A widely used correction for these effects uses information on the vegetation type (parameter b) and the vegetation water content (W_{veg}) as follows:

$$e_{\mathrm{surf}_{fp\theta}} = 1 + [e_{\mathrm{obs}_{fp\theta}} - 1]\exp[-2b W_{veg} \cos\theta] \qquad [5]$$

The corrected emissivity represents that of the soil surface (e_{surf}). Methods have been developed for estimating the vegetation-type parameter (typically derived from land cover) and vegetation water content using visible/near-infrared remote sensing.

After performing the vegetation correction, one can obtain an estimate of the emissivity of the soil surface, which includes the effects of surface roughness. These effects must also be removed in order to determine the equivalent smooth-surface soil emissivity, which is required for the Fresnel equation inversion. Techniques are available for doing this that use statistical characterization of the surface heights and land-use information.

Figure 1 is a simulated set of curves showing the relationship between soil moisture and emissivity for bare soil and vegetated conditions. Vegetation decreases the sensitivity to soil moisture. Errors in the model, parameters, and the precision of measurements become more important and at some point will overwhelm the information in the observation.

Active Microwave Methods

Active microwave sensors or radars measure the sent and received power to yield a variable called the backscattering coefficient (σ^0). The backscattering coefficient is related to the surface reflectivity. As described previously, the reflectivity is then used to determine surface soil moisture. For active techniques, the link between the measurement of the backscattering coefficient and the surface

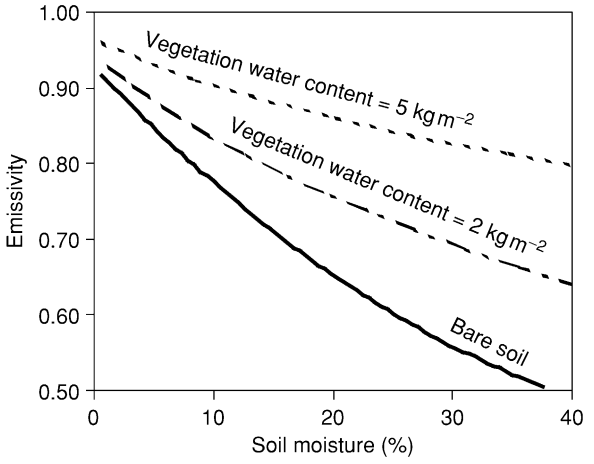

Figure 1 Relationships between soil moisture and emissivity for bare soil and vegetation. The configuration is a passive microwave instrument operating at 1.4 GHZ, horizontal polarization, and a 40 degree viewing angle.

reflectivity is more complex than for passive methods. The geometric properties of the soil surface and vegetation have a greater effect on these measurements and simple correction procedures are difficult to develop.

The signals sent and received by a radar are usually linearly polarized, either horizontal (H) or vertical (V). Possible combinations are HH, VV, HV, and VH. Advanced multipolarization systems can make all of these measurements simultaneously.

For bare soils, all models that relate the backscattering coefficient to soil moisture require at least two soil parameters, the dielectric constant and the surface-height standard deviation. This means that, in order to invert these models, the surface-height standard deviation must be accurately estimated.

For a given sensor configuration of frequency and viewing angle, different results are obtained at different polarizations. Therefore, most approaches to determining soil moisture with active microwave methods utilize dual polarization measurements. With two independent measurements of two dependent variables, both the dielectric constant and the surface height standard deviation can be solved for. Algorithms incorporating this approach for bare soils are available in the literature. A robust approach to account for vegetation has not yet been developed and validated.

Active microwave sensors on aircraft and spacecraft typically employ synthetic aperture radar (SAR), which utilizes the motion of the platform to synthesize larger antennas. Exceptional spatial resolutions with footprints of about 20 m can be achieved from satellite altitudes.

Aircraft Platforms and Application Example

Aircraft-based microwave instruments are especially useful in studies requiring the mapping of large areas. In most cases, they offer better spatial resolution (as low as several meters) than satellite systems, as well as more control over the frequency and timing of coverage. Many of the recent soil moisture studies have utilized the electronically scanned thinned-array radiometer (ESTAR). ESTAR is an L-band H-polarized passive microwave instrument that provides image products. It is also a prototype for a new type of sensor system that uses synthetic aperture antenna technology to solve the high-altitude spatial resolution problem described earlier.

Several active-microwave aircraft systems are in operation. One of the most widely used for studies related to soil moisture is the AIRSAR, operated by NASA Jet Propulsion Laboratory. The AIRSAR flies on a DC-8 aircraft and provides multipolarization data at frequencies of 5.2, 1.2, and 0.4 GHz (C, L, and P-band). It is very efficient for mapping large areas and provides exceptional spatial resolution, on the order of several meters.

Perhaps the most informative and widely studied aircraft data set is that obtained from Washita'92. This was a large-scale study of remote sensing and hydrology conducted using ESTAR over the Little Washita watershed in southwestern Oklahoma, USA. Passive and active microwave observations were made over a 9-day period in June 1992. The watershed was saturated with a great deal of standing water at the outset of the study. During the experiment, no rainfall occurred and observations of surface soil-water content exhibited a dry-down pattern over the period. Observations of surface soil-water content were made at sites distributed over the area. Significant variations in the level and rate of change in surface soil-water content were noted over areas dominated by different soil textures.

Passive microwave observations were made on 8 of the 9 days of the study period. The ESTAR data were processed to produce brightness-temperature maps of a 740-km^2 area at a 200-m resolution on each of the 8 days. Using the retrieval algorithm of soil water content, these brightness-temperature data were converted to images of soil-water content. Gray-scale images for each day are shown in Figure 2. These data exhibit significant spatial and temporal patterns. Spatial patterns are associated with soil textures, and temporal patterns are associated with drainage and evaporative processes.

Follow-on analyses revealed that these types of observations had potential in determining the

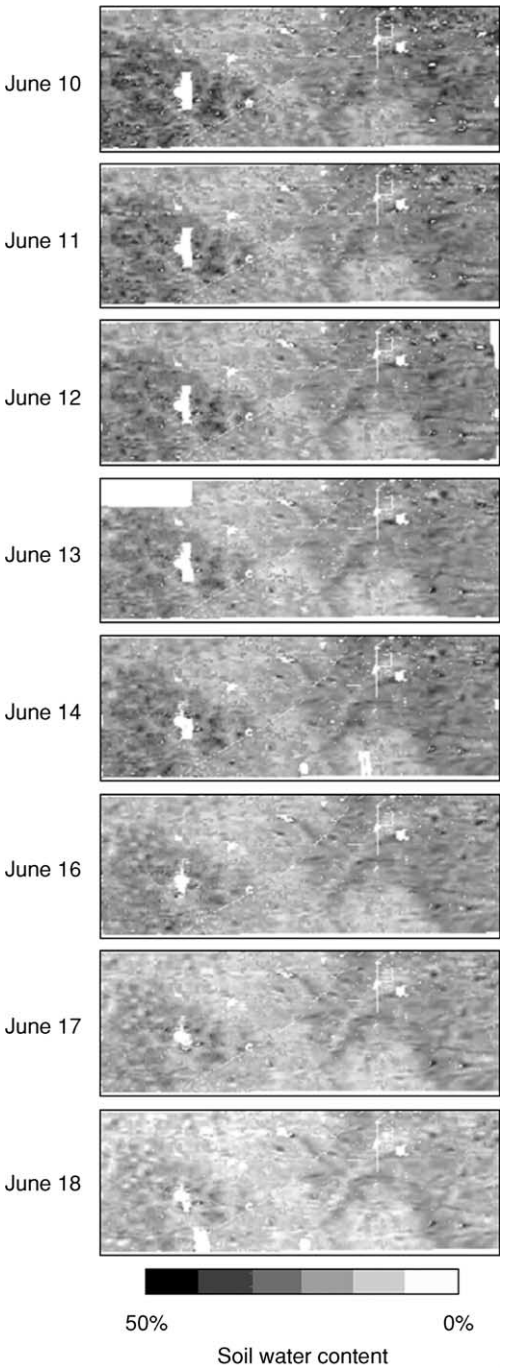

Figure 2 Maps of soil water content for the Little Washita watershed (Oklahoma, USA) derived from passive microwave data for June 1992. Spatial resolution is 200 m.

hydraulic properties of the soils. Like soil moisture, these data can be obtained at the field point scale; the data are not available over large areas, do not take into account spatial variability, and are costly and difficult to obtain. Temporal observations of soil moisture have been used in several investigations to estimate hydraulic properties. These studies constrained the problem by minimizing the role of the surface flux, or by specifying it, in order to estimate the hydraulic properties of the integrated soil profile.

It has been hypothesized that the change in soil-surface moisture following a wetting event and 2 days later could be used to determine the average hydraulic conductivity of the soil profile. Using simulations for soils of different textures, it has been observed that a relationship exists that is strongest for sandy soils and weakens as clay content increases. In addition, it has been observed that a measurement of the 0–5 cm layer provides as much information as a 0–30 cm observation on the deep soil moisture profile. These relationships were affected by evaporation; however, the effect was more significant for soils with lower hydraulic conductivity and with a shallow depth of observation.

This concept has been applied utilizing remotely sensed data from Washita'92 to derive spatially distributed information. As noted above, investigators hypothesized that surface soil-moisture changes could be used to identify soil-texture classes. A conclusion was that even if this method were not highly accurate for each and every sensor resolution element (pixel), the results would significantly improve the definition of the spatial domain of the soil hydraulic properties. In their opinion, this result was more valuable than the accuracy of individual point estimates.

Passive Microwave Satellite Observing Systems and Products

Special Satellite Microwave/Imager

Currently, all passive microwave sensors on satellite platforms operate at high frequencies (>6 GHz) (Table 1). Of particular note, due to the longevity of its data record, is the Special Satellite Microwave/Imager (SSM/I) package on the Defense Meteorological Satellite Platforms. These satellites have been in operation since 1987 and provide high frequencies and two polarizations. Interpreting data from the SSM/I to extract surface information requires accounting for atmospheric effects on the measurement. When one considers the atmospheric correction, the significance of vegetation attenuation, and the shallow contributing depth of soil for these high frequencies, it becomes apparent that the data are of limited value for estimating soil-water content. Spatial resolution of the SSM/I is very coarse (Table 1).

There have been few attempts at generating standard land-surface products using SSM/I data. To date the only standard soil-moisture-related product produced from SSM/I data is the Soil Wetness Index (SWI).

Table 1 Microwave satellite or sensor systems

Satellite	Period of coverage	Frequency (GHz)	Polarization	Spatial resolution of lowest frequency	Repeat frequency (days)
Passive					
SSM/I	1987–present	19.4, 22.2, 37.0, 85.5	H and V	70 km	1–2
TMI	1998–present	10.7, 19.4, 21.3, 37.0, 85.5	H and V	60 km	1
AMSR-E	2002–present	6.9, 10.7, 18.7, 23.8, 36.5, 89.0	H and V	75 km	2–3
Windsat	2003–present	6.8, 10.7, 18.7, 23.8, 37	H and V (U in some channels)	50 km	2–3
SMOS	(2007)	1.4	H and V	50 km	2–3
HYDROS	(2010)	1.4	H and V (passive) HH, VV (active)	40 km (passive) 3 km (active)	2–3
Active					
ERS	1991–present	5.3	VV	30 m	35
Radarsat-1	1995–present	5.3	HH	7 to 100 m	24
Envisat	2002–present	5.3	HH and VV or HH and HV or VV and VH	30 m	35
Radarsat-2	(2005)	5.3	HH, VV, HV and VH	3 to 100 m	24
ALOS	(2005)	1.27	HH or VV and HV or VH	10 to 100 m	46

This index is intended to provide information on significantly wet soil conditions (areal extent of flooding), which can be more reliably detected than variations at lower levels of soil moisture.

A few studies have attempted to extract actual soil moisture from SSM/I data, with some degree of success. For the limited validation data set available the approach performed relatively well. However, part of this may be attributable to the limited conditions and light vegetation conditions evaluated.

Tropical Rainfall Measurement Mission Microwave Imager

Another current option is the Tropical Rainfall Measurement Mission (TRMM) Microwave Imager (TMI). It is a five-frequency, dual-polarized, and passive-microwave radiometer. The lowest TMI frequency is 10 GHz, about half that of the SSM/I. The TMI has a higher spatial resolution (Table 1) as compared to the SSM/I. TRMM only provides coverage of the tropics, which includes latitudes between 38°N and 38°S for the TMI instrument. However, a unique capability of the TMI is its ability to collect data daily, and in many cases more often, within certain latitude ranges. The data from the TMI have been used to generate validated soil-moisture products for 5 years over the southern USA.

Advanced Microwave Scanning Radiometer

Several new multifrequency passive-microwave satellite systems were launched in 2002 and 2003. As opposed to the previously available systems, these offer a lower-frequency channel operating at C band (~6 GHz), which should provide a more robust soil moisture measurement. These satellites were the NASA Aqua, Japanese ADEOS-II, and the US interagency Coriolis satellite. The ADEOS-II satellite stopped operations in October of 2003 and will not be discussed here.

Aqua includes an instrument called the Advanced Microwave Scanning Radiometer (AMSR). AMSR has a 6.9 GHz (C-band) channel with a nominal 60-km spatial resolution. This instrument should be able to provide information about soil-water content in regions of low vegetation cover, less than 1 kg m^{-2} vegetation water content. Aqua collects data at nominal times of 1.30 a.m. and p.m. local time.

As opposed to previous passive-microwave satellite missions, the Aqua project will include soil moisture as a product. The algorithm planned for use by NASA is the multiple-channel approach. The Japanese Aerospace Exploration Agency will also produce a soil-moisture product using one of four algorithms under consideration. Preliminary studies indicate that there is widespread radiofrequency interference (RFI) in the C-band channels. Therefore, it is likely that the most useful channels for soil moisture will be those operating at the slightly higher X band.

The Coriolis satellite includes the Windsat instrument, which is a multifrequency passive microwave radiometer system. It is similar to AMSR with some differences in frequencies and more polarization options. It is a prototype of one component of the next generation of operational polar orbiting satellites that the USA plans to implementing by the year 2010.

Future Passive Systems

Programs are underway to develop and implement space-based systems with a 1.4 GHz (L-band) channel that would provide improved global soil-moisture information. Toward that goal the European Space Agency (ESA) is developing a sensor system called the Soil Moisture Ocean Salinity (SMOS) mission and NASA has initiated a mission called Hydros.

SMOS will utilize two-dimensional synthetic aperture radiometry at L band and provide 40-km H and V polarizations. The ability of SMOS to obtain multiple-incidence angle observations of the surface is the key element of the soil-moisture retrieval algorithm. The launch of the mission is anticipated in 2007.

Hydros will use an active and passive L-band instrument design for mapping at resolutions ranging from 3 to 40 km. Soil moisture will be estimated by Hydros using a microwave radiometer and radar data separately and in combination, taking advantage of the simultaneous, coincident, and complementary nature of the measurements. Hydros is scheduled for 2010.

Active Microwave Satellite Observing Systems

Current Active Systems

At present, several radar satellites are in orbit. ESA has operated a satellite synthetic aperture radar (SAR) series called ERS since 1991, which provides C-band VV data. It includes both a SAR and a scatterometer. Although numerous investigations have been conducted that attempt to utilize ERS SAR data, few results have been reported in the area of soil-moisture estimation. This is due to the limitations of using a single mid-frequency channel single-polarization SAR with an exact repeat cycle of 35 days.

The most recent satellite in the ERS series is called Envisat (launched in 2002) and it has a C-band advanced synthetic aperture radar (ASAR) with multiple polarization capabilities. It also offers the option of varying the incidence angle to allow for different viewing angles and more frequent coverage if angle is not a critical parameter in the application. Data from ASAR are just beginning to be made available to investigators.

The Canadian Space Agency operates a C-band satellite SAR called Radarsat, which offers HH polarization and has a variable viewing angle and a wide swath (large range of incidence angles). These choices offer more frequent temporal coverage of a particular region of the Earth if angle is not important.

There have been a several of attempts at using the single-channel SAR data to retrieve soil moisture. The general consensus from these studies is that there are too many physical variables that have to be known in order to derive soil moisture. These variables include soil moisture, surface roughness, and vegetation. Site-specific studies and creative selection of data sets have resulted in some degree of success.

Future Active Systems

Japan will include an L-band SAR called PALSAR on the Advanced Land Observing System (ALOS) in 2005 or later. PALSAR will have a multipolarization mode as well as varying incidence angles. Canada is developing Radarsat-2, which will be similar to Radarsat-1 but will be fully polarimetric. The satellite will include a mode in which the spatial resolution is 3 m. The expected launch is in 2005.

As noted above, progress in SAR soil moisture mapping has been limited by the available data, single channel. The new generation of multipolarization SAR systems will provide at least one additional measurement. There is hope that more robust soil moisture retrieval methods can be developed as these data become available.

List of Technical Nomenclature

θ	Viewing angle (degrees)
σ^0	Backscattering coefficient (decibels)
b	Vegetation parameter ($m^2\,kg^{-1}$)
e	Emissivity (dimensionless)
f	Frequency (GHz)
k	Dielectric constant (dimensionless)
p	Polarization (dimensionless)
r	Reflectivity (dimensionless)
T	Physical temperature (degrees Kelvin)
T_B	Brightness temperature (degrees Kelvin)
VWC	Soil moisture (volumetric percent)
W_{veg}	Vegetation water content ($kg\,m^{-2}$)

RHIZOSPHERE

A C Kennedy and L Z de Luna, USDA Agricultural Research Service, Pullman, WA, USA

Published by Elsevier Ltd.

Introduction

The rhizosphere is a narrow zone of soil surrounding and influenced by the root of vascular plants. This zone is characterized by intense biological activity owing to the release of root exudates, which stimulate or inhibit rhizosphere organisms. The interactions between the soil, the plant, and organisms that comprise the rhizosphere characterize the complexity and the dynamics of this region. Plant/microbe and plant/faunal interactions abound in the rhizosphere. These interactions range from symbiotic relationships such as N_2 fixation and mycorrhizal associations to pathogenic interactions. Management strategies such as bioremediation and biological control may be successful when rhizosphere ecology is considered. A greater understanding of the rhizosphere and its effects on organisms that inhabit this area will allow for manipulations that benefit plant production and the environment.

Hiltner coined the term 'rhizosphere' in 1904 to describe the zone of soil under the influence of plant roots. His observations were initially based on the interactions between symbiotic N_2-fixing bacteria and the legume root, but were then expanded to include all interactions. This zone of soil ranges from only a few hundred micrometers to greater than 5 mm from the root surface (**Figure 1**). Within this region increased root exudation and changes in physical and chemical soil properties may increase the activity and populations of most soil microorganisms. The rhizosphere is constantly in a state of dynamic flux. Several overlapping gradients in this zone vary with time and distance from the root, and influence rhizosphere colonization by soil organisms.

These gradients and the many interactions within them make the understanding of this zone difficult. The most dramatic gradient in the rhizosphere is formed by nutrients released by the root. Plant roots excrete various organic substances into the

Figure 1 The rhizosphere habitat. rhizosphere, and these substances provide a rich source of nutrients for the microbial community. The greatest exudation arises from those cells involved in cell elongation and lateral root formation. Carbon compounds decline exponentially as the distance from the root increases. Increased exudation can result from extremes in temperature, water stress, P deficiency, increased light intensity, and increased populations of microorganisms. Herbicides, pathogens, foliar treatments, and symbiotic associations may also influence exudation rate. Decreased exudation from the root can result from N deficiency and decreased light intensity. There may also be a relationship between exudate pattern and microbial populations colonizing the root surface (rhizoplane) or the cell layers of the root itself (endorhizosphere).

Plant exudates of high molecular weight, which are primarily released by root tips, form a sheath of slime on the external surface of the root called mucilage. In contrast, mucigel contains plant mucilage and other plant products, as well as bacterial cells and their products. These secretions are important because they help to form and maintain stable soil aggregates. Most soils are extremely low in readily available C, and C-containing substances leaked by the root are of major importance to microbial growth. Exudates can be sugars, amino acids, vitamins, tannins, alkaloids, phosphatides, and other substances such as growth factors, fluorescent substances, nematode cyst or egg-hatching factors, and fungal growth stimulants and inhibitors. Sugars and amino acids, the most-studied root exudates, provide readily available nutrients to the rhizosphere inhabitants and may be a factor in governing susceptibility or resistance of plants to root-infecting fungi.

Plant transpiration can induce severe changes in the water potential at the root surface, which may cause water stress for the organisms near the root as well as reducing the movement of necessary nutrients. Dry soils may inhibit the growth of the root and enhance the release of exudates. Waterlogged soils on the other hand reduce oxygen availability and may increase exudation due to root injury. These conditions may influence the quantity of exudates released and the growth of the microbial and macrofaunal populations in the rhizosphere. Root exudates and the release of H^+, HCO_3^-, or organic compounds, as well as nitrogen nutrition influence rhizosphere pH. Rhizosphere pH can fluctuate as much as one or two pH units over very short time periods. These changes in the soil pH can also affect the growth and survival of the soil biota both positively and negatively. In general, bacteria are negatively affected by low pH, while fungi are not as sensitive to extremes in pH.

Although there is an increase in microbial activity in the rhizosphere, the distribution of those organisms on the root surface is quite variable. Electron micrographs show that microorganisms colonize only 7–15% of the actual root surface. Bacteria are found on the root surface in small colonies at the junctions of epidermal cells or at tears in the root surface (Figure 2). Colonization of the root surface and the rhizosphere is dependent upon factors involving the organisms, the plant, and the environment (Table 1). Microorganisms are thought to move down the root by three different mechanisms: (1) motility of the organism (active transport); (2) water movement on the surface of the root (passive transport); and (3) movement of microorganisms on the root apex as the root cells elongate (passive transport).

Organisms in the Rhizosphere

Bacteria

Rhizosphere bacteria play vital roles in plant nutrition, growth promotion, and disease interactions. Several studies have indicated that bacteria are the most numerous inhabitants of the rhizosphere, although they account for only a small portion of the total

biomass due to their small size. Typically, a 1-g sample of rhizosphere soil contains approximately 10^8–10^{12} bacterial cells; Gram-negative bacteria predominate in the rhizosphere; of these, the most efficient bacterial root colonizers belong to the genus *Pseudomonas*. Actinomycetes are filamentous chemoorganotrophic bacteria that form asexual spores. Populations of these bacteria are usually higher in rhizosphere than in nonrhizosphere soil. There are indications that actinomycetes may comprise higher percentages of the total bacterial numbers than fluorescent pseudomonads in the root zone of some plants. Although some actinomycetes may cause plant diseases, many species have the potential to produce antibiotics that could impact plant–microbe interactions, such as nodulation in legumes or biocontrol efforts against plant pathogens.

Fungi

Fungi are eukaryotic, nonphotosynthetic, spore-forming organisms that are primarily responsible for residue decomposition and organic matter accumulation through the mineralization of cellulose, lignin, and other organic materials. In the rhizosphere and rhizoplane, fungi may function as symbionts, pathogens, nutrient sinks, and a food source for other soil microorganisms. Fungal mycelia also bind soil particles together to form aggregates.

Fauna

Animals that spend part or all of their lives in close association with plant roots and have significant effects on the structural and functional properties of the rhizosphere make up the rhizosphere fauna. Soil fauna are classified into three types based on body size. Single-celled animals such as protozoa belong to the microfauna, while rotifers, nematodes, and microarthropods are classified as mesofauna. Earthworms, millipedes, centipedes, and insects comprise the macrofauna.

Microfauna (protozoa) Protozoa are eukaryotic, unicellular organisms, most of which are microscopic in size, although some members may attain macroscopic dimensions. While the group exhibits differences in feeding behavior, all require a water film for metabolic activity. It is estimated that there are between 10^4 and 10^5 protozoa per gram of soil. Populations of protozoa are generally higher in rhizosphere soil (R) than bulk soil (S), with large numbers occurring in hotspots such as around dead plant roots. Protozoa feed on bacteria and fungi and thus contribute to the mineralization of N, leading to an increase in N uptake by plants. When rhizosphere protozoa prey on bacteria, up to 60% of the excess N and P is excreted in forms that can be readily utilized by plants. Plants may also benefit from the suppression of pathogenic bacteria and fungi by protozoa in the rhizosphere. Detrimental effects of

protozoa include a suppression of *Rhizobium* populations in the rhizosphere, resulting in reduced root nodulation of *Phaseolus vulgaris*.

Mesofauna (nematodes and microarthropods) Nematodes are microscopic, unsegmented, round worms, usually 0.5–2.0 mm in length. There are five trophic groups of nematodes: bacterivores, which feed on bacteria; fungivores, which feed on fungal mycelia; predators, which feed on other nematodes and small invertebrates; omnivores, which feed on a variety of foods; and herbivores, which are plant parasites. Nematodes play a significant role in mineral cycling. Their consumption of bacteria and other food sources results in excretion of N, mainly in the form of ammonia, and enhanced mineralization of P and S in some systems. Nematodes are also very important in agriculture, because some species are parasitic on crops. Feeding by these plant-parasitic nematodes results in wilting, nutrient-deficiency symptoms, yield losses, and other problems linked to damaged root systems.

Microarthropods such as mites (Acari: Arachnida) and springtails (Collembola: Insecta), are a major fraction of the mesofauna present in soils; however, they generally do not harm plants. Although some soil mites prey on nematodes and other small arthropods, they are generally fungal feeders. A few species pierce roots and suck plant sap, ingest roots, or feed on decomposing plant matter.

Table 2 Activities of organisms in the rhizosphere

Decomposition of plant residue and organic material
Humus synthesis
Mineralization of organic N, S, and P
Increased plant nutrient availability of P, Mn, Fe, Zn, Cu
Symbiotic mycorrhizal associations
Production of organic chelating agents
Oxidation–reduction reactions
P solubilization
Biological dinitrogen fixation
Free-living bacteria and blue-green algae
Associative microorganisms
Symbiotic legume and nonlegume
Plant growth promotion
Production of plant growth hormones
Protection against root pathogens and pseudopathogens
Enhanced nutrient-use efficiency
Plant growth inhibition
Pathogenicity by root pathogens
Growth reduction by deleterious rhizobacteria
Biological control
Reduction of plant diseases
Inhibition of soil nematodes and insects
Reduction in weed growth
Bioremediation
Degradation of industrial and agricultural chemicals
Volatilization of metal contaminants
Hyperaccumulation of metals in plant tissues
Enhanced drought tolerance of plants
Improved soil aggregation

Interactions in the Rhizosphere

There are a myriad of interactions occurring in the rhizosphere (Table 2). The most studied of these are N_2-fixation, mycorrhizal associations, plant growth promotion, and plant growth inhibition. In recent years, bioremediation and biological control have also been investigated.

Dinitrogen-Fixation Symbiosis

Dinitrogen-fixing bacteria can make otherwise unavailable N_2 available to the plant. Rhizobia and related bacteria form nodules on the roots of plants. This interaction can be mutually beneficial as the plant provides nutrients and protection for the bacteria and the bacteria provide N for the plant. Other N_2-fixing organisms form associations with plants. These bacteria colonize the root surface and interior cells, and intercellular spaces between the cortex and endodermis and in the xylem cells of grasses. Along with plant-available N, they may provide other plant growth-promoting compounds also.

Mycorrhizal Associations

Mycorrhizal fungi form a mutualistic symbiosis with plants and infect roots without causing root disease. These fungi can be found in the rhizosphere of most plants and form associations with all gymnosperms and more than 83% of dicotyledonous and 79% of monocotyledonous plants. Mycorrhizal fungi can form structures either on the outside (ectomychorrhizae) or inside (endomycorrhizae) of plant roots. The fungal hyphae allow the roots to contact a greater volume of soil. Some types of mycorrhizal fungi increase the solubilization of nutrients such as phosphorus. They assist the plant in increasing nutrient absorption, especially in stressed environments (e.g., phosphorus- and water-deficient soils), selective ion uptake, and provide protection from extremes in the environment. Plant exudation patterns may be altered after colonization by these fungi, thus affecting the rhizosphere microbial and macrofaunal communities. The fungi may also protect plant roots from invasion by pathogens. Extraradicle hyphae of endomycorrhizae secrete glomalin, a glycoprotein

that aggregates soil particles, increasing water-stable aggregates and improving soil structure. This association can increase the survival and growth of a plant, especially in adverse or low-nutrient environments, and may have potential in the revegetation of disturbed sites.

Plant Growth-Promoting Organisms

Plant growth-promoting organisms are those organisms that in some way enhance the growth of plants. Plant growth-promoting organisms enhance seed germination and plant growth and are often specific bacteria or fungi. Many different mechanisms are responsible for plant growth promotion. These organisms have been used in biological control programs to protect plants against plant pathogens, as biofertilizers to fix atmospheric N_2, and in phytostimulation, which directly improves plant growth through the production of plant growth regulators. Some may make nitrogen more available to plants and have the potential to reduce application of inorganic fertilizers. These organisms may produce plant growth-stimulating compounds such as gibberellic and indoleacetic acid. The reduction in pathogen load may also be a mechanism of plant growth promotion. Iron-chelating compounds called siderophores can function to make iron more available to an organism and less available to the plant pathogen, thus impairing the pathogen. Since iron is a key nutrient in metabolism and a cofactor in enzyme activity, microbial growth may be influenced by these siderophores. The microbial populations that colonize the interior of the root and form intimate associations with the root are considered endophytes. Endophytic bacteria may increase plant growth, confer disease resistance, and aid the plant in withstanding stresses such as drought. The success of endophytes in colonizing the rhizosphere may be the ability of the microorganism to compete with other bacteria on the external or internal portions of plant roots. Introduction of plant growth-promoting organisms may change the overall composition of the microbial community, especially in the rhizosphere.

Plant Growth-Inhibiting Organisms

Organisms that inhibit plant growth colonize the rhizosphere and can alter plant development. Plant growth inhibition can occur with or without disease symptoms. The rhizosphere harbors pathogens such as fungi and bacteria that attack germinating seeds and plant roots. Pathogens may produce extracellular enzymes that liquefy cell walls, thereby allowing degradation of the cell contents. Some pathogens produce toxins that affect the permeability of the cell membrane or inhibit an enzyme, leading to interruptions in a metabolic pathway. These microbial toxins may affect many species across different plant families or they may be host-specific. Polysaccharides produced by some pathogens may block vascular tissues and cause wilting. Excessive production of auxins and cytokinins, resulting from integration of a tumor-inducing bacterial plasmid into the plant genome, leads to gall formation in the roots. Feeding by plant-parasitic nematodes exposes root cells to destructive enzymes and toxic metabolites, which ultimately result in decreased water and nutrient uptake in plants. Puncture wounds from the feeding process could also become infection courts for the entry of other microbial pathogens into the roots. Deleterious rhizobacteria (DRB) inhibit plant growth without causing obvious disease symptoms. These organisms are present on the root surface and may occur in the intercellular spaces of cortical cells. DRB do not parasitize the plant, but survive on organic compounds released by plant root cells. Their detrimental effects on plant growth are due mainly to the production of metabolites that disturb plant physiological processes, including phytotoxins, plant growth regulators, volatile substances, or antibiotics. Their colonization and inhibition are often found to be species- or cultivar-specific, and root exudates may play a part in some plant–DRB interactions.

Bioremediation

Industrial development and intensification of agriculture in the past several decades have contributed to environmental contamination, releasing hazardous wastes into terrestrial ecosystems. Due to their toxic and carcinogenic nature, and tendency to bioaccumulate in humans and other organisms, the timely and cost-effective clean-up of contaminated areas has become a priority. Plant–microbial systems have shown potential in bioremediation, a process that utilizes the natural role of plants and microorganisms in transformation, mineralization, and complexation of organic and inorganic pollutants. In contrast to conventional soil remediation technologies, bioremediation is less costly, utilizes relatively simple technology, and is minimally disruptive to the contaminated site. Bioremediation may be facilitated by plant root exudates that show high binding affinities to certain pollutants or by rhizosphere microorganisms that mineralize contaminants into their nontoxic derivatives.

Plant roots, together with their associated microbial communities, may enhance mineralization of hazardous compounds in the soil. The 'rhizosphere effect' on bioremediation may occur in several ways. First, it is thought that carbon substrates from roots stimulate increases in xenobiotic degrader populations and activity. Second, the presence of dense populations of diverse microorganisms in the rhizosphere may enhance bacterial conjugation, which could result in the evolution of new pathways of degradation. Third, plants may provide a substrate that increases the production of the enzymes involved in mineralization of the hazardous compound. Rhizosphere organisms can influence the degradation of recalcitrant compounds in the soil (Table 3). Rhizosphere microorganisms may also facilitate the

removal of metal contaminants such as mercury, selenium, and zinc from the soil. Bacterial isolates and consortia have been extensively studied in bioremediation, but fungi, actinomycetes, mycorrhizal associations, and even rhizosphere fauna have shown degrading abilities. Clearly, the greatest challenge in bioremediation technology is the elucidation of mechanisms involved in remediation of contaminated sites by plants and their associated organisms. This knowledge will allow for the selection and engineering of the best plant–microbe combinations and optimization of the remediation process.

Biological Control

The rhizosphere is the location for biological control interactions that make use of pathogens, parasites, or other predators to reduce the population or activity of another organism. Three major strategies for biological control are classical, inundative, and integrated management. The classic approach involves the use of natural enemies for release, dissemination, and self-perpetuation on target pests. The inundative approach is most often used in the rhizosphere and involves the addition of a virulent strain of a biocontrol agent to suppress pests. In this case, the biocontrol agent is not self-sustaining and must be applied to the target host every season. The integrated management approach is a broad strategy that involves management practices to conserve or enhance native enemies of pests.

Biological control can be used in the management of pathogens, nematodes, and weeds. The use of biological control in disease management allows for alternatives to chemical control (Table 4). The interactions of organisms in the rhizosphere and the ecological significance of these interactions that occur in the root and seed environment assist in the success of biocontrol strategies. The reduction in plant pathogens such as *Fusarium oxysporum*, *Gaeumannomyces graminis*, *Pythium*, and *Phytophthora* species due to suppressiveness of some soils is thought to be due to physiochemical and microbial soil factors. The suppression is specific and may have various mechanisms. The mechanisms can include antibiosis, production of siderophores or volatile compounds, parasitism, competition for nutrients, and competition for ecologic niches and induced disease resistance. Crop monoculture can, with time, result in a decrease in disease due to the development of disease-suppressive soils. Other management practices that may alter the rhizosphere environment and be considered as biocontrol approaches are crop rotation, soil amendments, cover cropping, fumigation, or soil solarization.

Fungal pathogens of protozoa and nematodes can be used in biological control of these plant pests. Fungal mycelial growth into the cortical cells is thought to assist in controlling clubroot disease caused by protozoa. Plant-parasitic nematodes alter the exudate patterns of the plant as they feed. This in turn changes the microbial community of the rhizosphere at these sites, which affects the colonization of the fungal and bacterial antagonists of the nematodes. One of the more interesting and most studied fungal interactions for biological control is the use of nematode-trapping fungi to reduce nematode populations.

Table 4 Examples of plant diseases for which potential biological control agents have been identified

Disease	*Host plant(s)*	*Antagonist*

Verticillium wilt (*Verticillium dahliae*)	Eggplant	*Talaromyces flavus*
	Pepper	*Pythium oligandrum*

[a]Nonpathogenic strain.

These predatory fungal species produce many different types of trapping structures such as constricting rings and adhesive knobs or hyphal meshes. However, the factors that induce significant predaceous behavior need to be studied further.

Soil microorganisms that have potential in weed management have been increasingly studied in recent years. Fungal and bacterial pathogens of weeds that attack weed seeds or cause root damage are in various stages of development as biological control agents. These organisms may reduce weed populations through weed inhibition or mortality. Deleterious rhizobacteria that are host-specific have been isolated from many grass and broadleaf weed species. Bacteria have been shown to inhibit winter annual grass weeds and velvetleaf (*Abutilon theophrasti* Medik.). Rhizosphere fungi may also be used to control weeds. Propagules of *Fusarium oxysporum* f. sp. *erythroxyli* applied to soil results in vascular wilt symptoms and death of cocoa plants. The saprophytic, soilborne fungus *Gliocladium virens* produces viridiol, a steroidal phytotoxin that causes severe root necrosis in susceptible weed seedlings. Isolates belonging to *Fusarium* spp. have also shown promise for biological control of leafy spurge. Future development of biological control strategies require ecologic investigations of these systems and will enhance pest-management programs.

Summary

The rhizosphere is a dynamic region governed by complex interactions between plants and the organisms that are in close association with the root. The composition and pattern of root exudates affect microbial activity and population numbers, which in turn have an impact on the nematodes and microarthropods that share this environment. Beneficial or harmful relationships exist between rhizosphere organisms and plants, which ultimately affect root function and plant growth. In addition, the rhizosphere may include organisms that do not directly benefit or harm plants but clearly influence plant growth and productivity. A better understanding of the soil–root and soil–seed interface is needed to manage microorganisms, increase plant growth, and reduce the impact of plant production and agriculture on the environment. The benefits of studying the rhizosphere include the use of plant growth-promoting organisms and the suppression of plant diseases and weeds using biocontrol agents. Rhizosphere organisms can also be used to enhance the formation of stable soil aggregates and as bioremediation agents of contaminated soils. With greater understanding of the ecology and biota in the rhizosphere, this zone of increased nutrients, biotic activity, and interactions can be manipulated to improve plant productivity and environmental quality.

RICHARDS, LORENZO A.

W R Gardner, Texas A & M University, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Most soil physicists, past or present, would agree that L.A. Richards was one of the pre-eminent soil physicists of the twentieth century. Although he was primarily an experimentalist, his name will always be associated with the equation describing the movement of water in unsaturated soil, one of the most useful equations in soil physics.

Richards was born in Fielding, Utah, on 24 April, 1904, and died in Riverside, California on 12 March, 1993. Fielding is a small agricultural community some 25 miles (40 km) west of Logan, which is the site of Utah State University. This proximity was fortunate for Ren (as he was known to his friends), because it made it possible for him to attend Utah Agricultural College (UAC) (as it was then called), as did three of his brothers, Bert L. Richards, Matthias C. Richards, and Sterling J. Richards. He married Zilla Linford, whose family was also replete with scientists. Among them were her brothers Maurice, Leon, Hooper, and Henry. Ren, Sterling, and Leon all majored in physics. Ren and his brother Sterling eventually ended up in Riverside, California, working in soil physics.

All three studied physics at the UAC under Willard Gardner, who received the eighth PhD in physics from the University of California in Berkeley. From this association came Ren's first scientific publications entitled 'The usefulness of capillary potential in soil moisture and plant investigations.' This paper summarized the current understanding of capillary potential as described by Edgar Buckingham and later expanded by Willard Gardner. It went on, however, to describe the principles and construction of the tensiometer and proposed a tension plate apparatus. The latter was intended for use on small samples of soil in the laboratory. He included in the paper water retention data as a function of capillary potential for four soils, some of the first data published. Following the work of Buckingham and Gardner, Richards also extended Darcy's law to unsaturated soils:

$$V = -\mathrm{K}\ \mathrm{grad}\Phi \qquad [1]$$

where V is the flux density of the water, K is the permeability, and Φ is the capillary potential. Possibly influenced by his older brother Bert, who was a plant scientist, Ren went on to consider the availability of water to plants as it moved through the soil to plant roots. He pointed out that the term 'availability' involves two notions: namely the ability of plant roots to absorb the water with which it is in contact and the readiness or velocity with which the water moves to replace that which has been used by the plant. The first was dependent upon the capillary potential or the security with which the water was held by the soil combined with the osmotic potential or salinity. He was to return often to the problem of the measurement of this property in his later career. The second factor or rate of flow of water to the plant roots should be described by the appropriate solution of eqn [1]. Eqn [1], when combined with the equation of continuity:

$$q = -\rho\partial\theta/\partial t \qquad [2]$$

yields:

$$\begin{aligned}\partial\theta/\partial t = {} & \partial(D\partial\theta/\partial \mathrm{x})\partial \mathrm{x} \\ & + \partial(D\partial\theta/\partial \mathrm{y})\partial \mathrm{y} \\ & + \partial(D\partial\theta/\partial \mathrm{z})\partial \mathrm{z} \\ & + \partial \mathrm{K}/\partial \mathrm{z}\end{aligned} \qquad [3]$$

where θ is the soil water content and D is the soil water diffusivity and ρ is the bulk density of the soil.

Eqn [3] is known as Richards' equation. It was not widely attributed to him until towards the end of his scientific career, but will undoubtedly always carry his name. The equation can also be written in terms of the matric or capillary potential ψ. There seems to be little doubt that eqn [3], or at least the capillary form of the equation, was known at Logan during the time that Ren was a graduate student there; however, it was not published until Richards included it as an important element in his PhD thesis from Cornell. It is appropriate that he be given the credit for it. His thesis, published in 1931, was titled 'Capillary conduction of liquids through porous medium.' In this Richards used two parallel porous fired ceramic plates to apply a differential pressure across a sample of soil and measured the flux between the plates. By varying the pressure across the plates he could maintain a variable degree of unsaturation in the soil. He had suggested the use of porous plates to evaluate the capillary potential of soil samples in his master's thesis. His PhD was apparently the first actual use of such plates.

After graduation from Cornell University with his PhD, Richards, like most physicists of that day, had difficulty in finding a job to his liking. Finally in 1935

he was offered a position at Iowa State University with a joint appointment in both the Physics and the Agronomy Departments. Here he began to apply his ideas to real problems and began to make his mark as an experimental physicist.

At that time the tensiometer was largely a novelty. At Logan he was introduced to the principle. The first attempts usually consisted of a glass funnel to which a porous plate was attached across the mouth of the funnel. Securing the plate to the funnel without leakage proved almost impossible. It was most fortuitous for the future of soil physics that Zilla Richards developed into a skilled ceramist. Ren and Zilla's collaboration eventually resulted in ceramic tubes which could be sealed very effectively to copper (and later acrylic) tubing and remain leakproof for days and eventually weeks. The diffusion of air through the ceramic then became the major limitation to their use, and this could be dealt with by periodic refilling with de-aired water.

Richards studied the use of tensiometers in field soils and in lysimeters and demonstrated their practicality and utility. During this time he also explored a number of other physical properties of soils, including the use of thermojunctions for the measurement of the relative humidity of soils. This particular problem was to occupy much of his time for the remainder of his career. Ren devised a method for measuring the flow of water in soils. He and his only student, M.B. Russell, studied the heat of wetting of soils and he and other colleagues pursued the use of tensiometers in the field.

In 1938 Ren was offered a position at the US Salinity Laboratory. Here he established a soil physics program which attracted visitors from all over the world and found an ideal scientific home for his researches for the remainder of his career. At this laboratory he continued to perfect the tensiometer and developed the pressure-membrane and pressure-plate apparatus. The pressure-membrane apparatus was initially conceived as a means of extracting water from soil by applying pressure to a soil sample supported on a porous membrane, with the entire apparatus contained in a brass chamber vented to the atmosphere below the membrane. However it soon became apparent that by increasing the air pressure by increments to 15 atmospheres and measuring the water remaining in the soil sample the capillary potential could be measured. As anticipated by Richards, this proved to be a significant advance.

Richards' work on soil physics was interrupted in 1943 by World War II when Ren joined the staff of the Jet Propulsion Laboratory at the California Institute of Technology. Here he worked on sea-borne rocket launchers. He worked with the diligence and insight that characterized all his research, and he was able to see this project through to completion and traveled to the Pacific Theater of Operations to observe the launchers in action. He eventually obtained several patents on his design. These he added to most of the early patents on tensiometers and pressure plates.

Upon his return to the Salinity Laboratory at the war's end, he completed his work on the pressure-membrane apparatus. After satisfying himself that the sausage casing which he initially used for the membrane was permeable to water but not to salts, he began to employ them widely. The design had one drawback. The membrane was subject to punctures in soil samples that contained small stones and eventually developed leaks. Eventually Zilla succeeded in making increasingly large clay plates, which could withstand pressure up to 15 000 cm (15 atmospheres), the presumed limit for plant growth. These plates were 30 cm in diameter, rendering them suitable for large samples or a large number of small samples. Replacement of the sausage by ceramics made the equipment usable by almost anyone. There rapidly developed such a demand for ceramic cups and plates that Richards set his sons up in a business known as the LARK Instrument Company. This stood for L.A. Richards' kids, who by participating in the manufacture of the ceramics helped pay their way through college.

In 1947 through 1949 Ren published the definitive papers on the measurement of soil moisture tension (capillary pressure). There has been little need for improvement in the equipment since that time. The demand for tensiometers and pressure plates continued to grow until Richards' assistant Percy Skaling set up his own business in order to meet this demand. Skaling was very careful to follow the design of the equipment exactly as described by Richards, except for very minor changes to facilitate manufacture. When colleagues would complain that their own equipment did not seem to work so well as Richards claimed, his response was always the same. He inquired if they had built it exactly as shown and had followed the experimental procedure exactly. They almost always confessed that they had attempted to make improvements in some way. He would tell them to go back into the laboratory and follow his design and instructions to the letter and then if it still did not work he would listen to them. They seldom came back, because he had already tried and discarded almost all variations in favor of the final design.

Ren learned much about soil water properties that is now taken for granted and is often rediscovered at regular intervals. More than any other individual L.A. Richards made soil physics an experimental science, in both field and laboratory. He made it possible to measure with considerable accuracy one of the most fundamental physical properties of soils,

the relation between the soil water content and the capillary (matric) potential. He showed that this relationship was not single-valued but, rather, exhibited hysteresis. The relationship was dependent upon the previous history of wetting and drying and depended in particular upon the number of such cycles a soil sample had been through. To facilitate field measurements of the soil moisture gradient, he developed a multiple tensiometer to measure the matric potential at several depths simultaneously.

Richards always had his eye on the main problem. In a laboratory filled with the best equipment available, most of it of his own design, and with a thorough understanding of the limitations of this equipment, he set himself the task of quantifying most of the known soil physical properties. He often suggested that, at best, we could only measure some of the soil properties on some soils, some of the time. It is still true.

A good estimate of the upper limit of available soil water for plant growth was needed in order to characterize the salinity of a soil. For about 48 h after irrigation the soil continues to drain, albeit ever more slowly. He had already devised the content of 'leaching requirement' for a soil, i.e., the water content at which the drainage rate is equal to the irrigation rate, thus establishing a steady-state soil water content. When the leaching requirement is met, the accumulation rate of salts in the soil no longer continues to increase and the salt content remains constant over the long term. Many attempts were made to determine the water content at which the leaching rate would equal the application rate but, since the drainage rate was more nearly a function of the conductivity of the soil than the water content, these attempts were not very satisfactory. Richards and his colleagues carried out a series of field experiments, and finally suggested that the field capacity concept, i.e., the upper limit of available water, was at best an elusive or approximate concept and had done more harm than good. He concluded that field profiles should be characterized by a curve rather than a single point.

At the other end of the plant growth continuum, the wilting point, the soil water content had been related to the cessation of the elongation of sunflower leaves. Richards developed a freezing-point method to provide a much simpler means of estimating the wilting point of soils.

From his observations of the decreasing rate of outflow from the pressure plate apparatus, Richards concluded that it should be possible to estimate the unsaturated conductivity of the soil as a function of soil water content. A number of individuals attempted this and eventually W.R. Gardner, with Richards' help, succeeded in achieving this by means of a series of successive linear approximations.

Upon completion of the development of the tensiometer and pressure plate apparatus, Richards returned to the thermojunction or thermocouple method of measuring the vapor pressure of soil moisture. This method had the advantage over the tensiometer in that it used the vapor pressure of the soil moisture to measure the total (matric plus osmotic) potential well beyond the tensiometer range and also make measurements on plant or other wet material. This was especially desirable for work in arid regions where the tensiometer was of limited utility. It also had the advantage over the pressure plate apparatus in that it was not limited to soil samples but could be used *in situ* on plants as well as soil. Richards had become familiar with early attempts with this method at Logan, where M.D. Thomas had published work on it. While a student, Ren's brother-in-law Leon Linford had assisted Thomas with the measurements. Later at Iowa State, Ren had begun work on the method but with limited success. At Riverside he devised a constant-temperature bath with a precision approaching one-ten-thousandth of a degree in the hope of measuring the difference between a small droplet of water and temperature of the soil moisture with which it had been equilibrated to within a few hundredths of a degree. Eventually it was with the availability of high-gain electronic amplifiers that Richards was able to eliminate the need for such stable temperatures and also the need for a very precise galvanometer. He finally succeeded in achieving a goal that he had been pursuing for some 30 years. While his colleagues were quick to apply this technology to several problems, Ren was reluctant to use it until it could be applied to plant leaves *in situ* and continued the pursuit of greater sophistication.

While Richards was working on the fundamental problem of measuring the vapor pressure of soil water, he always had two or three lesser problems which he addressed while he thought about the number-one problem. He devised the saturation extract and the portable electrical resistant bridge, which gave a very good approximation of soil salinity. He invented a device for the measurement of the modulus of rupture for soil samples. This was useful in estimating the effect of sodium salts on the crusting of soils, a common problem with alkali soils.

Richards guarded his research time jealously, but at the same time possessed a strong sense of loyalty to the laboratory that afforded him virtually unlimited freedom. Therefore, he accepted the responsibility of editing *Diagnosis and Improvement of Saline and Alkali Soil* better known as Handbook 60. Released in 1954, this handbook became the 'bible' of saline and alkali soils and proved to be one of the most popular and useful US Department of Agriculture

publications. It summarized the information and techniques developed during the first 15 years in the life of the Salinity Laboratory. It is a remarkable document that has stood the test of time, in that many of the concepts and equipment are still valid as a first approximation. A listing of the chapter headings gives a good idea of the scope of the Handbook: (1) Origin and nature of saline and alkali soils; (2) Determination of the properties of saline and alkali soils; (3) Improvement and management of arid and semiarid regions in relation to salinity and alkalinity; (4) Plant response and crop selection for saline and alkali soils; (5) Quality of irrigation water; (6) Methods of soil characterization; (7) Methods of plant culture and analysis; (8) Methods of analysis of irrigation waters.

Chapters 1, 2, 3, and 5, particularly, show Richards' influence. One particular example is the characterization of saline and alkali soils. The Russian school of soil science dealt with saline and alkali soils as though they always were and always would remain so. Handbook 60 assumed that soils could be 'reclaimed' if properly treated and managed. Although Richards was far from the first to espouse this idea, the Handbook gave this concept validity by showing how to achieve and sustain this goal The fact that it has not always been achieved is usually due to improper management, or some impediment to proper management, a *sine qua non*. To put it in Richards' own words, "the question for this laboratory to answer is whether or not irrigated agriculture can be made permanent."

Some 60 years later it would be difficult to improve upon the flow diagram that Richards and his collaborators devised for the diagnosis and reclamation of saline and alkali soils. This Handbook solidified Richards' position not only as the philosopher of the Laboratory but as the philosopher of soil physics. He understood what was important and how it differed from what was merely useful. While he worked from time to time on the latter, he never strayed for long from the former.

As significant as was the equation which bears his name, and the perfection of the tensiometer and invention of the pressure plate, they were eclipsed by Ren's collaboration with C.H. Wadleigh on the chapter in *Soil Water and Plant Growth*. For some time there had been an ongoing controversy between F.J. Veihmeyer at the University of California at Davis on the one side and many physicists and physiologists on the other. The debate centered on the issue of whether soil water was equally available to plants between the upper and lower limits of soil water. Veihmeyer said yes and almost everyone else said no. Wadleigh and Richards researched the American and English literature thoroughly and combined it with their own researches and concluded unequivocally that Veihmeyer was essentially wrong. The problem was in the measurement of soil water. In very sandy soils, especially in the case of fruit trees, Veihmeyer's approximation was not far wrong. In the general case, it was not good enough. Although Veihmeyer remained unconvinced, Richards' and Wadleigh's view has prevailed.

Richards has also had a profound effect upon the terminology of soil physics. In 1940 he published some comments on the permeability units for soils. In 1952 he chaired a committee of the Soil Science Society of America that recommended adoption of units of permeability and infiltration. In 1956, almost in passing, he suggested that the term 'soil suction' be abandoned in favor of the 'matric potential.' He eschewed the term 'capillary potential' because it implied that capillarity was the only physical mechanism influencing the water potential. Such was Richards' influence in the field of soil physics that the term was accepted almost by acclamation and with little public debate.

In 1951–1952 Richards was elected President of the Soil Science Society of America. In this position he succeeded in achieving a long-sought goal. He was able to persuade the Society, which heretofore had published only the papers presented at the Annual Meeting, to change from proceedings to a true journal which published peer-reviewed papers submitted by its members and meeting set standards. It was to be several years before it changed its name to the *Journal of the Soil Science Society of America*, but Richards had made this move inevitable. In 1965, Richards was elected President of the American Society of Agronomy. In this role he provided vigorous leadership to the society and organized and codified the business of the Society with a numerical scheme somewhat analogous to the system used by libraries. This system was sufficiently flexible and easily used so that it was adopted immediately by the Soil Science and the Crop Science Societies and continues in use long after only a few members know where it came from. Well beyond his official retirement Ren continued to work on an automated irrigation system and numerous related patentable devices.

ROOT ARCHITECTURE AND GROWTH

L E Jackson, University of California–Davis, Davis, CA, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Root architecture and root growth are important for exploration of soil for water and nutrients, as the acquisition of these resources drives plant growth. There are a myriad of root forms, ranging from woody roots to root hairs, and many of their various functions still remain unknown. Several important concepts, however, govern the development of roots and their direct and indirect effects on plant growth: (1) roots are highly plastic, i.e., architecture and growth are highly responsive to environmental conditions and therefore can optimize resource acquisition; (2) tradeoffs exist in root form and function. The

costs of producing roots can yield benefits in terms of the acquisition of soil water and nutrients, and ultimately plant growth and fitness; (3) enormous variation exists among plant species in their root responses to abiotic stress; (4) genetic analysis has revealed that root architectural traits are often multigene or quantitative traits; and (5) roots affect attributes of plant communities and ecosystems, due to their effects on resource acquisition, growth, productivity, water budgets, and nutrient cycling.

Description of Roots and Root Architecture

Root systems are composed of the primary root that originates as part of the developing embryo in the seed, postembryonic, shoot-borne roots, and lateral roots that emerge from all root types. In the monocotyledonous plants such as grasses, seminal root axes (also called primary axes) grow out of the developing embryo, while nodal axes (also called secondary, adventitious, crown, or brace roots) subsequently arise from the shoot and gradually replace the seminal axes. In contrast, for dicotyledonous plants, the entire root system originates as a single root in the embryo, from which laterals arise, and which can later become a taproot, and/or thicken and become woody owing to cambial activity. Root hairs are extensions of epidermal cells and vary in length from 0.2 to 2 mm, depending on the species. They are continually being produced near the elongating root tip and are short-lived. Rhizomes, which occur in both types of plants, are underground, elongate stems that can be distinguished from roots by the presence of leaves, leaf scars, or buds.

Root anatomy changes along the growing root. The root tip consists of four overlapping zones (Figure 1): the root cap that protects the meristem, the meristem itself, a region of elongation, and a region of maturation, where root hairs emerge and vascular tissues form. A cross section of the mature root also has several distinctive zones. The epidermis is the outer layer of the root, with the protective exodermis immediately underneath it. These layers surround the cortex, which stores nutrients. The endodermis is the innermost layer of the cortex. The Casparian strip is a waxy substance that is present in endodermal cell walls. It forces water and nutrients to pass through the protoplasts of the endodermal cells, presumably to increase the selective uptake of nutrients and thus regulate ion absorption and accumulation. Within the vascular cylinder of the root, the xylem consists of

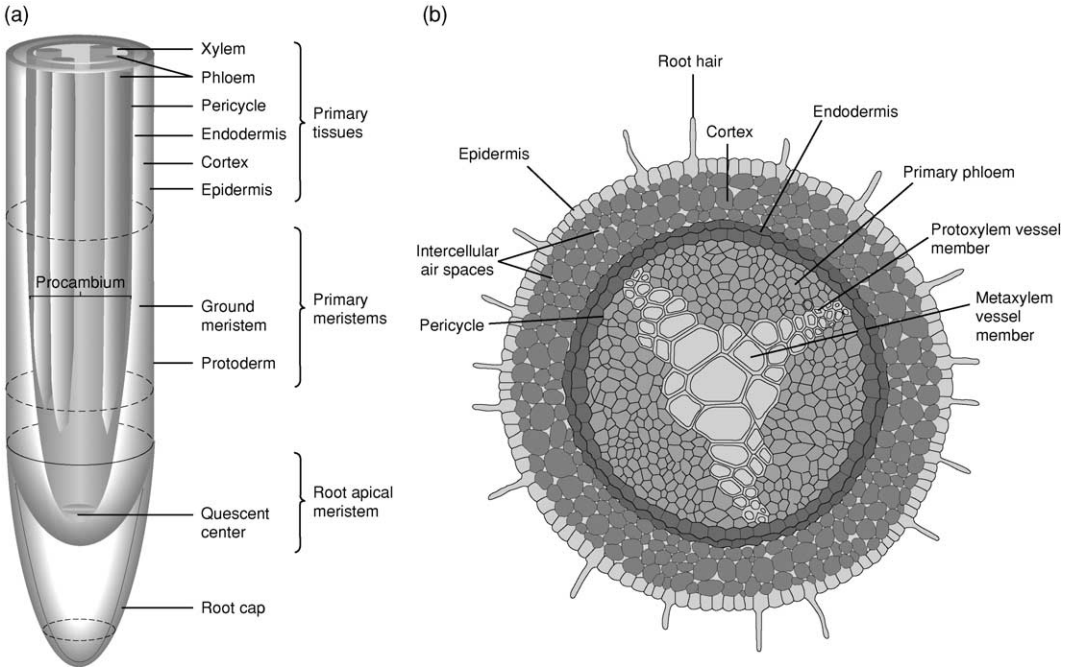

Figure 1 Longitudinal view of a developing root (left) and cross section of a maturing root (right), showing the different tissues, meristems, and differentiation of xylem and phloem elements. The outermost layer is the epidermis and root hairs, and the protective exodermis. In the cortex, there are intercellular air spaces between the cells. The endodermis and pericycle perform specialized functions related to uptake and differentiation, respectively, and surround the vascular cylinder, which contains the xylem and phloem. (Reproduced with permission from Rost TL, Barbour MG, Stocking CR, and Murphy TM (1998) *Plant Biology*. Belmont, CA: Wadsworth Publishing.)

hollow tracheids, which are important for water transport, and phloem elements, which are food-conducting tissue. Within the xylem, protoxylem is the first formed element of the primary xylem. Metaxylem is the part of the primary xylem that differentiates after the protoxylem and before the secondary xylem if any of the latter is formed in a given taxon. Phloem differentiates in the areas between the columns of xylem cells. The pericyle is the outermost boundary of the vascular cylinder. Its long-lived cells are the sites where woody secondary growth originates, as does the bark of woody roots; also lateral roots are initiated here and then grow outward through the cortex and epidermis.

Formation of lateral roots, branching to form clusters of fine roots, differentiation of root hairs, mechanics of soil penetration, and changing root distribution with depth are among the root architectural characteristics that affect nutrient and water acquisition from the soil. In addition, other processes such as nutrient absorption kinetics, root exudates, and microbial activity in the rhizosphere affect nutrient availability and therefore plant uptake of nutrients from the soil. (*See* **Nitrogen in Soils:** Plant Uptake.)

Use of topological models for the description of root architecture has proven to be a useful way to quantify the branching structure of root systems (Figure 2). Topological models consider the number of links and their arrangement: interior links are internodes between two branching points, and external links originate at a branching point and end in a meristem. The number, length, and spatial distribution of internal and external links can be markedly different between even closely related species and can change with developmental age and environmental conditions. In wheat, root axes are produced synchronously with development of specific leaves, and, in other species, vascular connections direct the nutrient and carbon flow between particular shoots and roots. Thus, root topology can be related to shoot development and physiology. Combining topological analysis with measures of root length and allocation, in relation to shoot biomass, provides a robust way of describing the architecture, growth, and response to the environment of a root system (Figure 3).

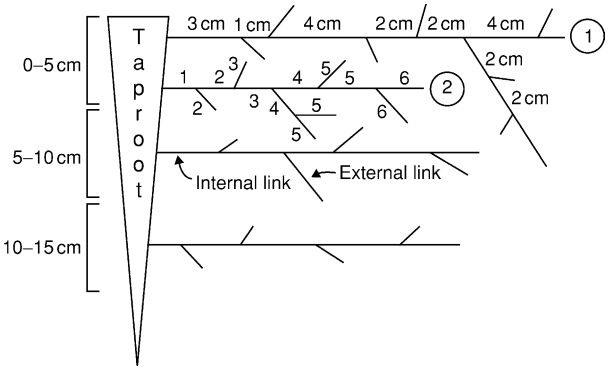

Figure 2 Schematic of the root system of a dicotyledonous species with a taproot, illustrating root topology as described by Fitter. Interior links are between two branching points, and external links originate at a branching point and end in a meristem. The magnitude of the root system or lateral axis is the number of external links (7 for lateral 2), the altitude is the number of links in the longest unique path from the base link to an external link (6 for lateral 2). The numbering on lateral 2 shows all pathlengths. Measurements of length and biomass of the root axes enhance the descriptive information obtained from the topological indices, which theoretically are related to nutrient uptake and growth strategy.

Roots branch in response to endogenous and exogenous factors. The plant hormone auxin has a key role in the initiation of lateral root primordia. It can accumulate at the root apex, which usually exerts some degree of apical dominance, in the developing lateral root primordial, or both. Cytokinins, another type of plant hormone, inhibit lateral root formation. Low nutrient levels, especially of nitrogen, can act as a stress signal that decreases cytokinin content, and this is associated with higher root-biomass allocation. The ratio of auxin and cytokinin concentrations is thought to be important for the regulation of developmental steps for the complete formation of lateral roots. Ethylene, a plant hormone that is involved in root response to stress, can either enhance or repress root growth, depending on its concentration. Plant hormones clearly have important effects on root branching, but the complexity of their interactions is still a major unknown in plant physiology.

Lateral root formation and the relative growth rate of roots are stimulated by nitrate, ammonium, and phosphate, such that highly branched roots and high root-length density are found in enriched soil patches. For immobile ions, root proliferation can increase nutrient uptake from such patches. In contrast, a mobile ion such as nitrate can be readily captured by a root system with low root-length density. It has been hypothesized, however, that localized root proliferation in response to nitrate may be a mechanism by which competing plants can quickly usurp a limiting resource. Water uptake is also enhanced by increased root surface area, even though its transport may be limited by the hydraulic conductivity of the xylem elements in some circumstances.

Tradeoffs in Root Form

Construction and maintenance costs of roots must be considered in the assessment of root architectural patterns. An optimization approach suggests that

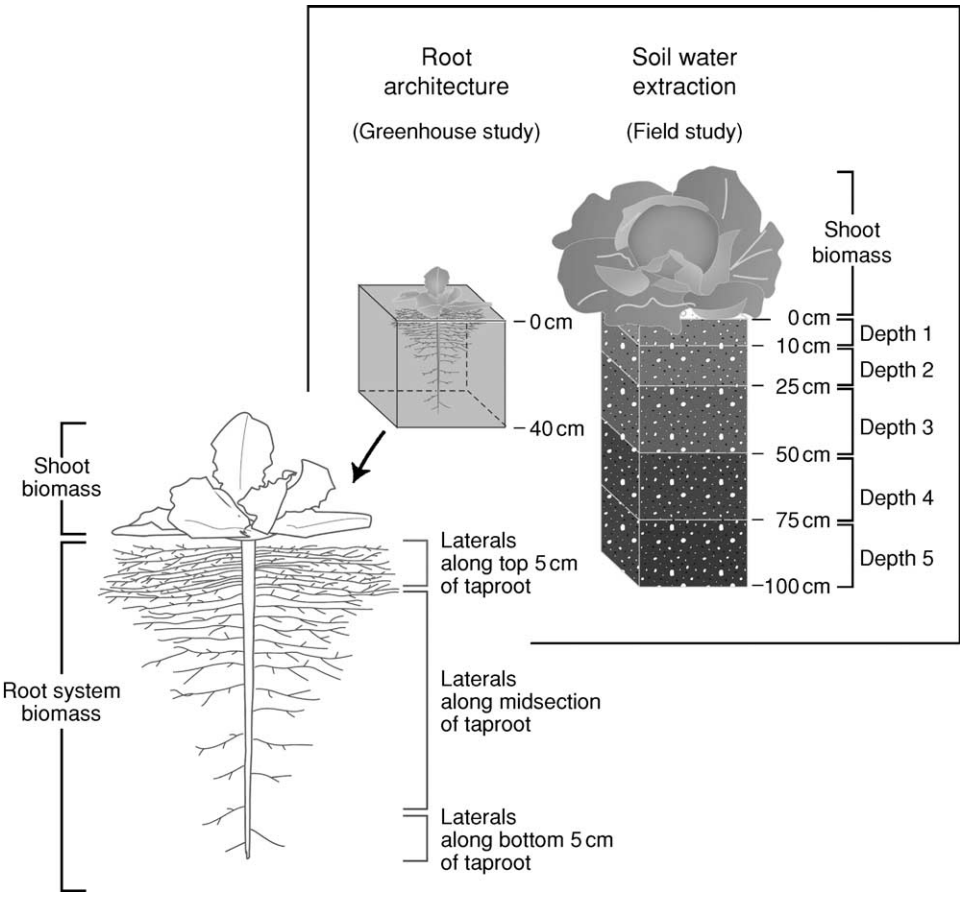

Figure 3 A strategy for examining relationships between root structure and function. In a greenhouse study in pots, root architectural traits were measured, while in a field study, water extraction was measured at different depth increments. When closely related lines of lettuce were tested with both methods, genotypes with higher numbers of laterals near the tip of the taproot or with longer taproots tended to extract more deep water from soil (traits were scaled for biomass), and this resulted in identification of quantitative trait loci (QTL) that could be genetically mapped. (Reproduced with permission from Johnson WC, Jackson LE, Ochoa O, van Wijk R, Peleman J, St. Clair DA, and Michelmore RW (2000) Lettuce, a shallow-rooted crop, and *Lactuca serriola*, its wild progenitor, differ at QTL determining root architecture and deep water extraction. *Theoretical and Applied Genetics* 101: 1066–1073.)

total plant growth will be largest when the root system maximizes nutrient and water acquisition per unit resource supplied by the shoot. Allocation of large amounts of carbohydrates and nutrients to roots may detract from shoot growth, leaf area, and photosynthetic carbon gain, thereby reducing total plant growth, especially if the increased root allocation does not achieve increased rates of nutrient uptake. Under low nutrient availability, root diameter often decreases, and thinner roots are thought to increase the capacity for exploration of soil per unit carbon expenditure than would thicker roots. Roots produced in enriched soil patches can be short-lived, eliminating their maintenance costs when soil depletion causes nutrient acquisition rates to decrease. In contrast, carbon allocation to long-lived storage roots and woody roots, which have high construction costs, limits shoot growth and thus leaf area and the potential for photosynthetic carbon gain; yet long-term beneficial effects for nutrient and water uptake may outweigh these initially negative effects on total growth.

Root Traits for Stress Tolerance

Plants cope with environmental stresses such as drought, soil compaction, salinity, nutrient limitation and imbalances, acid soil, heavy metal toxicity, and waterlogging. Each stress is mediated in part through the root system. Some plant species show highly specific adaptations, involving in many cases root architecture and root growth, to these abiotic stresses, along with certain physiological mechanisms.

Drought tolerance is partially mediated by root characteristics. Some plants have deep root systems that access water that would otherwise be lost to drainage. Another way for roots to exploit deep moisture is hydraulic lift, whereby deep moisture is

transferred at night to upper soil layers with higher root-length density for extraction during the following day. Low root hydraulic conductance is another trait that enables drought avoidance by decreasing the rate at which water is transported to and used by the shoot in dry environments with deeply stored soil water, e.g., Mediterranean-type environments. By restricting water use during the early part of the growing season via low transport rates, more water is available during the latter period of the year when rainfall is absent or minimal. Delayed maturation of the metaxylem vessels in developing roots is one mechanism by which low root hydraulic conductance is achieved. Another example of root-mediated drought tolerance is found in the developmental plasticity of cactus roots, where roots in moist microsites have less lignification and suberization, and higher hydraulic conductivity than roots in dry microsites, thereby apparently maximizing the potential for water uptake from wet patches and minimizing water loss from roots in dry patches.

As soil dries, hydraulic conductivity between the root and soil decreases. Shrinkage of roots also decreases the contact between root and soil. Low transpiration rates ensue, further causing the movement of liquid water by mass flow in the soil to decline. Roots grow through and away from dry sites and toward wetter patches in soil. The root cap is probably the site where this hydrosensing occurs.

Roots in contact with dry soil can be the source of inhibitors of shoot growth and stomatal opening, which in turn limits water loss from the plant. Hydraulic signals that elicit physiological responses to drought move from the roots to the shoots in the transpiration stream, and the hormone abscisic acid (ABA) and root-derived cytokinins appear to play a role in this signaling process. ABA modulates the expression of many genes and physiological processes that protect cells from excessive water loss (*See* **Water-Use Efficiency**), and it also appears to be involved in increasing root growth and consequently root-to-shoot ratio, which would increase water uptake from deeper, moister layers of the soil profile and reduce dehydration when upper layers of the soil profile dry out. Experiments have compared plants with root systems split between well-watered and dry zones of soil, i.e., partial root-zone drying, and a well-watered control. With partial root-zone drying, there can be an increase in water-use efficiency (WUE), along with a decrease in stomatal conductance and total vegetative growth, but little effect on fruit production, presumably because the developing fruit creates a strong sink for carbohydrate partitioning. The mechanisms by which root signals are transported and operate on various plant organs still remains largely unknown, but, even so, partial root-drying may be a potential method to limit water use and still maintain high yields in the commercial production of fruit-bearing crops such as grapes.

In environments where drought is normally a temporary event, maintaining viable roots under drought stress may be advantageous, especially for perennials that benefit from the higher production and maintenance costs of long-lived roots over a period of years. In species from deserts and Mediterranean-type environments, however, where plants intermittently experience severe and long-term soil drought, especially near the soil surface, fine roots are often shed when soil dries, and new root production can occur rapidly after rewetting by rainfall. Many crop species also shed roots in dry surface soil.

Compaction, like soil drying, increases the mechanical impedance to root penetration of soil. In soils with high bulk density, roots become clumped into small pores, since larger pores are scarce, and this limits the soil volume for nutrient and water uptake. While growing through soil, roots must overcome radial, axial, and frictional forces, and there is typically a negative correlation between root elongation rate and penetrometer resistance. The osmotic potential of root cells increases in impeded root tips, possibly as a mechanism to increase cell turgor and soil penetrability. Root impedance by mechanical forces in soil also triggers root signals that reduce leaf expansion and transpiration rates. Reduced leaf-expansive growth and shoot water-loss induced by mechanical stress, even under conditions of high nutrient and water supply, may be responses that prepare the plant for the high probability that these resources may soon become scarce as a result of reduced root growth.

Salinity inhibits root-elongation growth and development in nonhalophytes, and this, in turn, indirectly limits the ability of roots to explore soil for nutrients and water, which decreases the growth rate of the plant. Direct effects of salinity on roots include the osmotic stress from low soil-water potential that can induce both the biosynthesis of costly organic osmolytes to regulate osmotic adjustment in the root and the accumulation of specific ions in the root tissue which can lead to induced toxicities and deficiencies. Salt tolerance is achieved by maintaining a ratio of low levels of Na^+ and high levels of K^+ in the cytoplasm. Elevated Ca^{2+} concentrations in the soil medium can increase the root elongation rate in some plant taxa in saline soils, possibly because there is less displacement of membrane-associated Ca^{2+} by Na^+ than in less salt-tolerant genotypes.

Nutrient limitations are well known to be mediated by continuous root growth into unexplored soil, as well as by high total root surface area, both of which increase the capacity of the root system to take up nutrients. Nutrient bioavailability is mediated by root interception, mass flow, and diffusion (**Figure 4**). As roots grow, they displace soil and intercept available nutrients, for example, adsorbed on to soil particles. This process of root interception, however, is thought to provide only a small proportion of the plant's total nutrient uptake. Mass flow is the transfer of water and dissolved nutrients to the root surface and is driven by transpiration. Rates of diffusion, i.e., transport in soil along the concentration gradient, depend on the mobility and effective diffusion coefficients of specific ions, soil replenishment, and plant uptake. When transpiration rates are high, large quantities of water and dissolved solutes travel to the root via mass flow, but, when soils dry, diffusion of nutrients becomes the main way by which roots access nutrients.

Both old and newer regions of the root are important for nutrient absorption. Even though older parts of the root system are more suberized and may be surrounded by depletion zones, they have been shown to be capable of high potentials for nutrient uptake in laboratory experiments. Since they constitute a large proportion of the root surface area of the plant, they are probably important for a considerable proportion of total nutrient uptake. The highest rates of nutrient uptake per unit root length, however, are found in the region just behind the root apex, where root hairs are most abundant.

Nutrient-poor soils elicit several changes in root morphology, as well as physiology, such as increased capacity for nutrient uptake (*See* **Nitrogen in Soils: Plant Uptake**) but the degree of these responses can be very different among plant taxa. Higher root-to-shoot ratios and lower total root biomass typically occur with nutrient deprivation.

Phosphate (P), an immobile nutrient, does not move readily to the root by either mass flow or diffusion. P-deficient soils tend to cause large changes in a number of root characteristics. Under low-phosphate conditions, roots become thinner and the elongation of laterals increases, especially those at higher orders, i.e., near the meristematic tips of each lateral root axis, and leaf expansion and surface area decline. Also, more root hairs are produced and they have faster elongation rates. Root hairs have their greatest effect on absorption of ions that diffuse slowly in soil. Expansion of root surface area via increased production of root hairs is much less costly than a greater investment in roots.

Acid soils (*See* **Acid Rain and Soil Acidification; Acidity**) decrease root growth, partly due to direct effects of low pH, and also due to the higher availability and toxicity of heavy metals, such as aluminum. Aluminum toxicity decreases both root elongation and cell division, and root cells become shorter and wider, giving roots a stubby appearance. The root tips are the primary sites of aluminum toxicity. In many tropical soils that experience low pH and aluminum toxicity, P is either deficient or is readily fixed to soil particles. Thus, the low root-length density of plants in response to aluminum toxicity is an important limitation to P uptake and total plant growth. Other heavy metals, such as cadmium, copper, and zinc, also decrease root elongation, and root dry mass to a lesser extent, but the mechanisms for these responses are not clearly understood.

In waterlogged or flooded soils, air is displaced from soil pore spaces, and various degrees of oxygen

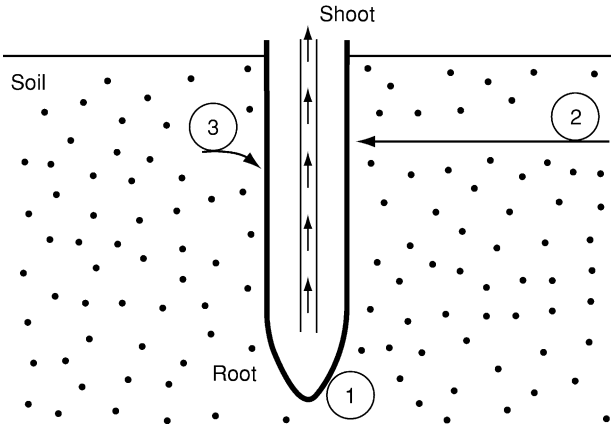

Figure 4 Schematic of the movement of minerals in soil to the root surface: 1, With root interception, the soil volume is displaced by the root volume; 2, With mass flow, the bulk soil solution is transported along the water potential gradient, which is driven by transpiration; 3, With diffusion, nutrient ions are transported along the concentration gradient. (Reproduced with permission from Marschner H (1995) *Mineral Nutrition of Higher Plants*. San Diego, CA: Academic Press.)

depletion typically occur in heterogeneous microsites in the soil. Flooding of a previously well aerated plant can cause immediate cessation of root growth, root respiration, and root death, partly due to the production of toxic substances such as nitrite or acidification of the root cells due to lactic acid produced during anaerobic fermentation. In some plant species after waterlogging, adventitious roots with well-developed aerenchyma, large air spaces in the root cortex, can emerge from the base of the stem, or existing roots can develop aerenchyma (Figure 5). The formation of aerenchyma under hypoxic conditions is associated with the production and accumulation of the plant hormone ethylene. Aerenchyma increases the root porosity and the long-distance transport of oxygen to apical zones of the root system. Pressurized gas transport, driven by temperature gradients between aboveground aerated parts of the plant and submerged root systems, also exists in some flooding-tolerant species.

Mycorrhizal symbioses help overcome some types of stress. Mycorrhizal colonization increases the surface area of the root system by extending hyphae beyond the root surface and consequently increases nutrient uptake, especially of ions with low mobility in soil, e.g., phosphorus, zinc, and copper. Mycorrhizae increase the distance of nutrient exploration away from the root and are important in sites with patchy distribution of nutrients. Water uptake is thought to be increased for some plant species. Arbuscular mycorrhizae (AM) are endophytes with intracellular colonization by Zygomycete fungi, whereas ectomycorrhizae are either Ascomycete or Basidiomycete fungi that form a mantle or sheath enclosing the rootlet. Dependence on AM tends to be highest in plants with coarse, fibrous root systems with few root hairs. Many herbaceous species with more fibrous root systems and high specific root length, i.e., thinner roots, are facultative mycotrophs that become less mycorrhizal with increased phosphorus

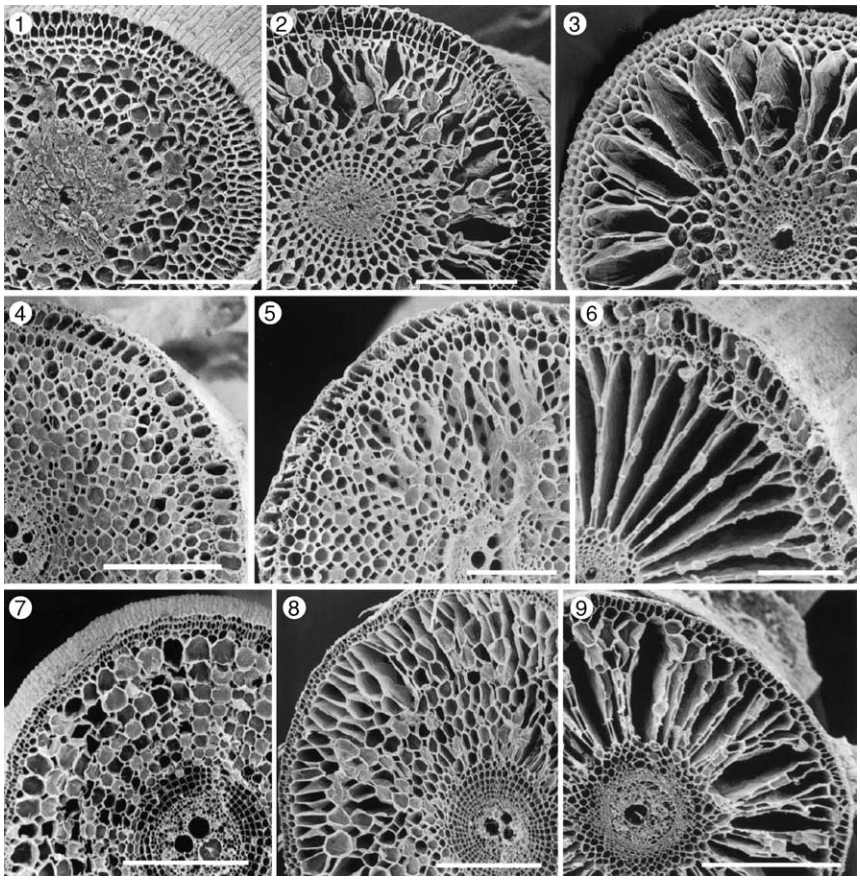

Figure 5 Scanning electron micrographs of transverse sections of roots of wetland plant species at differing distances from the root tip. Micrographs 1–3 show *Sagittaria lancifolia* at 5, 23, and 45 mm from the root tip, respectively. Micrographs 4–6 show *Thalia geniculata* roots at 2, 8, and 32 mm, respectively. Micrographs 7–9 show *Pontederia cordata* 6, 31, and 58 mm, respectively. The development of cortical air spaces (aerenchyma) in roots is an adaptive response to flooding. availability. Several studies indicate that root branching and lateral root formation increase with AM colonization. In some plant species, a decrease in specific root length (centimeters per gram of dry weight root) occurs in AM versus noncolonized roots, i.e., mycorrhizal roots are thicker. For ectomycorrhizal roots, the bulky tissue of the mycorrhizal mantle surrounding the roots serves a role in nutrient storage and in root-fungus contact, but does not greatly increase the surface area for nutrient uptake. Instead the extraradical mycelium that extends from the mantle and their rhizomorphs, conglomerations of hyphae with distinct structural shapes, perform this function. Ectomycorrhizal colonization can increase the number of root tips on laterals. Both AM and ectomycorrhizal colonization frequently result in allocation of a lower proportion of total plant weight to root dry weight.

Genetic Analysis of Root Traits

As with many aspects of plant growth and development, root architecture and morphological traits are usually under the control of a complex gene system in which several genes, rather than a single gene, operate together to create a given phenotype. Multigene control of root traits and root responses make the study of root genetics difficult. Also, roots are hard to study due to the large numbers of plants needed for genetic studies, especially in soil in field experiments, where their phenotypic evaluation is most valid.

For rice, a large effort has been invested in understanding root responses to drought. Genetic variation among rice cultivars exists for root thickness, total root length, and root penetration ability, i.e., for proliferation in a soil hardpan. Using quantitative trait locus (QTL) analysis that relates phenotypic variation to specific genetic regions in a genetically segregating population, these traits have been genetically mapped, and several chromosomal regions have been found to affect each of the traits. Like root traits, drought avoidance traits in rice, e.g., relative water content and the extent of leaf rolling that limits transpirational surface area, also give many QTLs that differ between sites and between years at the same site. Yet there is little co-location on the genetic map of drought avoidance and root morphological QTLs, implying that root traits do not seem to be contributing consistently to drought avoidance in rice. Whether this is true or an artifact due to screening techniques remains to be seen. A more straightforward outcome has been achieved for lettuce. In lines derived from a cross between wild and cultivated lettuce, QTLs for deep water extraction and deep rooting traits co-localize (Figure 3), and genetic markers for these QTL regions are now being introgressed into cultivated lettuce, with the hope of creating a deeper-rooted crop that requires less irrigation input.

Single-gene traits for root morphological traits have been identified in some plants, but are best studied in the tiny crucifer *Arabidopsis thaliana*, a current model species used by plant geneticists. Mutants for traits such as failure to initiate lateral roots, auxin-related lateral root growth, and variable lateral root initiation in response to the soil environment exist in this species. Transgenic *Arabidopsis* plants have also been used to demonstrate the function of a specific gene controlling the proliferation of lateral roots in nitrate-rich patches. In normal, nontransgenic plants, the expression of this gene is induced rapidly when nitrate is supplied, but, in transgenic plants in which the gene is repressed, roots no longer proliferate in response to nitrate. The gene may therefore be a key factor in determining the developmental plasticity of roots in response to an environmental cue.

The strong effect of the abiotic and biotic environment in the soil on root development and branching patterns is obviously important for understanding the inheritance of root traits and their adaptation to specific habitats, and for crop improvement for more sustainable use of water and nutrients. For many crops, extensive genotypic variation exists for root-system traits among cultivars, but the exact genetic basis of these traits is difficult to ascertain and therefore hard to implement in crop-breeding programs. Molecular techniques including QTL analysis and marker-assisted selection will help to overcome these problems.

Root Architectural Effects on Plant Communities and Ecosystem Processes

Plant species and ecotypes are adapted to the environments in which they grow. Plant communities of nutrient-poor sites are typically composed of plants with slow growth rates, high nutrient concentrations in tissue, and high root-to-shoot ratios. Even with a high nutrient supply, they have low rates of nutrient uptake and growth. In contrast, natural vegetation on nutrient-rich sites, e.g., many disturbed sites, often consists of species with the capacity for high rates of nutrient uptake and growth, rapid response to increased availability of soil nutrients, and low root-to-shoot ratio. These traits ultimately contribute to higher fitness even though the specific respiratory costs for nutrient uptake may be high. Despite these generalities, different ecophysiological strategies can usually be found within the same plant community. For example, in the vegetation of the arid Great Basin in

the USA, sagebrush and one prevalent perennial grass showed no root response to enriched fertile microsites, while another perennial grass species exploited P via rapid root proliferation in the patches.

Spatial and temporal patterns of changes in root growth, architecture, and distribution affect nutrient and water availability in soil, as well as retention and loss of these resources to the atmosphere, runoff, and leaching. These relationships are best understood for crop systems. Like most annuals, crop plants proliferate roots in the top 0.5 m of soil until subject to drought, at which time roots grow increasingly deeper and rely on deeply stored water. Many annual species reduce or terminate root growth at anthesis, and reproductive growth and seed production often rely heavily on remobilization of nutrients and carbon from roots and other vegetative parts. To examine these effects on water and nutrient budgets, models increasingly rely on information on root growth, activity, and phenology, rather than using solely a 'root-sink' term to explain unaccounted-for fluxes in the soil. These include accounting for matric and osmotic potential effects on water and passive nutrient uptake, root-age effects on root water and nutrient uptake activity, as well as the influence of nutrient deficiency and ion toxicity on root growth.

Root distribution often reflects changes in soil strength and drainage channels in the soil profile. For *Eucalyptus* trees, fine roots concentrate in the surface soil and in zones of preferential infiltration, causing rapid drying and nutrient depletion in these areas. During the wet season, some roots grow into compacted zones, utilizing seasonally available water when moisture reduces soil strength in these areas. Thus, both spatial and temporal aspects of root growth help to reduce nutrient loss caused by deep drainage.

Competition between plants in the same plant community affects root distribution, water uptake, and WUE. The water source used by the roots of different species can be traced with deuterium (^2H) and oxygen-18 ($^{18}O_2$), which are stable isotopes that vary among rainwater, soil water, and groundwater. Carbon isotope composition ($\delta^{13}C$) is related to plant intrinsic WUE, which is the ratio between CO_2 assimilation and leaf water vapor conductance. Studies that use isotopic techniques along with measurements of root biomass and leaf gas exchange combine an assessment of root distribution, and short- and long-term physiological activity. In tree–grass mixtures, for example, grasses exert a negative effect on tree root growth, but usually not vice versa. Drought, however, typically has a more negative effect on grass than on trees, which have more conservative leaf gas exchange characteristics and deeper roots, which utilize deeply stored water. Sorting out these complex, competitive relationships has been possible with a combination of techniques, including stable isotopes. An example is tracking the natural abundance of the stable isotope ^2H in soil water, which varies with depth in dry environments, and in plant xylem water, which gives a weighted average of all soil water acquired by functional roots (**Figure 6**).

Successful plant invasion is due in part to root traits, along with a suite of related ecophysiological characteristics. For salt cedar (*Tamarix* sp.), a non-native phreatophytic species in riparian areas of

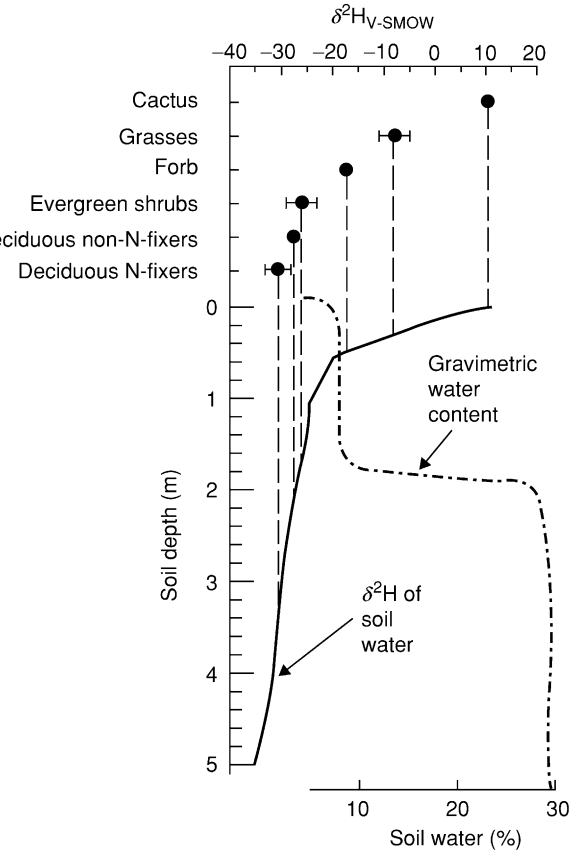

Figure 6 Hydrogen isotope content, δ^2H, in soil water and plant xylem water in a subtropical savanna in Texas, USA. *Prosopis glandulosa*, honey mesquite, is the dominant woody plant. In the soil, δ^2H decreases exponentially with depth, and gravimetric moisture is higher below approximately 2 m depth. Shallow-rooted plant functional groups (grasses, forbs, and cacti) obtain their water from the upper 1 m of the profile, based on their δ^2H. More negative δ^2H values of plant and soil water indicate that tree and shrub roots access water in the zone of high gravimetric content, while roots of grasses, cacti, and forbs do not. Hydrogen isotope composition, δ^2H or $^2H/^1H$, is expressed relative to a conventional standard, V-SMOW (Vienna Standard Mean Ocean Water). North American deserts, greater root allocation and deeper roots allow higher transpiration and photosynthesis rates under dry, hot conditions than can be achieved by native riparian species. These root traits, along with prolific seed production and vegetative reproduction, help explain the widespread invasive success of salt cedar in this environment.

At a regional scale, root distribution can affect hydrology. An example is the replacement of deep-rooted perennial trees and shrubs, up to 20 m deep, by shallow-rooted pasture and crop plants in the seasonally dry Murray–Darling Basin in Australia. Historically, the native vegetation would have relied on deep soil recharge and groundwater, while the shallow-rooted agroecosystems today occupy only the top meter of soil and utilize far less water than the forest and woodland communities, whose evergreen canopies had higher evapotranspiration rates. The current outcome of the vegetation transition is groundwater recharge and rising water tables, and since the groundwater is now usually saline, secondary salinization.

Improved understanding of the factors controlling root construction, biomass allocation, and distribution will improve ecological, hydrological, and global climate models. Roots are central to many ecosystem processes, including water absorption, which affects groundwater and atmospheric water fluxes, and indirectly influences water availability for soil microbial processes that control carbon dioxide, NO_x, and methane fluxes, as well as nutrient concentrations and fates, which also play a role in these processes. Fine-root biomass and surface area, and distribution through the profile are particularly important for these processes due to their relatively short lifespan, low C:N ratio, which enhances turnover rates, and their impact on nutrient absorption and thus primary production. A recent analysis indicates that substantial differences exist between biomes in total fine root biomass and depth distribution (**Table 1**), and that approximately 33% of global net primary production is used for fine-root production. These findings indicate the need for more physiological and ecological information on the importance of roots in terms of total plant productivity, carbon turnover, and long-term storage of carbon in perennial roots in different ecosystems.

Introduction

Plant roots influence the physical, chemical, and biological conditions of the soil in the rhizosphere. The biogeochemical reactions induced by microorganisms at the soil–root interface (i.e., rhizosphere) play an important role in the bioavailability of nutrients and metals to plants. This microenvironment is characterized by distinct physical, chemical, and biological conditions compared with the bulk soil, largely created by the plant roots and its microbial associations. Such associations can include nonsymbiotic and symbiotic organisms such as bacteria and mycorrhizal fungi. The microbial populations are an essential part of the rhizosphere and affect the rhizosphere soil by their various activities such as water and nutrient uptake, exudation, and biological transformations.

Organic acids, sugars, amino acids, lipids, coumarins, flavonoids, proteins, enzymes, aliphatics, and aromatics are examples of the primary substances found within this microzone. Among them, the organic acids have received considerable attention owing to their role in providing substrates for microbial metabolism and for serving as intermediates for biogeochemical reactions in soil.

Nutrients and metals are typically present in the soil solution at low concentrations and tend to form sparingly soluble minerals (except nitrogen, sulfur, and boron), or may be adsorbed to a solid phase through ion exchange, hydrogen bonding, or complexation. The extent to which they are transferred from the soil to the biota (i.e., microbes or plants) is dependent on the biogeochemical interactions and/or processes among the soil, plant roots, and microorganisms in the rhizosphere. At this interface, the presence of root exudates may influence chemical reaction kinetics within the soil environment and subsequently affect biological activities. As such, understanding the role of the rhizosphere on biogeochemical processes within the soil is essential for developing bioremediation technologies of inorganic and organic contaminants.

Rhizosphere Microzone

The rhizosphere, first described in 1904 by Lorentz Hiltner, has been the focus of intensive research for many years because of its importance in plant nutrition and pathogenesis. More recently, research on the rhizosphere has been directed toward its influence on controlling the persistence, mobility, and bioavailability of contaminants in soils.

The rhizosphere generally refers to the portion of soil found adjacent to the roots of living plants. The rhizosphere is subject to the influence of chemicals

excreted by roots of living plants and the microbial community in this microzone. Its domain varies for different plant species and for age and morphology of roots. Depending on plant species, the width of the rhizosphere zone has been shown to extend from 2 to 80 mm away from the root surface. The soil in the rhizosphere supports a typically diverse and densely populated microbial community and is subject to chemical transformations caused by the presence of root exudates and metabolites of microbial degradation.

The rhizosphere microzone is distinguished from the bulk soil zone, more commonly known as the edaphosphere, by enhanced microbial activity and increased concentration of root exudates. Nevertheless, it is rather difficult to separate this zone physically from the root surface or rhizoplane. The rhizosphere effect is expressed quantitatively as the ratio of the number or activity of microorganisms or level of root exudates in rhizosphere soil (R) to that in the edaphosphere soil (E), i.e., the R/E ratio. The R/E ratio for microorganisms and root exudates is often found to range, respectively, from 2 to 20 and from 5 to 100, indicating enhanced microbial activity in the rhizosphere.

Root exudates are known as one of the most important factors affecting microbial growth in the rhizosphere. For example, cell numbers are several orders higher in the root zone than in the background soil lacking plants. The microbial community is more diverse, active, and synergistic than in nonrhizosphere soil. Root exudates can also selectively influence the growth of bacteria and fungi that colonize the rhizosphere by serving as selective growth substrates for soil microorganisms. For example, *Pseudomonad* species are particularly stimulated by enhanced carboxylic acid production from root exudation. Rhizosphere microbial communities can also vary in structure and species composition in different root locations or in response to other environmental factors, including soil type, plant species, or nutritional status.

Microorganisms and Structure of Microbial Communities in the Rhizosphere

Rhizosphere communities are comprised of many cultivable and noncultivable microorganisms. Mycorrhizal fungi that live in symbiosis with higher plants are essential living components of the rhizosphere. Bacteria are also prominent components and may be active participants in the community or simply adventitious members. Therefore, the rhizosphere is the ideal system to study when seeking an understanding of the critical functional interdependence and metabolic capabilities of complex microbial communities containing both prokaryotic and eukaryotic members.

The rhizosphere of land plants hosts a large, diverse community of microorganisms that interact with each other and with the plant's roots. The mycorrhizal fungi are very important, ubiquitous groups within this community. The vegetative mycelium of mycorrhizal fungi and the root tips of more than 90% of land plants, including angiosperms, gymnosperms, and pteridophytes, form a mutually supportive symbiosis. This novel composite organ, the mycorrhiza, is the site of nutrient and carbon (C) transfer between the symbionts. The various mycorrhizal associations allow plants to colonize and grow efficiently in suboptimal environments and, in most terrestrial ecosystems mycorrhizae, not roots, are the chief organs of nutrient uptake by land plants. The arbuscular endomycorrhizae (AM) and the ectomycorrhizae (EM) are the most important mycorrhizal types.

The AM symbiosis is probably the most ancient of all such root-microbe symbioses. Approximately 80% of the higher green plants, including numerous crop species, are symbiotic with AM glomalean fungi, a relatively small group of filamentous fungi with aseptate hyphae and multiple nuclei within distinct cell wall boundaries. In soil, this small monophyletic group of aseptate filamentous fungi forms a very fragile mycelium that can produce large asexual spores filled with numerous nuclei. The extraradical hyphae of most AM fungi improve the uptake of immobile resources, notably inorganic phosphate, since they can acquire these beyond the depletion zone surrounding a root. They can also interfere with pathogens, increasing micronutrient uptake and altering drought-resistance. In some circumstances, AM fungi benefit plants by increasing the uptake of the more mobile inorganic- or even organic-nitrogen (N) compounds.

Only approximately 3% of perennial woody plants develop ectomycorrhizas. Ectomycorrhizal trees, *Betulaceae*, *Fagaceae*, *Salicaceae*, and *Pinaceae*, dominate forest ecosystems in boreal, temperate, and Mediterranean regions. The mycobionts span all of the phyla of true fungi, the *Zygomycota*, *Ascomycota*, and *Basidiomycota*, with at least 15 families within the *Basidiomycota* and *Ascomycota*. The mycelia of EM fungi are usually much more structurally differentiated than those of AM fungi. Many ectomycorrhizal fungi seem to be long-lived and form large genets in stable, established forest ecosystems. The huge diversity of fungal partners optimizes the uptake and mobilization of mineral resources distributed in discrete substrates in soil, litter, and within other soil organisms. EM fungi have better access than plant

roots or AM fungi to organic phosphorus (P) and N compounds and seem well adapted to colonize the heterogeneous organic soil and litter layers of forests.

Both the AM and EM associations form an extraradical- and an intraradical-hyphal network that are functionally different entities. The extraradical hyphae colonize and exploit the soil volume to scavenge efficiently essential micro- and macronutrients. The intraradical hyphal network provides essential nutrient resources (e.g., phosphate and amino acids) to the plant. These nutrient contributions are reciprocated by the host's provision in its roots of a stable carbohydrate-rich niche for the fungal partner, making the relationship one of mutual symbiosis.

In the rhizosphere of plants, mycorrhizal fungi are always accompanied by another important group of microorganisms, the bacteria that also prosper in the organic-rich environment (mostly sugars, amino acids, and organic acids) released from the roots and mycorrhizal fungi. Among them, there is a large category of growth-promoting rhizobacteria that influence plant growth directly or indirectly by releasing a variety of compounds, from mineral nutrients to phytohormones and antimicrobial compounds. The establishment of mycorrhizae on roots is affected by the microbial populations of the rhizosphere, and especially by some bacteria, which can have either a positive or a negative effect on mycorrhiza formation. Plant-associated rhizosphere bacteria also have an important role in establishing and improving plant growth on different soil types, since they affect the availability of essential elements and provide plants with extra N.

Composition of Root Exudates

Root exudates refer to a suite of substances in the rhizosphere that are secreted by the roots of living plants and microbially modified products of these substances. They consist of low-molecular-weight organic compounds that are freely and passively released root-cell material and mucilage associated with roots. Root exudates are a complex mixture of soluble organic substances, which may contain sugars, amino acids, organic acids, enzymes, and other substances (Table 1). The rhizosphere also contains cell lysates, which are released when root cortex cells are ruptured by mechanical damage, microbial grazing, fungal infection, or the emergence of lateral roots that break through the root epidermis. In addition to these substances, rhizodeposition includes the secretion of enzymes, such as acid phosphatase secreted in response to P deficiency.

Although the identified components differ in molecular weight, amount released, and biochemical role, the dominant exudate components have consistently been shown to be organic acids, sugars, and amino acids. Typically, the total organic acid concentration in roots is approximately 10–20 $\mathrm{mmol\,l^{-1}}$ (i.e., 1–4% of total dry weight) for corn (*Zea mays* L.), with the other main organic solutes, namely amino acids (10–20 $\mathrm{mmol\,l^{-1}}$) and sugars (90 $\mathrm{mmol\,l^{-1}}$), present in root cells. Higher concentrations are generally found in rhizosphere soil than in bulk soil. The carboxylic acids that play a significant role in complexing metal ions in soils are not utilized as rapidly as carbohydrates by the soil microorganisms. It appears that microorganisms preferentially utilize the carbohydrates in root exudates. Consequently, organic and amino acids may be the prevalent chemical substances in root exudates.

Typical organic acids found in root exudates are malic, malonic, acetic, citric, fumaric, succinic, lactic, tartaric, oxalic, and others. Organic acids of root exudates seem to have a major role in solubilization of mineral nutrients. Malic and citric acids are major root exudate components for some plant species under aseptic conditions. For example, in corn grown under

Table 1 Composition of root exudates

Compositions	*Substances identified*
Organic acid	Acetic, butyric, citric, glutaric, lactic, maleic, malic, malonic, oxalic, propionic, pyruvic, succinic, tartaric, valeric
Amino acid and amide	α-Alanine, β-alanine, arginine, asparagine, aspartic acid, cystine/cysteine, glutamine, glycine, histidine, lysine, methionine, phenylalanine, proline, serine/homoserine
Enzyme	Amylase, invertase, phosphatase, protease, polygalacturonase
Growth factor	*p*-Amino benzoic acid, auxins, biotin, choline, inositol, *n*-methyl nicotinic acid, niacin, pantothenate, pyridoxine, thiamine
Phenolic acid and coumarin	Caffeic acid, cinnamic acid, coumarin, ferulic acid, salycilic acid, syringic acid, vanillic acid
Sugar	Arabinose, fructose, fucose, galactose, glucose, maltose, oligosaccharide, raffinose, rhamnose, ribose, sucrose, xylose
Others	Nucleotide, flavonone, fatty acids, proteins, sterols, lipids, aliphatics, aromatics, carbohydrates

sterile conditions, exudation of malic and citric acids increases significantly under nutrient deficiency.

Compared with the organic acids, amino acids appear to play a less significant role in complexing or mobilizing plant nutrients. The proteinaceous amino acids are not readily detected in root exudate solutions. The nonproteinaceous amino acids (phytosiderophores) in the rhizosphere have been shown to enhance the mobility of plant micronutrients in soils.

Collection and Quantitation of Root Exudates

Upon reaching a predetermined growth stage, root exudates must be separated from the growing medium. If plants are grown in solution culture, aliquots of the nutrient solution can be purified and concentrated for the assay. The plants can also be transferred from a nutrient solution to another container and, upon a predetermined exposure time, root exudates are collected in water. When plants are grown in solid medium such as soil, root exudates are collected by first removing the plant from the soil then placing it in aerated and sterilized, double-distilled water for 2–6 hours. Subsequently, the exudates are separated and concentrated for analysis. Typically, solutions are filtered using 0.2- or 0.45-μm membrane filters that are then concentrated by rotary evaporation or by lyophilization. The collected material is stored at temperatures ranging from -20 to 4°C until analysis then diluted to a smaller volume for analysis.

Root exudates might be adsorbed on XAD-4, a porous polymer resin, which behaves in a way similar to C-18 high-pressure liquid chromatographic material when used in the reversed-phase mode. Root exudates trapped on the resin are extracted with either distilled water or methyl alcohol for lipids. The system has several advantages over previously used extraction procedures and is easily adaptable to large-scale recovery and extremely low-level concentrations of substances, as is very often the case with germination stimulants and other biologically active exudates.

Only a few attempts have been made to analyze comprehensively the chemical composition of root exudates. This is due to the necessity of employing a wide array of analytical methods for characterizing the different exudate components. Prior knowledge of the presence of substances is essential for selecting the methodologies for proper separation, identification, and quantification of substances from the mixtures. In addition, concentrations of substances in root exudates may be low, further complicating their detection and quantification.

The chemical behaviors of low-molecular-weight organic acids commonly found in root exudates are similar, making their separation in a chromatographic column a challenging analytical problem. A gas chromatographic (GC) approach based on differences in the chemical structure of organic acids has also been utilized. GC with mass spectrometry (GC-MS) analysis has been used to quantify the changes of quantities of root exudate in relation to colonization of roots by mycorrhizal fungi in which the concentrated root exudate solution is injected directly into the instrument. To enhance the resolution, root exudates can be separated into cationic, anionic, and neutral fractions prior to analysis by GC-MS using ion exchange resins. Compounds are then identified by comparing the retention time and mass spectra to respective reference compounds. Organic acids in the root exudates have also been determined by ion chromatography (IC) operating at room temperature. The separation is carried out on an IonPac AS 11 or AS 6 column (250×4 mm) protected by an IonPac AG 11 guard column (50×4 mm).

Factors Affecting Root Exudates

The quantity and composition of root exudates are affected by environmental factors (Table 2). Acidification, chelation, precipitation, and redox reactions in the soil can change the nature and composition of root exudates. For example, nutritional stress

Table 2 Influence of environmental factors on root exudation

Factors	*Effect*
Age of the root	Roots in the initial stages secrete exudates more frequently
Light intensity	High light intensity increases exudation
Microorganism	Presence of microorganisms increases exudation
NH_4^+/NO_3^-	Roots under NH_4^+ have lower organic acid concentrations
Nutrient availability	Nutrient deficiencies increase exudation
Oxygen status	Compositions are different under aerobic and anaerobic conditions
Plant species	Different plants and cultivars have different exudate compositions
Salinity	More organic and amino acids are produced under low salinity
Soil moisture	Relieving drought stress increases exudation
Soil pH	Acidification changes composition of exudates
Soil temperature	High temperature stimulates exudation
Soil texture	Sandy substrate produces greater amounts of exudates
Stress condition	Stress changes the composition of exudates

experienced by plants, such as deficiencies of P, zinc (Zn), or iron (Fe), may increase root exudation. Plant roots alter the redox potential in the rhizosphere soil directly by excreting CO_2, and indirectly through the supply of readily available carbon sources for enhanced microbial respiration. In general, the redox potential is lower in the rhizosphere than in the bulk soil. The decrease in redox potential is likely to have important consequences in the redox reaction of contaminants such as arsenic (As), selenium (Se), Fe, manganese (Mn), and chromium (Cr).

Temperature and photoperiod have profound effects on the quality and quantity of root exudates because they affect photosynthesis, translocation, and respiration in plants. Increase in exudation at high temperature has been reported for many crops. The rate of exudation of certain organic acids by plants, while in vegetative and reproductive stages, may increase with the elevation of temperature and the extension of photoperiod, the mean rate being two or more times higher than the minimum exudation at low temperature with shorter photoperiod.

The imbalance in plant absorption of cation and anion affects the concentration of organic acids in the rhizosphere. In situations where roots take up cations in excess, particularly K^+, negative charges that are provided by organic acids, such as malic, malonic, oxalic, and citric acids, are required to maintain an electrostatic balance. Roots grown in NH_4^+-fertilized fields have lower concentrations of the organic acids than those grown in NO_3^--fertilized fields.

Role of Root Exudates on Plant Nutrient and Metal Dynamics

The enhanced activity of microorganisms, including mycorrhizal fungi, in the rhizosphere is important in relation to the bioavailability and mobility of nutrient ions, metals, and organic contaminants. For example, it has often been shown that the dissolution and release of water-insoluble fertilizer materials such as elemental sulfur (S) and apatite phosphate rocks are enhanced in the presence of plants; this has been related to the increased activity of S-oxidizing microorganisms and the release of organic acids. The enhanced microbial activity is likely to reduce the mobility of nonreactive ions such as nitrate and sulfate through microbial immobilization.

Interactions of Fe, Mn, copper (Cu), and Zn, and the effect of organic acids on P dissolution in soils have been researched. In addition to their role in plant nutrition, root exudates may affect vital soil processes, such as the soil organic matter transformation, cycling of nutrients in soils, and development of stable soil structure. Root exudates (e.g., polysaccharide gum) enhance stabilization of soil structure in the rhizosphere by increasing the strength of bonds between soil particles.

Organic acids such as oxalic, lactic, and succinic exuded by roots are effective in releasing metals from sparingly soluble mineral forms by forming stable chelate complexes with the metal ions. The extent of complexation depends on the organic acids involved (number of carboxylic groups), the concentration and type of metal, and the pH of the soil. Organic acids with only one carboxyl group, such as acetic, formic, and lactic acids, have very little metal-complexing ability. Based on the stability constants summarized in Table 3, malic and oxalic acids have high affinities for metals. These are the most frequently found organic acids in soils. However, this does not always entail efficient complexation at all soil pH levels. For example, using Geochem-PC, a descendant of the multipurpose chemical speciation program and the PC-compatible version of Geochem, the complexation of Fe by malic and oxalic acids is shown to be highly dependent upon soil pH, with little or no complexation at high soil pH.

Biogeochemical reactions occurring in the rhizosphere play an important role in the bioavailability of metals. These reactions can be heavily influenced, notably by the release of protons and organic acids from the roots. The acidifying protons can affect the chemical speciation and mobility of micronutrient metals and heavy metals/metalloids, possibly favoring the formation of ionic species in the rhizosphere. Additionally, organic acids such as those mentioned earlier had the ability to complex metals, with the resultant metalorgano complexes possessing greater mobility. Thus the combined effects of the protons and organic acids may result in chemical speciation and much-enhanced mobility of the metals that could facilitate their uptake by the root or leaching.

Phosphate dissolution rate can be greatly accelerated in soil in the presence of organic acids of root exudates, depending on soil type and concentration of organic acids. There are several possible mechanisms by which P release can occur. The first mechanism involves competitive sorption reactions (direct ligand exchange) in which exuded organic acids compete with P for common sorption sites on soil particles, thus releasing P from the solid phases. For example, citrate may be able to desorb phosphate from sesquioxide surfaces by anion exchange. The second mechanism could involve the modification of the surface characteristics in which organic ligand sorption modifies the surface charge of P sorbents. Anionic organic acids may be sorbed by minerals in the rhizosphere, which may lead to an increase in the net negative charge of clays. Along with this,

acidification due to proton exudation accelerates dissolution reaction affecting clay minerals. The third mechanism involves the complexation of metal ions in the solid, which constitute the exchange matrix holding the P. The action of organic chelates in solubilizing phosphates and phosphate minerals is attributed to the formation of complexes with calcium (Ca), Fe, or aluminum (Al), thereby releasing phosphate in water-soluble form. Solubilization of P compounds by organic acids is accomplished by the formation of complexes of organic acid ligands with P-associated metal ions such as Fe, Al, and Ca. The substitution of organic ligands for orthophosphates frees up P for plant uptake. This process depends on the number and position of carboxyl (-COOH) and phenolic (-OH) functional groups in the organic acids.

The pH of the rhizosphere is important in determining contaminant and nutrient mobilization and uptake. Root-induced pH change in the rhizosphere is a known phenomenon and has been shown to have an effect on the bioavailability or solubility of nutrients such as P, Fe, Mn, Zn, and Cu by rhizosphere acidification. Rhizosphere pH can be more than 2 units lower than the bulk soil pH. Several hypotheses have been postulated to explain the differential ability of plant species to affect rhizosphere pH. These include differences in root exudates, especially low-molecular-weight organic acids and the evolution of respiratory CO_2 from differential uptake in cations/anions.

Root Exudates and Biodegradation of Organic Contaminants

Rhizosphere degradation of organic compounds is often a key factor in successfully applying a phytoremediation-based strategy. Secretion of plant exudates not only stimulates overall microbial activity, but some induce specific bacterial- and fungal-degradation pathways. For instance, phenolic root exudates trigger cometabolism of chlorinated organic solvents, including trichloroethylene (TCE), by rhizosphere bacteria. The combined activity of mycorrhizal fungi and bacteria might help to overcome environmental stress imposed on plants by the presence of organic xenobiotics: consortia of mycorrhizal fungi and pseudomonads with toluate-degrading capacity improve the survival of mycorrhizal symbionts and, at the same time, promote toluate degradation in the rhizosphere. Some hydrophobic organic xenobiotics such as polyaromatic hydrocarbons (PAH) are

not taken up efficiently by plants. Phytoremediation of PAHs, therefore, strongly depends on rhizosphere processes such as enhanced degradation by bacteria or fungi.

Root exudates affect the bioavailability of nutrients by directly influencing the chemistry of the rhizosphere soils and indirectly enhancing microbial activity in the rhizosphere soils. Microorganisms utilize sugars, organic acids, amino acids, vitamins, and high-molecular-weight compounds exuded by roots as sources of C and substrates for growth. Microbial metabolites may in turn increase root exudation through stimulation of root activity and growth, thus increasing the surface area over which the exudation occurs. Similarly, Fe deficiency leads to the development of shifted bacterial communities that differ qualitatively and quantitatively in species composition.

Microbial degradation is the major process by which organic contaminant residues are removed from the soil. The rate of degradation of organic contaminants has often been found to be faster in the presence of growing plants. Figure 1 indicates the distribution of the water-soluble C, the microbial activity, and the 2,4-dichlorophenoxyacetic acid (2,4-D) residues in soil samples taken at different distances from the rhizoplane in a microcosm root container. There is an increase in the amount of soluble C in soil samples taken from close to the root surface. The increase in soluble carbon is related to the rhizodeposition of root exudates, which include low-molecular-weight organic acids, carbohydrates, and amino acids. There is a corresponding increase in microbial activity as measured by the amount of oxygen consumed by the microorganisms in this soil section. This enhanced microbial activity is related to an increase in the supply of organic substrate (i.e., root exudates) as a source of C and energy for microbial growth. There is a decrease in the amount of 2,4-D remaining in the soil, indicating that microbial degradation of pesticides occurs during plant growth. The amount of residual 2,4-D remaining in the pesticide cores is less in the soil section close to the root surface than in the other section. Since grass roots are unlikely to absorb considerable amounts of 2,4-D residues, by inference the low amount of 2,4-D residues close to the root core is attributed to the root-induced degradation of the pesticide. The enhanced degradation of pesticide in the soil section close to the root surface is related to the rhizosphere-induced cometabolism of the pesticide that requires the presence of a growth substrate other than the compound to be mineralized. Plant roots excrete a wide range of root exudates, and the availability of these exudates is considered to be the major cause for the existence of an enriched microbial population in the rhizosphere, resulting in accelerated degradation of the pesticide.

It is likely that an increase in the activity of pesticide-degrading microorganisms in the rhizosphere of certain plants is a mechanism by which plants are protected from the toxic effects of pesticides. Selective enrichment of microorganisms is likely to have a significant impact on the rhizoremediation (or

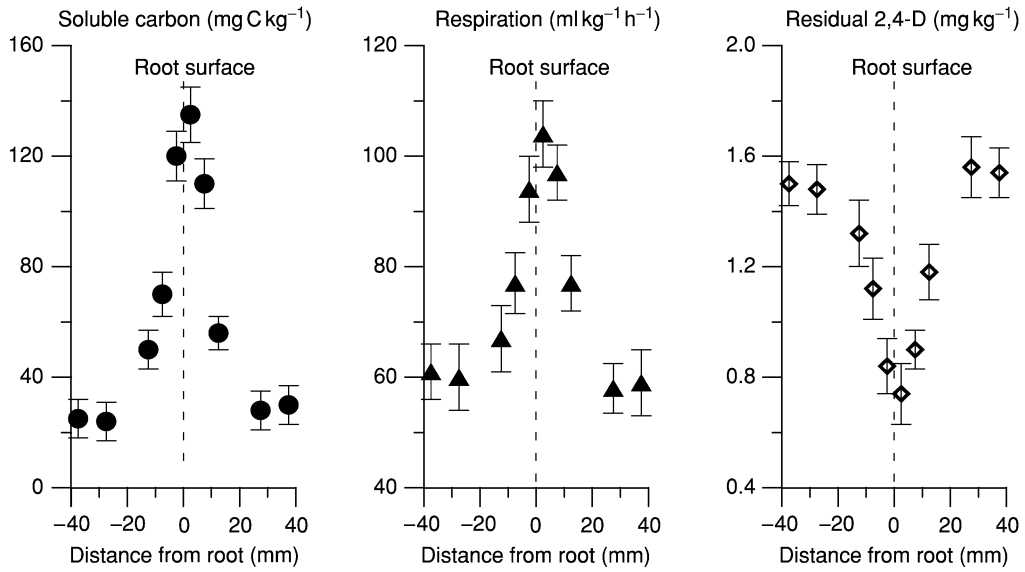

Figure 1 Distribution of soluble carbon, biological activity, and the residual 2,4-dichlorophenoxyacetic acid (2,4-D) in thin sections of soils in the pesticide cores.

more commonly, phytoremediation) of recalcitrant organic contaminants in soils. It has become apparent that the role of the rhizosphere in the natural attenuation of pollutants in soils is being recognized increasingly.

Summary

Plants and their associated microorganisms from complex communities, called rhizosphere communities, have diverse functions and capabilities that are important in many processes related to C management and recycling, biochemical cycling of nitrogen and P, biomass production and conversion to biofuel, and phytoremediation of heavy metals, radionuclides, and organic xenobiotics.

The relationships and interactions between and among microorganisms, plants, and water-borne chemicals are still not well-understood. However, many processes, such as the successful growth of plants, the optimization of biomass production, and carbon sequestration require that we acquire such understanding at the level of diversity, structure, functional interdependence, and capabilities of rhizosphere communities.

Origin and Distribution of Saline Soils

Excessive levels of salts occur in large areas of soil around the world and profoundly affect land use. Two major types of soil have been defined within this group, saline and sodic soils. The former refers to a soil that contains excess soluble salts that impair its productivity. The excess salts are comprised largely of the chloride and sulfate anions and sodium, magnesium, and calcium cations in the soil solution. Sodic soils contain excess sodium in the exchange complex that impairs their productivity. Sodic soils may or may not contain excess soluble salts and may contain free sodium carbonate.

Estimates of the areas of the globe covered by salt-affected soils are presented in Table 1. The salt content of soils above which plant growth is affected depends upon several factors, among which are the texture of the soil, the composition of the salt, and the species of the plant. The electrical conductivity (EC) of the saturation extract has been adopted by the US Salinity Laboratory as the preferred scale for general use in estimating soil salinity; and saline soils are defined as soils with EC exceeding $4\,\mathrm{dS\,m^{-1}}$. Based on this classification, the total area of saline soils on the globe is 351.5 millions hectares, with most of the saline soils located in Asia (194.9×10^6 ha) (Table 1). The decision regarding what level of exchangeable sodium in the soil constitutes an excessive degree of saturation is complicated by the fact that there is no sharp change in the properties of the soil as the degree of saturation with exchangeable sodium is increased, and that the effect of sodicity depends on the EC of the soil solution, the soil texture, the soil mineralogy, organic matter content, sesquioxide content, and the soil conditions (e.g., the wetting rate of the soil, the antecedent moisture content, and the aging effectl Thus, in the USA, and subsequently throughout much of the rest of the world, a value of exchangeable sodium percentage (ESP) greater than 15 is the criterion for separating sodic soils, whereas in Australia a value of ESP greater than 6 is used (*See* **Sodic Soils**). This explains the disproportiol large areas of sodic soils in Australia (Table 1). Whatever the definition of sodic soils, it is evident from Table 1 that the area of sodic soils in the world is approximately twice that of saline soils.

The original and direct source of the salts in soils are the primary minerals found in soils and in exposed rocks of the Earth's crust. During the process of chemical weathering, which involves hydrolysis, hydration, solution, oxidation, and carbonation, the salts are gradually released and made soluble. Although weathering of primary minerals is the indirect source of nearly all soluble salts, there are few instances where sufficient salts have accumulated from this source alone to form a saline soil. Saline soils usually occur in areas that receive salts from other locations, and water is the primary carrier. The ocean is the source of salts in low-lying soils along the margin of sea coasts. Sometimes salt is moved inland through the transportation of spray by winds. More commonly, however, the direct source of salts is surface water and groundwater. Water acts as a source of salts when used for irrigation and when groundwater rises close to the soil surface.

Saline soils occur for the most part in regions of arid or semiarid climate. In arid regions, leaching and transportation of soluble salts to the ocean are not as complete as in humid regions. Restricted drainage is a factor contributing to the salinization of soils and may involve the presence of a high groundwater table. Where there is a high water table, upward movement of saline groundwater and evaporation of surface water result in the formation of saline soil.

Properties of Saline and Sodic Soils

Properties of saline and sodic soils are determined by the composition of the soil solution and that of the

solid phase. The composition of the soil solution is determined by the following characteristics:

1. Total concentration of soluble salt, or 'salinity';
2. Concentration of sodium relative to other cations, or 'sodicity';
3. Anionic composition of the water, especially that of bicarbonate and carbonate;
4. Concentration of elements toxic to plants (e.g., boron, B).

Total Salt Concentration

The effect of salt on crop growth is largely of an osmotic nature. Osmotic pressure is a colligative property and is related to the total salt concentration rather than the concentration of individual ionic species. Total salt concentration is determined by total dissolved solids (TDS) in milligrams per liter of salts, by the ionic concentration in millimoles of charge per liter and by the electrical conductivity (EC) in decisiemens per meter. The relationship between salt concentration, either millimoles of charge per liter or milligrams per liter, and EC of various salt solutions is presented in Figure 1a and 1b, respectively. For a mixture of salts, the relationship between TDS and EC is given by:

$$\text{TDS (ppm)} = 640 \times \text{EC (dS/m)} \qquad [1]$$

Sodicity and Sodium Adsorption Ratio

When soils are leached with salt solutions until equilibrium is attained, a linear relation is obtained between the ratio of the concentrations of exchangeable sodium and divalent cations (ESR, exchangeable sodium ratio) and the ratio of the concentration (in millimoles of charge per liter) of the sodium cation to the square root of the concentration of the divalent cations in the solution (SAR) (Figure 2).

$$\text{SAR} = [\text{Na}]/([\text{Ca} + \text{Mg}]/2)^{1/2} \qquad [2]$$

where [Na] and [Ca + Mg] are the concentration of the soluble ions in millimoles of charge per liter. Analysis of a large number of soil samples from the western USA has led to the empirical equation:

$$\text{ESR} = \text{Na}_{\text{exch}}/[\text{Ca} + \text{Mg}]_{\text{exch}} = -0.0126 + 0.01475 \qquad [3]$$

where Na_{exch} and $[\text{Ca} + \text{Mg}]_{\text{exch}}$ are the concentrations of the exchangeable ions, presented in Figure 2.

A nomogram relating the ESP of soils to the SAR of the soil solution is presented in Figure 3.

Anionic Composition

A major factor affecting the final SAR value of soil water is the change in Ca and Mg concentration due to precipitation or dissolution of alkaline earth carbonates. In irrigation waters containing high concentrations of bicarbonate ions, there is a tendency for calcium and, to a lesser extent, magnesium to precipitate in the form of carbonate as the soil solution becomes more concentrated, thus leading to an increase in the SAR of the soil solution and consequently to an increase in the ESP of the soil. Bicarbonate concentration in underground water may be high because of the high partial pressure of CO_2. On exposure to the atmosphere, the excess CO_2 is released, while calcium and magnesium carbonates precipitate. Eaton assumed that all calcium and magnesium would precipitate as carbonates and proposed the concept of residual sodium carbonate (RSC) for evaluating high-carbonate water:

$$\mathrm{RSC} = (\mathrm{CO_3} + \mathrm{HCO_3}) - (\mathrm{Ca} + \mathrm{Mg}) \qquad [4]$$

where the concentration of the ions is expressed in millimoles of charge per liter. From the results of some limited leaching experiments, Eaton concluded that water with RSC greater than 2.5 is not suitable for irrigation. He defined the range of RSC between 1.25 and 2.5 as marginal, and less than 1.25 as safe. Although the RSC is still commonly reported in irrigation water analyses, its use is not justified. A better estimate of the precipitation tendency of carbonates is provided by the so-called saturation index. However, its application to soils leached with bicarbonate water is complicated and limited in its accuracy.

Concentration of Elements Toxic to Plants

Some soluble trace elements may have an inhibitory effect on plant growth. Elements in this category include B, lithium, selenium, and some heavy metals. In terms of saline soils, B is probably the most important. B is essential for plant growth but is exceedingly toxic at concentrations only slightly greater than optimum. B deficiency is found primarily in humid regions or in sandy soils, while toxicity occurs most frequently in arid and semiarid regions. Crops vary in their response to B. The threshold concentration for the most sensitive crop is $0.5\,\mathrm{mg\,l^{-1}}$ (lemon) and for the most tolerant is $6–10\,\mathrm{mg\,l^{-1}}$ (cotton). Since

an appreciable proportion of the B added to soils in irrigation water is sorbed by the soil, and plants respond to the B in soil solution, then conditions affecting equilibrium between sorbed and soluble B are highly relevant to considerations of B toxicity. Owing to adsorption, irrigation water containing marginal levels of B may not be toxic immediately; but after prolonged irrigation with such water, soluble B levels equal or exceed those of irrigation water.

Response of Crops to Salinity

Since the publication of Handbook 60 by the US Salinity Laboratory Staff, the salt tolerance of crops has been reevaluated as a result of new data obtained under conditions of variable soil salinity. It is now thought that most plants are able to withstand higher salinities in the drainage water than previously reported.

Salinity affects plant growth by three mechanisms:

1. Osmotic effects limit the ability of plants to absorb water from the soil solution. The osmotic effect is demonstrated when plant growth is reduced in a similar way by iso-osmotic solutions, and when osmotic and soil-water matric potential have a similar and additive effect on plant growth;
2. Specific ion toxicity results from excessive concentrations of Na or Cl ions, an effect most commonly found in woody species;
3. Changes in soil physical and chemical properties can affect plant production.

Crop yield is not reduced until a threshold salinity level is exceeded. Beyond the threshold level, the yield decreases linearly with rising salinity (Figure 4). The salinity values at zero yields provide an estimate of maximum salinity that plants can tolerate. Plants can be divided into four groups (sensitive to tolerant) according to their response to salinity. Of the field crops, barley, cotton, and sugar beet belong to the tolerant group, wheat and soybean belong to the moderately tolerant group, peanut and rice belong to the moderately sensitive group, and beans and cowpeas belong to the salt-sensitive group.

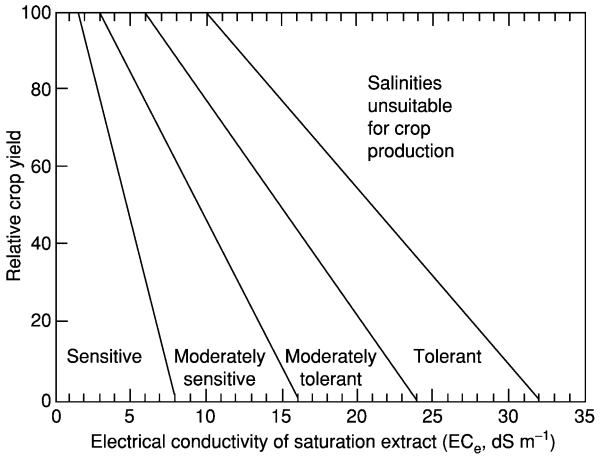

Figure 4 Relative crop yield as a function of the salinity of the soil saturation extract. Reproduced with permission from Shainberg I and Oster JD (1978) Quality of Irrigation Water. International Irrigation Information Center, Volcani Center, Israel.

Plant response to salinity depends also on soil, climate, and plant factors. Soil-water content and frequency of irrigation affect the tolerance of crops to soil salinity. Shortening the irrigation intervals minimizes the deleterious effect of salinity. The salt tolerance of many crops is enhanced when daily drip irrigation is used. Climate can also modify plant response to salinity. Salt tolerance is often reduced under hot, dry conditions; also, crops appear to be more salt-tolerant in areas with air pollution that limits plant growth.

Plant factors such as stage of growth, variety, and rootstock affect plant response to salinity. Rice, barley, wheat, and corn are most sensitive to salinity during the early seedling stage. Beet and sunflower are more sensitive to salinity during germination than in later stages of growth. Salinity effects on the vegetative growth of many plants (e.g., cotton, wheat) are greater than on seed or fiber production. Normally, salinity suppresses top growth more than root growth. The type of rootstock of woody plants may also affect the specific tolerance of fruit crops to salinity.

Response of Soils to Salinity and Sodicity

The physical and mechanical properties of soils (e.g., clay swelling and dispersion, aggregate stability, hydraulic conductivity, runoff, and erosion) are affected by soil salinity and sodicity. The main factor that determines the extent of the deleterious effect of Na on soil properties is the salt concentration in the soil solution. With low soil-solution salinity, as is the case in humid regions or during the rainy season in semiarid regions, even a low sodicity (ESP <5) has a marked and irreversible negative effect on the physical properties of most soils. Conversely, when the salt concentration reaches even a moderate level (10–20 $mmol_c/l$), high sodicity levels ($10<$ ESP <30) cause only small to moderate changes in the physical and hydraulic properties of soils. This is demonstrated in Israel, where irrigation water of 4.6 dS m^{-1} and SAR of 26 are used for irrigation of cotton. During the irrigation season (summer), no deterioration of soil physical properties is observed in spite of the high soil sodicity, because the high salt concentration prevents the adverse effects of sodicity. On the other hand, during the subsequent rainy season, the electrolyte concentration in the soil solution at the soil

surface becomes low, rendering the soil susceptible to crusting, low permeability, and increased runoff and erosion.

The response of soils to sodicity and salinity depends on the soil properties (e.g., texture, clay mineralogy, lime and sesquioxides content). Smectitic soils are more susceptible to sodicity than kaolinitic soils. Calcareous soils are less susceptible to sodicity than noncalcareous soils. Soils rich in sesquioxides are less affected by sodicity than soils with low sesquioxide content. However, the response of soils to sodicity depends also on time-dependent properties such as wetting rate of the dry soil, antecedent moisture content, and aging (time since cultivation or wetting). Fast wetting of dry soils disintegrates the aggregates and increases the susceptibility of the soils to sodicity. The effect of wetting rate depends on the antecedent moisture content of the soils. Less slaking of soil aggregates upon fast wetting occurs when the antecedent moisture content of the soil is high and the moist soil is less susceptible to the deleterious effect of sodicity. Similarly, upon aging of a moist soil, the stability of the soils' aggregates increases (aging effect) and their susceptibility to sodicity decreases.

Reclamation of Salt-Affected Soils

In ideal soils under piston flow conditions, the EC of soil water and applied water would be equal after the passage of one pore volume of rainfall or irrigation water. However, soils are not ideal for two reasons: (1) water flows faster through soil cracks and large pores between soil aggregates than through smaller pores within aggregates. This difference in localized water flow velocities is commonly referred to as 'bypass flow,' or 'preferential flow'; (2) salt diffusion and chemical reactions are not sufficiently rapid to allow salt concentration to be the same among all pores of differing sizes, particularly during periods of rapid water movement.

Salt transport models have provided considerable insight into these processes. However, suitable mathematical models are not available to describe the multiple concurrent processes of water flow, including spatially variable hydraulic properties and all the chemical reactions – exchange, dissolution, precipitation, and CO_2 liquid–gas equilibriums – involved in salt transport on a field scale. Consequently, reclamation guidelines are largely based on experimental relations obtained from field and lysimeter reclamation experiments.

The method of water application and soil type are the primary variables affecting the amount of water required to reclaim saline soils. For saline soils, 60% or more of the salts initially present is leached by a depth of water equal to the depth of soil (Figure 5) under continuously ponded conditions. Sandy loam soils with low saturated water contents have higher leaching efficiency than clay loam or clay soils (Figure 5). Soil pores in sandy soils are more uniform in diameter than in clay loam or clay soils. The finer-textured soils can have large cracks with large pores when dry, and fine pores within aggregates when wet. Such bypass channels reduce leaching efficiency.

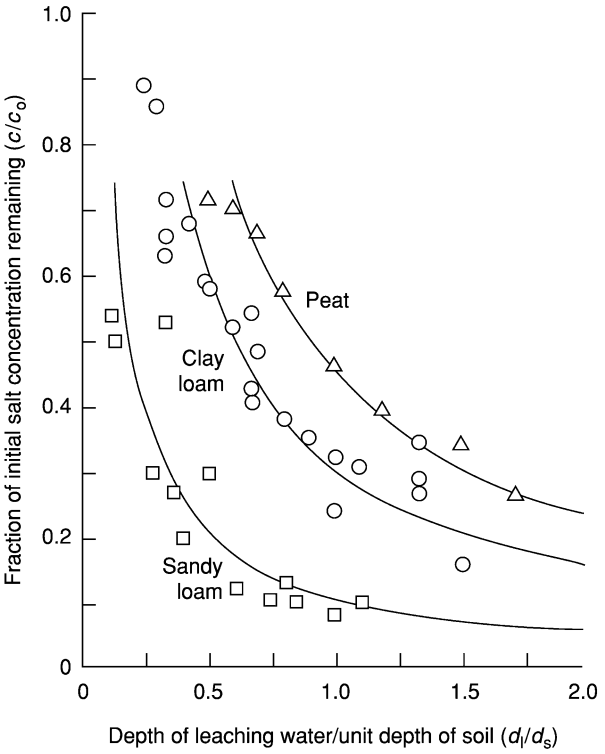

Figure 5 Depth of leaching water per unit depth of soil required to reclaim a saline soil by continuous ponding. (Adapted from Oster JD, Shainberg I, and Abrol IP (1996) Reclamation of salt affected soils. In: Agassi M (ed.) *Soil Erosion Conservation and Rehabilitation*, pp. 315–342. New York: Marcel Dekker.)

The water requirement for leaching can be reduced by intermittent application of ponded water, particularly for fine-textured soils (Figure 6). Under intermittent ponding, unsaturated conditions prevail in the soil profile and the inefficient bypass flow in large cracks and pores is prevented. Similarly, with sprinkler irrigation, reclamation occurs under unsaturated conditions and the efficiency of leaching increases.

Reclamation of Sodic Soils

The reclamation of sodic soils depends on the supply of Ca salts to replace exchangeable sodium and in maintaining adequate soil salinity to counteract the

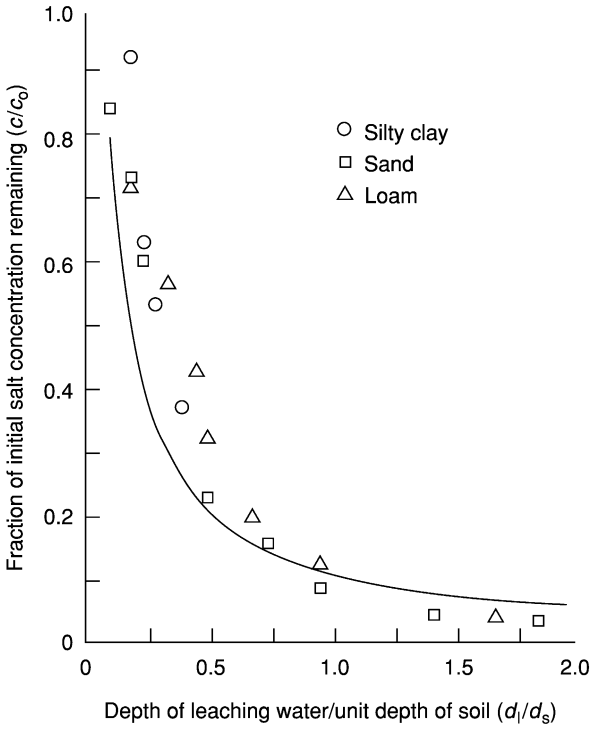

Figure 6 Depth of leaching water per unit depth of soil required to reclaim a saline soil by ponding water intermittently. (Adapted from Oster JD, Shainberg I, and Abrol IP (1996) Reclamation of salt affected soils. In: Agassi M (ed.) *Soil Erosion Conservation and Rehabilitation*, pp. 315–342. New York: Marcel Dekker.)

adverse effect of sodicity on the hydraulic properties of the soils.

Gypsum, either incorporated into the soil or left on the soil surface, is the calcium source most commonly used to reclaim sodic soils and to improve soil water infiltration that has been decreased by low salinities. Sources include mineral deposits and phosphogypsum, a by-product of the phosphate fertilizer industry. When gypsum is incorporated into the soil, the reduction in ESP upon irrigation and leaching is primarily limited to the soil depth interval where gypsum is present. This is a consequence of the greater selectivity of exchange sites for calcium than for sodium. The gypsum required for reclamation can be estimated from the amount of exchangeable sodium in the soil layer to be reclaimed – the gypsum requirement concept.

Since the soil surface is most susceptible to sodicity, reclamation of sodic soils by spreading phosphogypsum at the soil surface is being practiced in Israel. The amounts of gypsum that are applied depend on the depth of rain, assuming that gypsum concentration in the infiltrating rain reaches 50% of gypsum saturation. Thus, in a region with winter rain of 300 mm, the amount of gypsum spread at the soil surface is 3 Mg ha^{-1}, and, in a region with 500 mm of rain, the amount of gypsum applied is 5 Mg ha^{-1}. In the commercial fields in Israel that have been irrigated with saline and sodic water as described above, phosphogypsum is spread annually on the soil surface, following tillage in the autumn, at a rate of 3–5 Mg ha^{-1}. This prevents seal formation and maintains high infiltration rates which, in turn, provide sufficient infiltration of rainfall to leach salts from the root zone. Dissolution of the gypsum provides enough electrolytes to prevent seal formation and maintain high infiltration rates in spite of the fact that the soil surface is not completely reclaimed. This management in the rainy season, coupled with adequate irrigation with the saline-sodic water to meet crop needs during the summer months, results in cotton yields that are similar to those obtained when nonsaline water is used for irrigation.

Summary

Under arid and semiarid conditions, and in regions of poor natural drainage, there is a real hazard of salt accumulation in soils. The processes by which soluble salts accumulate in soils include irrigation with water containing salts, upward movement of moderate-to-saline water from high water tables, and weathering of primary and secondary minerals in the soils. Accumulation of soluble salts in the soil solution imposes stress on growing crops that can lead to decreased yields and, in severe cases, complete crop failure. Use of poor-quality water is increasing due to growing municipal demands for the available supplies of good-quality water and the need to dispose of municipal wastewater and agricultural drainage water. As a result, a better understanding of soil reclamation is becoming an increasingly important component of water and soil management to ensure the long-term sustainability of irrigated agriculture.

Natural and Induced Soil Salinity

The term 'salinity' refers to the presence in soil and water of electrolytic mineral solutes in concentrations that are harmful to many agricultural crops. Except along seashores, saline soils seldom occur in humid regions, thanks to the net downward percolation of fresh water though the soil profile, brought about by the excess of rainfall compared with evapotranspiration. In arid regions, on the other hand, there may be periods of no net downward percolation and hence no effective leaching, so salts can accumulate in the soil. Hence the combined effect of meager rainfall, high evaporation, the presence of salt-bearing sediments, and – in many places, particularly river valleys and other low-lying areas – the occurrence of shallow, brackish groundwater which gives rise to saline soils.

Less obvious than the appearance of naturally saline soils, but perhaps more insidious, is the inadvertent induced salination of originally productive soils, caused by human intervention. Irrigation waters generally contain appreciable quantities of salts. (For example: Even with relatively good-quality irrigation water containing no more than 0.3 kg salts m^{-3}, applying 10 000 mm water per season would add as much as 3 000 kg salts ha^{-1} per year!) Crop plants normally extract water from the soil while leaving most of the salt behind. Unless leached away (continuously or intermittently), such salts sooner or later begin to hinder crop growth. Where internal drainage is impeded, attempts to leach the soil can do more harm than good, by raising the water table, waterlogging the soil, and causing capillary rise to the surface, where evaporation infuses the topsoil with cumulative quantities of salt.

Overall salinity is generally expressed in terms of the total dissolved solutes (TDS) in milligrams per liter of solution (approximately equivalent to parts per million, ppm). Salinity may also be characterized by measuring the electrical conductivity (EC) of the solution, generally expressible in terms of decisiemens per meter ($dS\,m^{-1}$).

Quantitative criteria for diagnosing soil salinity were originally formulated by the US Salinity Laboratory at Riverside, California (in its *Handbook 60*, first issued in 1954), in terms of the EC of the soil's saturation extract (i.e., the solution extracted from a soil sample that had been presaturated with water). Those criteria are still in wide use today. Accordingly, a saline soil has been defined as having an EC of more than $4\,dS\,m^{-1}$. This value generally corresponds to approximately 40 mmol salt l^{-1}. In the case of a sodium chloride solution, this equals about $2.4\,g\,l^{-1}$.

The clay fraction in saline soils is generally well flocculated. As the salts are leached, however, the

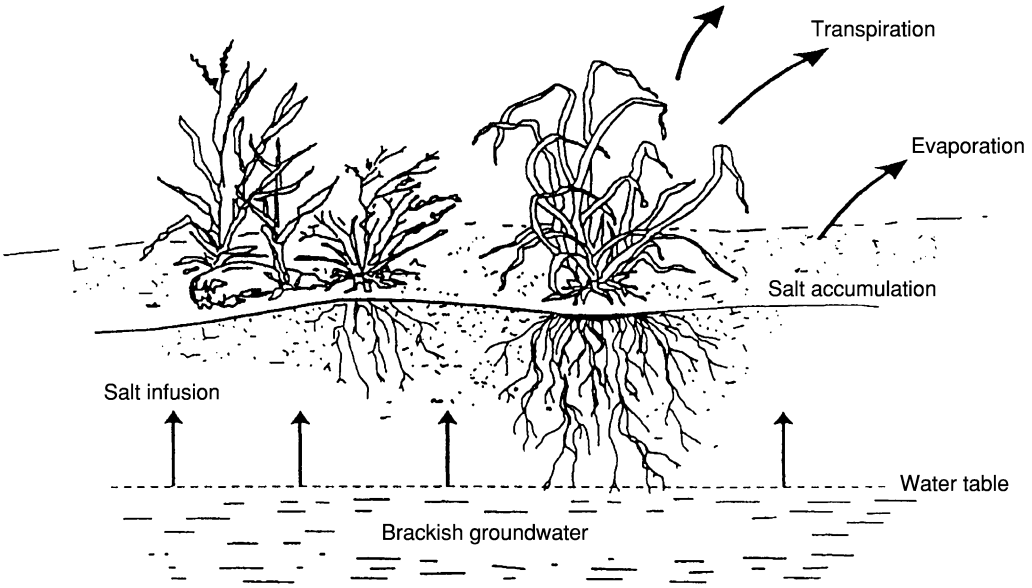

Figure 1 The process of waterlogging and salination. Reproduced with permission from Hillel D (1998) Environmental Soil Physics, Elsevier.

flocs may tend to disperse and the soil aggregates to break down (or slake). This especially occurs where an appreciable concentration of sodium is adsorbed on to the clay particles. The tendency for flocs to disperse and for aggregates to slake and collapse results in the deterioration of soil structure by the clogging of large pores in the soil, and consequently in the reduction of soil permeability. This leads to the associated phenomenon of soil sodicity, also known as alkalinity (Figure 1).

Irrigation Water Quality

Solutes can be added to the soil solution in rainfall (especially along seacoasts, where sea spray mixes with the rain) or in irrigation water infiltrated from above, in groundwater rising by capillarity from below, in the dissolution of salts initially present in solid form within the soil and subsoil, and in the artificial application of agricultural chemicals (e.g., fertilizers, pesticides, and soil amendments). Methods for removal of solutes from the soil include uptake by plants (generally of minor importance), downward transport by percolation and drainage (leaching), erosion of the soil surface by overland flow and by wind, precipitation or adsorption on to the solid phase and conversion to insoluble or unavailable forms, and – for some substances – volatilization of gaseous compounds. To avoid the accumulation of salts to toxic levels, their inputs to the soil must not exceed the rate of their removal from the soil or their conversion to unavailable forms within it. The control of soil salinity must therefore include measures to control both the inputs and the outputs of salts.

Among the various inputs of salts listed above, irrigation water often plays a major role. The quality of irrigation water may affect soil salinity and sodicity, cation exchange, soil acidity or alkalinity, nutrient availability, clay dispersion and flocculation, as well as soil structure, infiltration, and aeration. Clearly, therefore, the composition of irrigation water is an important determinant of soil productivity, crop growth, and agricultural drainage quality. The hazard posed by irrigation water containing salts of varying composition and concentration depends on soil conditions, climatic conditions, crop species and variety, and the amount and frequency of the irrigation applied. In general, irrigation water of EC less than $0.7\,\mathrm{dS\,m^{-1}}$ poses little or no danger to most crops, whereas EC values more than $3.0\,\mathrm{dS\,m^{-1}}$ may restrict the growth of most crops. The major components of salinity are the cations Ca, Mg, and Na, and the anions Cl, SO_4, and HCO_3. The potassium, nitrate, and phosphate ions, though important nutritionally, are usually minor components of soil salinity. In addition, certain constituents (such as boron) may have an important effect on crop growth even though their concentrations are usually too low to have any substantial effect on the soil's total salinity.

Irrigation waters of different sources, locations, and seasons vary greatly in quality (Table 1). Some irrigation waters contain as little as $50\,\mathrm{g\,salts\,m^{-3}}$, and others as much as $3000\,\mathrm{g\,salts\,m^{-3}}$. Since the volume of water applied in irrigation to a crop during its growing season commonly varies between 5000 and $20\,000\,\mathrm{m^{-3}\,ha^{-1}}$, the salt input to a crop may range between 250 and $60\,000\,\mathrm{kg\ ha^{-1}}$.

Table 1 Classification of water quality according to total salt concentration

Designation	*Total dissolved salts (ppm)*	*EC ($dS\,m^{-1}$)*	*Category*
Fresh water	<500	<0.6	Drinking and irrigation
Slightly brackish	500–1 000	0.6–1.5	Irrigation
Brackish	1 000–2 000	1.5–3	Irrigation with caution
Moderately saline	2 000–5 000	3–8	Primary drainage
Saline	5 000–10 000	8–15	Secondary drainage and saline groundwater
Highly saline	10 000–35 000	15–45	Very saline groundwater
Brine	>35 000	>45	Seawater

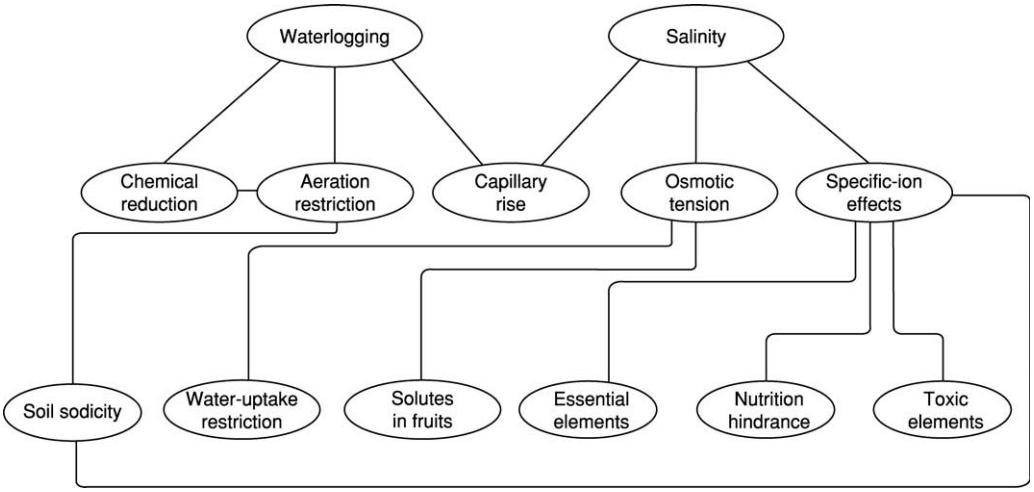

Figure 2 Effects of salinity and sodicity on plants.

Another important criterion of irrigation water quality is the sodium adsorption ratio (SAR). High alkalinity of irrigation water, manifested when the pH value is more than 8.5, generally indicates the predominant presence of sodium ions (often associated with the bicarbonate anion) and poses a danger of soil sodification. Freshly pumped groundwater may have a high SAR even if the pH is less than 8.5, owing to the presence of dissolved CO_2 (samples of such water should be aerated to allow the carbon dioxide to effervesce prior to measurement of the pH).

With high-SAR water, irrigation by sprinkling will increase the soil's tendency to form a surface seal (crust) under the impact of the drops striking the bare soil. Flood irrigation may also cause the breakdown of soil aggregates by air slaking. On the other hand, application of water by drip irrigation at spaced points on the surface or below it, may lessen the physical disruption of soil structure that would otherwise take place under the influence of high-SAR water. High-pH water may cause nutritional as well as structural problems. The addition of gypsum to the water or to the soil surface may help in both respects, by promoting the flocculation of clay and the nutritional balance of the soil solution.

In certain circumstances and with appropriate precautions, brackish water may safely be used for the irrigation of salt-tolerant crops. This includes the secondary use, or reuse, of drainage waters. Especially suitable for this purpose are deep sandy soils that are prevalent in some arid regions, where internal drainage is unrestricted and there is little risk of either groundwater rise or of soil salination and sodification.

The use of brackish water for sprinkling irrigation, however, may cause foliar injury. The degree of injury depends on the following factors: concentrations of ions in the water, sensitivity of the crop at various growth stages, water stress of the plants prior to irrigation, and frequency of irrigation. The potential damage also depends on the prevailing environmental conditions, including the temperature and relative humidity of the atmosphere, which affect the rate of evaporation. Sprinkling at night, when the atmospheric temperature and evaporativity are relatively low, can reduce foliar absorption and injury.

The greater the rate of evapotranspiration and the longer the interval between irrigations, the more concentrated the residual solution in the root zone and the more severe the salt stress imposed on the plants (Figure 2). Hence, when irrigation water is brackish,

a common management strategy is to increase the frequency of irrigation so as to maintain a high content of water and to prevent the rise of salt concentration in the root zone. Thanks to its ready adaptability to high-frequency irrigation, drip irrigation beneath the canopy appears to be the most appropriate method to use with brackish water, especially as it avoids direct foliar exposure to saline water.

Brackish drainage water may also be used in a system of agroforestry. Salt-tolerant trees are capable of thriving when irrigated with brackish water, and also of lowering the water table by the extraction and transpiration of water from deeper layers in the soil, thus reducing the volume and expense of needed drainage in some areas. Among the trees suitable for this type of agroforestry and biodrainage are certain species of eucalyptus, acacia, casuarina, poplar, mesquite, and tamarisk. The harvested wood may be used for fuel, pulp, or construction.

The use of drainage wastewater entails certain distinct hazards. In some places, the concentration of nitrates may become excessive, and contribute to groundwater and surface-water contamination. Heavy metals and various other toxic materials can pose a problem. They tend to accumulate in the soil and thence enter the biological food chain. Especially hazardous are industrial waste products that may be carcinogenic as well as toxic.

Groundwater Drainage

The presence of a high water table can be either a blessing or a curse. The blessing occurs when, in periods of low rainfall or deficiency of water for irrigation, upward capillary flow from the water table augments the water supply to the roots. The curse occurs as the rising water brings up salts from below and thereby salinizes the root zone. In the field, upward capillary rise and downward percolation may take place alternately during the year. Percolation occurs typically during the rainy and early irrigation seasons, when the water requirements of the crop are relatively low and the water supply from above is high. On the other hand, upward flow takes place later in the irrigation season, when the water requirements are high and both rainfall and irrigation are restricted. Over the long term, a net downward flow of salt-bearing water through the root zone is essential to sustainable productivity.

The term 'drainage' can be used in a general sense to denote outflow of water from soil. More specifically, it can serve to describe the artificial removal of excess water, or the set of management practices designed to prevent the occurrence of excess water. The removal of free water tending to accumulate over the soil surface by appropriately shaping the land is termed 'surface drainage' and is outside the scope of this article. Finally, 'groundwater drainage' refers to the outflow or artificial removal of excess water from within the soil, generally lowering the water table or preventing its rise.

In waterlogged soils, gas exchange with the atmosphere is restricted to the surface zone, while, within the profile, oxygen may be almost totally absent and carbon dioxide may accumulate. Under anaerobic conditions, various substances are reduced chemically from their normally oxidized state. Toxic concentrations of ferrous, sulfide, and manganous ions can develop. These, in combination with products of the anaerobic decomposition of organic matter (e.g., methane) can greatly inhibit plant growth. At the same time, nitrification is prevented, and various plant and root diseases (especially fungal) are more prevalent. High-moisture conditions at or near the soil surface make the soil susceptible to compaction and puddling by animal and machinery traffic. Necessary operations (e.g., tillage, planting, spraying, and harvesting) are thwarted by poor trafficability (i.e., the ability of the ground to support vehicular traffic). Furthermore, the surface zone of a wet soil does not warm up readily at springtime, owing to greater thermal inertia and downward conduction, and to loss of latent heat by the higher evaporation rate. Consequently, germination and early seedling growth are retarded. All these phenomena are in addition to the tendency of waterlogged soils, especially in arid areas, to become saline.

The artificial drainage of groundwater is generally carried out by means of drains, which may be ditches, pipes, or 'mole channels,' into which groundwater flows as a result of the hydraulic gradients existing in the soil. The drains themselves are made to direct the water, by gravity or by pumping, to the drainage outlet, which may be a stream, a lake, an evaporation pond, or the sea. In some places, drainage water may be recycled or reused for agricultural, industrial, or residential purposes, as well as for agroforestry or the irrigation of ornamental plants. Because drainage water may contain potentially harmful concentrations of salts, fertilizer nutrients, pesticide residues, and various other toxic chemicals, as well as biological pathogens, it is not enough to provide means to 'get rid' of it; attention must be devoted to the quality of the water to be disposed of and to the long-term consequences of its disposal.

The disposal of salt-bearing effluent may pose a danger to rivers and to groundwater. If the drainage water is returned to a river or an aquifer serving as a water source, or if the drainage is to be reused directly,

Table 2 Prevalent depths and spacing of drainage pipes in different soil types

Soil type	Hydraulic conductivity ($m\,day^{-1}$)	Spacing of drains (m)	Depth of drains (m)
Clay	1.5	10–20	1–1.5
Clay loam	1.5–5	15–25	1–1.5
Loam	5–20	20–35	1–1.5
Fine, sandy loam	20–65	30–40	1–1.5
Sandy loam	65–125	30–70	1–2
Peat	125–250	30–100	1–2

its load of corrosive salts and other pollutants may affect downstream agriculture, households, water utilities, and industry. Where persistent pesticides are applied to irrigated land, their residues can cause further damage to biotic communities in riverine, estuarine, and lacustrine habitats, as well as to public health. Construction of evaporation ponds for disposal of drainage water generally requires the allocation of approximately 10% of the land area. Care must also be taken to avoid leaks and consequent salination of the underlying groundwater. The loss of potentially valuable land, the costs of construction and conveyance, and the environmental impacts may make such ponds impractical in some cases.

Various equations, empirically or theoretically based, have been proposed for determining the desirable depths and spacings of drain pipes or ditches in different soil and groundwater conditions. In the Netherlands, the country with the most experience in drainage, common criteria for drainage are to provide for the removal of approximately 7 mm per day, and to prevent a water table from rising above a depth of 0.5 m from the soil surface. In more arid regions, because of the greater evaporation rate and groundwater salinity, the water table must generally be kept much deeper. In the Imperial Valley of California, for instance, the drain depth ranges from approximately 1.5 to 3 m, and the desired water table depth midway between drains is at least 1.2 m. For medium- and fine-textured soils, the depth should be even greater where the salinity risk is high. Since there is a practical limit to the depth of drain placement, it is the density of drain spacing that must be increased under such circumstances (Table 2).

Leaching Processes

To prevent salts from accumulating in the root zone during repeated cycles of irrigation and evapotranspiration, the obvious remedy is to apply water in an amount greater than evapotranspiration, so as deliberately to cause a fraction of the applied water to flow through the root zone and flush away the excess salts. However, unless the water table is very deep or lateral groundwater drainage is sufficiently rapid, the extra irrigation can cause a progressive rise of the water table. Therefore, the amount of water applied must be optimized to allow leaching without water-table rise. The concept of 'leaching requirement' was first developed by the US Salinity Laboratory in Riverside, California. It has been defined as the fraction of the irrigation water that must be percolated out of the bottom of the root zone in order to prevent average soil salinity from rising above some specifiable level.

According to the standards developed there, the maximum concentration of the soil solution in the root zone, expressed in terms of EC, should be kept below 4 $dS\,m^{-1}$ for sensitive crops. Salt-tolerant crops such as beets, alfalfa, and cotton may give satisfactory yields at values up to 8 $dS\,m^{-1}$. The problem encountered in any attempt to apply such a simplistic criterion is that in the field (unlike the case of plants grown in solution culture or in small containers) the concentration of the soil solution varies greatly in space and time. In addition, the sensitivity of any crop to salinity depends on its stage of growth and on such variables as ambient temperature, atmospheric humidity, soil matric suction, and nutrient availability.

The leaching requirement depends on the salt concentration and composition of the irrigation water, on the amount of water extracted from the soil by the crop, and on the salt tolerance of the crop, which determines the maximum allowable concentration of the soil solution in the root zone. Assuming steady-state conditions of throughflow (thus disregarding short-term fluctuations in soil-moisture content, flux, and salinity), and furthermore assuming no appreciable dissolution or precipitation of salts in the soil and no significant removal of salts by the crop or capillary rise of salt-bearing water from below, the following simple equation is obtained:

$$V_d/V_i = c_i/c_d \qquad [1]$$

in which V_d and V_i are the volumes of drainage and of irrigation, respectively, and c_d and c_i are the corresponding concentrations of salt. Water volumes are normally expressed per unit area of land as equivalent depths of water, and salt concentrations are generally measured and reported in terms of EC. Because the volume of water drained is the difference between the volumes of irrigation and evapotranspiration (i.e., $V_d = V_i - V_{et}$), we can transform the last equation as follows:

$$V_i = [c_d/(c_d - c_i)]V_{et} \quad [2]$$

This is equivalent to the formulation given in the US Salinity Laboratory's Department of Agriculture (USDA) Handbook No. 60:

$$d_i = [E_d/(E_d - E_i)]/d_{et} \quad [3]$$

where d_i is the depth of irrigation, d_{et} the equivalent depth of 'consumptive use' by the crop (evapotranspiration), and E_d and E_i are the electrical conductivities of the drainage and irrigation waters, respectively.

The leaching requirement equation implies that, by varying the fraction of applied water percolated through the root zone, it is possible to control the concentration of salt in the drainage water and hence to maintain the concentration of the soil solution in the main part of the root zone at some intermediate level between c_i and c_d. However, the leaching requirement concept disregards the distribution of salts within the root zone itself, as it is affected by the frequency and spatial variability of irrigation, as well as by its quantity and water quality. In particular, the variation of root-zone salinity is affected by the pattern and degree of soil moisture depletion between irrigations. The less frequent the irrigation regime, the greater the buildup of salt between successive irrigations. In some cases, the commonly recommended leaching fraction may not be sufficient to prevent the reduction of yield below its potential, especially if the climatically imposed evaporation rate is high and the irrigation water is brackish.

With modern methods of high-frequency irrigation, it is possible to maintain the soil solution in the surface zone at a concentration nearly equal to that of the irrigation water. This zone can be deepened by increasing the volume of water applied. Beyond this zone, the salt concentration of the soil solution increases with depth to a salinity level depending on the leaching fraction. High-frequency irrigation not only lowers the concentration of the soil solution in the upper zone (where most roots proliferate), but also tends to minimize the matric suction of soil moisture.

Extensive research has shown that leaching soils at a water content below saturation (e.g., under low-intensity sprinkling or intermittent ponding) can produce more efficient leaching that can be achieved by the once-standard method of continuous flooding. In a soil with macropores – cracks, wormholes, or decayed root channels – much of the water under ponding moves rapidly down those large passageways, bypassing the greater volume of the soil containing the salt, so it is largely ineffective in leaching the micropores of the soil matrix. In contrast, under low-intensity sprinkling, the soil never becomes saturated, so a greater portion of the applied water moves through the soil matrix, thus producing more efficient leaching per unit volume of water infiltrated. However, the processes of infiltration and unsaturated flow under low-intensity sprinkling are inherently slower and require more time than saturated infiltration under ponding.

Nonuniformity of irrigation as well as of soil is a complicating factor. If the leaching requirement is not met throughout the field, soil salinity will prevail in spots, wherever leaching is insufficient. Whether to apply copious amounts of water to the entire field so as to ensure that the leaching requirement is met everywhere, or to accept some reduction in yield in parts of the field, must be determined from an economic analysis of costs and benefits. Such an analysis should take into consideration the danger that saline spots might recur (and perhaps even grow in extent and severity) from year to year. One answer is to apply extra water preferentially to the spots that need it most, but such a strategy requires a flexible irrigation system that would allow controlled variability of water delivery. Although such a specialized irrigation system is likely to be expensive to install and operate, it may well be worthwhile in the long run.

Soil Amendments

The leaching process is enhanced if the applied water contains a sufficient concentration of electrolytes to reduce swelling and dispersion of clay in the soil. Where leaching occurs with water of very low salinity (e.g., rainwater), soil permeability can be increased by the surface application of a slowly soluble electrolytic salt – preferably a substance containing a divalent cation such as calcium, to prevent the sodium ion from dispersing the clay. Such materials, commonly known as soil amendments, can replace exchangeable sodium with flocculation-promoting divalent ions.

The most commonly considered soil amendment for the purpose of improving the structure and the permeability of soils, especially those prone to becoming sodic, are dihydrate calcium sulfate (gypsum) and dihydrate calcium chloride. Gypsum is generally the preferred soil amendment, thanks to its ready availability in many places and to its relatively low cost. It may be derived from mining or be available as a by-product of the phosphate-fertilizer industry. The solubility of pure gypsum is approximately 2.15–2.63 $kg\,m^{-3}$, depending somewhat on temperature. Applied gypsum dissolves in the soil solution until its solubility limit is reached or until its supply is exhausted. The rate of dissolution of applied gypsum depends on its source and degree of granulation. Industrial gypsum generally dissolves more rapidly

than mined gypsum, which generally contains impurities. The amount of gypsum needed to replace the exchangeable sodium depends on the initial exchangeable sodium percentage, the soil's total cation exchange capacity, its bulk density, and the depth of the soil to be treated effectively. If elemental sulfur is added to a sodic soil in lieu of gypsum, it must be oxidized *in situ* to become effective. Upon oxidation, it forms sulfuric acid, which then reacts with lime in the soil to produce gypsum.

Early-Warning Systems

In many cases, irrigation systems are organized and irrigation is begun long before drainage is installed. Indeed, an irrigation project can often function unimpeded for years, even decades, without artificial drainage. In some cases, the land is so well drained naturally that irrigation can thus be continued for a very long time. However, far more typically, the processes of groundwater rise and salt accumulation proceed inexorably, so that sooner or later (especially in ill-drained river valleys, where most irrigation development takes place) the provision of artificial drainage becomes essential.

Granted that a drainage system must be planned in advance at the very outset of an irrigation project, the crucial question is when to begin installing and operating it. If installed too early, the drainage system may lie unused for some time and therefore be both unnecessary and uneconomical, and it may deteriorate in the interim before it comes into use. On the other hand, if installed after waterlogging and salination have advanced, it may be too late to restore productivity economically. These considerations emphasize the importance of having an early-warning system to indicate, before the problem becomes acute, that soil salination is incipient and that the need for drainage is imminent. Soil salinity is normally monitored by a combination of soil sampling, soil-solution sampling by vacuum extraction, and *in situ* salt sensors. Mobile devices with combined electromagnetic induction and four-electrode soil conductivity sensing systems are now under development for monitoring and mapping the distribution of soil salinity over an entire field, but such instruments have not yet entered into general use.

The detection and diagnosis of salinity are difficult in the early stages of its occurrence. Visual inspection of the soil surface may be misleading. For example, the white precipitate formed on the surface of furrow-irrigated or drip-irrigated soil may be due to relatively harmless calcite or gypsum. Visual inspection of crops provides obvious clues to salt stress only after the condition is well advanced. Crop plants suffering salt stress eventually exhibit stunted growth, smaller leaves than normal, and discoloration. Such symptoms first occur in spots, rather than uniformly over the field. Since factors other than salinity (e.g., water stress, nutrient deficiencies, or misapplied pesticides) may produce similar symptoms, visually observed indications of apparent salinity should be checked by chemical analyses of soil, plant, and water samples. One good way to detect the early appearance of salinity is to place plants that are known to be particularly salt-sensitive at regularly spaced intervals throughout the irrigated area. Such interspersed detector plants may reveal early symptoms of physiological stress and thus provide a timely warning of problems that are likely to be exacerbated over time.

An important indicator of the salinity hazard is the depth of the water table. There is cause for concern whenever it approaches within 1.5–2 m of the soil surface. Hence the water table should be monitored regularly by means of observation wells and piezometers (Figures 3 and 4). Both are vertical tubes that

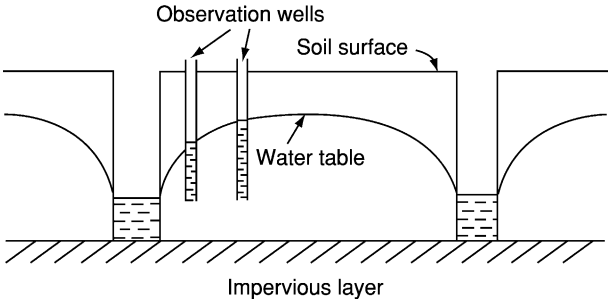

Figure 3 Observation wells to determine elevation of the water table. Reproduced with permission from Hillel D (1998) Environmental Soil Physics, Elsevier.

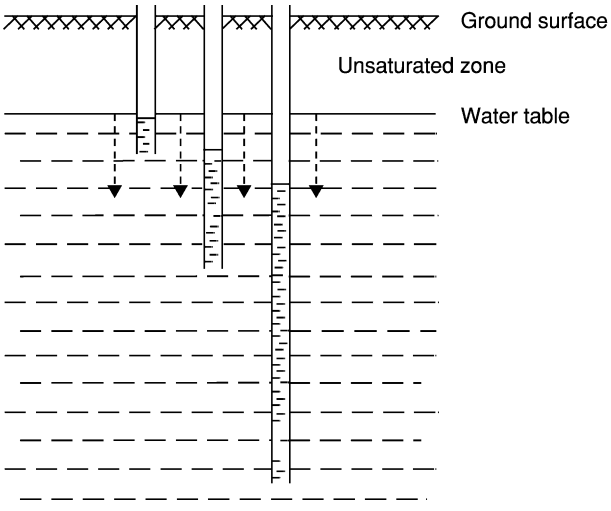

Figure 4 Piezometers to determine vertical pressure gradients below the water table. Reproduced with permission from Hillel D (1998) Environmental Soil Physics, Elsevier.

are inserted into the soil to a depth far below the water table. The difference is that an observation well is perforated to permit free inflow of groundwater along the length of the tube below the water table; in contrast, a piezometer's only opening is at the bottom. Hence a piezometer indicates the hydraulic head (pressure) of the water at the bottom of the tube, rather than the position of the water table. Several piezometers, inserted side by side to different depths, can indicate the vertical gradient of the hydraulic head below the water table. The direction and magnitude of that gradient are indicative of the tendency of the groundwater to rise or fall.

Introduction

Environmental control and agricultural management problems involve the simultaneous transport of water and mixed salts solutions with ions that interact with the soil matrix. The soil solution–soil matrix interactions include phenomena such as cation exchange, anion exclusion, precipitation and dissolution, swelling and reorganization of the soil colloid structures, and, concurrently, rearrangement of the soil pore-size distribution; the latter can affect the soil hydraulic conductivity and retentivity. These interactions, therefore, may considerably affect water flow and solute transport.

The magnitude of the soil solution–soil matrix interactions depends to a large extent upon the types and amounts of inorganic and organic soil colloids. Among soil mineral colloids, the most reactive constituents are the smectite minerals (e.g., montmorillonite, beidellite, monronite), characterized by dioctahedral structure. The presence of these minerals imparts a considerable cation exchange capacity and/or specific surface area to soils from arid and semiarid regions. Furthermore, the smectite minerals are capable of considerable expansion at moderate-to-high exchangeable sodium levels in the presence of relatively low salt soil-solution concentration. Hence, they can impart rather substantial salinity-dependent water retention and conductivity changes to soils, and, concurrently, may considerably affect water flow and solute transport.

Here the emphasis is on the effect of salinity on soil physical properties relevant to water flow and solute transport, in particular, soil water retentivity and conductivity.

Water Retention and Swelling in Salt-Affected Soils

The amount of water retained by the soil depends largely upon the mineral and organic colloid contents of the soil, although the structural arrangement of soil

pores may also be of considerable importance in this respect. In particular, the presence of substantial quantities of soil organic matter and/or smectite minerals results in a considerable water-retention capacity. Soils with high smectite content may also swell considerably more in the presence of high sodium and/or low salt concentrations. Soils high in organic colloids are much more stable and do not tend to swell excessively under adverse chemical conditions. They may disperse, however, at high pH levels or in the presence of low salt concentrations.

The effects of concentration and composition of the soil solution on water retention by a soil containing 20% clay (dominated by montmorillonite) are depicted in Figure 1. The functional relationships (under wetting conditions) are given in terms of the capillary pressure head, h (considered here as a positive quantity), volumetric soil-water content, θ, and equilibrium solution concentration, $C = C_{Na} + C_{Ca}$, where C is concentration in milliequivalents per liter, and composition (expressed in terms of sodium adsorption ratio: $SAR = C_{Na}/\sqrt{(C_{Ca}/2)}$. The points in Figure 1 represent actual measurements for various values of SAR and C; the solid lines represent best visual fits between measured points. Note that the ordinate scale of Figure 1 is shifted upward by an order of magnitude and the data are accordingly translated along this axis, to distinguish between different sets of concentrations. In general, each of the water-retention relationships in Figure 1 can be represented by a single continuous curve. When solution concentration exceeds 50 mEq l^{-1} a single-valued function is obtained for any value of SAR. The same is true for SAR = 0 and 2 mEq $l^{-1} < C < 5$ mEq l^{-1}, as can be seen from the lowest curve of Figure 1. Within the range 2 mEq $l^{-1} < C < 10$ mEq l^{-1} and $0 < SAR < 50$, water content θ depends not only on the pressure head, h, but also on both concentration and composition of the soil solution. For a given h, θ increases as C decreases and as SAR increases.

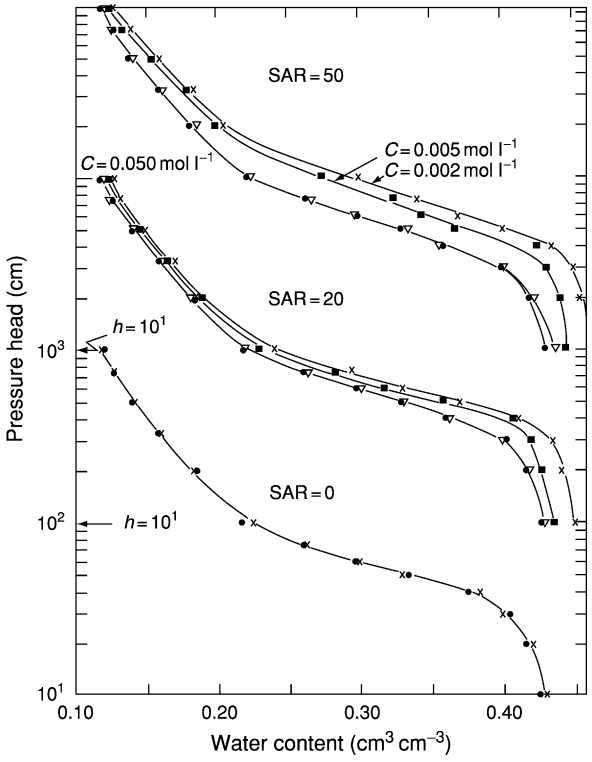

Figure 1 Capillary pressure head, h, as a function of water content, θ, for selected values of the concentration, C, and the sodium adsorption ratio, SAR, of the equilibrium solution. Arrows indicate that the point $h = 10$ cm is shifted and the data are translated along the h-axis. The experimental findings presented in Figure 1 can be qualitatively explained in terms of electrostatic properties and the porous nature of the soil. It is assumed that the soil pore space can be divided into structural and textural porosity. The latter is regarded as an intrinsic property of the soil, arising from the size and arrangement of basic particles within the soil mass. In these pores the $h(\theta)$ function can be determined quantitatively from the pressure that develops between the clay platelets, within the clay mass between the pores as the soil solution composition and concentration vary.

The classic view of the osmotic pressure of soil colloids is that cations in the diffuse layer between clay particles reduce the free energy of the water relative to that in the external equilibrium solution. This causes water molecules to diffuse into the space between the clay particles, since the cations are electrostatically constrained from leaving the interlayer region. Hence, the particles move apart to accommodate the extra water. If, on the other hand, the clay particles are confined, hydraulic pressure develops between them. For an Na/Ca-Cl soil-water system, this pressure may be determined on the basis of the mixed-ion, diffuse double-layer theory (see eqn [2]).

Equation [2] can be regarded as a reasonably good first-order approximation of the water-retention forces acting within the textural porosity. It predicts that for a given hydrostatic pressure, P, the volume of water retained by the clay mass (which is proportional to the distance between the clay particles) increases as the equilibrium solution becomes more diluted (C decreases) and as the value of SAR increases. In the structural pores, which are sensitive to external forces arising from interactions between clay particles within the textural porosity, the $h(\theta)$ function can be determined from the pressure within the water-filled pores relative to that within the

air-filled pores. In the former pores, at equilibrium, the pressure increases as the pore radius decreases or, for a given pressure, higher values of θ are associated with a larger number of pores having a given corresponding radius. Thus, the functional relationships between h and θ in the structural porosity depend on the total porosity and the pore-size distribution. Changes in the total structural porosity and its distribution result from changes in the volume occupied by the clay mass within the textural porosity. For a given pressure, the space between the clay particles increases as the value of SAR increases and as C decreases. This results in an increase in the amount of water retained by the clay mass, and, concurrently, in the volume that is occupied by the clay mass. For a constant-volume system, changes in the volume of the clay mass are at the expense of the structural porosity and its distribution. Thus, as can be observed in Figure 1, the amount of water retained by the soil for a given capillary pressure head increases with decreasing C and increasing SAR.

Effects of Salts on Soil Hydraulic Conductivity

The retention curves in Figure 1 may be viewed as representatives of the soil's pore-size distribution. The data in Figure 1, therefore, suggest that swelling of the clay fraction within the soil, induced by relatively low C and high SAR, may alter the geometry of the soil pores and thus affect the intrinsic soil permeability, $\kappa(\theta)$. Investigations have confirmed that soil permeability or hydraulic conductivity, $K(\theta) = \kappa(\theta)\gamma/\eta$ (where γ and η are the specific gravity and the dynamic viscosity of water, respectively), is highly affected by the soil-solution concentration, C, and composition, expressed in terms of SAR. It has been suggested that the swelling of clay particles in a confined soil system causes the size of large soil pores to decrease, and that breakdown of domains of clay platelets (tactoids) and the subsequent movement and dispersion of the clay platelets may further block soil pores. Low permeability can result from such geometric restrictions. There is a positive correlation between relative soil permeability and the swelling of extracted soil clays, which, in turn, is affected by the soil-solution concentration and composition. Inasmuch as soil-solution composition may affect the breakdown of tactoids (and the subsequent movement and dispersion of clay platelets) on the one hand, and soil-swelling on the other hand, in much the same way, the relative importance of swelling and dispersion in affecting soil permeability remains essentially unresolved. There are situations (relatively coarse-textured soils associated with relatively high influx rates) in which the demixing of adsorbed ions, which concentrates Na on external particle surfaces, may lead to the breakdown of tactoids and the subsequent movement and dispersion of clay platelets.

The effect of concentration and composition of the soil solution on the hydraulic conductivity function $K(\theta)$ in a soil containing 20% clay (dominated by montmorillonite) is depicted in Figure 2. The functional relationships are given in terms of water

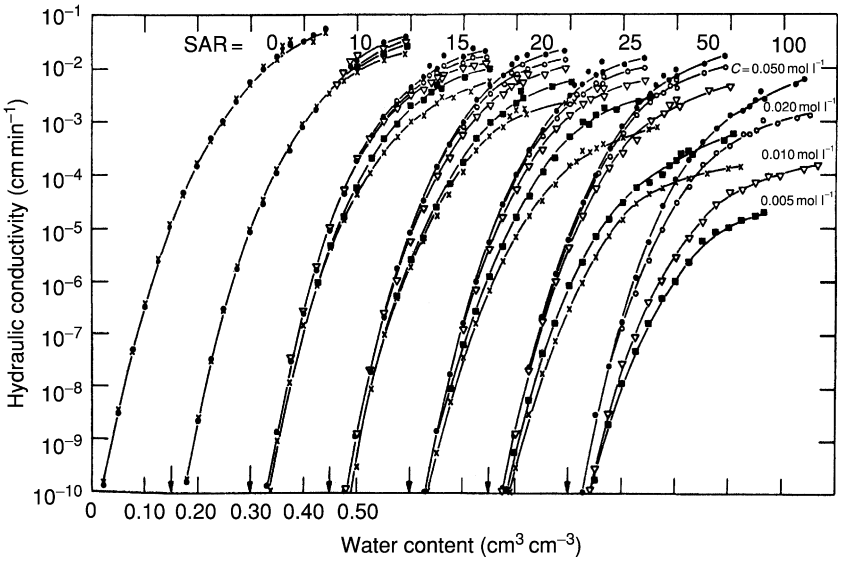

Figure 2 Hydraulic conductivity, K, as a function of water content, θ, for selected values of the concentration, C, and the sodium adsorption ratio, SAR, of the equilibrium solution. Arrows indicate that the point $\theta = 0$ is shifted and the data are translated along the θ-axis. (Reproduced with permission from Russo D and Bresler E (1977) Effect of mixed Na-Ca solutions on the hydraulic properties of unsaturated soils. *Soil Science Society of America Journal* 41: 714–717.)

content, θ, and equilibrium solution concentration, C, and composition, SAR. The points in Figure 2 represent actual measurements for various values of SAR and C; the solid lines represent best visual fits between measured points. Note that the abscissa scale in Figure 2 has been shifted to the right and the data are accordingly translated along the θ-axis to distinguish among different sets of concentrations.

In general, each of the $K(\theta)$ functions in Figure 2 can be represented by a single continuous curve. Furthermore, for the calcium-saturated system (SAR = 0 and $2\,\text{mEq}\,\text{l}^{-1} \leq C \leq 50\,\text{mEq}\,\text{l}^{-1}$), a single-valued $K(\theta)$ is obtained. In the mixed Na-Ca system, however, values of $K(\theta)$ decrease with both θ and C for a given SAR. The differences among the various functions increase as θ becomes larger and as C becomes smaller. These differences are pronounced when SAR and θ are greater than 15 and 0.25, respectively, and when C is equal to or less than $10\,\text{mEq}\,\text{l}^{-1}$. In other words, relatively low values of soil-water content compensate for the negative effects of high SAR and low C on the hydraulic conductivity.

The experimental data depicted in Figure 2 can be explained qualitatively in terms of soil water–clay interactions and the porous nature of the soil. The unsaturated hydraulic conductivity function $K(\theta)$ depends upon the size distribution of water-filled pores and the total water-filled porosity. As mentioned previously, the diffuse double-layer theory for mixed-electrolyte systems predicts that, for a given pressure, the space between clay particles and, concurrently, the amount of water retained by the clay mass increase as SAR increases and C decreases. For a constant-volume system, changes in the volume of the clay mass are at the expense of the quantity and distribution of the soil pores. Thus, for a given pressure head, h, the amount of water retained by the soil increases (Figure 1) and the hydraulic conductivity decreases (Figure 2) as SAR becomes larger and solution concentration, C, decreases. Since the swelling of clay decreases as h increases, the increase in the amount of water retained and the decrease in hydraulic conductivity become smaller as h increases. In addition, both water content and hydraulic conductivity, and, concurrently, water velocity, may considerably decrease with increasing h. Consequently, increasing h may reduce the possibility that movement and dispersion of clay platelets will lead to additional blocking of the pore space available for water flow.

Modeling Hydraulic Conductivity and Water Retentivity in Salt-Affected Soils

In the preceding sections it was shown that in salt-affected soils, both the hydraulic conductivity, $K(h)$, and the water retentivity, $\theta(h)$ may depend on soil-solution concentration and composition. In the present analysis, ion precipitation or dissolution is not taken into account; thus, the simple but credible soil-water system containing only Na, Ca, and Cl ions is considered. The equilibrium solution is quantified in terms of the sum of the molar concentrations of the cations, $C_0 = c_{Na} + c_{Ca}$, and the ratio between the molar concentration of mono- and divalent cations, $R = c_{Na}/c_{Ca}$.

For the modeling of the hydraulic conductivity, $K(h, R, C_0)$, and the water retentivity, $\theta(h, R, C_0)$, functions, it is further assumed: (1) that the soil clay fraction is mostly montmorillonite (having a constant effective surface charge density, Γ_s), which may exist in packets of platelets or domains called tactoids; (2) that the ions on the external surfaces of the tactoids (the 'exchange phase') are distributed according to the planar mixed-ion diffuse double-layer theory; (3) that the number of clay platelets per tactoid depends on the pressure acting on the system and on the exchangeable sodium percentage (ESP); and (4) that, due to the continuity of the pressure in the soil solution, the pressure difference between two adjacent clay particles and the bulk solution (given by the swelling pressure, P (eqn [2]) is equal to the pressure difference across the air–water interface within the soil pores, i.e., the difference between the pore-water pressure, P_w, and the atmospheric pressure, P_a, as given by the capillary pressure, $P_c = P_w - P_a = -\gamma h$.

Calculations of the $b(h, R, C_0)$ and $N(h, R, C_0)$ Functions

For the Na/Ca-Cl soil system considered here, the general equation of the interacting double layer is obtained from the first integration of the one-dimensional Poisson–Boltzmann equation given by:

$$\frac{dY}{dx} = \frac{G}{\sqrt{R+1}}\left[R\left(\exp^{Z_{Na}Y} - \exp^{Z_{Na}Y_d}\right) + \left(\exp^{Z_{Ca}Y} - \exp^{Z_{Ca}Y_d}\right) + (R+2)\left(\exp^{Z_{Cl}Y} - \exp^{Z_{Cl}Y_d}\right)\right]^{1/2} \quad [1]$$

where $Y = \epsilon\psi/kT$ is the scaled electrical potential, Z is the valence of the ion shown subscript, ψ is the electrical potential, ϵ is the charge on the electron, k is the Boltzmann constant, T is the absolute temperature, x is the distance to the charged surface (where $x = s$ and $Y = Y_s$), Y_d is Y at the midplane between two adjacent tactoids (at the plane $x = d$, where $dY/dx = 0$), $G = (8\pi C_0 L\epsilon^2/10^3 DkT)^{1/2}$, L is the Avogadro number, and D is the dielectric constant of the bulk solution.

For dilute solutions, the swelling pressure, P, i.e., the pressure difference between the equilibrium solution (where $Y=0$) and the midplane between two adjacent tactoids (at the plane $x=d$, where $Y=Y_d$), is obtained by substituting the Boltzmann distribution law into the Van't Hoff relation. For the Na/Ca-Cl soil system considered here, with tactoids that are at a distance of $2b$ apart (where $b=d-s$), the swelling pressure, P is given by:

$$P = B\left[R(e^{Z_{Na}Y_d}-1)+(e^{Z_{Ca}Y_d}-1) +(R+2)(e^{Z_{Cl}Y_d}-1)\right] \quad [2]$$

where $B=kLTC_0/10^3(R+1)$. Substituting $P=\gamma h$ in eqn [2], one can obtain, after rearrangement:

$$a_1 e^{Z_{Na}Y_d}+a_2 e^{Z_{Ca}Y_d}+a_3 e^{Z_{Cl}Y_d}+a_4=0 \quad [3]$$

where $a_1=R$, $a_2=1$, $a_3=R+2$, and $a_4=-[a_1+a_2+a_3+10^3\gamma h(R+1)kLTC_0]$.

Thus, the solution of the nonlinear eqn [3] yields Y_d as a function of h, R, and C_0. Estimation of $b(h, R, C_0)$ also requires the knowledge of the scaled electrical potential at the charged surface, Y_s, which can be estimated from the integration of eqn [1] and from the condition of electroneutrality requiring that the surface charge density, Γ_s, be equal to the total space charge density, $\delta(x)$, within the range $s\le x\le d$, thus:

$$\left(\frac{dY}{dx}\right)_{x=s}=\frac{4\pi\pi\Gamma_s}{DkT} \quad [4]$$

Evaluating eqn [1] at the plane $x=s$ (where $Y=Y_s$), using eqn [4], one obtains, after rearrangement:

$$a_1 e^{Z_{Na}Y_s}+a_2 e^{Z_{Ca}Y_s}+a_3 e^{Z_{Cl}Y_s}+a_4=0 \quad [5]$$

where $a_4=-\{[2\Pi 10^3(R+1)\Gamma_s^2/LDkTC_0]+a_1 e^{Z_{Na}Y_d}+a_2 e^{Z_{Ca}Y_d}+a_3 e^{Z_{Cl}Y_d}\}$, and a_i, $i=1, 2, 3$, as before.

The solution of the nonlinear eqn [5] yields Y_s as a function of Γ_s, R, C_0, and $Y_d(h, R, C_0)$. From the values of Y_d and Y_s, the distance from the midplane $x=d$ (where $dY/dx=0$ and $Y=Y_d$) to the charged surface (where $x=s$ and $Y=Y_s$), $b=d-s$, can be obtained by direct integration of eqn [1]. Rearranging eqn [1] yields:

$$\frac{G}{\sqrt{R+1}}\int_d^s dx=\int_{Y_d}^{Y_s}(a_1 e^{Z_{Na}Y}+a_2 e^{Z_{Ca}Y}+a_3 e^{Z_{Cl}Y}+a_4)^{-1/2}dY \quad [6]$$

where $a_4=-[a_i e^{Z_{Na}Y_d}+a_2 e^{Z_{Ca}Y_d}+a_3 e^{Z_{Cl}Y_d}]$ and a_i, $i=1, 2, 3$, as before. Thus a numerical integration of eqn [6] yields $b=d-s$ as a function of h, R, and C_0.

Once $Y_d(h, R, C_0)$ has been estimated from eqn [3], the fractional excess of Na on the exchange phase, Γ_{Na}/Γ_s can be estimated from:

$$\frac{\Gamma_{Na}}{\Gamma_s}=\frac{R\sqrt{C_0}}{\Gamma_s\sqrt{\alpha(R+1)}}\sinh^{-1}\left(\frac{\Gamma_s}{\sqrt{C_0}}\frac{\sqrt{\alpha(R+1)}}{(R+4\cosh Y_d}\right) \quad [7]$$

where Γ_{Na} is the quantity of sodium ionic charges per unit area of the charged surface, and $\alpha=8000\Pi/L\epsilon\kappa T$. Note that, inasmuch as $Y_d=Y_d(h, R, C_0)$, the exchangeable sodium percentage, $ESP=100\Gamma_{Na}/\Gamma_s$ is also a function of h, R, and C_0. For given pressure head, h, and $ESP(h, R, C_0)$, the number of clay platelets per tactoid, $N=N[h, ESP(h, R, C_0)]$, is calculated by using experimental data on the dependence of N on h in a calcium system, and by experimental data on the dependence of N on ESP in clay suspensions.

Calculations of the $\theta(h, R, C_0)$ and $K(h, R, C_0)$ Functions

To estimate the $K(h, R, C_0)$ and the $\theta(h, R, C_0)$ functions, a confined volume element, V, of a homogeneous and isotropic porous medium with uniform porosity, φ^0, is considered. This soil volume, which is large compared with the typical pore size of the porous medium, is subdivided into n equal subvolumes, v_i, $i=1$–n, in such a way that only one value of the average pressure head, h_i, the equivalent radius of the water-filled pores, $r_i^0=2\sigma/\gamma h_i$, (with σ being the surface tension at the air–water interface), and the average number of pores having a unit length, $l_i=\varphi^0 v_i/\Pi(r_i^0)^2$, can be defined in each subvolume, v_i. Using the functions $b(h_i, R, C_0)$ and $N(h_i, R, C_0)$, the water content in each v_i is calculated from:

$$\theta_i(h_i, R, C_0)=\theta_i^0(h_i)+[\nu_i(h_i, R, C_0)-\nu_i^0(h_i)] \quad [8]$$

where θ_i^0 is the water content in a reference state (that is, a soil in equilibrium with a concentrated calcium chloride solution), at pressure head h_i, and ν_i^0 and ν_i are the volumes of water retained by the clay particles in a unit volume of the soil, in the reference state, and in equilibrium with a soil solution of a given R and C_0, given by:

$$\nu_i^0(h_i)=\frac{A_s}{2\,N_i^0(h_i)}\{2b_i^0(h_i)+2b_0[N_i^0(h_i)-1]\}\rho_b \quad [9]$$

and

$$\nu_i(h_i, R, C_0)=\frac{A_s}{2\,N_i^0(h_i)}\{2b_i(h_i, R, C_0)[1+N_i^0(h_i) -N_i(h_i, R, C_0)]+2b_0[N_i(h_i, R, C_0)-1]\}\rho_b \quad [10]$$

respectively, where A_s and ρ_b are the specific surface area and the bulk density, respectively, of the soil at the reference state, the superscript zero refers to the reference state, and $2b_0$ is the thickness of the water film between two adjacent clay platelets within a tactoid ($2b_0 = 9 \times 10^{-8}$ cm, regardless of h, R, or C_0). Similarly, since in the confined soil element the increment in the water retained by the clay fraction is at the expense of the pore space in which water flow takes place, the effective porosity, φ_i, in each subvolume, v_i, is given by:

$$\varphi_i(h_i, R, C_0) = \theta_i^0(h_i) - [\nu_i(h_i, R, C_0) - \nu_i^0(h_i)] \quad [11]$$

and the mean equivalent radius of the pores, r_i, in each subvolume, v_i is given by:

$$r_i(h_i, R, C_0) = \left[\frac{\varphi_i(h_i, R, C_0)v_i}{\pi 1_i}\right]^{1/2} \quad [12]$$

Given the values of $\varphi_i(h_i, R, C_0)$ and $R_i(h_i, R, C_0)$, the relative hydraulic conductivity can be calculated on the basis of the capillary bundle theory. Using a modified series-parallel model of the porous medium, the hydraulic conductivity relative to the reference state is given by:

$$K_i^r(h_i, R, C_0) = \frac{[\varphi_i(h_i, R, C_0)]^2 \sum_{j=i}^{n}[2j-1][r_j(h_j, R, C_0)]^2}{[\varphi_i^0(h_i)]^2 \sum_{j=i}^{n}[2j-1][r_j^0(h_j)]^2} \quad [13]$$

where φ_i^0 is the soil effective porosity in subvolume v_i, in the 'stable' reference state, $h_i < h_{i+1}$, and $i = 1$–n. Thus the soil hydraulic conductivity is given by:

$$K_i(h_i, R, C_0) = K_i^0(h_i)K_i^r(h_i, R, C_0) \quad [14]$$

where $K^0(h)$ is the hydraulic conductivity function of the soil at the 'stable' reference state.

A comparison between the calculated and measured water retention curves in a soil containing 20% clay (dominated by montmorillonite), for different combinations of $C = 10^{-3}\,C_0[1 + (R+1)^{-1}]$ and $\mathrm{SAR} = R[10^3 C_0(R+1)^{-1}]^{1/2}$, is presented in Figure 3. The abscissa scale in Figure 3 is shifted to the right and the data are accordingly translated along the θ-axis to distinguish between the calculated and the measured curves for different sets of concentrations. For calcium-saturated soil (SAR = 0), the experimental retention curves are independent of the solution concentration, whereas the calculated curves are slightly dependent on it. The small discrepancy between the calculated and the measured curves can serve as a measure of the error in the assumptions and

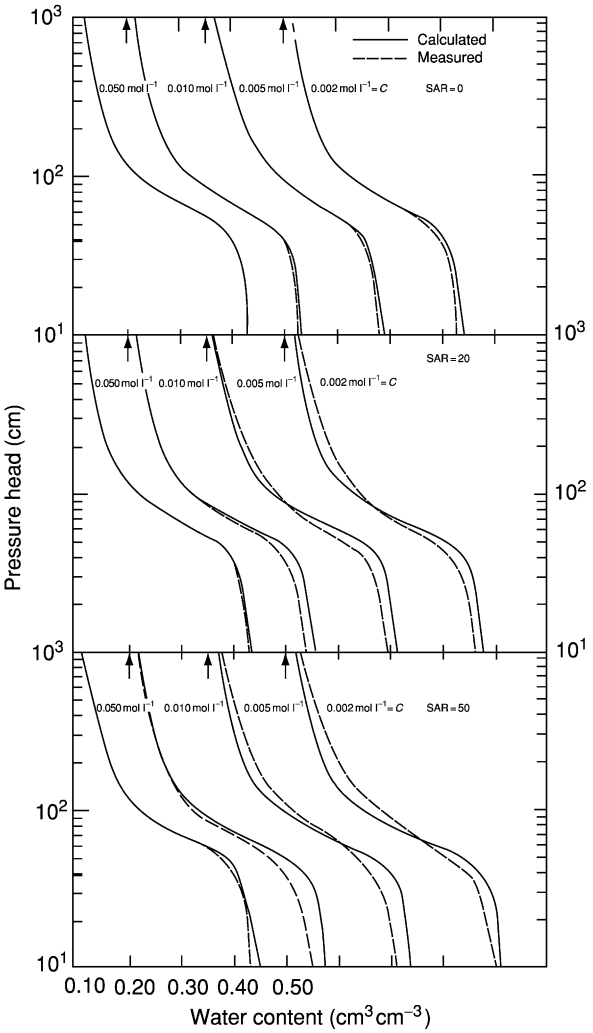

Figure 3 Capillary pressure head, h, as a function of water content, θ, for selected values of the concentration, C, and the sodium adsorption ratio, SAR, of the equilibrium solution. Computed results (solid lines) are compared with measured data (dashed lines). Arrows indicate that the point $\theta = 0.10$ is shifted and the data are translated along the θ-axis. (Reproduced from Russo D (1976) MSc Thesis (in Hebrew), *Analysis of the Saturated–Unsaturated Hydraulic Conductivity in a Mixed Sodium-Calcium Soil System*. Faculty of Agriculture in Rehovot. Jerusalem, Israel: The Hebrew University Press.)

of the ability of the calculations to predict soil-water retention. For the mixed systems, there is reasonably good agreement between measured and calculated retention curves. The agreement improves for lower sodic systems (SAR decreases) and as the system becomes more concentrated.

A comparison between the calculated and measured relative hydraulic conductivity, $K^r = K(\Theta, \mathrm{SAR}, C)/K^0(\Theta)$, where $\Theta = (\theta - \theta_r)/(\theta_s - \theta_r)$ is the effective water saturation, and θ_s and θ_r are the saturated and residual values of θ, respectively, in a soil containing 20% clay (dominated by montmorillonite), for

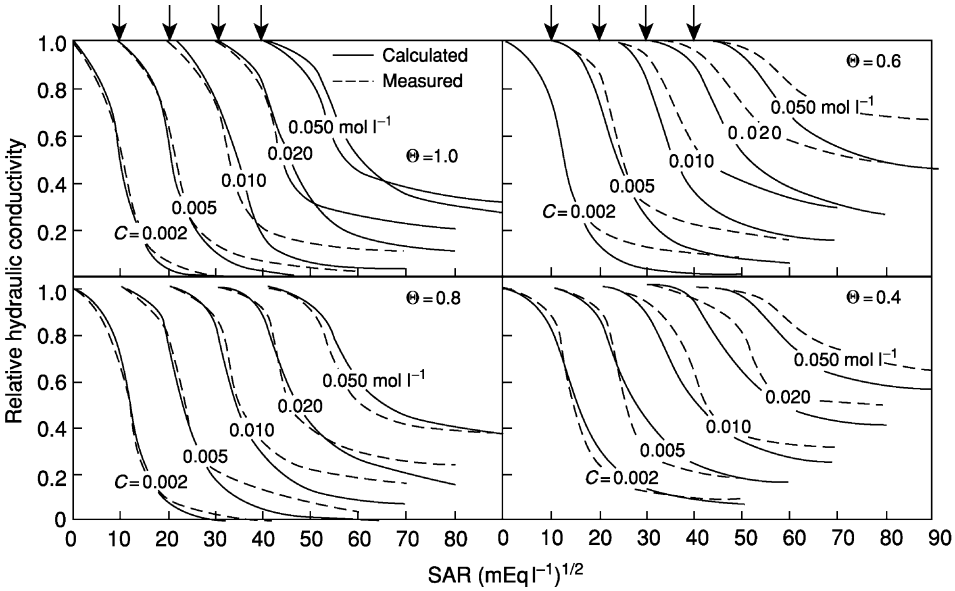

Figure 4 Relative hydraulic conductivity, K^r, as a function of the sodium adsorption ratio, SAR, of the equilibrium solution, for selected values of the solution concentration, C, and degree of water saturation, Θ. Computed results (solid lines) are compared with measured data (dashed lines). Arrows indicate that the point SAR = 0 is shifted and the data are translated along the SAR axis. (Reproduced with permission from Russo D and Bresler E (1977) Analysis of the saturated–unsaturated hydraulic conductivity in a mixed Na-Ca soil system. *Soil Science Society of America Journal* 41: 706–710.)

various combinations of Θ, C, and SAR, is presented in Figure 4. The abscissa scale in Figure 4 is shifted to the right and the data are accordingly translated along the SAR axis to distinguish between the calculated and the measured curves for different sets of concentrations. There is relatively good agreement between calculated and measured data in most cases. For the combinations of Θ, SAR, and C depicted in Figure 4, the calculated K^r deviates by less than twice the value of the measured K^r.

The comparison between calculated and experimental results indicates that a reasonable first-order approximation to the soil-water retentivity and conductivity functions can be obtained for relatively wide ranges of soil-solution concentrations and compositions. This can be done by taking into account the porous nature of the soil, the interactions between the charged solid phase and the ions in the liquid phase within the soil, and the effects of the water pressure and the soil solution composition on the organization and structure of the clay platelets.

Soils of differing textures, containing clay fractions that are mostly montmorillonite, have essentially the same surface charge density ($\Gamma_s \approx 4.5 \times 10^4$ esu cm^{-2}); consequently, they are characterized by essentially the same $\Gamma_{Na}(h, R, C_0)/\Gamma_s$ (eqn [7]) and $\Gamma_{Cl}(h, R, C_0)$ (see eqn [16]) relationships. On the other hand, the $\theta(h, R, C_0)$ and the $K^r(h, R, C_0)$ functions (Figure 5), and, concurrently, the $K(h, R, C_0) = K^0(h)K^r(h, R, C_0)$ function, associated with soils of different texture (see Table 1) may be quite different.

The functions depicted in Figure 5 suggest that the interaction between the soil matrix and the soil solution affects the differences among the various soil types, in their hydraulic properties. In the case of the water retention curves, the differences between the values of θ associated with the various soils generally increase as h and SAR increase and as C decreases. As for the hydraulic conductivity function, the differences between the values of K^r and, concurrently, between values of $K = K^rK^0$, associated with the various soils increase as SAR increases and as h and C decrease. Figure 5 suggests that, because of soil-solution–soil-matrix interactions, the capability of the coarse-textured soil to transmit water and solutes faster than the finer-textured soils is extended to a larger pressure head (smaller degree of saturation) as the soil solution SAR increases and as C decreases.

Both the experimental and the theoretical results presented in the previous sections suggest that, for a given soil solution concentration and composition, the effect of the soil matrix–soil solution interactions on the hydraulic conductivity decreases with decreasing water saturation. This is demonstrated in Figure 6, in which combinations of soil-solution concentration (C) and composition (SAR) required to maintain $K^r \geq 0.75$ (that is, no more than a 25%

reduction in K relative to the 'stable' reference state) are given for various degrees of water saturation, and for soils of several textures (Table 1). Note that the curves in Figure 6 generalize the concept of

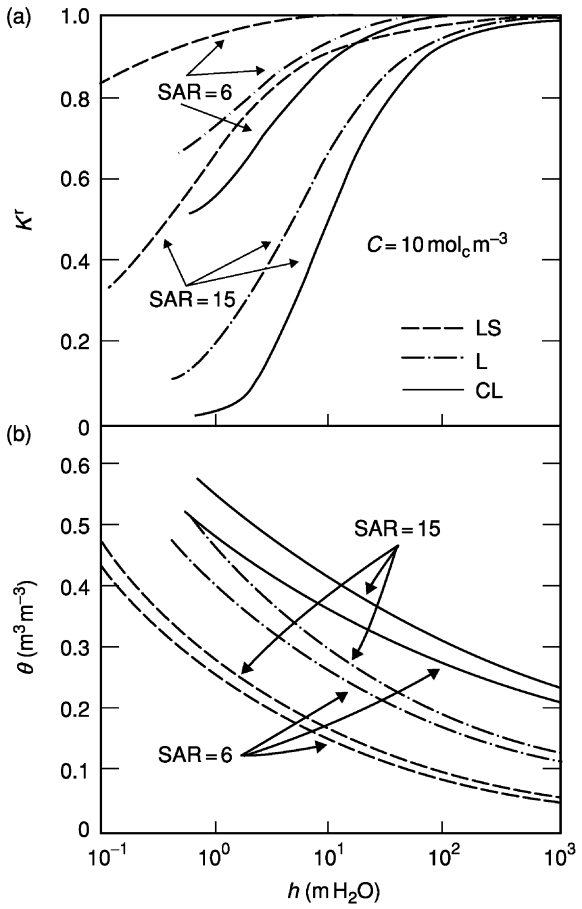

Figure 5 Relative hydraulic conductivity, K^r (a) and water content, θ (b) as a function of the capillary pressure head, h, for selected values of the concentration, C, and the sodium adsorption ratio, SAR, of the equilibrium solution, for three soils of different texture: loamy sand (LS), loam (L), and clay loam (CL). the 'threshold concentration' in terms of soil properties and soil-water status. Consequently, they may be used for water-quality classification in relation to soils of different textures, and for water and soil management. For a given SAR, the solution concentration required to maintain $K^r \geq 0.75$ (that is, the 'threshold concentration') decreases as the soil-water content decreases and as the soil texture becomes coarser. **Figure 6** suggests that a decrease in the water application rate and, concurrently, in water saturation, may improve the efficiency of the reclamation of sodic soils, especially fine-textured ones.

Implications for Flow and Transport

Soil-solution–soil-matrix physicochemical interactions, enhanced by dilute soil solutions with relatively high sodium-to-calcium ratios, can affect the flow parameters considerably (i.e., hydraulic conductivity and water retention functions). Furthermore, these interactions may affect the transport parameters (i.e., retardation and elution factors). In other words, soil-solution–soil-matrix physicochemical interactions may affect both water flow and solute transport.

Generally, for a given soil, and given boundary and initial conditions, the water flow is governed by the soil hydraulic properties. Thus, the effect of the soil-matrix–soil-solution interactions is to reduce the water flow relative to that of a 'stable' reference soil. For a given soil, the retardation of the water movement by the soil matrix–soil solution interaction will increase as either the initial soil solution SAR or the SAR of the applied water increases, as either the initial soil-solution concentration or the solution concentration of the applied water decreases, and as the surface water application rate increases.

On the other hand, the solute transport is governed by the water flow as well as by cation exchange and anion exclusion processes. Thus, in this case, the soil-matrix–soil-solution interactions may act in two opposing directions: the retardation of the solute movement because of reductions in the soil hydraulic conductivity and because of cation exchange, and the acceleration of the solute movement because of anion exclusion. The retardation effect caused by the reductions in the soil hydraulic conductivity and, concurrently, in water velocity, increases with increasing SAR and decreasing C and h, especially in relatively fine-textured soils. The retardation effect because of Na/Ca exchange is given by the retardation factor, R_f:

$$R_f(h, R, C_0) = 1 + \frac{[R+1]\Gamma_{Na}(h, R, C_0)FA_{ad}\rho_b}{Z_{Na}R\,C_0\theta(h)} \quad [15]$$

where F is the Faraday constant, A_{ad} is the specific adsorption surface area of the soil, and Γ_{Na} is the quantity of sodium ionic charges per unit area of the charged surface (eqn [7]). The retardation caused by Na/Ca exchange (expressed in terms of R_f) increases with increasing SAR and decreasing C and h, especially in relatively fine-textured soils.

Anion exclusion can be calculated from the distribution of the scaled electrical potential, $Y(x)$ (eqn [1]) within the domain $s \leq x \leq d$, which, in turn, for given values of $b(h, R, C_0)$ and $Y_s(h, R, C_0)$, is obtained from the solution of eqn [1], by the Runge–Kutta method. Applying the Boltzmann distribution law for the Na/Ca-Cl system considered here, the amount of excluded chloride per unit surface area is calculated from:

$$\Gamma_{Cl}(h, R, C_0) = \frac{|Z_{Cl}|C_0(R+2)}{(R+1)} \times \int_s^d \{1 - \exp[-Y(x; h, R, C_0)]\}dx \quad [16]$$

which, in turn, is used to calculate the elution factor, E_f, given by:

$$E_f(h, R, C_0) = 1 - \frac{[R+1]\Gamma_{Cl}(h, R, C_0)A_{ex}\rho_b}{|Z_{Cl}|C_0[R+2]\theta(h)} \quad [17]$$

where A_{ex} is the specific exclusion surface area.

The acceleration effect due to the chloride exclusion, which is determined by the second term on the right-hand side of eqn [17], increases with increasing SAR and decreasing C and h, especially in relatively fine-textured soils. The net effect of the soil matrix–soil solution interactions on the solute transport is determined, therefore, by the relative magnitudes of all of these processes, which, in turn, depend on the soil type and the boundary and initial conditions imposed on the flow system.

The effect on water flow and solute transport in a salt-affected soil of the conditions at the soil surface pertinent to an irrigation event and a rain event is demonstrated in **Figures 7 and 8**, respectively. The simulated profiles of water content, θ (top), salinity (in terms of electrical conductivity, EC; middle), and hydraulic conductivity, K (bottom) in **Figures 7 and 8** are presented for three different soils ignoring (**Figures 7a and 8a**) and considering (**Figures 7b and 8b**) soil solution–soil matrix interaction. **Figures 7 and 8** clearly demonstrate that in, salt-affected soils, the retardation of water and solute movement by soil matrix–soil solution interaction increases as the soil texture is finer and the clay fraction is larger, particularly during a rain storm (**Figure 8**) associated with diluted solution and relatively high application rate.

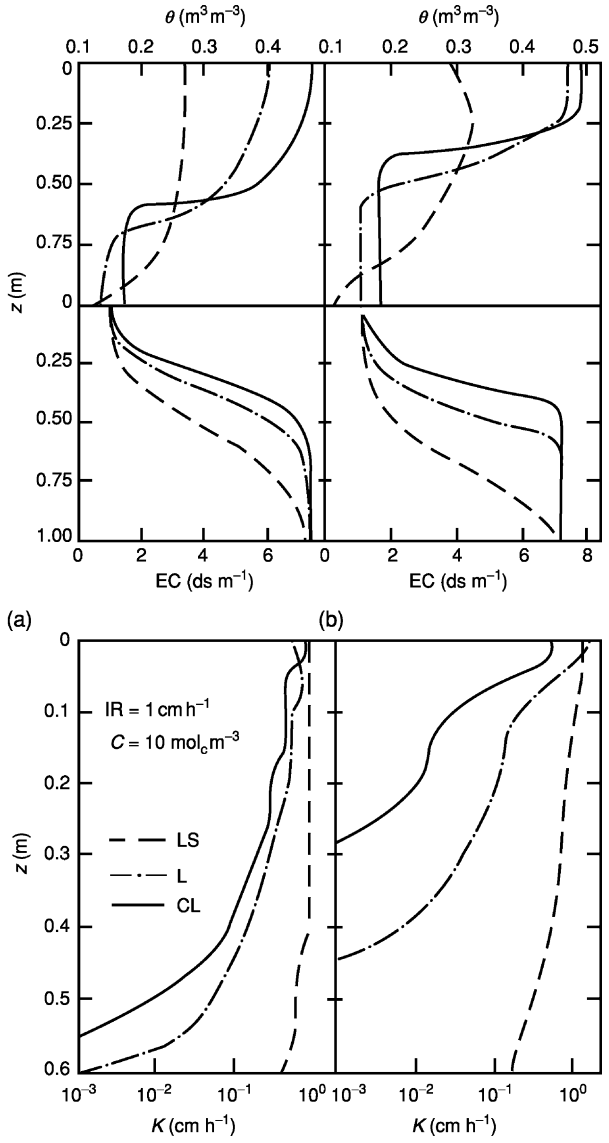

Figure 7 Profiles of simulated soil-water content, θ, soil-solution electrical conductivity, EC, and soil hydraulic conductivity, K, after 12 h of infiltration (irrigation), and for the three different soils (Table 1). Initial profiles are given by $\theta(z, 0) = \theta_s - 0.3$, $C(z, 0) = 70$ mEq l^{-1}, and SAR$(z, 0) = 25$ (mEq l^{-1})$^{1/2}$. Summary

Soil solution–soil matrix interactions can alter the geometry of the soil pores and thus may affect the soil hydraulic conductivity, $K(h)$, and water retentivity, $\theta(h)$. The effect of soil solution–soil matrix interactions on $K(h)$ and $\theta(h)$, the retardation factor, R_f, and the elution factor, E_f, and, concurrently, on water flow and solute transport may be significant and generally increases as the soil solution sodium adsorption ratio increases; as both the soil solution concentration and the capillary pressure head decrease; as the clay fraction of the soil increases; and as the soil texture becomes finer.

It is worthwhile emphasizing that the experimental and the theoretical findings discussed here are relevant to soils whose clay fraction is dominated by smectite minerals (e.g., montmorillonite), with solutions containing Na, Ca, and Cl ions only. Furthermore, the model of the hydraulic functions in salt-affected soils presented here is based on a simplified description of the porous medium (the series-parallel model), and of the physicochemical interactions between the soil solution and the soil

matrix (the mixed-ion diffuse double-layer theory). The model concentrates on the change in the soil pore-size distribution caused by the swelling of clay particles in a confined soil system, which, in turn, may be magnified by the breakdown of the domains of the clay platelets (tactoids) when the soil ESP exceeds a critical value. However, the model disregards the subsequent dispersion and movement of the clay platelets which may occur in coarse-textured soils subjected to a relatively large influx rate and, which, in turn, may further block the soil pores. Nevertheless, the data presented here are sufficiently reliable to indicate appropriate trends.

List of Technical Nomenclature

$\alpha = 8000\Pi/LDkT$	(eqn [7]) ($erg\,mol^{-1}$)
β	pore-size distribution index (dimensionless)
Γ_{Cl}	quantity of the excluded chloride per unit area of the charged surface ($mEq\,cm^{-2}$)
Γ_{Na}	quantity of sodium ionic charges per unit area of the charged surface ($esu\,cm^{-2}$)
Γ_s	surface charge density ($esu\,cm^{-2}$)
γ	specific gravity of water ($g\,cm^{-2}\,s^{-2}$)
δ	space charge density ($esu\,cm^{-3}$)
ϵ	electronic charge (4.803×10^{-10} esu electron^{-1})
η	dynamic viscosity of water ($g\,cm^{-1}\,s^{-1}$)
Θ	effective water saturation (dimensionless)
θ	volumetric water content ($cm^3\,cm^{-3}$)
θ_s, θ_r	saturated and residual values of Θ ($cm^3\,cm^{-3}$)
ℓ	average number of pores having a unit length (cm)
κ	permeability (cm^2)
ν	volume of water retained by clay particles in a unit volume of soil ($cm^3\,cm^{-3}$)
ρ_b	bulk density ($g\,cm^{-3}$)
σ	surface tension at the air–water interface ($erg\,cm^{-2}$)
φ	porosity ($cm^3\,cm^{-3}$)
ψ	electrical potential ($erg\,esu^{-1}$)
A_d	specific surface area for adsorption ($cm^2\,g^{-1}$)
A_e	specific surface area for exclusion ($cm^2\,g^{-1}$)
A_s	specific surface area ($cm^2\,g^{-1}$)
a_i(i = 1–4)	coefficients in eqns [3], [5], and [6] (dimensionless)
$B = kLTC_0/10^3(R+1)$	(eqn [2]) ($erg\,cm^{-3}$, where $1\,erg = 1\,g\,cm^2\,s^{-2}$)
b	half-distance between two adjacent tactoids (cm)
C_{Na}	concentration of the ion identified subscript ($mEq\,l^{-1}$)
$C = C_{Na} + C_{Ca}$	($mEq\,l^{-1}$)
$C_0 = c_{Na} + c_{Ca}$	($mol\,l^{-1}$)
c_{Na}	molar concentration of the ion identified subscript ($mol\,l^{-1}$)
D	the dielectric constant of water (dimensionless)
d	position of the midplane between two adjacent tactoids (cm)
E_f	elution factor (dimensionless)
F	Faraday constant (2.893×10^{11} esu mEq^{-1}, where $1\,esu = 1\,g^{1/2}\,cm^{3/2}\,s^{-1}$)
$G = (8\Pi C_0 Le^2/10^3 DkT)^{1/2}$	(molecules electron^{-1} cm^{-1})
h	capillary pressure head (cm)
h_b	air entry value of h (cm)
i, j	indices (dimensionless)
K	hydraulic conductivity ($cm\,s^{-1}$)
K^r	relative hydraulic conductivity (dimensionless)
k	Boltzmann constant (1.38×10^{-16} erg deg^{-1} molecule^{-1})
L	Avogadro number (6.0225×10^{23} molecules mol^{-1})
P	swelling pressure ($erg\,cm^{-3}$)
P_w, P_a, and $P_c = P_w - P_a$,	water, air, and capillary pressures, respectively ($erg\,cm^3$)
$R = c_{Na}/c_{Ca}$	(dimensionless)
R_f	retardation factor (dimensionless)
r	equivalent radius of water-filled pore (cm)
s	position of the plane of the charged surface (cm)

SAR	sodium adsorption ratio $(C_{Na}/\sqrt{C_{Ca}/2})((\text{mEq l}^{-1})^{1/2})$
T	absolute temperature (degrees Kelvin)
V	volume (cm^3)
v_i	subvolume ($\Sigma_{V_i} = V$) (cm^3)
x	distance (cm)
Y	scaled electrical potential (molecule electron^{-1})
Y_d	value of Y at the midplane between two adjacent tactoids (molecule electron^{-1})
Y_s	value of Y at the charged surface (molecule electron^{-1})
Z_{Na}	valence of the ion subscript (electron molecule^{-1})

Introduction

Saline and sodic soils exist in arid and semiarid regions and in regions of poor natural drainage. These soils have poor physical properties owing to high sodicity and high pH. Under these conditions, slow water infiltration into the soil, soil erosion, slow internal drainage, poor aeration, compaction, and waterlogging on lower lands commonly occur due to soil swelling and dispersion.

Considerable progress has been made in managing and controlling salinity, sodicity, and alkalinity in irrigated lands. However, because of natural hydrological and geochemical factors, as well as irrigation-induced activities, soil salinity, sodicity, alkalinity, and associated drainage and soil erosion continue to plague agriculture. Control of salinity and sodicity is essential to establish a sustainable, successful agriculture.

Effect of Salts on Soil Properties

Hydraulic Conductivity

Many soils in arid to humid regions have an unstable structure, which makes them difficult to manage because of their tendency to swell and disperse. Since soil permeability decreases with the square of the pore radius, a small reduction in size of the large pores due to swelling and clay migration has a large effect on soil permeability for water and gases. The extent of swelling and dispersion of clays depends on the clay mineralogy, the composition of the adsorbed ions, and the electrolyte concentration (EC) of the soil solution. Whether clay will migrate or seal the soil depends on the extent of swelling. Clay swelling is a continuous process that increases gradually with decreases in EC, whereas clay dispersion is possible only at EC below the flocculation value (FV). The degree of clay swelling before replacing the solution with one that has an EC below the FV of the clay determines whether clay will migrate in the conducting pores, or whether the clay particles will be trapped in the narrow pores (sieving effect) and the hydraulic conductivity (HC) of the soil will further decrease.

Even in arid and semiarid regions where irrigation is practiced, rainstorms occur occasionally. Under such conditions, sodicity damage to the soil will not take place during the irrigation season when the EC in the applied water may be high enough to counter the dispersive effect of the exchangeable Na. The sodicity damage will occur during the rainy season when the EC decreases to values below the threshold concentration determined by the properties of the soil and the exchangeable sodium percentage (ESP). Thus, when soils are exposed to rainwater, susceptibility to low levels of ESP is enhanced. It is obvious, therefore, that any attempt to assess the sodicity hazard in soils, the clay mineralogy, and the total EC of percolating solution should be considered. At any particular ESP, the influence of exchangeable Na is greater with exchangeable Mg as the complementary ion than it is with Ca.

Infiltration Rate

In soils having stable surface structures, decreases in infiltration rate (IR) result from the inevitable decrease in the matric suction gradient which occurs as infiltration proceeds. Decreases in soil IR from an initially high rate can also result from gradual deterioration of soil structure and the formation of a surface seal. When a seal of very low HC is formed, its reduced permeability determines the IR of the soil, and the wetting-front depth has only a slight effect on it. The presence of a seal increases detachment forces owing to runoff, but at the same time increases the shear strength of the soil surface. Thus, the net effect depends on the forces acting between soil particles at soil surface and the energy involved in water-drop impact and shearing forces of the overland flow.

The IR is much more sensitive to ESP than is HC. The higher sensitivity of the soil surface to ESP when the soil surface is exposed to rainwater is explained by: (1) the mechanical impact of the raindrops, which enhances clay dispersion; (2) the absence of the soil matrix, which slows clay transport; and (3) the low EC in the soil surface. Low EC and high ESP cause clay swelling and dispersion, which enhance seal formation and therefore runoff. Adsorbed Mg has a specific effect on soil erosion and IR for montmorillonitic, noncalcareous and calcareous soils.

Reclamation of Salt- and Sodium-Affected Soils

Reclamation of Salt-Affected Soils

Salinity control in the root zone is one of the main problems of irrigation in arid and semiarid regions. In these regions a salinity problem caused or complicated

by poor drainage cannot be adequately controlled unless the water table is stabilized and maintained at a safe depth. This requires open or tile drains, or drainage wells to remove a part of the subsurface saline water and transport it to an acceptable sink for safe disposal.

Effective salinity control depends largely on the initial soil salinity, the content of the soil water during leaching, hydrodynamic dispersion, spatial variation, the salt tolerance of the crops, the depth of the water table and, when applicable, layout of the drainage system. The prevailing concept in earlier reclamation trials was to leach all excess salts from the entire root zone. Under well-drained conditions, however, the aim should be to reduce salinity in the upper soil layer (depending on crop type) to below the threshold value of the growing crop.

Leaching Methods

Continuous and intermittent ponding The efficiency of salts leaching can be defined as the quantity of soluble salts leached per unit volume of water applied. The time factor should also be considered when leaching takes place under conditions of high evaporation. The range of soil pore-size distribution also affects the leaching efficiency. Pore sizes may vary enough to cause substantial changes in hydrodynamic dispersion, especially during ponded leaching. The hydrodynamic dispersion decreases under unsaturated flow, resulting in the more efficient transport of salt. Thus, the efficiency increases as the soil water content decreases during leaching.

On the basis of leaching theory, a water volume of one replacement of pore volume (pv) will reduce soil salinity by one-half, and a pv of 1.5–2.0 of water should remove approximately 80% of the soil salt content. This volume corresponds approximately to an equivalent depth of water per unit depth of soil (assuming a pv of 50%).

Based on field data from various parts of the world, the following empirical formula for salt transport efficiency under one-dimensional leaching is:

$$\frac{C}{C_0} = \frac{k}{(D/D_S)} \qquad [1]$$

where C and C_0 are the salt concentration in the soil at any given time during leaching and the initial concentration, respectively, D and D_S are the depth of leaching water applied and the soil depth to be leached, respectively, and k is an empirical coefficient that ranges from 0.1 to 0.3 for sandy loam and clay soil, respectively, under ponding leaching as shown in Figure 1. Under intermittent ponding with 50–150 mm of water per application or under sprinkler irrigation, the empirical coefficient is approximately 0.1, irrespective of the soil type. This equation applies in the range of $D/D_S > k$. The salt transport efficiency decreases sharply when D/D_S exceed 0.5 or 0.75 for sandy loam and for clay loam to clay soil, respectively.

When natural drainage conditions are limited and an artificial drainage system is required to remove leaching water, leaching efficiency may decrease because the hydraulic gradient is steeper near the drains than away from the drains. Therefore, a larger fraction of the leaching water will flow through the soil next to the drains. This amount depends on the drain spacing (S) and the depth (Y). For example, when $S/Y = 2.5$, only 30% of the area between drains will be leached with maximum efficiency. To increase leaching efficiency, drain spacing and depth should be determined by the use of a drainage equation.

The intermittent ponding method is especially suitable in fields with tile drains, as it allows the water table to draw down, which greatly increases leaching efficiency. When soils develop a surface seal, intermittent ponding may also help water to infiltrate by forming cracks. However, the longer period of wet soil exposure increases water evaporation. Combining intermittent ponding with mulching greatly improves the leaching efficiency.

When fields consist of several types of soils, leaching takes place in sandy soils at rates different to those of more clayey soils. If leaching is continued until the clay soil is sufficiently leached, an excessive amount of water percolates into the sandy soil. This problem is pronounced under ponded leaching, during which ponded water percolates predominantly through the sandy soil. To leach much more efficiently, it is possible to use the stochastic analysis of solute transport in spatially variable fields to divide a field into small sections that need different amounts of water.

Sprinkling As mentioned above, the leaching efficiency increases as the soil water content decreases. Thus, leaching by sprinkling at rates lower than the infiltration rate of the soil will result in a more efficient removal of accumulated salts than will be leached by ponding. Ponded leaching requires three times as much water as sprinkling to reduce soil salinity by the same increment. Sprinklers can be used advantageously when the field is unprepared for ponded leaching or for sandy soils. This method has a high leaching efficiency, except under high evaporation, because the leaching takes place under unsaturated conditions. This method can also be used advantageously when water for leaching is scarce and costly.

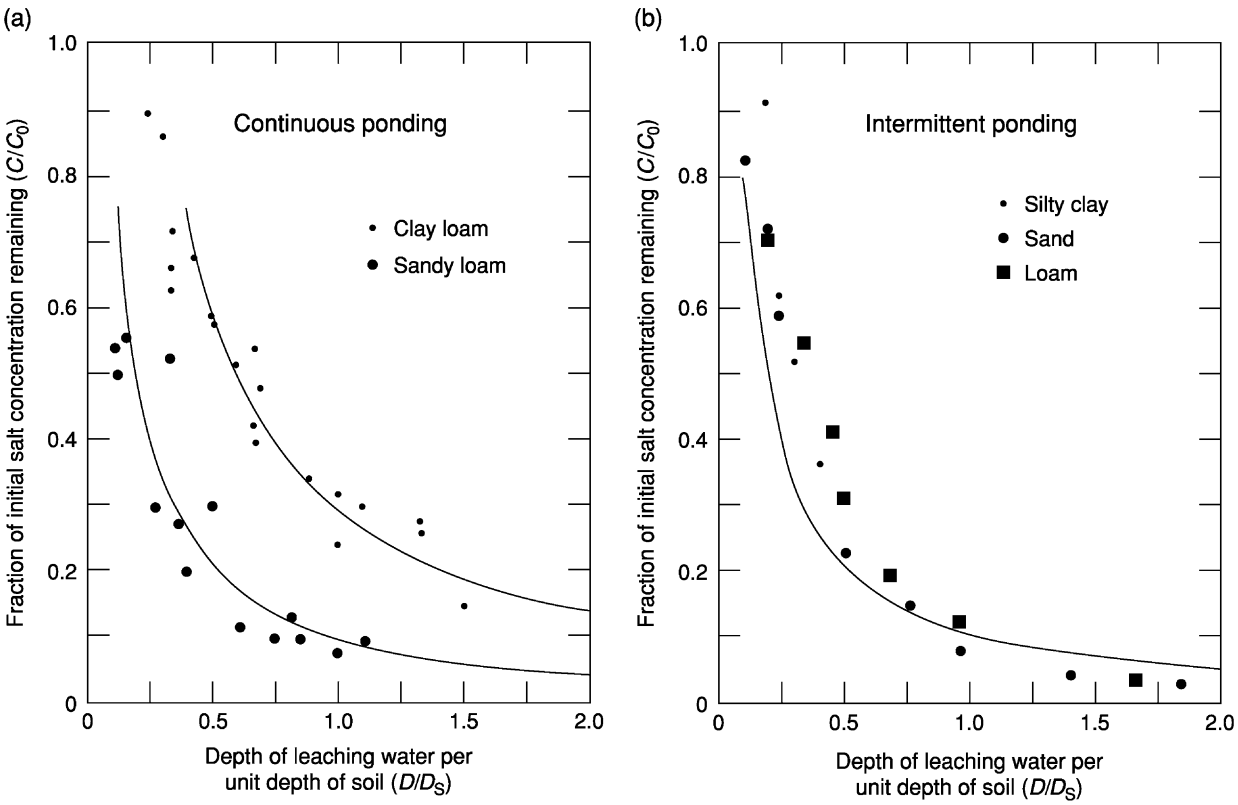

Figure 1 Relationship between fraction of initial salt concentration remaining in soil, C/C_0, and depth of leaching water applied per unit depth of soil, D/D_S: (a) for continuous ponding; (b) for intermittent ponding. (Adapted from Hoffman GJ (1980) Guidelines for the reclamation of salt-affected soils. In: O'Connor GA (ed.) *Second Inter-American Conference on Salinity and Water-Management Technology*, pp. 49–64. Juarez, Mexico.)

In summary, the intermittent-ponding method requires less water than the continuous-ponding method to achieve the same degree of leaching, and the sprinkling method is more efficient than the other methods at removing salt from small pores in the soil profile.

Postleaching operation Prolonged ponding destroys the structure of the soil. Therefore, the last phase of reclamation is drying the soil and, when necessary, taking steps to enhance soil structure, such as applying gypsum or organic matter. Sprinklers or intermittent ponding generally cause less soil-structure destruction and may not require elaborate postleaching measures.

Reclamation of Sodium-Affected Soils

In order to reduce runoff and erosion in sodic soils, reclamation is a common practice. Reclamation of sodic soils involves replacement of exchangeable Na by Ca. The source of Ca for replacing adsorbed Na can be external sources such as gypsum, calcium chloride, and irrigation water containing Ca ions, or the soil itself, involving the dissolution of Ca-containing minerals.

Although chemical amendments may be effective in restoring water penetration after reduction caused by either excessive adsorbed sodium or a low salt concentration in the applied water, they will not be effective if low permeability is due to soil texture, compaction, or water-restricting layers. Thus, reclamation requires a certain flow of water through the soil profile, and an appropriate IR and HC must be achieved.

Reclamation by Adding Soil Amendments

Gypsum Gypsum is the most commonly used amendment for sodic soil reclamation and for reducing the harmful effects of high-sodium irrigation waters because of its solubility, low cost, and availability. Gypsum added to a sodic soil can cause permeability changes by increasing EC and by cation exchange effects. The relative significance of the two effects is of interest for several reasons. If the electrolyte effect is sufficiently high to prevent dispersion and swelling of soil clays, the surface application of

gypsum may be worthwhile. In this case the amount of gypsum required depends on the amount of high-quality water applied and the rate of gypsum dissolution. It is somewhat independent of the amount of exchangeable Na in the soil profile. Conversely, in soils where the EC effect is not enough due to the high ESP level, or in order to obtain permanent improvement, then the amount of gypsum required depends on the amount of exchangeable Na in a selected depth of soil.

The benefit of gypsum for reclaiming sodic soils depends not only on the infiltration characteristics of the soil, but also on the gypsum-dissolution properties. The main mechanism by which gypsum affects the IR of soils exposed to rainwater is by its dissolution and release of electrolytes into the soil solution. The dissolution rate of gypsum is an important factor in IR because of the short contact time between rainwater and gypsum particles at the soil surface. Some of the factors that influence the dissolution rate of gypsum are the surface area of the gypsum particles, the soil water velocity during leaching, and the electrolyte composition of the soil solution.

Gypsum source, application rate, and particle size all have their effect on crust formation and IR (Figure 2). Although the IR for soil without gypsum decreases sharply as the cumulative rainfall increases, the IR remains relatively high in the presence of phosphogypsum (PG), whereas the effectiveness of mined gypsum (MG) on IR is significantly less. The higher efficiency of PG in maintaining high IR is attributed to its high rate of dissolution (Table 1). Application of gypsum on sodic calcareous soil is very effective in lowering surface runoff under field conditions (Table 2). Spreading the gypsum over the soil is more effective than mixing it in the upper 10 cm of soil. Although gypsum affects the ESP of the soil in the upper 0- to 15-cm layer very little (Table 3), it has a large effect on IR (Figure 2). The gypsum has a significant effect on the amount of soil erosion. The effectiveness is greater when the gypsum particles are spread over the soil rather than mixed in the top 10 cm of soil. The presence of gypsum on the soil surface increases soil stability by increasing EC in the percolated solution and by decreasing ESP. This effect of gypsum on soil erosion is due to two reasons: (1) reducing runoff by increasing IR, and (2) changing the erodibility factor. The erodibility of the soil is essentially related to the stability of soil aggregates and to the cohesive forces holding the aggregates together.

In order to obtain permanent improvement, however, the cation exchange effect is most important. The amount of exchangeable sodium to be replaced during reclamation depends on the initial ESP (ESP_i), the cation exchange capacity (CEC; in moles of cation charge per megagram), soil bulk density (ρ_b; in megagrams per cubic meter), the desired final exchangeable sodium fraction (ESP_f) and the depth of soil to be reclaimed (L; in meters). Once the above parameters have been determined, the amount of exchangeable Na to be replaced per unit area of land (Q_{Na}; in moles of cation charge per hectare) can be calculated from:

$$Q_{Na} = 10^4 L \rho_b (CEC)(ESP_i - ESP_f) \qquad [2]$$

The ESP_f value depends on the response of the soil in terms of its physical conditions.

The amount of gypsum needed to reclaim a sodic soil, in metric tonnes per hectare, can be calculated using eqn [3]:

$$GR = 8.61 \times 10^{-5} Q_{Na} \qquad [3]$$

The efficiency and rate of exchange, namely, the percentage of applied Ca that exchanges for adsorbed Na, varies with ESP, being greater at high ESP values. Removal of Na at ESP levels below 10 is slow, and some of the applied Ca displaces exchangeable Mg so that the efficiency declines to about 30%. Efficiency may also be low (20–40%) in fine-textured soils, because of the slowness of exchange of Na inside the structural units.

Generally, soil water penetration is too low to allow reclamation of sodic soils to be attained in a single leaching. For example, a 50-cm depth of water applied for leaching can only dissolve about 12 Mg ha^{-1} of gypsum (reaching a saturation solution in respect to gypsum). Larger gypsum applications, therefore, will not be effective unless soil water penetration is sufficient for larger water applications. Thus, sodic soil can normally only be reclaimed to a shallow depth the first year (depending on the depth of water applied for leaching), but this will often permit a shallow-rooted crop to be grown after leaching (**Figure 3**). Subsequently annual applications of amendments and leaching volumes can be applied to reclaim the entire profile over a period of years.

In estimating the amount of gypsum to be applied, little attention has been directed to the possibility that

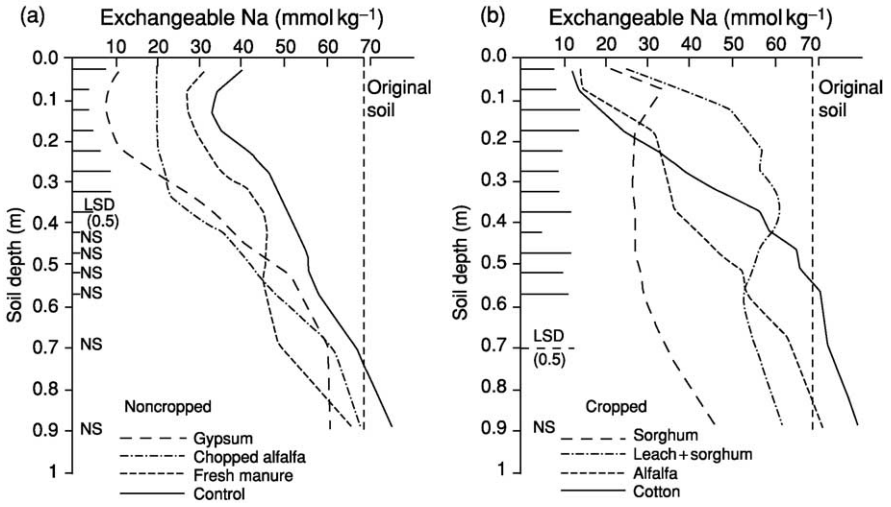

Figure 3 Final distribution of exchangeable Na levels with soil depth resulting from reclamation treatments for (a) noncropped and (b) cropped treatments. LSD, least significant difference; NS, no significance. (Adapted from Robbins CW (1986) Sodic calcareous soil reclamation as affected by different amendments and crops. *Agronomy Journal* 78: 916–920, with permission.)

incorporating large amounts of gypsum powder into the soil may cause temporary reduction in HC because excess small particles of gypsum may block conducting pores in the early stage of the dissolution process.

The soil solution in the gypsum layer reaches equilibrium (in the presence of excess gypsum) only when the contact time between an elemental volume of solution and gypsum particle surface is sufficiently long, or when the surface area of the gypsum fragments per volume of water is sufficiently large. Some of the factors that influence the rate of gypsum dissolution are the surface area of the gypsum particles, the soil water velocity during leaching, and the electrolyte composition of the soil solution.

The gypsum dissolution rate is written as:

$$(\mathrm{d}C/\mathrm{d}t) = k(C_s - C) \qquad [4]$$

where $\mathrm{d}C/\mathrm{d}t$ is the net rate of dissolution, k is the dissolution coefficient, and C_s and C are the solution concentration at saturation and at time t, respectively. Increasing solution flow velocity increases the dissolution rate coefficient, but decreases the contact time between gypsum and the flowing solution; the net effect is a decreasing dissolution rate with increasing soil solution flow velocity.

Integrating eqn [4] yields:

$$-\ln\left(1 - \frac{C}{C_s}\right) = kt \qquad [5]$$

Since the thickness of the stationary film of solution around the gypsum particles changes with the soil water velocity, the dissolution rate coefficient for a given surface of gypsum particle also changes. Thus, the lines obtained from eqn [5] are not linear. The left-hand side of eqn [5] is empirically related linearly to the square root of time:

$$-\ln\left(1 - \frac{C}{C_s}\right) = \alpha t^{1/2} + \beta \qquad [6]$$

where α and β are the slope and intercept, respectively, and t is the time for an increment of solution to leave a given soil depth:

$$t = \frac{L}{V} \qquad [7]$$

where L is the length of the layer of soil-gypsum mixture and V is the soil water velocity. Combining eqns [6] and [5] and introducing eqn [7] yields:

$$k = (V/L)^{1/2}\left[\alpha + (V/L)^{1/2}\beta\right] \qquad [8]$$

The dissolution rate coefficient as a function of water flow velocity can be evaluated for a given surface area of gypsum. Since the permeability of a sodic soil is low, the dissolution rate is relatively high during the initial stage of reclamation. During the reclamation process, however, the permeability increases and the dissolution rate decreases. Thus, the soil regulates gypsum-dissolution rate during reclamation. When it is possible to control water flow velocity in soils (e.g., sprinkler irrigation), reduced velocities are to be preferred for increased gypsum dissolution rate and greater efficiency of cation exchange reaction due to increase in contact time between water and gypsum particles (**Figure 4**).

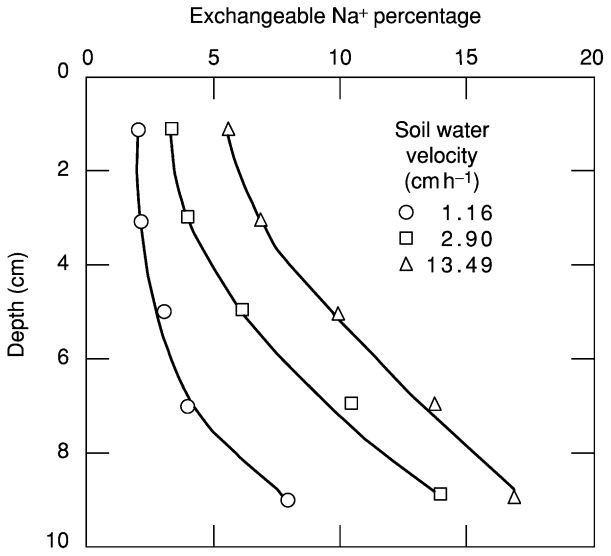

Figure 4 Distribution of exchangeable sodium percentage with soil depth as a function of soil water velocity for a given amount of dissolved gypsum. (Adapted from Keren R and O'Connor GA (1982) Gypsum dissolution and sodic soil reclamation as affected by water flow velocity. *Soil Science Society of America Journal* 46: 726–732, with permission.)

Several chromatographic models have been used for simulating reclamation of sodic soils with gypsum. The models include many of the known chemical reactions occurring in natural soils as a result of $CaCO_3$ and $CaSO_4$ dissolution, salt leaching, and ion exchange reactions. These models have been field-tested with data from sodic-soil reclamation leaching plots. The difference between measured and computed results is no more than the horizontal variations typically found in salt-affected lands. These models provide powerful tools for quantitative predictions of water and gypsum required to reclaim soil profiles to prescribed levels of salinity and ESP.

In another approach, a source term for gypsum dissolution has been introduced into a steady-state solute-transport model. However, considerable difficulties have been encountered in matching calculated concentration–time curves to column experimental data. Miscible displacement models coupled with chemical reaction models provide insight into the processes of reclamation. However, they have not been used extensively in the field, because solving them requires extensive data specific to the site.

It is clear from the literature that the assumption of chemical equilibrium for dissolution of gypsum may not be applicable to soil-reclamation modeling. Another approach is to couple dissolution kinetics of gypsum and exchange-cation reactions to a salt-transport model.

Acids and sulfur These amendments are of value for ameliorating soils containing $CaCO_3$, with which the acid interacts to form gypsum (using H_2SO_4) or calcium chloride (using HCl). In some areas, the availability of acid waste products arising from mining and industrial activities is increasing markedly. Use of these waste products as soil amendments may provide a safe means of disposal and could greatly influence the economics of any amendment proposal. Being highly corrosive, neither H_2SO_4 nor SO_2 should be added to water that flows through metal or concrete irrigation systems. Sulfur (S) requires an initial phase of microbiological oxidation to produce H_2SO_4. Other amendments such as pyrites and polysulfides, which must first be oxidized by soil microorganisms, will be slower-acting than H_2SO_4. Their effectiveness in field experiments has been variable, perhaps being related to the presence or absence of appropriate microbial populations.

Reclamation without Adding Soil Amendments

Calcium carbonate Reclamation of a sodic soil without amendments is possible when a soil source of Ca exists (e.g., calcium carbonate), the drainage through the soil profile is good, and adequate leaching water is present. The rate at which $CaCO_3$ dissolution in water approaches equilibrium is dependent upon a number of factors, which include the surface area-to-solution volume ratio, the ionic composition of the solution, the ion composition of the adsorbed phase, affinity of the clay minerals to cations, the temperature, and the partial pressure of CO_2 in the soil atmosphere. In general, a supersaturation with respect to calcite is observed in solution extracts from calcareous soils.

In soils, the kinetics of $CaCO_3$ dissolution is not a simple diffusion-controlled or first-order reaction. In these calcareous systems, the transfer of atmospheric CO_2 to solution is a limiting step in the kinetics of dissolution. There are several uncertainties in modeling the kinetics of carbonate chemistry: at low pH the rate depends significantly on the thermodynamic transport constant for H^+, which is not well defined, and reaction-site density and controls on pH at the surface interface between the crystal and the bulk solution are also not well understood. Moreover, kinetics of precipitation and dissolution of $CaCO_3$ have not yet been modeled for soil water systems.

Soil $CaCO_3$ may be dissolved slowly to contribute Ca but its solubility is enhanced in saline sodic soils. Moreover, incorporation of fresh organic matter in calcareous soil increases native calcium carbonate mineral dissolution, owing to elevation of CO_2 partial pressure in the soil atmosphere, and therefore

significantly enhances sodic soil reclamation rate (Figure 3).

Successive dilutions of highly saline water When soil physical conditions have deteriorated and HC of the soil is so low that the time required for reclamation or the amount of amendment required is excessive or if a sodic soil is to be leached with a water so low in salinity that water infiltration decreases adversely, the use of the high-salt water-dilution method may be applied. The method involves application of successive dilutions of highly saline water containing divalent cations. This principle has been tested successfully in experiments, and reclamation at various stages of leaching can now be predicted. In the early phase, the high salinity of the water prevents clay dispersion and induces flocculation of the soil colloids, the Ca content provides a source of Ca for exchange with Na, and the sodicity level decreases. On dilution with high-quality water, the sodium adsorption ratio of the irrigation water is reduced by the square root of the dilution factor. When sufficient water is applied at each step of dilution, then, to ensure exchange equilibrium to the desired depth, the total equivalent surface depth of water for reclamation should be about nine times the depth of soil to be reclaimed. The method is particularly effective for soils of the expanding-clay type, which have extremely low soil HC.

SAND DUNES

H Tsoar, Ben Gurion University of the Negev, Beer Sheva, Israel

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Sand dunes are found in all continents and in all world climates. They cover approximately 20% of the world's arid and extremely arid zones but are also found in humid regions of North America and Europe and along most of the coasts of the world. In total they cover an area of more than 5 000 000 km^2, of which 99% is desert. Sand dunes appear in many different shapes as a result of the factors that form them, such as variability in wind direction, grain size, and vegetation cover.

As a soil, dune sand is usually considered to be devoid of any beneficial characteristics for flora and fauna because sand is known to have low fertility, low water-retaining capacity, and sand-sized particles are cohesionless. Wind magnitudes of 4 Beaufort force (5–7 $m\,s^{-1}$) and above can easily erode sand, thus causing another limitation for flora and fauna. As a result, aeolian sand encroachment has become synonymous with desiccation and desertification in arid and semiarid lands.

Dune Sand Texture

Soil particles are grouped according to their sizes into four classes: gravel, sand, silt, and clay. Sedimentologists and geomorphologists use a grade scale consisting of a series of classes in which the boundaries between adjacent size classes differ by a factor of 2. This scale is modified by transforming the grade boundaries into a phi (φ) scale (Table 1), which is defined as:

$$\varphi = -\log_2 d \qquad [1]$$

where d is the grain diameter in millimeters.

Wind should be above the threshold velocity to initiate sand transport. The threshold velocity depends directly on grain size and the cohesiveness of the grains (Figure 1). Grain particles less than 0.10 mm tend to cohere, as the rate of cohesiveness increases with decreasing size. Accordingly, particles of fine-sand size have threshold velocities of erosion that are lower than those of silt and clay by factors of 2–3. The mode size of most dune sand all over the world is in the class of fine sand (0.125–0.250 mm), which has the lowest wind-threshold velocities. Fine sand can be transported most easily on the windward slope of sand dunes under storm winds of average intensity. Coarser grains of medium, coarse, and very coarse sand are unable to climb slopes. This is the main reason for the formation in deserts of sand sheets composed of bimodal sand in which the coarser mode is always greater in grain size than fine sand.

The cohesionless nature of sand causes it to be swept away easily by the wind in a leaping movement, known as 'saltation,' which describes a ballistic path very close to the bed, descending at high speeds and low angles. Less-exposed grains or coarser grains are either pushed in a short-distance movement, ensuing from the scatter of the impact of the saltating grains, known as 'reptation,' or driven forward along the surface in a creep mode through the impact of the saltating grains.

The low cohesiveness and the ensuing form of transportation by saltation have a major implication for plants. The easy erosion of sand by the wind exposes plant roots, causing damage to the plants through grain bombardment, thus making the plants vulnerable to disease. Some plants overcome this by growing minute roots that produce a sticky liquid. Sand particles are glued to these roots, forming a shield which protects them from damage.

The most common adaptational response of animals to low cohesiveness of sand is to increase the surface area of the soles and fingers, either by enlarging or adding scales to the fingers (as do many lizards and skinks), or by growing stiff hairs on the sole (as do many mammals, particularly rodents and carnivores). The other technique used to overcome low cohesiveness of soil is sand-swimming, engaged in by animals such as skinks and some insects, which have relatively long and narrow bodies and short legs that help them to move while winding their bodies between the sand particles.

Table 1 Size classes of grain particles

Grain size (mm)	*Grain size (μm)*	*Grain size (φ)*	*Classification*
>2	>2000	<−1	Gravels
1–2	1000–2000	0 to −1	Very coarse sand
1/2–1	500–1000	1 to 0	Coarse sand
1/4–1/2	250–500	2 to 1	Medium sand
1/8–1/4	125–250	3 to 2	Fine sand
1/16–1/8	62–125	4 to 3	Very fine sand
1/256–1/16	4–62	8 to 4	Silt
1/4096–1/256	0.243–4	12 to 8	Clay

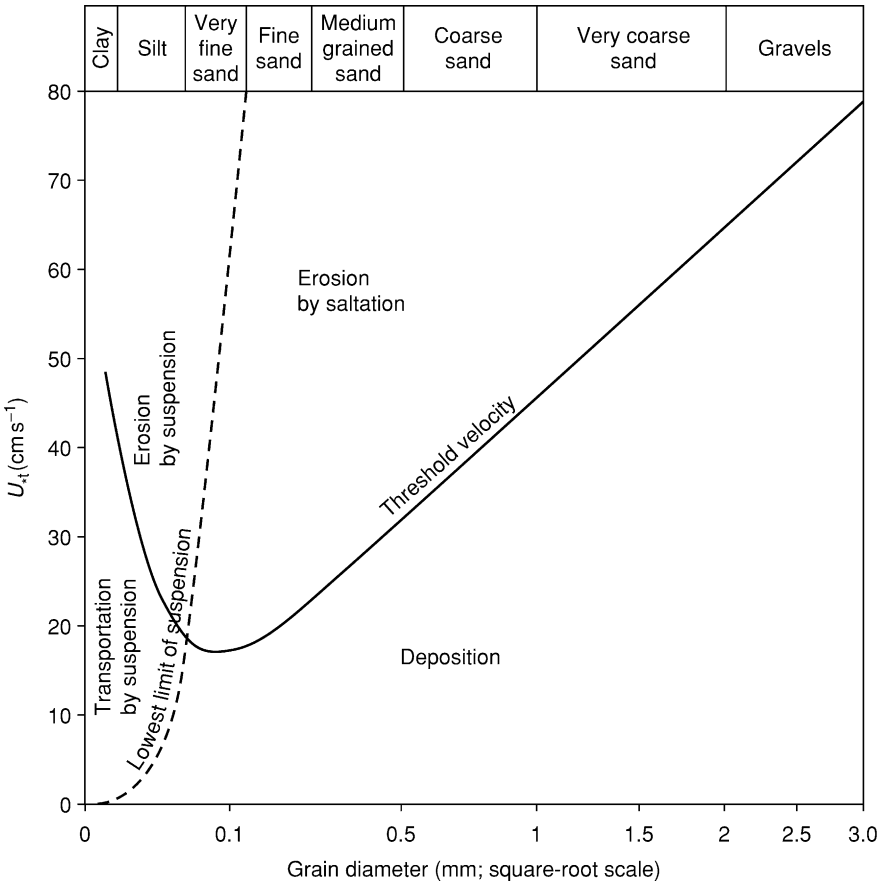

Figure 1 Threshold friction velocity (U_{*t}) curve for quartz grains of different diameters (continuous line). The dashed line separates saltation from suspension. Adapted from Pye K and Tsoar H (1990) Aeolian Sand and Sand Dunes, London: Unwin Hyman.

Particle sizes of clay, silt, and very fine sand are so small that they have low settling velocities relative to the velocities of the vertical component of the turbulent wind flow. As a result, these particles remain in suspension or quasisuspension in their transportation mode and are considered as dust (Figure 1). Dust does not easily accumulate together with sand unless the latter is covered by vegetation, thus serving as a trap for the suspended particle load in the lower atmosphere. Biogenic crust is formed on sand dunes in some desert areas when vegetation spreads and reduces the sand movement. Filamentous cyanobacteria are known to form crusts in the northwestern Negev sand dunes (Figure 2). This crust serves as trap for atmospheric dust, resulting in a feedback mechanism between the amount of dust that is deposited on the surface and the mass of the cyanobacteria. There is a significant correlation in the northwestern Negev between the percentage of fines (silt + clay) and the percentage of organic matter in the crust. For approximately 1.5% of organic matter, there are more than 30% of fines. Rainwash leaches part of the fines to a depth of 30–50 cm, which is the average penetration depth of rain for small, frequent storms in the Negev desert.

The Effect of Dune Sand Texture on Water Infiltration

One of the most important attributes of sand dunes, resulting from the sand texture and the relatively big pore spaces, is low field capacity and a low value for soil moisture availability for plants (Figure 3), as well as a high rate of infiltration and leaching, resulting in the washing away of nutrient elements necessary for plant growth.

The hydraulic conductivity at saturation for sand dunes is very high (between 10^{-3} and 10^{-4} m s^{-1}). Unlike most soils composed of silt and clay, the hydraulic conductivity of sand responds very little to changes in moisture content. The high rate of hydraulic conductivity determines the depth of water infiltration. The maximal depth of infiltration in linear sand dunes in the northwestern Negev, during a year with rainfall that is 10.5% lower than the climatological mean (95 mm), reached 60–90 cm,

Figure 2 Crust on sand dunes in the northwestern Negev desert, where the annual rainfall is 85 mm. The crust is formed by filamentous cyanobacteria. Note an area with exposed sand in the middle lower part of the picture.

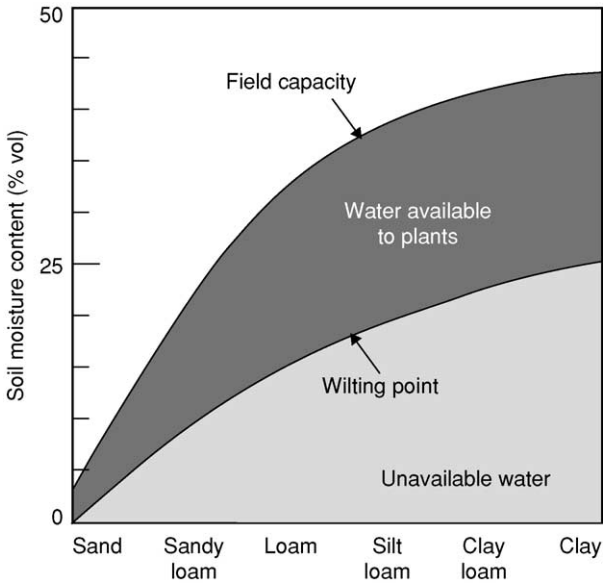

Figure 3 The effect of soil texture on the wilting point, field capacity, and the emanative moisture that is available to plants. Note that sand has the lowest wilting point but also a very low field capacity, which leaves very little amount of moisture available to plants as most of the water infiltrates easily towards the groundwater.

while, in a nearby interdune area covered mostly by silt and clay, the infiltration was limited to a depth of 30–40 cm. During a wetter year, with rainfall 38% higher than the average, the range of infiltration in the same linear dune was in the range of 90–120 cm and in some cases down to 180–210 cm. In the fine-grained interdune layer, it was limited to a depth of 30–60 cm. Deep infiltration to a depth of 180–400 cm occurs in sand only in response to rain that accumulates to 100 mm in less than 2 months.

Sand dunes are known to have an internal laminar structure of varying geometry. The laminae result from two main modes of deposition: grainflow and grainfall. These two types of deposition produce different arrangements of grain packing and distinct concentrations of fine and coarse sand. The internal structure of aeolian sand dunes affects the direction of infiltration into the dune. If the aeolian sand is composed of grainflow deposits that dip at angles of 32–34°, infiltration will deviate by 50–60° from vertical downward movement ('piston infiltration'). The capillary tension caused by closely packed or fine-grained laminae that are near-horizontal or parallel to the surface inclination brings about subsurface lateral water flow. Such a flow can be found in sand dune areas where the mean annual rainfall is more than 200 mm. Areas with approximately 100 mm annual rainfall experience lateral movement only during periods with rainfall much above the average.

The biogenic crust formed on top of ungrazed sand dunes in the western Negev (Figure 2) has a lower hydraulic conductivity than dune sand because of the high proportion of fines. However, the biogenic crust on the Negev sand dunes is not hydrophobic and therefore absorbs rainwater until saturation is reached and the infiltration rate drops to 9–12 mm h^{-1}. Since the prevailing sealing process of bare crust by the impact of intensive raindrops is not effective in the Negev, there is no correlation of runoff yield with rain amount or intensity. Runoff is generated in the Negev on saturated crust by rain intensity

of 9–12 mm h^{-1} lasting for 1–2 min only, and its yields are low to very low.

The Effect of Sand Texture on the Thermal Properties of Sand Dunes

When sand is devoid of or has only meager vegetative cover, its texture and mineralogical composition play an important role in determining the thermal properties of its environment. Heat is absorbed from solar shortwave radiation and is concentrated in the sand's surface to a thickness of approximately 1 mm.

The rate at which modification of temperature takes place within sand (k) is directly proportionate to its thermal conductivity (K) or to its ability to transmit heat, but is inversely proportionate to its specific heat (c) or the amount of heat required to achieve the modification of temperature. This relationship is described in the following equation:

$$k = K/c\gamma \qquad [2]$$

where k is known as the thermal diffusivity, and γ is the bulk density of the sand (approx. 1600 kg m^{-3}). The units of k are meters squared per second. The smaller the value of k, the more slowly heat will diffuse through the substance. The thermal diffusivity of sand is approx. 3.75×10^{-7} m^2 s^{-1}, which is relatively low and induces a very slow penetration of surface temperature changes. This results in a very acute and thin near-surface accumulation of heat. As a consequence, the maximal sand surface temperatures are higher by 10–20°C than the air temperature, at 2 m high, during the afternoon (Figure 4). This steep lapse rate gives rise to local up-rushes of hot air and descent of cooler air, which increases the air turbulence, and the erosivity of the wind. Under certain conditions the ascending hot air develops into whirlwinds known as 'dust devils.' The minimal sand surface temperature is only lower by 1–3°C than the minimal air temperature in the early morning (Figure 4).

These thermal qualities of sand result in three significant, diurnal changes in temperature at deeper levels of dune sand: (1) the maximal temperature is lessened with depth; (2) the diurnal amplitude is degraded with depth; (3) there is a lag between the daily maximum and minimum temperature from the surface to various depths (Figure 4).

The unique thermal qualities of sand dunes have important implications for animals living in this habitat. The most common animal adaptation to high surface temperatures is avoidance: most animals living in sand dune habitats in deserts are nocturnal or are active during the early morning or late evening, when soil temperature decreases to tolerable temperatures. During the rest of the day, most of these animals take shelter below the sand surface, where the temperatures are moderate, either in their own burrows or in holes dug by other animals. Many of the diurnal animals have relatively long legs (lizards, beetles) and can elevate themselves high above the hot surface, thus keeping their bodies at relatively low temperatures while only some parts of their legs are in contact with the hot sand.

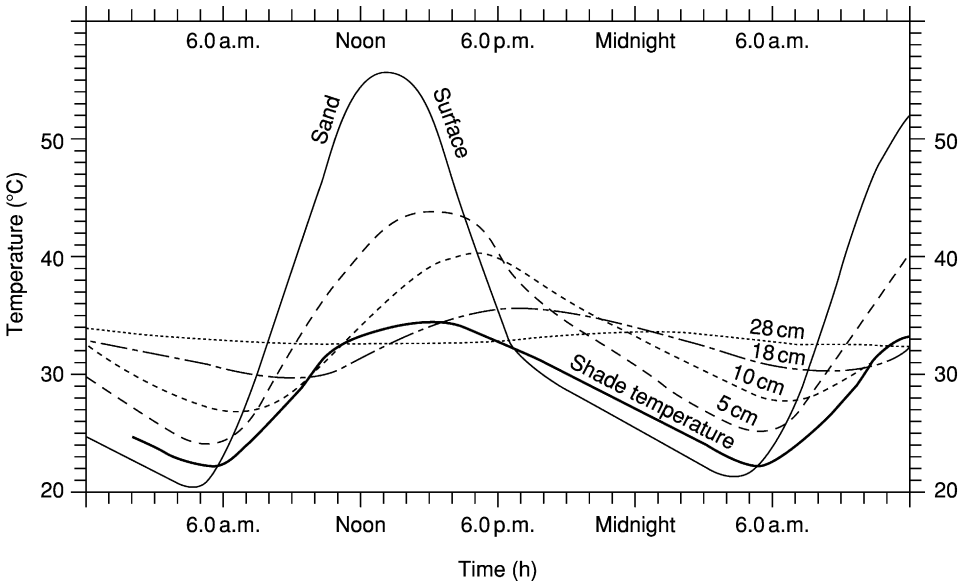

Figure 4 Variation in sand temperature with depth as measured in August. Shade temperature was measured at an elevation of 2 m above the surface. Adapted from Pye K and Tsoar H (1990) Aeolian Sand and Sand Dunes, London: Unwin Hyman.

The Advantage and Disadvantage of Sand Texture on Vegetation Growth in Deserts

Vegetation can grow on sand dunes in arid areas with less than 100 mm of annual mean rainfall (Figure 2). The primary limitation of vegetation growth on dune sand is human impact; the most dominant natural limitation is wind power. Rainfall is a limiting factor only where the annual mean is very low (<50 mm).

Two unique and distinct attributes of dune sand affect vegetation growth on dunes: (1) dune sand has low fertility and low water-retaining capacity (Figure 3); (2) sand grains are not cohesive and therefore are easily carried by the wind (Figure 1). For this reason, plants on sand are sparsely distributed and they are absent where wind erosion is severe, such as the windward slopes of dunes. Accordingly, the amount of vegetation on dunes depends on the wind power. There are arid and humid areas where the wind power is so high that it does not enable vegetation to thrive on these dynamic dunes, such as the Oregon coastal dunes.

The attribute of high hydraulic conductivity of sand relative to silt and clay is advantageous in deserts. In humid areas with abundant precipitation, the main cause of soil-moisture loss in sand is the high rate of infiltration beyond the root layer. In arid and semiarid lands, the situation is quite different. These areas have little precipitation, resulting in infiltration to depths of only 60–120 cm. Perennials can use the moisture at these depths, which are deep enough to protect the sand moisture from the high rate of evaporation typical of deserts during the long dry and hot rainless periods. As a result, moisture retention is assured in desert sand below the upper 30–60 cm. In other desert soils such as loess, which are mostly composed of silt and clay, the infiltration reaches a much shallower depth of 30–40 cm, where evaporation is effective. The delineation between the advantage of coarse-textured sand (low evaporation) over fine-textured soil (silt and clay) versus its inherent disadvantage (high hydraulic conductivity) lies somewhere between a mean of 300 and 500 mm of precipitation.

The moisture content of sand at the wilting point is very low. Therefore, a small amount of water input brings sand moisture to values much above the wilting point, whereas the same amount of water added to loamy soils does not, making the water unavailable for plants (Figure 3).

The effect of soil texture on biomass has been tested on the three soil types (loam, sandy loam, and sand) located in the same area in the Negev desert where the annual mean rainfall is 100 mm. Biomass measurements (annuals only) were taken during two winters with approximately average rainfall (104.6 and 111 mm), but with dissimilar distribution. The highest biomass for the 2 years was formed on the sand soil (647.18 g m^{-2}), with the second highest on the sandy loam (569.95 g m^{-2}), while the loam had the least amount of biomass (115.53 g m^{-2}).

Mobility and Stability of Sand Dunes

There is no direct relationship between the amount of rainfall and the vegetation cover on the dunes. Active dunes with no vegetation cover are found in humid areas (e.g., the Oregon coastal dunes, or the Alexandria coastal dunes in South Africa) while dunes fully stabilized by microphytes and macrophytes are found in the arid part of the Negev desert. Several wind erosion or mobility indices (M) have been developed for various parts of the world for the purpose of climatic changes and their implications on sand dune mobility. All of these indices are based on two factors that increase or decrease dune mobility. The first one deals with the degree of windiness. Most dunes will be mobilized if windiness were to increase. The second factor is the ratio between the mean precipitation (P) and the evaporation (E), known as precipitation-effectiveness index ($P - E$). Based on the above factors, a simple and widely accepted M-index is:

$$M = \frac{W}{(P/\mathrm{PET})} \qquad [3]$$

where W is the percentage of days during the year with sand-moving winds and P/PET is the ratio of mean annual precipitation to mean annual potential evapotranpsiration. The M-index of eqn [3] is calibrated in South Africa. Dunes are fully active when values for M exceed 200 and most dunes are completely stabilized by vegetation when M is less than 50. Because of its simplicity, the M-index of eqn [3] is commonly used by scientists studying the effect of climate change on sand mobility and stability in North America. The sand dunes along the coastal plain of Israel and in the northwestern Negev desert should be active with no vegetation cover according to eqn [3] ($M > 200$). In fact, the northwestern Negev desert dunes in areas of annual mean rain of 100 mm are fully stabilized by vegetation and biogenic crust (Figure 2), and the more humid coastal dunes are partially vegetated.

Dune sand has the lowest moisture content (Figure 3). Thus, chiefly in humid climates, most of the rain is lost to the groundwater and is not available to the plants. Hence the amount of rainfall is not a decisive factor in sand dune stabilization except by increasing the cohesiveness of the sand. The deep infiltration of rainwater in dune sand reduces the effect of

evaporation (PET in eqn [3]) mostly in arid areas relative to other soils composed of fine particles of silt and clay.

Wind power is the most important factor in sand dune mobility because of the noncohesiveness of the sand. Wind above a certain wind power can erode sand to such an extent that it prevents seeds from germinating in the sand and stabilizing it. According to the sand transport equation, the sand flux (q) is directly proportional to the cube of the wind:

$$q = 5.2 \times 10^{-4}(U - U_t)^3 \qquad [4]$$

where q is in metric tons per meter width per hour, U is the wind velocity, measured at a height of 1 m, and U is the threshold wind velocity, which is equal to $4\,m\,s^{-1}$. According to eqn [4], 1 h of wind velocity at $16\,m\,s^{-1}$ can carry the same amount of sand as 72 days with wind velocity of $5\,m\,s^{-1}$, or 27 h of wind velocity at $8\,m\,s^{-1}$. Hence, the factor W of eqn [3] that refers to the wind by the percentage of days during the year with sand-moving winds is a poor representation of the sand-moving power of the wind.

A much better index of wind power is the drift potential (DP) of the wind, which is based on eqn [4]:

$$DP = \Sigma q = \frac{U^2(U - U_t)}{100}t \qquad [5]$$

where $\sum q$ is related to the total sand flux from all wind directions, and t is the amount of time the wind blows above the threshold (in percent). The drift potential (DP) is given in vector units and it is customary to base the calculations on wind velocities measured in knots. An index of wind direction variability is illustrated by the ratio between the resultant drift potential and the drift potential (RDP/DP), where values close to one indicate narrow unidirectional DP, and values close to zero indicate multidirectional DP.

The total yearly average DP and the ratio RDP/DP can explain the mobility and stability of sand dunes mostly because the limiting factor for vegetation on dune sand is wind erosion. When RDP/DP is low, wind energy is distributed on more than one slope of the dune and the energy exerted on each slope is lower. Sand dunes in areas where the annual mean rainfall is $\geq$50 mm are unvegetated and mobile under wind conditions in which M (according to eqn [6]) exceeds 1:

$$M = \frac{DP}{1000 - (750(RDP/DP))} \qquad [6]$$

Table 2 displays the DP, RDP, and M (according to eqn [6]) in various dune sites of the world. It shows that rainfall is not as decisive a factor for dune mobilization or stabilization as is the DP. In the Negev desert, dunes are fully stabilized where the mean yearly rainfall is 90 mm. The dunes in Sinai (east of Al-Ismailiya) and the coastal dunes in Gaza are fully active due to human impact. Dunes that were artificially stabilized, such as along the Netherlands coast, will become active once vegetation is artificially destroyed.

Dune Shape and Dynamics

The tremendous variety of sand dunes in the world deserts makes their classification a difficult task. Sand accumulates into piles of various shapes because of three main causes:

1. Obstruction to the wind flow such as a cliff, boulder, etc.
2. Vegetation cover;
3. Self accumulation of sand into piles.

Classification according to the above three factors is depicted in Figure 5. The first two causes result from the immobilization of sand by vegetation or topographic obstructions. The last one is related to aerodynamics. In addition, other factors, such as

Table 2 Drift potential (DP), directional variability of the wind (resultant drift potential (RDP/DP), *M*-index (eqn [6]), and rainfall of several dune field sites

Location	*Country*	*DP*	*RDP/DP*	*Average yearly rainfall (mm)*	M	*Dunes status*
Al Ismailiya	Egypt (western Sinai)	62	0.47	50	0.10	Fully active
Nizzana	Israel (Negev)	108	0.70	90	0.23	Fixed (fully vegetated)
Gaza	Palestine (coast)	158	0.73	400	0.35	Active (partly vegetated)
Ashdod	Israel (coast)	147	0.71	500	0.31	Semiactive (partly vegetated)
Upington	South Africa (Kalahari)	520	0.66	183	1.03	Stabilized linear dunes
Port Elizabeth	South Africa (coast)	951	0.49	660	1.5	Fully active with no vegetation
Lüderitz	Namibia (coast)	2300	0.85	<100	6.34	Fully active with no vegetation
Ijmuiden	Netherlands (beach)	3999	0.51	768	6.48	Fully stabilized by vegetation; active when vegetation is destroyed

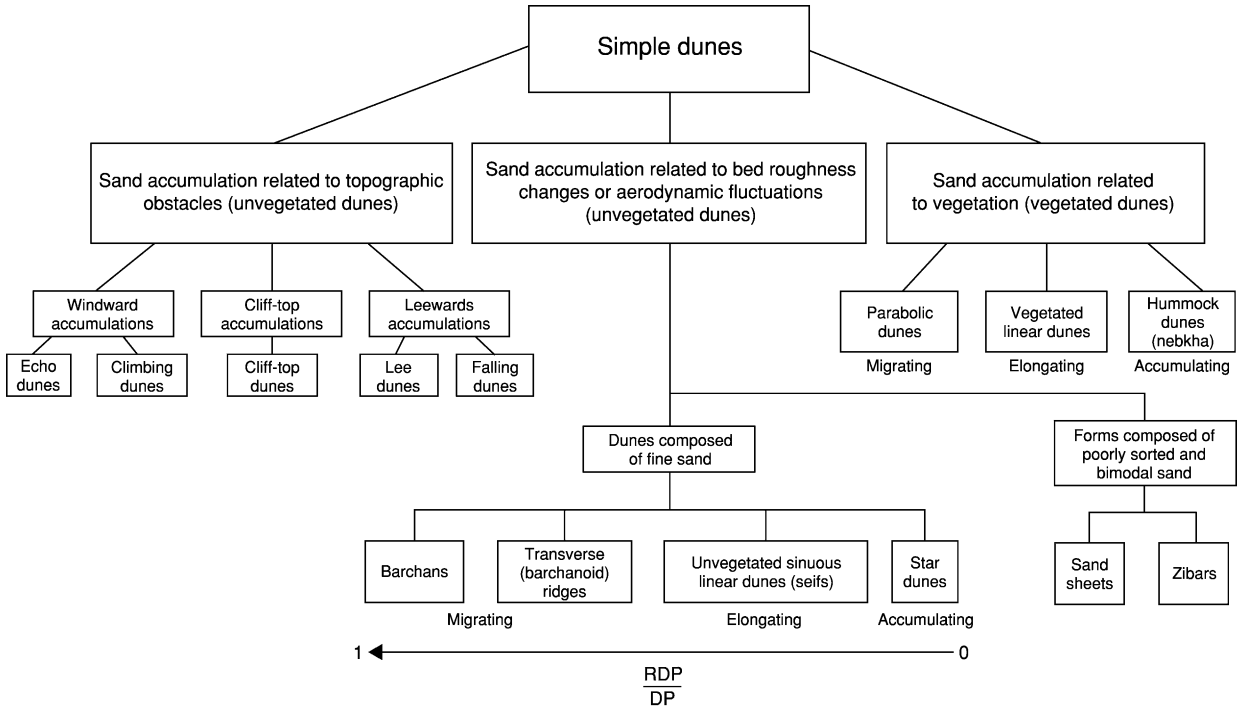

Figure 5 Classification of major dune types based on the way sand is accumulated into dunes and the effect of wind direction variability. RDP, resultant drift potential; DP, drift potential. Adapted from Pye K and Tsoar H (1990) Aeolian Sand and Sand Dunes, London: Unwin Hyman.

variation in wind direction, climatic changes manifested by dramatic shift in wind direction and magnitude, velocity, and frequency of storms, sand availability and thickness of sand cover, and sudden removal of vegetation cover, can have an effect on dune morphology.

From a dynamic point of view, sand dunes can be classified into three distinct groups:

1. Migrating dunes, where the whole dune body advances with little or no change in shape and dimension; best represented by transverse and barchan dunes.
2. Elongating dunes, where the dunes elongate and become extended in length with time; best represented by linear dunes.
3. Accumulating dunes, where the dunes have little or no net advance or elongation; best represented by star dunes.

These three groups are distinguished according to the wind directional variability for dunes without vegetation (Figure 5). The migrating dunes are formed by a wind regime that is unidirectional or close to unidirectional. The wind directions of the elongating dunes are bidirectional with a 70–90° separation between the two directions. The accumulating dunes are formed under multidirectional winds, where the two main directions form an obtuse angle that is approximately 180°.

The migrating and elongating dunes are under the influence of two different types of sand movement and deposition. Migrating dunes such as barchan and transverse dunes have two distinct slopes, a moderate windward and a steeper leeward. The windward slope undergoes erosion and the sand is carried to the lee slope where it is deposited on the upper part of the slope. When the upper lee slope reaches the critical angle of internal friction, a failure begins. The slide of grains from the upper slope downward reduces the slope inclination and the avalanche ceases at the angle of repose (33°), forming a slip-face (Figure 6).

Elongating dunes have a more complicated mechanism of sand transport and deposition because, when winds encounter the dune crest line at an acute angle, the flow at the lee side is deflected to parallel the crest line. Accordingly, the leeward slope is not merely a zone of deposition, but also a zone of erosion by the diverted lee flow. The occurrence of erosion and transport or deposition of sand depends upon the angle of incidence between the wind and the crest line. When this angle is $<40°$, the deflected wind has the power to erode sand and carry it along the lee slope, with little deposition on the upper lee slope. When the angle of incidence is close to 90°, the velocity of the wind in the lee slope drops and deposition largely occurs as it does with migrating dunes. For angles between 40° and 90°, there is a gradual transition in the lee slope, from dominant erosion

and transport to deposition. For that reason the linear seif dunes tend to meander (Figure 7) and consequently change the angle of incidence and the function of the lee side from an erosional to a depositional zone.

Star dunes as representative types of the accumulating dunes are recognized by their distinctive shape of sinuous arms radiating from a central pyramidal peak (Figure 8). Both mechanisms of migration and elongation act upon the star dunes from several directions. Star dunes are formed in a wind regime with high directional variability (RDP/DP < 0.4), and for that reason they are found mainly in the high latitudes of deserts with marked seasonal changes in wind direction.

The transverse, barchan, seif, and star dunes are formed without the presence of vegetation. There are also several typical vegetated dune types, which are located in arid and humid areas (mostly along the coasts).

Isolated clumps of vegetation act as sand traps and thus lead to the formation of nebkhas (coppice dunes) – hummocks that can reach up to 30 m high and 100 m across (Figure 9). The most effective pioneer plant forming nebkhas is *Ammophila arenaria*, which grows in clumps and can grow up through an accumulation of sand.

The most commonly found vegetated sand ridges on sandy backshores are foredunes that are formed where pioneer vegetation can grow and trap aeolian sand. Foredunes develop into continuous vegetated ridges, which lie parallel to coastlines exposed to onshore, sand-transporting winds (Figure 10). The foredune is a static dune that can only grow upward, and the only dune type that involves the exchange of sand with the beach. Other coastal dunes are mostly transgressive types (barchan, transverse, and parabolic dunes), formed when sand is transferred inland where foredunes are absent, or through blowouts (wind-excavated gaps through which sand is transported landward) in the foredune ridges.

Figure 9 Nebkha (coppice dune) formed by vegetation that traps sand.

Parabolic dunes, as their name implies, are U-shaped, with vegetated arms pointing upwind. Parabolic dunes can be active and transgressive or fully stabilized and inactive (Figure 11). The mechanism of parabolic dune formation in coastal humid areas is due to the fact that vegetation is more easily established at the base of the dune near the water table. Vegetation or dampness along the lower sides of the dune retards sand motion and both are considered to be anchors. Vegetation in parabolic dune formation is said to protect the less-mobile arms against the force of the wind action, thereby allowing the central part to advance downwind. In this way the advancing apex leaves behind trailing ridges that elongate and turn the dune into a hairpin form.

It has recently been found that barchan and transverse dunes turn into parabolic dunes in areas of low wind power where human impact is reduced. According to the profile of barchan or transverse dunes, erosion on the windward slope of the dune diminishes gradually toward the crest, which is an area

Figure 10 Foredune of approximately 5 m height formed on the backshore, where vegetation can thrive.

Figure 11 Parabolic (U-dune) formed by the effect of vegetation on sand transport.

Figure 12 Aerial photograph of vegetated linear dunes. This linear dune elongates in the direction of the dominant, strong wind. Note the straight alignment of the dune (different from the meandering seif of Figure 7) and the Y-junctions, which indicate wind direction from lower left to upper right.

of neither erosion nor deposition. Hence, once human impact stops, vegetation will recover on the barchan crest, thereby starting the process of transformation of these dunes into parabolic ones.

Vegetated-linear dunes belong to the group of elongating sand dunes found in many deserts of the world (Australian deserts, the Kalahari, Indian deserts, and the Negev). Vegetated-linear dunes are low with rounded profiles (Figure 12). They range in height from a few meters up to dozens of meters. Vegetation covers them, sometimes entirely, and sometimes abundantly on the plinth and lower slopes, but is very sparse or absent on the crest. Those that are fully covered by vegetation have become partly or wholly stabilized. Vegetated-linear dunes may run in parallel for scores of kilometers.

An exclusive attribute of vegetated-linear dunes is the tendency for two adjacent dunes to converge and continue as a single ridge. Convergence is in the form of a Y-junction (a tuning-fork shape) commonly open to formative winds. Vegetated-linear dunes are distinguished from seif dunes by: (1) coextension along the strongest dominant-wind direction; (2) the cover of vegetation; (3) straight alignment with no tortuosity; and (4) Y-junctions.

Introduction

The physical properties of field soils exhibit a high degree of spatial variability that complicates any attempt to predict their temporal evolution using conventional models based on nonlinear partial-differential equations. This complexity can be reduced by assuming that the varying local values of soil physical properties in a field are connected to one another by arbitrary scale factors, while the form of the governing partial-differential equation remains the same everywhere in the field ('scale invariance'). This assumption turns out to require soil hydraulic properties to be power-law functions of volumetric wetness (water content) and, in particular, it requires a power-law relation between hydraulic conductivity and matric potential. These power-law relationships have often been observed in controlled field experiments, indicating the applicability of scale invariance and opening the way for fractal models of soil physical properties. However, types of relationship other than power-law have also frequently been observed, pointing to the limitation of scaling as a means of reducing the complexity of spatial variability.

Scale Invariance

The physical properties of natural soils are inexorably variable when observed from place to place. Volumetric wetness – to choose perhaps the simplest example – can vary substantially over the span of an agricultural field, even if only the surface horizon of the field soil is examined and care has been taken to provide a uniform input of water prior to examination. The complexity that this kind of variability would bring to any attempt to understand and predict the temporal evolution of volumetric wetness across an entire field is evident, and the same conclusion follows for other important soil physical properties. (*See* **Spatial Variation, Soil Properties**.)

Now suppose that a simplifying hypothesis is made: that the underlying cause of spatial variability in soil physical properties has to do with the vicissitudes of soil texture or structure, but not with the fundamental mechanisms by which the physical properties may change in response to inputs of matter and energy. If this supposition is true, then the underlying physical laws that govern the behavior of these properties must be uniform across a field, even if the properties themselves are not. Moreover, functional relationships between the properties (e.g., the relationship of volumetric wetness to matric potential) should also be uniform, in the sense that each such relationship is quantified by the same parametric equation everywhere in a field, albeit with different (and highly varying) values of the parameters at different places.

That spatial uniformity in the physical laws describing the behavior of soil properties implies a similar uniformity in the functional relationships between these properties may not seem obvious, but this conclusion follows once the physical laws are expressed mathematically in the form of nonlinear partial-differential equations. Fundamentally, imposing the condition of spatial uniformity on a governing partial-differential equation places a strong constraint on the relationships between its dependent variable and the nonconstant coefficients that appear in the equation, with the result that these relationships necessarily must also be uniform.

To make these ideas concrete, let us consider the well-known, nonlinear partial-differential equation that governs isothermal, isohaline, isochoric infiltration processes in a uniform pedon (i.e., the Richards equation in the 'mass picture'):

$$\partial\theta/\partial t = \partial[D(\theta)\partial\theta/\partial z]/\partial z - (\partial K/\partial\theta)(\partial\theta/\partial z) \qquad [1]$$

where θ ($L^3\,L^{-3}$) is volumetric wetness, $t(T)$ is time, $z(L)$ is vertical position, $D(\theta)$ (L^2T^{-1}) is water diffusivity under a gradient in θ, and $K(\theta)$ (LT^{-1}) is hydraulic conductivity. Eqn [1] describes the temporal evolution of volumetric wetness in terms of two empirical transport coefficients, $D(\theta)$ and $K(\theta)$,

whose relationship to θ must be specified in order to apply the equation in a predictive manner. Eqn [1] could be used to model infiltration in an instrumented field plot, with the expectation that $D(\theta)$ and $K(\theta)$ would have widely varying values across an array of such plots, even at the same value of θ. The hypothesis of uniformity requires that eqn [1] apply to observations of $\theta(t, z)$ anywhere in the array, irrespective of the high spatial variability. This latter supposition, in turn, requires that $D(\theta)$ and $K(\theta)$ each preserve the same functional relationship to θ anywhere in the field.

The uniformity hypothesis being imposed on eqn [1] is expressed formally by defining three arbitrary parameters that connect two sets of its dependent and independent variables evaluated at any two places where the equation applies:

$$\theta' = \mu\theta, \quad t' = \delta t, \quad z' = \alpha z \qquad [2]$$

where μ, δ, and α are (positive-valued) scale factors. These scale factors relate $\theta'(t', z')$ in one place to $\theta(t, z)$ in another, the premise being that, since the governing physical law is the same at both places, all of the spatial variability in the volumetric wetness across a field can be captured quantitatively solely by changes in the scales ('magnification' or 'reduction') over which the dependent and independent variables are observed. To be consistent with this premise, eqn [1] must still hold at the 'prime' location, i.e., after it is transformed by multiplying θ on both sides of the equation by μ, then changing t to t' on the left side and z to z' on the right side, using eqn [2]:

$$\begin{aligned}\partial\theta'/\partial t' = {} & (\alpha^2/\delta)\partial[D(\theta)\partial\theta'/\partial z']/\partial z' \\ & - (\mu\alpha/\delta)(\partial K/\partial\theta')(\partial\theta'/\partial z')\end{aligned} \qquad [3]$$

Eqn [3] will have the same mathematical form as eqn [2] only if the scale transformations:

$$\begin{aligned}D'(\theta') &\equiv D(\mu\theta) = (\alpha^2/\delta)D(\theta), \\ K'(\theta') &\equiv K(\mu\theta) = (\mu\alpha/\delta)K(\theta)\end{aligned} \qquad [4]$$

are also imposed on the two transport coefficients. Eqn [4] connects values of the water diffusivity and hydraulic conductivity at any two places. When they hold, the governing partial differential equation for $\theta(t, z)$ will have the same mathematical form under arbitrary scaling anywhere in a field. In this sense, the equation (and the physical behavior which underlies it) is said to be 'scale-invariant.' It is thus immune to the vagaries of spatial variability, these being epitomized instead in the three scale factors (eqn [2]) and the required scale transformations of the transport coefficients (eqn [4]).

Scaling Relationships

It is apparent that eqn [4] cannot be true for just any functional dependence of the two transport coefficients on θ, unless the scale factor μ always happens to have the value 1.0. In other words, if the transport coefficients do not change compatibly with the scaling of eqn [1], then scale invariance of the equation is vacuous. This critical issue can be investigated rigorously with methods in the mathematical theory of Lie groups. This investigation shows that $D(\theta)$ and $K(\theta)$ must have the following functional forms in order that eqn [4] be satisfied:

$$D(\theta) = a(\theta + b)^{\mathrm{m}} \qquad [5]$$

$$K(\theta) = \left[ca^{\beta}/(1 + m\beta)\right](\theta + b)^{1+\mathrm{m}\beta} \qquad [6]$$

where a, b, c are constants to be determined by the units of D and K and the datum of θ, while m and β are empirical parameters related to the scale factors in eqn [2]. Their relation to the scale factors emerges clearly after imposing eqn [4] on eqns [5] and [6]:

$$D'(\theta') \equiv a(\mu\theta + \mu b)^{\mathrm{m}} = \mu^{\mathrm{m}} D(\theta) = \left(\alpha^2/\delta\right)D(\theta) \qquad [7]$$

$$\begin{aligned}K'(\theta') &\equiv \left[ca^{\beta}/(1 + m\beta)\right](\mu\theta + \mu b)^{1+\mathrm{m}\beta} \\ &= \mu^{1+\mathrm{m}\beta}K(\theta) = (\mu\alpha/\delta)K(\theta)\end{aligned} \qquad [8]$$

(In eqns [7] and [8], the arbitrary constant b is assumed to be determined by the datum for θ and, therefore, to scale as θ does.)

It follows that:

$$\left(\alpha^2/\delta\right)^{1/\mathrm{m}} = (\alpha/\delta)^{1/\mathrm{m}\beta} \qquad [9]$$

and, therefore:

$$\delta = \alpha^{(2\beta-1)/(\beta-1)} \qquad [10]$$

Either eqn [9] or [10] then yields the relation:

$$\mu = \alpha^{1/\mathrm{m}(1-\beta)} \qquad [11]$$

for the scale factor of θ. Thus, only one of the three scale factors can be chosen independently once the values of m and β have been measured. (Note also that $m \neq 0$, $m\beta \neq -1$, must be finite and $\beta \neq 1$ or 1/2. These conditions are required in order that eqns [6], [9], and [10] be determinate.)

The physical significance of the scale factor α can be appreciated more incisively after using the definition of the water diffusivity:

$$D(\theta) \equiv K(\theta)\frac{\partial\psi}{\partial\theta} \qquad [12]$$

along with eqns [5] and [6] to derive an equation for the matric potential $\psi(\theta)(L)$ that is consistent with scale invariance:

$$\psi(\theta) = [(1 + m\beta)/cm(1 - \beta)](\theta + b)^{m(1-\beta)} \quad [13]$$

The corresponding equation for $\psi'(\theta') \equiv \psi(\mu\theta)$ then follows from eqn [11]:

$$\psi'(\theta') = [(1 + m\beta)/cm(1-\beta)](\mu\theta + \mu b)^{m(1-\beta)}$$
$$= \mu^{m(1-\beta)}\psi(\theta) = \alpha\psi(\theta) \quad [14]$$

The scale factor α is found to transform the matric potential from one place to another. Similarly, the transformation of the hydraulic conductivity follows from eqns [4], [10], and [11] as:

$$K'(\theta') = \alpha^{-\eta}K(\theta) \quad [15]$$

where

$$\eta \equiv (1 + m\beta)/m(\beta - 1) \quad [16]$$

The right side of eqn [15] is more conventionally expressed in terms of the square of a scale factor ω, defined by:

$$\omega \equiv \alpha^{2/\eta} \quad [17]$$

such that the scale transformation of $K(\theta)$ takes the form:

$$K'(\theta') = \frac{K(\theta)}{\omega^2} \quad [18]$$

Eqns [14] and [18] are known as 'Warrick–Nielsen scaling relationships,' and the exponent η that relates them in eqn [17] is the 'Russo–Jury exponent.'

A further connection between eqns [6] and [13] and conventional practice in soil physics can be made after defining the datum constant b to equal $-\theta_r$, where θ_r is the 'residual volumetric wetness,' a measure of the volume of 'immobile water' that does not participate in flow on the time scale over which eqn [1] is applied. Adding to this the conventional definitions:

$$\psi_s \equiv \psi(\theta_s), \qquad K_s \equiv K(\theta_s) \quad [19]$$

where θ_s is porosity, one can rewrite eqns [6] and [13] in a more convenient power-law form:

$$\psi(S) = \psi_s S^{m(1-\beta)} \quad [20]$$

$$K(S) = K_s S^{1+m\beta} \quad [21]$$

where

$$S \equiv (\theta - \theta_r)/(\theta_s - \theta_r) \quad [22]$$

is the degree of saturation. Eqns [20] and [21] indicate that this scale-invariant variable is a natural one with which to express the relationship between either matric potential or hydraulic conductivity and volumetric wetness. If S is eliminated between eqns [20] and [21], hydraulic conductivity can be connected directly to matric potential:

$$K(\psi) = K_s(\psi_s/\psi)^{\eta} \quad [23]$$

upon noting eqn [16]. The Russo–Jury exponent is now seen as the parameter that determines the power-law dependence of hydraulic conductivity on matric potential, as implied by eqn [17].

Example: Hamra Soil Field Experiment

Eqns [20–23] can be illustrated by their application to a 0.8-ha field comprising an Alfisol (Hamra series) on which 30 instrumented plots were established. Table 1 lists field-wide mean values and coefficients of variation (CVs) for ψ_s, K_s, m, and β as deduced from measurements of $\psi(\theta)$ and $K(\theta)$ made at four depths in the soil profile. Notable in the table are the typical decline in K_s with depth and the relatively large CVs (mean divided by standard deviation) for

this parameter and the two exponents m and β. The lesser spatial variability of ψ_s parallels that observed for θ_s (all-depth field-wide mean of 0.37, with CV = 0.11). The field-wide mean values of the Russo–Jury exponent also tended to decline with depth: 4.3 ± 1.6, 3.3 ± 0.9, 2.9 ± 0.8, 2.9 ± 0.7; the all-depth mean being 3.3, with CV = 0.36. Other field studies show that η usually lies in the interval (2.0, 4.5) with a typical CV in the range 0.2–0.5.

The complete data set for the Hamra soil has been used to compute values of $\psi(S)$ and $K(S)$ at fixed values of S in the interval (0.750, 0.975) based on eqns [20] and [21]. The resulting all-depth mean values and CVs of the dimensionless ratios, $\psi(S)/\psi_s$ and $K(S)/K_s$, are listed in Table 2 for 10 values of the degree of saturation S. The very large CVs at smaller values of S are immediately apparent. It is this extreme spatial variability that the scale factors α (eqn [14]) and ω (eqn [18]) are designed to mediate. In particular, it should be possible to substitute the all-depth mean values of $\psi(S)/\psi_s$ and $K(S)/K_s$ into the left side of eqns [14] and [18] in order to calculate α and ω anywhere in the field (subject to imposing an all-depth mean value of 1.0 for each scale factor, since only the ratios $\psi(S)/\psi_s$ and $K(S)/K_s$ are used). The result of such a calculation is summarized in Table 3, which indicates that α and ω have virtually identical CVs over the field and that the field-wide mean value of η linking them (eqn [17]) is the same as found from examining values of the matric potential and hydraulic conductivity directly.

Physical Significance of Scaling

Now let us step back to take stock of what the scaling of soil physical properties and processes actually means. The basic premise is that fundamental physical laws governing the behavior of the properties are scale-invariant. The example taken was the Richards equation for infiltration (eqn [1]), which describes volumetric wetness changes when water moves downward in a soil profile whose water diffusivity and hydraulic conductivity are known. Scale invariance of this equation implies that it is equally valid from place to place in a field, with uniform functional relationships between its two transport coefficients and the volumetric wetness. These latter three variables may fluctuate wildly across a field, but they are none the less connected by scale factors that relate their values between any two places. Their spatial variability is thus epitomized solely by differences in the local scales of volumetric wetness, position, and time (eqn [2]) that prevail at different locations, or if the degree of saturation (eqn [22]) is chosen as the dependent variable in the Richards equation, solely by differences in the scales of position and time that attend water movement at different locations in a field. Evidently these differences of scale arise from localized soil textural or structural characteristics, although the precise cause of spatial variability is left unspecified.

Implicit in the scale invariance of the Richards equation is the fact that this equation must also apply on average to an entire field of soil:

$$\partial S/\partial t = \partial[D_m(S)\partial S/\partial z]/\partial z - (\partial K_m/\partial S)(\partial S/\partial z) \quad [24]$$

where $D_m(S)$ and $K_m(S)$ are field-wide mean values of the transport coefficients. Eqn [24] is ultimate testimony to the hypothesis that the mechanism of infiltration is the same irrespective of the scale of observation. Indeed, the dependent variable in eqn [24] is scale-invariant, and the mean transport coefficients are related to local values at any place 'P' through the Warrick–Nielsen scaling relationships:

$$\alpha_P^2 D_P(S)/\omega_P^2 = D_m(S) \quad [25a]$$

$$K_P(S)/\omega_P^2 = K_m(S) \quad [25b]$$

with a corresponding equation for matric potential:

$$\alpha_P \psi_P(S) = \psi_m(S) \qquad [25c]$$

(eqn [25a] follows from eqns [12], [14], and [18].)

In field experiments like the one performed on the Hamra soil, ψ_m and K_m are first calculated, then they are used along with local values of the matric potential and hydraulic conductivity to estimate a set of α_P and ω_P, thus giving pragmatic substance to the reality of eqn [24]. Indeed, using this approach, one need only solve the mean Richards equation for a chosen boundary-value problem and have in hand a set of scale factors $\{\alpha_P, \omega_P\}$ in order to apply the solution at every point in a field – clearly an advantage in predictive applications of the flow equation. However, this computational efficiency can only be realized if there is truly no scale dependence of the mechanism of water flow, a matter for continuing field experimentation to evaluate.

The compatibility conditions in eqns [5], [6], and [13] ensure that the scale invariance of the Richards equation is not a vacuous hypothesis. The matric potential and the two transport coefficients are required to be power-law functions of the volumetric wetness or, equivalently, the degree of saturation. This power-law form has been widely used to describe the functional relationship between matric potential and volumetric wetness in field soils, under which application it is termed the 'Brooks–Corey model':

$$S = (\psi_s/\psi)^{\lambda} \qquad [26]$$

where the Brooks–Corey exponent $\lambda = 1/m(\beta - 1)$ according to eqn [20]. Representative values of the parameters ψ_s and λ have been calculated using hydraulic data on hundreds of soils according to texture. These data show that the 'air-entry value' ψ_s tends to increase, while the Brooks–Corey exponent λ tends to decrease, as the clay content of a soil becomes larger. Eqn [26] can also be derived from a fractal model of soil pore space in which the pore-size distribution is scale-invariant and $\lambda \equiv 3 - D$, where $D < 3$ is the fractal dimension that characterizes the degree of 'lacunarity' of a soil, i.e., the extent to which its pores are space-filling at the expense of the solid matrix. Given the typical range of values observed for the Brooks–Corey exponent ($0.1 < \lambda < 0.7$), it follows that $2.3 < D < 2.9$, with larger fractal dimensions corresponding to clayey soils. Thus, in clayey soils, 'lacunarity,' or the degree to which pores are space-filling, is expected to be larger than in sandy soils, in agreement with the respective porosities of these soils.

A power-law relation is also expected between hydraulic conductivity and volumetric wetness or, more generally, between hydraulic conductivity and matric potential (eqn [23]), if the Richards equation is scale-invariant. This relationship is often observed, but other models of $K(\psi)$ are abundant in the literature of soil physics. For example, the Gardner model postulates an exponential relationship instead of a power-law relationship for $K(\psi)$:

$$K(\psi) = K_s \exp\left[-\frac{\psi_s - \psi}{D_s/K_s}\right] \qquad [27]$$

If this equation accurately describes the behavior of hydraulic conductivity in a soil, the Richards equation cannot be scale-invariant over a field containing that soil. Indeed, application of the scaling relations in eqns [14] and [15] to both sides of eqn [27] is impossible. The reason for the failure is signaled by the presence of the ratio, D_s/K_s, in eqn [27]. This ratio has the dimensions of length and serves as a measure of how quickly $K(\psi)$ declines as ψ decreases below the air-entry value in a 'Gardner soil.' It is, therefore, an intrinsic length scale in the Gardner model, i.e., a length scale that is determined uniquely by the values of D_s and K_s at each separate location in a field soil. In terms of conventional water-desorption methods of measuring the cumulative pore-size distribution in a soil (by combining data on $\psi(S)$ with the Young–Laplace equation to calculate the effective pore radius as a function of the degree of saturation), the length scale D_s/K_s is interpreted as that of the very first pores to empty when ψ drops below the air-entry value, ψ_s. (*See* **Porosity and Pore-Size Distribution**.) The existence of such an intrinsic length scale stands in direct contradiction to the use of an arbitrary scale factor for relating matric potential at two places in a field (eqn [14]). Therefore, in a Gardner soil, the arbitrary scaling of matric potential (and, correspondingly, of all the variables in eqn [1]) is not possible because the intrinsic length scale D_s/K_s preempts that possibility. This example of broken scaling symmetry is valuable, in that it illuminates by contrast the underlying significance of eqns [14–18]: that the flow equation operates everywhere in a field soil without prejudice as to the local scales of length, time, or water content.

Transport Processes

R P Ewing, Iowa State University, Ames, IA, USA

Introduction

'Scaling of transport properties' refers to the common and often troublesome observation that the model parameters describing dispersion at one scale are frequently incorrect at another scale. Worse, sometimes one model is applicable at one scale, and a different model at another scale. The word 'scale' denotes extent, most often of space or time, so to say that dispersion scales is to say that different results are obtained from measuring it at different spatial or temporal scales. The most common situation is that one measures dispersion at a small scale and predicts it at a larger scale, then finds that the actual dispersion as measured later at the larger scale is greater than predicted. Further evidence of scaling is the observation that dispersion coefficients compiled from many separate experiments show a strong trend of dispersion increasing with distance. Is this scaling inherent to the dispersion process?

Because prediction of solute transport is generally based upon the advection–dispersion equation (ADE), which uses a diffusion-type description of transport, to say that transport scales often implies that it does not conform to a simple diffusion-like description. Scaling of dispersion is often thought to be an exceptional case, sometimes called 'anomalous dispersion,' implying that dispersion which obeys the ADE is the norm. But as more so-called anomalous transport has been found, it is increasingly accepted as both more general and widespread: 'normal' transport actually represents a special and unusual case. In this article, dispersion that conforms to the ADE will be called 'Gaussian.'

This article discusses the simple case of one-dimensional dispersion of a nonreactive, neutral, conservative solute during steady-state isothermal saturated flow, ignoring any density and viscosity effects of solute concentration. This simple case is already sufficiently difficult, but the reader must remember that real-world situations also include reactive, degrading, sorbing, and/or charged solutes moving nonisothermally and transiently under multiple driving and dispersing forces.

Diffusive–Dispersive Transport

Hydrodynamic dispersion (called 'dispersion' here for convenience) is the result of two mechanisms: mechanical dispersion and molecular diffusion. In simplistic terms, mechanical dispersion is caused by the medium, while diffusion is inherent to the fluid. Mechanical dispersion results from differences in travel times along different streamlines. At the scale of a single pore, these differences result from flow being slower close to a pore wall and faster at pore centers. At a larger scale, streamlines differ in velocity due to heterogeneity of the medium, such as variations in pore size and connectivity, and the presence of structure across multiple scales from pore-scale correlations to large-scale layering and fractures. When flow is rapid, mechanical dispersion

contributes most of the total dispersion, but at slow flow rates dispersion is predominantly diffusive.

Molecular diffusion is the random motion of fluid molecules, so diffusion of solutes is a function of the fluid (solvent and solute). The diffusion equation describes net solute flux as being proportional to, and opposite in direction from, the concentration gradient. In one dimension and in bulk fluid (no solid phase):

$$\frac{\partial C}{\partial t} = D_{\text{aq}} \frac{\partial^2 C}{\partial x^2} \qquad [1]$$

where C is solute concentration (M L^{-3}), t is time (T), D_{aq} is the diffusion coefficient ($\text{L}^2\,\text{T}^{-1}$) of the solute in water, and x is distance (L). In the presence of a solid phase, the molecular diffusion coefficient can be adjusted by the porosity ϕ of the medium and the tortuosity τ of the diffusive path length, giving an effective diffusion coefficient: $D_{\text{eff}} = D_{\text{aq}}\,\phi/\tau$. If solute is introduced at time t_0 in a plane at concentration M per unit area, within an infinite medium having initial concentration $C_0 = 0$, then the resulting concentration at a distance x from that plane at time t is:

$$C(x,t) = \frac{M}{2\sqrt{\pi D t}} \cdot \mathrm{e}^{-\mathrm{x}^2/4\,\mathrm{Dt}} \qquad [2]$$

which is a Gaussian (normally distributed) concentration profile whose width increases in proportion to the square root of time.

Dispersion is often estimated using data from an experiment in which water in the sample is replaced by water with a tracer. If the output is tested for the presence of the tracer, a steady increase in flux concentration is seen as the original water is replaced by water with the tracer. If instead the tracer's resident concentration is measured inside the sample at a single instant, a decrease in tracer concentration is seen from the inlet to the outlet end of the sample. The output of a flux concentration dispersion experiment can be summarized graphically using a breakthrough curve (BTC) (Figure 1). In these curves, the x-axis is presented in units of pore volumes, the amount of water needed to replace the original water in the soil sample precisely once. The y-axis is expressed as the ratio of the measured to the final concentration, C/C_0. This normalization of the two axes allows curves from different experiments (flow rates, column lengths, etc.) to be compared.

Sir Geoffrey Taylor and the Spreading of Solute in a Tube

While diffusion is only one component of dispersion, the physicist Sir Geoffrey Taylor showed that

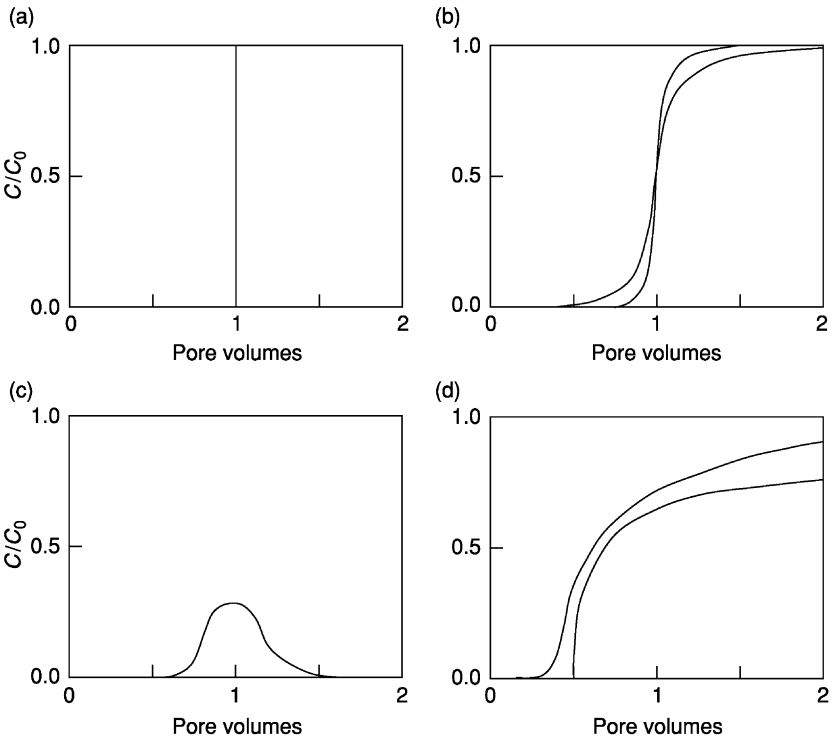

Figure 1 Sample flux concentration breakthrough curves for: (a) a step input with piston flow; (b) a step input with Gaussian dispersion; (c) a Dirac (pulse) input with Gaussian dispersion; and (d) non-Gaussian dispersion. See text for explanation.

dispersion of a solute in fluid flowing steadily through a tube can – under certain conditions – be precisely described by superimposing the mean fluid velocity on to a diffusion-like dispersion term. The main condition is simply that flow be sufficiently slow that solute molecules have time to diffuse freely between fast (tube center) and slow (tube wall) regions, a condition that is often well approximated, at least at the pore scale, under natural conditions in soils and aquifer materials. Taylor's experimental setup – a uniform tube with steady flow – clearly does not match any naturally occurring porous media. Nonetheless, the analogy between dispersion and diffusion has historically been applied to solute movement in porous media generally. The analogy is particularly attractive because the diffusion equation has been widely studied, and operating within this analogy allows use of a wealth of mathematical solutions.

Sir Geoffrey Taylor's three seminal papers on dispersion of solutes in a tube, combined with Rutherford Aris' subsequent analysis, established much of how both engineers and soil scientists now think about dispersion. An earlier paper by Griffith had stated that a drop of dye, placed into water flowing through a glass tube, moves at the mean water velocity, with its dispersion along the tube being symmetrical. Reading Griffith's paper, Taylor was struck by its two 'remarkable' implications: first, movement with the mean water velocity implied that water in the center of the tube, flowing at twice the mean velocity, must pick up dye as it traveled toward the center of the dye slug, then release it after passing the center of the slug; and second, the longitudinally symmetrical dispersion seemed at odds with the radially asymmetrical (parabolic) velocity distribution of water in the tube. Taylor set to work to examine these phenomena both experimentally and mathematically.

Starting by assuming that there was no diffusion at all, Taylor realized that the parabolic velocity profile:

$$v(r) = v_0(1 - r^2/a^2) \qquad [3]$$

(where $v(r)$ is velocity ($\mathrm{L\,T^{-1}}$) at a distance r from the tube center, v_0 is the maximum velocity, a is the tube radius (L), and r is distance from the tube center (L) such that $0 \leq r \leq a$), coupled with a step input of dye, would yield the linear breakthrough curve:

$$C/C_0 = \left(1 - \frac{x}{v_0 t}\right) \qquad [4]$$

where t is time (T), for $0 < x < v_0 t$. He also noticed that the diffusion coefficient D_{aq} ($\mathrm{L^2\,T^{-1}}$) was small in comparison with the observed dispersion coefficient $D(\mathrm{L^2\,T^{-1}})$: apparently longitudinal diffusion (diffusion in the direction of flow) was an insignificant contributor to dispersion. Radial diffusion (normal to the direction of flow), however, could explain the movement of solute molecules between the fast-flowing tube center and the negligible velocities near the wall.

Taylor's analysis of the interaction between radial diffusion and the parabolic velocity profile shows that the dispersion behaves exactly like diffusion, that is, it yields a Gaussian concentration profile the width of which grows in proportion to the square root of time (Figure 2). The theoretical dispersion coefficient D, which agrees well with his observations, is given by:

$$D = \frac{a^2 v_0^2}{192\, D_{aq}} \qquad [5]$$

that is, dispersion is proportional to velocity squared. But this relationship only holds if two conditions are met. The first condition states that $av/D_{aq} \gg \sqrt{48}$, where v is the mean velocity. The quantity av/D_{aq} actually defines the Peclet number (the ratio of advective to diffusive transport), so this condition can be simply restated as $\mathrm{Pe} \gg 7$. Aris, noting that Taylor's D explicitly excluded longitudinal diffusion, added it back into Eqn [5] to obtain:

$$D = D_{aq} + \frac{a^2 v_0^2}{192\, D_{aq}} \qquad [6]$$

thereby eliminating the need for this first condition. Notice that the resulting dispersion coefficient is explicitly the sum of diffusive and mechanical dispersive forces.

The second condition states that $a^2/4D_{aq}t$ must be small; that is, there must be sufficient time for radial

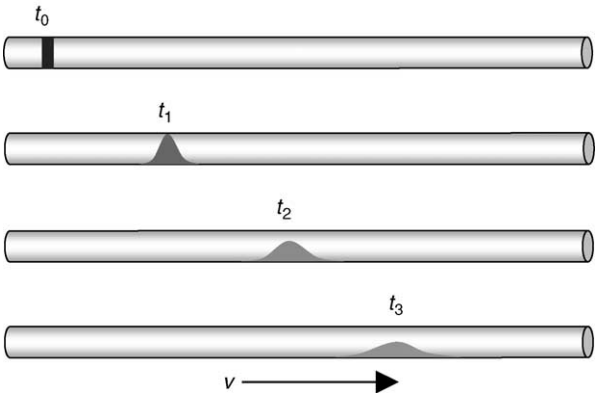

Figure 2 How the solute flows and disperses with time in a tube into which solute is introduced at a single instant in time.

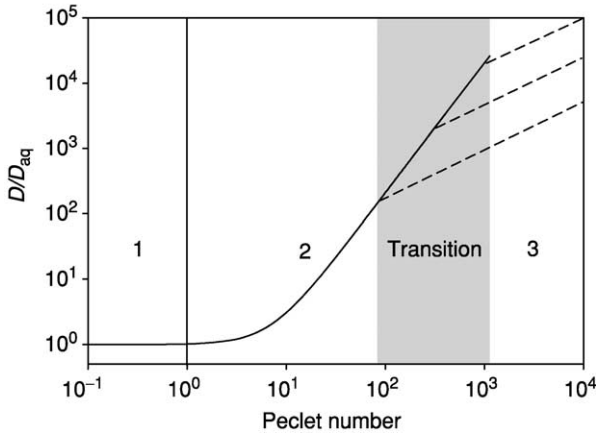

Figure 3 Mechanical dispersion over total dispersion as a function of the Peclet number. Above some Peclet number whose exact value varies with length, dispersion transitions to being linear with time; below that, it scales with the square of time. See text for explanation.

diffusion to move molecules a distance equal to the radius of the tube. When the elapsed time is too short, radial diffusion is insignificant and the dispersion can be approximated by Eqn [4], Taylor's first analysis, based upon the assumption of no diffusion. In terms of the Peclet number, this second condition may be expressed as $\mathrm{Pe} \ll 4L/a$, where L is the distance from the dye injection point at which the measurement is made.

The conditions for Taylor's analysis can be shown by plotting the ratio of total dispersion to diffusion as a function of the Peclet number (**Figure 3**). The solid line represents the Aris equation (Eqn [6]), which shows different behavior in each of three regions; the dashed lines show the behavior that would be seen if the second condition were violated. In the first region ($\mathrm{Pe} \ll 7$), diffusion is an important contributor to total dispersion and so Taylor's original analysis (Eqn [5]) does not hold, although Aris' (Eqn [6]) does. In the second region, both conditions are met and the slope of the line is approximately 2. The Peclet number above which the second condition fails, $\mathrm{Pe} \ll 4L/a$, is shown as a gray region rather than a single line because it changes for different L. In this third, preasymptotic region, dispersion is linearly related to velocity. Because for any given velocity and tube radius the second condition does not hold for some short time or distance, we can refer to short times and/or distances as being 'preasymptotic.'

Solute Spreading in Soils

Superimposing a mean velocity on to the diffusion equation yields the ADE, also called the convection–dispersion equation (CDE). A one-dimensional form of the ADE for nonreactive solutes describes the change in concentration as resulting from the sum of dispersive and advective terms:

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} - \nu\frac{\partial C}{\partial x} \qquad [7]$$

where D is the dispersion coefficient ($\mathrm{L}^2\,\mathrm{T}^{-1}$) and ν is the mean water velocity ($\mathrm{L}\,\mathrm{T}^{-1}$). Analytical solutions to this equation have been derived for a wide variety of initial and boundary conditions, and numerous computer programs are also available. In a simple case, a point injection of a solute will move at the mean water velocity, while spreading as if it were diffusing with a diffusion coefficient equal in magnitude to the dispersion coefficient D. Non-Gaussian behavior is often seen at early times and/or short distances, but such situations will yield increasingly Gaussian behavior with increasing distance and/or time. Accordingly, non-Gaussian behavior is sometimes called 'preasymptotic,' implying that all dispersion eventually becomes Gaussian.

In the field, dispersion is often observed to increase linearly with fluid velocity. The CDE can in this case be generalized with respect to velocity by defining the dispersivity $\alpha(\mathrm{L})$ as $\alpha = D/\nu$, and replacing the dispersion coefficient D in the ADE with $\alpha\nu$. This dependence on velocity may seem counterintuitive: if dispersion is the sum of molecular diffusion and mechanical dispersion, then mechanical dispersion (which results from the medium) should be independent of velocity, whereas slower flow (having more time) should result in greater diffusion-based dispersion. But as Taylor's studies of dispersion in a tube have shown, D increases with ν within a specific range of Peclet numbers, so dispersion increasing with velocity is not entirely surprising. On the other hand, dispersion in soils is observed to be proportional to ν rather than ν^2, so Taylor's analysis provides only a partial explanation of the whole process.

Unfortunately, the assumption that dispersion can be treated mathematically as if it were diffusion often leads to a poor match between model and data. This is frequently because one or more of the equation's assumptions have been violated: probably either the medium is not uniform (let alone tubular!) or there is insufficient exchange between solute molecules traveling on different streamlines. Because diffusion and flow are not strictly additive with respect to dispersion except under specific conditions, the basic concept of the ADE is not sufficiently general for many situations found in the real world. Much of the recent research on solute dispersion concerns struggles with the poor predictions produced by the ADE, frequently focusing on developing alternative conceptual models.

Scale

Soil science is concerned with processes taking place from the nanometer to the kilometer scale and beyond, and from the near-instantaneous to geologic timescales. It is common to speak of scales in a colloquial manner – 'pore-scale,' 'lab-scale,' 'overnight' – and the mental images that these terms invoke can be useful, although they are not quantitative. Less useful are terms such as 'microscale,' which naturally carry widely different meanings between, and even within, different disciplines. Because soil science is inherently interdisciplinary, such words will have different meanings even to different soil scientists and should be avoided. If quantitative terms are needed, then using the size itself is best: 'meter-scale,' for example.

Some properties are specific to a defined range of scales. To illustrate, suppose one wants to measure the porosity of a sand using computed tomography (CT). If the CT unit measures with a resolution of 0.01 mm, then most voxels (volume elements from the CT scan) will represent either the inside of a solid particle or the center of a pore. In neither case will it be useful to speak of the porosity of an individual voxel: porosity is a property of a volume and becomes meaningless as that volume shrinks to a point. If we coarsen the scale slightly, each individual voxel will sample just a few grains and pores, and so individual measurements will be highly variable. But when porosity is measured over a sufficiently large number of grains and pores (at least 30 is a good guideline), the measured value is stable. This illustrates the concept of the representative elementary volume (REV), the smallest volume over which a given property can be measured with reasonable confidence. Notice that the REV must be larger than the characteristic scale of variability of the medium (if one exists).

At this point we must also make a distinction between scale and level. Scale is strictly about physical extent, while level involves a conceptual difference or a change in properties. The two are easily confused, because changes in physical size often entail changes in level also. For example, a soil core 10 cm deep may come from a single horizon, but 'scaling up' to a 20-cm core may yield a sample with two distinct horizons in it – a difference in level as well as scale. Likewise, scaling up from a 10-cm core to a pedon may introduce fractures or wormholes into the system, and so, rather than studying a soil matrix, one now faces a macropore-matrix or dual-permeability system. The distinction between scale and level may be quite subtle. For example, buoyancy effects may not be evident during fast flow of a weak salt solution through a 1-cm-diameter soil column, but they may be evident during slower flow through a larger-diameter soil column. In the second case, the increase in size (scale) allows the emergence of a previously negligible mechanism (level), so the second system under study is not equivalent to the first. It can be useful to compare relevant dimensionless groups to help discern whether changing the scale also allows new processes to come into play. Relevant dimensionless groups may include the Peclet number (ratio of advective to diffusive forces), the Bond number (ratio of buoyancy to capillary forces), the Reynolds number (ratio of inertial to viscous forces), and the Schmidt number (ratio of kinematic viscosity to molecular diffusivity).

A further difficulty is that many parameters of interest can each be best measured within a fairly narrow range of scales. For example, dispersion is generally estimated from solute concentration, based upon samples at the scale of a liter or less. Measuring solute concentration over a large area is generally accomplished by collecting many small samples, because collecting the entire outflow of a large area is generally impractical, if not impossible. So studies of dispersion generally operate at many scales: the scale of the individual observations (where different observations may themselves have different scales), the scale of the current composite (for example, the inferred pollutant plume based upon some 100 individual core samples), the scale of the desired prediction, and the characteristic scale, if any, of the soil's heterogeneity. While we are mainly concerned here with the disparity between the middle two, any difference in scale may contribute to scaling.

Conceptual Models

Several conceptual models are in common use for predicting dispersion. The ADE, described above, is widely used in both subsurface hydrology and soil science. Conceptually equivalent to flow through a tube (**Figure 4a**), it does not adequately describe the complexities encountered in flow through soils and so frequently fails to predict dispersion correctly. One common failure is finding that the value of the dispersion coefficient increases with the distance over which the solute has moved. A second failure is a non-Gaussian output which persists across many length scales, despite the prediction of the ADE that the dispersion will asymptotically become Gaussian. A common instance of this is 'slow tailing,' in which the breakthrough curve resulting from a step input shows early arrival and a slower-than-Gaussian increase to the final concentration. This has been addressed in some models by the use of a fractional ADE (fADE), which uses a fractional form of the error

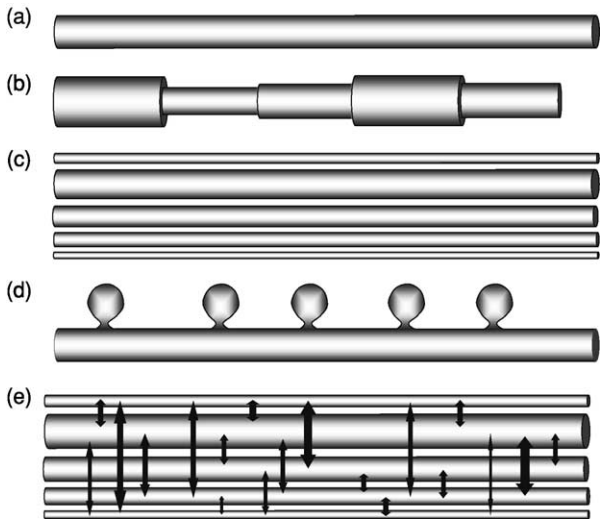

Figure 4 (a) A single tube with constant cross section; (b) a tube with varying cross section; (c) a bundle of tubes of different but constant cross sections; (d) a single tube with dead-end 'pores'; and (e) a bundle of tubes of different cross sections with solute exchange between tubes.

Table 1 Scaling with time (T) of solute mass mean and standard deviation according to four transport models

Model	*Mean*	*Standard deviation*	*Standard deviation/mean*
ADE	T	$T^{1/2}$	$T^{-1/2}$
MIM	T	$T^{1/2}$	$T^{-1/2}$
CLT	T	T	Constant
CTRW ($0 < \beta < 1$)	T^{β}	T^{β}	Constant
CTRW ($1 < \beta < 2$)	T	$T^{(3-\beta)/2}$	$T^{(1-\beta)/2}$

ADE, advection–dispersion equation; MIM, mobile–immobile model; CLT, convective lognormal transfer function model; CTRW, continuous-time random walk model.

function to generate a near-Gaussian distribution with 'fat tails.' This approach, being more general, usually results in a better fit than the original ADE. However, it is somewhat more complex mathematically and only accounts for a subset of cases that are not well fit by the ADE. Interestingly, the ADE is unable to account correctly for dispersion resulting from flow through layered soils, conceptually equivalent to different tubes in series, as shown in Figure 4b: it predicts identical results regardless of which soil comes first, while experimentally the order of the layers affects the final value of the dispersion coefficient.

A second common conceptual model is the so-called streamtube model or transfer function model, in which solute transport is considered to take place through multiple parallel but noninteracting streamlines (Figure 4c). Because mean solute velocity within a tube is proportional to tube radius squared, dispersion results from the differences in velocity among the various streamtubes. Because in principle it is possible to reproduce any possible breakthrough curve by generating the correct streamtube distribution, this method is very flexible. This model is essentially a multiple-tube equivalent of the dispersion that would result from flow in a tube in the absence of diffusion, and so, because their dispersion results from insufficient mixing, streamtube models may be considered to be preasymptotic. Streamtube models are most applicable to media in which flow really does take place through parallel but noninteracting pathways, such as horizontal flow through an aquifer with homogeneous layers of contrasting properties. Some variants of this model allow dispersion within each streamtube, while others assume no local dispersion (i.e., piston flow). One common version, Jury's convective lognormal transfer function model (CLT), specifies the distribution of the solute travel times (or, by analogy, the tube radii) and thus the form of the final BTC.

Knowing the dispersion at one scale only allows correct prediction at a different scale if the chosen model scales the same way as the observations. For example, while the ADE predicts that solute-spreading scales with the square root of time, the CLT (a specific streamtube model) predicts solute-spreading that scales linearly with time (Table 1). Solute movement that is consistent with a streamtube-like mechanism will therefore appear to scale if analyzed using the ADE; likewise, solute transport that is well described by the ADE will scale incorrectly if analyzed using the CLT.

The streamtube models assume zero interaction between streamlines, in contrast to the ADE, which assumes that streamlines do interact. These two models therefore represent extremes along a continuum of streamline interaction. In principle, the streamtube model should better represent early or preasymptotic times, before streamlines have had time to intermix adequately, and the ADE later times. Because in the streamtube model dispersion scales linearly with time (Table 1), invoking a streamtube model at short (preasymptotic) times and the ADE at later times provides a plausible explanation for some scaling behavior: one can argue that the observations took place within the transition between the two models. By this reasoning, the time or distance needed to mix – to make the transition from

streamtube-like dispersion to ADE-like dispersion – should provide an estimate of the soil's REV with respect to dispersion, and so some indication of the characteristic length of the soil's structure.

A third model in common use is the mobile–immobile (MIM) model, also known as the two-region model. Originally developed to explain dispersion in terms of dead-end pores, this model has been widely adopted to describe dispersion in structured soils. The idea is that the soil is composed of mobile regions (such as interaggregate pores) through which most or all of the flow actually moves, closely interconnected with immobile regions (e.g., the interior of aggregates) that exchange mass with mobile regions by diffusion only (Figure 4d). The parameters of the model are therefore the dispersion in the mobile region (identical to the dispersion term in the ADE), the mass exchange coefficient, describing diffusive exchange between the mobile and immobile regions, and the mobile pore fraction. The model can equivalently be thought of as describing chemical sorption to soil particles that comes in two varieties, instantaneous and slow, but, in keeping with the focus here on nonreactive solutes, this view will be ignored. Because diffusive exchange between regions is generally slow relative to advection, a given layer of soil is generally out of equilibrium with the solute flowing through it for some time, so this model is often said to describe nonequilibrium flow. When the immobile region has zero volume, or when the diffusive exchange is instantaneous, the MIM reduces to the ADE; this extreme can be though of as describing a soil of low heterogeneity. As might be expected from its close ties with the ADE, the MIM predicts identical scaling behaviors (Table 1). On a practical level, the MIM often suffers from nonunique solutions; that is, a given BTC may be equally well fit by more than one single set of parameters. This nonuniqueness implies that the equation has too many fitting parameters (three for the MIM versus one for the basic ADE), and casts some doubt on the physical interpretation of those parameters.

Observations and Mechanisms

There is a strong tendency for dispersivity to be greater at larger scales, as documented (for example) in several metastudies, each examining many different field studies of solute transport. Unfortunately, the scatter in the data is great enough that no universal scaling behavior can unambiguously be inferred. While the cause of this trend is not clear, the most common explanation is that, as a solute travels farther, it encounters increasing scales of heterogeneity. This means that at larger scales solute molecules will on average sample a larger range of velocities than they did at a smaller scale. The travel time for each molecule is the sum of many different times at many different velocities; increasing the range of velocities will therefore (assuming random and independent sampling by each molecule) result in a wider distribution of travel times and thereby a larger dispersivity. A fractal medium, with its ever-increasing scale of heterogeneity, results mathematically in dispersivity increasing with distance, i.e., scaling.

But increasing scales of heterogeneity are apparently not necessary for scaling to occur. For example, one laboratory experiment used a two-dimensional flow cell packed with two sands: 16% of the volume consisted of blocks of fine sand randomly placed within a coarse sand matrix, with the hydraulic conductivities differing by a factor of 20. Within approximately 1 m, the fit dispersivity increased from 0.073 to 0.127 m. The skew of the data was fairly constant, suggesting that a change from preasymptotic to asymptotic behavior was not occurring. Similarly, the Borden aquifer tests saw dispersivity increase by a factor of 8 over a distance of some 10 m in what was considered a homogeneous sand. And of course dispersion that occurs primarily through a streamtube-like mechanism, wherein regions that differ in velocity are isolated from each other, will also show scaling of ADE-calculated dispersivity.

Discussion of the 'scale of heterogeneity' also raises the question of the importance of heterogeneity at smaller scales. If much of dispersion is driven by heterogeneity, and that heterogeneity exists at all scales, then presumably the nature of the heterogeneity below the scale of heterogeneity is also important. But because both models and measurements are blind to processes below their respective nonzero-size scales, there are always smaller-scale processes that they cannot take into account, but which still influence the large-scale outcome. An exclusive focus on the largest-scale heterogeneities implicitly assumes that the smaller-scale heterogeneities are either negligible or diffusive in nature, but neither is necessarily the case. The smaller-scale influences can be significant and nondiffusive; for example, the presence of undetected cracks in a soil profile may lead to arrival of solute at the water table well in advance of prediction.

Soils and other geologic porous media are neither purely random nor purely structured; instead they vary in their degree of randomness across most or all scales. But while understanding of soil properties has historically concentrated on the measurements themselves, and only relatively recently on the spatial structure of the properties, generally the topological structure is still ignored. As a consequence,

researchers in the theory of contaminant transport have long considered (for example) what proportion of an aquifer is sand or clay, and even how thick the average sand layer might be, but not the question of whether there is a continuous sand pathway through the system. Continuity and interconnectedness are critical to diffusive and advective exchange across streamlines, and to the range of velocities encountered within a given streamline. They therefore make the difference between the ADE and streamtube models, and so are critical determinants of the scaling behavior of a given soil or aquifer.

In most situations, solute transport in soils or other geologic porous media is subject to all of the mechanisms mentioned so far: diffusive exchange between neighboring streamlines, parallel pathways with little exchange between them, and diffusive exchange between more and less mobile regions of the medium. There are also other important dispersive processes, such as advective (and even turbulent) exchange between streamlines, streamline-specific sorption based upon mineralogy, biodegradation based upon differences in microhabitat, and streamlines with nonconstant velocity, that do not show up in these models. Certainly the extent to which each mechanism contributes to dispersion is difficult to determine in advance, nor can one know in advance whether the length scale at which dispersion is to be predicted is greater than or less than the scale of heterogeneity (if any) of the medium.

Model Selection

An investigator attempting to predict future dispersion from current conditions is faced with the choice of three conceptual models, each based upon quite different mechanisms and assumptions. Prediction therefore involves two tasks: selecting the appropriate model, and fitting it to the data in order to make a prediction. The wrong model choice may result in scaling, such that the predicted behavior may be severely rather than merely slightly wrong. But in fact the choice of models is still quite narrow, in the sense that only two scaling behaviors are available (Table 1), even though intermediate behaviors are commonly observed.

An alternative is to use a new model, originally developed to describe electrical conductivity of amorphous silicon. The continuous-time random walk model (CTRW) has been used to describe solute transport only since the mid-1990s, but it has been shown to be capable of capturing the entire range of behavior seen in the three models discussed above. Each of the three models is a special case of the CTRW, indicating that the CTRW is a generalized transport model that can handle both the extremes and the intermediate cases.

The CTRW conceives of the soil as having a variety of pathways of higher and lower conductivity. What determines the dispersion is not only the range of velocities represented by these pathways, but also the probability with which a solute molecule will transition from one pathway to another (Figure 4e); such transitions can take place both through diffusion and through advective pathways merging and separating. Transition probabilities are given by a joint probability distribution function $\psi(s,t)$, which describes the probability of a particle moving a distance and direction s within time t. The long-time behavior is dominated by transitions at long (asymptotic) times, and asymptotic forms of probability functions tend to decrease monotonically. (In the context of the CTRW, asymptotic behavior is always reached quickly.) The distribution can then be characterized by exponential decay, which leads to ADE-like behavior, and power-law decay in which $\psi(s,t) \sim t^{-1-\beta}$ for $0 < \beta < 2$. Power-law decay yields anomalous transport except for $\beta > 2$. The value of the exponent β controls the rate of decay, and thereby the scaling of the solute mean and standard deviation (Table 1).

A wider range of scaling behaviors is attained with the CTRW than with the original three models combined. Significantly, because the choice of β changes both the shape of the BTC and its temporal scaling, the CTRW implicitly considers temporal scaling to be an inherent aspect of dispersion, rather than a separate phenomenon. This raises the possibility that in the future the concept of scaling as a distinct issue will cease to exist, being replaced by an understanding that dispersion has inherent scale-related behaviors.

SEPTIC SYSTEMS

Introduction

Since the advent of societal living, humankind has relied on the soil environment to treat a wide variety of its wastewater residues. The use of soil-based treatment systems continues to be a common practice in essentially all countries of the modern world. For centuries people have relied on the capacity of soil to purify waters contaminated from solid-waste disposal facilities, plague-infested communities, municipal sewage collection systems, industry, agriculture, cemeteries, and more commonly small residential, institutional, and commercial wastewater-producing facilities. Given adequate retention or treatment time, and sufficient spacing from surface and groundwater resources, many soils can effectively degrade organics through microbial processes; adsorb, precipitate, or complex most metals; and subsequently release an effluent that is near potable quality. In many parts of the world, soil-based wastewater-treatment systems function in close proximity to public or private drinking-water supplies, with little or no adverse effect on potability. In densely populated areas, however, where appropriate separation and treatment distance are not provided for soil-based treatment systems, potable water contamination from bacteria, viruses, nutrients, metals, and other contaminants has occurred.

Unfortunately, the generally small size of on-site wastewater-treatment systems ('septic systems') has created a global policy where most of them are built without regulations, technical guidelines, or protocols for maintaining and operating them. In highly regulated areas, more stringent controls may exist, but even where septic-system regulations do occur, their requirements are seldom founded on the principles of sound soil science or soil physics. In the USA, municipalities often use septic-system regulations to control development, and all too often the regulations become counterproductive in protecting the environment and public health. A classic example of this paradox is the encouragement of septic systems in highly permeable soils where groundwater and surface-water resources can quickly become polluted.

Technical and Historical Overview

The most common septic systems in use worldwide include outhouses and cesspools. In spite of their simple nature, they are often effective in treating human wastewater and protecting groundwater and surface-water resources. During the 1960s, the Commonwealth of Massachusetts embarked on a region-wide program to install cesspools in populated areas surrounding its Boston water supply known as Quabbin Reservoir. The program was largely successful, and the reservoir continues to provide surface water supplies in the Northeast part of the USA.

Outhouse – Structure and Function

In structure, outhouses are little more than a hole in the ground, usually 1–2 m deep. A wooden structure or 'house' is erected above the hole, with one or more seats. Liquid wastes percolate into surrounding soils, while insect larvae and bacteria degrade the solid component. In time, the hole fills from regular use. The outhouse is then relocated above a new excavation and the process repeats itself. In warm weather, hydrated lime can be added to the waste to reduce odors.

Cesspool – Structure and Function

The advent of indoor plumbing has added relatively large volumes of water to daily domestic wastewater production rates. For much of the world today, showers, flush toilets, laundry, and dishwashing needs result in a per capita production rate of approximately 200 l day^{-1} of wastewater. To accommodate these increased volumes, outhouse holes in the ground have been increased in depth and diameter. Many of these excavations are lined with stone or cribbed with timbers. Properly constructed, the common cesspool can provide decades of service with little or no maintenance needs other than periodic removal of the solids. A secure cover over the top of concrete or wood is required for safety reasons.

The Modern Septic System

For more technically oriented households, the use of strong soaps, bleaches, and cleaning products quickly reduces the ability of fecal bacteria to degrade the solids associated with the wastestream. Cesspools accumulate solids more quickly, minimizing the solid–water interface's ability to effectively conduct water out of the unit. For this reason a separate solids containment unit has evolved that is commonly called a septic tank.

Septic Tank

With mean hydraulic retention times of a day or more, approximately 65% of the solid matter can be removed by simple settling in a septic tank. A baffle or 'T' at the inlet end helps reduce short-circuiting of incoming surges, and a similar structure at the outlet end prevents floating grease and oils from leaving the unit. Although some biological degradation does occur anaerobically, the modern septic tank usually requires cleaning every 2–5 years. Concrete, metal, fiberglass, and other synthetics are commonly used to build septic tanks, but wood structures are also fairly common. The tanks are normally watertight and buried 30–60 cm belowground to facilitate the gravity flow of wastewater from the dwelling. A gas vent from the building sewer is typically hidden in the outside wall of the dwelling, where it normally exits at the roof eve. Anaerobic gases from the septic tank migrate upwards through the building sewer and out the roof vent. During periods of thermal inversion, vent-stack gasses can sink to ground level, giving false signs of septic system failure by way of odor.

Soil Absorption Systems

Once the liquid component of wastewater exits in a septic tank, it must be disposed of in some acceptable manner that is safe for the environment and public health. Soil absorption systems (SASs) satisfy this need in a very effective manner. A SAS can be built in a variety of shapes and configurations, but all SASs are generally designed to do the following:

1. Provide sufficient surface area to permit 100% water exfiltration for many years following the development of a typical soil interface 'scum layer';
2. Provide sufficient separation distance to insure that the wastewater does not enter the groundwater before treatment;
3. Provide sufficient retention time to insure adequate treatment of the liquid component in the SAS, the scum layer (usually 10 cm); and in the underlying unsaturated soils.

Typically a SAS is built in a shallow excavation 50–100 cm deep made in naturally occurring soils. Perforated 10-cm pipes are used to distribute liquid throughout the excavation. The pipes (usually plastic, concrete, or ceramic) are surrounded by clean coarse stone to further enhance the distribution process. A layer of fine stone, synthetic fabric, asphalt, paper, or hay covers the stone bed to prevent infiltration of natural soils that are replaced above. Grass is usually planted over a SAS so that the unit blends in naturally with the surrounding landscape.

From time to time an SAS must be elevated aboveground infill to provide adequate separation distance either to bedrock or the groundwater table. These aboveground units often require that a pump be used to lift wastewater from a 'pump tank' that follows the septic tank. Typical SAS configurations are often referred to as 'beds,' 'trenches,' 'galleries.' Gallery units are often prefabricated using plastic, concrete, or other structurally sound materials. They can also be built using concrete blocks, wood cribbing, or stone. In each case, the SAS is built on a level base to promote the uniform distribution of wastewater over the entire base area. When deeper SAS units can be constructed (i.e., greater than 50 cm), the sidewall area may be utilized to provide part of the required absorption surface area.

SAS Size and Soil Infiltration Rates

Although heuristic methods are often used to size SAS units, it is more common to employ some type of soil-testing to evaluate infiltration rates. These methodologies include: percolation-testing, *in situ* infiltrometer methodologies to determine coefficients of permeability (meters per day), or laboratory hydraulic-conductivity measurements using permeameters. Where testing is required, regulations typically prescribe a loading rate (volume per area) for SAS

units, as well as design-flow rates based on the number of dwelling bedrooms, bathrooms, or inhabitants. Flow-rate estimates are also available for categories of use (e.g., schools, cafeterias, hotels, restaurants).

Percolation testing is an *in situ* procedure requiring that a hole of specific diameter and depth (e.g., $30\,\text{cm} \times 45\,\text{cm}$) be hand dug into the soil strata being considered for a SAS. Once filled with clean water, the rate of water percolating is measured and reported as centimeters per minute or some arbitrary unit of depth versus time. Usually the slower the percolation rate, the greater the area required for loading, thereby increasing the total surface area needed for a SAS unit being designed for a given design-flow rate. In fine soils (silts, fine sands, and clays), a three-bedroom residential structure may require a SAS area several hundred square meters. In coarse-textured soils (sands and loamy sands), the required area for the same dwelling may be as little as $50\,\text{m}^2$. Regardless of the methodologies used, the objectives are to (1) contain 100% of the liquid fraction even during periods of peak loading; (2) provide adequate treatment time to reach acceptable infiltration concentration; and (3) provide appropriate separation distances to protect groundwater and surface-water resources.

Advanced Treatment Systems

Because septic systems have proliferated in some areas in a relatively uncontrolled manner, groundwater and surface water problems have evolved. Usually these problems take the form of nitrate (NO_3^{-2}) contamination in groundwater, or nutrient addition to surface waters that accelerate eutrophication processes. In some instances bacterial and viral contamination has also occurred in wells and surface-water resources. When these situations occur there are usually two paths of action considered. One is to sewer the area to provide municipal treatment. The other is to upgrade SAS units to provide appropriate levels of advanced treatment (e.g., disinfection, nitrate removal, nutrient removal). In the latter half of the twentieth century, many innovative alternative technologies have been developed. Unfortunately, most of these units require some degree of operation and maintenance that individual homeowners may not be able to provide. There has also been increased interest in decentralized sewerage systems where small community systems can be constructed.

Artificial Wetlands

A new variety of SAS incorporates the treatment processes known to be occurring in natural wetlands. These artificial or manmade wetlands can be constructed with or without liners, depending on soil texture and groundwater-protection needs. Top-loading, vertical flow, submerged bed systems are constructed to provide a park-like environment, while simultaneously producing a near drinking-water effluent. Generally these operate with no chemicals, no moving parts, and little or no energy needs other than the sun and gravity. Wetland plants growing in a coarse-textured medium provide oxygen to soil bacteria that in turn function as a biofilm of microbes metabolizing both organic and inorganic wastewater components. A dense stand of grasses and reeds is generally grown in these systems.

Summary

In the USA alone, it has been estimated that approximately 25% of all wastewater produced is treated with on-site septic systems. As rural lands continue to develop, the demand for individual treatment systems will surely rise. Considerable data emerging to show that conventional wastewater-treatment technology is not very environmentally friendly, nor is it always safe for public health.

Large quantities of fossil fuels are consumed each year, providing the energy needs that conventional technology demands. Disinfection processes using chlorine introduce carcinogens into surface waters. Conventional systems seldom are designed to remove nutrients, so that nitrogen, phosphorus, and potassium compounds are being directly discharged into lakes, rivers, and oceans. As these aging wastewater-treatment facilities become more costly to maintain, alternative technologies are likely to play a leading role in the industry. This is especially true for industrially emerging countries in Southeast Asia, Central and South America, and Africa. Properly designed, built, and operated, the conventional septic systems can help to meet the environmental and public health needs in many regions.

Introduction

Soil, the three-dimensional upper layer of the Earth's crust that directly or indirectly supports all terrestrial life, is a nonrenewable resource over the human time scale. Further, soil resources of the world are finite, unequally distributed among geographical regions, and prone to severe degradation by misuse and mismanagement. Consequently, soil resources are shrinking with continuous increase in human population, due to degradation and conversion to nonagricultural uses, including urban encroachment. Therefore, judicious management of soil is critical to global food security, the health and welfare of humans and animals dependent upon it, the overall economy, and regional social and political stability.

Soil management implies strategic planning of all inputs into and outputs from the soil ecosystem so that there is a favorable balance of essential components that constitute the basis of soil's life-support system. These components comprise the soil organic matter (SOM) pool, reserves of essential plant nutrients (e.g., N, P, K, Ca, Mg, Zn, Cu, Mo, etc.), water balance and plant-available water capacity (AWC), and effective rooting depth. It is the imbalance caused by drastic differences between outputs and inputs of one or more of these components that sets in motion soil degradative processes. For example, depletion of SOM or biological degradation is caused when removal of crop residue and agronomic output exceeds the input of compost and other biosolids. Soil fertility declines and nutrient depletion occurs when nutrients harvested in plant and animal produce exceed nutrients supplied as chemical fertilizers or organic amendments. Depletion of bases (e.g., Ca, Mg, K) from soil can lead to acidification and elemental imbalance, resulting in excess of Al, Mn, and Fe. Waterlogging and soil salinization are caused by excessive use of irrigation water without provisions for drainage. The problem is aggravated if irrigation water is of poor quality and the subsoil contains a high concentration of water-soluble salts, as is generally the case in soils of arid and semiarid regions. Exposure of a structurally fragile soil to climatic elements (e.g., intense rains, flowing water, and blowing wind) can lead to removal of topsoil, its transport into streams and reservoirs, truncation of the rooting depth, and decline in the soil's productivity and environment moderation capacity.

It is this imbalance in outputs and inputs, due to soil misuse and mismanagement, that causes soil degradation (Figure 1). The latter is defined as a decline in the soil's capacity to perform functions of interest to humans. These functions include biomass productivity; filtering pollutants out of water; biodegradation of contaminants and pathogens; and cycling/storage

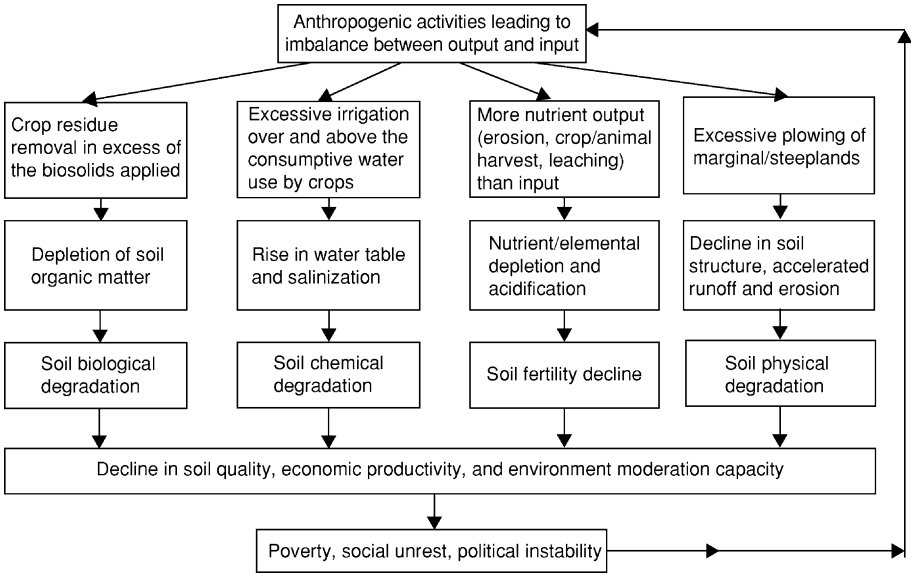

Figure 1 Soil degradation caused by imbalance between outputs and inputs.

of carbon (C), nitrogen (N), and other elements. Degradation severely jeopardizes the soil's capacity to perform these functions.

Soil degradation has been a challenge to humanity since the dawn of agriculture some 10 000 years ago. Severe soil degradation caused some of the once-thriving ancient civilizations to vanish. Indeed, it was the severe erosion caused by deforestation of cedar forests in the Mediterranean Basin that toppled the Phoenicians and destroyed granaries of the Roman Empire. The fertile land of Mesopotamia, present-day Iraq, was converted to desert and shifting sand dunes by deforestation, severe erosion of the hills and watersheds that nurtured the ancient irrigation system, and salinization of agricultural lands. The extinction of the Harappan-Kalibangan civilization in the pre-Aryan Indus Valley has been attributed to erosion-caused desert encroachment and salinization. The collapse of the 1700-year-old Mayan culture in Central America about AD 900 was caused by severe erosion of a thin topsoil by excessive cultivation necessary to support a rapid increase in population. In most cases, soil degradation was caused by the 'tragedy of the commons,' which could have been avoided by rational management and conservation of soil and natural resources.

Therefore, 'conservation' of soil resources is vital to the survival of the human race. The term 'soil conservation' means 'a judicious use of soil so that its productivity and environment moderation capacity are perpetually maintained.' Soil conservation also means 'rehabilitation of degraded soils for restoring their productivity and environment moderation capacity.' In view of the high demographic pressure and conflicting demands on shrinking soil resources, soil management and conservation are more important now than ever before. In fact, the importance of soil management and conservation can never be overemphasized.

Shifting Cultivation

Soil management and conservation have a special significance to regions where shifting, cultivation is practiced. The term 'shifting cultivation' refers to farming or agricultural systems in which a short but variable cultivation phase on 'slash-and-burn' cleared land alternates with a long, equally variable fallow period. Shifting cultivation is the most ancient system of agriculture in which soil fertility is restored by long periods of fallowing rather than by off-farm inputs of fertilizers and amendments, nutrients are recycled between natural vegetation and crops, and ecological balance is maintained by adopting diverse and complex cropping systems rather than monoculture. Shifting cultivation is still being practiced in some parts of the tropics and subtropics, especially in the humid tropics of west and central Africa, Southeast Asia and South/Central America. It is an extensive system of agriculture, with a wide range of variation depending on soil type, vegetation, terrain, climate, and social/ethnic factors. The system is stable where the ratios of the fallow period to cultivation phases are up to 10 or more. The system breaks down, causing severe soil degradation and decline in productivity, when the fallow period is drastically reduced. An important reason for the reduction in fallow period is an increase in the demographic pressure, and an attendant decrease in available soil resources.

Shifting cultivation systems have the following characteristics:

1. They are highly diverse and complex, involving simultaneous growing of 10 or more crops in combination with trees and livestock. Mixed cropping is the general rule.
2. Shifting cultivation systems are labor-intensive with minimal use of purchased off-farm inputs. Restoration/management of soil fertility is based on nutrient cycling through lengthy fallow, biological nitrogen fixation (BNF), and choice of compatible species.
3. Shifting cultivators are generally small-size landholders with a normal size of <2 ha. Therefore, farm operations are performed by the farm family.

There are several attempts to classify shifting cultivation systems. A farming system is designated nomadic herding if the value of the land-use factor, $L \geq 10$; bush fallow or land rotation for L between 5 and 10; rudimentary or sedentary agriculture for L between 2 and 4; compound farming terrace farming or paddy rice cultivation for $L < 2$. Most classification systems are based on 'intensity' or 'frequency' of cultivation. The various categories designate different degrees of intensification as evaluated on the basis:

$$L = (C + F)/F \qquad [1]$$

where C is the number of years of cultivation and F is the number of years fallow. Traditional systems are also classified on the basis of the degree of intensification:

Phase I: Hunting and gathering
Phase II: Subsistence agriculture
Phase III: Early consumer stage
Phase IV: Primary mechanization stage

The true shifting cultivation or the hunting and gathering stage ($L = \geq 10$) is no longer widespread in any region. Yet, subsistence agriculture including

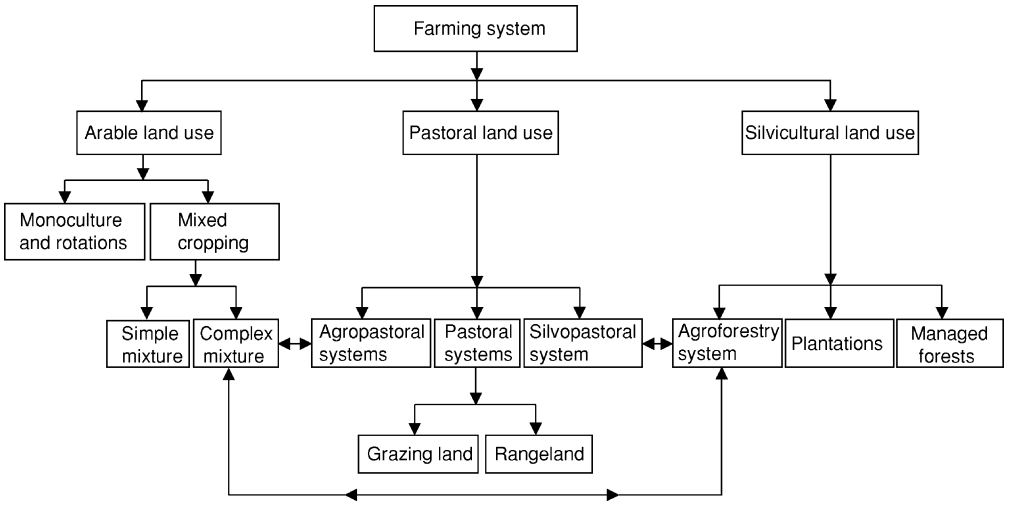

Figure 2 Permanent farming system.

bush fallow rotation ($L = 5$–10) is practiced in some regions of Africa, Asia and South/Central America. Subsistence farmers grow a variety of crops (mixed cropping) in association with selected tree species and animals, and as much as 90% of the produce is consumed on the farm. A majority of the shifting cultivators in the tropics practice rudimentary sedentary agriculture at the early consumer stage ($L = 2$–4). These farmers market less than 50% of their produce, and practice mixed farming. Farmers may also use some machinery and low rates of fertilizers. A predominant type of mechanization use by phase-III farmers involves tractor-based tillage.

In contrast to shifting cultivation, farming systems involving permanent agriculture are outlined in Figure 2. These systems are based on three principal land uses and appropriate two-way or three-way combinations. For example, agropastoral systems are based on a combination of crops and livestock, and agrosilvopastoral systems are based on a combination of crops, livestock, and trees.

Productivity of Complex Farming Systems

Because a large number of crops are grown simultaneously on the same piece of land, and often harvested at different times, it is a challenging task to assess the productivity of such complex systems. Some of the indicators commonly used to assess productivity include the following:

1. Productivity: Productivity can be assessed as biomass (agronomic) yield or income. It can be expressed either as a simple productivity or total factor productivity (TFP):

$$P = p/R \quad [2]$$

$$\text{TFP} = p/\sum_{i=1}^{n}(R_i \times C_i) \quad [3]$$

where P is productivity, p is total production, R is the resource consumed/used, and C is the cost of the resource. Being truly resource-based, it may be difficult to assess the true cost of all resources used for phases I and II of shifting cultivation systems. Therefore, the following indices are used to assess productivity.

2. Land equivalent ratio: Productivity of mixed cropping systems is assessed by computing the land equivalent ratio (LER):

$$\text{LER} = \sum_{i=1}^{n} y_i/(y_m) \quad [4]$$

where y_i and y_m are yields of component crops in the intercrop and monoculture system, respectively, and n is the number of crops involved.

3. Area × time equivalency ratio (ATER): In shifting cultivation systems (phases II and III), there is a wide range and a large number of crop/tree species involved. These species vary widely in their maturity period. The ATER index assesses productivity while considering the crop duration:

$$\text{ATER} = 1/t\left(\sum_{i=1}^{n}(d.y_i)/y_m\right) \quad [5]$$

where d is the growth period of crop in days and t is the total time in days for which the field remained occupied, i.e., the growth period of the longest-duration crop. The numerical value of ATER index

approaches that of LER for a mixture consisting of crops of approximately identical growth periods, i.e., when $t = d$ in eqn [5].

4. Resource-use efficiency: When some off-farm inputs are used (phase IV), the productivity can also be assessed in terms of the resource-use efficiency. This is a relevant option in case of a system with the most limited resource such as P, N, water, soil organic carbon (SOC), or energy use.

5. Carbon dynamics: In view of the rapid increase in atmospheric concentration of CO_2 and other greenhouse gases, assessing C dynamics is an important indicator of the productivity.

$$P = \left(C_o / (\sum_{i=1}^{n} C_i) \right)_t \qquad [6]$$

where P is productivity, C_o is carbon produced in above- and belowground biomass, C_i is carbon input in all components including fertilizers and pesticides etc., and t is time. The higher the ratio, the more sustainable is the system.

Ecosystem-Related Constraints to Agricultural Intensification

Shifting cultivation systems are ecologically viable as long as there is enough land for long (10–20 years) restorative fallow, and expectations of crop yield and the attendant standards of living are not too high. These systems are naturally suited for harsh environments and fragile ecosystems of the tropics. That is why attempts at finding viable alternatives to shifting cultivation have met with only limited success. There are several soil-related and climate-related constraints (Table 1) that must be alleviated. These constraints lead to severe problems of soil degradation upon conversion from shifting cultivation to mechanized intensive agriculture. Consequently, many large-scale mechanized farming schemes introduced in the humid tropics have been a failure.

Table 1 Ecological constraints to finding viable alternatives to shifting cultivation

Soil-related constraints	*Climate-related constraints*
1. Low inherent soil fertility	1. Low level of radiation during the growing season
2. High susceptibility to soil erosion	2. High relative humidity
3. Severe soil physical degradation	3. High storage losses
4. Nutrient/elemental imbalance	4. Problems with grain drying
	5. High incidence of pests and disease
	6. High-intensity rains

The severe problem of soil degradation is caused by indiscriminate and intensive land use based on monoculture regardless of soil capability, introduction of pastures with high stocking rate and uncontrolled grazing, or intensive cropping without input of chemical fertilizers or compost at the required rates. The problem of soil degradation is exacerbated by harsh climate characterized by intense rains of high erosivity and structurally weak soils.

Sustainable Management of Soils Under Shifting Cultivation

Any viable alternative to shifting cultivation system must successfully:

1. maintain soil structure at a favorable level so that risks of soil physical degradation (e.g., crusting, compaction, low infiltration) are minimized;
2. control excessive runoff and accelerated soil erosion so that effective rooting depth is maintained and the nutrient-rich topsoil is not eroded away;
3. strengthen nutrient-recycling mechanisms so that nutrients are not lost out of the ecosystem, and are effectively recycled through incorporation of woody perennials and legumes in the rotation cycle, and judicious use of chemical fertilizers and organic amendments;
4. manage pests through enhancing biodiversity and using a healthy balance between predators and parasites through strategies of integrated pest management; and
5. increase farm income through value-added products and off-farm employment.

While traditional shifting cultivation systems meet these requirements through low cropping intensity and lengthy fallows, new systems have to be identified that produce high yields per unit area of land and per unit time. Sustainable soil management technologies must address specific ecological constraints such as those outlined in Table 1. Any viable alternative must address the synchrony between food security and environment quality without jeopardizing the soil/natural resources, which are already under great stress. Therefore, sustainable soil management systems must:

1. assure food security for a high and increasing population;
2. enhance soil productivity through ecosystem restoration and judicious use of off-farm input;

3. improve environment quality, especially that of water and air, and reduce emissions of greenhouse gases into the atmosphere; and
4. transform subsistence farming into commercially viable agriculture.

Characteristics of an Improved/ Sustainable Soil Management System

Important characteristics of an improved/sustainable soil management system are outlined in Figure 3. The new system must have high energy flux in terms of drastic increases in crop yield brought about by discriminant or judicious use of off-farm input. The objective is to increase nutrient input into the system through integrated nutrient management (INM). The latter involves elemental recycling (e.g., use of crop residue, BNF, use of compost and city sludge, etc.), supplemented by a judicious use of chemical fertilizers. The objective is to increase energy efficiency and flux, because a low-output system can be highly efficient but unproductive, just as a high-output system can be extremely inefficient. Therefore, the goal is to develop a high-output and highly efficient production system. The efficiency can be increased by decreasing the losses. To be sustainable, the system must of necessity be soil-restorative. Most soils under shifting cultivation are being depleted and degraded because of nutrient mining over a long period of time. Some components of an improved system comprise the following:

1. New land development: The emphasis should be toward intensification of existing land so that there is no need for additional deforestation and conversion of a natural to an agricultural ecosystem. If deforestation is absolutely necessary, it must be done in a way to cause as little perturbation in the ecosystem as possible, especially with regards to the following:
   a. water and energy budgets, which are disturbed by deforestation, causing an increase in surface soil temperatures and acceleration of surface runoff with the attendant problem of severe erosion. Thus the objective is to cause a minimal disturbance to the hydrological cycle, especially the surface runoff component, which must be kept under control.
   b. maintenance of soil structure, which is crucial to ensuring a high water infiltration rate, minimizing risks of crusting and compaction, and decreasing risks of accelerated soil erosion. Application of crop-residue mulch and establishment of cover crops are necessary to enhance activity of soil biota and improve soil structure.
   c. increasing plant nutrient reserves, which is important to obtaining high crop yields. This can be achieved by replacing nutrients harvested in crops and those lost by erosion and leaching through use of INM strategies.

Therefore, removal of existing vegetation can be done either manually or by those machines that cause least disturbance to the surface soil (e.g., those with shear blade). Land-use capability assessment and proper planning are essential to any successful development of new land.

2. Intensive use of existing lands: Because of the shortage of potentially suitable new land and the undesirability of converting forest/savanna ecosystems into croplands, an increase in production in several countries must be achieved by more intensive cultivation of land already developed. It is equally important to restore productivity of degraded soils. Therefore intensification of existing arable land is a high priority.

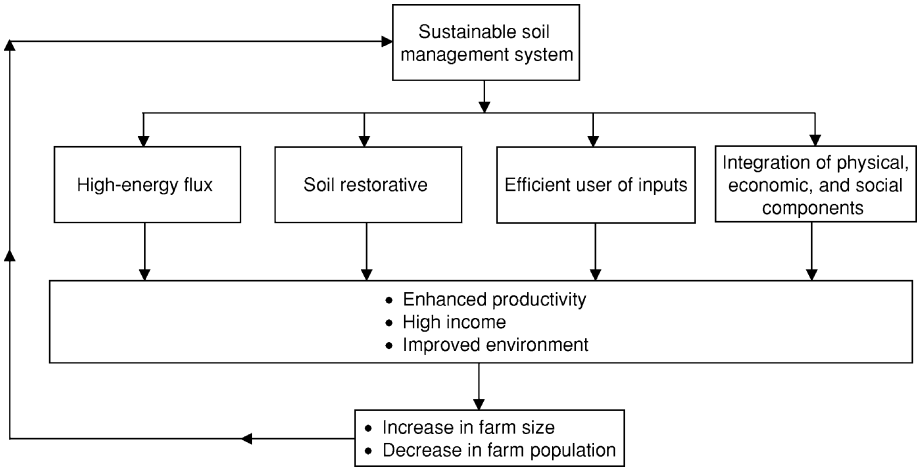

Figure 3 Characteristics of a viable alternative to shifting cultivation systems.

Examples of Sustainable Soil Management Systems

Farming systems, the right combination of several components and subsystems, are soil- and site-specific. Therefore, it is difficult to provide examples of generic farming systems that may be applicable to diverse soils and environments. A logical approach is to identify integral components that can be combined into site-specific farming systems to meet the site-specific needs. Some examples of improved components and subsystems to address specific issues include the following:

1. Erosion management: Conservation-effective techniques for reducing soil-erosion risks involve the following strategies:
   a. using crop residue mulch to minimize the raindrop impact;
   b. improving soil structure through bioturbation for reducing surface crust and soil compaction, and maintaining high infiltration rate;
   c. installing terraces for decreasing the slope length; and
   d. constructing grassed waterways to dispose of excess runoff safely.

Principal techniques of erosion management are outlined in Figure 4. Preventive measures are based on the principles of soil management that reduce the impact of high rainfall erosivity by reducing the raindrop impact and maintaining a high infiltration rate. These measures include mulch farming techniques involving conservation tillage, using cover crops in the rotation cycle, and providing a continuous ground cover through diverse (mixed) cropping systems. Two principal constraints to a widespread adoption of conservation tillage are high cost of herbicides for weed control and lack of appropriate seeding equipment to plant through wet crop-residue mulch. Soil compaction is another impediment to adopting conservation tillage in structurally inert soils of low organic matter content.

Erosion control measures are designed to reduce runoff amount and its velocity by using engineering structures that lead to safe disposal of excess runoff. These structures are grouped under two broad categories: structures to reduce runon (e.g., diversion channels, cut-off drains), and structures to dispose of runoff safely (e.g., terraces, waterways, drop structures). Cultivation of sloping lands (slope gradient > 5%) requires using a combination of erosion preventive and control measures, especially in situations where erosion cannot be effectively controlled by preventive measures alone. In such situations, engineering structures are needed as back-up measures. However, design and installation of these structures require engineering skills and proper planning. Further, such structures are costly to install and maintain. It is also important to realize that failure of engineering structures can lead to deep gullies, mass movement, and often irreversible damage to soil and terrain.

2. Nutrient management: Once soil erosion is controlled and the risks of drought are reduced by water conservation, management of plant nutrients or soil fertility is essential to obtaining high yields. Most soils under shifting cultivation have low inherent soil fertility, and nutrient supply from off-farm sources is essential. The goal is to use an INM strategy (Figure 5), not by reducing external inputs but by minimizing the use of chemical fertilizers through

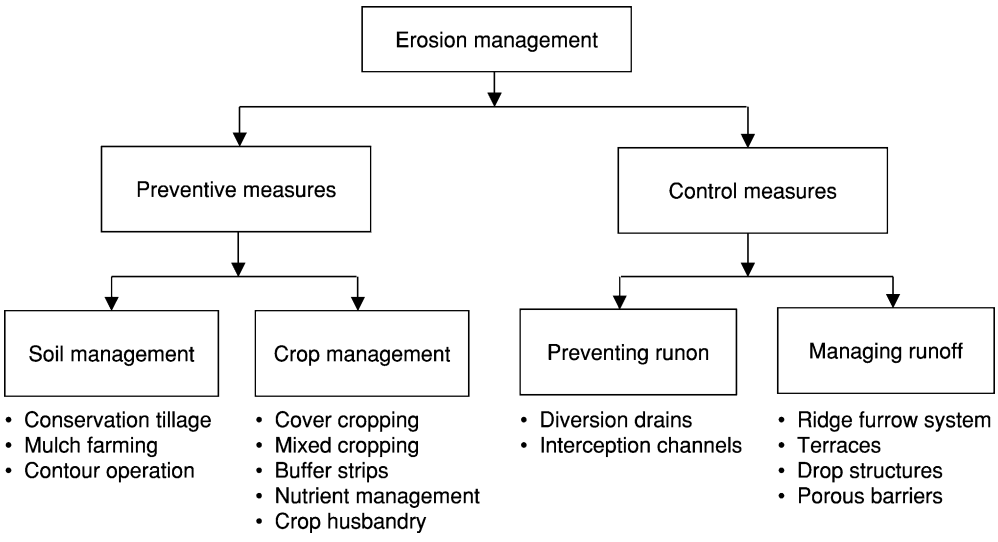

Figure 4 Soil, crop, and runoff management techniques for erosion control.

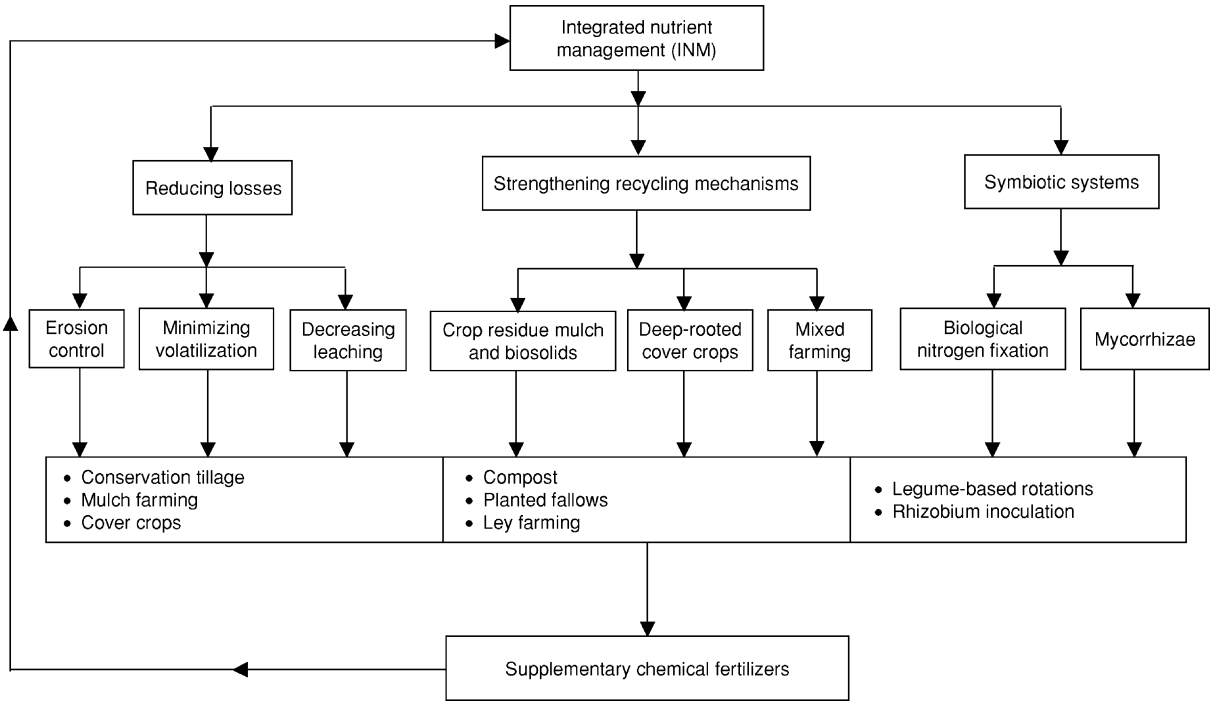

Figure 5 Integrated nutrient-management strategies are designed to enhance nutrient supply without increasing dependence on chemical fertilizers.

decreasing losses, recycling nutrients and increasing BNF. Reducing losses of plant nutrients (in runoff, soil erosion, leaching, and volatilization) is crucial to enhancing nutrient-use efficiency. Equally important is recycling of plant nutrients through the use of biosolids as compost, sludge, and manure. Planting deep-rooted perennials, as in agroforestry systems, is also important to recycling nutrients. Soil N reserves can be enhanced through BNF by incorporating legumes in the rotation. All these measures can decrease the amount of chemical fertilizers required to obtain the desired yield. The objective is not to eliminate chemical fertilizers but to decrease the quantity required and increase the use efficiency of critical elements (e.g., N, P).

3. Water management: There is a strong link between nutrient management and water management. The nutrient-use efficiency cannot be increased without increasing the water-use efficiency. Similar to nutrient management, the overall goal is to decrease losses, strengthen water recycling, and provide supplemental irrigation (Figure 6). The latter may be needed to enhance crop yields in those regions of subhumid and semiarid tropics that are prone to short-term droughts during the growing season. In addition to losses by runoff, those by soil evaporation must be minimized, especially in the tropics, which have high evaporative demand throughout the year. Therefore, mulch farming is an important strategy. Recycling of water, similar to that of plant nutrients, also requires establishing compatible mixtures of diverse crops. Planting shallow-rooted annuals in association with deep-rooted perennials can enhance water-use efficiency. Excess runoff during the rainy season can be stored in small farm ponds and used for supplemental irrigation to prolong the growing season and alleviate drought. If supplemental irrigation involves use of canal (surface water) or tubewell (groundwater), it is absolutely necessary to make provisions for surface/subsurface drainage and reduce risks of a rise in the water table and build-up of excessive salts in the root zone.

Ecological Approach to Management of Soils under Shifting Cultivation

The traditional shifting cultivation systems ($L = >5$) are ecologically compatible with harsh tropical environments because these systems do not cause drastic perturbations in ecosystem functions such as water balance, energy budget, elemental cycling, above- and belowground biodiversity. Therefore, any successful transformation of a resource-based (low input) and extensive (low productivity) system into viable (high energy flux) and commercial (profitable) farming must be based on similar principles of causing the least possible disturbance to ecosystem functions. Yet, the energy and biomass flow must be increased while strengthening mechanisms of recycling and

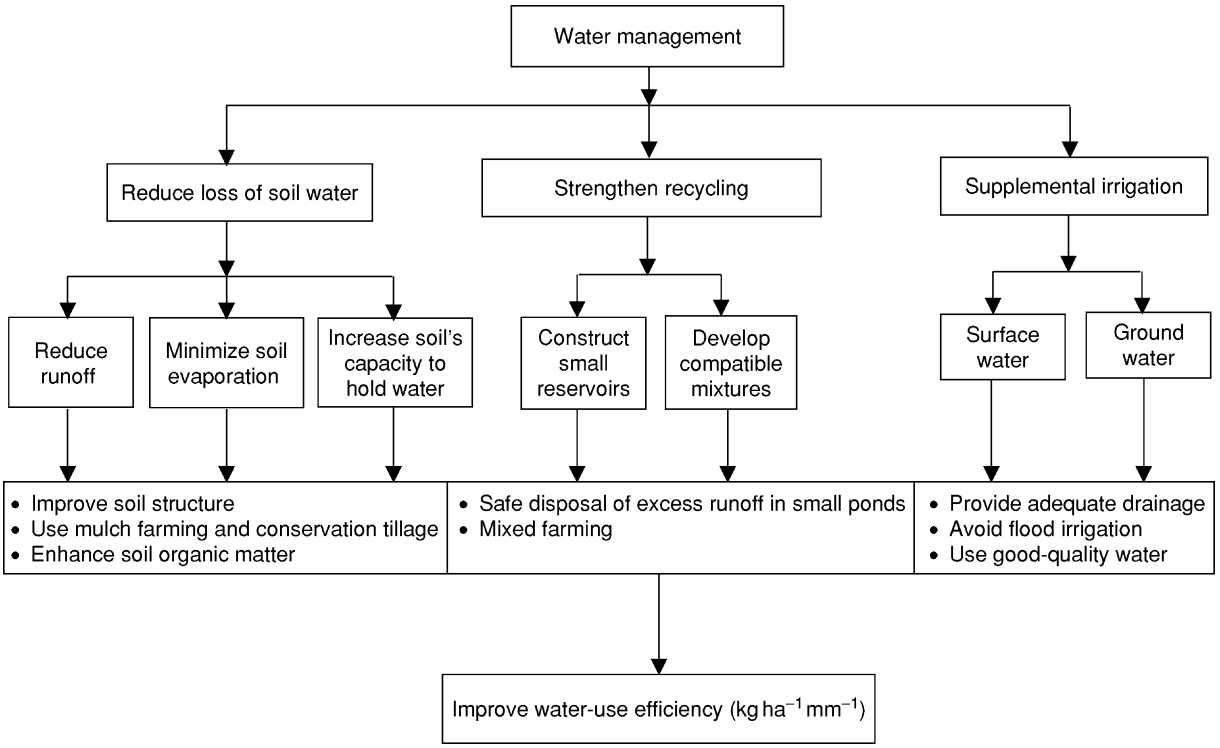

Figure 6 Strategies for water management to enhance water-use efficiency.

minimizing loses through erosion. Essential components of an ecological approach are outlined in Figure 7, and involve science-based interventions. In addition to enhancing production, these technological interventions must minimize risks to the environment. The strategy is to increase productivity while sequestering C within soil and biota, and without releasing chemicals (fertilizers and pesticides) into the environment.

In this regard, the importance of improved germplasm cannot be overemphasized. The strategy is to introduce ecologically compatible crop/tree species and genetically improved varieties. Indeed, some of the soil-related constraints (e.g., toxicity of Al and Mn in the subsoil) may be alleviated by the introduction of improved varieties. Damage by pests can also be reduced through introduction of improved germplasm.

Research and Development Priorities

There is a need to adopt proven technology through on-farm adaptive research with strong participation of the farming community. There is also a need for basic research in addressing new and evolving issues.

1. Terrestrial carbon sequestration: There is a strong link between the cycles of C, N, and H_2O. Harvesting N in the biomass for growing food crops by shifting cultivation systems has been responsible for emissions of CO_2 and other greenhouse gases (CH_4, N_2O) into the atmosphere. In fact, 1.5–2.0 Pg C is annually emitted into the atmosphere by deforestation and land-use change in the tropics. Rather than a source, tropical ecosystems can be a major sink for atmospheric C. Therefore, understanding the cycling of C, N, P, S, and other elements in natural and managed ecosystems, and enhancing their retention within soil and biota are crucial to reducing emissions of greenhouse gases into the atmosphere.

In this regard, restoration of degraded soils and ecosystems is extremely important. Degraded ecosystems are severely depleted of their C and N pools, and have been sources of greenhouse gases. Restoration of these ecosystems would enhance biomass productivity and soil quality, and increase the C pool within the soil and biota. It is important, therefore, to understand elemental cycling in natural and managed ecosystems and how recycling can be enhanced, losses reduced, and use-efficiency increased. Understanding the link between water and elemental cycling is also important to identifying ecologically compatible systems.

2. Soil quality and soil resilience: There is a close link between elemental cycling and soil quality. Rapid and severe soil degradation is linked to depletion of SOC reserves and elemental imbalance, but the exact mechanisms are not widely understood. An answer to the question of how can soil degradative trends be

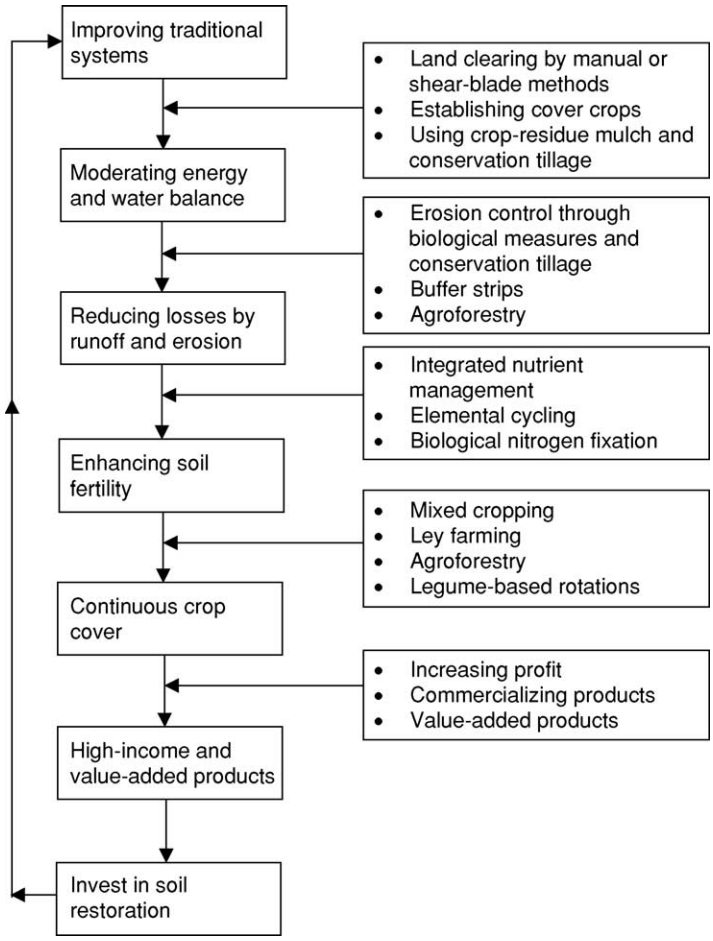

Figure 7 An ecological approach to transforming subsistence agricultural systems.

reversed lies in understanding the relation between soil quality and soil resilience. The strategy is to enhance soil resilience and improve soil quality while improving productivity. Therefore, soil-specific research is needed to understand the mechanisms and processes responsible for enhancing soil resilience and improving soil quality. The maintenance of high levels of the SOC pool may be one such strategy.

3. Agricultural intensification: It is important to develop innovative systems of enhancing the productivity of existing agricultural lands by alleviating soil, biotic, and social/economic constraints. Restoration of productivity of depleted/degraded soils is crucial to achieving food security and improving the environment.

4. Indicators of sustainability: It is important to formulate quantitative criteria of assessing the sustainability of a farming system. Developing quantifiable and scientifically sound indicators of sustainability is a high priority.

5. Modeling: Predictive models are needed to assess the impact of land use and farming systems on soil quality, water balance, micro- and meso-climate, agronomic/biomass productivity, and sustainability. Validation of such models for specific soils and ecosystems necessitates strengthening the database on soil resources, hydrology, vegetation, and climate.

Conclusions

Shifting cultivation and related bush fallow systems have served a useful purpose in preserving the ecological balance in regions of low population pressure. Although subsistence and low in productivity, such systems had minimal adverse impact on the environment. With increasing population pressure and concerns about environmental pollution and contamination by biomass burning and resource degradation, there is a need to identify viable alternatives to these systems. The available research indicates that productivity of these soils can be substantially increased by adopting improved and science-based technologies. Whereas soil and water conservation are achieved by

biological measures based on mulch farming and cover crops, soil fertility can be enhanced by nutrient recycling, BNF, and supplemental fertilizer use. Principal attributes of sustainable systems of soil and water management are erosion control, maintenance of soil structure, increase in SOC pool and biotic activity of soil fauna, and judicious use of chemical fertilizers to create synergistic effects between fertilizers and biosolids.

Major characteristics of sustainable systems are high energy fluxes that increase productivity and use-efficiency of inputs, restorative effects on soil and environments, and increasing C stocks in soil and biota. There is a strong need to conduct basic research in understanding the principles and processes that govern soil degradation, soil quality, and soil resilience. Understanding the link between SOC dynamics on the one hand and elemental cycling (e.g., C, N, P, S) and water balance on the other is critical to developing sustainable systems that are viable alternatives to shifting cultivation.

SITE-SPECIFIC SOIL MANAGEMENT

C J Johannsen and P G Carter, Purdue University, West Lafayette, IN, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

A new approach to intensive agricultural production, called 'site-specific agricultural management,' has gained acceptance by many farmers and producers around the globe since the 1990s. Site-specific management makes use of new tools, known as 'spatial technologies,' which encourage intensive management of soil resources using tools such as global positioning systems (GPS), geographic information systems (GIS), and remote sensing. Other frequently used terms to describe this intensive agricultural system include 'precision agriculture,' 'prescription farming,' and 'variable-rate technology' (VRT). Site-specific management has been defined as:

> an information- and technology-based agricultural management system to identify, analyze, and manage a site relating to the spatial and temporal variability within fields for optimum profitability, sustainability, and protection of the environment

Another definition puts it more simply as:

> using information technologies to tailor soil and crop management to fit the specific conditions found within a field

Services are available to farmers that involve satellites for collecting data and transmitting geographic information, sensors on airplanes to provide measurements as an aid to crop and soil management, sensors on farm equipment to monitor soil and crop parameters, and computer systems for receiving or analyzing digital spatial information. The word 'spatial' is frequently used related to site-specific management and means the area represented around a data point or reference. Spatial data contain information on location, shape, and relationships among geographic features such as soil, vegetation, and hydrology. Therefore data may be collected to represent an entire field, where one sample of 220 t may be the total yield, or data may be collected to represent a small portion of the field, such as an element from a yield monitor of 4 m^2, where the specific yield might be 22 t ha^{-1}.

Successful application of spatial technologies at the farm scale is dependent upon having a defined management system that has the capability to handle large volumes of data in an organized way, and a solid base of experience. It arises at the confluence of three principal technologies: GPS, GIS, and remote sensing.

New technologies make data collection, analysis, and interpretation more beneficial for site-specific farming and are important in improving the soil environment. Some of these technologies include GIS for integrating data layers and data (soil properties, topography ('digital terrain'), slope, and slope aspect) to assist in the analysis of collected data; GPS for relating the location of ground observations and measurements; and remote sensing for defining soil and crop anomalies within a field and assessing their crop production impact. In addition to these technologies, improvements in communications, e.g., the internet, are providing rapid delivery of newly acquired, remotely sensed data and timely transfer of information.

Technologies

GPS was first used during the 1980s by military forces. Composed of 24 satellites and generically identified as a GPS, Navistar blankets the globe with location-finding radio signals that can help determine a person's location to within less then 1-m accuracy. GPS assist farmers to locate areas within a field where application of fertilizer and chemicals is necessary; adjustment of application rates is based on soil conditions and yield data.

The Navistar satellite system produces a low-energy signal containing a 'data message' that includes information about its location, its atomic clock status, and its general condition. These data messages can be 'read' and interpreted by GPS receivers anywhere on the ground, at sea, or in the air. For higher accuracy, simultaneous readings are taken from four or more satellites.

The value of the GPS to a farmer includes: (1) knowing the locations of soil samples, so laboratory results can be compared with a digitized soil map; (2) knowing the locations of soil properties (clay and organic matter content) and soil conditions (relief and drainage) so that fertilizer and pesticides can be applied optimally; (3) the use of lightbar technology which provides guidance in the exact direction for accurately applying and documenting the rates of pesticides; and (4) being able to monitor and record yield data from harvesting equipment within the fields. All of these applications involve more precision in the collection of data and information, which means that the farmer or producer needs a system for keeping track of these data for future decision-making.

GIS technology is also essential to precision farming, because it is the system for keeping track of data and information. GIS is computer software that is used to collect, sort, analyze, map, graph, store, and move data. A GIS records many different types of data in stacked layers that are all precisely aligned geographically. For the farmer this means that information obtained from a field at different times can be easily integrated into a composite profile of each small unit or spatial area of the field. Not only can farmers store yield information by location, but they can also layer the yields on top of their soil map to correlate yield with soil type. A GIS also allows farmers to see costs of production for any part of the field. Accurate data are required and need to be accessed by the GIS software.

Without a GIS, data from soil tests, dates of planting, fertilizer application rates, weather, and yield are often stored as piles of paper on the farmer's desk to sort manually for making decisions. The key attribute of GIS is that all data must be referenced to a common geographic base. This is usually a base map; one of the most commonly used is digital orthophotography, which has geographic references for each pixel (picture data point) such as a longitude and latitude reference. There are more than 40 different reference systems; fortunately, software has been written to convert all of these to a selected base map. Once the base has been selected, all other data

that are collected are referenced to that base. GPS is the most common means of providing the reference points for the collected data.

Remote sensing, the third technology available to precision farming, entails the use of aircraft or satellites as platforms, from which farmers capture images of their fields during the growing season. The images are used to assess whether something unusual has occurred; this information can be used to help improve yield and profit. Remote sensing technology has improved, especially since the late 1990s, to include finer spatial resolution, more wavelengths of recorded light energy, and more frequent coverage over a specific location. Because of improvements in sensors, computer chips, software, and services, intensive agricultural systems may now reap benefits from these technologies.

Farmers can either analyze this remotely sensed information themselves or rely on commercial companies to perform this service for them for a fee. Satellite images from Landsat and SPOT, US and French satellites, respectively, have been used to distinguish locations affected by such problems as weeds, excessive moisture, low soil pH, and imbalance of plant nutrients. Satellites such as the IKONOS, Quickbird, and Orbview satellites have allowed farmers to obtain the equivalent of aerial images of their fields and have already shown benefits for management of intensive crops such as vegetables, orchard fruits, and grapes.

The cost and timeliness of obtaining the images have been the biggest deterrent to date to regular use of such remotely sensed data. Satellites launched during the last few years by Digital Globe, Space Imaging, and others are competing for the agricultural market; however, there are not enough satellites available to provide cloud-free images for critical periods. These multispectral satellites provide images in three to six different frequencies plus black-and-white images at 0.6- to 4-m spatial resolutions.

Remote sensing needs to prove itself in the grain crop areas, since the profit margin of these crops has been low. It has, however, been tested successfully on potato, sugar beet, and cotton fields in some parts of the world. Commercial remote-sensing companies have used weekly images to map the acreage of these crops and monitor their conditions throughout the growing season. The images and interpretations provide growers with an improved bargaining position when contracting with food processors, since they have a prediction of harvest dates and knowledge of how their competitor's crops are performing.

The value of precision farming is that the farmer can perform more timely operations related to better soil management such as tillage, plan more accurate crop-protection programs, adjust seeding rates, and know the yield variations commonly caused by soil differences within a field. The potential value of this system therefore translates into increased net return per acre; improved efficiency of such inputs as seeds, fertilizers, and chemicals; improvement of the soil environment; reduced threat to water quality; and increased managerial skills. This potential, while promised in many farm advertisements, still needs to be proven in a consistent manner and depends on the grower's management style. Farmers need to learn how to use these technologies to improve soil and crop quality based upon conditions found within their fields.

Soil Management

Soil management is a key to the success of site-specific soil management. It starts with a farmer's ability to vary the depth of tillage according to soil conditions and is important in proper seedbed preparation, control of weeds, and fuel consumption, with the potential to lower production costs within an individual field. With a GPS as their guide, farmers using conservation tillage (the practice of leaving residues on the soil surface for erosion control) can adjust tillage depth as they traverse the different soil types. With conservation and reduced tillage, the amount of soil disturbance is minimal, but adjustments according to soil conditions such as texture, moisture content, and pH are important to seed depth and fertilizer placement. The adjustments may contribute to higher yields and safer production at lower cost. This part of site-specific farming is in its infancy. Equipment companies are developing tillage equipment with GPS and selected controls tailored to site-specific farming that will be evolving over the next decade.

The application of chemicals in proper proportions is of environmental and economic concern to farmers. Environmental regulations call for the discontinuance of certain pesticide applications within 30 m of a stream, water body, or well, or within 20 m of an intermittent stream. Using a GPS along with a digital drainage map, a farmer is able to apply these pesticides with VRT in a safer manner (**Figure 1**). Spraying equipment can be preprogrammed to turn off automatically when it reaches the distance limitation or buffer along the drainage feature. Additionally, farmers can preprogram the amount of pesticide to be applied according to the soil characteristics in each area of the field. This saves money and allows for safer use of these materials.

Some companies are marketing sprayers utilizing a sensor positioned ahead of each spray nozzle for applying herbicides in chemical–fallow conditions

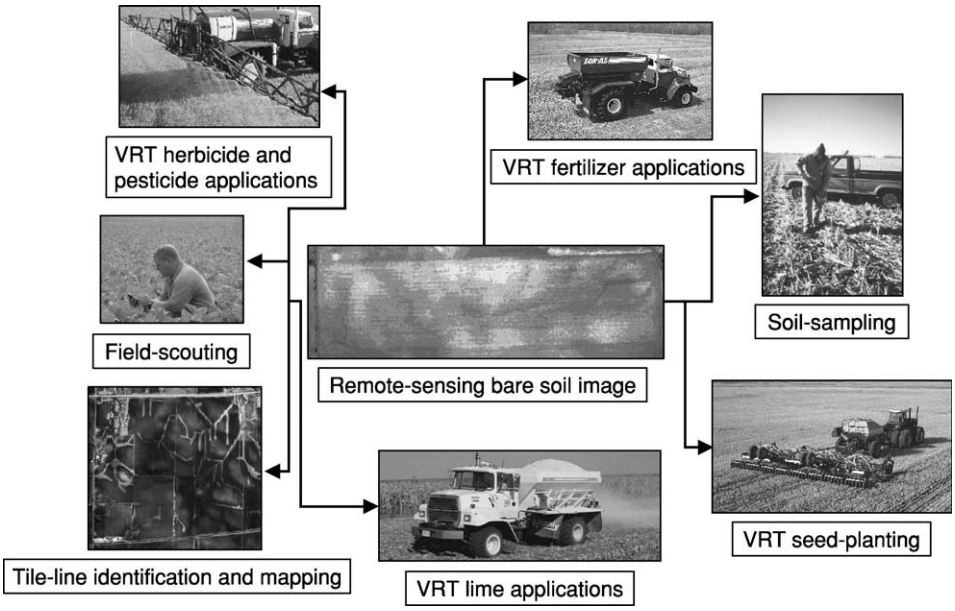

Figure 1 Agricultural global positioning system (GPS) applications as related to a remotely sensed image. The image provides the information to develop variable-rate technology (VRT) application maps.

where a crop is grown every other year. Incident light sensors detect and measure green vegetation, and, when the vegetation, e.g., unwanted plants or weeds, takes up more than 5% of a detector's field of view, a controller automatically turns on the individual spray nozzle. This type of sprayer, which greatly reduces the area sprayed and expenditure on chemicals, is a good conservation tool.

Similarly, nutrient applications of nitrogen and other materials are gaining acceptance owing to effective soil testing, such as taking samples according to soil maps or soil management zones. The application of lime to correct soil acidity by development of application maps based on soil samples has gained acceptance among many farmers.

Proper Seeding

Crops grow best when seeds are spaced such that plants obtain maximum sunlight and moisture and are placed at a proper depth within the soil. This is best accomplished by varying the seeding rate according to soil conditions such as texture, organic matter, and available soil moisture. For example, fewer seeds would be planted in sandy soil than in silt loam soils due to the amount of available moisture. To maximize yield per plant, seeds would be sown at a lower density, which would usually produce larger heads (ears) of harvested seeds because of more soil nutrients and sunlight available per plant.

However, planting fewer seeds runs counter to the practice of increasing seed density to increase yields, a trajectory that when overdone can yield a biomass so dense that some sunlight is blocked and the plants receive insufficient sunlight to produce seeds. The farmer's challenge is to find the right seed density to match all the localized factors affecting plant growth. Since soils can vary significantly across one field, the farmer can change seeding rates while crossing the field and thereby maximize the seeding rate according to the soil conditions.

Equipment modifications needed for VRTs have been designed for corn planters, grain drills, and air seeders (Figure 1). The desired rates are usually determined by reviewing previous yield images and/or soil productivity estimates. A computerized soil map of a specific field on a computer fitted on the tractor along with a GPS can provide farmers with their exact position in the field and guide them in adjusting the seeding rate accordingly. Seed companies are beginning to make recommendations on various seeding rates for individual hybrids, which will help the farmer with the settings on the planter.

Harvesting

A key benefit in the use of site-specific management techniques such as the adjustment of seeds, pesticides, fertilizers, and tillage as a field is crossed is in knowing the precise yields at every location. Harvesting equipment can be equipped with yield-monitoring devices that are coupled to a GPS, which provide a yield measurement for specific areas. A yield amount and location can be obtained every 1–5 s as the field is traversed. With appropriate software, a yield map

Figure 2 Collection of soil and plant measurements in the field for site-specific management: (a) field spectrometer; (b) chlorophyll meter; (c) electrical conductivity; (d) soil-sampling.

can be produced showing the yield variation throughout the field. This allows farmers to inspect the precise location of the highest- and the lowest-yielding areas of the field and determine why the differences exist. It allows the analysis of costs and yield to determine the most profitable practices and rates that apply to each field location. This provides farmers with their own research information that can be used in a practical and profitable way.

For farmers wanting to adopt precision farming, yield monitors are a good place to start. Yield monitors are already in use for measuring corn, soybeans, cotton, and other small grains such as oats and wheat, and monitors for other crops such as potatoes and peanuts are being developed. Farmers are also encouraged to monitor their fields closely by scouting (walking the field) and using remote-sensing techniques so that they have proof of problems or changes. By using a GPS unit they can go to a specific low-yield location and soil sample to determine whether lack of specific nutrients is the cause (Figure 2). With this information, farmers can assess the cost-effectiveness of the additional input. Some low-yield areas might best be ignored for growing crops.

Adoption Considerations

Farmers must know how the technology operates and be computer-literate. If they are working with a crop consultant who can analyze their data and make recommendations for them, that is a start, but being computer-literate is an advantage (Figures 3 and 4).

The number of farmers involved in precision or site-specific management practices around the globe is not known. It is likely that approximately 50% of the farmers in developed countries have had exposure to the use of VRT applications of soil-nutrient amendments and pesticides. Many new combines have yield monitors as standard equipment, which means that the opportunity to learn how to use yield images and/or maps increases with each combine that is purchased. The use of the yield images has caused farmers to request remotely sensed images during the growing season for comparison. Most are hoping to determine the crop yield prior to harvest and in the process are learning that this is difficult to achieve; however, the knowledge of the locations of crop and soil anomalies is beneficial to improving their management skills. Current trends in the use of remote sensing data in agriculture are driven by goals that are part of site-specific crop management. Farmers can adopt precision-farming techniques through cooperatives and through consultants who use GPS technologies (Figures 3 and 4).

The Future

Several companies are starting to market GIS record-keeping systems so farmers can record all of the field operations, including planting, spraying, cultivation,

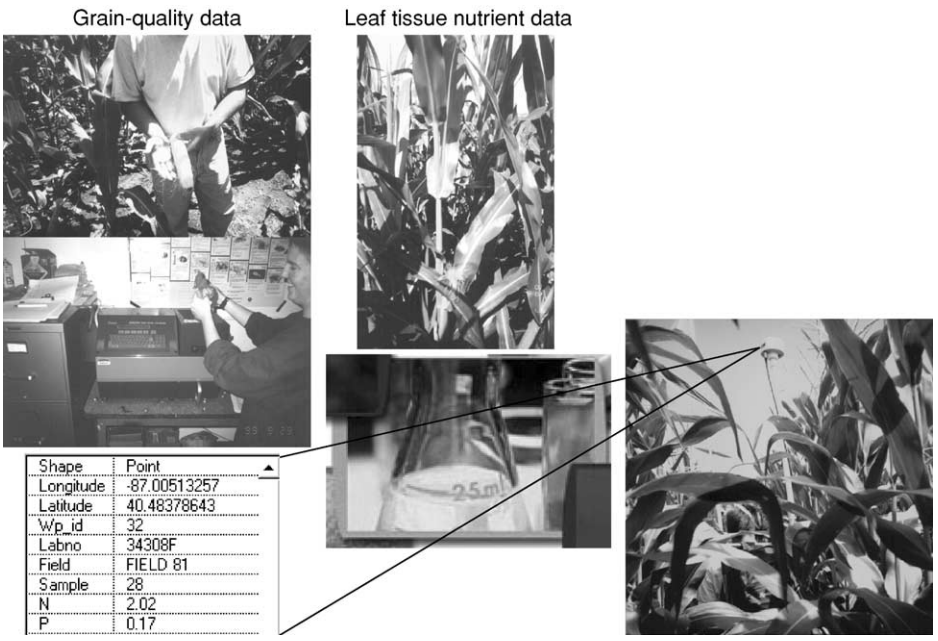

Figure 3 Global positioning system (GPS) technology is used to record the field locations where ground reference plant samples are collected. GPS locations make it possible to relate sample results to remote sensing image data.

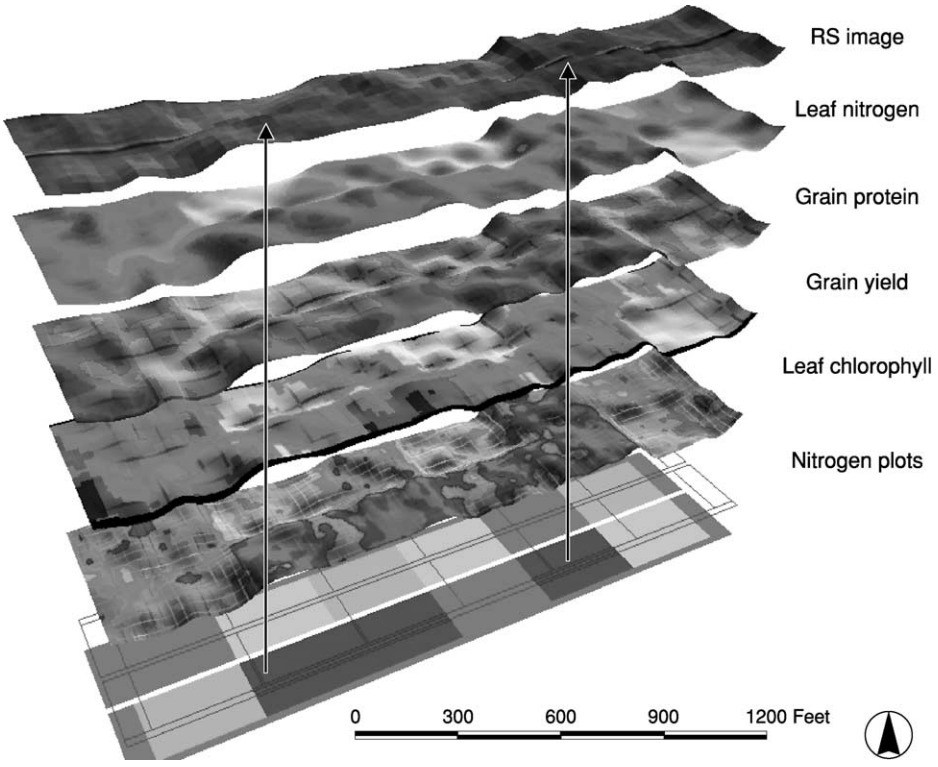

Figure 4 GIS layers in a digital terrain format showing a remotely sensed (RS) image and measured plant properties for a field experiment testing four rates of nitrogen that would provide two inadequate rates, an adequate and an excessive rate within three random replicated corn plots.

and harvest (along with specific information such as type of equipment used, usage rates, weather information, time of day performed, and weather data). Additionally, farmers can record observations such as weed growth, unusual plant stress, coloring, and growth conditions throughout the season. All GPS-collected data can be automatically recorded and used in conjunction with a GIS program.

Remotely sensed data can be analyzed and added to the GIS using soil maps and digital-terrain and field-operations information as ground references. This can be used to guide further field operations such as spraying, fertilizing, and irrigating; plus it is part of a permanent record. A number of new satellites provide data with increased spatial resolution such as 1, 5, and 10 m, which is similar to digital aerial images. This means that remotely sensed data would complement the yield data collected.

Additionally, the spectral resolution will be increased through hyperspectral image data, meaning that, instead of a few broad bands of 100 nm bandwidth, there will be more than 100 narrow bands of 5 and 10 nm bandwidth. This helps to define the colors more sharply, which leads to more detail about leaf pigments, soil organic matter, and other plant and soil properties. Much research is being done to determine precisely what is being measured.

On the horizon are sensors operated from the tractor that will measure soil properties such as organic matter, clay content, and soil moisture in real time. This will have a significant impact on planting operations. It means that, based on measurements from sensors mounted on planters, farmers will be able to adjust seeding, fertilizer application, and chemical application rates as they plant. By recording these inputs and tracking rates by location, they will be able to overlay the yield information and calculate the precise cost of production for any portion of their fields. Precision farming is making a strong impact on the way farmers in highly mechanized systems are able to protect their soil environment and manage their farm operations. The steady growth of remote sensing, GIS, and GPS technologies will continue to encourage site-specific soil management.

SODIC SOILS

G J Levy and I Shainberg, The Volcani Center, Bet Dagan, Israel

Introduction

Presence of sodium (Na) as an exchangeable cation is found in many soils worldwide. Sodic soils exhibit poor soil–water and soil–air relations, which in turn adversely affect root growth and plant production, increase soil erosion, and make the soils difficult to farm. Problems associated with sodic soils are expected to increase. The need to provide food to an ever-expanding population, coupled with the increasing demand for good-quality water from the urban and industrial sectors, results in poorer-quality water (e.g., treated effluents) and soils being used for food production. Understanding the behavior of sodic soils and its effects on agriculture and the environment is, therefore, essential in order to manage sodic soils properly for securing crop production and maintaining sustainable agriculture worldwide.

Definition of Sodic Soils

Two important parameters are used to define sodic soils. The first is a soil property – the exchangeable sodium percentage (ESP), which describes the level of adsorbed Na in soil:

$$\text{ESP} = (\text{exchangeable Na}/\text{cation exchange capacity}) \cdot 100 \qquad [1]$$

Instead of cation exchange capacity it is also possible to use the sum of exchangeable cations (Ca + Mg + Na + K). The second parameter which indicates the sodicity level of the irrigation water or soil solution is termed sodium adsorption ratio (SAR):

$$\text{SAR} = (\text{Na})/((\text{Ca} + \text{Mg})/2)^{0.5} \qquad [2]$$

where parentheses reflect cation concentration in $\text{mmol}_c\ l^{-1}$. Thus, SAR has units of $(\text{mmol}_c\ l^{-1})^{0.5}$. It must be emphasized that the sodicity hazard of solutions is related to the ratio of Na to the divalent cations present in the water and not to Na concentration solely.

Exchange reactions take place between the soil solution and the exchangeable phase. Thus, soil ESP can be estimated from the SAR of saturated paste extracts using the following empirical relationship:

$$\text{ESP} = 100(-0.0126 + 0.01475 \cdot \text{SAR})/(1 + [-0.0126 + 0.01475 \cdot \text{SAR}]) \qquad [3]$$

or from the nomograph presented in Figure 1.

To date there is no widely accepted critical ESP value which separates sodic from nonsodic soils. This is because the effects of ESP cannot be separated from that of the electrolyte concentration (EC) of the soil solution. The interrelationship between ESP of the soil or SAR of its equilibrium solution and the EC of the soil solution may help estimate whether a sodic or nonsodic behavior will occur.

Origin and Distribution of Sodic Soils

In many sodic soils sodicity originates from the nature of the parent material and pedogenic processes. There are also sodic soils where sodicity arises from anthropogenic processes (human activity), and this is termed secondary sodification. Irrigation with sodic water or without proper drainage, forest clearing, and other land management practices that lead to water logging

are key activities that may yield rapid secondary sodification.

The total area worldwide of sodic soils is estimated at 210 million ha. The area of sodic soils in each continent and in some countries where they form an important proportion of the soils is presented in Table 1. The spatial distribution of sodic soils indicates that they occur in a range of climates. However, the outlined distribution of sodic soils and the conditions promoting their formation are based on a pedological approach. Following the increase in the contribution of human activity to soil sodification, the definition of sodic soils is now based on soil behavior. Many agricultural soils that exhibit sodic behavior may not fit into the classical sodic soil group. Consequently, the sizeable area these soils cover remains unaccounted for.

Mechanisms Responsible for Sodic Behavior

Among the various soil constituents, the fraction that considerably determines the physical behavior of soils is the colloidal clay. Compared with other soil constituents, the clay fraction possesses a large specific surface area (surface area per gram of clay), which, combined with its charge, makes the clay a very reactive soil constituent in physicochemical processes, mainly swelling and dispersion. These two processes largely determine the microstructure of the soil, thus significantly affecting many of its physical properties.

The intensity of swelling and dispersion processes and the magnitude of their adverse effects on soil properties become more severe with the increase in soil sodicity. However, the swelling and dispersion behavior of soil clays differs significantly from that of pure clay systems, possibly because soil clays usually occur as mixtures and because of their association with other minerals, oxides, and organic matter present in the soil. It has been demonstrated that the EC required for preventing dispersion of soil clays is two- to 10-fold higher than that for pure clays. On the other hand, the presence of hydrous oxides or sparingly soluble minerals such as $CaCO_3$ has resulted in lower levels of soil clay dispersivity. Thus, extrapolation from pure clay systems to soil systems may often prove problematic.

Structural Stability of Sodic Soils

Soil structure is commonly referred to as the size, shape, and arrangement of particles (micro- and macroaggregates) and pores in soil. Soil structural stability is therefore the ability of the soil to retain its arrangement of solids and pores when exposed to different stresses. The presence of high levels of sodicity aggravates aggregate susceptibility to breakdown and slaking. However, these effects of sodicity are intricate and should not be considered independently of the EC of the soil solution and soil texture (Figure 2).

Sodicity-related degradation of soil structure leads to deterioration in soil water transmission properties, and increased susceptibility to crusting, runoff, and erosion. Water movement in the soil profile is commonly characterized by its hydraulic conductivity (HC). In cases where a thin seal is formed at the soil surface, water penetration into the soil is characterized by the infiltration rate (IR) rather than HC. Because the properties of the seal differ from those of the underlying soil, and its thickness is difficult to measure, this makes the determination of its HC extremely difficult.

Hydraulic Conductivity

The HC of a soil depends on its properties and those of the percolating fluid. Existing models have failed in adequately predicting soil HC, largely because they do not take into account the effect of fluid properties

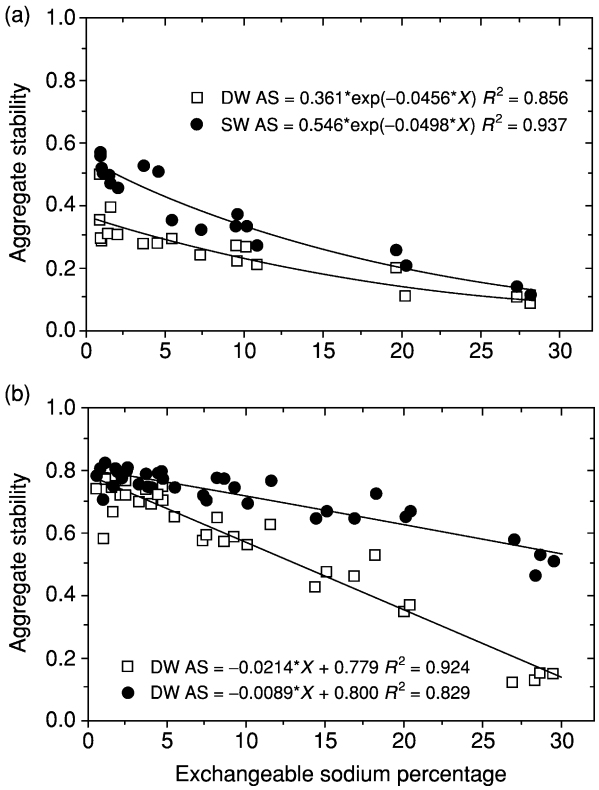

Figure 2 Aggregate stability (AS, expressed as a fraction) as a function of exchangeable sodium percentage and electrolyte concentration for (a) soils with clay content ≤25% and (b) soils with clay content ≥35%. DW, distilled water; SW, saline water. on the soil matrix geometry. Swelling and dispersion of clay in response to sodic conditions and the level of EC in the percolating solution change the size of the conducting pores and hence affect the HC.

Sodicity and electrolyte concentration The realization that soil HC depends on both the SAR and the EC of the percolating solution led to the development of the 'threshold concentration' concept, which was defined as the EC required to prevent a given decrease in the HC for a given soil ESP or SAR of the percolating solution (Figure 3). This concept has been tested and validated on a large variety of soil types. It explains observations of decreased HC in soils, even Ca-soil and soils of low ESP, exposed to water of low salinity (e.g., rain or snow water). The decrease in HC is because salt concentration in the soil solution is not sufficient to prevent swelling and clay dispersion. For instance, in Australia under rain-fed conditions, soils (especially clayey ones) often waterlog during the rainy season because what little salt is present is leached in the first rain, causing the clay to disperse and the HC to drop sharply. Conversely, it is possible to maintain high HC in an Na-saturated soil provided the EC is sufficiently large. In Israel, experience from commercial fields showed that, for Na-affected soils, irrigation with water having an SAR value as high as 26 with an EC of 4.6 dS m^{-1} exhibited no permeability problems, as the electrolyte concentration in the irrigation water was sufficient to prevent the dispersive effect of Na. However, upon applying electrolyte-free water (to simulate rainwater in winter), soil HC dropped to a small fraction of its initial high value.

A distinction should be made between the effects of clay swelling and those of clay dispersion on the HC of soils. Soils begin to swell as the EC of the soil solution is reduced, but the effect of swelling on HC becomes apparent only at SAR values above 10 in medium- and heavy-textured soils. In light-textured soils the effect of swelling on reducing the conducting pores and hence HC is hardly noticeable. Furthermore, the swelling process is reversible; thus an increase in HC can be noted following an increase in EC of the soil solution. Clay dispersion, on the other hand, can take

place at already low ESP levels provided the EC is below a critical level. When clay dispersion occurs, the dispersed clay particles move down the soil profile and may even cause a complete blockage of the conducting pores, and hence an irreversible change in the HC. Consequently, the effects of reducing EC on the HC are likely to be more severe when clay dispersion, rather than swelling, is the predominant cause.

Soil properties affecting sodic behavior The response of soils to sodic conditions varies among soils, mainly because soil properties have a significant effect on the dependence of the HC on sodicity. A major factor causing differences among various sodic soils in their susceptibility to hydraulic failure when leached with low-EC water is their rate of salt release from mineral dissolution. Mineral dissolution determines the electrolyte concentrations of percolating solutions and hence soil HC. Sodic soils containing minerals ($CaCO_3$ and a few primary minerals) that readily release soluble electrolytes will not readily disperse when leached with distilled water (DW) at moderate ESP values, because a sufficiently high electrolyte concentration ($\sim 3\,mmol_c\,l^{-1}$) can be maintained to prevent clay dispersion. In addition, the ESP level will decrease, because most of the cations released are divalent (Ca and Mg).

Clay content, through its effect on pore size distribution, contributes significantly to the response of soils to sodic conditions. The sensitivity of HC to sodic conditions is generally greater for soils having medium and high clay content. When clay content is high, clay swelling may significantly reduce the size of the water-conducting pores and lead to low HC. Similarly, under dispersive conditions the dispersed clay particles clog the pores and cause a reduction in soil HC. Conversely, in sandy soils, due to the low clay content, clay swelling has only a limited effect on the HC. Conditions supporting clay dispersion may cause the HC first to decline and subsequently to recover. This phenomenon is explained by the change in flow pattern, from a solution flowing through a matrix of sand covered with clay which starts to disperse and reduce HC, to a flow of a clay suspension in a pure sandy matrix having large pores resulting in subsequent increase in HC.

Other soil properties that may affect the response of soils to sodic conditions include:

1. Presence of aluminum and iron oxides: These oxides, commonly found in highly weathered soils, enhance soil stability, via a cementing action, and substantially decrease its susceptibility to sodic conditions.
2. Clay mineralogy: Soils with a high content of 2:1 layer silicates (e.g., montmorillonite) are the most labile ones while those high in kaolinite and sesquioxides are the least labile.
3. Exchangeable Mg: Although in many soils the exchangeable Ca/Mg molar ratio is high, in some soils the reverse is true. The effect of adsorbed Mg on soil hydraulic properties seems to depend on soil type. In calcareous soils, the presence of Mg enhanced the dissolution of $CaCO_3$, producing electrolytes which prevent clay dispersion and HC decay, while in non-calcareous soils Mg causes a decrease in the HC of the soils beyond that of the Na/Ca system. There is the direct ('specific') effect of exchangeable Mg in causing a decrease in HC, and there is the inability of Mg in irrigation water to counter the accumulation of exchangeable Na in the soil.

Sodicity and conditions prevailing in the soil It has recently been recognized that the soil response to sodic conditions depends not only on soil properties but also on the conditions prevailing in the soil (e.g., antecedent moisture content and wetting rate). Soil conditions affect aggregate stability/breakdown and thus the pore size distribution and consequently the HC. Aggregate breakdown results from dispersion and from slaking during wetting, whose rate determines the degree of slaking. It has been observed that the HC of sodic soils leached with DW decreased more steeply and to lower values with the increase in the rate at which the soil was wetted. Fast wetting, which increases aggregate slaking, increases the susceptibility of the soils to sodic conditions. Conversely, slow wetting decreases significantly the effects of sodicity on soil HC, especially in fine-textured soils (Figure 4).

Infiltration Rate

Soil infiltration rate (IR) is defined as the volume flux of water flowing into the profile per unit of soil surface area under any set of circumstances. Often when water is supplied to soil, the IR decreases from its initial high rate due to formation of a thin layer (<2 mm) at the soil surface, termed seal. The discussion to follow will focus on structural seals usually formed by the impact energy of water drops.

Sensitivity of seal formation and IR of a smectitic loamy sand to ESP when exposed to distilled water under laboratory-simulated rain is presented in Figure 5. Even at the lowest sodicity (ESP 1.0), a seal was formed and the IR dropped from an initial value >100 to a final infiltration rate (FIR) of $7.0\,mm\,h^{-1}$. An ESP value of 2.2 was sufficient to cause a further drop in the final IR of the sandy loam to $2.4\,mm^{-1}$. The amount of rain required to approach the FIR (i.e., the rate of seal formation) was

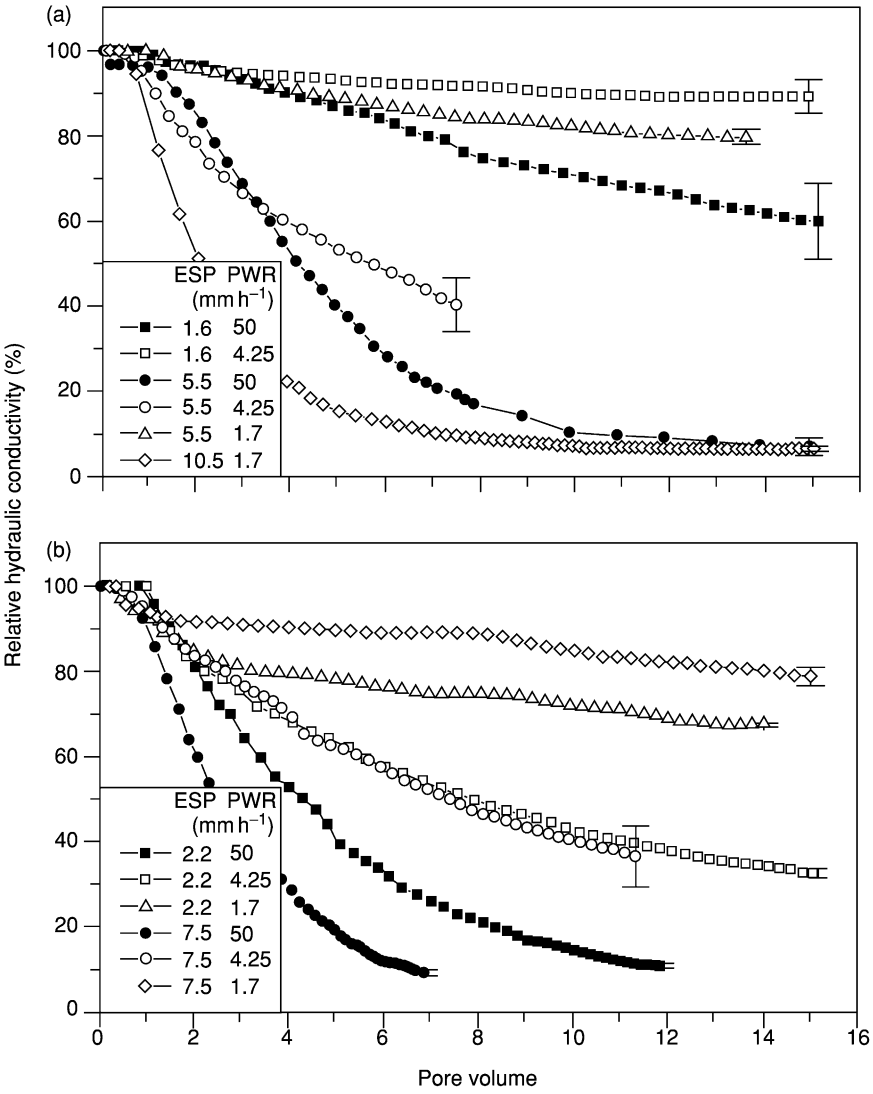

Figure 4 Relative hydraulic conductivity of (a) sandy clay with exchangeable sodium percentage (ESP) of 1.6, 5.5, and 10.5, and (b) clay Y with ESP 2.2 and 7.5 as a function of three prewetting rates (PWR: 50, 4.25, and 1.7 mm h^{-1}) and leaching with deionized water. Reproduced with permission from Shainberg I, Levy GJ, Goldstein D *et al.* (2001) *Australian Journal of Soil Research* 39: 1279–1291. CSIRO Publishing, Melbourne, Australia.

also affected by sodicity (Figure 5). As raindrop impact energy was the same in all the experiments, the differences in IR curves for the various treatments were the result of chemical dispersion of the soil clay caused by sodicity. The high sensitivity of the soil surface to sodicity (even at low ESP values) is explained by the mechanical impact of the raindrops, which enhances chemical dispersion, and the almost total absence of electrolytes in the applied distilled water.

In cases where soil is exposed to overhead irrigation (e.g., sprinklers), IR is sensitive to both the EC and SAR of the applied water. The lower the concentration of the electrolyte solution, the faster the rate at which the IR decreases (Figure 6). For similar electrolyte concentrations, increasing soil ESP leads to a sharper decrease in and a lower final IR (Figure 6). Increasing EC greatly affected IR even at low sodicity. It was reported for Californian soils that final IR increased from 2 to 28 mm h^{-1} as cation concentration in the applied water having SAR <5 increased from 5 to 28 $cmmol_c\ l^{-1}$. These results, and others, indicate that IR is far more sensitive than HC to both SAR and electrolyte concentration of the applied water. Furthermore, when Mg is the complementary cation to Na, then IR in Mg-Na soil may often be lower than that in the Ca-Na soil, especially under conditions where chemical dispersion is dominant in controlling IR (i.e., water drops with low to medium kinetic energy).

ESP, exchangeable sodium percentage; DW, distilled water; EC, electrical conductivity. Reproduced from Agassi M, Shainberg I, and Morin J (1981) *Soil Science Society of America Journal* 45: 848–851.

Similarly to HC, it has recently been noted that the IR of sodic soils depends not only on soil properties but also on the conditions prevailing in the soil (e.g., antecedent moisture content and wetting rate) because IR is greatly affected by aggregate stability/breakdown. The dependence of IR of sodic soils on the rate of aggregate wetting is closely associated with soil texture. In coarse- and medium-textured soils, sodicity effects on IR are only slightly altered by aggregate wetting rate. In fine-textured soils, decreasing the rate of aggregate wetting prior to exposing them to rain significantly decreases the sensitivity of the IR to sodic conditions (Figure 7).

Sodicity and Soil Productivity

Sodic conditions are expected to affect soil productivity adversely because such conditions can lead to poor aeration, restricted root development, and enhanced root disease. Moreover, sodic conditions can lead to nutritional imbalances and micronutrient deficiencies since they could alter soil redox potential, pH, and dissolved organic carbon concentration.

Nitrogen, phosphorus, and potassium are the most important nutritional elements. Phosphorus and potassium do not pose a nutritional problem in sodic soils. Conversely, sodic soils may suffer from inadequate nitrogen availability. The reasons for this may stem from low rates of nitrogen mineralization, denitrification under restricted aeration conditions, volatilization of ammonia under alkaline conditions, and inhibition of nitrate (NO_3) uptake by chloride (Cl) or sulfate (SO_4) ions which are usually in abundance in sodic soils. Sodic soils may also suffer from impaired uptake of Ca. The ratio of Ca to total cation concentration (TCC) is considered a better indicator of Ca availability to plants than actual Ca concentration. Saturated paste extracts of sodic soils often exhibit Ca/TCC < 0.1, which for many crops indicates Ca deficiency. In addition, high Mg/Ca ratios, often found in sodic soils, can also cause Ca deficiency.

Two approaches exist with respect to studying crop tolerance to sodicity, i.e., in the presence or absence of sodicity-related adverse soil physical conditions. Studies on crop tolerance to sodicity based merely on nutritional factors have indicated that, already at relatively low ESP levels (2–10), some crops show signs of sodium toxicity; however, most field crops are classified as moderately tolerant or tolerant to sodicity (Table 2). On the other hand, studies that have been carried out under conditions where soil structure had been allowed to be affected by sodicity indicated that grasses were tolerant, wheat and barley were moderately tolerant, and pea and beans were

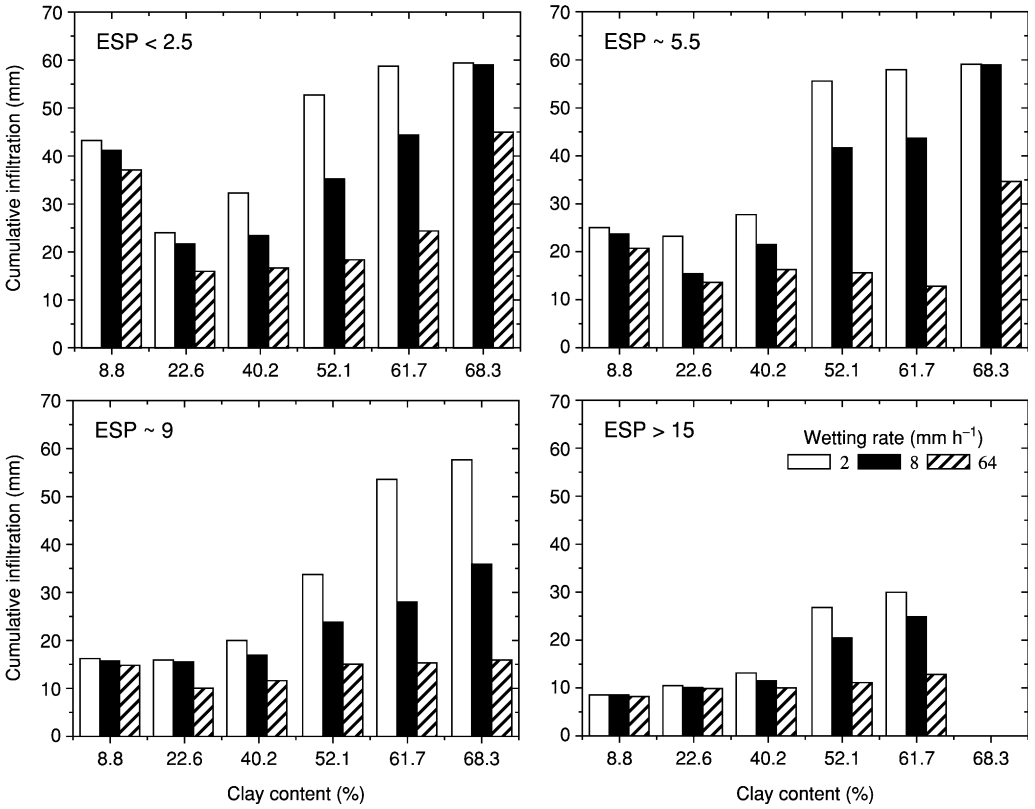

Figure 7 Effects of wetting rate on the cumulative infiltration from a 60-mm rain storm for six soils varying in clay content and for four exchangeable sodium percentage (ESP) levels.

Table 2 Tolerance of various crops to exchangeable sodium

Tolerance to ESP	*Crop*
Extremely sensitive (ESP 2–10)	Deciduous fruits
	Nuts
	Citrus
	Avocado
Sensitive (ESP 10–20)	Beans
Moderately tolerant (ESP 20–40)	Clover
	Oats tall fescue
	Rice
	Dallis grass
Tolerant (ESP 40–60)	Wheat
	Cotton
	Alfalfa
	Barley
	Tomatoes
	Beets
Most tolerant (ESP >60)	Crested and fairway wheat grass
	Tall wheat grass
	Rhodes grass

ESP, exchangeable sodium percentage. Reproduced from Pearson GA (1960) Tolerance of crops to exchangeable sodium. *US Department of Agriculture Information Bulletin* 216.

sensitive to sodicity. It should be borne in mind that the results of such studies could be site-specific, and may thus hinder their applicability to other soil types.

Reclamation of Sodic Soils

Reclamation of sodic soils, which is the mending of soil structure, is essential if productivity is to be maintained. The main concept for reclamation of sodic soils advocates the addition of a source of Ca for replacing exchangeable Na coupled with excess water to leach the Na from the root zone deep into the soil profile. Less common methods include the addition of a variety of organic ameliorants to maintain high levels of organic matter in the soil and thus stabilize its structure.

Chemical Reclamation

Reclaiming sodic soils via the addition of divalent cations can be achieved by using chemical amendments that release Ca ions to the soil, or by applying successive dilutions of high-salt water containing divalent cations.

Chemical amendments Typical amendments are those containing a source of soluble Ca or that dissolve Ca on reaction in the soil. Common amendments include gypsum, lime, $CaCl_2$, sulfuric acid, and sulfur.

Gypsum ($CaSO_4$), from both geological and non-geological sources (industries that produce $CaSO_4$ by-products), is the most commonly used amendment for sodic soil reclamation, primarily because of its low cost, reasonable solubility, and availability. Gypsum added to a sodic soil can increase its permeability by means of both EC and cation-exchange effects. The electrolyte effect is important during application of water with extremely low EC.

The cation exchange effect is important in soils where treating high ESP of the soil profile is important. The amount of gypsum required depends on the amount of exchangeable Na in a selected depth of soil. The amount of exchangeable Na to be replaced per unit land area (Q_{na}, $mol_c\,ha^{-1}$) during reclamation depends on the initial and desired final exchangeable Na fraction, the cation exchange capacity of the soil, its bulk density, and the depth of soil to be reclaimed. Thus, the amount of gypsum (in $Mg\,ha^{-1}$) needed to reclaim the soil, termed 'gypsum requirement' (GR), is calculated as follows:

$$GR = (8.61 \times 10^{-5})Q_{na} \quad [4]$$

The efficiency and rate of exchange, namely the percentage of Ca that exchanges for adsorbed Na, vary with ESP, being much greater at initially high ESP values. A number of GR models exist, and provide a powerful tool for quantitative predictions of water and gypsum required to reclaim a soil to a predetermined level of sodicity.

The use of $CaCO_3$ to reclaim sodic soils is considered to be of limited value, mainly because of its low solubility and low dissolution rate. Naturally occurring $CaCO_3$ may help soil reclamation by maintaining EC in the soil solution at a level high enough to prevent clay dispersion and a subsequent reduction in soil HC. However, because of its low solubility, $CaCO_3$ is not effective in maintaining high permeability at the soil surface during rain.

Successive dilutions of high-salt water In areas where water is not a limiting factor, reclamation of sodic soils can be obtained by leaching the soil with successive dilutions of high-salt water containing divalent cations. In the early stage of the leaching, the high EC in the applied water prevents clay dispersion and induces flocculation of the soil colloids. Simultaneously, the Ca ions in the water decrease sodicity by replacing exchangeable Na. Upon dilution of the saline water with high-quality water, the SAR of the water is reduced. To ensure successful soil reclamation, the depth of water added should be at least 9–10 times the depth of soil to be reclaimed.

Management of Sodic Soils

In order to maintain sustainable agriculture in sodic soils, and keep their productivity, proper management practices must be applied, including the use of soil amendments, tillage, and cropping.

Soil Amendments

Common soil amendments used to maintain high permeability in sodic soils include gypsum that provides electrolytes to prevent clay dispersion and organic polymers that stabilize soil aggregates. Phosphogypsum (PG) and flue gas desulfurization gypsum (FGDG), which are by-products of the phosphate and power generation industries, are readily available and therefore frequently used. Spreading powdered PG at rates of $5\,Mg\,ha^{-1}$ on the soil surface can be effective in slowing down the rate of IR decline and maintaining a higher final IR compared with the control, even in soils of ESP < 2.5 (Figure 5), indicating that some chemical dispersion takes place even at very low ESP values, and possibly even in Ca-saturated soils. The use of PG is also very effective in maintaining high IR in soils with high ESP (Figure 5). The favorable effect of PG on IR should be attributed not only to its effect on the EC of the percolating water but also to: (1) the physical interference with the continuity of the seal; and (2) the partial mulching of the soil surface which protects the soil from the beating action of the raindrops.

Organic polymers used for improving aggregate stability, maintaining high IR, and reducing seal formation are mainly polysaccharides (PSD) and polyacrylamides (PAM). The addition of small amounts of these polymers ($10–20\,kg\,ha^{-1}$), either sprayed directly on to the soil surface or added to the applied water, was noted to be effective in stabilizing and cementing aggregates together at the soil surface, and hence maintaining high IR values in soils with ESP < 5. On the other hand, when added to soils with high ESP (>20), polymers were ineffective in controlling seal formation and maintaining high IR values; in soils with moderate ESP (10–15) the effects of polymers were inconsistent and depended on water quality and the amount of polymer added. The efficacy of anionic polymers in preventing seal formation is enhanced when the soil clay is maintained in a flocculated state and the resulting final IR could be 10 times higher than the control. It is therefore recommended that in soils exposed to rain, polymer application should be accompanied by spreading a source of electrolytes (e.g., gypsum) at the soil surface. Of the polymers currently available and under study, anionic polyacrylamide with high molecular weight ($>10^6$ Da) has been found to be the

most effective in controlling seal formation and maintaining high IR.

Tillage

Tilling sodic soils may result in the improvement of soil physical and hydraulic properties, especially when accompanied by some reclamation measures. Tillage reduces bulk density and increases total porosity (especially macroporosity), and improves internal drainage and saturated and unsaturated HC. Deep tillage (1–2 m) or ripping breaks up hardpans, and cemented layers mix soil layers and generally cause a permanent improvement in soil structure and physical properties. However, deep tillage can sometimes lead to waterlogging and infiltration problems by bringing sodic subsoil to the surface. An alternative to deep tillage in the case of sodic subsoil is the use of ridges instead of bed farming techniques. With ridges, the plants are located about 0.25 m above the neighboring furrows and thus aeration is improved, especially in heavy-textured soils suffering from water logging in the subsoil. Shallow tillage (disking or chiseling) is effective in reducing soil permeability problems associated with surface crusts, hardsetting, and compaction. Shallow tillage requires repetition from time to time.

Sodicity-Related Environmental Hazards

Sodic soils are more susceptible to clay dispersion and surface sealing, which generate runoff flow and subsequently lead to elevated levels of soil erosion, a serious problem from the crop production point of view. In addition, off-site damages of runoff and erosion from cropped fields are severe; in the USA alone the cost of these damages is estimated to be in excess of $1 billion. Sediments can clog drainage ditches and irrigation canals and decrease the capacity of water reservoirs, thus increasing their maintenance costs. In addition, sediments can damage or entirely destroy fish-spawning areas. Sedimentation of rivers and streams reduces their capacity to carry water and increases the danger of flooding and consequent damage to property and to human health.

The presence of suspended sediments in water increases its turbidity (a measure of water clarity). Under certain conditions, common in sodic soils (e.g., high pH and Na levels), organic matter can dissolve in runoff water and enhance clay dispersion and mobilization, and hence increase water turbidity. Turbid water is less attractive for recreational activities and thus this reduces the value of the water. Turbidity also impedes the passage of sunlight through the water, thus negatively affecting biological productivity of the water. High turbidity in water bodies used for domestic consumption requires cleaning the water, which in turn causes an increase in their price.

An additional environmental hazard stemming from sodic soils is the transport of various contaminants by soil colloidal material, whether to groundwater or to surface water bodies via runoff. Metals which are usually fairly immobile in soil have a strong affinity to soil colloids and thus have been shown to move together with the mobile colloids. Similarly, insoluble pesticides and herbicides, and some nutrients (e.g., phosphate), have a high affinity for soil colloids and can thus be transported with the suspended solids to adjacent water bodies and groundwater. The increased concentration of suspended colloids in runoff water due to sodic conditions greatly increases the danger of higher than permitted loadings of these pollutants in groundwater and surface water bodies.

Conclusions

Many soils worldwide contain sodium at levels that may negatively affect their behavior, and should thus be considered sodic soils. The area occupied by sodium-affected soils is expected to grow due to increased use of poor-quality soils and water for agricultural production. The adverse effects of sodic conditions on soil physical and hydraulic properties are aggravated when the soil is exposed to good (i.e., low EC) water and aggregates are slaked. Productivity of sodic soils is likely to decline, not only because of physical soil degradation but also because of nutritional imbalances, especially with respect to nitrogen and Ca. Sodicity enhances runoff and soil erosion, which lead to both on-site (cultivated fields) and off-site (environmental) damages. However, sodium-related soil degradation and loss of productivity are, to a certain degree, reversible as sodic soils can be reclaimed by the addition of amendments or by excessive leaching. Realization of sodicity hazards and consequent adoption of proper management tools allow for a safe and sustainable use of sodium-affected soils, without the danger of them being abandoned.

Introduction

The dominant distinguishing feature of the Earth, in comparison with all other celestial bodies we observe, is the presence of life. Humans, as a part of life on Earth, attempt to understand all of the life system, albeit from an anthropocentric perspective. James Lovelock proposed a perspective that was unsettling to some and appealing to others when he suggested that the entire Earth may be functioning as a living organism. As our integrative understanding of living systems within the soil–plant–atmosphere continuum (SPAC) grows, the idea that a whole ecosystem can function as a living entity becomes more acceptable.

Consider a terrestrial ecosystem on land: The most essential ingredient for life on Earth is water and most of the water is not on the land. However, a rapid, long-distance system for transporting water from oceans to land is available through the atmosphere, much like the xylem system in a tree, which transports water long distances (relative to cell sizes) from the soil to the leaves high above the ground. This long-distance atmospheric transport system is driven unceasingly by the uneven, solar heating of the Earth. On the land, where many organisms reside, water moves much more slowly through the soil than through the atmosphere and this provides an essential storage reservoir that maintains the critical continuous flow of water to plants in the presence of fluctuations in the atmospheric supply. The rapid atmospheric transport system that is so critical to moving water from the ocean to the land also fluctuates wildly over the life span of most organisms. The combination of a low-storage, highly fluctuating system for rapid global transport in the atmosphere and a large-storage, stable, low-flow buffer in the soil redistributes water over the Earth to sustain life on land. This is a highly structured system like an organism. Furthermore, the living systems exert a strong influence on this larger system to enhance their functioning, just as we humans modify our environment to improve our lot.

Water is the most obvious component of the SPAC, and the interaction of this water with energy is the cornerstone of our understanding of how life interacts with its environment. Every schoolchild learns the water cycle: evaporation of liquid water from surfaces supplies water vapor to the atmosphere, where air currents lift this water to heights that cool it and cause condensation of the water vapor back to the liquid form of droplets, which fall back to the Earth to be recycled. The extraction of energy from the surface as a result of evaporation and the release of energy to the atmosphere by condensation represent the primary means by which the energy from the sun ultimately warms the atmosphere. This 'latent heat,' which is associated with the change of phase of water between liquid and vapor states, and not a temperature change, provides the key feedback between water and energy cycles that stabilizes the soil–plant–atmosphere system, permitting it to sustain life.

Materials such as water flow through the ecosystem seamlessly, moving from place to place, serving innumerable functions, and consuming or releasing energy to achieve a phase suitable to the medium that contains it. This is the SPAC; 'continuum' here does not refer to the material storage forms so apparent to our eyes such as plant leaves or roots, lakes, raindrops, the soil itself, or even the air we breathe; rather it refers to the unimpeded flow of many forms of material and energy throughout an elegant system

for sustaining life on land. Animals are as much a part of this system as plants, but in this article plants are our emphasis. This ceaseless flow of material and energy sustains life at every level; from the molecular interactions that sustain and mutate the genetic 'memory,' to cellular processes that make up whole organisms, to the global level of a living, breathing planet.

Living systems cycle matter through the SPAC and themselves to create and maintain their structure and extract energy for powering their life functions. All material necessary for sustaining life is cycled on all spatial levels from subcellular to global. The connectedness and functioning of the SPAC can be illustrated by reference to water, the most critical mass constituent to life on Earth. However, understanding the SPAC through water will necessarily involve some considerations of at least carbon and energy.

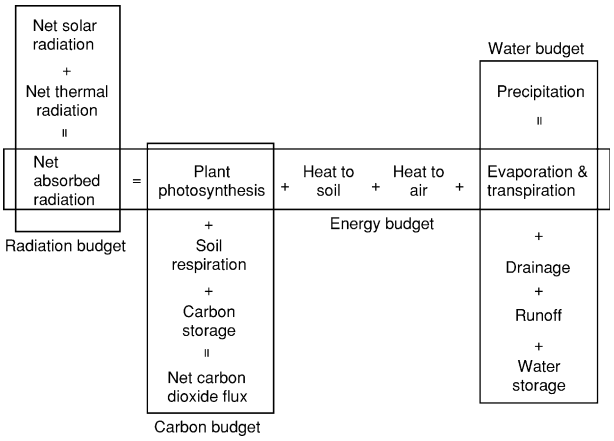

Figure 1 The interlocking energy and mass budgets for water, carbon, and energy in the soil–plant–atmosphere continuum. Altering individual components can cascade through the system and affect many seemingly unrelated factors.

Fundamental Principles

Two general principles are indispensable for studying the SPAC: (1) the conservation principles that take the form of mass and energy 'budgets,' and (2) the transport principles that relate the flow of some quantity to the difference or gradient of other quantities that influence or 'force' the flow and describe the 'state' of the exchange process.

The principles of conservation of mass and energy are the backbone of integrative studies of the SPAC. Because mass and energy can take many forms as they move throughout the SPAC, and even interact with each other, budgets are constructed to quantify the important stores and flows of important life-enabling constituents such as water, carbon, or energy. A budget is simply the application of the conservation principles (mass or energy) to a specific system that must be carefully defined. This system may be defined as a leaf, a community of plants, or even the entire Earth. Like balancing a bank account, a budget is a formal statement of the following: Incoming quantity minus outgoing quantity equals the increase in storage of the quantity in the system. In the case of water (W), carbon (C), and energy (E), the budgets become the following (Figure 1):

$$W_{IN} - W_{OUT} = \Delta W$$

$$C_{IN} - C_{OUT} = \Delta C$$

$$E_{IN} - E_{OUT} = \Delta E$$

The intertwined budgets of water, carbon and energy inflow, outflow and storage within the soil–plant–atmosphere system are shown in Figure 1. Understanding the SPAC through the role of water will involve simultaneous consideration of carbon and energy budgets on a spatial scale appropriate for living systems.

Consider the energy budget: Energy can exist in many forms as it flows through the soil–plant–atmosphere system, and the energy budget represents a way to keep track of the energy, no matter what its form. The rate of energy flow (joules per second = watts) per unit of area (meters squared) is a convenient way to describe the energy budget for a particular land area, because the size of the area does not matter and the emphasis can be on the energy exchanges. The radiant energy from the sun and surroundings can be absorbed by a leaf (this is referred to as the net radiation) and be transformed to the following: (1) sensible heat energy that is convected away from the leaf by moving air that is cooler than the leaf; (2) latent energy in molecules of water that are converted from liquid to vapor inside the leaf as they are transpired (evaporated) from the leaf; and (3) biochemical energy in the form of organic compounds such as sugars and starches created through photosynthesis and other physiological processes to sustain life. These components of the leaf energy budget are shown in Figure 1.

The transport principle simply states that the flow of some quantity such as water is equal to an appropriate 'driving force' divided by a resistance to transport exerted by the various media through which the quantity moves. The transport principle is more difficult to use than the conservation principle because the 'driving forces' and transport resistances depend on the characteristics of the system and mechanism of transport. For example, the diffusion of liquid water

depends on the water potential difference across a hydraulic transport resistance, whereas the transport of water vapor depends on the water vapor pressure difference across a diffusive transport resistance. In addition, movement of liquids or vapor by mass flow is 'driven' by pressure differences across transport resistances. In general, diffusion is an effective mode of transport over small distances, but mass flow can move materials and energy over longer distances. Heat transport is driven by temperature differences. The relevant thermal resistance depends on whether the heat is moving through a solid such as soil (conduction, which is analogous to diffusion), or through a moving fluid such as air (convection, which is analogous to mass flow and is a much more rapid transport mechanism than diffusion). Heat transport by radiation depends on still-different formulations. Thus much research on the SPAC relates to determining appropriate transport resistances and state variables for characterizing the flow of important quantities throughout the system. A complete understanding of this soil–plant–atmosphere system is a formidable task, but such an understanding will improve the ability of humans to make choices that will sustain a diverse and resilient ecosystem, upon which our survival depends. The fundamental concepts of energy and mass conservation and transport relations constitute the theoretical backbone of environmental biophysics (the study of the SPAC).

Water in the Soil–Plant–Atmosphere-Continuum

The smallest spatial scale that is usually associated with the SPAC is a field plot (square meters to thousands of square meters) from the bottom of a root zone (a few meters deep) to a few tens of meters above the top of the vegetation. Although individual studies may use smaller systems such as individual leaves or potted plants to reveal mechanisms, the scale of at least a small field is required to encompass most of the essential components of the natural SPAC and yet be accessible to direct measurement. Researchers generally use formulations nearly identical to those measured in field plots to represent idealized patches of the Earth's surface thousands of square kilometers in size; then they combine these patches to understand better the human influence on global climate processes. Typical time scales for small-scale studies vary from minutes to months or even years. On these spatial and temporal scales, researchers attempt to measure all the important flow and state variables, which are used to validate models that can be applied in systems that cannot be measured directly. After all, society cannot afford to measure everything everywhere, but will support measuring some things in many places and many things in a few places.

The transport and storage of water in the SPAC are shown in Figure 2. The flow of liquid water from the soil into the plant depends on the plant having a lower water potential than the soil; thus the soil water potential determines the availability of soil water for diffusion into the plant. The water potential is the amount of energy (joules) that can be obtained from moving a mass of water (kilograms) to a pool of pure water at atmospheric pressure and specified elevation; and in the soil and plant it is usually negative, indicating that energy must be expended to remove the water. As soils dry, the water potential decreases, making it more difficult for plants to obtain the water they need to grow. The soil water potential is related to the water content of the soil through the 'moisture-release curve,' which varies from soil to soil. Moisture-release curves have been measured for many different soil types. Typically soils can provide an amount of water to plants from storage that is equivalent to 5% (sands) to 20% (silt loams) of the plants' rooting depth. Thus for a plant rooted to a depth of 1 m, soils can provide approximately 50–200 mm of water to the plant. With evapotranspiration rates of 2–10 mm day^{-1}, soils can store enough water to sustain plants for a month or more without rainfall or irrigation.

Once water enters the plant through its roots, it moves through the plant vascular system to the leaves if the leaves have lower water potentials than the roots. Since the transport resistance to mass flow in the stem xylem is usually less than the transport resistance to diffusion through the root, and the flows through both root and xylem must be equal according to conservation principles, the water potential difference from the soil to the root xylem will usually be greater than the water potential difference from the root xylem to the leaf.

Water is lost from plants through pores in the leaf surfaces, called stomata. Evaporation from cells just below the stomatal pores draws water from the leaf cells, which in turn are hydraulically connected to a continuous water column down to the roots. As water is transpired through the stomata, additional water is drawn through the xylem to replace it, very much like suction applied to a straw in a soda. Of course, this evaporation that occurs just below the leaf surface consumes most of the Sun's energy that is absorbed by the leaf, because water vapor molecules carry away latent energy that was not contained in the liquid water that came up from the roots. While the flow of liquid water from the soil to the leaf is proportional to water potential differences, the flow of water

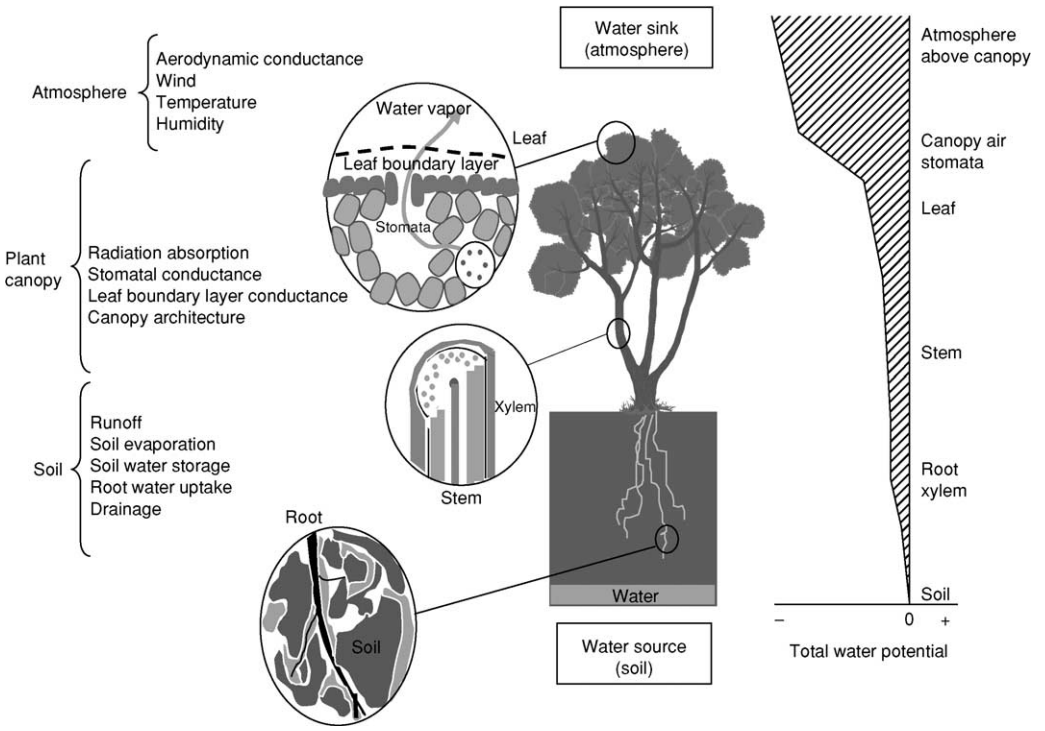

Figure 2 Water movement and storage in the soil–plant–atmosphere continuum. The graph on the right indicates the decrease in water potential that occurs as water moves from the soil to the atmosphere. On the left the three components of the soil–plant–atmosphere system are listed with the major factors for each that should be considered in a model of intermediate complexity.

vapor from inside the leaf to the leaf surface is proportional to water vapor pressure differences. At the interface, a near-equilibrium exists between the liquid water and the water vapor in contact with it. Although different processes are used to describe water movement in different parts of the system, the flow of water is continuous across these discontinuities of processes.

A very small amount of the water that passes from the soil to the atmosphere through the plant remains in the plant as storage as the plant grows (less than 5%). An even smaller amount of the hydrogen and oxygen in the water taken up from the soil remains in the plant in the form of organic molecules synthesized by the plant.

Water that exits the stomata must pass through a thin, still-air layer adjacent to the leaf, called the leaf boundary layer, and be transported through the canopy space by turbulent mixing along the path of decreasing water vapor pressure. Ultimately the water vapor exits the plant canopy, passes through the planetary boundary layer in the lower few thousand meters of the atmosphere, and is lifted high into the atmosphere, where it condenses into clouds and eventually falls back to the Earth as precipitation to repeat the cycle.

Small-Scale Observations and Model Building

In plant-environment studies, research derives and validates the transport principles on small, manageable systems in the laboratory or in field plots where direct measurements are possible. These principles are then applied at the ecosystem and global levels, where direct measurements are not possible, to obtain estimates of the important flow or state variables to quantify human impacts.

Consider the measurements that are necessary to understand the cycling of water in the SPAC. Precipitation falls on a field and either runs off the soil surface to streams or infiltrates into the soil itself (studied in the discipline of hydrology). The infiltrated water may be stored in the soil matrix (soil physics), evaporated from the soil surface (micrometeorology), transpired from plants (plant physiology), or drain below the plant root zone. Water that drains below the plant roots becomes part of the groundwater system (hydrogeology) and may reenter rivers (hydrology). Plants are sustained by the water stored in the soil, and the quantity of this storage depends on the type of soil. Nearly all the water taken up by plants is transpired to the atmosphere at a rate that

depends on solar radiation absorbed, weather variables, and the amount of vegetation. The amount of vegetation is estimated from the fraction of ground area covered by plants (vegetative cover). By keeping track of the daily water budget (Figure 1 and Table 1), the amount of water stored in the soil can be estimated, and in turn the influence of this stored water on direct evaporation from the soil and plant transpiration (together referred to as evapotranspiration) can be quantified. The maximum amount of water available to plants depends not only on soil properties, but also on plant rooting depth. Plant physiologists have measured rooting depths for the major classes of vegetation so that, given vegetation type and soil maps, the amount of water available to the plants for growth and transpiration can be estimated.

Table 1 contains an example of a 40-day-long water budget for a corn crop that begins about a month after emergence, during the period when the crop is growing rapidly. The incoming solar radiation column represents the maximum amount of evapotranspiration that could occur if all the solar radiation were used to evaporate water; of course some

Table 1 Simulation of corn growth and water use from 31 to 70 days after emergence, during a rapid growth phase. The solar radiation is in units of millimeters per day of evaporation that could occur if all solar radiation were to evaporate water. Vegetative cover increases as the crop grows and crop biomass increases. Soil evaporation tends to decrease as the soil surface dries out after rainfall and as vegetative cover increases; evapotranspiration (transpiration plus soil evaporation) exceeds rainfall so soil water storage is gradually depleted

radiation is reflected so the actual evapotranspiration is the sum of the transpiration and direct evaporation from the soil, which is approximately one-third of the maximum possible evapotranspiration. The maximum amount of water that can be stored in the rooting zone of the soil is 200 mm for this soil, and clearly the corn crop is using water faster than the rainfall is replenishing it, so that at the end of 70 days of growth approximately half of the maximum soil water storage has been used up. At this point the water depletion in the soil will begin to cause the growth rate of the corn to decrease unless there is more rainfall. This buffering capacity of soil is crucial to growing crops in continental climates all over the world.

Measurements of water transport and storage are difficult and expensive to make, so they can only be done at a few sites under a few conditions. Models that capture the fundamental conservation and transport principles are therefore essential to applying results of limited SPAC studies to a wider range of conditions than could possibly be measured directly. A wide array (hundreds) of computer models are available for quantifying the role of water in the SPAC and the range of applicability of such models depends on having a minimal, faithful representation of critical factors in each component of the SPAC; namely in the soil, the plant, and the atmosphere. SPAC models can be divided into three classes: simple, intermediate, and complex.

Simple SPAC models are the easiest to create, generally emphasize the knowledge base of one discipline with a narrowly focused purpose, and are the most limited in applicability. For example, the Simple Inverse Yield Model, for precision agriculture, and the CERES Maize model, for crop yield and water-use prediction, neglect the effect of vegetation roughness and wind on evapotranspiration, reflecting their agricultural roots and limited applicability. There is also a simple micrometeorological model of evapotranspiration that omits soil processes, reflecting its atmospheric origins and limited applicability.

Intermediate SPAC models incorporate at least a minimal consideration of key soil, plant, and atmospheric components to provide wide applicability without undue complexity. These intermediate models incorporate atmospheric factors (radiation, wind, temperature, humidity, and precipitation), vegetation factors (plant type, vegetative-cover fraction and height, rooting depth), and soil properties (soil evaporation, root-zone water transport and storage). Examples of Intermediate SPAC models include the Two-Source Model, for remote sensing applications, and the ALEX (atmosphere–land exchange) model, for local site-specific studies.

Complex SPAC models incorporate most of the processes known to be important at small (leaf to field) scales, and can be applied to a wide range of cover types and climatic conditions. Because they are very detailed, they generally involve a large array of coefficients related to specific plant and soil types. For this reason, complex models are often not well-suited to regional scale applications, where these myriad of parameters need to be defined at all locations. The greatest value of complex SPAC models lies in improving our understanding of key processes and using this knowledge to derive intermediate models with the fewer parameters and wider applicability.

An example of this use of a complex SPAC model is the derivation of the Two-Source and ALEX models from the complex Cupid model. The Cupid model predicts plant–atmosphere exchanges of carbon, water, and energy in a very detailed mechanistic way, and it requires dozens of species-specific coefficients related to plant physiology. By studying the behavior of the Cupid model, the ALEX model could be created using only a few carefully chosen physiological coefficients and yet achieve a surprising level of generality compared with Cupid. Not only does ALEX link growth and water use in a way nearly as fundamental as Cupid, but it does so with a widely used 'light-use efficiency' coefficient that is already tabulated for most vegetation types around the world. The result of this process is a robust model suitable for continental-scale applications.

Complex SPAC models have also been used to study the relation between the architecture of vegetation canopies and their remotely sensed signatures from aircraft and satellites. Since remote sensing is the only way to characterize vegetative cover on the regional and continental scales, we must understand how to interpret remotely sensed land observations to accommodate the profound influence of vegetation density on energy and material exchanges in the SPAC. For example, in Table 1, the increased importance of transpiration (and extraction of soil water to great depths by plant roots) over evaporation from the soil (water extraction to only a few centimeters of soil depth) is apparent as the vegetation cover increases from 17% to almost 90% during the 40 days of growth.

Determining the level of complexity appropriate for an application depends on the objective of the endeavor; typically, the simplest model that provides adequate results is the model of choice. Our understanding of energy and water flows in the SPAC is sufficiently well developed to extend this knowledge to larger scales, where direct measurements are only rarely, if ever, possible and evaluate implications of human activities on ecosystem health.

Application to Regional and Global Scales

The impact of humans on the global ecosystem has become so profound that extending our understanding of biophysical processes from small fields to whole regions is becoming critical for our survival. The extension of process-level understanding of energy and material flows in the SPAC to larger scales imposes a severe constraint that is not present in plot-scale studies; namely, that the allowable input quantities are limited to state variables that can be monitored over large areas. Only a few state variables are routinely measured widely in networks across the world and thus can be considered generally available for monitoring the SPAC. For example, near-surface weather variables (air temperature, humidity, wind speed and direction, precipitation, and cloud cover), solar radiation, atmospheric carbon dioxide, soil maps, vegetation-type maps, river and stream monitoring, and satellite images are routinely obtained at many locations in many countries of the world. This means that these are the main quantities that can be assumed to be generally available everywhere (not always true, but a reasonable assumption). All other inputs required for SPAC models must be computed from fundamental principles or from quantitative relations derived from validation experiments at small scales. This pursuit has been exceedingly challenging, but systematic research over decades in numerous disciplines has identified many of the critical processes, and integrative computer modeling has synthesized much of this information so that monitoring water transport and storage on continental scales may now be possible.

Consider an example of a suite of models that has been assembled to explore systematically the energy and material flows in the SPAC over a range of scales from small fields to the continental USA (Figure 3).

At the heart of this suite of models is a pair of Intermediate SPAC models; namely ALEX for computing in the forward direction and the Two-Source Model for inverse computation using satellite observations as inputs. When the sky is cloudless for a few hours in the morning, operational satellites can be used to quantify vegetative cover and monitor surface temperature to estimate the surface flows of

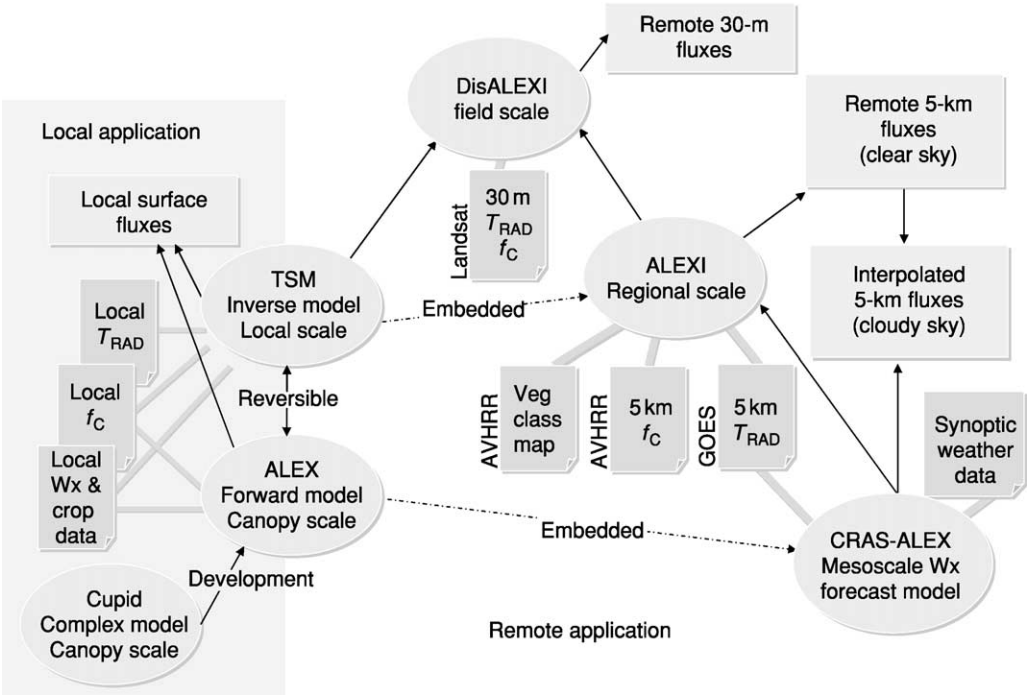

Figure 3 Suite of models for estimating evapotranspiration on large spatial scales (remote application) based on measurements from studies on small fields (local application). Cupid, the Atmosphere–Land Exchange model (ALEX), and the Two-Source Model (TSM) are used on the field scale and require inputs that can be directly measured in field studies. ALEX Inverse (ALEXI) disaggregation ALEXI (DisALEXI), and CRAS-ALEX (Cooperative Institute for Meteorological Satellite Studies (University of Wisconsin) weather forecast model) are used on the 5- to 10-km-grid scale for continental-sized applications, and they require inputs from satellites (Landsat, AVHRR, or GOES) or national weather measurement networks (synoptic weather data). The TSM is used at the local scale, embedded in ALEXI for use at the continental scale, and used in DisALEXI for remote estimates at the large field scale; likewise, ALEX is used at the local scale and also embedded in the weather forecast model for use on the continental scale. GOES, geosynchronous operational environmental satellite; AVHRR, advanced very-high-resolution radiometer satellite; T_{RAD} radiometric temperature; f_C, fraction of vegetative cover on the ground; Wx, weather.

energy and water at the 5- to 10-km scale and larger using the atmosphere–land exchange Inverse ALEXI model (Figure 3). ALEXI is a combination of the Two-Source Model and a meteorological model of the behavior of the lower 2000 m of the atmosphere (the planetary boundary layer). The ALEXI model can be used to update a mesoscale weather forecast model wherever a cloudless morning occurs. Likewise, the weather forecast model can be used to interpolate quantitites used in ALEXI whenever the satellite view is obscured by clouds. Mesoscale weather forecast models capture important feedbacks between land and atmospheric processes so that, as humans change the land characteristics, these models consider how these changes may affect subsequent weather. Meteorologists have refined these mesoscale models for decades and can now capture the transport of quantities from spatial scales of approximately 10 km and time scales of minutes to continental spatial scales over days, months, or even years of time.

The combination of the mesoscale model and ALEXI can yield time-continuous maps of the flow of water and energy in the SPAC at scales of 5–10 km and larger. How can the accuracy of such estimates be validated? Two methods have been used: (1) the use of research aircraft in intensive field experiments, and (2) the application of a disaggregation technique (DisALEXI), which uses data from a high-spatial-resolution satellite (such as Landsat, with a 30-m spatial resolution) to disaggregate 5- to 10-km ALEXI flux estimates to the spatial scale of in situ ground measurements (hundreds of meters) based on micrometeorological methods such as eddy covariance. Not only can the DisALEXI model assist with validation of the ALEXI model, but it can be used to update crop growth and water-use models in agriculture by providing occasional independent estimates of the flow of energy and water on the fine spatial scale of 30 m.

This process of using fundamental principles to infer global implications of plot-scale measurements reminds one of a statement Mark Twain once made: "There is something fascinating about science. One gets such wholesale returns of conjecture out of such a trifling investment of fact." Clearly the power that fundamental principles give scientists to extend the influence of humans is difficult for nonscientists to comprehend.

Institutional Issues

Studies of the SPAC are interdisciplinary (involving research in areas that are not claimed by existing disciplines) and multidisciplinary (requiring collaboration among scientists from numerous disciplines). For example, to understand the influence of vegetation on weather forecasts involves the following activities: meteorologists study the effect of the surface energy and water exchanges on the lower few thousand meters of the atmosphere called the planetary boundary layer; physiologists characterize the dependence of photosynthesis and stomatal processes on atmospheric and soil environmental factors; soil scientists measure the heat- and water-holding characteristics of the soil as well as carbon-exchange processes; micrometeorologists relate vegetation-canopy characteristics and atmospheric variables to the exchange of heat, mass, and momentum with the atmosphere; and hydrologists consider the runoff characteristics of the soil surface and the recharge of groundwater by percolation. The study of vegetative-canopy architecture, within-canopy processes, and the interaction between remote sensing and vegetative cover are key interdisciplinary areas that are not associated with any particular discipline.

Most scientific research is funded by government agencies and conducted within a disciplinary structure of research establishments or universities; therefore, competition among disciplines for funding and the limited perspective of individual researchers mitigate against developing an integrated view of the SPAC. Although much lip service has been paid to the value of interdisciplinary and multidisciplinary research, no sustaining structure in the research establishment is apparent for such integrative activities, and progress continues to be dominated by ad hoc efforts from committed individuals or teams with determination and vision. One strategy that has been most valuable in recent decades is the organization and execution of large, international, multidisciplinary, intensive field experiments, with broad objectives that appeal to scientists in many disciplines. The wide distribution of and open access to data from such experiments have been responsible for tremendous gains in understanding of the SPAC in recent years. Two examples of such experiments are the First ISLSCP (International Satellite Land Surface Climatology Project) Field Experiment (FIFE) in the grasslands of Kansas, USA, and the Boreal Ecosystem Atmosphere Study (BOREAS) in the Canadian boreal forest.

The time-honored reductionist perspective of 'changing a single variable and holding all other factors constant' is not possible in holistic studies of the profoundly interconnected SPAC. Instead the challenge of exploring important processes without the constraints of limiting paradigms and parochial disciplines must be confronted, a formidable challenge for environmental scientists. Efforts to synthesize knowledge from various components of the SPAC into a holistic view continue to be challenging

in a scientific world dominated by technological reductionism. The view of the Earth as a complex, self-organized system gains wider acceptance as our knowledge of the interconnectedness among components of the SPAC improves.

SOLUTE TRANSPORT

Introduction

The movement of chemicals in soils and groundwater aquifers (solute transport) plays a central role in global biogeochemical cycling. Human activities have placed many new chemicals into the environment and greatly enhanced the local loading of wastes to the subsurface. Obvious applications of an understanding of solute transport in porous media include the efficacy and fate of agricultural chemicals (fertilizers and/or pesticides); the treatment and disposal of wastewaters and wastewater treatment products from human, animal, and industrial sources; and contamination resulting from landfills, mining operations, industrial activities, high-level radioactive waste disposal, etc. Given its great importance in the maintenance of safe water supplies, the nourishment

of plants, regulation of the fate of soil-applied chemicals, and many other critical hydrologic processes, solute transport has long been the focus of intense research in soil science, groundwater hydrology, and chemical engineering. Nevertheless, our *a priori* capability to predict solute transport remains limited.

Pores may contain water, soil gases, and/or introduced materials such as nonaqueous-phase liquids. Chemicals can be transported in any or all of these three fluid phases. The general aspects of transport are similar in each potential phase so the emphasis here and in much of the solute transport literature is on the transport of chemicals in aqueous solution. A solute is a chemical that is dissolved in a solvent to form a solution.

Three mechanisms operate to transport solutes in soils and aquifers. 'Advection' (or synonymously 'convection' in the solute transport literature) refers to the movement of chemicals with soil fluids and groundwater. Advection often dominates the solute transport process. Diffusion is the omnidirectional spreading of a chemical that results from thermal (Brownian) motion of the fluid and solute molecules. Dispersion results primarily from variations in fluid velocity that occur at all scales. Dispersion is anisotropic and enhanced in the overall direction of flow.

Breakthrough curves display the variation in solute concentration as a function of time or distance. These measurements and the advection–dispersion equation are the primary tools used in the evaluation of solute transport.

Solutes can interact strongly with soil surfaces by physical or chemical adsorption and their transport can be appreciably slowed in a process known as retardation. Repulsion or exclusion of solutes from soil surfaces can result in transport more rapid than that of the carrier fluid.

Transport Processes

Advection

In the most simplistic sense, dissolved solutes are carried along with moving soil fluids. Here, 'fluid' refers to either a gas or a liquid phase; simultaneous treatment of interacting gas and liquid phases requires coupling of the treatment described below. A fluid flowing through a porous medium at a flux q (volume of fluid per unit area of soil per unit time) with a solute concentration C (mass of solute per unit volume of fluid) carries with it a solute flux $\mathbf{J}_c = qC$ (mass of solute per unit area of soil per unit time). The mean velocity of the flow v (and the solute, assuming no losses, production, or interaction with the solid phase) can be computed from knowledge of the flux $\mathbf{q}$ and the volumetric fluid content θ via $\mathbf{v} = \mathbf{q}/\theta$. Under steady flow, $x = vt$ (where v is the magnitude of $\mathbf{v}$), and the distance x traveled by an average solute molecule in time t, or the time t needed for the solute to traverse a given distance x, can be calculated. The advective solute flux J_c can also be written in terms of the mean velocity, the concentration, and the fluid content: $J_c = v\theta C$. In some instances, for example when the solute source is continuous and the solute concentration is uniform in the flowing fluid, advection dominates the solute transport process and may be the only process that need be considered.

Diffusion

Diffusion is the spreading of a solute due to thermally induced Brownian motion. It is generally considered to be omnidirectional and driven by concentration gradients according to concentration-independent coefficients, though close study reveals that it is more complicated when solute concentrations are high. Under the typical assumptions, diffusion can be treated with Ficks first law, which gives the diffusive solute flux J_s as a function of the concentration gradient ∇C and the bulk diffusion coefficient D_b, i.e., $J_s = -D_b \nabla C$.

In soils, the diffusion paths are obstructed by solid particles and solutes are constrained to follow the tortuous, connected pore network. The connected network changes as the fluid content changes. The effective diffusion coefficient D_e must therefore be computed from the bulk diffusion coefficient and the soil water content and porosity. A commonly used empirical expression for the estimation of the effective diffusion coefficient is $D_e = D_b\theta^{10/3}/\phi^2$, where ϕ is the porosity.

Dispersion

Consideration of saturated water flow in perhaps the simplest possible pore geometry – a straight capillary tube with circular cross section – provides insight into the processes that take place in the more tortuous and convoluted pore networks that characterize natural porous media. The velocity of fluid in such a tube depends on the pressure drop between the ends of the tube (a distance L apart), the tube's radius r, and the dynamic viscosity η. In general, the velocity is not uniform across the tube's cross section. In the laminar flow regime, generally thought to apply to water movement in most soils, the velocity profile in a capillary tube is parabolic:

$$v(y) = 2v\left(1 - \frac{y^2}{r^2}\right) \quad [1]$$

where $v(y)$ is the velocity as a function of radial distance y from the tube center.

The mean velocity v can readily be determined from Stokes law in the form:

$$v = \frac{r^2 \Delta P}{8\eta L} \quad [2]$$

According to this model, the maximum velocity at the center of the tube ($y = 0$) is $2v$, and there is zero velocity at the tube's inner surface ($y = r$).

A solute introduced at concentration C_0 at the upstream end of the tube at time zero ($t = 0$) will be convected rapidly in the center of the tube and more slowly near the tube's surface (Figure 1). Taking integrated samples from various cross sections along the tube at a later time ($t > 0$) results in the collection of fluid containing no solute and fluid containing solute at the introduced concentration C_0 in various proportions. Dilution of the solute with solute-free fluid in the sample occurs according to the relative cross-sectional areas of the solute paraboloid and the solute-free fluid. Thus, the solute front is spread out or dispersed.

In addition to the dispersion introduced by velocity variations within individual pores, the variable sizes and path lengths of pores in a natural porous medium and mixing at pore intersections also contribute to dispersion. Buoyancy factors may cause fingering and attendant mixing of a dense solution into a less-dense one. If the dispersion arises from such velocity and path-length variations, and hydrodynamic mixing alone, it is referred to as 'hydrodynamic dispersion.' The impact of variable velocities, path lengths, and mixing accumulates through the entire hierarchy of scales pertinent to the particular porous medium under consideration. Unsaturated conditions found in most soils generally add additional complexity to flow fields within individual pores and increase the tortuosity. Hence, the degree of dispersion is usually greater under partially saturated conditions than in the fully saturated case.

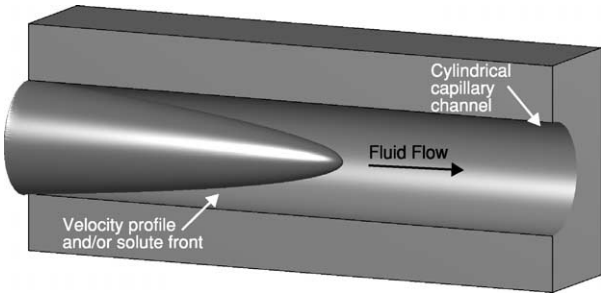

Figure 1 Schematic velocity profile and/or solute front position in an idealized cylindrical capillary tube. Flow from left to right.

Diffusion results in a spreading of solute fronts similar to that induced by dispersion. It is generally not possible to separate out the effects of diffusion and dispersion. They are typically considered to be additive with a lumped diffusion–dispersion coefficient D_d given by $D_d = D_h + D_e$, where D_h is the coefficient of hydrodynamic dispersion. The diffusive–dispersive solute flux $\boldsymbol{J}_d$ is then treated assuming a Ficks law-like formulation: $\boldsymbol{J}_d = -D_d \boldsymbol{\nabla} C$.

The diffusion–dispersion coefficient has been notoriously difficult to estimate *a priori* and is generally determined via inverse modeling. Excellent computer programs for its determination from transport measurements are available. However, this reliance on measurements of the actual transport process for parameter estimation is unfortunate, because the measurements are difficult and time-consuming, and can rarely be carried out at the scale of interest.

Inside a pore, the dimensionless Peclet number ($Pe \equiv vl/D_b$, with l a characteristic length) indicates the relative importance of diffusion and advection; large values of Pe indicate an advection-dominated process, while small values of Pe indicate the dominance of diffusion. Similarly, the dimensionless diffusion–dispersion coefficient $D^* \equiv D_d/D_b$ reflects the relative importance of hydrodynamic dispersion and diffusion. For porous media with well-defined characteristic lengths (i.e., bead diameter in packed beds of uniformly sized glass beads), D^* can be estimated from Pe. Different classes of behavior have been proposed based on the observed relationship between Pe and D^* (Figure 2). Class I is characterized by very slow flow and the dominance of diffusion. Class II is transitional, with approximately equal and additive hydrodynamic dispersion and diffusion. Hydrodynamic dispersion dominates the dispersion process in classes III and above. In class III, the role of diffusion is still nonnegligible, but it ceases to be significant in class IV. Finally, in class V, the velocity is so high that the flow of many fluids is turbulent.

Dimensionality

The dimensionality of the solute transport process is an important factor. In many soil science applications, for example the uniform application of a pesticide to the soil surface, the process can be treated as one-dimensional. However, in other instances two- or

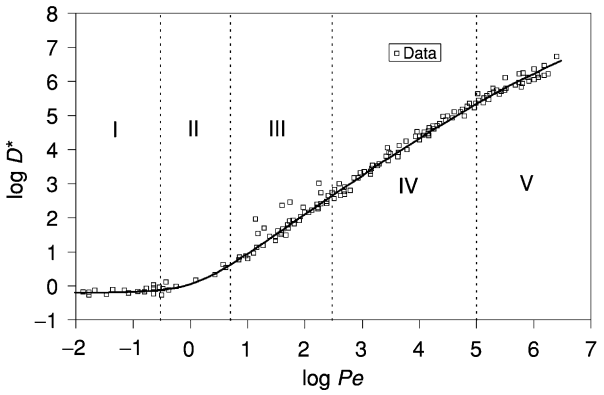

Figure 2 Empirical relationship between dimensionless dispersion coefficient (D^*) and Peclet number (Pe) with data for uniformly sized particle beds. Roman numerals indicate behavioral class (see text). (Adapted from Fried JJ and Combarnous MA (1971) Dispersion in porous media. *Advances in Hydroscience* 7: 169–282, with permission.)

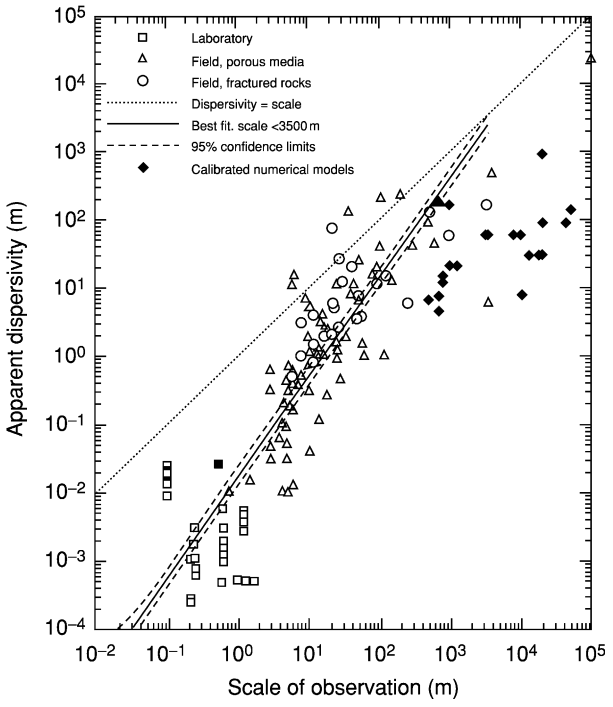

Figure 3 Apparent dispersivity versus scale for laboratory and field measurements. (Adapted from Neuman SP (1995) On advective transport in fractal permeability and velocity fields. *Water Resources Research* 31: 1455–1460, American Geophysical Union, with permission.)

three-dimensional aspects of the transport process cannot be neglected. The problem can be viewed in terms of the geometrical configurations of the source and sink of interest. In the case of uniform soil application, the source is considered planar and the sink may be a planar water table. In contrast, a chemical spill limited to a small area overlying a thick vadose zone may need to be considered a point source in a fully three-dimensional system where solute may be dispersed both horizontally and vertically.

Even in a flow field that is macroscopically one-dimensional, dispersion is an anisotropic process and is enhanced in the direction of flow relative to transverse directions. A fully three-dimensional treatment of dispersion therefore requires a tensorial representation. For simplicity, we will restrict our discussion of solute transport to one-dimensional flow, where the effects of dispersion are embodied in a single scalar, the longitudinal dispersion coefficient, and the related longitudinal dispersivity.

Longitudinal Dispersivity

The relationship between the one-dimensional diffusion–dispersion coefficient and mean pore-water velocity is frequently modeled with the empirical equation $D_d = m + \alpha v^n$, where m and n are fitting parameters, and α is the longitudinal dispersivity. In the hydrodynamic dispersion-dominated regime, the magnitude of m is negligible and n approaches unity. Under these conditions, the longitudinal dispersivity has dimensions of length and can be defined as $\alpha \equiv D_d/v$.

The dispersivity ideally would be a constant for a particular porous medium, and efforts have been made to relate it to other medium properties. In general, it has been observed that under saturated conditions the magnitude of the dispersivity depends upon the scale of the domain under consideration (Figure 3). The reasons for this scale dependency are unclear, but, at a macroscopic scale, the phenomenon may be related in part to spatial variations in the underlying saturated hydraulic conductivity field. New approaches for treating the relationship between α and scale have recently appeared and are described further below.

Another important influence on dispersivity under saturated conditions is soil structure, as influenced by differences in texture. In general, sandy soils have a narrower range of pore sizes and a smaller dispersivity than finer-grained soils. The combined effects of measurement scale and soil texture on α for soil columns (based on empirical relationships between dispersivity and soil hydraulic parameters and power law scaling of dispersivity with length) are shown in Figure 4.

Breakthrough Curves

Plotting the downstream changes in solute concentration against time at a fixed position or against distance from the source at a fixed time results in a

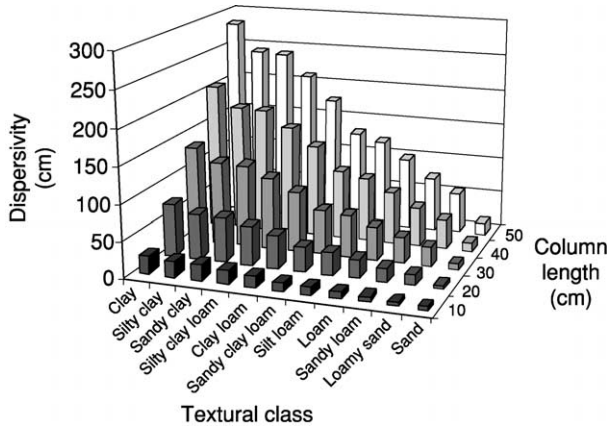

Figure 4 Approximate effects of measurement scale and soil texture on dispersivity for soil columns based on empirical relationships between dispersivity and soil hydraulic parameters and power-law scaling of dispersivity with length.

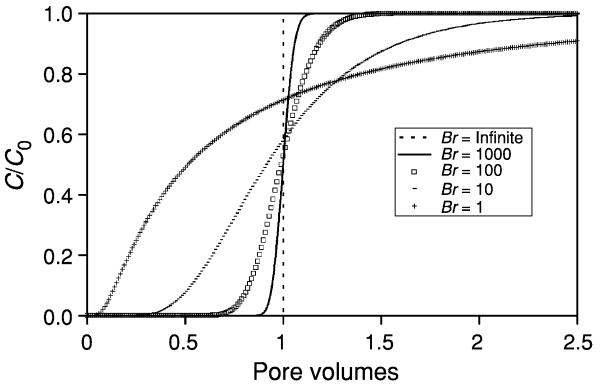

Figure 5 Effect of Brenner number (Br) on relative concentration (C/C_0) in column effluent for a step-change application of solute.

breakthrough curve. Breakthrough curves generated from a continuous source will be approximately sigmoidal (resembling a cumulative Gaussian distribution function) provided the Brenner (or column Peclet) number ($Br \equiv vL/D_d$, where L is the column length) is large enough. Complete breakthrough occurs when the effluent concentration (C) is equal to the influent concentration (C_0), giving a relative concentration $C/C_0 = 1$. If the solute is introduced as a short pulse, complete breakthrough may not be attained and the solute concentrations will eventually fall and return to background levels. In this case, a breakthrough curve will resemble a Gaussian density function for adequately large Brenner numbers. Small Brenner numbers (usually due to short columns or high dispersion coefficients) result in asymmetrical breakthrough curves.

It is common to plot breakthrough curves from soil columns as relative concentration against the number of pore volumes eluted from the column. Because the computation of eluted pore volume incorporates time and column length, it is a means of non-dimensionalizing the x-axis. The pore volume in a column of length L and cross-sectional area A is $LA\theta$. The volume of fluid eluted over time t is $At v\theta$. Thus, the number of pore volumes T eluted at any given time t is $(At v\theta)/(LA\theta)$ or $T = tv/L$.

This representation has instructive and conceptual benefits because, during piston-type flow where the solute front is not dispersed, it is fairly obvious that, after the input of one pore volume of solution containing solute at concentration C_0 into an initially solute-free column, the concentration of the effluent will immediately jump from $C = 0$ to $C = C_0$. This is shown in Figure 5 where it corresponds to the curve with infinite Brenner number. Decreasing the Brenner number (for example by increasing the dispersion coefficient or shortening the column) causes spreading of the solute elution. Some solute travels faster than the mean velocity and elutes before one pore volume of fluid has entered the soil, while some travels slower than the mean and elutes after one pore volume of fluid is injected. When the Brenner number is relatively high (Figure 5; $Br = 1000$ and $Br = 100$), the early- and late-arriving solute masses are approximately equal, and the breakthrough curve is approximately sigmoidal and well described by a cumulative Gaussian distribution. The value of C/C_0 at one pore volume on this curve is approximately 0.5; this is considered a hallmark of an 'ideal' solute transport process by many practitioners, with deviations calling for elaborate modifications to standard theory. Inspection of the gross asymmetry introduced by decreases in the Brenner number (Figure 5; $Br = 10$ and $Br = 1$) indicates that such deviations should be expected under many conditions. This effect is pronounced for solute pulses, and is perhaps somewhat counterintuitive in that smaller Brenner numbers (more dispersion) can actually lead to higher peak concentrations than larger ones (Figure 6; $Br = 1$ vs. $Br = 10$).

Adsorption and Exclusion

Adsorption of solutes on to soil solids generally causes them to move at a fraction of the velocity of the fluid. The most simplistic (and common) treatment of adsorption involves the assumption of a linear adsorption isotherm that relates the adsorbed concentration on soil solids (C_s, mass of solute per unit mass of soil) to the concentration in solution at equilibrium via $C_s = K_d C$, where K_d is the soil/water partitioning or

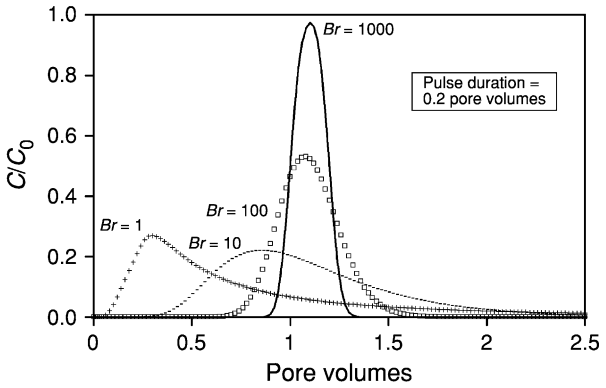

Figure 6 Effect of Brenner number on concentration in column effluent for a pulse application of solute. Pulse duration is 0.2 pore volumes.

distribution coefficient with dimensions $L^3 M^{-1}$. The linear isotherm is primarily applicable to low-solute concentrations and adsorption of a nonspecific physical nature.

K_d can be measured independently in the laboratory by mixing soil and solution and determining the equilibrium partitioning of the solute between the solid and fluid. In practice, however, the K_d of organic solutes is often estimated from the organic carbon partitioning coefficient $K_{oc}(L^3M^{-1})$ using $K_d = K_{oc} f_{oc}$, where $f_{oc}(MM^{-1})$ is the mass fraction of organic carbon in a soil. There are many tables of K_{oc} values available (e.g., Table 1) and f_{oc} is a commonly measured soil property. Solutes with low K_d values have a low affinity for soil surfaces and, for a conservative solute, $K_d = 0$. Other solutes can be strongly bound to soil and have very high K_{oc} and K_d values.

Exclusion, in which a solute is repelled from solid surfaces and hence concentrated in more rapidly flowing fluid away from pore walls, has also been observed. In particular, negatively charged anions are often excluded from negatively charged soil mineral surfaces. Thus, they may elute earlier from a column than the carrier fluid with which they were introduced.

Adsorption and exclusion phenomena are often incorporated into solute transport models through the use of a retardation factor, R, given by:

$$R = 1 + \frac{\rho_b K_d}{\theta} \qquad [3]$$

where ρ_b is the soil bulk density. For conservative solutes, $R = 1$, for sorbing solutes, $R > 1$, and, for excluded solutes, $R < 1$.

Figure 7 shows the effects of solute adsorption and exclusion relative to the breakthrough curve for a

conservative solute ($R = 1$, $Br = 10$, in Figure 7). The retarded curve ($R = 2$, $Br = 10$, in Figure 7) shows a considerable delay in solute elution. Note also that the degree of solute dispersion is enhanced, even though the dispersion coefficient itself is unchanged. Conversely, the curve representing anion exclusion ($R = 0.7$, $Br = 10$, in Figure 7) shows early elution of the solute and less dispersion of the solute front.

For a continuous source under piston flow conditions, the solute front advances without dispersion and the velocity of the front (v_s) relative to the mean velocity of the fluid is $v_s = v/R$. With moderate dispersion and adequate transport length, the front assumes a sigmoidal shape, and v_s represents the position of the front defined by $C/C_0 = 0.5$. For a pulse source, v_s characterizes the velocity of the solute center of mass. In some instances, these simple relations may be adequate for estimating the solute front position or peak arrival. However, dispersion can play a critical role in determining the peak concentration and its duration. Evidence suggests that brief exposures to high concentrations may be exceptionally detrimental to human health in some instances.

Advection–Dispersion Equation

The advection–dispersion equation (ADE, or convection–dispersion equation, CDE) has long been used as a model for solute transport. It can be derived from the flux terms described above (here taken as one-dimentional in the x direction) and a solute mass balance. The flux of solute due to convection is $J_c = v\theta C$, while the diffusive–dispersive flux is $J_d = -D_d \partial C/\partial x$. Combining these two fluxes, we have $J = J_c + J_d = v\theta C - D_d \partial C/\partial x$. Consider a volume of soil (Figure 8) and steady one-dimensional flow. If the inflow of solute mass at $x = 0$ and the outflow at $x = L$ are not equal, then mass must accumulate in or be lost from the soil volume. Assuming for the moment that the solute can only be stored in the fluid, then either the volume of fluid at a constant concentration – given by $AL\theta$ – must change, or the solute concentration (C) in a fixed volume of fluid must change. The dimensions of the volume AL are constant and, when the flow is steady, the fluid content θ is constant. Therefore, only the concentration can change. The time rate of change in solute mass inside the volume is $AL\theta\, dC/dt$.

The difference in the inflow and outflow of mass per unit time can be written as $(\text{mass}_{out} - \text{mass}_{in})/\Delta t$. The flux J is the mass per unit area and time, so an equivalent expression is $A(J_{x=L} - J_{x=0})$. The spatial rate of change in solute flux is $\partial J/\partial x$, and the difference between the outflow and inflow is $A[J_{x=0} - (J_{x=0} + L\partial J/\partial x)]$. Equating this difference to the change in the stored mass gives:

$$AL\theta \frac{\partial C}{\partial t} = A\left[J_{x=0} - \left(J_{x=0} + L\frac{\partial J}{\partial x}\right)\right] \qquad [4]$$

which readily simplifies to:

$$\theta \frac{\partial C}{\partial t} = -\frac{\partial J}{\partial x} \qquad [5]$$

Incorporating our earlier expression for the solute flux J, we have:

$$\theta \frac{\partial C}{\partial t} = -\frac{\partial \left(v\theta C - D_d \frac{\partial C}{\partial x}\right)}{dx} \qquad [6]$$

Finally, with D_d, v, and θ constant, the ADE is:

$$\frac{\partial C}{\partial t} = -v\frac{\partial C}{\partial x} + \frac{D_d}{\theta}\frac{\partial^2 C}{\partial x^2} \qquad [7]$$

Eqn [7] is often written with D_d/θ replaced by an apparent diffusion–dispersion coefficient D.

The ADE can readily be modified to incorporate adsorption by accommodating solute storage on the soil solids in addition to storage in the fluid phase. Thus, the storage term becomes $AL\theta C + AL\rho_b C_s$ or, in terms of the solute concentration in the fluid and assuming a linear isotherm, $AL(\theta C + \rho_b K_d C)$. Then Eqn [6] becomes:

$$(\theta + \rho_b K_d)\frac{\partial C}{\partial t} = -\frac{\partial\left(v\theta C - D_d\frac{\partial C}{\partial x}\right)}{\partial x} \qquad [8]$$

Note that this formulation also assumes that the adsorption equilibrium is attained instantaneously. Alternative derivations that remove this restriction are available. Removing the constants from the differentials and dividing by θ yields:

$$R\frac{\partial C}{\partial t} = -v\frac{\partial C}{\partial x} + \frac{D_d}{\theta}\frac{\partial^2 C}{\partial x^2} \qquad [9]$$

where R is the retardation factor given by Eqn [3].

Other isotherms, including the Langmuir (which introduces an adsorption maximum) and the Freundlich (which introduces a nonlinear concentration dependence), have been used to describe adsorption during solute transport. Realistic transport simulations of reactive species must often rely on considerably more complex, coupled reaction–transport models.

Many chemical species are susceptible to production or decay in the soil. Zero-order decay proceeds at a rate that is independent of the concentration of the substance where $\partial C/\partial t$ is a constant. First-order production and decay proceed at rates that depend on the concentration and follow $\partial C/\partial t = kC$, where k is the rate constant (T^{-1}). Such potential sinks and sources, as well as physical sinks (e.g., root uptake) can readily be incorporated into the ADE.

Estimates of the parameters in the ADE can be obtained by moment analysis of solute breakthrough curves. A number of analytical solutions for the ADE are also available. Depending on the concentration detection mode (column effluent or 'resident' pore water) the following solutions have been recommended for a step change in concentration from C_0 to C at time $t = 0$:

$$\text{Flux mode}: \frac{C}{C_0} = \frac{1}{2}\text{erfc}\left[\frac{Rx - vt}{2(DRt)^{\frac{1}{2}}}\right] + \frac{1}{2}\exp\left(\frac{vx}{D}\right)\text{erfc}\left[\frac{Rx + vt}{2(DRt)^{\frac{1}{2}}}\right] \qquad [10]$$

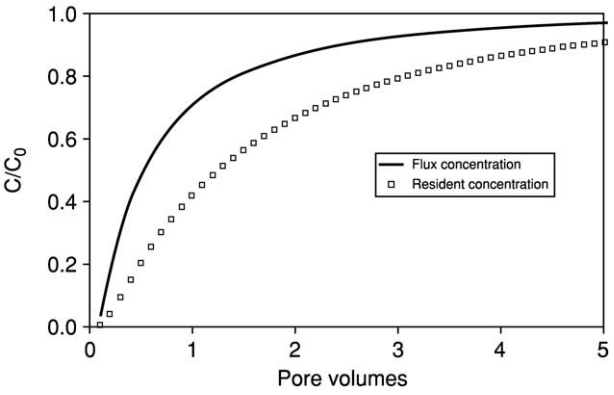

Figure 9 Effect of concentration detection mode on breakthrough curve at $Br = 1$.

$$\text{Resident mode}: \frac{C}{C_0} = \frac{1}{2}\text{erfc}\left[\frac{Rx - vt}{2(DRt)^{\frac{1}{2}}}\right] + \left(\frac{v^2 t}{\pi D r}\right)^{\frac{1}{2}}\exp\left(-\frac{(Rx - vt)^2}{4DRt}\right) - \frac{1}{2}\left(1 + \frac{vx}{D} + \frac{v^2 t}{DR}\right)\exp\left(\frac{vx}{D}\right)\text{erfc}\left[\frac{Rx + vt}{2(DRt)^{\frac{1}{2}}}\right] \qquad [11]$$

Here 'exp' and 'erfc' are the exponential function and complementary error function, respectively. The differences between the two solutions become appreciable in highly dispersive systems. Figure 9 shows the solutions at $Br = 1$. More complex and multidimensional formulations of the ADE generally require numerical solutions.

Two-Region Advection–Dispersion Equation

This equation, also referred to as the 'mobile–immobile water model' (MIM), is a special case of the ADE, in which the liquid phase is divided into two distinct (mobile and immobile) regions. Advective–dispersive solute flux occurs within the mobile water region, with solutes entering and leaving the immobile water region by diffusion. The ADE for solute transport within the mobile water region can then be written as:

$$\frac{\partial C_m}{\partial t} = D\frac{\partial^2 C_m}{\partial x^2} - v_m\frac{\partial C_m}{\partial x} - \left(\frac{\theta_{im}}{\theta_m}\right)\frac{\partial C_{im}}{\partial t} \qquad [12]$$

where the subscripts 'm' and 'im' refer to the mobile and immobile regions, respectively. The kinetic term

$\theta_{im}dC_{im}/dt$ is usually expressed in terms of a first-order rate constant and the concentration difference $C_m - C_{im}$. Eqn [12] can be solved analytically with or without making any assumptions about the spatial arrangement of solids and voids. In the first case, the mobile and immobile liquid regions are explicitly defined in terms of pore-space geometry. The majority of these models are for packed beds of uniform-sized, spherical soil aggregates; here θ_m is the macropore or inter-'aggregate' water content, and θ_{im} is the intra-'aggregate' water content. While it is possible to extend this approach to nonuniform and nonspherical aggregates, its predictive capability is limited. This is because the relationship between packed beds of sieved aggregates and the pore characteristics of undisturbed soil is far from clear. In the second case, the mobile–immobile water fraction is simply a fitting parameter.

Eqn [12] is commonly employed to parameterize asymmetric solute breakthrough curves with 'heavy tails.' Deviations from the Gaussian distribution associated with the ADE are often observed in breakthrough curves where more of the observed distribution is in the tails. Improvements in fit associated with the MIM as compared to the ADE can probably often be attributed to the presence of additional model parameters. Since it is rarely possible to measure the mobile and immobile water fractions independently, this parameter is usually estimated inversely. A two-site conceptualization of the soil, where a fraction of the adsorption sites are considered to have noninstantaneous adsorption, leads to an equivalent mathematical formulation.

Fractional Advection Dispersion and Continuous Time Random Walk Models

Recently, a fractional advection–dispersion equation (or FADE) and the continuous time random walk (CTRW) model have been proposed. These models appear to address the issues of scale-dependent dispersivity and heavy-tailed breakthrough curves well.

The FADE makes use of fractional calculus and is a generalization of the ADE that incorporates the family of Lévy distributions, of which the Gaussian distribution is a member. At the root of the FADE is the incorrect assumption in the derivation of the ADE above that the mass balance based on fluxes and fluid content applies in the infinitesimally small continuum limit. In fact it cannot, as the soil clearly divides into discrete pores and solids, and the averaged concepts of flux and fluid content lose meaning.

Instead of using a space-dependent dispersion coefficient to accommodate the apparent increase in D with scale, the FADE uses a constant dispersion coefficient and a non-Fickian fractional derivative for the diffusive–dispersive flux. The one-dimensional, symmetrical FADE can be written:

$$\frac{\partial C}{\partial t} = -v\frac{\partial C}{\partial x} + \frac{1}{2}D\left[\frac{\partial^{\gamma} C}{\partial x^{\gamma}} + \frac{\partial^{\gamma} C}{\partial(-x)^{\gamma}}\right] \qquad [13]$$

where γ is the fractional order of the derivative and D has dimensions $L^{\gamma}T$.

Figure 10 shows resident solute concentration data (measured with time-domain reflectometry probes) at different distances from the end of a single column. In this case, solute is being leached from the column. The data are fitted to both the ADE and the FADE. Clearly, the FADE is superior in its ability to fit the heavy tails of the breakthrough curves. Table 2 lists

the dispersion coefficients for each of the models at each distance. Perhaps more important than the fitting of the tails is the fact that a single dispersion coefficient (approx. $0.03\,cm^{1.6}\,min^{-1}$) represents all of the curves in the case of the FADE, while the dispersion coefficients required to fit the ADE grow from approximately $0.035\,cm^2\,min^{-1}$ at 11 cm from the source to more than $0.04\,cm^2\,min^{-1}$ at 23 cm as the solute advances through the column. The FADE allows the parameter describing the changes with scale ($\gamma \approx 1.6$ in this case) to be separated from the transport parameter D, which ideally needs to be measured at one scale only.

Like the FADE, the CTRW model is founded on a conceptual picture in which solute particles move along various paths and encounter spatially varying velocities. The particle spatial transitions (direction and distance given by displacement vector **s**) in time t are represented by a joint probability density function $\Psi(\mathbf{s}, t)$. Estimation of this function is central to application of the CTRW model. The functional form $\Psi(\mathbf{s}, \sim t) \sim t^{-1-\beta}$ ($\beta > 0$) has been found to be of particular interest. β characterizes the nature and magnitude of the dispersive processes. $\beta \geq 2$ is reported to be equivalent to the ADE. β between 1 and 2 reflects moderate non-Fickian behaviour, while $0 < \beta < 1$ indicates strong 'anomalous' behaviour.

The ability of the CTRW model to fit observations is similar to that of the FADE for the results in Figure 10. Three parameters (β, C^*, and C_1) are involved. For breakthrough curves in time, available fitting routines return β, T^*, and r^*, which, for $1 < \beta < 2$, are related to C^* and C_1 as follows:

$$T^* = LC_1 \text{ and } r^* = C_1^*/\beta L^{-1+1/\beta}$$
$$C_1$$

where L is the distance from the source. Inverting these equations gives C^* and C_1, which can then be used to compute breakthrough curves at different locations. Thus C^* and C_1 should be constants for a 'stationary' porous medium (Table 3). Here there is systematic variation, but the precise nature of the medium and the significance of the magnitude of this variation are unknown.

Despite the promise of these models, their application in soil science remains almost completely unexplored currently.

Table 3 Parameters for continuous time random walk (CTRW) fitted to data in Figure 10. C^* and C_1 should be constant for solute transport in a 'stationary' porous medium

List of Technical Nomenclature

α	Longitudinal dispersivity (L)
β	Characterizes the nature of magnitude of CTRW dispersive processes (–)
γ	Order of fractional derivative
ΔP	Pressure drop (MLT^{-2})
η	Dynamic viscosity (MLT^{-1})
θ	Volumetric fluid content (L^3L^{-3})
θ_{im}	Volumetric water content of the immobile region (L^3L^{-3})
θ_m	Volumetric water content of the mobile region (L^3L^{-3})
ρ_b	Soil bulk density (ML^{-3})
ϕ	Porosity (L^3L^{-3})
$\Psi(\mathbf{s}, t)$	Joint probability density function for CTRW (–)
A	Cross-sectional area of column and elemental volume (L^2)
Br	Brenner number
C	Solute concentration (ML^{-3})
C_0	Source solute concentration (ML^{-3})
C_{im}	Solute concentration in the immobile water region (ML^{-3})
C_m	Solute concentration in the mobile water region (ML^{-3})
C_s	Adsorbed concentration on soil (MM^{-1})
C^*, C_1, r^*, T^*	CTRW parameters
D	Apparent diffusion–dispersion coefficient (L^2T^{-1}) in ADE and ($L^\gamma T^{-1}$) in FADE
D^*	Dimensionless diffusion–dispersion coefficient (–)
D_b	Bulk diffusion coefficient (L^2T^{-1})
D_e	Effective diffusion coefficient (L^2T^{-1})
D_d	Lumped diffusion–dispersion coefficient (L^2T^{-1})
f_{oc}	Fraction of organic carbon in a soil

J	Solute flux ($ML^{-2}T^{-1}$)
J_c	Convective flux of solute ($ML^{-2}T^{-1}$)
J_d	Diffusive-dispersive flux of solute ($ML^{-2}T^{-1}$)
J_s	Diffusive flux of solute ($ML^{-2}T^{1}$)
k	First-order rate constant (T^{-1})
K_d	Soil and/or water partitioning or soil-water distribution coefficient (L^3M^{-1})
K_{oc}	Organic carbon partitioning coefficient (L^3M^{-1})
l	Characteristic length (L)
L	Length of column, elemental volume, and capillary tube (L)
Pe	Peclet number (–)
q	Fluid flux ($L^3L^{-2}T^{-1}$)
r	Capillary tube radius (L)
R	Retardation factor (–)
$\mathbf{s}$	Spatial transition vector in CTRW (L)
T	Pore volumes eluted (–)
t	Time (T)
v	Average fluid velocity (LT^{-1})
v_m	Average liquid velocity in the mobile region (LT^{-1})
v_{max}	Maximum velocity (LT^{-1})
v_s	Solute velocity (LT^{-1})
x	Spatial coordinate aligned with average fluid velocity (L)
y	Radial distance (L)

Introduction

The sorption (retention) of metals, including alkali (e.g., K), alkaline earth (e.g., Ca), and transition (e.g., Cd and Ni), on soil mineral and organic constituents is one of the most important processes in controlling the fate, transport, and bioavailability of metals in soil and water environments. This review discusses terminology for sorption processes, the role of surface functional groups on inorganic and organic soil components in sorption of metals, the types of surface complexes and products that metals can form in soils, characteristics of metal sorption in soils, and the importance of surface precipitation of metals such as Co, Ni, and Zn in sequestering metals in soils.

Terminology and Role of Sorption Processes in Soils

Adsorption, surface precipitation, and polymerization are all examples of sorption, a general term that is used when the retention mechanism at a surface is unknown. Adsorption can be defined as the accumulation of a substance or material at an interface between the solid surface and the bathing solution. Adsorption can include the removal of solute (a substance dissolved in a solvent) molecules from the solution, solvent (continuous phase of a solution, in which the solute is dissolved) from the solid surface, and attachment of the solute molecule to the surface. Adsorption does not include surface precipitation (the formation of a three-dimensional phase product on a surface), or polymerization (the formation of small multinuclear inorganic species such as dimers or trimers) processes. There are various metal sorption mechanisms that can occur at soil mineral surfaces involving both physical and chemical processes (Figure 1). It is useful to define a number of terms pertaining to retention (adsorption/sorption) of metal ions. The adsorbate is the material that accumulates at an interface, the solid surface on which the adsorbate accumulates is referred to as the adsorbent, and the ion in solution that has the potential of being adsorbed is the adsorptive. If the general term 'sorption' is used, the material that accumulates at the surface, the solid surface, and the ion in solution that can be sorbed are referred to as sorbate, sorbent, and sorptive, respectively.

Adsorption is one of the most important chemical processes in soils. It determines the quantity of plant nutrients, metals, pesticides, and other organic chemicals that are retained on soil surfaces and therefore is one of the primary processes that affects transport of nutrients and contaminants in soils. Adsorption also affects the electrostatic properties, e.g., coagulation and settling, of suspended particles and colloids. Both physical and chemical forces are involved in adsorption of solutes from solution. Physical forces include van der Waals forces (e.g., partitioning) and electrostatic outer-sphere complexes (e.g., ion exchange). Chemical forces result from short-range interactions that include inner-sphere complexation (which is defined below) involving a ligand exchange mechanism, covalent bonding, and hydrogen bonding.

Surface Functional Groups

Surface functional groups in soils play a significant role in adsorption processes. A surface functional group is a chemically reactive molecular unit attached at the boundary of a solid with the reactive groups of the unit exposed to the soil solution. Surface functional groups can be organic (e.g., carboxyl, carbonyl, phenolic) or inorganic molecular units. The major inorganic surface functional groups in soils are the siloxane surfaces associated with the plane of oxygen atoms bound to the silica tetrahedral layer of a phyllosilicate (clay mineral) and hydroxyl groups that are associated with the edges of inorganic minerals such as kaolinite, amorphous materials, and metal oxides, oxyhydroxides, and hydroxides.

Surface Complexation

When the interaction of a surface functional group with an ion or molecule present in the soil solution

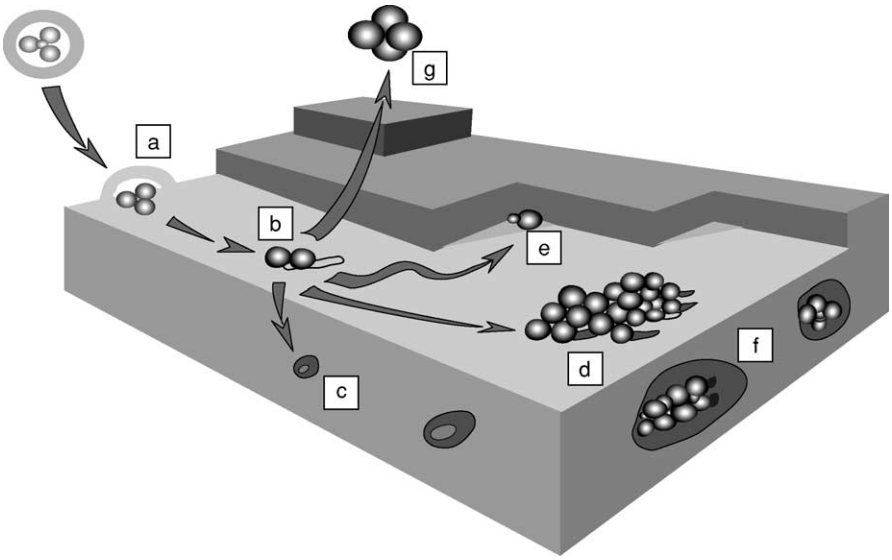

Figure 1 Various mechanisms of sorption of an ion at the mineral–water interface: (1) adsorption of an ion via formation of an outer-sphere complex (a); (2) loss of hydration water and formation of an inner-sphere complex (b); (3) lattice diffusion and isomorphic substitution within the mineral lattice (c); (4) and (5) rapid lateral diffusion and formation either of a surface polymer, (d), or adsorption on a ledge (which maximizes the number of bonds to the adatom) (e). Upon particle growth, surface polymers end up embedded in the lattice structure (f); finally, the adsorbed ion can diffuse back in solution, either as a result of dynamic equilibrium or as a product of surface redox reactions (g). Reproduced from Charlet L and Manceau A (1993) Structure, formation, and reactivity of hydrous oxide particles: insights from X-ray absorption spectroscopy. In: *Environmental Particles*, pp. 117–164. Boca Raton, FL: Lewis Publishers.

creates a stable molecular entity, it is called a surface complex. The overall reaction is referred to as surface complexation. There are two types of surface complexes that can form: outer-sphere and inner-sphere. Figure 2 shows surface complexes between metal cations and siloxane ditrigonal cavities on 2:1 clay minerals. Such complexes can also occur on the edges of clay minerals. If a water molecule is present between the surface functional group and the bound ion or molecule, the surface complex is termed outer-sphere. If there is not a water molecule present between the ion or molecule and the surface functional group to which it is bound, this is an inner-sphere complex. Inner-sphere complexes can be monodentate (metal is bonded to only one oxygen) and bidentate (metal is bonded to two oxygens) and mononuclear and binuclear.

Outer-sphere complexes involve electrostatic coulombic interactions and are thus weak compared to inner-sphere complexes in which the binding is covalent or ionic. Outer-sphere complexation is usually a rapid process that is reversible, and adsorption only occurs on surfaces that are of opposite charge to the adsorbate.

Inner-sphere complexation is usually slower than outer-sphere complexation; it is often irreversible. Inner-sphere complexation can increase, reduce, neutralize, or reverse the charge on the sorptive regardless of the original charge. Adsorption of ions via inner-sphere complexation can occur on a surface regardless of the original charge. It is important to remember that outer- and inner-sphere complexation can, and often does, occur simultaneously.

Ionic strength effects on metal sorption are often used as indirect evidence for whether an outer-sphere or inner-sphere complex forms. For example, if metal sorption is dependent on ionic strength (I), outer-sphere complexes are assumed to form, while if metal sorption is independent of I, inner-sphere complexes are assumed to be the predominant surface complex. However, such conclusions are based strictly on macroscopic investigations. To determine definitively the type of surface complex or product that metals form on soil surfaces, one must employ molecular-scale investigations.

Over the past decade or more, *in situ* (under natural conditions where water is present) molecular-scale analytical techniques such as X-ray absorption fine-structure spectroscopy (XAFS) and Fourier transform infrared spectroscopy (FTIR) have been employed to determine the type of metal surface complexes and products that form on soil surfaces. Based on these studies, one can conclude that alkali metals and alkaline earth metals primarily form outer-sphere complexes, while trace and heavy metals primarily form inner-sphere complexes. At higher

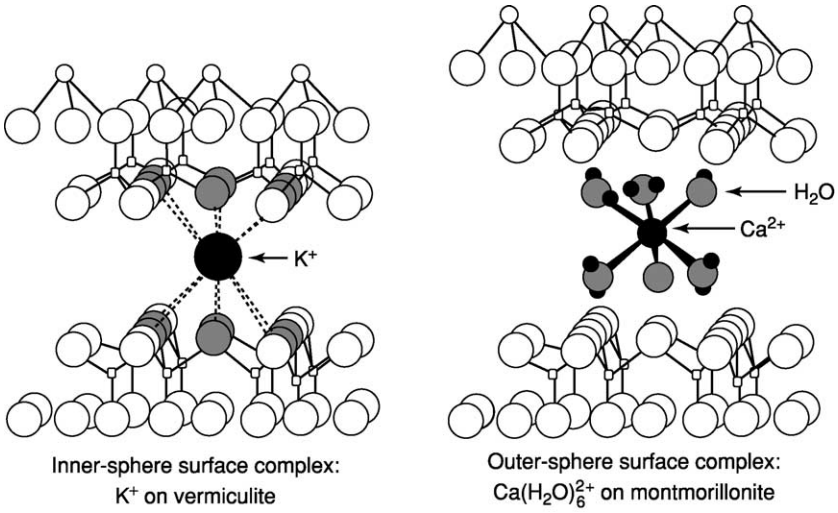

Figure 2 Examples of inner- and outer-sphere complexes formed between metal cations and siloxane ditrigonal cavities on 2:1 clay minerals. Reproduced with permission from Sposito G (1984) *The Surface Chemistry of Soils*. New York: Oxford University Press.

metal loadings and pHs, sorption of metals such as Co, Cr, Ni, and Zn on phyllosilicates and metal hydr(oxides) can result in the formation of surface precipitates. Thus, environmental factors such as pH, surface loading, ionic strength, type of sorbent, and time all affect the type of sorption complex or product. An example of this is shown for Pb sorption on montmorillonite over an I of 0.006–0.1 and a pH range of 4.48–6.77 (Table 1). Employing XAFS analysis, at a pH of 4.48 and an I of 0.006, outer-sphere complexation on basal planes in the interlayer regions of the montmorillonite predominated. At a pH of 6.77 and I of 0.1, inner-sphere complexation on edge sites of montmorillonite was most prominent, and at pH of 6.76, I of 0.006 and pH of 6.31, I of 0.1, both inner- and outer-sphere complexation occurred. These data are consistent with other findings that inner-sphere complexation is favored at higher pH and ionic strength. Clearly, there is a continuum of adsorption complexes that can exist in soils.

Sorption of Metal Cations

Sorption of metal cations is pH-dependent and is characterized by a narrow pH range where sorption increases to nearly 100%, traditionally known as an adsorption edge (Figure 3). The pH position of the adsorption edge for a particular metal cation is related to its hydrolysis or acid-base characteristics. In addition to pH, sorption of metals is dependent on sorptive concentration, surface coverage, and the type of the sorbent.

One can measure the relative affinity of a cation for a sorbent or the selectivity. The properties of the cation, sorbent, and the solvent all affect the selectivity. With monovalent alkali metal cations, electrostatic interactions predominate and the general order of selectivity is $Li^+ < Na^+ < K^+ < Rb^+ < Cs^+$. This order is related to the size of the hydrated radius. The ion in the above group with the smallest hydrated radius, Cs^+, can approach the surface the closest and be held the most tightly. However, on some hydrous oxides, the reverse order is often observed.

This has been particularly noted for some hydrous metal oxides. The reason for this selectivity is not well understood, but may be related to the effect of the solid on water that is present on the oxide surface or to variation in the solution matrix.

With divalent metal ions there is little consistency in the selectivity order. The type of surface and the pH both appear to have major effects on the selectivity sequence. Differences in the H^+/M^{n+} (where M^{n+} is a metal ion of valence n) could cause reversals in selectivity since the ion with the higher H^+/M^{n+} stoichiometry would be favored at higher pH. Divalent transition and heavy metal cations, both of which are often sorbed as inner-sphere complexes, are more strongly sorbed than alkaline earth cations.

Metal Surface Precipitation

As the amount of metal cation sorbed on a surface (surface coverage or loading which is affected by the pH at which sorption occurs) increases, sorption can proceed from mononuclear adsorption to surface precipitation. There are several thermodynamic reasons for surface precipitate formation: 1) the solid surface may lower the energy of nucleation by providing sterically similar sites; 2) the activity of the surface precipitate is <1; and 3) the solubility

Table 1 Effect of ionic strength (I) and pH on type of Pb adsorption complexes on montmorillonite

I ($mol\,l^{-1}$)	pH	Removal from solution (%)	Adsorbed Pb(II) ($mmol\,kg^{-1}$)	Primary adsorption complex[a]
0.1	6.77	86.7	171	Inner-sphere
0.1	6.31	71.2	140	Mixed
0.006	6.76	99.0	201	Mixed
0.006	6.40	98.5	200	Outer-sphere
0.006	5.83	98.0	199	Outer-sphere
0.006	4.48	96.8	197	Outer-sphere

of the surface precipitate is lowered because the dielectric constant of the solution near the surface is less than that of the bulk solution. There are several types of surface precipitates. They can arise via polymeric metal complexes (dimers, trimers, etc.) that form on mineral surfaces and via the sorption of aqueous polymers. Homogeneous precipitates can form on a surface when the solution becomes saturated and the surface acts as a nucleation site. When adsorption attains monolayer coverage sorption continues on the newly created sites causing a precipitate on the surface. When the precipitate consists of chemical species derived from both the aqueous solution and dissolution of the mineral, it is referred to as a coprecipitate. The composition of the coprecipitate varies between that of the original solid and a pure precipitate of the sorbing metal. The ionic radius of the sorbing metal and sorbent ions must be similar for coprecipitates to form. Thus Co(II), Mn(II), Ni(II), and Zn(II) form coprecipitates on sorbents containing Al(III) and Si(IV) but not Pb(II) which is considerably larger (1.20 Å). Coprecipitate formation is most limited by the rate of mineral dissolution, rather than the lack of thermodynamic favorability. If the formation of a precipitate occurs under solution conditions that would, in the absence of a sorbent, be undersaturated with respect to any known solid phase, this is referred to as surface-induced precipitation.

Thus there is often a continuum between surface complexation (adsorption) and surface precipitation. This continuum depends on several factors: 1) ratio of the number of surface sites vs. the number of metal ions in solution; 2) the strength of the metal-oxide bond; and 3) the degree to which the bulk solution is undersaturated with respect to the metal hydroxide precipitate. At low surface coverages surface complexation (e.g., outer- and inner-sphere adsorption) tends to dominate. As surface average increases, nucleation occurs and results in the formation of distinct entities or aggregates on the surface. As surface loadings increase further, surface precipitation becomes the dominant mechanism (Figure 4).

Using an *in-situ* molecular-scale technique, X-ray absorption fine structure spectroscopy (XAFS), it has been shown by a number of scientists that multinuclear metal hydroxide complexes and surface precipitates of Co(II), Cr(III), Cu(II), Ni(II), Pb(II), and Zn(II) can form on metal oxides, phyllosilicates, soil clays, and soils. These metal hydroxide phases occur

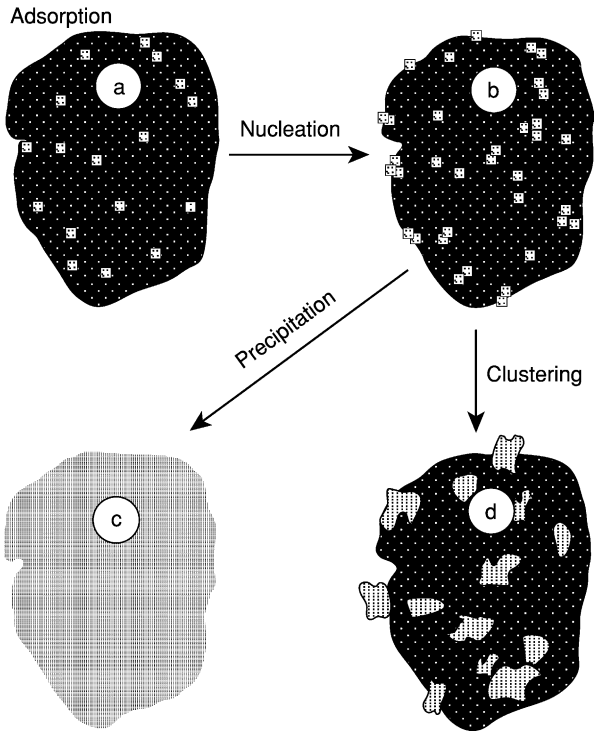

Figure 4 An illustration of metal ion sorption reactions on (hydr)oxide. (a) At low surface coverage, isolated site binding (adsorption) is the dominant sorption mechanism; (b) with increased metal loading. M-hydroxide nucleation begins; (c) further increases in metal loadings results in surface precipitation or (d) surface clusters. at metal loadings below a theoretical monolayer coverage and in a pH range well below the pH where the formation of metal hydroxide precipitates would be expected according to the thermodynamic solubility product.

Sorption of Co, Ni, and Zn, on an array of phyllosilicates and Al-oxide, can result in formation of mixed metal-Al hydroxide surface precipitates which appear to be coprecipitates. The precipitate phase shares structural features common to the hydrotalcite group of minerals and the layered double hydroxides (LDH) observed in catalyst synthesis. The LDH structure is built of stacked sheets of edge-sharing metal octahedra containing divalent and trivalent metal ions separated by anions between the interlayer spaces. The general structural formula can be expressed as $[Me^{2+}_{1-x}\,Me^{3+}_{x}(OH)_2]^{x+}\cdot(x/n)A^{-n}\cdot -mH_2O$, where for example, Me^{2+} could be Mg(II), Ni(II), Co(II), Zn(II), Mn(II), and Fe(II) and Me^{3+} is Al(III), Fe(III), and Cr(III). The LDH structure exhibits a net positive charge x per formula unit which is balanced by an equal negative charge from interlayer anions A^{n-} such as Cl^-, Br^-, I^-, NO_3^-, OH^-, ClO_4^-, and CO_3^{2-}; water molecules occupy the remaining interlayer space. The minerals takovite, $Ni_6\,Al_2(OH)_{16}\,CO_3\cdot H_2O$ and hydrotalcite, $Mg_6\,Al_2(OH)_{16}\,CO_3\cdot H_2O$ are among the most common natural mixed-cation hydroxide compounds containing Al.

The mechanism for the formation of metal hydroxide surface precipitates is not clearly understood. It is clear that the type of metal ion determines whether metal hydroxide surface precipitates form, and the type of surface precipitate formed, i.e., metal hydroxide or mixed metal hydroxide, is dependent on the sorbent type. The precipitation could be explained by the combination of several processes. First, the electric field of the mineral surface attracts metal ions, e.g., Ni, through adsorption, leading to a local supersaturation at the mineral–water interface. Second, the solid phase may act as a nucleation center for polyhydroxy species and catalyze the precipitation process. Third, the physical properties of water molecules adsorbed at the mineral surface are different from free water, causing a lower solubility of metal hydroxides at the mineral–water interface. With time Al, which is released by weathering of the mineral surface, slowly diffuses into the octahedral layer of the mineral and partially replaces the metal (e.g., Ni) in the octahedral sites. A Ni-Al (LDH) is formed, which is thermodynamically favored over α-Ni hydroxide.

The formation of metal hydroxide surface precipitates appears to be an important way to sequester metals. As the surface precipitates age, metal release is greatly reduced. Thus, the metals are less prone to leaching and being taken up by plants. This is due to silication of the interlayer of the LDH phases creating precursor phyllosilicate surface precipitates.

Introduction

Organic chemicals enter soils through the use of pesticides, application of sewage sludge, or the disposal or accidental release of petrochemicals or industrial wastes. Some have negative effects on the environment and public health. A key process in soils regulating the transport, bioavailability, and reactivity of organic compounds is sorption. 'Sorption' and the opposite term, 'desorption,' refer to the process of molecular exchange between the gas or solution phase and an immobile phase (the sorbent). The sorbed component is sometimes referred to as the sorbate (American) or sorptive (British).

Sorption may be categorized by the type of intermolecular attractive forces between sorbate and sorbent. Physisorption and ion exchange sorption involve relatively weak intermolecular forces, while chemisorption involves strong bonding of a covalent nature. Physisorption is, by far, the most common type encountered in the context of soil and environmental sciences.

The reactive mineral components in soils are silicate clays and oxyhydroxide minerals of Si, Fe, Al, Mg, Mn, etc. Soil organic matter (SOM) consists mainly of polymeric humic substances derived from decomposition of biological materials such as lignin and cutin. Other substances within the scope of SOM are carbonaceous materials such as soot and charcoal. SOM is usually the predominant sorbent unless the SOM content is extremely low – some estimates suggest less than 0.01% of organic carbon by weight – or unless the water content is low. Therefore, the focus here is on sorption by SOM. Emphasis is placed on sorption of nonionic compounds in water-saturated systems, because the majority of organic compounds, including pesticides, are uncharged within the range of pH usually encountered in soils (5.5–7.5), and because water is abundant, especially in the subsurface.

Physisorption of Nonionic Compounds

General Considerations

Forces involved Physisorption involves weak intermolecular forces such as London–van der Waals forces and hydrogen bonding. These forces act simultaneously in combinations permitted by the structures of the interacting species. London–van der Waals forces include dipole–dipole, dipole–induced dipole (attraction of a permanent dipole with the dipole it induces in its neighbor), and induced dipole–induced dipole (mutual attraction of momentary dipoles produced by the synchronization of electronic motion in interacting neighbors). Additionally, the interaction of a charge with a neutral molecule may involve charge–dipole and charge–induced-dipole forces. The strengths of London–van der Waals interactions depend on the molecular area of contact, separation distance (to the inverse sixth power), and applicable molecular properties of the interacting species such as dipole moment, ionization potential, and polarizability.

The most common type of hydrogen bond is between an acidic proton and a lone pair of electrons (i.e., $XH\cdots:Y$) which are located on O, N, or S atoms. This bond is highly oriented (XHY angle, $180^\circ \pm 15^\circ$), ranges in enthalpy from 12 to 35 kJ mol^{-1}, and involves a combination of dipole–dipole attraction and molecular orbital overlap. Other much weaker hydrogen bonds are known, such as the one formed between an acidic proton and the π system of an aromatic ring, but whether they are important in soil systems in competition with hydrogen bonds from water molecules is unclear.

Categories Physisorption is often broadly classified as absorption or adsorption. Absorption (often called partitioning) occurs when molecules penetrate the solid–fluid interface and are allowed to roam the internal molecular or atomic matrix of the sorbent. SOM is the only natural component of soils that is penetrable in this way, but polluted soils may contain additional absorptive phases such as solvents, oils, tars, etc.

Adsorption is a term used in the phenomenological sense to imply association at a solid–fluid interface. Mechanistically, however, adsorption may encompass several qualitatively different processes, including binding of molecules independently to discrete surface sites, partitioning of molecules into an ordered hydration phase near the surface, condensation of the sorbate into a liquid-like or solid-like state in small pores, and adsorption on the surfaces of water films associated with the particles.

Thermodynamic considerations Net sorption from water (eqn [1e]) can be written as a series of steps in a thermodynamic cycle:

$$\{x\} \rightleftharpoons \{\ldots\} + x_g \quad [1a]$$

$$\{\ldots\} \rightleftharpoons (\ ) \quad [1b]$$

$$\mathbf{M} \rightleftharpoons \mathbf{M}' \quad [1c]$$

$$x_g + \mathbf{M}' \rightleftharpoons x\mathbf{M}' \quad [1d]$$

$$\{x\} + \mathbf{M} \rightleftharpoons (\ ) + x\mathbf{M}' \quad [1e]$$

Equation [1a] represents removal of solute x from water to the gas phase, where {} symbolizes the solvation shell around x. Equation [1b] represents collapse of the solvation shell into the cavity vacated by the solute and reconfiguration of solvation-shell water molecules to the bulk water state symbolized by ( ). Equation [1c] is reorganization of the sorbent matrix $\mathbf{M}$ to some altered state $\mathbf{M}'$ that may be necessary to accommodate the sorbate; and eqn [1d] represents formation of bonds between sorbate and the altered sorbent.

Matrix reorganization may include displacement of water or other sorbed molecules into solution, or structural changes in the sorbent such as swelling and pore flexing in response to the adsorbate. Little is known about matrix changes and their effects on sorption thermodynamics.

When sorption is from the vapor state, eqns [1a] and [1b] do not apply, and net sorption is the sum of eqns [1c] and [1d]:

$$x_g + \mathbf{M} = x\mathbf{M}' \quad [1f]$$

The curve defining the equilibrium relationship between sorbed-phase concentration S and fluid-phase concentration C at constant temperature is the sorption isotherm. Various isotherm models have been used depending on the mechanism(s) involved.

It is convenient to define the sorption distribution ratio, K_d, as:

$$K_d = \frac{S}{C} \quad [2]$$

Fluid concentration is expressed in units of pressure or in moles per unit volume. The units of S depend on convention and the implied mechanism being invoked. Ideally, adsorption processes should be based on surface area (or pore volume if condensation is considered) and absorption on solid volume. However, sorbent dry weight is commonly used as a surrogate for these properties, since they are often not

accurately known. K_d is concentration-dependent unless the isotherm is linear.

K_d is related to the Gibbs free energy of sorption, ΔG^0_{sorp} by:

$$K_d = \exp\left(-\frac{\Delta G^0_{sorp}}{RT}\right) \quad [3]$$

where R is the gas constant and T is temperature. ΔG^0_{sorp} – which is concentration-dependent if K_d is concentration-dependent – encompasses all enthalpy and entropy changes that occur during sorption. This means that the position of equilibrium depends on (1) the difference in the strengths between all sorbate–sorbent and all solute–water interactions, and (2) the entropy changes associated with eqns [1a–1d]. There are virtually no examples where the contributions of these factors have been fully delineated.

Parts of molecules that carry no charge, are not strongly polarized, and lack functional groups that can form strong hydrogen bonds with water are said to be hydrophobic. The hydrophobic effect operates on such molecules when dissolved in aqueous solution and is due to entropy and enthalpy costs associated with the ordered alignment of water molecules near the hydrophobic regions of the solute (apparently, with –OH groups pointed toward the organic), and the consequent disruption of water–water hydrogen bonds. The hydrophobic effect reduces a compound's water solubility and thus contributes to the overall driving force for its sorption from water. For a series of compounds of related structure (e.g., aromatic hydrocarbons), K_d is found to correlate with the molecular hydrophobic surface area or with the *n*-octanol–water partition coefficient (K_{ow}), a commonly used parameter reflecting a compound's net hydrophobic character. This is true whether the sorbent domain is the polar surface of a mineral, or the comparatively apolar surface or interior of organic matter.

Physisorption of Nonionic Compounds to Mineral Solids

Minerals present mainly two kinds of environments for sorption: (1) the hydroxylated surface found on hydrous oxide minerals and the edges of aluminosilicate clays, and (2) the interlayers of layer silicate clays, which contain siloxane surfaces of variable charge density.

Hydroxylated surfaces have –OH groups protruding into solution from the topmost layer of lattice metal ions. Sorption of apolar compounds from dilute solution to nonmicroporous hydrous oxide surfaces is proportional to mineral surface area and is typically not very sensitive to surface charge, solution pH, and solution ionic strength (although high ionic strength may reduce water solubility and increase the tendency for sorption). It is also proportional to the hydrophobic surface area and to the K_{ow} of the sorbate, at least for closely related compounds. While data are sparse, sorption to hydroxylated surfaces tends to be endothermic and sorption isotherms tend to be linear to slightly nonlinear.

In the case of apolar compounds, there is good reason to believe that sorption to hydroxylated surfaces occurs by partitioning (i.e., absorption) of the sorbate into the semiordered multilayer of water under the influence of the surface, known as the vicinal water layer. This is depicted as 'B' in Figure 1a. Apolar molecules are thought to be unable to penetrate the closest one or two layers of water molecules

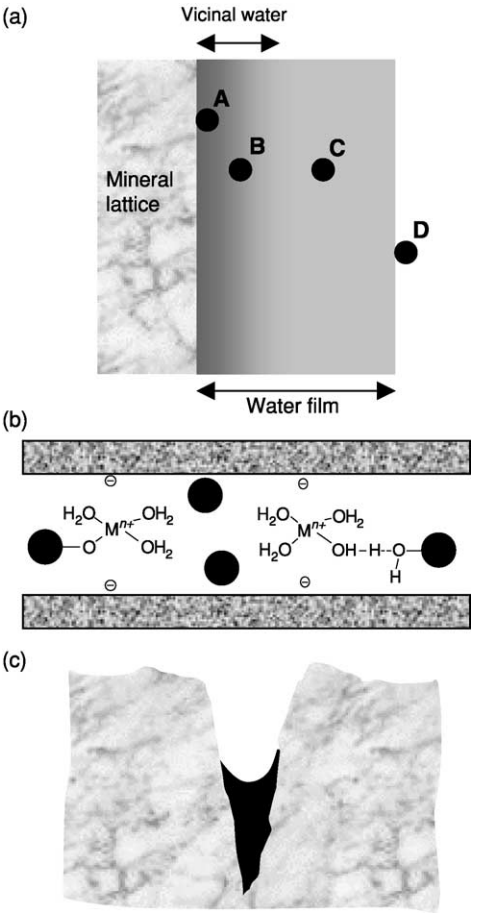

Figure 1 Depiction of different types of sorption in mineral particles: (a) interaction with discrete sites on the hydroxylated surface, A; partitioning in the vicinal water layer on the hydroxylated surface, B; dissolution in water films, C; and adsorption on the surface of water films, D; (b) sorption in a clay interlayer: left to right, direct coordination to interlayer metal ion; association with the uncharged siloxane surface; and hydrogen-bonding to a metal-coordinated water molecule; (c) condensation in a small pore.

and hence do not actually contact the surface. This is inferred from the observation that sorption of apolar organic vapors is strongly depressed by water vapor, and from the fact that per unit surface area of bare hydrous oxide surface heats of adsorption of organic molecules are much smaller than that of water. As the compound becomes more capable of hydrogen bonding to surface hydroxyl groups, it is better able to compete with strongly bound water molecules for surface sites ('A' in Figure 1a).

The siloxane surface existing on the faces of many layer silicate clays consists of oxygen atoms bridging underlying Si^{IV} atoms. The oxygens may bear permanent negative charge, depending on whether they lie near a point of isomorphic substitution in the underlying lattice. The charged sites are closely associated with metal or organic cations, and the surface in the vicinity of the charge is strongly hydrophilic (Figure 1b). Polar compounds can hydrogen-bond to metal ion-coordinated water molecules, or can coordinate directly with metal ions if they have an appropriate functional group. The neutral regions between charges are hydrophobic or only weakly hydrophilic; hence, hydrophobic molecules or parts of molecules may compete favorably with water for the bare surface in those regions. Sorption in clay interlayers is complicated by accessibility. The charge density and the exchangeable cation with its hydration sphere control the interlayer spacing and the size of the adsorption 'sites' available for molecules.

Under relatively dry conditions, multilayer adsorption, in which the sorbate condenses as a liquid-like phase on mineral surfaces, may also occur. Due to capillary forces, condensation progresses from the smallest to the largest of pores (or narrowest to widest part of a pore) as the partial pressure increases (Figure 1c).

Water has a strong negative effect on vapor adsorption to soils. Sorption of organic vapors decreases by an order of magnitude or more as the soil moisture content increases to approximately the wilting point, which corresponds to an average of 3–5 molecular layers of water (Figure 2). This inhibition is due to competition by water molecules for pore volume space and polar surface sites on inorganic surfaces. At moisture contents above the wilting point, sorption approaches what it would be in water-saturated soil.

When dealing with sorption of vapors to unsaturated soils, it is often necessary to take into account the association of organic sorbates with the water located in surface films and pores. This water is technically considered part of the immobile phase. Sorption may occur by a combination of aqueous-phase dissolution ('C' in Figure 1a) and vapor-phase adsorption at the gas–water interface ('D' in Figure 1a). The latter is especially important for compounds such as alkanes that are highly insoluble in water.

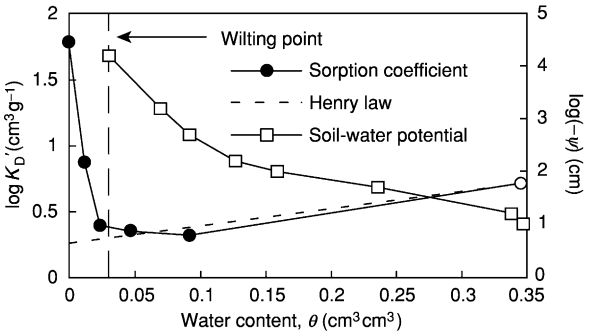

Figure 2 Toluene sorption coefficient (K_D') and soil-water potential (ψ) as functions of volumetric water content in Lundgaard soil (1.1% organic carbon). The Henry law line is the calculated sorption assuming dissolution into water and aqueous–solid partitioning only (i.e., zero vapor–solid sorption). Physisorption of Nonionic Compounds to Natural Organic Matter

General considerations SOM is usually the dominant sorbent of neutral compounds in soils, because it presents a hydrophobic domain for hydrophobic molecules. Sorption isotherms in SOM and SOM-rich soils usually obey the semiempirical Freundlich equation:

$$S = K_F C^N \qquad [4]$$

where K_F and N are constants. The value of N is almost always less than or equal to 1, reflecting a constant $(N = 1)$-to-diminishing $(N < 1)$ tendency for sorption with increasing loading. The Freundlich relationship is only approximate and N may vary depending on the range of concentrations over which it is measured. It should be noted that all sorption isotherms tend toward linearity below a certain concentration, a result the Freundlich equation fails to predict.

Many researchers have assumed N is 1, or have taken N to be 1 for purposes of simplifying the sorption term in transport or bioavailability models. In that case, the isotherm is given simply by:

$$S = K_p C \qquad [5]$$

where K_p is referred to as the partition coefficient.

On the assumption that sorption occurs exclusively to the organic matter component of the soil, the distribution, Freundlich, or partition coefficient is

often normalized to the fraction of organic carbon (f_{oc}) in the sample; i.e.:

$$K_{oc} = K_d(\text{or } K_F \text{ or } K_p) \cdot f_{oc}^{-1} \quad [6]$$

Linear free energy relationships between K_{oc} and parameters that represent hydrophobic properties such as K_{ow} or saturated water solubility (C_{sat}) have been extensively tested, e.g.:

$$\log K_{oc} = a + b\log K_{ow} \quad [7]$$

$$\log K_{oc} = c - d\log C_{sat} \quad [8]$$

where a and b or c and d are fitting parameters. Such relationships work best for a set of closely related compounds in a given soil; the reason being that the enthalpy and entropy of eqns [1a–1d] depend on sorbate molecular structure, and because soil organic matter is not uniform from place to place. Other structure–property relationships have been studied based on, for example, parachor, connectivity index, or UNIFAC group contribution method. Solution properties such as pH and ionic strength have modest – and often contradictory – effects on sorption of nonionic compounds to SOM.

Natural organic materials in soils A discussion of sorption to soil natural organic matter must take into account the nature and abundance of all the different types of refractory components that make it up. Ordinarily the most abundant component is humic substances. Humic substances are highly altered, refractory macromolecules derived from biomass. They may also contain recognizable fragments of carbohydrates and proteins covalently attached to, or sequestered in, the humic solid. Humic substances are operationally defined as consisting of fulvic acid (soluble at all pH), humic acid (soluble in alkaline solutions), and humin (insoluble at all pH and typically strongly associated with inorganic particles). The soil water may also contain 'dissolved' humic substances – ranging from small, truly dissolved molecules to colloidal particles – that can sorb organic compounds, although somewhat less effectively than particulate humic substances. Kerogens are biogenic, macromolecular substances that have undergone low-temperature chemical and physical diagenesis over geologic time. Kerogens are abundant in soft coals and shale and may be found in soils as a result of reworking processes. Hard coals are biogenic macromolecular substances that have been subjected to high-temperature and -pressure alteration (catagenesis) over geologic time and are found in some soils. Black carbon is the carbonaceous by-product of biomass burning (charcoal) or fossil fuel combustion (soot). Black carbon may constitute a minute-to-small fraction of total organic C in soil.

Physisorption to humic substances and kerogen Humic substances and kerogens are considered to be random-network macromolecular solids; that is, they are composed of macromolecules of heterogeneous structure that are randomly aggregated to form a three-dimensional phase. This phase is hydrated to a degree depending on the type of humic substance and relative humidity, and may contain metal ions coordinated to charged groups, such as carboxylate. From fulvic acid to humic acid to humin to kerogen, there is a trend of increasing molecular weight, apolarity, C content, fused ring size, density, cross-linking, and glass-to-rubber transition temperature.

For such materials, an absorption rather than an adsorption model is better supported by the evidence and is widely accepted. External surface areas are too low – approx. $10^0\,m^2\,g^{-1}$ for humic acid particles based on N_2 as the probe – to account for their high uptake of organic chemicals. Furthermore, their surfaces are not hard like a mineral crystal, but diffuse and flexible due to solvation and charge repulsion of polar interfacial groups. Organic molecules reaching the interface pass through and enter interior regions, where they intermingle with the strands of the macromolecules. A similar paradigm for small-molecule sorption by synthetic organic polymers is well established. Sorption to humic substances appears to be slightly exothermic, although few data are available.

According to established polymer theory, amorphous macromolecular solids may exist in 'glassy' or 'rubbery' states, depending on temperature. These states differ in physical properties and sorbent behavior. The rubbery state is more expanded and its macromolecular segments have greater mobility. Sorption in rubbery solids is similar to liquid dissolution in that specific sorption sites have fleeting existence and sorbed molecules experience an average chemical environment. This results in a linear isotherm, like eqn [5], and noncompetitive sorption behavior when multiple solutes are present.

The glassy state is denser and more rigid. Also, because the glassy state is incompletely relaxed, it contains internal voids not filled by macromolecules. These voids (or 'holes') are of molecular dimensions and may accumulate sorbate. Hence, sorption in the glassy state exhibits dual-mode behavior. One mode is 'dissolution' in the bulk solid that is linear and noncompetitive, analogous to sorption in the rubbery state. The other mode is 'hole-filling' in the voids that is best modeled by a Langmuir-type equation. The dual-mode isotherm is given by:

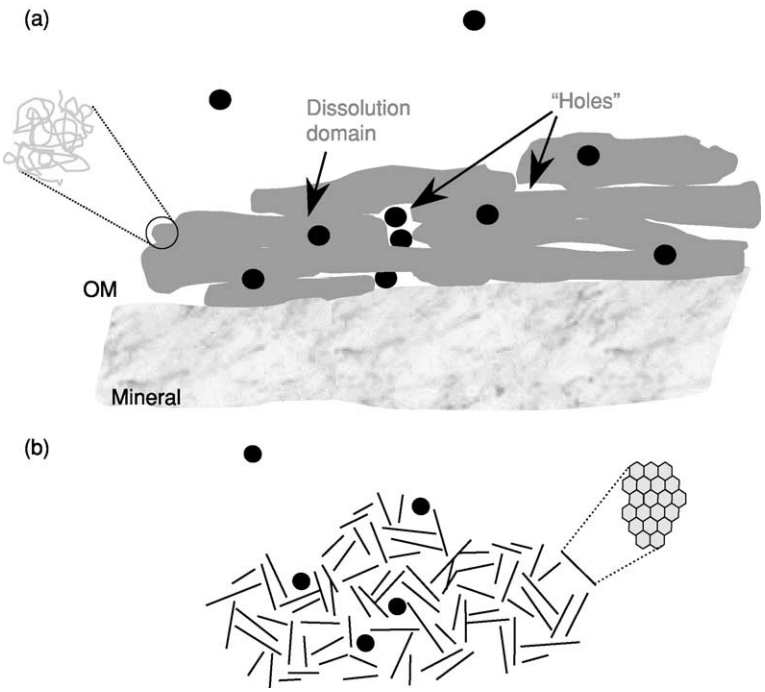

Figure 3 Sorption in soil organic matter (OM) fractions: (a) Macromolecular solids such as humic substances and kerogens: sorbate may undergo solid-phase dissolution in domains composed of macromolecules in a relatively fluid state and hole-filling in voids within the organic phase and between the organic phase and the mineral surface; (b) micrographitic substances such as black carbon: sorbate may adsorb in shallow micropores and some may penetrate into deep micropores between polyaromatic platelets.

$$S = K_D C + \frac{S_H^{max} K_H C}{1 + K_H C} \qquad [9]$$

where K_D is the dissolution domain partition coefficient, and S_H^{max} and K_H are the hole domain capacity and affinity parameters, respectively. Equation [9] predicts nonlinear and competitive sorption, both of which have been realized for many soils, humic acid reconstituted in particulate form, and kerogens.

In the context of SOM, holes may be regarded as semipermanent voids within the folds of individual macromolecules, between macromolecules, or between macromolecules and the mineral surface to which they are anchored. This is shown in **Figure 3a**. When eqn [9] is applied to heterogeneous natural materials: (a) the K_D term represents the sum of partition coefficients for all rubbery substances present and the dissolution domains of all glassy substances present; and (b) the Langmuir term represents a weighted average of holes of different sorption potential that may exist. The affinity for a given solute is greater in holes than in the dissolution domain.

As sorbate loading increases, the isotherm can become more complex. The glassy state may become softened ('plasticized') by the sorbate, causing it to become rubbery and the holes to disappear. At high loadings the isotherm in a rubbery solid begins to curve upward with respect to the solution concentration axis owing to the effects of swelling.

Natural organic matter in many samples appears to have glassy character. The glass transition temperature of some natural substances has been measured, including wet and dry humic acids (43–72°C), coals (>300°C), and wet lignin (60–90°C). Lignin is an amorphous, random polymer from the woody parts of plants that is regarded to be a major precursor of terrestrial humic substances. Whole-soil SOM may exhibit multiple glass transitions due to its heterogeneous nature. Synthetic polymers, humic acids, and coals have all been shown to have high internal surface area associated with the holes.

Nonlinearity and competitive effects tend to increase in the expected order of increasing glassy character of the solid:

$$\text{dissolved humic acid} < \text{particulate humic acid} < \text{whole-soil SOM} < \text{humin} < \text{kerogen}$$

Artificially cross-linking humic acid by flocculating it with polyvalent metal ions (e.g., Al^{3+}) increases nonlinearity and competition.

Figure 4 shows an example of sorption of a hydrophobic organic compound phenanthrene in SOM. It is evident that phenanthrene sorption is nonlinear with $N = 0.772$. It can also be seen that the dual-mode

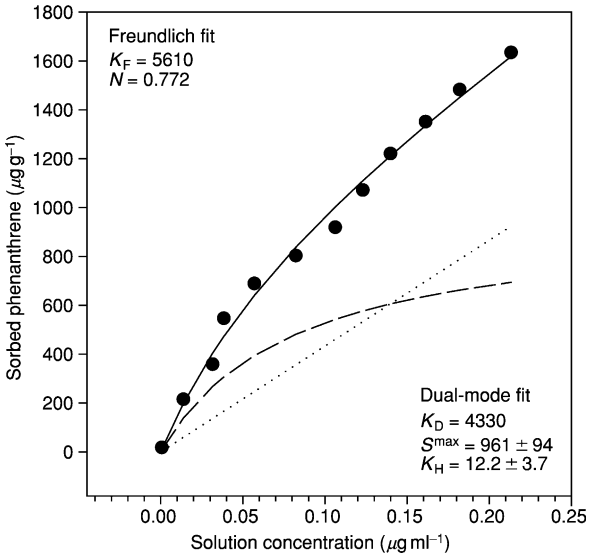

Figure 4 Phenanthrene sorption in soil with a high organic content. The fitting parameters of both Freundlich and dual-mode equations are shown. The solid line is the dual-mode fit, assuming only one type of Langmuir (hole) sites, and solid circles are actual data points; dotted and dashed lines are the contribution from partitioning and Langmuir (hole)-type sorption, respectively. The maximum surface sorption capacity calculated from surface area and molecular size is 286 $\mu g\, g^{-1}$. See text for details.

model fits the data well. Langmuir (hole) type of sorption dominates the overall uptake till the solution concentration reaches 0.14 $\mu g\, ml^{-1}$, then partitioning contributes more. The overall dissolution coefficient is 4330 $ml\, g^{-1}$ and Langmuir (hole) sorption capacity 961 $\mu g\, g^{-1}$. If the surface of this SOM sample (0.88 $m^2\, g^{-1}$) were rigid as an inorganic mineral, the maximal (external) surface coverage would be 286 $\mu g\, g^{-1}$ calculating from the molecular volume of phenanthrene as 182 $cm^3\, mol^{-1}$. Clearly, phenanthrene molecules have diffused into and sorbed within the SOM matrix, in contrast to surface adsorption.

SOM is heterogeneous and polydisperse in nature, and its characteristics can vary substantially as a function of age, source, diagenesis, and mode of transformation. Variations in SOM such as polarity and hydrophobicity strongly affect K_{oc}, up to several orders of magnitude. This is one reason why many different K_{oc}–K_{ow} free energy relationships are reported in the literature.

Aromatic and aliphatic moieties are the main structural components of SOM. Many investigations report positive correlations between the amount of HOC sorption and percentage of aromatic C of SOM. In addition, condensed aromatic domains are suggested to be the locations in SOM samples and isolated humic materials where nonlinear and competitive sorption occurs. Generally speaking, diagenetically altered organic matter samples are enriched in aromatic groups and show a higher degree of isotherm nonlinearity and competitive sorption, and a larger sorption capacity than geologically young samples. Organic matter in shale compared with recently deposited peat samples is an example in case. Therefore, HOC sorption is thought to be dominated by aromatic components of SOM rather than aliphatic components.

Recent research indicates that aliphatic components of SOM, particularly the paraffinic groups, can significantly sorb HOC. One example is that some soil humin samples often have a higher HOC sorption capacity than the humic acids extracted from the same soils, but these humic acids have higher aromatic content than the soil humins. It has been suggested that HOC is partitioned into the flexible, paraffinic carbon moieties to explain the high HOC sorption capacity. However, sorption of HOC by many soil humin samples is reported to be highly nonlinear and competitive, inconsistent with partitioning as the only sorption mechanism.

To account for both high sorption capacity and nonlinearity in soil humins, a new substructural conformation is proposed for the paraffinic carbons (Figure 5). Crystalline and amorphous aliphatic domains can coexist in SOM, which is supported by solid-state nuclear magnetic resonance (NMR) studies. A proposed conformation of semicrystalline polymer interphase is shown in Figure 5a. Sorption by crystalline regions is negligible due to their crystalline nature (inability for HOC molecules to diffuse). Upon interaction of the crystalline–amorphous complex with soil mineral surfaces, the first several molecular layers of the amorphous region may rearrange to take a more condensed form (Figure 5b). This condensed region can cause enhanced nonlinear sorption and both condensed and expanded amorphous aliphatic regions contribute to high HOC sorption. This proposed configuration is further supported by the experimental data reported in the early literature, where isotherm nonlinearity and competitive sorption of HOC by humic acids adsorbed on minerals are greater than unsorbed humic acids.

Physisorption to black carbon Black carbons are carbonaceous materials composed of single and stacked polyaromatic sheets in a highly disordered arrangement. The sheets may be functionalized along the edges with hydroxyl, carboxyl, keto, or other groups. The pore structure of black carbon depends on the source material and conditions of synthesis. From gas adsorption measurements it has high surface

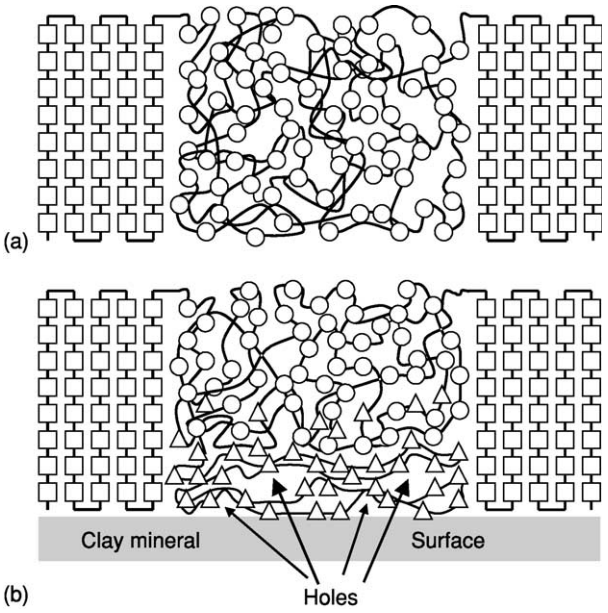

Figure 5 Schematic configuration showing the distribution of crystalline (squares) and amorphous (circles) aliphatic organic carbons (a). Interaction of the aliphatic carbons with a clay mineral surface rearranges part of the amorphous domain into a condensed configuration (triangles) having nanometer-sized holes (b). These holes are the locus of Langmuir adsorption sites, responsible for nonlinear and competitive sorption. (Reproduced with permission from Gunasekara AS and Xing B (2003) Sorption and desorption of naphthalene by soil organic matter: importance of aromatic and aliphatic components. *Journal of Environmental Quality* 32: 240–246.)

area (typically, more than $50\,m^2\,g^{-1}$), high porosity ($0.1–0.2\,cm^3\,g^{-1}$), and small pore size – i.e., below approximately 20 Å, with much porosity in the range 4–10 Å. Recent evidence shows that small apolar molecules can penetrate the interior of black carbon and cause swelling. Sorption isotherms of apolar compounds on prepared black carbons tend not to fit Freundlich or Langmuir models very well. For example, the isotherm of benzene in a wood charcoal is reverse S-shaped, with a linear region from 10^{-7} to 10^{-4} times its water solubility. While heats of sorption for black carbons have not been reported, sorption of apolar compounds from water to related carbonaceous sorbents such as graphite and activated carbon is exothermic.

A model that takes into account the existence of both macromolecular substances (humics plus kerogen) and black carbons in soils is clearly desirable. Models have been proposed of the form:

$$S = r_{HS} \cdot K_p C + r_{BC} \cdot f_{BC}(C) \qquad [10]$$

where r_{HS} and r_{BC} are the fractions of total organic carbon as humic substance and black carbon, respectively; S, K_p, and C are as defined above; and $f_{BC}(C)$ is a nonlinear function describing sorption to black carbon. In one example, $f_{BC}(C)$ is a Freundlich term like that in eqn [4]. In another, $f_{BC}(C)$ is a term that represents the potential to condense into liquid-like or solid-like form in pores that are assumed fixed in size and shape and similar to those that exist in synthesized activated carbons. Such models assume linear sorption in humic substances, which is not always true. Multicomponent models will be improved by advances in our understanding of the true nature of sorption to black carbon.

Kinetics of Physisorption

The rates of uptake and release from soil particles often control the transport and bioavailability of chemicals in soil systems. In well-mixed soil-water suspensions it is found experimentally that a large fraction of the sorbate is taken up or released within a few hours, but days, weeks, or even months may be required to reach complete equilibrium, depending on compound and soil. Moreover, exhaustive desorption at ordinary temperatures to air or water may reveal a minor fraction that seems permanently bound, yet is recoverable by solvent extraction or other vigorous means.

In general, soils contain structures that can hinder the diffusion of molecules to and from all available sites. These structures include pore networks in the interstices of particle aggregates as well as organic matter, which can be considered a highly viscous absorptive phase. Models based on pore diffusion and intraorganic matter diffusion being rate-limiting to sorption have been presented in the literature. Because most organic compounds have such a high affinity for the organic matter, it is tempting to regard intraorganic matter diffusion as rate-limiting unless the fraction of organic matter is very low. Generally, intraparticle sorption or desorption rate coefficients decrease with molecular size (or K_{ow} as a surrogate for size) and also appear to decrease with the introduction of hydrogen-bonding functional groups. This finding alone, however, does not distinguish pore diffusion and intraorganic matter diffusion. Fractions that become highly resistant to desorption have been generated in purely inorganic as well as purely organic reference materials. (Sorption or desorption in clay interlayers appears to be rapid, however, and does not generate resistant fractions.) Diffusion rates in soils are frequently independent of nominal particle radius, implying that the controlling diffusion length-scale is much smaller, perhaps as small as 10–100 nm.

Diffusion is highly dependent on the nature and geometry of the diffusing medium and the boundary conditions. Classic diffusion laws are difficult to

apply to soils owing to their heterogeneous nature in both composition and particle geometries. From studies on homogeneous inorganic reference materials, it is known that diffusion in fixed-pore networks containing mesopores (widths of 2–50 nm) or macropores (greater than 50 nm) is slowed by sorption to pore walls and by tortuosity. Tortuosity includes deviation from straight-line paths and pore noninterconnectedness. Diffusion in fixed micropore (less than 2 nm) networks, where pore openings are not much larger than the diffusant diameter, is additionally slowed by steric effects.

Intraorganic matter diffusion behavior depends on whether the solid is in the rubbery or glassy state. Diffusion in rubbery solids involves a more-or-less cooperative interchange between diffusant and polymer strands. The ideal rubbery sorbent is characterized by linear sorption isotherms, concentration-independent diffusion coefficients, and curves describing fractional mass uptake and release with time that are coincident. Diffusion in glassy sorbents generally shows the opposite. Molecules traversing the glassy solid experience a more condensed matrix and they encounter holes along the way where the diffusant can be momentarily detained. For these reasons, diffusion in glassy solids may be several orders of magnitude slower than in rubbery solids. The apparent diffusion coefficient in glassy solids is concentration-dependent because the availability of holes is concentration-dependent, and because the solid can undergo transition to a rubbery state at high concentrations. Diffusion coefficients of toluene, *n*-hexane, and acetone in pressed humic acid disks are in the range 10^{-8}–10^{-9} $cm^2\,s^{-1}$, about the same as in rubbery polymers and 3–4 orders of magnitude smaller than those in water. There is evidence to suggest that the diffusivity of a given compound follows the order: humic acid > humin > kerogen/coal. Diffusion within black carbons has received little attention so far.

To avoid difficulties inherent in the application of diffusion models to soils, many people have employed nonmechanistic rate models based on simpler mathematics. Recent ones include the two-site, multicompartment, and stochastic models. Although these models have met with some success, they usually suffer from an inability to translate to new systems. The two-site model, which is often used in soil-column elution studies, partitions the sorbate into instantaneous and kinetic compartments. The kinetic compartment is described by first-order terms for the forward and reverse steps. Overall the rate law has three parameters: fraction in the kinetic compartment, bulk solid equilibrium sorption coefficient, and rate constant for desorption from the kinetic compartment. The multicompartment model is popular in batch experiments in which molecules are instantly removed as they desorb by a stream of gas or by a polymeric sorbent included in the suspension. This model assumes that desorption occurs concurrently from 'fast,' 'slow,' and sometimes 'very slow' compartments, each described by a first-order term having two parameters: the rate constant and the fraction of chemical in that compartment. Stochastic models assume that the rate can be described with an array of equilibrium sorption coefficients and/or first-order rate constants that are distributed continuously according to a probability density function. Such models have three or two parameters, respectively.

Physisorption Hysteresis

Hysteresis in the sorption isotherm exists when the curve constructed by allowing the solid to take up the compound (the sorption branch) is different from the curve constructed in the reverse manner, by diluting the fluid and reequilibrating (the desorption branch). Typically, the desorption branch is shifted upward of the sorption branch, and may appear to extrapolate to a nonzero sorbed concentration at zero solution-phase concentration. Hysteresis has been observed in many studies. An example is given in Figure 6. Hysteresis poses a challenge to the elucidation of sorption mechanism and to using sorption models predictively.

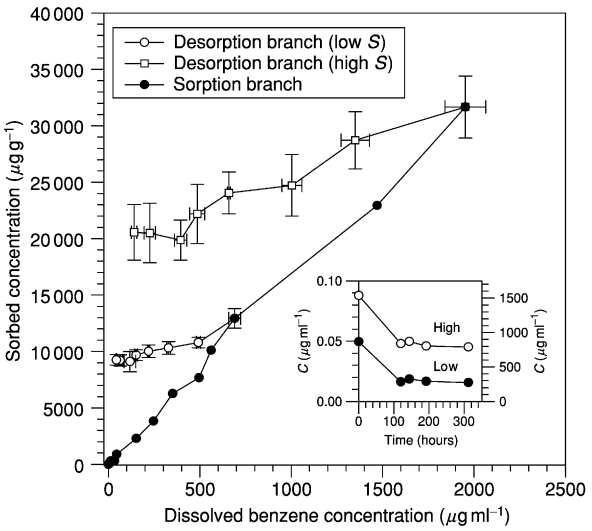

Figure 6 Hysteresis of benzene in a reference soil (Pahokee) from the International Humic Substances Society. Sorption was carried out in one step for 14 days. Desorption was carried out in consecutive steps (triplicate samples), each step for 14 days. Inset shows uptake rate curves (change in solution concentration) at two concentrations, indicating apparent equilibrium after approximately 4 days.

Hysteresis may be an artifact of the experimental technique. When sorbed concentrations are determined indirectly based on the amount taken up from solution, as is often the practice, artificial hysteresis may result from chemical or biological reactions or from dilution of competing substances such as cosolutes or colloidal sorbents in the desorption step. Failure to allow enough time for diffusion to all sites can give artificial hysteresis regardless of whether sorbed concentration is determined directly or indirectly. Nevertheless, in many cases hysteresis is observed even when those artifacts have been eliminated.

True hysteresis (also referred to as irreversible sorption) is caused by spontaneous mechanisms associated with irreversible pore-filling and -emptying. Since it would violate the laws of classical thermodynamics for both isotherm branches simultaneously to represent the reversible state, true hysteresis always indicates a nonequilibrium condition. Proposed explanations for true hysteresis fall into three categories: formation of metastable states of the sorbate, network percolation effects, and irreversible pore deformation. The first two are associated with capillary condensation of vapors in mesoporous solids. During uptake in a pore there can be a delay in the transition from the metastable multilayer film to the thermodynamic condensed plug state; evaporation from the meniscus of the condensate is less favorable than from the film surface. Hysteresis due to network percolation effects may arise in complex systems of pores, and it results when desorption is delayed because condensate in some pores does not have a continuous vapor channel to the surface. Capillary condensation hysteresis applies primarily to fixed-pore mesoporous materials.

Irreversible pore deformation has been identified in sorption of organic vapors or solutes by organic sorbents, including dry smectite clays, organosmectite clays, glassy polymers, and (recently) natural organic matter in soils and prepared charcoals. By this mechanism, the incoming molecule causes dilation of the pore due to the flexibility of the organic matrix, and the pore does not instantly relax when the molecule leaves. When this happens it may be surmised that some of the free energy of sorption goes into expanding the pores and the sorbate leaves from pores existing in a different thermodynamic state than the ones they entered. When desorption abruptly occurs, it is possible that some molecules get trapped in the collapsing organic matrix.

Ion-Exchange Sorption

Permanently charged and ionizable organic molecules in their ionic form can undergo 'ion-exchange' reactions with charged sites in soil particles from which existing ions are displaced. Cation exchange is far more common than anion exchange due to the prevalence of negative charges in soil particles. Examples of permanently charged compounds that can undergo cation exchange include tetraalkylammonium surfactants and cationic herbicides such as paraquat and diquat. Alkylamines, aromatic amines, and *N*-heterocyclic aromatic compounds are examples of ionizable compounds that can sorb via ion exchange, depending on the degree of their protonation, which, in turn, depends on soil pH.

Typically, cation exchange is nonlinear and subject to competition by other cations present. According to diffuse double-layer theory, cation exchange on mineral surfaces occurs by an accumulation of organic ions in the vicinal water film near the surface due to electrostatic force between the ion and the oppositely charged surface. However, sorption of organocations often exceeds the cation exchange capacity (CEC) of the solid in proportion to the apolar content of the molecule, such as alkyl chain length or aromatic ring content. This may be rationalized by a contribution to overall sorption from the hydrophobic effect operating on the apolar parts of the ion. In order to maintain electrical neutrality, organocations in excess of the CEC must carry along a counterion (e.g., Cl^-) to the interfacial region. Thus, sorption of organocations is best represented as the sum of true ion exchange and sorption of the ion pair:

$$R^+ + M^+ \cdots \equiv \rightleftharpoons M^+ + R^+ \cdots \equiv \qquad [11]$$

$$R^+ + X^- + \equiv \rightleftharpoons R^+X^- \cdots \equiv \qquad [12]$$

where R^+ represents the organocation, X^- a counter ion, M^+ a competing cation, and $\equiv$ the surface.

Ion-exchange reactions in SOM also occur. Organocations interact electrostatically with dissociated carboxyl or phenoxyl groups on humic molecules; hence, ion exchange in SOM is strongly pH-dependent. Ion exchange in SOM may be facilitated by physisorptive interactions of the noncharged parts of the molecule with humic groups other than the negative charge itself. Just like ion exchange on minerals, the hydrophobic effect may be expected to play some role in the sorption of organocations. Sorption of organoanions to SOM is typically weak, since positively charged sites on SOM are rare and the solid is negatively charged overall at ordinary pH. However, some organoanions – e.g., alkylbenzene sulfonate surfactants and the anion of pentachlorophenol – appear to be capable of sorbing to SOM, possibly as their ion pairs with Na^+ or other cations.

Chemisorption

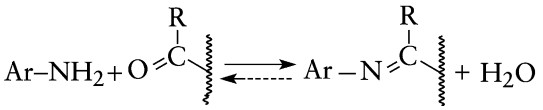
Chemisorption entails appreciable overlap of molecular orbitals between sorbate and sorbent, such as ligand–metal coordination bonds and covalent bonds. Molecules capable of chemisorption may also be capable of physisorption.

Ligand–metal bonds may be formed between carboxylate, phenolate, thiolate, sulfonate, or phosphate groups on the solute and metal ions – especially Fe^{3+} and Al^{3+} – on the surface of minerals, usually in exchange for hydroxyl or water ligands:

$$\equiv M{-}OH(-OH_2) + L^- \rightleftharpoons \equiv M{-}L + OH^-(H_2O) \quad [13]$$

where $\equiv$ represents the surface, M a metal ion, and L a ligand. Equation [13] is more favorable when L is bidentate; for example, salicylate, oxalate, catecholate, or *o*-phthalate and their derivatives. In that case the ligand can coordinate through both functional groups and to more than one metal ion. It is also possible for the metal ion to be attached to SOM through an appropriate functional group on the humic structure; in that case, an organic ligand (e.g., 2,4-dichlorophenoxyacetate (2,4-D anion)) may coordinate to the cation and thus be linked through cation-bridging to SOM. The energetics and kinetics of surface ligand exchange reactions are not well characterized. The intrinsic equilibrium constant seems to depend on structure in the same way as when the corresponding reaction takes place between the ligand and free metal ion in solution.

Covalent bonds between sorbate and humic substances are comparatively rare. Aromatic amines often generate nonextractable residues and are postulated to react, quasi-reversibly, with certain carbonyl groups on humic macromolecules to form imines:



[14]

The reactive carbonyl may be present in ketone, aldehyde, or quinone functional groups. The rate and extent of imine formation are currently unpredictable.

Other cases are known in which the organic solute is converted to reactive forms that then couple covalently with humic substances. Concern about potential remobilization of these so-called bound residues has spawned an active area of research. Coupling reactions are technically outside the definition of sorption, since the molecules undergoing coupling are transformed species, not the original ones, and since they are seldom reversible in the sense that the original chemical is liberated. Examples are found among pesticides, explosive compounds, phenols, aromatic amines, and polycyclic aromatic hydrocarbons (PAHs). Typically, the initial reaction is an enzyme- or mineral surface-catalyzed oxidation reaction, although reduction reactions have been reported. Rarely has the coupling reaction itself been assigned with certainty to a biotic or an abiotic origin, much less a specific mechanism. In most cases coupling is inferred by the inability to recover by solvent extraction a portion of an isotope when the compound is added in isotopically labeled form. Oxidative coupling of some compounds – for example the fungicide cyprodinil and the herbicide 2,4-dichlorophenoxyacetic acid – has been verified by nuclear magnetic resonance spectroscopy. In another example, trinitrotoluene was microbially reduced to amino toluenes that subsequently coupled to organic matter, most likely abiotically via eqn [14]. It has been proposed that aromatic amines are oxidized by manganese oxide minerals in soils to give free radicals that subsequently couple with humic substances.

Oxyanions

Introduction

An oxyanion is a net negatively charged compound consisting of a cation at its center surrounded by oxygens. There are many different oxyanions present in soils. The most common ones of interest to soils include phosphates (PO_4^{3-}), arsenite (AsO_3^{3-}), arsenate (AsO_4^{3-}), selenite (SeO_3^{2-}), selenate (SeO_4^{2-}), chromate (CrO_4^{2-}), molybdate (MoO_4^{2-}), carbonate (CO_3^{2-}), sulfate (SO_4^{2-}), nitrate (NO_3^-) and perchlorate (ClO_4^-). Oxyanions are prevalent in nature, and most of these are essential nutrients for plants. Most all of them, however, are also toxic to plants and the environment when their concentrations rise above a certain critical level. For example, excessive amounts of some oxyanions, namely nitrates and phosphates, are directly responsible for the eutrification of our ponds and lakes.

There are, of course, numerous other oxyanions that are discussed in the environmental literature, particularly in connection to industrial and nuclear waste disposal, or spills and remediation. Industrial oxyanion wastes include many of those already mentioned above. Radioactive waste and environmental studies may include oxyanions such as pertechnetate (TcO_4^-). Since no stable isotopes of Tc exist (which are prepared in very small amounts in cyclotrons), and since it is rather dangerous to work with this radionuclide, a surrogate oxyanion is typically studied instead, namely perrhenate (ReO_4^-).

The fate of oxyanions in soils in the environment is strongly dependent on their sorption to soil mineral components. That is, an oxyanion that is adsorbed to an immobile solid phase will not be transported to a new location, because movement of oxyanions in the environment is through the liquid phase. Retention by solids results in a longer availability of oxyanions in a defined area. For example, leaching from the soil's upper horizons down toward groundwater does not occur as long as it is sorbed to the immobile solid phase. Lateral liquid movement to nearby streams is also minimized, as is its subsequent transport to larger bodies of water.

All this, of course, assumes that the solid phase that the oxyanion is sorbed to is itself immobile. Keep in mind, however, that various solids (such as colloidal-sized particles) are very small and can be translocated by the moving water. This translocation of mobile solids along with the ions sorbed on them can be either vertically through soil horizons, or horizontally with the groundwater flow, or as soil erosion moving horizontally over the soil surface.

An understanding of sorption of oxyanions to solid soil components is very important for an evaluation of the quality of the environment. If the oxyanions are retained weakly, then the moving water will easily remove them from the soil. If the retention of oxyanions by the immobile solid-phase is moderate in strength, then the moving water will remove the oxyanions from the area slowly. Conversely, if the oxyanions are retained strongly by immobile solids, then the moving water will remove them from the area very, very slowly. If the solid phases are small enough to be mobilized by the moving water, then attention to the turbidity of the liquid phase or the presence of surface soil erosion must be included in any evaluation of the environmental quality present. Once again, this is because the mobile solids typically will have sorbed contaminants on them.

Techniques for Detection and Quantification of Oxyanions in Solution

Quantitative studies of the adsorption of oxyanions on soils and minerals require determination of the oxyanion concentration remaining in the aqueous phase. That is, the amount adsorbed equals the amount of anion added to the solid-liquid suspension minus the amount remaining in the liquid phase at equilibria. Many different instruments can be used for the liquid-phase analysis, such as ion-selective electrodes, colorimetric methods, ion chromatography, atomic absorption, and inductively coupled plasma-atomic emission spectrometry. With some of these methods (namely, the first three mentioned), one must be particularly cautious to avoid problems attributed to speciation and complexation interferences. These complications can usually be avoided by measuring the liquid phase concentration with

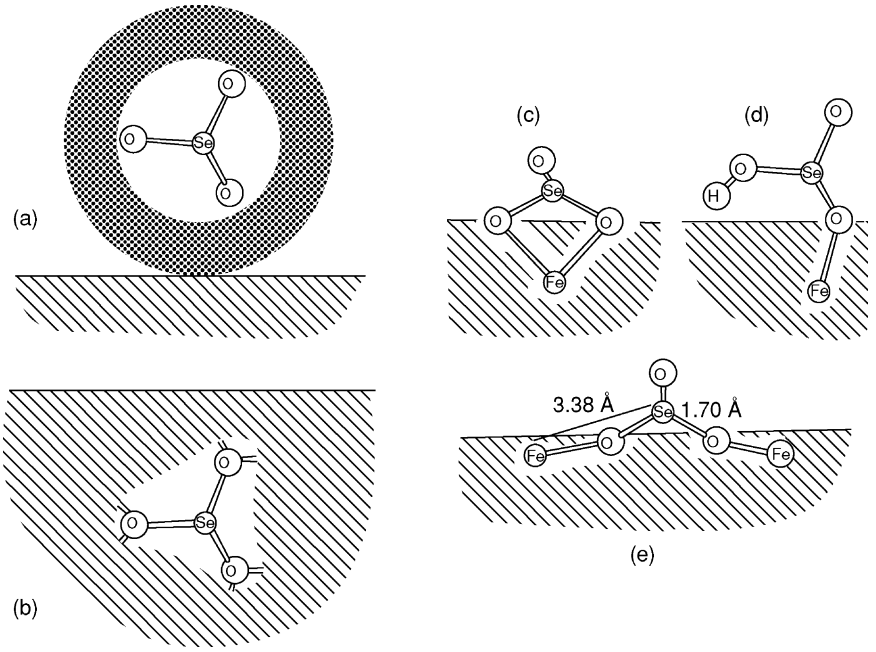

Figure 1 Schematic of several of the possible geometric arrangements of an oxyanion at the solid–water interface. Selenite is the adsorbate oxyanion and an iron oxide the adsorbent mineral. The area above each surface (indicated by solid horizontal lines) is water, while the solid mineral phases are below the solid horizontal lines. (Reprinted from Brown GE Jr, Parks GA, and Chisholm-Brause CJ (1989) *In-situ* X-ray absorption spectroscopy studies of ions at oxide–water interfaces. *Chimia* 43: 248–256.)

a high background ionic strength and at a specified pH condition. One does not generally quantify the amount of oxyanions adsorbed by direct measurement of the solid-phase concentration. This is because many of the solid-phase measuring methods require expensive instruments and/or the quantitative precision is not satisfactory.

Techniques for Investigation of Oxyanions Adsorbed at Mineral–Water Interfaces

Various surface-sensitive techniques have been used to obtain structural information of surfaces and surface species that are needed to identify adsorption mechanisms and reactions. An important aspect of the application of spectroscopic techniques to the investigation of adsorbed species is the experimental conditions under which the spectra of the sample are collected. Invasive or *ex situ* methods commonly require extensive sample dessication and vacuum, and therefore have the potential for modifying or destroying sorption complexes normally present at the solid–liquid interface in an aqueous environment. Conversely, noninvasive or *in situ* methods require little or no alteration of a sample from its natural state. Clearly, in order to resolve the structure of surface species present at a mineral–water interface of natural particles, *in situ* spectroscopy techniques are needed that can be applied in the presence of liquid water. Three examples of *in situ* techniques that have been used for the investigation of oxyanions on mineral–water interfaces are attenuated total reflectance–Fourier-transformed infrared (ATR-FTIR), Raman, and X-ray absorption spectroscopy (XAS). A very brief overview of these is given below.

The predominant application of spectroscopic analysis of adsorbed oxyanions at the solid–liquid interface is to understand the symmetry and binding mechanism of the anion on the surface. Quantitative measurements ("How many ions are adsorbed?") is not the primary focus, because, as was noted above, this is much more easily determined based on the mass balance of the elements added and recovered from the liquid phase. Spectroscopy is the only method, however, that can determine how the ions are held on the surface. Figure 1 shows five commonly encountered possibilities. Using selenite as the example oxyanion, it can be held as an outer-sphere (Figure 1a), where at least one molecule of water exists between the anion and the surface. It may be embedded in the internal regions of the mineral (Figure 1b) due to solid diffusion of the anion into the mineral or due to some coprecipitation of the anion with a cation onto the surface of the mineral. Figure 1c–e shows the anion held as an inner sphere, where the anion directly bonds with the mineral surface. An inner-sphere anion can be monodentate (Figure 1d) or bidentate

(Figure 1c, e). 'Monodentate' means that there is only one bond formed between the anion and the surface, whereas 'bidentate' means that there are two bonds formed between the anion and the surface. The bidentate inner-sphere bonds can be mononuclear (Figure 1c) or binuclear (Figure 1e), which refer to the minimum number of mineral cations that are needed to link the anion's oxygens to the mineral.

Vibrational Spectroscopies

Vibrational spectroscopy techniques such as FTIR and Raman spectroscopy probe the vibrational properties of molecules. Characteristic vibrational properties of oxyanions originate from *X*—O(H) stretching and bending vibrations. Each oxyanion has its characteristic pattern of vibrations that relates to its symmetry state. The symmetry, and consequently the vibration pattern, changes when an oxyanion complexes with other ions such as protons or metal cations. The changes in the number and position of the virbational bands provide information about the speciation and coordination state of the oxyanion. This behavior is the underlying principle of the determination of the types of surface species using vibrational spectroscopy.

Spectra of outer-sphere complexes are similar to the spectra of the free anion in solution. Differences in position and number of adsorption bands between the spectra of solution and adsorbed species indicate coordination with the surface, that is, inner-sphere complexation. Determination of the coordination state of an inner-sphere complex (mono- or bidentate and mono- or binuclear) is usually based on the comparison of spectra of adsorbed species with the literature data of spectra of coordinated compounds with known structures. Extensive infrared and Raman spectral data of inorganic and coordination compounds are available.

Attenuated total reflectance–Fourier-transformed infrared (ATR-FTIR) spectroscopy is an *in situ*, infrared sampling technique that can be used to provide information about surface species at the mineral–water interface. Note that, since water strongly adsorbs infrared, it was the introduction of ATR (and other similar detection modifications, such as cylindrical internal reflectance, CIR) that has given us the needed breakthrough to very effectively use FTIR in aqueous (i.e., natural) mediums. This technique has been applied successfully to investigations of various anions (PO_4^{3-}, $B(OH)_4^-$, SO_4^{2-}, CO_3^{2-}, NO_3^-) at metal oxide–solution interfaces.

The use of ATR-FTIR does not fully avoid water absorption of the infrared signal. The spectral window in metal oxide aqueous suspensions is limited by the strong adsorption by water and metal oxide lattice vibrations in the region below 1000 cm^{-1} and the strong adsorption by water in the region of 3000 – 4000 cm^{-1}. For example, the vibrations of the oxyanions of Se and As are expected below 1000 cm^{-1} and, consequently, are difficult to observe in these systems with the ATR-FTIR technique.

Diffuse reflectance FTIR (DRIFT) is an infrared sampling technique that requires air-drying of the sample. Usually this does not significantly affect the surface speciation and coordination of the adsorbed oxyanion because a very thin layer of water should remain on the mineral surface. Since there is less interference with the strong absorbing water, this sampling technique offers the possibility to investigate OH-stretching in the spectral range of 3400–3800 cm^{-1}. The OH-stretching bands can provide information about the effect of oxyanion adsorption on the surface OH groups of the mineral surface.

Raman spectroscopy can provide a window in the spectral region below 1000 cm^{-1} in the investigation of aqueous minerals and, accordingly, can offer complementary data to IR spectroscopy. One of the attractive aspects of Raman spectroscopy for its application to minerals in aqueous suspension is that Raman is transparent to water and, therefore, offers the possibility of *in situ* investigation of surface species. The recent advances in Raman instrumentation have brought new opportunities for applications to the investigation of surface species at mineral–water interfaces. Raman spectroscopy has been used to study the interfacial species on metal oxides of SeO_4^{2-}, SO_4^{2-}, AsO_4^{3-} and AsO_3^{3-}.

X-Ray Absorption Spectroscopy

X-ray absorption spectroscopy (XAS) is another techniques that can be applied to *in situ* studies of adsorbates at mineral–water interfaces. XAS is an element-specific, short-range probe, providing information about the local structural and compositional environment of an adsorbing atom. X-ray absorption near-edge structure (XANES) spectra provide information about the bonding and oxidation state of the adsorbing atom. Extended X-ray absorption fine structure (EXAFS) can provide information about the composition and structure in the vicinity of the element. The absence of back-scattering beyond the first shell indicates an outer-sphere complex. In the case of inner-sphere complexes, the number, distance, and type of back-scatterers provide information for identifying the type of inner-sphere complex (mono-versus bidentate). XAS has been used to identify the adsorption mechanisms of the oxyanions of Se, As, and Cr. The technique requires high-energy X-rays, which are only available at synchrotron facilities.

Sorption Strength of Oxyanions

The strength of the bond of oxyanions with mineral surfaces strongly affects the fate of the oxyanion in the environment. Weakly held anions leach easily and are lost from the upper soil horizons down toward the groundwater or are readily carried in the surface runoff to nearby streams. There are a few ways to determine the relative strength of these bonds. One common method used involves adsorption isotherms and another involves adsorption edges.

An adsorption isotherm analysis is based on measuring the amount of anion adsorbed by a solid phase as a function of the equilibrium concentration present in the liquid phase, as shown in Figure 2 for sulfate adsorption onto an aluminum oxide. The curvature of the isotherm, which is particularly visible at low aqueous concentrations, is a function of the adsorption strength. Qualitatively, the sharper the rate of increase and the sharper the amount of curvature observed in the adsorption isotherm, the stronger the adsorption strength of the compound with the surface. It is the curvature of the adsorption isotherm, not the adsorption maximum, that gives an indication of the adsorption strength.

Efforts to quantify the adsorption strength have been the focus of much debate in the literature for nearly a century. For example, if we assume a simple adsorption mechanism:

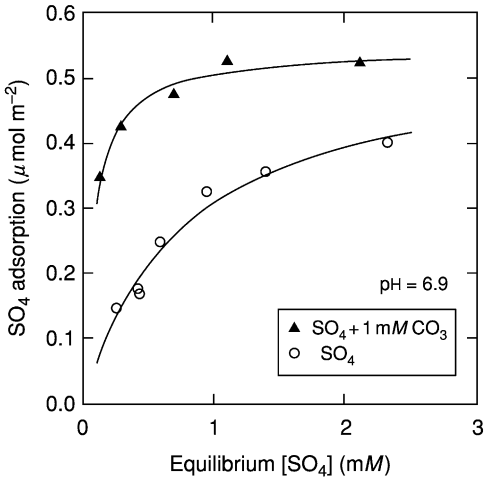

Figure 2 Adsorption isotherms of sulfate on an aluminum oxide (bayerite). Notice that the presence of carbonates increased the adsorption strength of sulfate, which is contrary to the competitive adsorption behavior typically observed when two adsorbing anions are in solution. (Reprinted from Wijnja H and Schulthess CP (2000) Interaction of carbonate and organic anions with sulfate and selenate adsorption on an aluminum oxide. *Soil Science Society of America Journal* 64: 898–908.)

$$\text{Solid Surface} + \text{Aqueous Anion} \rightleftharpoons \text{Adsorbed Anion} \qquad [1]$$

then the amount adsorbed can be predicted mathematically using data-fitting techniques on the Langmuir isotherm equation:

$$\text{Amount Adsorbed} = MKc/(1 + Kc) \qquad [2]$$

where M is maximum adsorption, which can be obtained from the isotherm at high aqueous concentrations; K is the Langmuir constant, which is equal to the ratio of P/R, with P the adsorbed anion concentration, R the (concentration of unoccupied surface sites) $\times$ (aqueous anion concentration); and c is the aqueous anion concentration at reaction equilibria. The adsorption strength is quantified here by the Langmuir constant, K. Much debate arises, however, about just how the adsorption mechanism should be modeled; that is, modeling the adsorption reaction by eqn [1] and other similar equations are not yet fully validated. Note that a model that does not fit the data is clearly disproved. However, a model that does fit the data is not automatically adequately validated.

One can also infer the relative strength of an adsorbing anion based on the pH value of the adsorption edge, which is shown in Figure 3. For a given mixture, the amount of aqueous anion adsorbed by the solid phase is strongly dependent on the equilibrium pH of the system. Working down the pH scale, there is no adsorption of anions at high pH values. At intermediate pH values, there is an abrupt increase in adsorption. The pH value measured at the midpoint of this abrupt adsorption increase is the pH value of the adsorption edge. At much lower pH values, there is a decrease in the amount of anions adsorbed. The entire bell-shaped curve is known as an adsorption envelope.

If we assume that the adsorption mechanism involves the coadsorption of hydroxyl anions (OH^-), for example:

$$\text{Surface—OH} + \text{Anion}^{n-}(\text{aq}) \rightleftharpoons \text{Surface—Anion}^{1-n} + \text{OH}^-(\text{aq}) \qquad [3]$$

then we can use the pH value of the adsorption edge to compare the relative adsorption strength of the anion. At equimolar concentrations, the anion that has a higher adsorption edge value is the anion that binds more strongly with the surface. Notice in eqn [3] that a strong surface–anion bond will require a higher concentration of OH^- anions to reverse the reaction. The midpoint of equilibria for eqn [3] occurs at the adsorption edge. Accordingly, if the

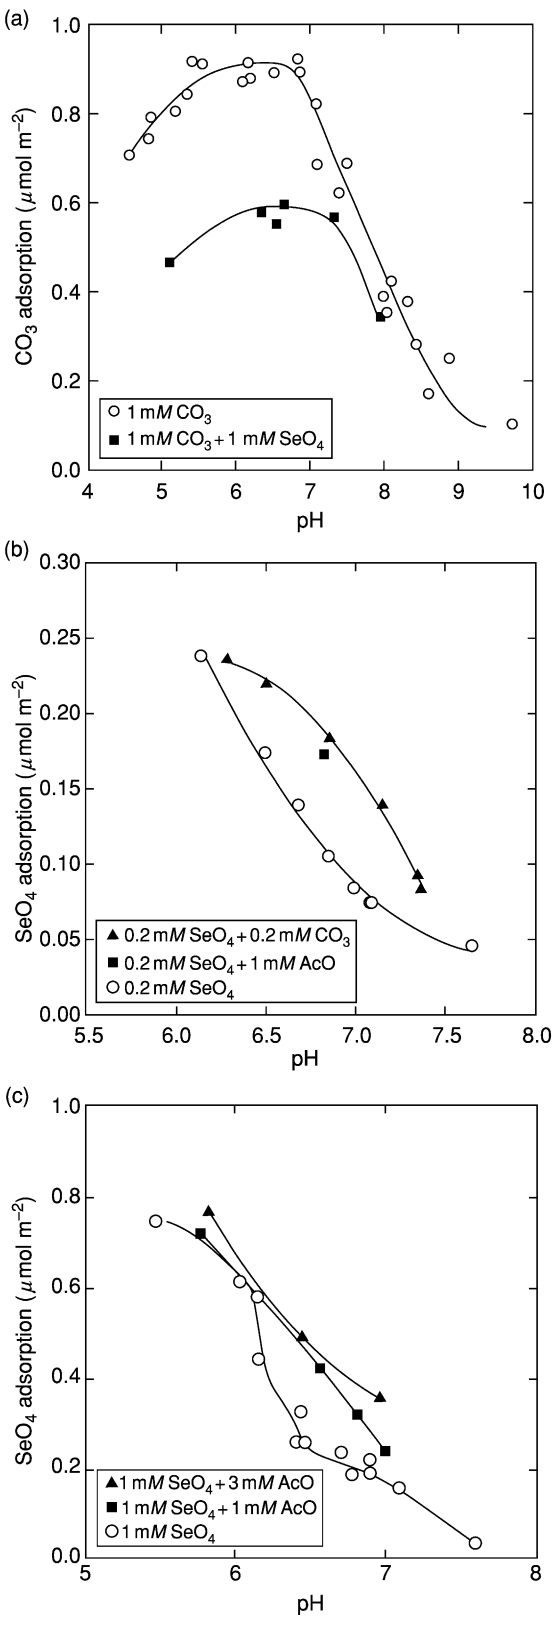

Figure 3 Adsorption envelopes (adsorption as a function of pH) for various oxyanions on goethite: (a) adsorption of carbonate. Notice the competitive behavior of selenate on carbonate adsorption; (b, c) adsorption of selenate in the presence of carbonate and acetate. Notice the enhancement by these oxyanions of selenate adsorption. (Reprinted from Wijnja H and Schulthess CP (2002) Effect of carbonate on the adsorption of selenate and sulfate on goethite. *Soil Science Society of America Journal* 66:1190–1197.)

adsorption of an anion is strong, then the quantity of OH^- anions needed to reverse the reaction will be high, and the pH value of the adsorption edge will be high also.

Efforts to quantify the adsorption strength based on the pH value of the adsorption edge are not yet fully resolved. The problem arises in that we are not definitively sure that eqn [3] or other similar equations fully describe the adsorption process. Consequently, the mathematical interpretation of the pH-dependent data is still discussed extensively in soil science research articles. We do know, however, that if the pH is kept constant, then eqn [3] will simplify to eqn [1], and equations similar to eqn [3] will simplify to equations similar to eqn [1]. We also know that anion adsorption does involve the release of hydroxyl anions. Note that it is difficult to distinguish hydroxyl release (which chemically removes protons from solution) from proton coadsorption (which physically removes protons from solution). Accordingly, essentially identical concepts can be presented using equations that illustrate proton coadsorption to the surface rather than hydroxyl release from the surface.

Using the tools outlined above, a general review of the published data suggests the following trend: the larger the negative charge present on the oxyanion, the stronger the affinity of the oxyanion toward the surface. Within each group, there is much uncertainty on which is more strongly adsorbed, and this is probably due to numerous reasons (such as, presence of surface contaminants). In general, the affinity of trivalent oxyanions follows the sequence: $AsO_3^{3-} > PO_4^{3-} \approx AsO_4^{3-}$. Divalent oxyanions adsorb more weakly, and in general follow the affinity sequence $SeO_3^{2-} > CrO_4^{2-} > CO_3^{2-} > SeO_4^{2-} \approx SO_4^{2-} > MoO_4^{2-}$. Monovalent oxyanions such as ReO_4^-, NO_3^- and ClO_4^- are very weakly adsorbed. Another, more useful observation is the close correlation of adsorption affinities of oxyanions with the stability constants (pK_a values) of their conjugate acids; noteworthy is the high adsorption affinity of $B(OH)_4^-$ by minerals. For these reasons, nitrates or perchlorates are sometimes used as background electrolytes in adsorption studies and are often assumed not to adsorb at all or to cause no significant impact on the adsorption process of the other compounds present.

Impact of Ions on Adsorption of Oxyanions

The presence of dissolved electrolytes in the mixture affects the adsorption of oxyanions. Adsorption studies, therefore, are pursued under constant ionic-strength conditions. These background electrolytes consist of dissolved cations and anions such as Na^+Cl^- or $Na^+NO_3^-$. It is critical to the adsorption study that the reactivity of these ions with the surface be minimal, preferably completely unreactive or at least constant in their reactivity. Sometimes, an aqueous phase complexation reaction occurs between the oxyanion being studied and the components of the background electrolyte. This will complicate the analysis and should be avoided as much as possible, preferably by using a different background electrolyte.

The presence of dissolved electrolytes affects the adsorption process in numerous ways. First, it raises the ionic strength of the solution. This tends to lower the electrostatic attraction of the adsorbate due to the lowering of surface potential or the masking of the surface charge. This impact on the adsorption process is not a serious concern as long as the ionic strength is kept constant throughout the study.

Second, the background anion can compete with the oxyanion for adsorption sites, which is very likely at high ionic-strength concentrations. Although the adsorption of the background anion (e.g., Cl^-) is typically extremely weak, it is rarely zero and its competitive impact increases significantly as its concentration in solution increases. This impact on the adsorption process is not serious as long as the concentration of the background ions are kept constant. It will, however, cause some complications to attempts to understand or quantify the adsorption strength of the oxyanion. When comparing adsorption isotherms or adsorption edges of adsorption envelopes, it is helpful if the oxyanions are compared at the same ionic strength and initial conditions. This impact is shown in Figure 3a at low pH, where the concentration of weakly competitive aqueous Cl^- anions has increased to the point of rendering it significantly competitive with the carbonate oxyanion. The source of the Cl^- anion at low pH is from the addition of acids (namely, HCl) needed to achieve the low-pH conditions.

Competition between anions is also shown in Figure 3a, where the presence of selenate significantly reduces the adsorption of carbonate. Competition between oxyanions is commonly observed. Competitive behavior should be expected due to the structural similarities of the oxyanions and the similarity of their adsorption sites. High Cl^- concentrations will also lower the amount adsorbed over a broad pH range due to competitive adsorption.

Third, the reactivity of the background anion (e.g., Cl^-) with the surface may be pH-dependent. Note that the first two problems mentioned above assume, for simplicity, that the reactivity of the background anion is pH-independent. However, this is perhaps one of the most serious problems that can arise in the study of oxyanion-adsorption processes. In these situations, the reactivity of the background anion must be monitored if the adsorption reactivity of the oxyanion with the solid surface is to be properly understood.

Fourth, some anions may be present in the mixture that actually enhance the adsorption reaction of the aqueous oxyanion with the solid surface. Note that this is a counterintuitive process because traditional views do not have an anion causing an increase in adsorption of another similarly charged ion. Figure 2 shows a sharp increase in adsorption of sulfate on an aluminum oxide in the presence of carbonate. Figure 3b and c shows that this enhancing effect is also pH-dependent. The enhancement of oxyanion adsorption, such as sulfate and selenate adsorption on aluminum oxide and iron oxide, has been observed in the presence of carbonates, acetate, and formate anions. At high concentrations, these anions seem to become competitive. Hence, an enhancing effect does not exclude the existence of a concurrent competitive effect. The enhancing effect is most pronounced at low concentration levels, where any possible competitive effect would also be at its lowest level (Figure 4). It is

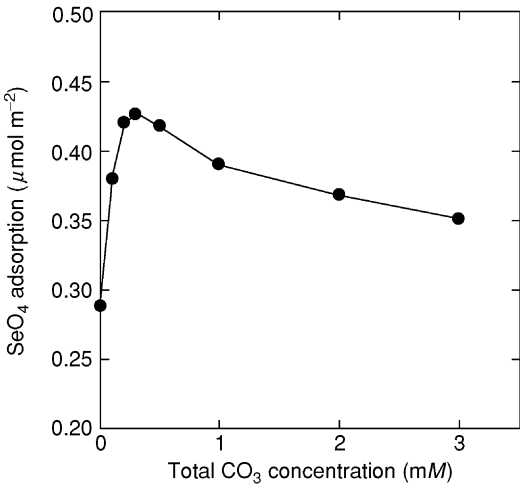

Figure 4 Adsorption of 1 m*M* selenate at pH 6.8 on an aluminum oxide (bayerite) as a function of the amount of carbonate added. Notice that the presence of carbonates increases the adsorption of selenate at low carbonate concentrations. (Reprinted from Wijnja H and Schulthess CP (2000) Interaction of carbonate and organic anions with sulfate and selenate adsorption on an aluminum oxide. *Soil Science Society of America Journal* 64: 898–908.)

not clear how prevalent the enhancing effect is in nature or in laboratory studies. We do know, however, that carbonates are nearly always present in aquatic systems. Their concentration in laboratory solutions varies widely depending on the pure water sources used or on the techniques used to minimize or control the carbonate concentrations. In other words, aqueous carbonate impurities can easily enter the sample preparations unbeknownst to the experimenters and cause a wide range in the variance of the data collected. This creates a serious problem for those that wish to understand and quantify the adsorption of oxyanions by solid surfaces in aqueous mediums.

Sorption Mechanisms of Oxyanions

The adsorption reaction of oxyanions at a mineral surface is described as a surface complexation reaction between the oxyanion and a surface functional group forming a surface complex. With respect to the types of surface complexes or adsorption mechanisms, there are commonly two major types distinguished: inner-sphere and outer-sphere complexes. An inner-sphere complex is formed via a ligand-exchange reaction with a surface-OH or surface-OH_2^+ group and is directly coordinated with the underlying surface metal ion. In a monodentate inner-sphere complex, one bond is formed with a surface group. In a bidentate complex, two bonds are formed, either with one surface metal ion (mononuclear) or with two surface metal ions (binuclear). In contrast, outer-sphere complexes form mainly by electrostatic interactions and at least one water molecule is interposed between the oxyanion and the mineral surface. Diffuse-ion swarm ions do not form a complex with a surface functional group, but instead are only bound through electrostatic interactions that neutralize the surface charge. Spectroscopic tools are essential for the development of detailed descriptions of the adsorbed oxyanion. A mechanistic description of the adsorption process requires spectroscopic information of the adsorbed species, plus information on the stoichiometry of the reaction and reaction rates, as well as a measure of the adsorption strength.

Oxyanions with a relatively high adsorption affinity such as PO_4^{3-}, AsO_4^{3-}, SeO_3^{2-}, and $B(OH)_4^-$ form predominantly inner-sphere complexes on metal oxide surfaces. Both monodentate and bidentate complexes have been found on metal oxides for several of these oxyanions. For example, it has been shown that the relative distribution of monodentate and bidentate inner-sphere complexes of AsO_4^{3-} and CrO_4^{2-} varies with the surface coverage.

The CO_3^{2-} anion forms monodentate inner-sphere complexes at metal oxide–water interfaces. Oxyanions with low affinity, such as NO_3^- and ClO_4^-, absorb mainly as outer-sphere and diffuse-swarm ions.

Several anions that have high or moderate sorption affinity, such as AsO_3^{3-}, SeO_4^{2-}, and SO_4^{2-}, show intermediate behavior, where both inner- and outer-sphere surface complexes coexist at metal oxide–water interfaces. For these moderately adsorbing anions, the relative distribution of inner- versus outer-sphere adsorption depends on pH, ionic strength, and type of mineral.

When an anion is held as an inner-sphere compound, then it has probably been preceded by an initial outer-sphere attraction to the mineral surface. The mechanism of forming an inner-sphere bond must involve the release of a molecule of water from the solid–liquid interface into the bulk solution. A net volume change occurs to the system whenever this process occurs, and this can be measured with a dilatometer. Based on measured volume changes, there is approximately one molecule of H_2O released into the bulk solution for every aqueous molecule of SO_4^{2-}, SeO_4^{2-}, or $H_2PO_4^-$ adsorbed onto an amorphous iron hydroxide at pH 4.5, which should be expected for inner-sphere adsorption of these oxyanions.

Anion adsorption is accompanied by proton uptake. The net proton uptake is the result of a ligand exchange reaction (OH release), surface protonation, oxyanion protonation on the surface, or a combination of these. Quantifying the number of protons coadsorbed (or OH released) by the surface per molecule of oxyanion adsorbed is an important component of our understanding of the adsorption process. This stoichiometry of the reaction directly affects how the surface reaction will be described, such as the 1:1 stoichiometry described in eqn [3]. This, in turn, also affects how the surface complexation model will be developed. The best way to obtain data on the adsorption or coadsorption of protons is by an acid–base titration method known as the backtitration technique.

Anion adsorption affects the electrostatic properties of mineral surfaces. The net surface charge of a mineral surface is the result of proton-transfer reactions and surface-complexation reactions. Electrophoretic mobility measurements can reveal the net surface charge changes due to oxyanion adsorption. In general, the adsorption of an oxyanion tends to lower the positive charge present on a surface. The positively charged surface does not necessarily become negatively charged following the adsorption of oxyanions. Instead, it tends to approach a net neutral surface charge. Taking these data in conjunction with the proton coadsorption data mentioned above, the adsorption of oxyanions and proton

coadsorption tends to form net neutral products on the mineral surfaces.

The adsorption of oxyanions generally reaches a maximum at around the pK_a value for the conjugate Bronsted acid, as shown in Figure 3a for carbonate adsorption ($pK_a = 6.3$). One can generally infer that the higher the value of the oxyanion's acidity constant (pK_a), the stronger will be its adsorption by a hydrophilic surface. This further reflects the importance of the coadsorption of protons on the adsorption mechanism of oxyanions. The mechanism of bringing the coadsorbed protons to the mineral surface does not necessarily follow a separate, independent path from that taken by the adsorbing oxyanion. The proton can be brought toward the mineral surface by the protonated oxyanions. The fate of the coadsorbed proton may be: (1) to remain complexed with the adsorbed oxyanion (hence, the oxyanion is held as a Bronsted acid on the mineral surface); (2) to remain complexed with the surface (hence, the oxyanion's negative charge is neutralized by a positively charged surface-OH_2^+ surface, which may or may not be directly below or adjacent to the adsorbing oxyanion); or (3) it may react with a surface-OH group and form an H_2O product that diffuses back to the bulk solution (this may also be described schematically as a hydroxyl exchange mechanism, where the hydroxyl is neutralized by free protons in the aqueous phase).

Site Preference and Site Reactivity

Surface hydroxyl groups constitute the complexation sites on metal oxide surfaces suspended in aqueous solutions. The surface groups behave as weak Bronsted acids or bases, capable of ionizing to yield a pH-dependent charged surface or serving as a ligand in surface complexation reactions. Analysis of the crystal structure of metal oxides indicates the existence of various different types of surface hydroxyl groups with different reactivities. Their reactivity depends, among other factors, on their coordination environment (singly, doubly, and triply metal-coordinated). The different crystal planes of a metal oxide mineral have a different composition with respect to the types of surface groups and densities of these groups.

With respect to complexation of oxyanions, the singly coordinated surface hydroxyls are believed to be most reactive. An FTIR study on the effect of As oxyanions on the various different types of surface groups has indicated that the singly coordinated surface groups are involved in the ligand exchange reaction to form inner-sphere complexes.

There are several things that the adsorbed oxyanion can do after it has adsorbed to the mineral surface. It can, of course, desorb from the surface and diffuse back to the aqueous bulk solution. Given the high energy of hydration of many of these oxyanions, this desorption step is very likely and is the basis for establishing the equilibrium condition where only a specific density of anions remain adsorbed to the surface for a given concentration of anions in solution.

The adsorbed oxyanion can also diffuse into the mineral through a process known as solid diffusion (product is shown in Figure 1b). Solid diffusion at ambient temperatures is a very slow process. However, the oxyanion may also became entrapped inside the mineral through the process of oxyanion-enhanced dissolution of the mineral followed by coprecipitation of the oxyanion–metal complex.

A final option for the adsorbed oxyanion is to migrate laterally, traveling horizontally on the mineral surface along a two-dimensional matrix. This is dependent on the strength of the bond of the oxyanion with the surface. The lateral, two-dimensional mobility of the oxyanion allows it to migrate toward a more stable adsorption site (more stable, that is, relative to its point of initial collision and reaction with the surface). Lateral mobility of adsorbed ions is known to occur on solid–gas interfaces, but data are missing that accurately quantify this mobility on solid–liquid interfaces.

Introduction

In the past two decades, as concerns and interests about soil and water quality have increased, soil and environmental chemists, environmental and chemical engineers, and geochemists have increasingly realized that sorption/desorption reactions in soil and other subsurface environments are time-dependent. Thus, to predict accurately the fate, mobility, speciation, and bioavailability of environmentally important plant nutrients, trace elements, radionuclides, and organic chemicals in soils, one must understand the kinetics and mechanisms of the reactions. This article will provide an overview of the topic of kinetics of sorption/desorption on soils with applications to environmentally important reactions.

Rate-Limiting Steps and Time Scales for Sorption Processes

A number of transport and chemical reaction processes can affect the rate of soil chemical reactions. The slowest of these will limit the rate of a particular reaction. The actual chemical reaction (CR) at the surface, for example, adsorption, is usually very rapid and not rate-limiting. Transport processes (Figure 1) include: (1) transport in the solution phase, which is rapid, and in the laboratory, can be eliminated by rapid mixing; (2) transport across a liquid film at the particle/liquid interface (film diffusion (FD)); (3) transport in liquid-filled macropores (>2 nm), all of which are nonactivated diffusion processes and occur in mobile regions; (4) diffusion of a sorbate along pore wall surfaces (surface diffusion); (5) diffusion of sorbate occluded in micropores (<2 nm) (pore diffusion); and (6) diffusion processes in the bulk of the solid, all of which are activated diffusion processes. Pore and surface diffusion can be referred to as interparticle diffusion while diffusion in the solid is intraparticle diffusion.

The energy of activation value (E_a), which can be obtained by employing the Arrhenius equation ($\ln k = \ln A_f - E_a/RT$ where k is the rate constant, A_f is the frequency factor, R is the universal gas constant, and T is absolute temperature), is a useful kinetic parameter to assess rate-limiting steps. Some E_a values for various reactions or processes are shown in Table 1. Low E_a values usually indicate diffusion-controlled transport and physical adsorption processes, whereas higher E_a values would indicate chemical reaction or surface-controlled processes.

Sorption reactions can range over a wide time scale – from seconds to years. The type of soil component can drastically affect the reaction rate. For example, sorption reactions are often more rapid on clay minerals such as kaolinite and smectites than on vermiculitic and micaceous minerals. This is in large part due to the availability of sites for sorption. For example, kaolinite has readily available planar external sites and smectites have primarily internal sites that are also quite available for retention of sorbates. Thus, sorption reactions on these soil constituents are often quite rapid, even occurring on time scales of seconds and milliseconds.

On the other hand, vermiculite and micas have multiple sites for retention of metals and organics, including planar, edge, and interlayer sites, with some of the latter sites being partially to totally collapsed. Consequently, sorption and desorption reactions on these sites can be slow, tortuous, and mass transfer-controlled. Often, an apparent equilibrium may not be reached even after several days or weeks. Thus, with vermiculite and mica, sorption can involve two to three different reaction rates: high rates on external sites, intermediate rates on edge sites, and low rates on interlayer sites.

Metal sorption reactions on oxides, hydroxides, and humic substances depend on the type of surface and metal being studied, but the CR appears to be rapid. For example, CR rates of metals and oxyanions on goethite occur on millisecond time scales. Half-times for divalent Pb, Cu, and Zn sorption on peat range from 5 to 15 s. Heavy metal sorption on oxide and clay minerals increases with longer residence times (contact time between metal and sorbent). The mechanisms for these lower reaction rates are not well understood, but have been ascribed to diffusion phenomena, sites of lower reactivity, and surface nucleation/precipitation.

Sorption/desorption of metals, oxyanions, radionuclides, and organic chemicals on soils can be very slow, and may demonstrate a residence time effect, which has been attributed to diffusion into micropores of inorganic minerals and into humic substances, retention on sites of varying reactivity, and surface nucleation/precipitation.

Sorption/Desorption Kinetics of Metals

The kinetics of heavy-metal sorption on soil components and soils is typically characterized by a biphasic process in which sorption is initially rapid followed by slow reactions (Figure 2). The rapid step, which occurs over milliseconds to hours, can be ascribed to CR and film diffusion processes. During this rapid reaction process, a large portion of the sorption may occur. For example, in Figure 2a one sees that ~90% of the total Ni sorbed on kaolinite and pyrophyllite occurred within the first 24 h. For Pb sorption on a Matapeake soil, 78% of the total Pb sorption

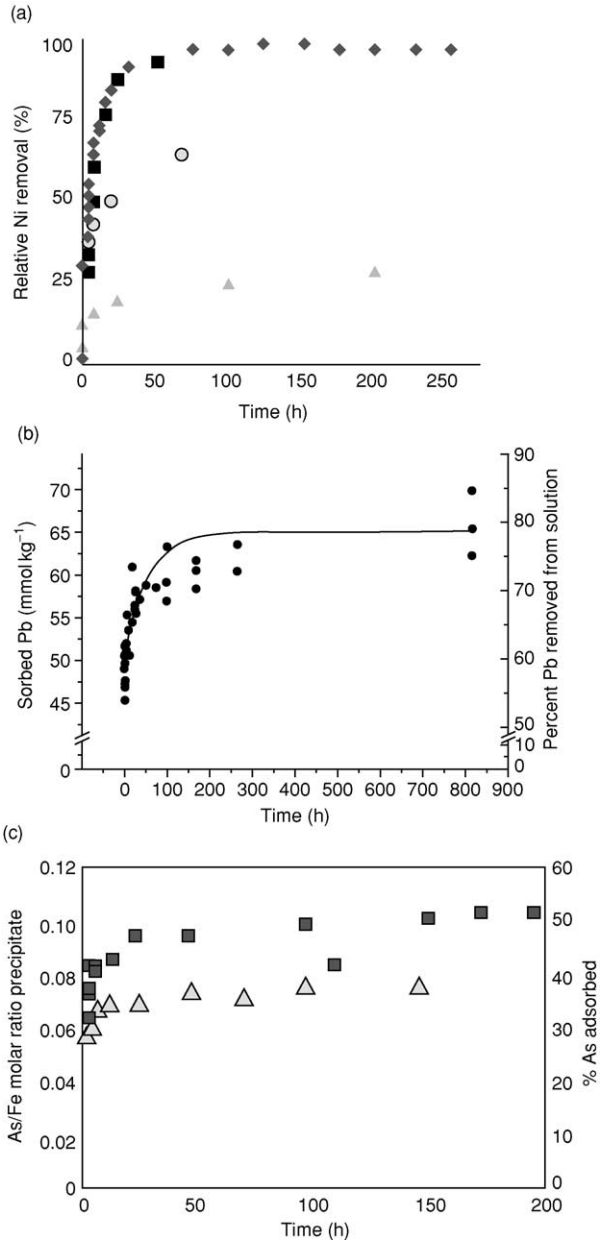

Figure 2 Kinetics of metal and oxyanion sorption on soil minerals and soil. (a) Kinetics of Ni sorption (%) on pyrophyllite (◆); kaolinite (■); gibbsite (▲); and montmorillonite (●) from a 3 mmol l^{-1} Ni solution, an ionic strength $I = 0.1$ mol l^{-1} $NaNO_3$, and a pH of 7.5. Reproduced with permission from Juller CC, Davis JA, and Waychunas GA (1993) Surface chemistry of ferrihydride: part 2, kinetics of arsenate adsorption and co-precipitation. *Geochimica Cosmochimica Acta* 57: 2271–2282.

occurred in 8 min. Following the initial fast reaction, slow sorption continued, but only about 1% additional Pb was sorbed after 800 h (Figure 2b). Figure 2c shows a biphasic reaction for As(V) sorption on ferrihydrite. Within 5 min, a majority of the total sorption had occurred. Slow sorption continued for at least 192 h.

However, in some cases, the magnitude of sorption can greatly increase with longer reaction times. For example, it has been found that metal (e.g., Cd, Ni, and Zn) sorption on porous Fe-oxides such as goethite can significantly increase as time increases. These observations have been ascribed to a three-step mechanism: (1) adsorption of metals on external surfaces; (2) solid-state diffusion of metals from external to internal sites; and (3) metal binding and fixation at positions inside the goethite particle.

The amount of contact time between metals and soil sorbents (residence time) can dramatically affect the degree of desorption, depending on the metal and sorbent. Examples of this are shown in Figure 3 and Table 2. In Figure 3 the effect of residence time on Pb^{2+} and Co^{2+} desorption from hydrous Fe-oxide (HFO) was studied. With Pb, between pH 3 and 5.5 there was a minor effect of residence time (over 21 weeks) on Pb^{2+} desorption, with only minor hysteresis occurring (hysteresis varied from <2% difference between sorption and desorption to ~10%). At pH 2.5, Pb^{2+} desorption was complete within a 16-h period and was not affected by residence time (Figure 3a). In a soil where 2.1% soil organic matter (SOM) was present, residence time had little effect on the amount of Pb desorbed, but marked hysteresis was observed at all residence times (Table 2). This could be ascribed to the strong metal–soil complexes that occur and perhaps to diffusion processes.

With Co^{2+}, extensive hysteresis was observed over a 16-week residence time (Figure 3b) and the hysteresis increased with residence time. After a 16-week residence time, 53% of the Co^{2+} was not desorbed, and even at pH 2.5, hysteresis was observed. The extent of Co reversibility with residence time was attributed to Co incorporation into a recrystallizing solid by isomorphic substitution and not to micropore diffusion. Similar residence time effects on Co desorption have been observed with both Fe- and Mn-oxides and with soil clays.

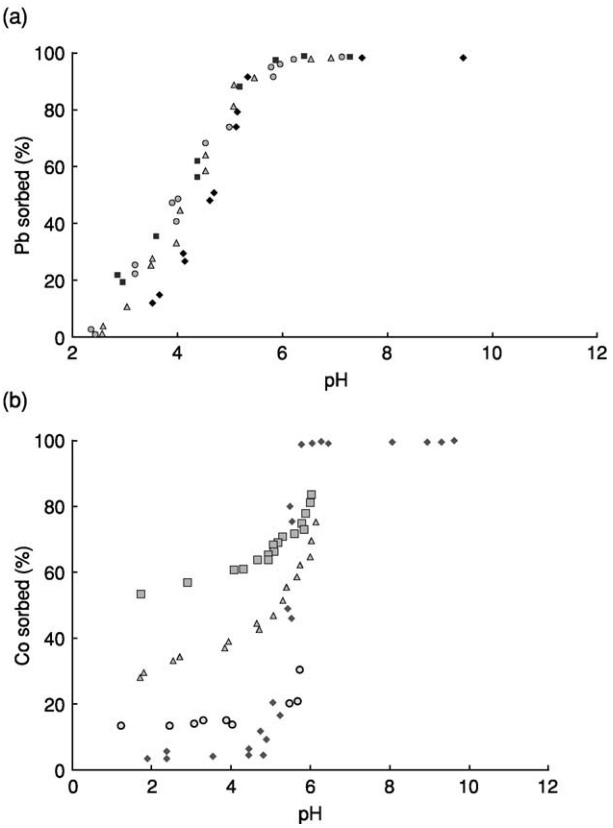

Figure 3 Fractional sorption–desorption of (a) Pb^{2+} (adsorption pH edge ◆ aging time = 0 weeks; desorption ■ aging time = 2 weeks; △ aging time = 12 weeks; ● aging time = 21 weeks) and (b) Co^{2+} (adsorption pH edge ◆ aging time = 0 weeks; desorption ○ aging time = 2 weeks; △ aging time = 9 weeks; ■ aging time = 16 weeks) to hydrous Fe(III) as a function of pH and HFO-Pb^{2+} (a) and HFO-Co^{2} (b) aging time. Kinetics of Metal Hydroxide Surface Precipitation/Dissolution

In addition to diffusion processes, the formation of metal hydroxide surface precipitates and subsequent residence time effects on soil sorbents can greatly affect metal release and hysteresis. Metal hydroxide precipitates can form on phyllosilicates, metal oxides, and soils. It has generally been thought that the kinetics of formation of surface precipitates was slow. However, recent studies have shown that metal hydroxide precipitates can form on time scales

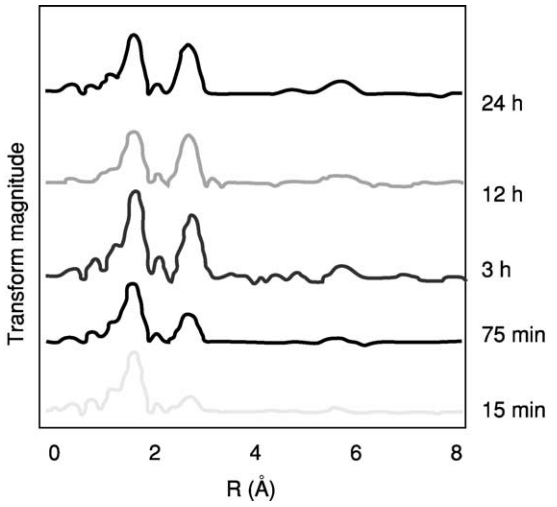

Figure 4 Radial structure functions (derived from X-ray absorption fine structure (XAFS) analyses) for Ni sorption on pyrophyllite for reaction times up to 24 h, demonstrating the appearance and growth of the second shell (peak at approximately 2.8 Å) contributions due to surface precipitation and growth of a mixed Ni-Al hydroxide phase. of minutes. In Figure 4 one sees that mixed Ni-Al hydroxide precipitates formed on pyrophyllite within 15 min, and they grew in intensity as time increased. Similar results have been observed with other soil components and with soils.

The formation and subsequent 'aging' of the metal hydroxide surface precipitate can have a significant effect on metal release. In Figure 5 one sees that as residence time ('aging') increases from 1 h to 2 years, Ni release from pyrophyllite, as a percentage of total Ni sorption, decreased from 23 to ~0%, when HNO_3 (pH 6.0) was employed as a dissolution agent for 14 days. This enhanced stability is due to the transformation of the metal-Al hydroxide precipitates to a metal-Al phyllosilicate precursor phase as residence time increases. This transformation occurs via a number of steps (Figure 6). There is diffusion of Si originating from weathering of the sorbent into the interlayer space of the layered double hydroxide precipitate (LDH), replacing the anions such as NO_3^-. Polymerization and condensation of the interlayer Si slowly transform the LDH into a precursor metal-Al phyllosilicate. The metal stabilization that occurs in surface precipitates on Al-free sorbents (e.g., talc) may be due to Ostwald ripening, resulting in increased crystallization. Thus, with time, metal (e.g., Co, Ni, and Zn) sorption on soil minerals often results in a continuum of processes from adsorption to precipitation to solid-phase transformation.

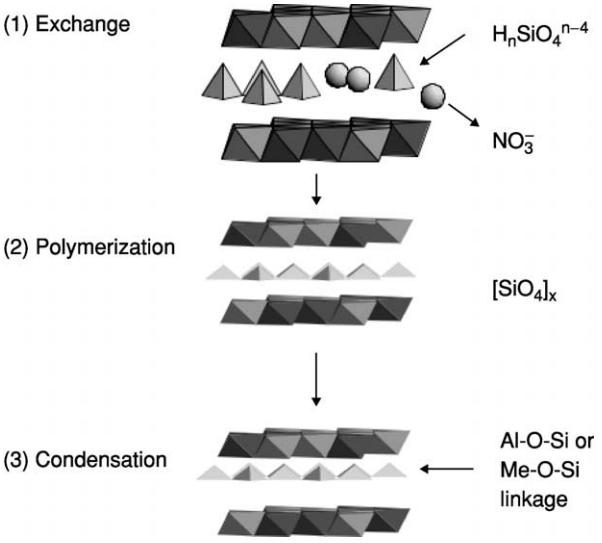

Figure 6 Hypothetical reaction process illustrating the transformation of an initially precipitated Ni-Al LDH to a phyllosilicate like phase during aging. The initial step involves the exchange of dissolved silica for nitrate within the layered double hydroxide (LDH) interlayer followed by polymerization and condensation of silica on to the octahedral Ni-Al layer. The resultant solid possesses structural features common to 1:1 and 2:1 phyllosilicates. Reproduced with permission from Ford RG, Scheinost AC, and Sparks DL (2001) Frontiers in metal sorption/precipitation mechanisms on soil mineral surfaces. *Advances in Agronomy* 74: 41–62.

The formation of metal surface precipitates could be an important mechanism for sequestering metals in soils such that they are less mobile and bioavailable.

Such products must be considered when modeling the fate and mobility of metals such as Co^{2+}, Mn^{2+}, Ni^{2+}, and Zn^{2+} in soil and water environments.

Kinetics of Organic Contaminant Sorption/Desorption

Similarly to metals and oxyanions, many investigations have shown that sorption/desorption of organic contaminants is characterized by a rapid, reversible stage followed by a much slower, nonreversible stage or biphasic kinetics. The rapid phase has been ascribed to retention of the organic chemical in a labile form that is easily desorbed. The labile form of the chemical is also available for microbial attack. However, the much slower reaction phase involves the entrapment of the chemical in a nonlabile form that is difficult to desorb and is resistant to biodegradation. This slower sorption/desorption reaction has been ascribed to diffusion of the chemical into micropores of organic matter and inorganic soil components.

Recent theories have explained the slow diffusion of the organic chemical in SOM by considering SOM as a combination of 'rubbery' and 'glassy' polymers. The rubbery-like phases are characterized by an expanded, flexible, and highly solvated structure with pores of subnanometer dimensions (holes). Sorption in the rubbery phase results in linear, noncompetitive, and reversible behavior. The glassy phases have pores that are of subnanometer size and sorption in this phase is characterized by nonlinearity and is competitive.

The above theories, relating slow diffusion into organic matter to diffusion in polymers, are partially validated in recent studies measuring E_a values for organic chemical sorption. E_a values of 60–70 kJ mol^{-1} have been determined for some chlorobenzenes, polychlorinated biphenyls (PCBs) and polycyclic aromatic hydrocarbons (PAHs) which are in the range for diffusion in polymers (Table 1). These values are much higher than those for pore diffusion (20–40 kJ mol^{-1}), suggesting that intraorganic matter diffusion may be a more important mechanism for slow organic chemical sorption than interparticle pore diffusion.

An example of the biphasic kinetics that is observed for many organic chemical reactions in soils/sediments is shown in Figure 7. In this study 55% of the labile PCBs was desorbed from sediments in a 24-h period, while little of the remaining 45% nonlabile fraction was desorbed in 170 h (Figure 7a). Over another 1-year period about 50% of the remaining nonlabile fraction desorbed (Figure 7b).

Similarly to some metals, it has been demonstrated that with increased residence time the nonlabile portion

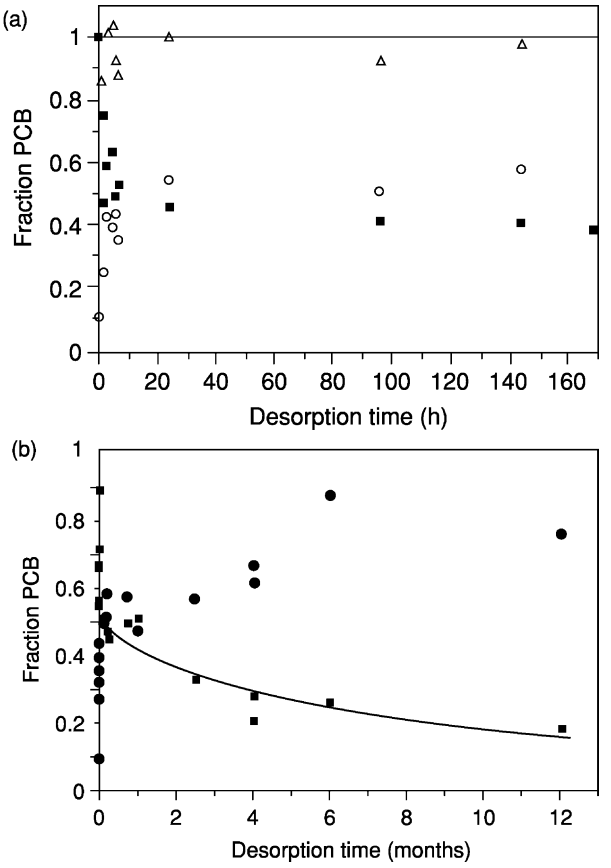

Figure 7 (a) Short-term polychlorinated biphenyl (PCB) desorption in hours (h) from Hudson river sediment contaminated with 25 mg kg^{-1} PCB. Distribution of the PCB between sediment (■) and XAD-4 resin (○) is shown, as well as the overall mass balance (△). The resin acts as a sink to retain the PCB that is desorbed. (b) Long-term PCB desorption in months from Hudson river sediment contaminated with 25 mg kg^{-1} PCB. Distribution of the PCB between the sediment (■) and XAD-4 resin (●) is shown. The line represents a nonlinear regression of the data by the two-box (site) model. Reproduced with permission from Carroll KM, Harkness MR, Bracco AA, and Balcarcel RB (1994) Application of a permeant/polymer diffusional model to the desorption of polychlorinated biphenyls from Hudson river sediments. *Environmental Science Technology* 28: 253–258.

of the organic chemical in the soil/sediment becomes more resistant to release and is less available for microbial degradation. Soils reacted in the laboratory over a short period of time often show more rapid organic chemical release than field soils that have been contaminated for many years. The difference in release has been ascribed to greater diffusion into micropores of clay minerals and humic components that occurred at longer times.

One of the implications of these results is that while many transport and degradation models for organic contaminants in soils and water assume that the sorption process is an equilibrium process, the above

studies clearly show that kinetic reactions must be considered when making predictions about the mobility and fate of organic chemicals. Moreover, K_d values that are determined based on a 24-h equilibration period and which are commonly used in fate and risk assessment models can be inaccurate since 24-h K_d values often overestimate the amount of organic chemical in the solution phase.

The finding that many organic chemicals are quite persistent in the soil environment has both good and bad features. The beneficial aspect is that the organic chemicals are less mobile and may not be readily transported in groundwater supplies. The negative aspect is that their persistence and inaccessibility to microbes may make decontamination more difficult, particularly if *in situ* remediation techniques such as biodegradation are employed.

Conclusions and Future Directions

This article has discussed various basic and applied aspects of kinetics of sorption/desorption processes on soils and soil components including: rate-limiting steps and time scales for sorption processes, sorption/desorption kinetics of metals, kinetics of metal hydroxide surface precipitation/dissolution, and kinetics of organic contaminant sorption/desorption.

While great strides have been made in our understanding of kinetics and mechanisms of sorption processes on soils, a number of areas need further investigation and will be undoubtedly frontiers in the field. These include: the role of microbes on sorption kinetics and mechanisms at the soil/mineral water interface; the coupling of macroscopic studies with molecular-scale tools to study sorption reactions in real time; development of more predictive kinetic models to describe sorption processes on multireactive, heterogeneous soils; long-term sorption and, particularly, desorption rate studies; and increased knowledge of nucleation/precipitation phenomena at the soil/water interface and their impact on nutrient/contaminant mobility and bioavailability in the soil environment.

SPATIAL PATTERNS

Introduction

Biological processes in the soil and associated properties are highly variable at different spatial scales. The sources of spatial variability in soils include both natural and anthropogenic processes that may act at microscopic, aggregate, field, landscape, or regional scale. Together these factors create complex mosaics of environments affecting biological processes at different scales. Identifying the sources of spatial heterogeneity and quantifying the heterogeneity of biological processes in soils are challenging. However, once understood, spatial heterogeneity may offer management options that affect ecosystem productivity, biodiversity, and soil and environmental quality.

Background

Soil biological processes provide crucial feedback between belowground decomposition and aboveground processes such as productivity, herbivory, and diversity. Soil organisms recycle much of primary productivity in terrestrial ecosystems, contributing to sustained ecosystem growth. At the ecosystem level, the interaction between decomposers and producers is well understood. However, high spatial heterogeneity of soil biological processes may obscure ecologic relationships at a finer scale. For this reason, the origins of spatial variability in soil biological processes have themselves become an important topic of research.

Soil biological processes and their spatial variability have gained practical environmental and economic recognition. For example: bioremediation relies on soil microorganisms that can metabolize organic pollutants; precision agriculture attempts to reduce the amount of agrochemicals applied by variable applications that depend on the spatial distribution of nutrients in a field; and riparian wetland buffers promote denitrification, which reduces nitrate loading to streams, lakes, and estuaries. Understanding soil spatial variability is essential to successfully managing soil biological processes to improve environmental quality.

Organisms are at the root of many soil processes, influencing the development of physical and chemical soil properties. The close relationship between soil organisms and their habitat confounds a clear distinction between biological and physicochemical soil properties. For example, soil porosity is a physical soil property, but biogenic mechanisms such as aggregation and bioturbation contribute to its development. Components of the nitrogen cycle affect soil pH. Conversely, soil biological processes are affected by physicochemical properties such as water content and pH. Here soil biological processes are defined as those that are clearly associated with the distribution of organisms, such as microbial biomass and functional diversity, and their metabolic activity, such as decomposition and nutrient mineralization.

A common characteristic of soil biological processes is their high spatial variability. Depending on sampling intensity, coefficients of variation range from ten to several hundred percent. Spatial heterogeneity of soil biological processes is linked to the patchiness of the distribution of population and community level processes, and to pedological factors. It is clear that their spatial variability derives from a superimposition of processes that occur at multiple scales. Spatial variability has been categorized into variations at microsite (approx. 10^{-3}–10^{-1} m), field (10^{0}–10^{2} m), landscape (10^{1}–10^{2} m), and regional scale (greater than 10^{3}–10^{5} m). A case could also be made for adding a continental and global scale in which climatic and vegetational factors of ecoregions determine soil biological processes.

Regardless of scale, spatial variation can be attributed to a combination of random and deterministic variations. Random variations are those in which soil properties or processes are spatially independent, i.e., the property value at one point is not related to values at any other point. Deterministic variations of a property are characterized by spatial dependence. Spatial dependence develops because of processes that connect points in space, such as migration of organisms, diffusion of chemicals, or the integrative effect of plant roots. In environments favoring patchy distributions of organisms, such as soils, spatial dependence includes within-patch and between-patch components. Statistical techniques exist to characterize the properties of both random and deterministic variations.

Sources of Variability

Pedological Factors of Soil Biological Variability

Factors influencing soil formation lay out a coarse, multiscale spatial pattern of factors that influence soil formation. Pedologists distinguish five factors, four

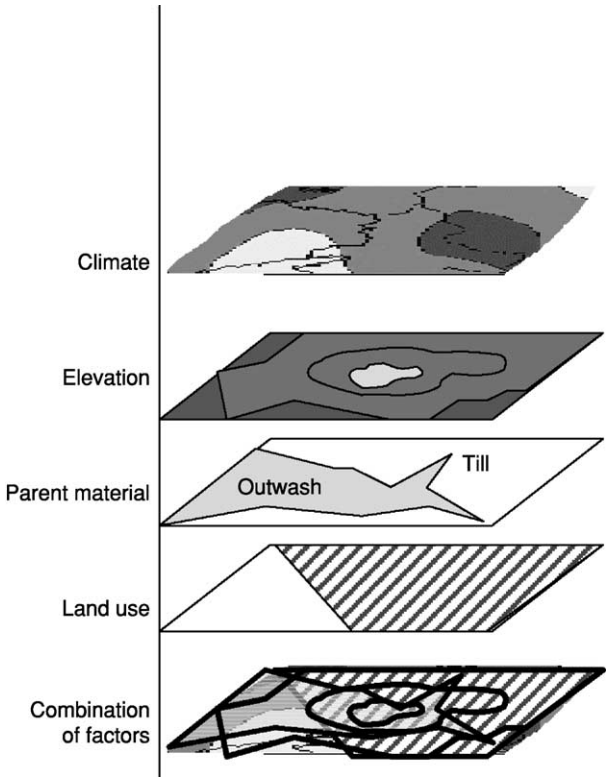

Figure 1 Superposition of intrinsic and extrinsic properties. Climate, elevation, parent material, and land use combine to form a complex soil-property pattern that affects soil biological processes.

of which are distributed at different spatial scales: parent material, climate, topography, organisms, and time. Parent material and topography are regarded as landscape-scale factors. Climate has an overarching function affecting soil biology at all scales. For example, soil moisture, an important factor of biological activity in soils, is affected by topography, i.e., landscape position, elevation, and aspect, but also by climate. At finer scales, the action of organisms may be affected by resource distribution, microclimates, and microtopography.

The superimposition of parent material, climate, and topography (Figure 1) within a region establishes a coarse pattern, which is modified by organisms to form soils, creating multiscale distributions of biological soil properties. For example, nematode distributions are affected by large-scale processes such as texture and climate, and small-scale, organism-related processes such as life-history traits. Denitrification also displays multiscale variability. Microsite characteristics such as localized anaerobiosis at the center of soil aggregates and the availability of detrital resources to denitrifying bacteria are essential for denitrification. Yet anaerobic conditions crucial to denitrification are also controlled by landscape-scale factors such as proximity of groundwater to the soil surface.

In managed ecosystems, additional factors impact the spatial heterogeneity of soil properties. Soil variability is introduced by intrinsic and extrinsic factors. Intrinsic factors are those that act in the absence of soil management and these may coincide with pedological factors of soil formation. Extrinsic factors are associated with land management. In silvicultural, agricultural, and urban ecosystems, management tools such as artificial drainage, tillage, fertilization, planting, and control of pH are superimposed on intrinsic soil processes, adding to the variability of soil biological properties and processes. For example, enzymatic activity has been shown to be high within a crop row and low in the spaces between rows. Non-point source pollution, acid deposition, and land-use patterns may add to soil variability at the landscape, regional, and continental scale.

Spatial Scales Related to Organisms

Biological processes occur at scales ranging from molecular (e.g., enzymes, extracellular polysaccharides, etc.) and organismal, to population and metapopulation. Thus, organisms create connections between points in space in several ways: their bodies occupy space; their motion spans distances between points in space; diffusion and bulk flow transport metabolic waste products (e.g., mineralized nutrients, gases); the presence and activities of larger organisms such as earthworms or plants may create spatially extended spheres of opportunity for other soil dwellers such as nematodes and microorganisms; small organisms may move by phoresis on, or in, larger motile organisms. These processes create spatial correlations that are expressed at different scales.

Whether spatial correlations due to body size are detected depends on the size of the soil sample taken. For example, the soil sample volume, also known as the sample support, is often many times greater than the dimensions of microscopic soil inhabitants, obscuring spatial correlation introduced by the body size of organisms. The longest linear dimensions of soil organisms range from less than a micrometer (microorganisms) to several meters (plants). Even within a group of organisms such as the soil fauna, sizes vary over several orders of magnitude (Table 1). The effect of plants on the spatial variability of mineral nitrogen can thus be detected, using typical soil cores (e.g., 5 cm in diameter and 10 cm long). However, the typical soil core is several orders of magnitude larger than the space occupied by a single nematode. The spatial effects of organisms many times smaller than a typical core, e.g., of a nematode, cannot be resolved

Table 1 Order of magnitude of body diameter ranges for selected soil animals in relation to pore-size classes

Pore-size range	*Faunal-size class*	*Organism*	*Order of magnitude of organism diameter (μm)*
Mesopores 1–100 μm	Microfauna	Ciliates	10^0–10^1
		Amebae	10^0–10^1
		Nematodes	10^1
	Mesofauna	Collembola	10^2–10^3
		Mites	10^2–10^3
Macropores >100 μm		Insects	
	Macrofauna	Spiders	
		Earthworms	10^3–10^4
		Millipedes	10^3–10^4

at that sampling scale. Finer-scale sample support has been used (e.g., $2.5 \times 2.5 \times 5$ mm), particularly in the investigation of genetic structure of microbial communities.

Spatial dependence related to populations and metapopulations may be more evident because these occupy more space. Indeed, the distribution of soil organisms is often clumped, introducing characteristic spatial correlations that are related to life-history traits and migration patterns. For example, entomopathogenic nematodes release their young in insect larvae. Juvenile nematodes spread from these larval contagions, creating spatial patterns that at least initially show strong aggregation around the point of contagion.

Because organisms, even when they are of dissimilar scale, are connected via trophic or symbiotic interactions, the spatial distribution of one organism can affect the distribution of another population. The rhizosphere is defined as soil attached to plant roots. It is the focus of microbial and faunal activity due to rhizodeposits, enriching the food resources of microorganisms. Similarly, the soil surrounding earthworm burrows, known as the drilosphere, has elevated abundances of soil organisms because of detrital resources translocated from the surface. As a result of the elevated biological activity and resource enrichment, carbon and nitrogen mineralization rates are enhanced.

The activities of organisms alter soil properties beyond their immediate neighborhood, thus affecting other organisms. For example, consecutive microbial transformations, e.g., ammonification followed by nitrification, may occur in different locations because molecules move from the transformation sites by diffusion or by bulk movement of water. The diffusion of substrates may link points in space, with different microorganisms acting locally. The relationship of processes at these points may not be immediately apparent, because they occur in different locations and at different times and are affected by microbial populations with different functions.

Migration of organisms introduces another scale of spatial dependence. Migration distances of microorganisms, micro-, and mesofauna are limited by the distribution of soil air and water, as well as resource distribution and transport (phoresis) by other organisms. Aquatic microfauna, soil animals that live in water-filled pores (e.g., nematodes and protozoa), and their aerial counterparts, soil animals that live in the air-filled pores (e.g., mites, Collembola), depend on connected water-filled or air-filled spaces, respectively. Unless macrofauna extend the dispersal distances, microfauna and mesofauna migrate distances up to several decimeters.

Resource distribution directs motion of chemotactic soil animals such as entomopathogenic and bacterivorous soil nematodes; but even in the absence of chemotactic adaptations, resource distribution affects the distribution of consumers. Thus, the range of motion of an organism depends on a complex set of factors such as soil type, water status, distribution of resources, and whether the organism has particular traits for finding its prey or grazing substrates. In addition, many organisms and microbiological transformations are sensitive to abiotic constraints such as pH, texture, moisture, substrate, and O_2 availability. For example, C mineralization depends on water content and quality, temperature, organic matter content, bulk density, and texture. Nematode abundance depends on similar factors. The actual scale of potential motion may thus be secondary to other factors.

Some studies aim at characterizing spatial distributions at an even smaller scale. Such studies may be conducted to investigate the distribution of organisms or soil microbial processes at aggregate scale, or genetic diversity at subaggregate scales. To investigate the potential for denitrification in unsaturated soils, microelectrodes have been used to map the distribution of oxygen availability in individual soil peds. Microbial diversity measured using genetic techniques has been conducted at the subaggregate scale ($2.5 \times 2.5 \times 5$ mm). Studies conducted at these scales are important for the elucidation of mechanisms which contribute to biodiversity, e.g., the probability of genetic exchange during bacterial encounters, or to a mechanistic understanding of biogeochemical processes.

Quantification of Spatial Properties

First-Order Statistics and Spatial Independence

In soil science, both first- and second-order statistics are used to quantify spatial variability. Typical measures of first-order statistics are mean and standard

deviation. Because of the patchiness of biological properties, distributions are skewed and the coefficient of variation is often high. For this reason, log-normal transformations or nonparametric techniques are used for inferential analysis of data. Coefficients of variation (CV) of greater than 150% have been reported for abundance of soil fauna. For enzymatic activity, CVs can be as low as 30% for phosphatase and protease, but as high as 130% for urease. CVs of several hundred percent have been reported for microbial transformation rates.

Mean and variance are used beyond inferential statistics. For example, the Taylor power law relates sample mean, μ, and variance, σ:

$$\sigma^2 = a\mu^{\mathrm{b}} \qquad [1]$$

where b is a measure of aggregation or 'clumpiness' of the distribution, and a is a scale factor. The Taylor power law is often invariant for a given population over a wide range of spatial scales. Tests of the invariance of the law might include rhizosphere scale, field scale, and farm scale. Invariance of the law has been interpreted to mean that the distribution of the population depends only on the dispersal traits of the organism, not on spatial constraints. Its scale invariance can be helpful, because, once a and b are known at one scale, the constants can be applied at another scale. The invariant properties of the Taylor power law are useful in the design of efficient sampling schemes for soil organisms and in the control of plant-parasitic nematodes.

Second-Order Statistics and Spatial Dependence

First-order estimates are appropriate when soil properties at all sample points are spatially independent. However, the variance of most properties has both random (spatially independent) and deterministic (spatially dependent) components. Total sample variance, σ^2_{T}, can be expressed as:

$$\sigma^2_{\mathrm{T}} = \sigma^2_{\mathrm{R}} + \sigma^2_{\mathrm{D}} \qquad [2]$$

where the variances associated with random and deterministic variations are σ^2_{R} and σ^2_{D}, respectively. Deterministic variance includes components such as trends, periodicities, and characteristic patch sizes. Organism size and its range of motion as well as physicochemical scales may contribute to the deterministic variations of biological soil properties. Care has to be taken when using the paradigm expressed in Eqn [2]. The perception of deterministic and random variations in soil may depend on sampling or investigative scale, when multiple scales are contributing to spatial variations. Increasing the scale of an investigation may change the ratio of deterministic to random contributions.

The assumption – inherent in first-order statistics – that samples taken from different locations are independent of each other is not valid at all scales. Second-order analyses are more appropriate when spatial dependence in the data is suspected. In soil science, the main tool to parameterize spatial dependence is semivariance analysis. For this analysis, data needs to satisfy the stationarity requirements which prohibits trends. For example, denitrification increases along a hydrosequence from dry, well-drained soils to poorly drained soils. Hence, semivariance analysis of denitrification along the entire hydrosequence would violate the stationarity requirement. Trends are easily detected and can be removed from the data prior to analysis.

Semivariance, $\gamma(h)$, measures how much of the variance of a spatial distribution can be explained by the relationship between points that are a given distance, h, apart:

$$\gamma(h) = 1/(2N(h))\Sigma(x_{\mathrm{i}} - x_{\mathrm{j}})^2 \qquad [3]$$

where x_{i} and x_{j} are all point pairs that are a distance h apart, and N is the number of pairs $(x_{\mathrm{i}}, x_{\mathrm{j}})$ separated by distance h. A semivariogram is constructed in two steps. First, the covariances of point pairs separated by particular lag distances, h, are computed and plotted against the lag distance (Figure 2). Then, a regression model is fitted to the covariance data to estimate three parameters: the range lag (R), the nugget variance (Co), and the spatial variance (C) (Figure 2). Co is given by the y intercept of the regression model. The nugget value estimates the compound variance associated with sampling too few points, analytical errors, and random variations. The sum of nugget and spatial structure variance is called the sill variance, $C + \mathrm{Co}$. The sill variance estimates variance at lags beyond the range lag, R, where sample pairs become spatially independent. The range lag, R, can be interpreted as the characteristic scale of a process.

The ratio $C/(C + \mathrm{Co})$ is called spatial structure and expresses how much of the total variance is attributable to spatial dependence. If the nugget is equal to the sill variance, the data have no spatial structure; it is not spatially dependent. Conversely, if the nugget is zero, spatial structure is high and spatial correlation between points is high.

Figure 3 shows three examples of variograms relating to microbial biomass N (Figure 3a), soil respiration (Figure 3b), and predaceous nematode (Figure 3c) data collected from an old field in southern New England, USA. The three variograms have distinctly different shapes. The variogram for microbial

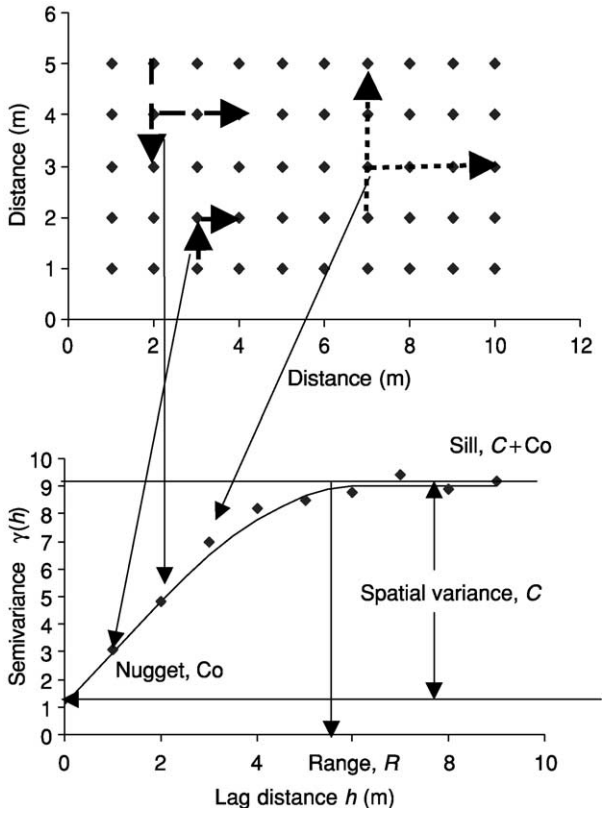

Figure 2 Examples of point pairs separated by distances of 1 m (thin arrows), 2 m (dashed arrows), 3 m (dotted arrows). Semivariance values are computed using Eqn [3] based on the entirety of point pairs for each lag distance, *h*. Nugget variance is the semivariance, Co, at zero predicted by a model line. Sill variance is the sum of nugget, Co, and spatial variance, *C*.

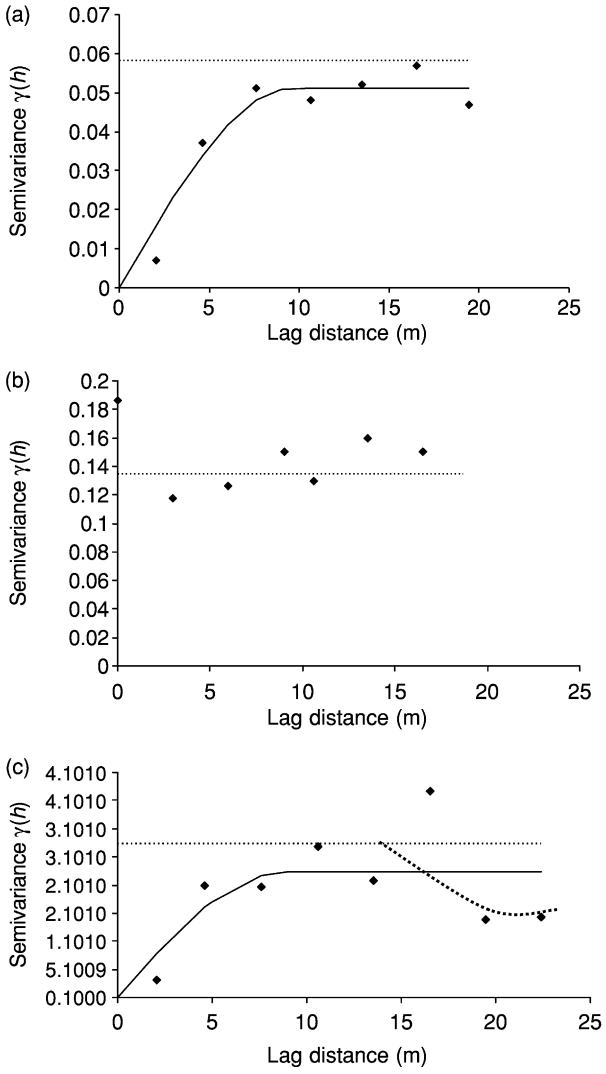

Figure 3 Typical semivariogram shapes of biological properties. Rhomboid, covariance at lag *h*; continuous line, fitted spherical model; dashed line, sample variance; dotted line, hole effect. (a) Biomass N; (b) soil respiration; (c) predaceous nematodes.

biomass N displays strong spatial dependence from 0 to 8 m, expressed by the gradual increase in semivariance from zero to the sill variance (Figure 3a). In contrast, the semivariogram of soil respiration has no spatial structure. Semivariance values are scattered about the sample variance, indicating that the nugget and the sill variances are identical and that there is no spatial correlation of respiration for the sample distance and the sample support (Figure 3b). The semivariogram for predaceous nematodes has an additional feature (Figure 3c): after the semivariance reaches the sill, its value drops again. This is known as the 'hole effect.' Semivariance holes are caused by strongly repetitive or patchy patterns. Both range and hole lag distances are characteristic scales of the pattern.

Sampling to Characterize Spatial Variability

Sampling schemes employed to collect soil samples for first- and second-order statistics are subject to specific sampling rules. Under the assumption that samples are independent of each other, random sampling can be employed, and the design is guided by the central-limit theorem and considerations of accuracy and confidence.

If spatial dependence is assumed, sampling schemes need to fulfill an additional criterion. In theory, sampling ought to comply with the Nyquist theorem to avoid misrepresentation of patterns, which is also called aliasing. The Nyquist theorem states that a pattern must be sampled at a frequency of greater than twice the wavelength of the shortest variation that can be resolved. Sampling design needs to trade off the physical dimension, or sample support, of each sample and the number of samples collected. If the sampling design does not comply with the Nyquist

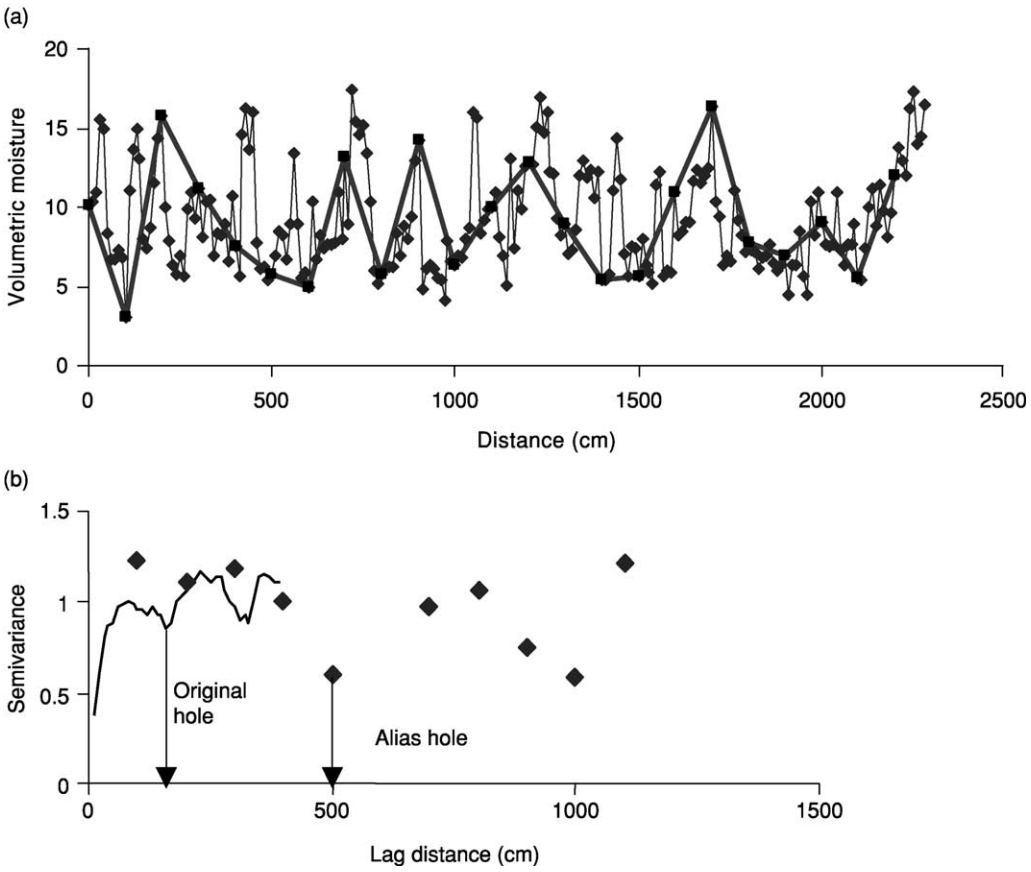

Figure 4 Sampling at an insufficient rate may result in aliasing, i.e., the misrepresentation of a fine-grain regular pattern by a coarser variation: (a) Moisture data of field transect with a ridge-and-furrow pattern of 1.5 m. Thin line with rhomboids, sampled at intervals of 10 cm (entire data set); thick line, sampled at 100-cm intervals (subsample); (b) semivariance: (continuous line) semivariogram of transect data sampled at 10 cm; rhomboid semivariance values for transect sampled every 100 cm. The 'hole effect' occurs at 140 cm when the entire data set is analyzed; it occurs at 500 cm when a transect is sampled every 100 cm.

theorem the field pattern may be misrepresented by an alias pattern, which usually overestimates the wavelength of the shortest variation. Aliasing may affect mean, variance, and scale estimates.

An example of aliasing is shown in Figure 4. Volumetric soil moisture was determined using time-domain reflectometry at 220 points along a field transect, oriented normal to the plow direction (Figure 4a, thin line). Sampling points were 10 cm apart. The associated semivariogram displays a hole at 1.4 m, roughly the distance between plough ridges (Figure 4b). A subsample was selected from the data sets, with point separations of 1 m (Figure 4a, thick line). This sample does not satisfy the Nyquist theorem (1.4 samples per small-scale variation, rather than the more-than-two samples required to satisfy the theorem). As a result, a long-wavelength variation is erroneously detected which finds expression in the semivariogram as a dilation of the hole lag distance. The larger variation seen in the subsample is called an 'alias' of the original data.

Nested sampling schemes are used to give consideration to the multiscale nature of soil variability. Nested sampling distributes sampling at a primary coarse scale with a finer-scale grid being applied locally at the coarse grid, yielding data at two dissimilar scales.

Examples of nested sampling schemes are shown in Figure 5. The nested, stratified random sampling scheme shown in Figure 5a was used to compare the spatial dependence of nematode distributions in soils from a forest and an old field. Plots (17×17 m) were divided into 25 subplots. For each subplot at least one sample was taken from a random location. In five randomly selected subplots, nine regularly spaced samples were taken from a 30×30 cm area surrounding the random location (Figure 5a). The range over which C mineralization was spatially correlated was dominated by nest-scale variations in the autumn, and by the large-scale variations for winter, spring, and summer sampling. Range values for nematode distributions and moisture indicate spatial dependence

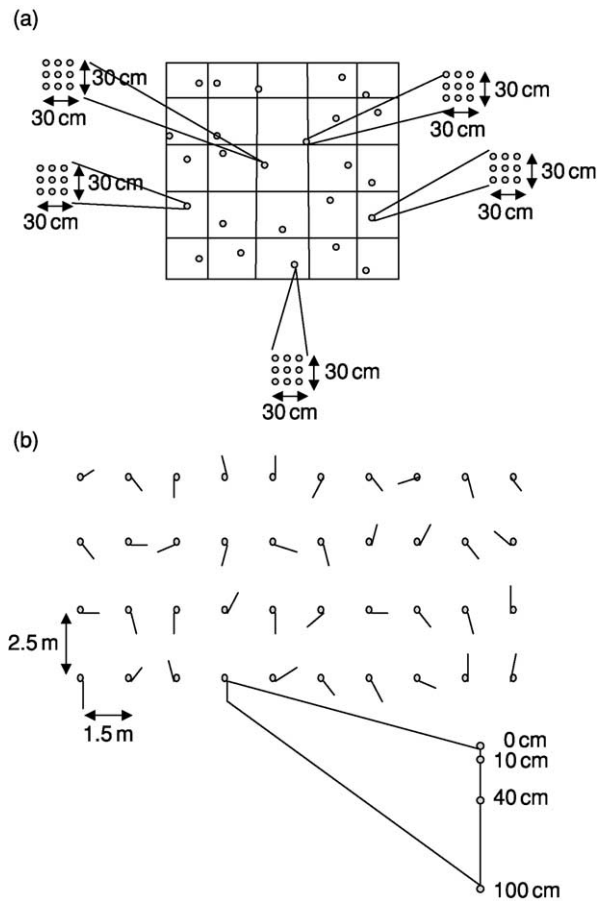

Figure 5 Examples of nested-sampling designs: (a) Nested sampling used for quantifying spatial dependence of nematode, CO_2, and soil-moisture distribution. (Adapted from Görres JH, Dichiaro MJ, Lyons JB, and Amador JA (1998) Spatial and temporal patterns of soil biological activity in a forest and an old field. *Soil Biology and Biochemistry* 30: 219–230 with permission.) (b) Nested sampling design to quantify spatial dependence of NO_3 availability. (Adapted from Gross KL, Pregitzer KS, and Burton AJ (1995) Changing scales of nitrogen availability in early and late successional plant communities. *Journal of Ecology* 83: 357–367, with permission.)

at a larger scale than for CO_2 for most sampling dates (Table 2).

The nested sampling scheme in Figure 5b was used to detect multiscale variations in soil nutrient availability. A primary grid of a field consisted of 40 points spaced at 2.5-m spacings in the N-S direction and at 1.25 m in the E-W direction. A 1-m-long transect originated at each grid point. Each transect was oriented at random and sampled at distances of 0, 10, 40, and 100 cm along the transect, giving the pattern in Figure 5b.

Nested sampling schemes are useful in discerning variability at different scales, an important step in elucidating spatial variability. Usually, only two scale components are investigated, and it is difficult

Table 2 Range values determined from semivariogram analysis of C mineralization, soil moisture, and total nematode abundance distributions in an old field and a forest soil using nested sampling

Semivariogram range						
	Total nematodes (m)		*C Mineralization (m)*		*Soil moisture (m)*	
Date	*Old field*	*Forest*	*Old field*	*Forest*	*Old field*	*Forest*
5 Jun 1994	2.9	1.0	0.9	5.6	14.0	4.9
4 Nov 1994	2.8	10.3	0.3	0.2	10.0	>20.0
20 Jan 1995	3.2	1.1	1.4	3.5	2.8	2.6
25 Mar 1995	6.0	2.6	0.9	0.9	6.7	1.3

to assess whether these are the only levels of nesting present. Detecting several levels of a spatial hierarchy may not be practicable because of the cost of collecting and analyzing many samples, a prerequisite in many spatial analyses.

Models of Spatial Variability

Linear Statistical Models

Statistical descriptions of spatial distributions in themselves do not explain the cause of variability. Attempts to attribute biological effects to physical, chemical, and biological factors with linear models are necessarily incomplete. Typically, variance of biological distributions is explained to approximately 50% even when a multitude of factors are used in the model. The difference between measured variance of a soil biological property and a multivariate model may be caused by analytical error, nonlinear effects of population dynamics, dissimilar scales between the variables, and the absence of important factors from the model.

Physical Mechanistic Process Models

Decision-making in environmental management is sometimes guided by mechanistic models describing processes with chemical, physical, or biological mechanisms. Mechanistic models are used to estimate the contamination of groundwater and surface water by nutrients and pesticides. They require information about soil physical structure, decomposition, and mineralization rates at the scales of interest.

Most mechanistic models simulate soil biological processes at a point. A point may represent a landscape unit, field, or forest stand. Usually, biological processes are treated as black boxes, while physical concepts in the model have strong mechanistic components. Some models of physical mechanisms

use multiple data layers as spatial input. The data required for the analysis are frequently found in and extracted from environmental data bases such as geographic information systems (GISs). Typically, simulations are run for every point independently, but connections between points can be made by including the contribution of groundwater or surface-water flow to simulated contaminant inputs.

Biological Mechanistic Process Models

Life-history traits and motility affect spatial population characteristics and can often be described by random processes such as the Neyman–Scott point process, which assumes that offspring disperses randomly from contagions, e.g., mother or parasitized organisms, which are themselves randomly distributed. The net effect of a Neyman–Scott process is a clumped distribution. Different levels of aggregation are shown in Figure 6. A simple random process (Figure 6a) distributes organisms almost evenly across an area. Any clumping here is a result of chance. In the double random Neyman–Scott process, the appearance of the distribution depends on the initial distribution pattern of the contagions and the distance that offspring could have traveled at the time of sampling. Both Figure 6b and c show Neyman–Scott processes, with dispersion distances of offspring of 7.5 m and 15 m, respectively.

An example of a Neyman–Scott process is that of endoparasitic nematodes, i.e., those that live within a root. Many endoparasites lay all their eggs in a single location, from where nematode larvae migrate, resulting in a clumped distribution. Aggregations arising from doubly random processes can have distinct spatial characteristics that increase spatial structure measured by semivariogram analysis even though they were caused by random processes.

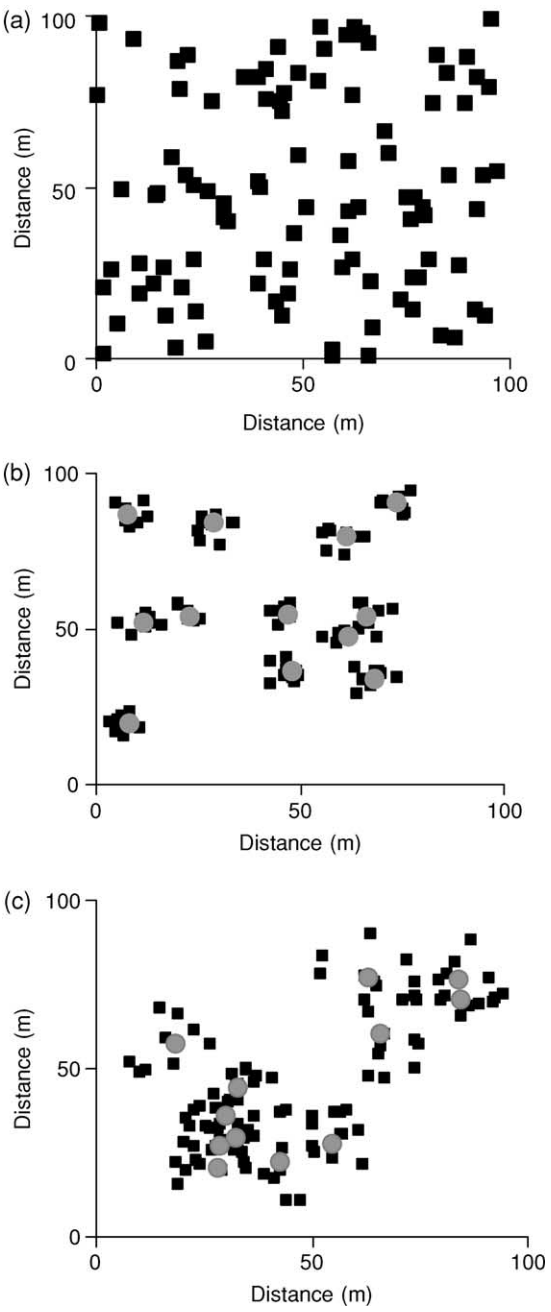

Figure 6 Distributions with different aggregation levels: (a) Distribution simulated with a single random process; (b) strongly aggregated distribution, simulated using the Neyman–Scott process with offspring dispersed randomly within a circle of 7.5 m radius around randomly distributed parent; (c) aggregated, distribution simulated using the Neyman–Scott process with offspring dispersed randomly within a circle of 15 m radius around randomly distributed parent.

Applications of Spatial Analysis

Environmental scientists and managers have become more aware of soil variability at different scales. Managers may use spatial information at landscape or field scale. Many data sets which are used to manage the environment are stored as spatially referenced information within GISs that have become important databases and analysis tools supporting decision-making and research. For instance, mapping of critical loads for soils has supported strategies to reduce soil acidification in Europe. The critical-loads approach requires several data layers pertaining to spatially variable soil biological processes. For nitrogen deposition, critical loads use spatial information of denitrification, plant uptake, and immobilization. Critical-load maps are essential to estimating where depositions of nitrogen and sulfur exceed the ability of the soil to buffer acidification and thus to taking steps to target specifically reductions in acid emissions.

Against the backdrop of the large amount of information available in spatially referenced form,

first- and second-order statistics parameters of soil variability allow managers to estimate uncertainty associated with mean property estimation. In turn, this enables the manager to assess the risk inherent in any management action informed by measures of central tendency. Farm managers using precision agriculture or integrated pest management use the spatial distribution of soil properties explicitly to dose agrochemical inputs to minimize environmental impacts while increasing farm productivity.

At smaller scales, information on the spatial variability of soil and vegetation properties can guide experimental or survey designs to support mechanistic studies of ecosystem processes. In this way, the power of inferential tests can be increased. In fundamental research addressing questions of soil biodiversity, knowledge of the spatial structure of small habitat units may help estimate the frequency or the chance of genetic exchange between microorganisms. Likewise, knowledge of how habitats of soil-dwelling predators and prey or of grazers and forage overlap can help estimate the flow of energy and matter through soil food chains.

Differences in space may be seen as gradients that drive ecologic processes such as the flow of materials in an ecosystem. As such the application of spatial analysis may both further knowledge of ecosystem functioning and improve environmental quality.

Summary

Soil biological processes are spatially variable. Many interacting factors together explain this variability at multiple scales. However, often spatial statistical descriptions of heterogeneity cannot explain the variation. Biological and physicochemical models are used to improve understanding of soil variability. Knowledge of the distribution of soil biological processes at point, field, and landscape scale can support management of environmental quality and ecosystem productivity as well as fundamental research.

ENCYCLOPEDIA OF SOILS IN THE ENVIRONMENT

FOUR-VOLUME SET

by Daniel Hillel (Editor-in-Chief)

Hardcover: 2200 pages
Publisher: Academic Press; 1 edition (November 8, 2004)
Language: English
ISBN-10: 0123485304
ISBN-13: 978-0123485304

Book Description

More than ever before, a compelling need exists for an encyclopedic resource about soil the rich mix of mineral particles, organic matter, gases, and soluble compounds that foster both plant and animal growth. Civilization depends more on the soil as human populations continue to grow and increasing demands are placed upon available resources.
The Encyclopedia of Soils in the Environmentis a comprehensive and integrated consideration of a topic of vital importance to human societies in the past, present, and future.

This important work encompasses the present knowledge of the world's variegated soils, their origins, properties, classification, and roles in the biosphere. A team of outstanding, international contributors has written over 250 entries that cover a broad range of issues facing today's soil scientists, ecologists, and environmental scientists.
This four-volume set features thorough articles that survey specific aspects of soil biology, ecology, chemistry and physics. Rounding out the encyclopedia's excellent coverage, contributions cover cross-disciplinary subjects, such as the history of soil utilization for agricultural and engineering purposes and soils in relation to the remediation of pollution and the mitigation of global climate change.

This comprehensive, yet accessible source is a valuable addition to the library of scientists, researchers, students, and policy makers involved in soil science, ecology, and environmental science.

Also available online via ScienceDirect featuring extensive browsing, searching, and internal cross-referencing between articles in the work, plus dynamic linking to journal articles and abstract databases, making navigation flexible and easy. For more information, pricing options and availability visit www.info.sciencedirect.com.

* A distinguished international group of editors and contributors
* Well-organized encyclopedic format providing concise, readable entries, easy searches, and thorough cross-references
* Abundant visual resources — photographs, figures, tables, and graphs — in every entry
* Complete up-to-date coverage of many important topics — essential information for scientists, students and professionals alike

FOREWORD

The *Encyclopedia of Soils in the Environment* is a vitally important scientific publication and an equally important contribution to global public policy. The *Encyclopedia* brings together a remarkable range of cutting-edge scientific knowledge on all aspects of soil science, as well as the links of soils and soil science to environmental management, food production, biodiversity, climate change, and many other areas of significant concern. Even more than that, the *Encyclopedia* will immediately become an indispensable resource for policy makers, analysts, and students who are focusing on one of the greatest challenges of the 21st century. With 6.3 billion people, our planet is already straining to feed the world's population, and is failing to do so reliably in many parts of the world. The numbers of chronically poor in the world have been stuck at some 800 million in recent years, despite long-standing international goals and commitments to reduce that number by several hundred million. Yet the challenge of food production will intensify in coming decades, as the human population is projected to rise to around 9 billion by mid-century, with the increased population concentrated in parts of the world already suffering from widespread chronic under-nourishment.

Unless the best science is brought to these problems, the situation is likely to deteriorate sharply. Food production systems are already under stress, for reasons often related directly to soils management. In Africa, crop yields are disastrously low and falling in many places due to the rampant depletion of soil nutrients. This situation needs urgent reversal, through increasing use of agro-forestry techniques (e.g. inter-cropping cereals with leguminous nitrogen-fixing trees) and increasing the efficient applications of chemical fertilizers. In other impoverished, as well as rich, parts of the planet, decades of intensive agriculture under irrigation have led to salinization, water-logging, eutrophication of major water bodies, dangerous declines of biodiversity and other forms of environmental degradation. These enormous strains are coupled with the continuing pressures of tropical deforestation and the lack of new promising regions for expanding crop cultivation to meet the needs of growing populations. Finally, there looms the prospect of anthropogenic climate change. Global warming and associated complex and poorly understood shifts in precipitation extremes and other climate variables all threaten the world's natural ecosystems and food production systems in profound yet still imperfectly understood ways. The risks of gradual or abrupt climate change are coupled with the risks of drastic perturbations to regional and global food supplies.

The *Encyclopedia* offers state-of-the-art contributions on each of these challenges, as well as links to entries on the fundamental biophysical processes that underpin the relevant phenomena. The world-scale and world-class collaboration that stands behind this unique project signifies its importance for the world community. It is an honor and privilege for me to introduce this path-breaking endeavor.

PREFACE

The term 'soil' refers to the weathered and fragmented outer layer of our planet's land surfaces. Formed initially through the physical disintegration and chemical alteration of rocks and minerals by physical and biogeochemical processes, soil is influenced by the activity and accumulated residues of a myriad of diverse forms of life. As it occurs in different geologic and climatic domains, soil is an exceedingly variegated body with a wide range of attributes.

Considering the height of the atmosphere, the thickness of the earth's rock mantle, and the depth of the ocean, one observes that soil is an amazingly thin body – typically not much more than one meter thick and often less than that. Yet it is the crucible of terrestrial life, within which biological productivity is generated and sustained. It acts like a composite living entity, a home to a community of innumerable microscopic and macroscopic plants and animals. A mere fistful of soil typically contains billions of microorganisms, which perform vital interactive biochemical functions. Another intrinsic attribute of the soil is its sponge-like porosity and its enormous internal surface area. That same fistful of soil may actually consist of several hectares of active surface, upon which physicochemical processes take place continuously.

Realizing humanity's utter dependence on the soil, ancient peoples, who lived in greater intimacy with nature than many of us today, actually revered the soil. It was not only their source of livelihood, but also the material from which they built their homes and that they learned to shape, heat, and fuse into household vessels and writing tablets (ceramic, made of clayey soil, being the first synthetic material in the history of technology). In the Bible, the name assigned to the first human was Adam, derived from 'adama,' meaning soil. The name given to that first earthling's mate was Hava (Eve, in transliteration), meaning 'living' or 'life-giving.' Together, therefore, Adam and Eve signified quite literally 'Soil and Life.'

The same powerful metaphor is echoed in the Latin name for the human species – Homo, derived from humus, the material of the soil. Hence, the adjective 'human' also implies 'of the soil.' Other ancient cultures evoked equally powerful associations. To the Greeks, the earth was a manifestation of Gaea, the maternal goddess who, impregnated by Uranus (god of the sky), gave birth to all the gods of the Greek pantheon.

Our civilization depends on the soil more crucially than ever, because our numbers have grown while available soil resources have diminished and deteriorated. Paradoxically, however, even as our dependence on the soil has increased, most of us have become physically and emotionally detached from it. Many of the people in the so-called 'developed' countries spend their lives in the artificial environment of a city, insulated from direct exposure to nature, and some children may now assume as a matter of course that food originates in supermarkets.

Detachment has bred ignorance, and out of ignorance has come the delusion that our civilization has risen above nature and has set itself free of its constraints. Agriculture and food security, erosion and salination, degradation of natural ecosystems, depletion and pollution of surface waters and aquifers, and decimation of biodiversity – all of these processes, which involve the soil directly or indirectly – have become abstractions to many people. The very language we use betrays disdain for that common material underfoot, often referred to as 'dirt.' Some fastidious parents prohibit their children from playing in the mud and hurry to wash their 'soiled' hands when the children nonetheless obey an innate instinct to do so. Thus soil is devalued and treated

as unclean though it is the terrestrial realm's principal medium of purification, wherein wastes are decomposed and nature's productivity is continually rejuvenated.

Scientists who observe soil closely see it in effect as a seething foundry in which matter and energy are in constant flux. Radiant energy from the sun streams onto the field and cascades through the soil and the plants growing in it. Heat is exchanged, water percolates through the soil's intricate passages, plant roots extract water and transmit it to their leaves, which transpire it back to the atmosphere. Leaves absorb carbon dioxide from the air and synthesize it with soil-derived water to form the primary compounds of life. Oxygen emitted by the leaves makes the air breathable for animals, which consume and in turn fertilize plants.

Soil is thus a self-regulating bio-physio-chemical factory, processing its own materials, water, and solar energy. It also determines the fate of rainfall and snowfall reaching the ground surface – whether the water thus received will flow over the land as runoff, or seep downward to the subterranean reservoir called groundwater, which in turn maintains the steady flow of springs and streams. With its finite capacity to absorb and store moisture, and to release it gradually, the soil regulates all of these phenomena. Without the soil as a buffer, rain falling over the continents would run off entirely, producing violent floods rather than sustained river flow.

Soil naturally acts as a living filter, in which pathogens and toxins that might otherwise accumulate to foul the terrestrial environment are rendered harmless. Since time immemorial, humans and other animals have been dying of all manner of disease and have then been buried in the soil, yet no major disease is transmitted by it. The term *antibiotic* was coined by soil microbiologists who, as a consequence of their studies of soil bacteria and actinomycetes, discovered streptomycin (an important cure for tuberculosis and other infections). Ion exchange, a useful process of water purification, also was discovered by soil scientists studying the passage of solutes through beds of clay.

However unique in form and function, soil is not an isolated body. It is, rather, a central link in the larger chain of interconnected domains and processes comprising the terrestrial environment. The soil interacts both with the overlying atmosphere and the underlying strata, as well as with surface and underground bodies of water. Especially important is the interrelation between the soil and the climate. In addition to its function of regulating the cycle of water, it also regulates energy exchange and surface temperature.

When virgin land is cleared of vegetation and turned into a cultivated field, the native biomass above the ground is often burned and the organic matter within the soil tends to decompose. These processes release carbon dioxide into the atmosphere, thus contributing to the earth's greenhouse effect and to global warming. On the other hand, the opposite act of reforestation and soil enrichment with organic matter, such as can be achieved by means of conservation management, may serve to absorb carbon dioxide from the atmosphere. To an extent, the soil's capacity to store carbon can thus help to mitigate the greenhouse effect.

Thousands of years are required for nature to create life-giving soil out of sterile bedrock. In only a few decades, however, unknowing or uncaring humans can destroy that wondrous work of nature. In various circumstances, mismanaged soils may be subject to erosion (the sediments of which tend to clog streambeds, estuaries, lakes, and coastal waters), to leaching of nutrients with attendant loss of fertility and eutrophication of water bodies, to waterlogging and impaired aeration, or to an excessive accumulation of salts that may cause a once-productive soil to become entirely sterile. Such processes of soil degradation, sometimes called 'desertification,' already affect large areas of land.

We cannot manage effectively and sustainably that which we do not know and thoroughly understand. That is why the tasks of developing and disseminating sound knowledge of the soil and its complex processes have assumed growing urgency and importance. The global environmental crisis has created a compelling need for a concentrated, concise, and definitive source of information – accessible to students, scientists, practitioners, and the general public – about the soil in all its manifestations – in nature and in relation to the life of humans.

INTRODUCTION

The *Encyclopedia of Soils in the Environment* contains nearly 300 articles, written by the world's leading authorities. Pedologists, biologists, ecologists, earth scientists, hydrologists, climatologists, geographers, and representatives from many other disciplines have contributed to this work. Each of the articles separately, and all of them in sequence and combination, serve to summarize and encapsulate our present knowledge of the world's variegated soils, their natural functions, and their importance to humans.

Concise articles surveying specific aspects of soils (soil genesis, soil chemistry and mineralogy, soil physics and hydrology, and soil biology) are complemented by articles covering transdisciplinary aspects, such as the role of soils in ecology, the history of soil utilization for agricultural and engineering purposes, the development of soil science as a discipline, and the potential or actual contributions of soils to the generation, as well as to the mitigation, of pollution and of global climate change.

This comprehensive reference encompasses both the fundamental and the applied aspects of soil science, interfacing in general with the physical sciences and life sciences and more specifically with the earth sciences and environmental sciences.

The *Encyclopedia of Soils in the Environment* manifests the expanding scope of modern soil science, from its early sectarian focus on the utilitarian attributes of soils in agriculture and engineering, to a wider and much more inclusive view of the soil as a central link in the continuous chain of processes constituting the dynamic environment as a whole. Thus it both details and integrates a set of topics that have always been of vital importance to human societies and that are certain to be even more so in the future.

SPATIAL VARIATION, SOIL PROPERTIES

R Webster, Rothamsted Research, Harpenden, UK

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

The soil mantles the land more or less continuously, except where there is bare rock and ice, and in a way so complex that no description of it can follow every detail. Further, our knowledge of the soil's properties beneath the surface is fragmentary because it derives from observations on small volumes of material widely separated from one another. Any representation of the whole mantle involves simplification and inference or prediction as to what the soil is like between sampling points with the uncertainty that they entail.

Research in the last 40 years has provided us with quantitative descriptions based on samples. Two main approaches may be discerned. In the first the soil is divided into discrete classes (strata) which are sampled to give estimates of mean values and variances using classical statistics. The other sees soil as a suite of continuous variables and seeks to describe the continuity in terms of spatial dependence and specifically uses geostatistics. The two approaches are not mutually exclusive and they can be combined.

Soil Classification

Peasant cultivators and farmers have for centuries recognized different kinds of soil, and they have divided their land where the soil changes so that they can manage it. In other words, they have classified the soil and land spatially. More formal classification of soil has its roots in nineteenth-century biological taxonomy and practice in geological survey. Finite circumscribed regions are divided into parcels by boundaries, which are sharp lines across which the soil changes in some sense. For any one region, the outcome is a map, technically a choropleth map, showing the region tessellated into spatial classes, which constitute a general-purpose classification. The map may purport to show the classes of some predefined scheme of classification; alternatively the boundaries on it may be drawn where the soil changes more than elsewhere and between which the soil is relatively homogeneous. There are thousands of examples.

The map has usually been accompanied by a text describing each of the classes displayed, with data on individual soil properties from representative sites. The spatial variation for any one soil property thus appears as a stepped function, as in Figure 1a of a transect across a region. Variation within the classes may be acknowledged, but it is not evident. The reality is more like Figure 1b, which is the same transect but now with all the data from sampling at 10-m intervals shown, and for which there is a summary in Table 1. Some of the boundaries can still be recognized where there are large jumps in the data, but others are not so obvious.

By the 1960s, taxonomists were putting numerical limits on the discriminating criteria for consistency. This helped to codify description. It did nothing, however, to quantify the variation in properties that could not be assessed readily in the field; and it was unhelpful to the map-maker who wished to place boundaries where there were maxima in the rate of change in the landscape. Description needed a formal statistical basis, a need first recognized by civil engineers in the 1960s.

Sampling and Estimation

In the classical approach, a soil property, z, takes values at an infinity of points, $\mathbf{x}_i = \{x_{i1}\, x_{i2}\}$, $i = 1, 2, \ldots, \infty$, in a region $\mathcal{R}$. These values, $z(\mathbf{x}_i)$, comprise the population, which has a mean, μ, and variance, here denoted as σ_i^2 signifying the total variance in $\mathcal{R}$. The region is divided into K spatial strata or classes, $\mathcal{R}_k$, $k = 1, 2, \ldots, K$, which are mutually exclusive and exhaustive and which are what the map displays; each has its own mean and variance, denoted μ_k and σ_k^2, respectively. The region is then sampled, and the property at the N sampling points is measured to give data, $z(\mathbf{x}_1), z(\mathbf{x}_2), \ldots, z(\mathbf{x}_N)$, of which n_k belong in class $\mathcal{R}_k$.

If sampling is unbiased, then the mean for the kth class is estimated simply by:

$$\hat{\mu}_k = \bar{z}_k = \frac{1}{n_k}\sum_{i=1}^{n_k} z(\mathbf{x}_i) \quad \text{for} \quad \mathbf{x}_i \in \mathcal{R}_k \qquad [1]$$

The variance within $\mathcal{R}_k$ is estimated from the same sample by

$$\hat{\sigma}_k^2 = s_k^2 = \frac{1}{n_k - 1}\sum_{i=1}^{n_k} \{z(\mathbf{x}_i) - \bar{z}_k\}^2 \quad \text{for} \quad \mathbf{x}_i \in \mathcal{R}_k \quad [2]$$

In the classical approach, the soil map plus the class means and variances summarize the available information on the spatial variation of z in $\mathcal{R}$. The analysis may be elaborated by adding skewness coefficients, computed from the third moments about the means

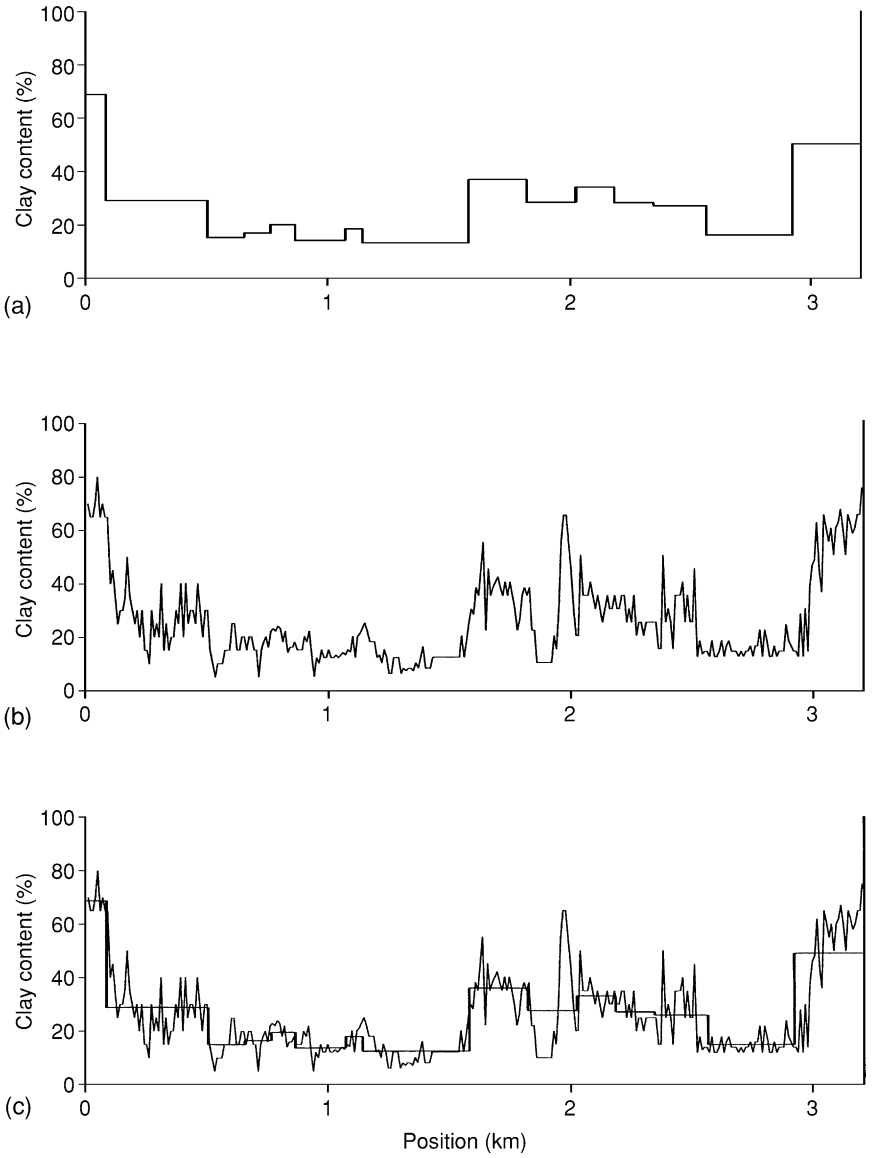

Figure 1 Variation of clay content along a transect: (a) as represented by a classification; (b) actual values measured in topsoil at 10-m intervals; and (c) superimposition of the classification on the reality.

Table 1 Summary of 321 observations of clay content (recorded as percentage by weight) in topsoil and subsoil

	Topsoil	*Subsoil*
Mean (%)	25.6	39.0
Median (%)	20.0	36.0
Variance $(\%)^2$	255.49	936.81
Standard deviation (%)	16.0	30.6
Skewness	1.2	0.2

for the classes, and perhaps higher-order moments. The data might be transformed so that they approximate a normal distribution and so that the means and variances are sufficient summaries.

More importantly, the statistics can be embraced in a single summary. When a soil surveyor subdivides a particular region to display the spatial distribution of the soil, he or she usually tries to create classes of the same categorical level, for example, all soil series or all soil families. Ideally the variances within these are equal, i.e., there is a common within-class variance:

$$\sigma_{\mathrm{W}}^2 = \sigma_k^2 \quad \text{for all} \quad k \qquad [3]$$

The differences between classes can be represented by the between-class variance, σ_{B}^2. This is essentially the variance among the means of the classes, and can be estimated from the data as follows. A quantity B is calculated as the sum of the squares of the differences

Table 2 One-way analysis of variance

Source	*Degrees of freedom*	*Mean square*	*Parameter estimated*
Between classes	$K-1$	$\frac{1}{K-1}\sum_{k=1}^{K} n_k(\bar{z}_k - \bar{\bar{z}})^2$	$n^*\sigma_B^2 + \sigma_W^2$
Within classes	$N-K$	$\frac{1}{N-K}\sum_{k=1}^{K}\sum_{i=1}^{n_k}\{z(\mathbf{x}_{ik}) - \bar{z}_k\}^2$	σ_W^2
Total	$N-1$	$\frac{1}{N-1}\sum_{i=1}^{N}\{z(\mathbf{x}_i) - \bar{\bar{z}}\}^2$	σ_T^2

between the class means and the mean of all the data, $\bar{z}_k - \bar{\bar{z}}$, the latter being the equivalent of $\hat{\mu}$:

$$B = \frac{1}{K-1}\sum_{k=1}^{K} n_k(\bar{z}_k - \bar{\bar{z}})^2 \quad [4]$$

If all the classes are sampled equally, so that $n = n_k$ for all k, then s_B^2 is computed from B simply by:

$$s_B^2 = (B - s_W^2)/n \quad [5]$$

If the n_k are not equal, n in Eqn [5] is replaced by:

$$n^* = \frac{1}{K-1}\left(N - \frac{\sum_{k=1}^{K} n_k^2}{N}\right) \quad [6]$$

and

$$s_B^2 = (B - s_W^2)/n^* \quad [7]$$

The whole can be set out in a one-way analysis of variance, as in Table 2.

For the whole population in $\mathcal{R}$, the variances σ_W^2 and σ_B^2 sum to the total variance, σ_T^2:

$$\sigma_T^2 = \sigma_W^2 + \sigma_B^2 \quad [8]$$

The ratios of these variances describe the relative effects of the spatial classification. One ratio is the intraclass correlation:

$$\rho_i = \frac{\sigma_B^2}{\sigma_W^2 + \sigma_B^2} \quad [9]$$

estimated by:

$$r_i = \frac{s_B^2}{\sigma_W^2 + \sigma_B^2} = \frac{B - s_W^2}{B + (n^* - 1)s_W^2} \quad [10]$$

The last expression enables the intraclass correlation to be calculated directly from the table of analysis of variance. The term derives its name from the fact that it expresses the 'correlation' among individuals within the same class.

The theoretical maximum of ρ_i is 1 when every class is uniform ($\sigma_W^2 = 0$). In practice there is always some variation within the classes, and so $\rho_i < 1$. Its theoretical minimum is zero when all the μ_k are equal, so that $\sigma_B^2 = 0$. Its estimate, r_i, and the estimate s_B^2 are often negative. The usual cause is sampling fluctuation, where the differences between means are small in relation to the variation within the classes, and one can take negative values of r_i as estimates of $\rho_i = 0$.

Another ratio expressing the effectiveness of the classification is simply s_W^2/s_T^2, sometimes called the 'relative variance.' Its complement, $1 - s_W^2/s_T^2$, can be regarded as the proportion of the variance accounted for by the classification, and in this respect it is like the coefficient of determination, R^2, in regression analysis. Like the intraclass correlation, it varies between 1 (uniformity within classes) and 0 (no differences between them), and for large N and K the two have very similar values.

This analysis is applied to the classification of the clay content of the topsoil at Sandford. Table 3 lists the means and variances of the 15 classes, and Table 4 summarizes the analysis of variance.

Table 3 Means and variances of clay content in the topsoil, recorded as percentage by weight, for 15 classes

Class	*Mean*	*Variance*
1	68.8	26.79
2	28.8	110.74
3	15.0	32.14
4	16.5	21.07
5	19.6	12.93
6	13.7	12.33
7	17.9	17.14
8	12.4	21.96
9	35.9	54.69
10	27.6	380.36
11	33.1	42.92
12	27.2	23.23
13	26.0	121.85
14	15.0	9.71
15	49.1	341.78

Table 4 Analysis of variance of clay content of topsoil

Source	*Degrees of freedom*	*Mean square*	*F-ratio*
Between classes	14	3786.67	40.3
Within classes	306	93.94	
Total	320	255.5	

The within-class component of variance (in Table 4) is $s^2_W = 93.94$, and the between-class component, s^2_B, is 176.1. This leads to an intraclass correlation for the classification as 0.65. The complement of the relative variance is 0.63.

There are substantial differences between the variances within the individual classes, so it is something of a liberty to treat them as estimates of the same quantity to arrive at sensible values for r_i and $1 - s^2_W/s^2_T$.

The Geostatistical Approach

The artificiality of imposing boundaries between classes to describe variation that is patently continuous worried quantitatively minded soil scientists, and soil physicists in a particular, for many years. A practicable alternative eluded them, however. They toyed with polynomials, but any such function would have to be of a very high order and could have no generality. The variation was too complex, perhaps chaotic, as Figure 1b shows. Such variation looks as though it might be random. It was this last idea that provided the breakthrough: if the variation appears random then why not treat it as if it were random? This is the basis of modern geostatistics and its approach to describing soil variation.

Random Variables and Random Functions

As in the classical approach, a region $\mathcal{R}$ is regarded as comprising an infinite number of points $\mathbf{x}_i$, $i = 1, 2, \ldots, \infty$. Whereas in the classical approach the values of z at these points constitute the population, in the geostatistical approach this population is assumed to be just one realization of a random process or random function that could generate any number of such populations. At each place $\mathbf{x}$ the soil property is a random variable, $Z(\mathbf{x})$ – notice the capital 'Z' – of many values. For a continuous variable such as hydraulic conductivity or pH, this number is infinite, and the whole process may be regarded as a doubly infinite superpopulation. The random variable at $\mathbf{x}$ has a distribution with a mean and variance and higher-order moments, and the actual value there, $z(\mathbf{x})$, is just one drawn at random from that distribution.

In these circumstances the quantitative description of the variation involves estimating the characteristics of what are assumed to be the underlying random processes. The characteristics include the means and variances, and perhaps higher-order moments, but most importantly the spatial covariances.

The spatial covariance between the variables at any two places $\mathbf{x}_1$ and $\mathbf{x}_2$ is given by:

$$C(\mathbf{x}_1, \mathbf{x}_2) = \mathrm{E}\left[\{Z(\mathbf{x}_1) - \mu(\mathbf{x}_1)\}\{Z(\mathbf{x}_2) - \mu(\mathbf{x}_2)\}\right] \quad [11]$$

where $\mu(\mathbf{x}_1)$ and $\mu(\mathbf{x}_2)$ are the means at $\mathbf{x}_1$ and $\mathbf{x}_2$, and E denotes the expected value. In practice $C(\mathbf{x}_1, \mathbf{x}_2)$ cannot be estimated, because there is only ever the one realization, and to overcome this apparent impasse assumptions of stationarity must be invoked.

Stationarity

Starting with the first moment, we assume that the mean, $\mu = \mathrm{E}[Z(\mathbf{x})]$, is constant for all $\mathbf{x}$, and so $\mu(\mathbf{x}_1)$ and $\mu(\mathbf{x}_2)$ can be replaced by the single value μ, which is estimated by repetitive sampling.

Next, when $\mathbf{x}_1$ and $\mathbf{x}_2$ coincide, Eqn [11] defines the variance, $\sigma^2 = \mathrm{E}[\{Z(\mathbf{x}) - \mu\}^2]$. This is assumed to be finite and, like the mean, to be the same everywhere. Equation [11] is then generalized so that it applies to any pair of points $\mathbf{x}_i$ and $\mathbf{x}_j$ separated by a vector, or lag $\mathbf{h} = \mathbf{x}_i - \mathbf{x}_j$, so that:

$$\begin{aligned} C(\mathbf{x}_i, \mathbf{x}_j) &= \mathrm{E}\left[\{Z(\mathbf{x}_i) - \mu\}\{Z(\mathbf{x}_j) - \mu\}\right] \\ &= \mathrm{E}\left[\{Z(\mathbf{x})\}\{Z(\mathbf{x} + \mathbf{h})\} - \mu^2\right] \\ &= C(\mathbf{h}) \end{aligned} \quad [12]$$

and this is also constant for any given $\mathbf{h}$. This constancy of the mean and variance and of a covariance that depends only on separation and not on absolute position constitutes second-order stationarity.

Equation [12] shows that the covariance is a function of the lag and only of the lag; it describes quantitatively the dependence between values of Z with changing lag. It is readily converted to the dimensionless autocorrelation by:

$$\rho(\mathbf{h}) = C(\mathbf{h})/C(\mathbf{0}) \quad [13]$$

where $C(\mathbf{0}) = \sigma^2$ is the covariance at lag $\mathbf{0}$.

Intrinsic Variation and the Variogram

In many instances the assumption of constant mean throughout a region is untenable, and if the mean changes the variance will appear to increase indefinitely with increasing area. The covariance cannot be defined then, because there is no value for μ to insert in Eqn [12]. Faced with this situation, geostatisticians consider the differences from place to place, and their squares, as follows. For small lag distances, the expected differences are zero:

$$\mathrm{E}\left[Z(\mathbf{x}) - Z(\mathbf{x} + \mathbf{h})\right] = 0 \quad [14]$$

and the expected squared differences define the variances for those lags:

$$\begin{aligned} \mathrm{E}\left[\{Z(\mathbf{x}) - Z(\mathbf{x} + \mathbf{h})\}^2\right] &= \mathrm{var}\left[Z(\mathbf{x}) - Z(\mathbf{x} + \mathbf{h})\right] \\ &= 2\gamma(\mathbf{h}) \end{aligned} \quad [15]$$

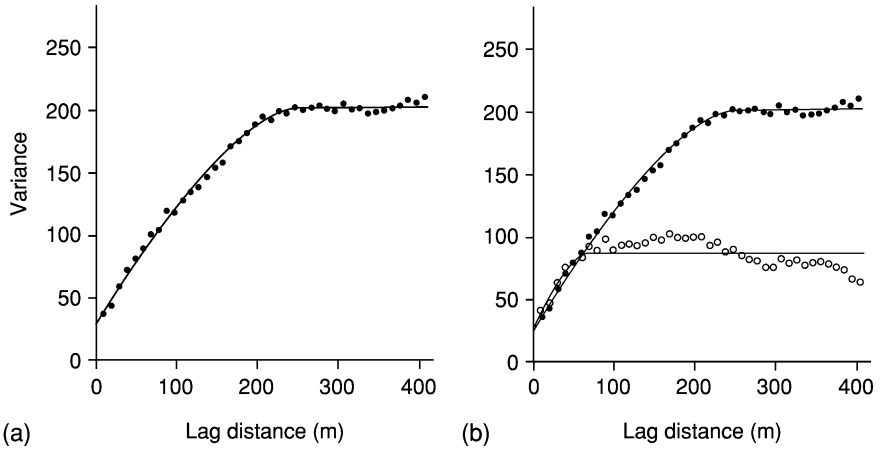

Figure 2 Experimental variograms of clay content of topsoil and the spherical models fitted to them: (a) global variogram with black circles for the experimental semivariances; and (b) the global variogram plus the within-class variogram with open circles for the experimental values.

Eqn [15] gives the variance of the difference at lag $\mathbf{h}$; and the quantity $\gamma(\mathbf{h})$, known as the semivariance, is the variance per point. Equations [14] and [15] constitute the intrinsic hypothesis of geostatistics. Like the covariance, the semivariance depends only on the lag and not on the absolute positions $\mathbf{x}$ and $\mathbf{x}+\mathbf{h}$. As a function, $\gamma(\mathbf{h})$ is the variogram, often still called the 'semivariogram.'

If the process $Z(\mathbf{x})$ is second-order stationary then the semivariance and the covariance are equivalent:

$$\begin{aligned}\gamma(\mathbf{h}) &= C(\mathbf{0}) - C(\mathbf{h}) \\ &= \sigma^2\{1 - \rho(\mathbf{h})\}\end{aligned} \qquad [16]$$

If it is intrinsic only, the covariance does not exist, but the semivariance remains valid, and it is this validity in a wide range of circumstances that makes the variogram so useful in summarizing spatial variation.

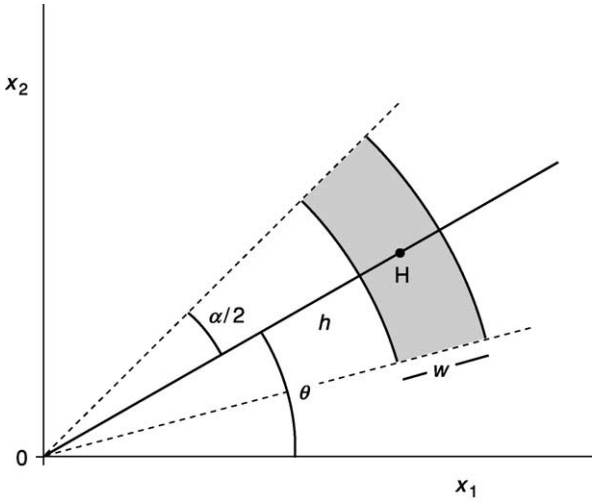

Figure 3 Discretization of the lag in two dimensions for irregularly scattered data. All separations within the gray sector are assigned to lag distance h and direction θ.

Estimating the Variogram

Semivariances are readily estimated from data, $z(\mathbf{x}_1)$, $z(\mathbf{x}_2), \ldots$, by the method of moments:

$$\hat{\gamma}(\mathbf{h}) = \frac{1}{2m(\mathbf{h})}\sum_{i=1}^{m(\mathbf{h})}\{z(\mathbf{x}_i) - z(\mathbf{x}_i+\mathbf{h})\}^2 \qquad [17]$$

in which $m(\mathbf{h})$ is the number of paired comparisons at lag $\mathbf{h}$. By changing $\mathbf{h}$ we obtain a sample or experimental variogram, which can be displayed as a graph of $\hat{\gamma}$ against $\mathbf{h}$. Figure 2a is an example in which the experimental semivariances for the data in Figure 1b are plotted as points against the lag distance, $h = |\mathbf{h}|$, for the one-dimensional transect.

The values of $\mathbf{h}$ define discrete points on the variogram, and so sampling is best planned with regular intervals along a line in one dimension or on a grid in two or three. Otherwise the actual separations have to be placed into 'bins,' with limits in separating distance and also in direction if there is more than one dimension (Figure 3).

Models for Variograms

The underlying variogram, Eqn [15], is a continuous function in as many dimensions as the variable $Z(\mathbf{x})$. The experimental variogram estimates it at a set of points with more or less error and point-to-point fluctuation arising from the sampling. To obtain a variogram to describe the spatial variation in $\mathcal{R}$, a plausible function is fitted to the experimental values. The usual approach is to fit the simplest model that makes sense.

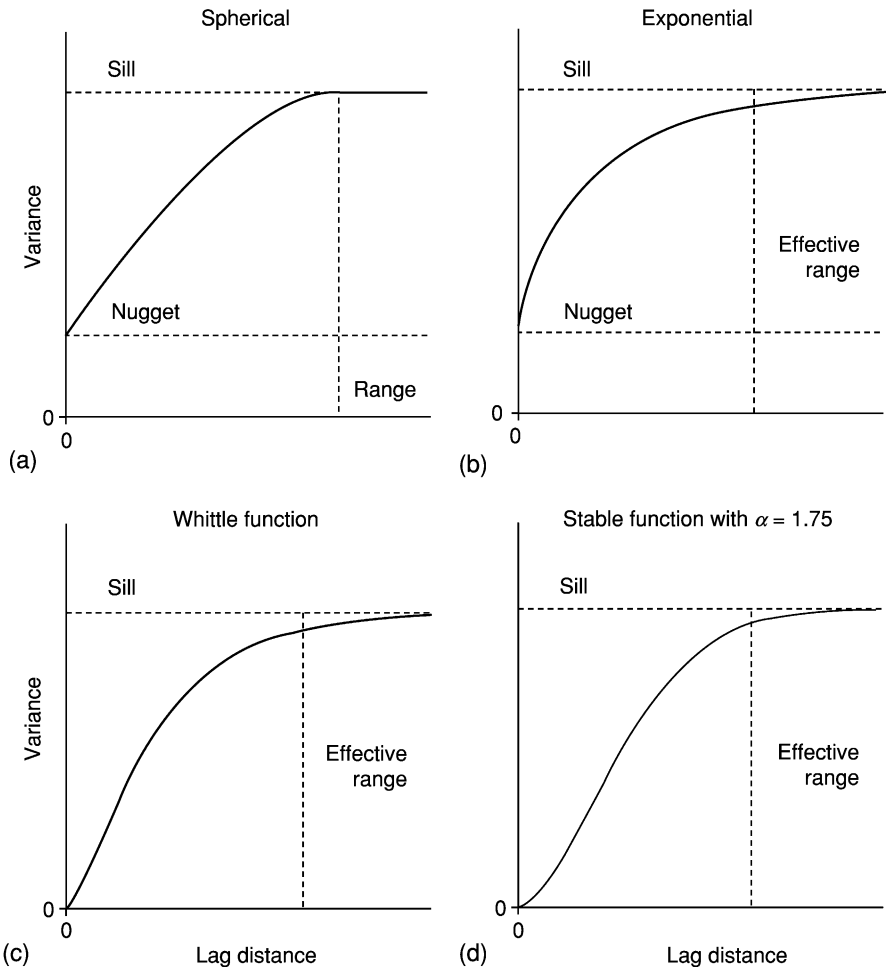

Figure 4 Four kinds of bounded variogram.

Figure 4a shows the principal features of many, if not most, experimental variograms. They are as follows:

1. The variance increases from near the ordinate with increasing lag distance;
2. The variance reaches a maximum at which it remains thereafter;
3. Any simple smooth line or surface placed through the points and projected to the ordinate cuts the ordinate at some value greater than zero.

The model must also be mathematically acceptable in that it cannot give rise to 'negative variances' when random variables are combined. Let $z(\mathbf{x}_i)$, $i = 1, 2, \ldots, n$, be a realization of the random variable $Z(\mathbf{x})$ with covariance function $C(\mathbf{h})$ and variogram $\gamma(\mathbf{h})$, and consider the linear sum:

$$y = \sum_{i=1}^{n} \lambda_i z(\mathbf{x}_i) \qquad [18]$$

where the λ_i are any arbitrary weights. The variable Y from which y derives is also a random variable, and its variance is given by:

$$\text{var}[Y] = \sum_{i=1}^{n} \sum_{j=1}^{n} \lambda_i \lambda_j C(\mathbf{x}_i - \mathbf{x}_j) \qquad [19]$$

where $C(\mathbf{x}_i - \mathbf{x}_j)$ is the covariance of Z between $\mathbf{x}_i$ and $\mathbf{x}_j$. This variance must be positive or zero; it may not be negative. If $Z(\mathbf{x})$ is intrinsic only then the covariances do not exist, and we must rewrite [19] as:

$$\text{var}[Y] = C(\mathbf{0}) \sum_{i=1}^{n} \lambda_i \sum_{j=1}^{n} \lambda_j - \sum_{i=1}^{n} \sum_{j=1}^{n} \lambda_i \lambda_j \gamma(\mathbf{x}_i - \mathbf{x}_j) \qquad [20]$$

where $\gamma(\mathbf{x}_i - \mathbf{x}_j)$ is the semivariance of Z between $\mathbf{x}_i$ and $\mathbf{x}_j$. The first term on the right-hand side of this equation is eliminated if the weights sum to zero, so that:

$$\text{var}[Y] = -\sum_{i=1}^{n}\sum_{j=1}^{n}\lambda_i\lambda_j\gamma(\mathbf{x}_i - \mathbf{x}_j) \qquad [21]$$

This too must guarantee non-negative variances, and only functions that do that are admissible. They are said to be 'conditional negative semidefinite,' the condition being that the weights in Eqn [21] sum to zero.

There are only a few families of simple functions that satisfy the above criteria. They can be divided into those that are bounded and those that are not. In the first group are the popular spherical and exponential models. Their formulae in their isotropic forms, i.e., for $h = |\mathbf{h}|$, are as follows.

Spherical The spherical function has the following equation:

$$\begin{aligned}\gamma(h) &= c_0 + c\left\{\frac{3}{2}\left(\frac{h}{a}\right) - \frac{1}{2}\left(\frac{h}{a}\right)^3\right\} \quad \text{for} \quad 0 < h \le a \\ &= c \quad \text{for} \quad h > a \\ &= 0 \quad \text{for} \quad h = 0\end{aligned} \qquad [22]$$

Here $\gamma(h)$ is the semivariance at lag h, and c is the *a priori* variance of the autocorrelated process. The quantity c_0 is the intercept on the ordinate and is known as the 'nugget variance,' a term derived from gold-mining. The combined $c_0 + c$ is known as the 'sill' of the model, and c is the sill of the correlated variance. These quantities are illustrated in **Figure 4a**, and **Figure 2a** shows the function fitted to the experimental variogram of clay content, **Figure 1b**. The values of the parameters, c_0, c, and a, are listed in **Table 5**.

The function has a distance parameter, a; this is its range, also know as its 'correlation range.' It marks the limit of spatial dependence; values at places closer to one another than a are more or less correlated, whereas those further apart are not. It implies that all the variance in $\mathcal{R}$ is encountered within that distance, and in this sense it corresponds to the concept of the representative elementary volume (REV). The spherical function gets its name from the formula for the volume of two intersecting spheres, which are of diameter a.

Table 5 Parameters of spherical models, Eqn [22], fitted to the experimental global and within-class variograms of clay in topsoil and subsoil

		Nugget, c_0	*Sill*, c	*Range*, a (m)
Topsoil	Global	28.2	172.8	265
	Within-class	28.1	59.3	70.9
Subsoil	Global	117.5	551.4	191
	Within-class	108.4	257.2	77.1
Subsoil × *topsoil*	Global	−1.1	210.8	229.6

The semivariance at lag zero is itself zero, and for continuous processes such as most physical properties of the soil, $\gamma(h)$ should increase gradually as h increases from zero. In practice, there are usually insufficient estimates of $\gamma(h)$ near the ordinate to fit a model through the origin, and therefore the conservative approach (described above) is taken. The nugget variance is therefore best regarded as embodying variation within the shortest sampling interval plus any measurement error.

Other functions with the same general form and finite ranges are the bounded linear function (valid in one dimension only), the circular (valid in one and two dimensions, but not in three), and the pentaspherical.

Exponential The equation for the exponential function is:

$$\gamma(h) = c_0 + c\left\{1 - \exp\left(-\frac{h}{r}\right)\right\} \qquad [23]$$

in which c_0 and c have the same meanings as before, but now with a distance parameter, r. The exponential model approaches its sill asymptotically and has no definite range therefore. A working range is often taken as $a' = 3r$, at which point the function has reached 95% of c. This model is shown in **Figure 4b**.

Models with reverse curvature at the origin Some variograms appear to approach the origin with decreasing gradients. These may be represented by the general equation:

$$\gamma(h) = c\left\{1 - \exp\left(-\frac{h^\alpha}{r^\alpha}\right)\right\} \qquad [24]$$

in which $0 < \alpha \le 2$. If $\alpha = 2$ we have the Gaussian function. This is at the limit of acceptability and gives rise to unstable prediction. It is best replaced by stable models with $\alpha < 2$; **Figure 4d** is an example. Another recommended function to describe such variation is the Whittle elementary correlation:

$$\gamma(h) = c\left\{1 - \frac{h}{r}K_1\left(\frac{h}{r}\right)\right\} \qquad [25]$$

in which r is again a distance parameter, and K_1 is the modified Bessel function of the second kind (**Figure 4c**). It has the added attraction in that it derives theoretically from diffusion in two dimensions. To all can be added a nugget variance, c_0, if desired.

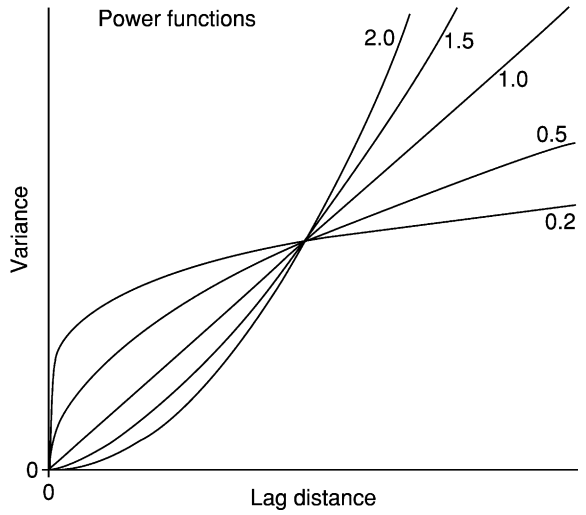

Figure 5 Four valid power functions, Eqn [26] with exponents, α, 0.2, 0.5, 1.0, and 1.5, plus the inadmissible limiting function with $\alpha = 2$.

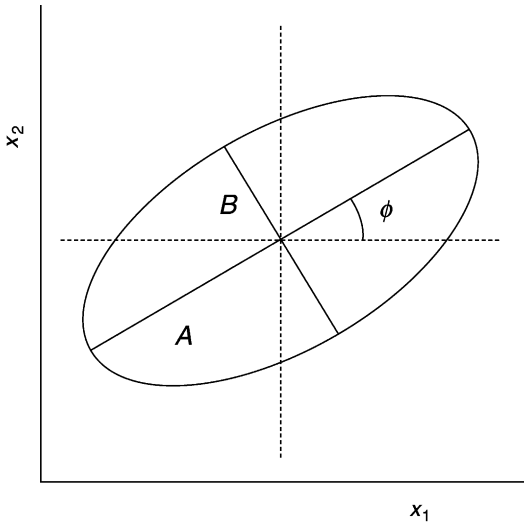

Figure 6 Ellipse showing parameters of anisotropy.

Unbounded models Variograms of processes that are intrinsic but not second-order stationary increase without bound as the lag distance increases. These can usually be fitted by power functions, for which the general equation including a nugget is:

$$\gamma(h) = c_0 + wh^{\alpha} \qquad [26]$$

The parameter w describes the intensity of the process, and the exponent, which must lie strictly between 0 and 2 (these limits are excluded), describes the curvature. If $\alpha < 1$ the curve is convex upward; if it is 1 we have a straight line; and if $\alpha > 1$ the curve is concave upward. The curve with $\alpha = 2$ is a parabola and describes a smoothly continuous process that is not random. Figure 5 shows the curves for several values of α.

Anisotropy The variogram of a two-dimensional process is itself two-dimensional, and if the process is anisotropic so is its variogram, which is then a function of both distance h and direction θ. In the simplest cases, the anisotropy is geometric, meaning that it can be made isotropic by a linear transformation of the coordinates. The transformation is defined by reference to an ellipse:

$$\Omega(\theta) = \sqrt{A^2\cos^2(\theta - \phi) + B^2\sin(\theta - \phi)} \qquad [27]$$

where A and B are the long and short diameters, respectively, of the ellipse, and ϕ is its orientation, i.e., the direction of the long axis (Figure 6). Equation [27] is embodied into the models as follows: For the bounded models, Ω replaces the distance parameter

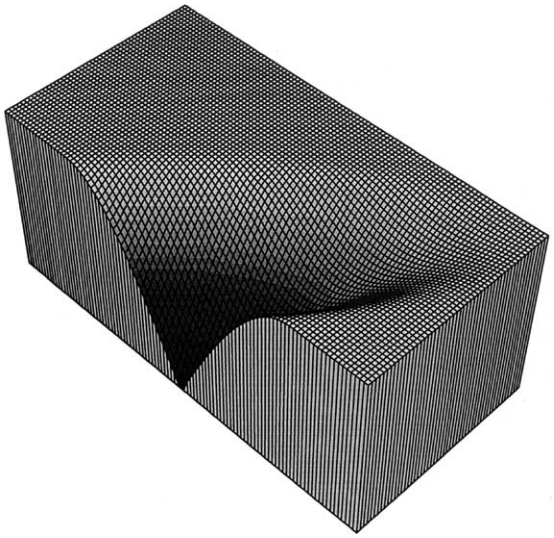

Figure 7 Perspective diagram of the variogram surface of an anisotropic spherical function.

of the isotropic variogram. So, for example, in the exponential:

$$\gamma(h,\theta) = c_0 + c\left\{1 - \exp\left(-\frac{h}{\Omega(\theta)}\right)\right\} \qquad [28]$$

and in the linear function:

$$\gamma(h,\theta) = c_0 + \Omega(\theta)h^{\alpha} \qquad [29]$$

in which $\alpha = 1$. Figure 7 shows an anisotropic spherical function. Notice how the range of the model changes with changing direction.

Combining Trend and Random Fluctuation

The above functions describe processes that are entirely random though correlated. We can represent the processes by the general model:

$$Z(\mathbf{x}) = \mu_V + \epsilon(\mathbf{x}) \quad [30]$$

in which μ_V is the mean, i.e., constant, in some neighbourhood V, and $\epsilon(\mathbf{x})$ is the autocorrelated variance as defined in Eqn [15]. It often happens that such models are unacceptable, either because there is an evident long-range trend across a region or because over short distances the variation appears smooth. In these circumstances, μ_V cannot be treated as constant but must be replaced by a deterministic term, say $u(\mathbf{x})$, that depends on the position $\mathbf{x}$. The model becomes:

$$Z(\mathbf{x}) = u(\mathbf{x}) + \epsilon(\mathbf{x}) \quad [31]$$

If $u(\mathbf{x})$ can describe the variation over the whole of $\mathcal{R}$ it is called 'trend.' If it is local only then is it known as 'drift.' In either event it is usually represented by a low-order polynomial, so Eqn [31] becomes:

$$Z(\mathbf{x}) = \sum_{j=0}^{J} a_j f_j(\mathbf{x}) + \epsilon(\mathbf{x}) \quad [32]$$

in which the a_j are unknown coefficients and the $f_j(\mathbf{x})$ known functions of our choosing.

It is fairly easy, even if somewhat arbitrary, to separate any long-range trend from the short-range, apparently random fluctuation and to estimate the parameters of the two components separately. It is not at all easy to do it where there is short-range drift. In these circumstances it involves a full structural analysis, effectively a process of trial and error.

Combining Classification with Geostatistics

In some instances neither a classification nor a variogram alone can serve to represent spatial variation in soil properties. The choropleth map implies abrupt changes, whereas the variogram is based on a model of random but continuous fluctuation. If there appears to be both kinds of variation then the two approaches may be combined. By recognizing the class boundaries, that is, by combining the information in **Figure 1a** and **1b**, and analyzing the variance (**Table 4**), residuals can be obtained from the class means. Their variance is the residual mean square, and a portion of this is likely to be autocorrelated and have its own variogram. **Figure 2b** shows by the circles an example of a within-class variogram obtained by superimposing the classification on the data. The curve through the points is again that of a spherical model with parameter values as given in **Table 5**.

The variogram of the residuals differs from the variogram of the original data in two important respects:

1. The sill of the fitted model is less by an amount approximately equal to the between-class variance, as expected;
2. The range of the model is much less. This is because the class-to-class variation, which evidently dominated the variation over the whole transect, has been removed to leave only the short-range correlation.

Coregionalization – Simultaneous Variation in Two or More Variables

Any two variables, say z_u and z_v, may be correlated and in particular linearly correlated. That relation is conventionally expressed by the product–moment correlation coefficient:

$$\rho = \frac{\mathrm{cov}[uv]}{\sqrt{\mathrm{var}[u] \times \mathrm{var}[v]}} \quad [33]$$

i.e., the covariance of z_u and z_v divided by the product of their standard deviations.

The two spatial random variables, $Z_u(\mathbf{x})$ and $Z_v(\mathbf{x})$, may also be spatially intercorrelated in that each is spatially correlated both with itself, i.e., autocorrelated, and with the other. The two variables are then said to be cross-correlated. In these circumstances, the two variables have autovariograms, one each, as defined by Eqn [15] and for present purposes denoted $\gamma_{uu}(\mathbf{h})$ and $\gamma_{vv}(\mathbf{h})$. They also have a cross-variogram, $\gamma_{uv}(\mathbf{h})$, defined by:

$$\gamma_{uv}(\mathbf{h}) = \frac{1}{2}\mathrm{E}\left[\{Z_u(\mathbf{x}) - Z_u(\mathbf{x}+\mathbf{h})\}\{Z_v(\mathbf{x}) - Z_v(\mathbf{x}+\mathbf{h})\}\right] \quad [34]$$

If both variables are second-order stationary with means μ_v and μ_v then will both have covariance functions, C_{uu} and C_{vv} as defined in Eqn [12], and a cross-covariance:

$$C_{uv}(\mathbf{h}) = \mathrm{E}[\{Z_u(\mathbf{x}) - \mu_u\}\{Z_v(\mathbf{x}+\mathbf{h}) - \mu_v\}] \quad [35]$$

There is also a cross-correlation coefficient, ρ_{uv}, given by:

$$\rho_{uv}(\mathbf{h}) = \frac{C_{uv}}{\sqrt{C_{uu}(0)C_{vv}(0)}} \quad [36]$$

This is effectively the extension of the Pearson product–moment correlation coefficient of Eqn [33] into the spatial domain, and when $\mathbf{h} = 0$ it is the Pearson coefficient.

The cross-covariance is in general not symmetric, i.e.:

$$\mathrm{E}[\{Z_u(\mathbf{x}) - \mu_u\}\{Z_v(\mathbf{x}+\mathbf{h}) - \mu_v\}] \neq \mathrm{E}[\{Z_v(\mathbf{x}) - \mu_v\}\{Z_v(\mathbf{x}+\mathbf{h}) - \mu_u\}] \quad [37]$$

In words, the cross-covariance between $Z_u(\mathbf{x})$ and $Z_v(\mathbf{x})$ in one direction is different from that in the other, or, expressed another way:

$$C_{uv}(\mathbf{h}) \neq C_{uv}(-\mathbf{h}) \quad \text{or equivalently} \quad C_{uv}(\mathbf{h}) \neq C_{vu}(\mathbf{h}) \quad [38]$$

since:

$$C_{uv}(\mathbf{h}) = C_{vu}(-\mathbf{h})$$

Asymmetry can be envisaged between two soil properties at different depths on a slope as a result of creep or solifluction. The subsoil would tend to lag behind the topsoil. Similarly, irrigation by flooding always from the same end of a field might distribute salts differentially in the direction of flow, but asymmetric covariances have not been reported in the literature as of 2003, as far as I know.

The cross-variogram and the cross-covariance function (if it exists) are related by:

$$\gamma_{uv}(\mathbf{h}) = C_{uv}(\mathbf{0}) - \frac{1}{2}\{C_{uv}(\mathbf{h}) + C_{uv}(-\mathbf{h})\} \quad [39]$$

This quantity contains both $C_{uv}(\mathbf{h})$ and $C_{uv}(-\mathbf{h})$ and in consequence loses any information on asymmetry; it is an even function, i.e., symmetric:

$$\gamma_{uv}(\mathbf{h}) = \gamma_{vu}(\mathbf{h}) \quad \text{for all} \quad \mathbf{h}$$

Cross-semivariances can be estimated in a way similar to that of the autosemivariances by:

$$\hat{\gamma}_{uv}(\mathbf{h}) = \frac{1}{2m(\mathbf{h})}\sum_{i=1}^{m(\mathbf{h})}\{z_u(\mathbf{x}_i) - z_u(\mathbf{x}_i+\mathbf{h})\}\{z_v(\mathbf{x}_i) - z_v(\mathbf{x}_i+\mathbf{h})\} \quad [40]$$

and the sample cross-variogram is formed by simple incrementation of $\mathbf{h}$. There is an equivalent formula for computing the cross-covariances. Notice that there must be numerous places where both z_u and z_v have been measured.

Modeling the Coregionalization

The cross-variogram can be modeled in the same way as the autovariogram, and the same restricted set of functions is available. There is one additional constraint. Any linear combination of the variables is itself a regionalized variable, and its variance cannot be negative. This is assured by adopting the linear model of coregionalization. In it the variable $Z_u(\mathbf{x})$ is assumed to be the sum of independent (orthogonal) random variables, $Y_j^k(\mathbf{x})$:

$$Z_u(\mathbf{x}) = \sum_{k=1}^{K}\sum_{j=1}^{k} a_{uj}^k Y_j^k(\mathbf{x}) + \mu_u \quad [41]$$

in which the superscript k is an index, not a power. There is a similar assumption for $Z_v(\mathbf{x})$. If the assumptions hold then the pair of variables has a cross-variogram:

$$\gamma_{uv}(\mathbf{h}) = \sum_{k=1}^{K}\sum_{j=1}^{k} a_{uj}^k a_{vj}^k g^k(\mathbf{h}) \quad [42]$$

The products in the second summation can be replaced by b_{uv}^k to give

$$\gamma_{uv}(\mathbf{h}) = \sum_{k=1}^{K} b_{uv}^k g^k(\mathbf{h}) \quad [43]$$

The quantities are the variances and covariances, e.g., nugget and sill variances, for the independent components of a spherical model. For two variables there are the three nugget variances, b_{uu}^1, b_{vv}^1, and b_{uv}^1, and similarly three for the sills of the correlated variances. The coefficients $b_{uv}^k = b_{vu}^k$ for all k, and, for each k, the matrix of coefficients:

$$\begin{bmatrix} b_{uu}^k & b_{uv}^k \\ b_{vu}^k & b_{vv}^k \end{bmatrix}$$

must be positive definite. Since the matrix is symmetric, it is sufficient that $b_{uu}^k \geq 0$ and $b_{vv}^k \geq 0$ and that its determinant is positive or zero:

$$\left|b_{uv}^k\right| = \left|b_{vu}^k\right| \leq \sqrt{b_{uu}^k b_{vv}^k} \quad [44]$$

This is Schwarz's inequality.

Any number of regionalized variables may be embodied in the linear model of coregionalization. If there are V of them the full matrix of coefficients, $[b_{ij}]$, will be of order V, and its determinant and all its principal minors must be positive or zero.

Schwarz's inequality has the following consequences:

1. Every basic structure, $g^k(\mathbf{h})$, present in the cross-variogram must also appear in the two autovariograms, i.e., $b_{uu}^k \neq 0$ and $b_{vv}^k \neq 0$ if $b_{vv}^k \neq 0$. As a corollary, if a basic structure $g^k(\mathbf{h})$ is absent from either autovariogram it may not be included in the cross-variogram;

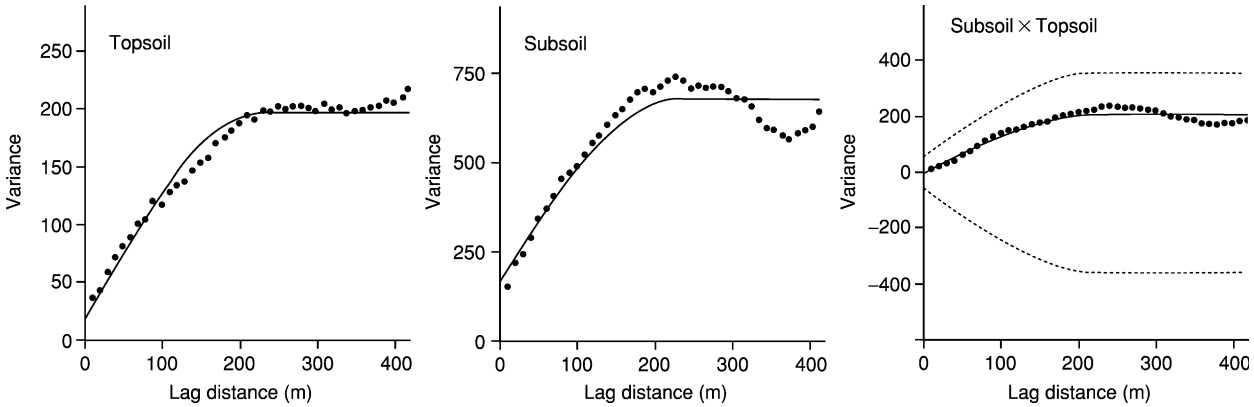

Figure 8 Auto- and cross-variograms of clay content in topsoil and subsoil with the linear model of coregionalization fitted. The dashed lines depict the hull of perfect correlation.

2. Structures may be present in the autovariograms without their appearing in the cross-variogram, i.e., b^k_{uv} may be zero when $b^k_{uu} > 0$ and $b^k_{vv} > 0$.

Parameters of the linear model of the coregionalization with the above constraints can be fitted by iteration. The distance parameters are usually first approximated by fitting models independently to the experimental variograms, and good compromise values are chosen from these. Then with those values fixed the values of the b^k_{uv} are found to minimize the sums of the squares of the residuals, subject to the condition that the solution guarantees non-negative variances, i.e., is conditionally negative semi-definite (CNSD). The validity of the resulting model may be checked by plotting it on a graph of the experimental cross-semivariances plus the limiting values that would hold if the correlation between the variables were perfect. These limits constitute the hull of perfect correlation, which is obtained from the coefficients b^k_{uu} and b^k_{vv} by:

$$\text{hull}\,[\gamma(\mathbf{h})] = \pm \sum_{k=1}^{K} \sqrt{b^k_{uu} b^k_{vv}}\, g^k(\mathbf{h})$$

The line should fit close to the experimental values for the model. It must also fall within the hull to be acceptable. If it lies close to the hull, the cross-correlation is strong; if, in contrast, it is far from the bounds, then the cross-correlation is weak.

Example The clay content of the subsoil was recorded at the same sampling points as those for topsoil in Figure 1b and, in combination with the topsoil data, illustrate the coregionalization. Table 1 contains a summary that includes the Pearson correlation coefficient, which is 0.59, indicating a modest correlation overall. The experimental autovariograms for the two depths together with their cross-variogram are shown in Figure 8 by the black circles. Spherical models can be fitted to all of them, and their parameters are listed in Table 5. Their ranges vary between 191 and 265 m, with a mean of 228 m. If this value is fixed for the coregionalization model the nugget and sill component components of the model are obtained as described above (Table 6). They are somewhat different from those fitted independently, but only somewhat. The final result is shown in Figure 8 by the solid lines through the plotted points. The model evidently fits well.

Table 6 Fitted nugget variance and sill variances of the correlated structure, i.e., the coefficients b^k_{uv} of Eqn [43], of the model of coregionalization of clay in topsoil and subsoil

		Topsoil	*Subsoil*
Nugget variance	Topsoil	17.841	
	Subsoil	−0.799	167.986
Sill variance	Topsoil	178.659	
	Subsoil	211.436	509.723

The dashed lines on the graph for subsoil × topsoil define the hull of perfect correlation. The cross-variogram falls within the hull, as it should, and the moderate distance it keeps from the upper bound is a measure of moderate cross-correlation over the lag distances computed.

Spatial Prediction – Kriging

The variogram and covariance functions are not only elegant mathematical descriptions of the real world of the soil, they are crucial for local estimation, or spatial prediction as it might better be called, by kriging.

'Kriging' is a general term for processes of weighted averaging of data to provide unbiased local estimates of unknown values of a variable with minimum

variance. It is named after D.G. Krige, who developed it for estimating the gold content of ore bodies in South Africa. In the simplest case, for a place $\mathbf{x}_0$ where the mean is unknown (the usual situation), the estimate is formed as:

$$\hat{Z}(\mathbf{x}_0) = \sum_{i=1}^{N} \lambda_i z(\mathbf{x}_i) \qquad [45]$$

where the $z(\mathbf{x}_i), i = 1, 2, \ldots, N$ are sample data at places $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_N$, and the λ_i are weights. The weights sum to 1 to assure unbiasedness, i.e., $\sum_{i=1}^{N} \lambda_i = 1$, and the variance of the estimate is given by:

$$\begin{aligned}\sigma^2(\mathbf{x}_0) &= \mathrm{E}\left[\left\{\hat{Z}(\mathbf{x}_0) - z(\mathbf{x}_0)\right\}^2\right] \\ &= 2\sum_{i=1}^{N} \lambda_i \gamma(\mathbf{x}_i, \mathbf{x}_0) \\ &\quad - \sum_{i=1}^{N}\sum_{j=1}^{N} \lambda_i \lambda_j \gamma(\mathbf{x}_i, \mathbf{x}_j) \qquad [46]\end{aligned}$$

Here $\gamma(\mathbf{x}_i, \mathbf{x}_j)$ is the semivariance between the data points $\mathbf{x}_i$ and $\mathbf{x}_j$, and $\gamma(\mathbf{x}_i, \mathbf{x}_0)$ is the semivariance between the data point $\mathbf{x}_i$ and the target point $\mathbf{x}_0$.

This variance is minimized by solution of the $N + 1$ equations:

$$\begin{aligned}\sum_{i=1}^{N} \lambda_i \gamma(\mathbf{x}_i, \mathbf{x}_j) + \psi(\mathbf{x}_0) &= \gamma(\mathbf{x}_i, \mathbf{x}_0) \,\forall\, j \\ \sum_{i=1}^{N} &= 1 \qquad [47]\end{aligned}$$

in which the $\psi(\mathbf{x}_0)$ is a Lagrange multiplier introduced for the minimization. The solution yields the optimum weights, and these are inserted into Eqn [45] to give the required estimate at $\mathbf{x}_0$.

The minimized variance is also obtained from the solution as

$$\sigma^2_{\mathrm{OK}}(\mathbf{x}_0) = \sum_{i=1}^{N} \lambda_i \gamma(\mathbf{x}_i, \mathbf{x}_0) + \psi(\mathbf{x}_0) \qquad [48]$$

This particular form of the technique is ordinary punctual kriging – 'ordinary' because it is the most used, and 'punctual' because the estimates are for points of the same size and shape, i.e., the same supports, as the bodies of soil or other material on which the measurements were made. It is readily generalized for estimating blocks, B, larger than the supports of the data. Eqn [45] holds for the averaging, though with B replacing $\mathbf{x}_0$. In Eqn [47] the individual semivariances on the right-hand sides are replaced by the means of the semivariances between the data points and the target block, B, $\bar{\gamma}(\mathbf{x}_i, B)$. Finally, the kriging variance is given by:

$$\sigma^2_{\mathrm{OK}}(B) = \sum_{i=1}^{N} \lambda_i \bar{\gamma}(\mathbf{x}_i, B) + \psi(B) - \bar{\gamma}(B, B) \qquad [49]$$

where $\bar{\gamma}(B, B)$ is the mean semivariance within B, i.e., the within-block variance.

When the kriging equations are solved, it usually turns out that only the few points nearest to the target point or block carry any appreciable weight; the weights of the others are so close to zero that they can be ignored. Kriging is thus a local weighted average. It has two other intuitively attractive features:

1. Where data points are clustered the weight of the cluster is divided among its members so that the individual weights are small compared with those of isolated points;
2. Where data points lie approximately in a line between the target and more distant points they screen the latter, which tend as a result to have virtually no weight, however close they are to the target.

This also has practical implications. The kriging systems, Eqn [47], need never be large; they are swiftly solved, and instabilities with matrix inversion are rare.

It is now evident why the variogram, or the equivalent covariance function, is so important; the kriging systems need values drawn from it. As above, these must not give rise to negative kriging variances, and so a valid function must be fitted to the experimental variogram.

Ordinary kriging will serve in some 90% of cases; it is the 'work horse' of practical geostatistics. It requires the fewest assumptions and the least knowledge. Kriging has been much used to map soil properties, including concentrations of plant nutrients, salinity, trace element contents, and nematode infestation. The kriging systems are solved at close intervals on a grid, from which isarithms, 'contours,' of the estimates can be drawn by other graphics programs. This has led to the application of kriging in land reclamation and precision agriculture. The kriging variances can be mapped similarly; patches of large variance coincide with sparse sampling, and so the maps can show where denser sampling is necessary or desirable to achieve more reliable estimates.

Kriging can be elaborated to embody other knowledge. Universal kriging takes into account known or estimated trend in the target variable. The underlying model is that of Eqn [31], usually with a simple

low-order polynomial for the trend, as in Eqn [32]. Another way of dealing with trend is to regard the target variable as an intrinsic random function of order k, $k > 0$ (IRF-k), and working with generalized covariances. Measurements on related subsidiary variables can be combined with those of the target variable by co-kriging, in which the semivariances are drawn from the model of coregionalization, Eqn [43], with all combinations of u and v in the model. Kriging with external drift embodies knowledge of the trend in related subsidiary variables and is an extension of universal kriging. Indicator kriging and disjunctive kriging form linear combinations of nonlinear transforms of data to estimate the probabilities of variables' exceeding specified threshold values, and these techniques are of potential value in statutory controls of pollution and restoration of contaminated land.

SPECIFIC SURFACE AREA

K D Pennell, School of Civil & Environmental Engineering, Atlanta, GA, USA

Introduction

The surfaces of soil particles play a critical role in many processes, including chemical reactions, contaminant adsorption, colloid filtration, and water imbibition and drainage. The specific surface area of soils and soil constituents can range from less than $0.1\,m^2\,g^{-1}$ or $1 \times 10^2\,m^2\,kg^{-1}$ up to $800\,m^2\,g^{-1}$ or $8 \times 10^5\,m^2\,kg^{-1}$. Soils consisting primarily of sands (i.e., particle diameters of 0.05–2.0 mm or 5×10^{-5} m to 2×10^{-3} m) possess relatively small specific surface areas, usually less than $0.5\,m^2\,g^{-1}$ or $5 \times 10^2\,m^2\,kg^{-1}$. In contrast, soils containing appreciable amounts of clay minerals and organic matter tend to have much larger specific surface areas (Table 1). Quantification of specific surface area may involve direct physical measurement of particle size and shape, adsorption of probe molecules from either the gas or aqueous phases, or the retention of polar liquids. The adsorption of nitrogen (N_2) gas, in conjunction with the Brenauer–Emmett–Teller (BET) equation, is the most common method of surface area determination. However, it is widely recognized that N_2 does not access the interlayer surfaces of expandable clay minerals upon drying. To overcome this limitation, the retention of polar compounds such as ethylene glycol monoethyl ether (EMGE) has been utilized to measure the total specific surface area (i.e., internal + external) of soils and expandable clay minerals. However, specific surface area values obtained by these two methods (i.e., N_2/BET and EGME) may be similar or divergent, depending upon sample composition and pretreatments. Therefore, it is important to recognize the dependence of specific surface area data on the measurement technique, and to select one or more methods that are appropriate for the system of interest.

Direct Physical Measurement

Direct physical measurement of specific surface area typically involves the use of light or electron microscopy to determine the shape and dimensions of individual soil particles. Such observations are often supplemented with X-ray diffraction measurements to assess crystallographic structure and interlayer spacing of clay minerals. Provided that a characteristic particle shape and size can be determined, the specific surface area can be obtained from mass–volume relationships. For example, the specific surface area (A_s) of a spherical particle may be calculated in the following manner:

$$A_s = \frac{4\pi r^2}{\rho_s V_s} = \frac{4\pi r^2}{\rho_s \frac{4}{3}\pi r^3} = \frac{3}{\rho_s r} \qquad [1]$$

where r is the radius of the solid particle, ρ_s is the density of the solid, and V_s is the volume of the solid. Using this approach, the specific surface area of quartz sand with a particle diameter of 1.0 mm

Table 1 Comparison of specific surface area values obtained by N_2 gas adsorption and ethylene glycol (EG) or ethylene glycol monoethyl ether (EGME) retention

Sample	Organic carbon content ($g\,kg^{-1}$)	Specific surface area ($\times 10^3\ m^2\ kg^{-1}$)	
		N_2/BET method	EG/EGME method
Kaolinite (KGa-1)[a]	0.0	10.05	16.0
Montmorillonite (SWy-1)[a]	0.0	31.82	662.0
Montmorillonite (SAz-1)[a]	0.0	97.42	820.0

or 1.0×10^{-3} m and a particle density of $2.65\,g\,cm^{-3}$ or $2.65 \times 10^3\,kg\,m^{-3}$ would be $2.26 \times 10^{-3}\,m^2\,g^{-1}$ or $2.26\,m^2\,kg^{-1}$. In practice, specific surface area values of sands determined by direct observation are often several orders-of-magnitude smaller than measured values due to presence of nonspherical particles, surface roughness, and fine particles (Table 1).

An analogous mass–volume approach can be used to estimate the specific surface area of clay minerals, provided that the structural formula and unit cell dimensions are known. For example, consider a montmorillonite with a nominal structural formula of $K_{0.66}Si_{8.0}(Al_{3.34}Mg_{0.66})O_{20}(OH)_4$ and unit cell dimensions of $a = 0.5$ nm or 5×10^{-10} m, $b = 0.9$ nm or 9×10^{-10} m, and $c = 9.5$ nm or 9.5×10^{-10} m. Assuming that the particle density is approximately $2.8\,g\,cm^{-3}$ or $2.8 \times 10^3\,kg\,m^{-3}$, and that the edge area (i.e., c-dimension) is negligible compared with the area of the basal surfaces (i.e., a- and b-dimensions), the specific surface area of the montmorillonite can be estimated in the following manner:

$$A_s = \frac{2ab}{\rho_s V_s}$$

$$= \frac{2(5.0 \times 10^{-10}\,m)(9.0 \times 10^{-10}\,m)}{(2.8 \times 10^3 kg\,m^{-3})(5.0 \times 10^{-10}\,m)(9.0 \times 10^{-10}\,m)(9.5 \times 10^{-10}\,m)}$$

$$= 7.52 \times 10^5 m^2\,kg^{-1} \quad [2]$$

Using a slight variation of eqn [2], the specific surface area of the montmorillonite can also be estimated from the molecular weight of the unit cell and Avogadro's number (N_A):

$$A_s = \frac{(2ab)(N_A)}{MW_{mont}}$$

$$= \frac{2(5.0 \times 10^{-10}\,m)(9.0 \times 10^{-10}\,m)(6.022 \times 10^{23}\,mol^{-1})}{7.447 \times 10^{-1}\,kg\,mol^{-1}}$$

$$= 7.52 \times 10^5 m^2\,kg^{-1} \quad [3]$$

The relationships shown in eqns [2] and [3] are applicable to clay minerals existing as flat, plate-like structures with a thickness corresponding to that of the unit cell. When water is removed from expandable clay minerals, the interlayers collapse. The resulting clay particle will then consist of several unit cells stacked on top of one another. If the number of unit cells contained in a collapsed montmorillonite particle is 10, the resulting surface area would be approximately $75\,m^2\,g^{-1}$ or $7.5 \times 10^4\,m^2\,kg^{-1}$, which is consistent with specific surface area values reported for dry montmorillonite samples based on N_2/BET analysis (Table 1).

The mass–volume approaches described above are generally limited in applicability to clean sands or pure clay mineral samples. Many soil constituents, including metal oxides and organic matter, exist as irregular or poorly defined amorphous structures which are virtually impossible to characterize. Furthermore, the specific surface area of natural soils cannot be treated as a strictly additive property due to surface coatings and mineral-organic matter associations. Except in a few limited cases (e.g., clean sands), the specific surface area of a whole soil should not be estimated using a summation procedure based on the surface area contributions of individual soil constituents.

Adsorption from Solution

The adsorption of dissolved molecules from solution can be used to estimate the specific surface area of a solid, provided that the resulting adsorption isotherm exhibits a limiting or maximum value. Such adsorption isotherms are classified as Type I, and can be described by the Langmuir adsorption model. The Langmuir model can be derived by assuming that, once equilibrium is reached, the rate of solute adsorption on to open surface sites is equal to the rate of solute desorption from occupied surface sites. Several assumptions are inherent to the Langmuir model, including: (1) adsorption is localized or site-specific; (2) no interactions occur between adsorbed molecules; (3) the energy of adsorption is constant for all adsorption sites; (4) the adsorption capacity of the solid is limited; and (5) the maximum adsorption capacity corresponds to monolayer coverage. Although the model was originally developed to describe the adsorption of gases on solids, for solid–liquid systems the Langmuir equation may be written as:

$$C_s = \frac{C_{s,max}\,\beta\,C_a}{1+\beta\,C_a} \qquad [4]$$

where C_s is the solid-phase concentration of solute at equilibrium, $C_{s,max}$ is the maximum solid-phase concentration, β is the ratio of the adsorption and desorption rates, and C_a is the aqueous-phase concentration of solute at equilibrium. A series of Langmuir isotherms is presented in **Figure 1** to illustrate the effect of increasing the value of β from 0.01 to $0.25\,l\,mg^{-1}$ with $C_{s,max}$ fixed at $1.0\,g\,kg^{-1}$. As the value of β increases, the rate at which the adsorption isotherm approaches the maximum sorption capacity of the solid ($C_{s,max}$) increases. However, the shape or steepness of the isotherm has no bearing on the maximum sorption capacity, which is used to calculate specific surface area.

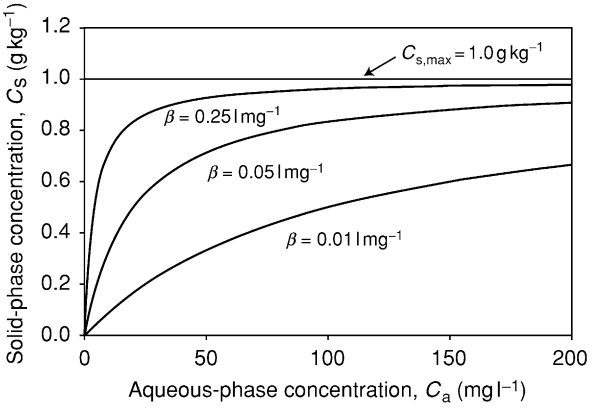

Figure 1 Effect of changes in the value of the β parameter (0.025, 0.05, and $0.01\,l\,mg^{-1}$) on Langmuir adsorption isotherms when $C_{s,max} = 1.0\,g\,kg^{-1}$.

In practice, the parameters β and $C_{s,max}$ can be obtained by directly fitting eqn [4] to experimental adsorption isotherm data (C_s versus C_a) using a nonlinear, least-squares regression procedure. Alternatively, eqn [4] can be rearranged to yield the linear form of the Langmuir equation:

$$\frac{C_w}{C_s} = \frac{1}{\beta\,C_{s,max}} + \frac{C_w}{C_{s,max}} \qquad [5]$$

Here, C_w/C_s (y-axis) is plotted against C_w (x-axis) and a linear regression procedure is then used to obtain a slope equal to $1/C_{s,max}$ and an intercept value equal to $1/\beta C_{s,max}$. With minor manipulation, the desired parameters are obtained as follows: $C_{s,max} = 1/\text{slope}$ and $\beta = (1/C_{s,max})(1/\text{intercept})$.

Several organic molecules have been used in conjunction with the Langmuir equation to determine specific surface area. In the past, organic dyes such as methylene blue were utilized because their concentration in solution could be determined by colorimetric analysis. More recently, cationic surfactants exhibiting visible or ultraviolet (UV) light absorbance have been employed for surface area determination. The cationic surfactant most widely used for this purpose is cetyl pyridinium bromide (CBP), which has a strong absorbance peak at wavelength of 259 nm or 2.59×10^{-7} m. On most mineral surfaces, adsorbed CPB molecules form a bilayer (i.e., double layer), yielding an effective molecular area (A_m) of $0.27\,nm^2$ or $2.7 \times 10^{-19}\,m^2$. If the measured value of $C_{s,max}$ for a nonexpanding clay mineral sample was $1.0\,g$ CPB kg^{-1} solid, the specific surface area would be calculated as:

$$\begin{aligned} A_s &= \frac{(C_{s,max})(N_A)(A_m)}{MW_{CBP}} \\ &= \frac{(1.0\,g\,kg^{-1})(6.22\times10^{23}\,mol^{-1})(2.7\times10^{-19}\,m^2)}{384.45\,g\,mol^{-1}} \\ &= 4.23\times10^{2}\,m^2\,kg^{-1} \end{aligned} \qquad [6]$$

Iron and aluminum oxides possess relatively low surface charge densities, and as a result CPB may not form complete bilayers on these surfaces. Therefore, soil samples are often treated to remove oxides prior to surface area analysis by CPB adsorption. In the case of expandable clay minerals such as montmorillonite, the adsorbed CPB bilayer on the interlayer surfaces is shared and therefore yields an effective molecular area of $0.54\,nm^2$ or $5.4 \times 10^{-19}\,m^2$. In addition, the external surface area must be obtained independently using the N_2/BET method in order to compute the contribution of internal surfaces to the overall adsorption of CPB.

Adsorption from the Gas Phase

The adsorption of gases is frequently used in conjunction with the BET equation to measure the specific surface area of soils and soil constituents. Gas adsorption on dry solid surfaces typically conforms to a Type II isotherm, characterized by the formation of multiple layers of adsorbed molecules. Derivation of the BET equation is based on the Langmuir model, modified to account for multilayer formation. The underlying assumptions of the BET equation are: (1) the heat of adsorption for the first layer is constant; (2) the heat of adsorption for the second and all succeeding layers is constant and equal to heat of condensation; (3) adsorption and desorption can only occur from exposed layers; and (4) the assumptions of the Langmuir model apply to each layer. Although originally derived on a molar basis, the BET equation can be expressed in terms of the solid-phase concentration (C_s) as:

$$C_s = \frac{(C_{s,mon})[(\alpha\ P/P_0)/(1-P/P_0)]\left[1-(n+1)(P/P_0)^n+n(P/P_0)^{n+1}\right]}{1+(\alpha-1)(P/P_0)-\alpha(P/P_0)^{n+1}} \quad [7]$$

where $C_{s,mon}$ is the solid-phase concentration at monolayer coverage, P is the vapor pressure, P_0 is the saturated vapor pressure, and n is the total number of adsorbed layers. The dimensionless parameter α is related to the heat of adsorption and is defined as:

$$\alpha = e^{[(Q_a-Q_c)/RT]} \quad [8]$$

where Q_a is the heat of adsorption on the exposed surface, Q_c is the heat of condensation of the liquid adsorbate, R is the ideal gas constant, and T is temperature. The BET eqn [7] reduces to the Langmuir eqn [4] when number of adsorbed layers is limited to one ($n=1$). If the number of adsorbed layers approaches infinity ($n=\infty$), eqn [7] reduces to the simplified form of BET equation commonly used for surface area determination:

$$C_s = \frac{(C_{s,mon})(\alpha)(P/P_0)}{(1-P/P_0)[1-P/P_0+\alpha(P/P_0)]} \quad [9]$$

A series of BET isotherms is shown in Figure 2 for α equal to 1, 10, and 100, with $C_{s,mon}$ fixed at $1\,g\,kg^{-1}$ and n equal to infinity. As the value of α increases, the inflection point or 'knee' of the BET adsorption isotherm becomes more evident. The inflection in the BET adsorption isotherm corresponds approximately to the point of monolayer coverage. Below the inflection point, gas adsorption occurs on exposed surfaces. The gradual increase in adsorption above the inflection point corresponds to multilayer formation on the surface, while the steep asymptotic rise in adsorption at relative vapor pressures approaching unity ($P/P_0=1$) corresponds to liquid condensation.

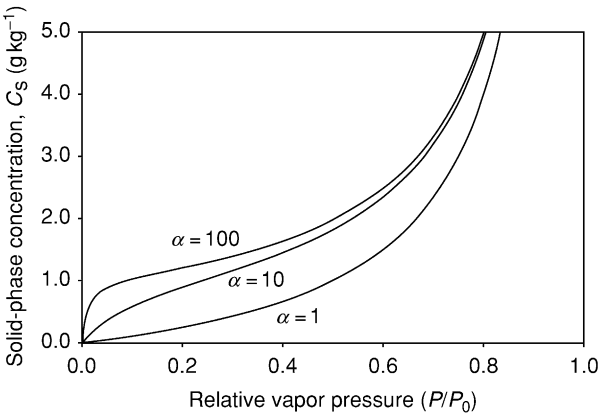

Figure 2 Effect of changes in the value of the α parameter (1, 10, and 100) on Brunauer–Emmett–Teller adsorption isotherms when $C_{s,man} = 1\ g\ kg^{-1}$ and $n =$ infinity.

The most common gas used for BET surface area analysis is nitrogen (N_2), although noble gases such as krypton (Kr) and argon (Ar) are used occasionally for solids possessing very small surface areas (less than approx. $0.1\,m^2\,g^{-1}$ or $1.0\times10^2\,m^2\,kg^{-1}$). Several volatile organic compounds (VOCs), including benzene, *p*-xylene, EGME, and water vapor have also been used for BET surface area analysis. Regardless of the gas or vapor used, the configuration of the adsorbed molecules on the surface must be known or estimated. The most common approach used to estimate the cross-sectional area of an adsorbed molecule (A_m) is related to the liquid density (ρ_l):

$$A_m = 1.091\left(\frac{MW}{\rho_l N_A}\right)^{2/3} \quad [10]$$

The coefficient of 1.091 in eqn [10] is based on the assumption of an ideal hexagonal packing of adsorbed molecules on the surface. For N_2, the value of A_m obtained using eqn [10] is $0.162\,nm^2$ or $1.62\times10^{-19}\,m^2$.

The adsorption of gases on solids can be measured experimentally using several methods. The most common method is based on the change in vapor pressure following the introduction of gas into a small glass bulb containing a dry soil sample. To obtain the adsorption isotherm, the volume of gas adsorbed is computed for each incremental gas dosage based on the change in vapor pressure at equilibrium. Upon reaching the saturated vapor pressure ($P/P_0=1$), the process may be reversed (the vapor pressure is incrementally reduced) to obtain a desorption isotherm, from which pore size analysis

can be performed. Several automated instruments based on this principle are available from commercial vendors. In general, automated surface area instruments report gas adsorption data as the volume of gas adsorbed per gram of soil (e.g., $1\,kg^{-1}$) at standard temperature and pressure (STP). Volumetric gas adsorption data are converted to a mass basis (grams per kilogram) using the molar volume of an ideal gas at STP ($22.414\,l\,mol^{-1}$) and molecular weight of the gas (e.g., $N_2 = 28.02\,g\,mol^{-1}$). The second experimental approach used to measure gas or vapor adsorption is based on the continuous introduction of gas stream at constant vapor pressure. Once equilibrium is attained, the soil sample is either weighed or extracted to determine the amount of adsorbed gas. The vapor pressure of the gas flow stream is then incrementally increased over the desired vapor pressure range to obtain an adsorption isotherm.

To obtain values for the two unknown parameters in the BET equation, α and $C_{s,mon}$, eqn [9] can be fit directly to the experimental adsorption data using a nonlinear, least-squares regression procedure. Alternatively, the experimental data can be expressed using the linear form of the BET equation:

$$\frac{P/P_0}{C_s(1-P/P_0)} = \frac{1}{C_{s,mon}\ \alpha} + \frac{(\alpha-1)P/P_0}{C_{s,mon}\ \alpha} \qquad [11]$$

Here, $(P/P_0)/[C_s(1 - P/P_0)]$ (y-axis) is plotted against P/P_0 (x-axis), and a linear regression procedure is used to obtain values for the slope, which is equal to $(\alpha - 1)/(\alpha\ C_{s,mon})$ and the intercept, which is equal to $1/(\alpha\ C_{s,mon})$. The two fitting parameters can then be obtained as follows: $\alpha = [(\text{slope})(1/\text{intercept}) + 1]$; and $C_{s,mon} = (1/\alpha)(1/\text{intercept})$. As a general rule, the value of α should be greater than 20 and the amount of sample should yield a total surface area between 40 and 120 m^2. In addition, it is often recommended that eqn [11] be applied to adsorption data over a relative vapor pressures range of 0.05–0.35. The specific surface area is then computed using the fitted value of $C_{s,mon}$ obtained from the experimental adsorption data and the cross-sectional area of the adsorbed molecule (A_m) from eqn [10]. For example, if $C_{s,mon}$ was determined to be $0.5\,g\,kg^{-1}$, the N_2/BET specific surface area (A_s) would be calculated in the following manner:

$$A_s = \frac{(C_{s,mon})(N_A)(A_m)}{MW_{N_2}}$$
$$= \frac{(0.5\,g\,kg^{-1})(6.022\times10^{23}\,mol^{-1})(1.62\times10^{-19}\,m^2)}{28.02\,g\,mol^{-1}}$$
$$= 1.74\times10^{3}\,m^2\,kg^{-1} \qquad [12]$$

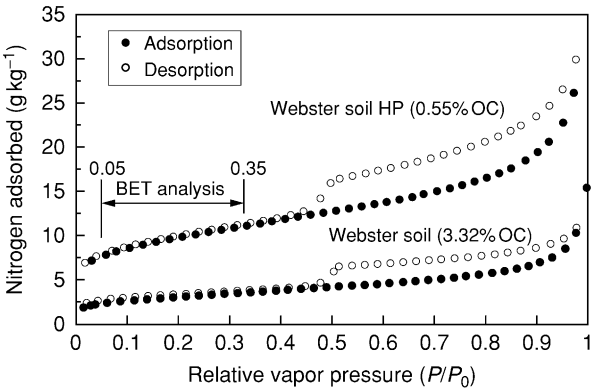

Figure 3 Adsorption and desorption of N_2 on hydrogen peroxide (HP)-treated and untreated Webster soil.

Treatment and preparation of soil samples prior to N_2 adsorption can strongly influence the measured specific surface area. For example, the removal of soil organic matter will often lead to increased specific surface area values; this has been attributed to the exposure of mineral surfaces covered by organic matter and the division of mineral particles held together by organic matter bridging. Nitrogen adsorption and desorption isotherms for hydrogen peroxide (HP)-treated and untreated Webster soil are shown in Figure 3. The resulting surface area values for the untreated and HP-treated samples were 0.79 and $7.38\,m^2\,g^{-1}$ or 7.9×10^2 and $7.38\times10^3\,m^2\,kg^{-1}$, respectively.

As noted previously, water must be removed from soil samples prior to the measurement of gas adsorption. The drying or dehydration process is known to collapse the interlayer space of expandable clay minerals, which are then not accessible to inert gases such as N_2. In addition, electron microscopy suggests that air-drying of soil samples results in the collapse and shrinkage of soil humic acid, whereas freeze-drying maintains a complex structural network characteristic of soil organic matter. Thus, freeze-drying of soils to remove water prior to N_2/BET analysis will tend to result in larger surface area values, which may be more representative of natural conditions.

Retention of Polar Liquids

The use of polar liquids such as ethylene glycol (EG) and EGME for surface area determination was based on the need to develop a relatively simple experimental technique that could be used to quantify the total surface area (i.e., internal + external) of expandable clay minerals. Due to the attractive forces between polar molecules and exchangeable cations, EG and

EGME are able to penetrate the interlayer space of expandable clay minerals. In practice, a dry soil or clay sample is placed in a vacuum desiccator containing EG or EGME as a free liquid or mixed with calcium chloride to maintain a constant vapor pressure of EG or EGME. Liquid EG or EGME is then added as drops to the solid sample until complete wetting is achieved. A suction of approximately 13.332 Pa or 0.1 mmHg is applied, and the sample is weighed over time until a constant weight is obtained. The specific surface area of the solid is then calculated as follows:

$$A_s = \frac{W_{EG/EGME}}{(W_{OD})(\text{EG/EGME conversion factor})} \quad [13]$$

where $W_{EG/EGME}$ is the weight of EG or EGME retained by the soil at the applied suction and W_{OD} is the oven-dry weight of the solid. The method is predicated on the assumption that EG and EGME are retained on solid surfaces at monolayer coverage. The mass-surface area conversion factors for EG and EGME are $3.1 \times 10^{-7}\,\text{kg}\,\text{m}^{-2}$ and $2.86 \times 10^{-7}\,\text{kg}\,\text{m}^{-2}$, respectively, and were derived from retention measurements performed on reference clay minerals with known unit cell dimensions and structural formula. It is usually recommended that the specific surface area of a reference expandable clay mineral, such as Wyoming montmorillonite (SWy-1), be measured to confirm the value of the conversion factor and to ensure that experimental procedure is operating properly. Although EG was used during the initial development of the retention method, more recent studies have employed EGME due to the shorter times required to attain a constant retention value.

Based on the success of the EG/EGME retention method for determining the total surface area of expandable clay minerals, the technique has subsequently been applied to natural soils to obtain a measure of total specific surface area. However, use of the EG/EGME retention method is complicated by the fact that polar molecules tend to form multilayers in the vicinity of cation exchange sites prior to complete monolayer coverage, retention may be influenced by the species of exchangeable cation, and the EG/EGME may partition into soil organic matter. As a result, the retention of EG or EGME by natural soils represents a measure of the uptake capacity of soils for a polar adsorbate, rather than a strict measure of total specific surface area. Despite this shortcoming, the EG/EGME retention method is an appropriate method for measuring the total specific surface area of pure clay minerals and soils that have been treated to remove organic carbon.

Selection of Surface Area Measurement Technique

Although the methods used to determine experimentally the specific surface area of soils and soil constituents are relatively well established, interpretation and appropriate use of the resulting data can be problematic. Complications arise primarily from two factors: (1) sample pretreatments including drying, organic-matter removal, and metal-oxide removal can markedly alter measured values of specific surface area; and (2) the use of different probe molecules and measurement techniques can result in similar or very divergent specific surface area values for the same soil. For example, soils that contain only trace amounts of organic matter and no expandable clay minerals will yield relatively consistent specific surface area values regardless of the method (see kaolinite and Lula aquifer sand in Table 1). In addition, the external and internal specific surface area of pure expandable clay mineral samples can be determined using a combination of N_2/BET (external surface area) and EG/EGME retention (total surface area; see SAz-1 and SWy-1 montmorillonites in Table 1). However, for natural soils containing appreciable amounts of organic matter and expandable clay minerals, the selection of an appropriate measurement technique, as well as the interpretation of specific surface area data, is far more difficult. This is particularly relevant if the intent is to quantify the total or internal surface area of a soil available under natural conditions using the EG/EGME retention method. Due to the potential for partitioning or dissolution of polar molecules into soil organic matter and interactions with exchangeable cations, the EG/EGME retention method is not suitable for most natural soils. In effect, EG/EGME retention provides an indication of the capacity of the soil to take up polar molecules, in contrast to a measure of total specific surface area. Despite the known limitations of N_2/BET surface area analysis, this method provides a relatively simple and reproducible technique for assessing the specific surface area of natural soils and soil constituents.

List of Technical Nomenclature

α	BET isotherm parameter
β	Langmuir isotherm parameter
ρ_l	Liquid density ($\text{g}\,\text{cm}^{-3}$)
ρ_s	Solid density ($\text{g}\,\text{cm}^{-3}$)
A_m	Area of adsorbed molecule (m^2)
A_s	Specific surface area ($\text{m}^2\,\text{kg}^{-1}$)

C_a	Aqueous-phase concentration ($mg\,l^{-1}$)
C_s	Solid-phase concentration ($kg\,kg^{-1}$)
$C_{s,max}$	Maximum solid-phase concentration ($kg\,kg^{-1}$)
$C_{s,mon}$	Monolayer solid-phase concentration ($kg\,kg^{-1}$)
N_A	Avogadro's number ($molecules\,mol^{-1}$)
n	Number of adsorbed layers
P	Vapor pressure (Pa)
P_0	Saturated vapor pressure (Pa)
P/P_0	Relative vapor pressure
Q_A	Heat of adsorption ($J\,mol^{-1}$)
Q_C	Heat of condensation ($J\,mol^{-1}$)
R	Ideal gas constant ($J\,K^{-1}\,mol^{-1}$)
r	Radius of particle (m)
V_s	Volume of solid (m^3)
W_{OD}	Weight of oven-dry solid (kg)

STATISTICS IN SOIL SCIENCE

R Webster, Rothamsted Research, Harpenden, UK

© 2005, Elsevier Ltd. All Rights Reserved.

Why Statistics?

Data on soil embody variation from many sources. Much of the variation is natural – from place to place at all scales from the global to the infinitessimal, and from time to time as the soil responds to weather, plant growth, and processes in the rhizosphere engendered by that growth. Farmers have added to the variation by their enclosing, reclaiming, clearing, and fertilizing of the land, though within fields they have removed some variation by cultivation and drainage. Further sources of variation are mineral extraction and subsequent reclamation, dumping of waste, and pollution of many kinds. Investigators design experiments and surveys in such a way that they can estimate the variation from particular sources such as imposed treatments or strata in a population and the differences between them. Variation in data also arises from the way observations are made; from the people who make the observations, from the imprecision instruments, from imperfect

laboratory technique, and from sampling fluctuation. One may like to think that the contributions from the laboratory are negligible, though 'ring' tests have often revealed them not to be so. In general, however, sampling fluctuation in the field, arising from the spatial variation there, is much larger.

Any one measurement of a soil property is influenced by contributions from at least some of these sources. It cannot be taken as an absolutely accurate representation of the truth therefore; rather it must be seen in relation to the probable error.

Statistics are needed in soil science to estimate and express this error and to apportion it to the different sources. In this way sense (signal) can be separated from meaningless or uninteresting variation (noise) in comparisons between classes of soil, in expressing relations, in assessing the effects of treatments in experiments, and in prediction. The statistical repertoire is huge, so here is presented the fairly elementary techniques that soil scientists most often need.

The techniques can be divided into two groups, namely, descriptive and analytical. They also have two fairly distinct fields of application: survey and experiment. In the first, investigators observe and record the soil as it is on samples, and descriptive techniques tend to dominate. In the second, they deliberately control some of the variation so that they can assess the effects of changes in one or a few factors that are of specific interest by analysis.

Population, Units, and Samples

The soil is regarded for statistical purposes as a population comprising elements or units. The units are the bodies of soil on which measurements are made. They are more or less arbitrary and determined largely by convenience and practicality. They may be individual cores of soil, pits, or pedons; each may be the volume of soil occupied by the roots of a single plant or that deformed under the wheel of a tractor; they may be pots in a greenhouse experiment, samples in lysimeters, plots in a field experiment, or whole fields or farms. The variation among them depends very much on the size of the units; the larger they are the more variation they encompass within them and the less there is between them to be revealed in data. The size, shape, and orientation of the units, known as the 'support' in survey, must be defined and adhered to throughout an investigation. The population is then all such units in a specified region or falling within some other definition for the purposes of the investigation. It is an operational definition, often known as the 'target population.' In a more restricted sense, the population and the units comprising it may be the values of a particular soil property in the defined supports.

Populations in surveys are typically very large, in many instances infinite, or hypothetical, and in some they are poorly defined. Measurement is feasible only on small subsets, i.e., on samples, and these subsets must properly represent their populations for the measurements to apply to the larger populations. The units in an experiment, in contrast, are typically a few dozen, though ideally the experimental material should be representative of some larger population.

Replication and Randomization

Estimating the mean in a population and its associated error from measurements on a sample requires both replication and randomization. The need for replication is evident: a single value can contain no information on variation. Randomization is needed to avoid bias. At its simplest it means choosing units such that all have the same chance of being selected.

In a survey this takes the form of simple random sampling. To apply it requires (1) that each unit can be identified uniquely, and (2) a rule for the selection. Simple random sampling, as in Figure 1a, tends to be inefficient in that it takes no account of anything known about the population beforehand, such as its spatial dependence, a soil map of the region, the relations between soil and vegetation or physiography, or the farming history. To take advantage of such knowledge, the population is first stratified either into small grid cells, as in Figure 1b, or by type of soil, vegetation, physiography, or farming, as in Figure 1c.

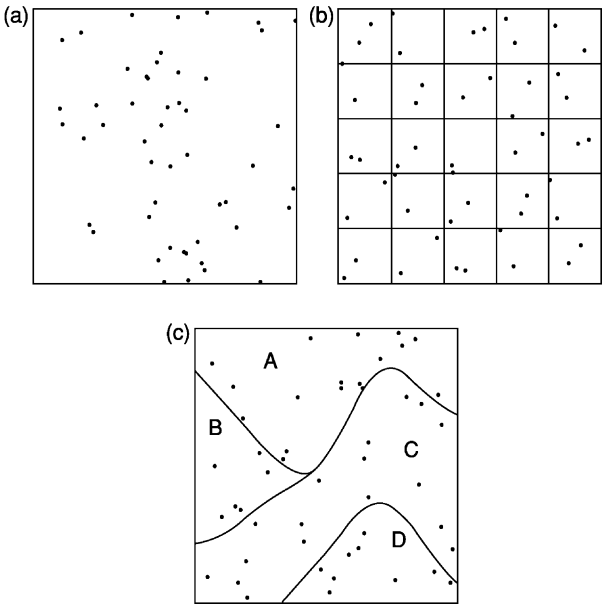

Figure 1 Probabilistic sampling of a region: (a) simple random sampling; (b) stratified random sampling with the region divided into 25 square cells (strata) and two points per cell; (c) stratified random sampling with four mapped classes (A–D) of soil as strata.

(a)

W	O	F	W	D
F	D	W	F	O
W	O	W	O	D
D	F	F	D	O

(b)

W	D	F	W	F
F	O	D	F	O
O	W	W	O	D
D	F	O	D	W

Figure 2 Layout of a randomized field experiment with four treatments; O (control), D (dung), W (industrial waste), and F (NPK fertilizer), and five-fold replication. (a) Completely randomized; (b) with the replicates arranged in five blocks.

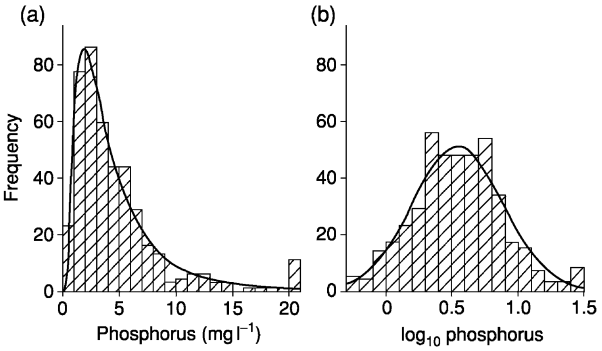

Figure 3 Histograms of 434 data on available phosphorus (a) in milligrams per liter and (b) transformed to common logarithms. The curve in b is that of the fitted normal distribution, and that in a shows the lognormal distribution.

The soil is then sampled at random within each stratum independently; this is stratified random sampling, and it enables the variation due to the strata to be distinguished from variation within them.

In experiments treatments are allocated to the units at random. The units may be arranged completely randomly, as in Figure 2a. In the field and greenhouse, they are usually grouped into blocks such that each block contains one unit of each treatment, as in Figure 2b; long-range variation then appears in the variation among blocks. There are many more elaborate designs.

Descriptive Statistics

The Mean

In almost all investigations, mean values are of prime interest. Provided sampling has been properly randomized, the mean of a set of N data, denoted z_1, $z_2, \ldots, z_N$,

$$\bar{z} = \frac{1}{N}\sum_{i=1}^{N} z_i \qquad [1]$$

estimates without bias the mean, μ, in the population from which the sample is drawn. How well it does so depends on the variation it embodies.

Characteristics of Variation

Histogram The variation in a set of measurements, if there are sufficient of them, can be displayed in a histogram. The scale of measurement is divided into segments of equal width, or 'bins,' the values falling in each bin are counted, and bars of height proportional to the counts are drawn. Figure 3 is an example; it summarizes graphically the way in which the frequency is distributed over the range of the data.

Variance Variation is best expressed quantitatively as variance. For a set of N data, it is the average squared difference between the observations and their mean:

$$S^2 = \frac{1}{N}\sum_{i=1}^{N}(z_i - \bar{z})^2 \qquad [2]$$

Its square root, S, is the standard deviation, which is often preferred because it is in the same units as the measurements and is therefore more intelligible.

Ideally this variance should estimate the variance of the larger population, of which the N observations are a sample. This variance of a population is by definition:

$$\sigma^2 = \mathrm{E}\left[(z-\mu)^2\right] \qquad [3]$$

where μ is mean of z in the population and E denotes expectation. Equation [2] gives a biased result, however: S^2 is a biased estimator, because $\bar{z}$ in the equation is itself more or less in error as the estimate of μ. To remove the bias, N must be replaced by $N-1$ in the denominator:

$$s^2 = \frac{1}{N-1}\sum_{i=1}^{N}(z_i - \bar{z})^2 \qquad [4]$$

The result, s^2, is now unbiased, provided the sampling was unbiased in the first place.

Estimation variance, standard error, and confidence Both S and s measure the dispersion in the observations; neither expresses the reliability of the estimate of μ. The reliance one can place in an estimate of the mean can be expressed in terms of the expected squared deviation of it from the true mean, i.e., $\mathrm{E}[(\bar{z}-\mu)^2]$. Its estimate is derived simply from s^2 by:

$$s^2(\bar{z}) = s^2/N \qquad [5]$$

This is the estimation variance, and its square root is the standard error, which is the standard deviation of means of samples of size N. The larger the sample is, the smaller this error is, other things being equal, and the more confidence there can be had in the estimate. So, the standard deviation, which describes the variation in a sample, is different from the standard error, which expresses the confidence associated with a mean. Standard errors accompany means in tables compiled from replicated measurements, and they can be shown by error bars on graphs.

Equation [5] gives the estimation variance for a simple random sample of size N. If the population has been divided into strata, then s^2, the population variance on the right-hand side of the equation, can be replaced by s^2_W, the variance within strata. The latter is generally less, often much less, than s^2, and so stratified sampling is more precise than simple random sampling by the factor $s^2_{\text{random}}(\bar{z})/s^2_{\text{stratified}}(\bar{z})$. It also means that one can achieve the same precision with a smaller sample, and in this sense stratified sampling is more efficient. This efficiency can be expressed as $N_{\text{random}}/N_{\text{stratified}}$. The within-stratum variance, s^2_W, can be estimated by the analysis of variance.

Standard errors can be converted to confidence intervals for known kinds of distribution. If the data are drawn from a normal (Gaussian) distribution and there are many of them, then an interval of $2s/\sqrt{N}$ centered on $\bar{z}$ spans a symmetric confidence interval of approximately 68%. Wider confidence intervals are readily calculated by multiplying by factors, η, such as in Table 1.

When data are few ($N < 30$) the above factors need to be replaced by Student's t for the number of degrees of freedom, f. The lower and upper symmetric confidence limits about a mean $\bar{z}$ are:

$$\bar{z} - t_f s/\sqrt{N} \quad \text{and} \quad \bar{z} + t_f s/\sqrt{N} \qquad [6]$$

where t_f is Student's t for f degrees of freedom. Values of t are available in tables and in most statistical computer packages. For $30 < N \leq 60$, t converges to η, and for $N > 60$ the values in Table 1 can be used.

There are formulae for calculating the confidence limits for other theoretical distributions. In many instances, however, it is easier to transform data to approximate a normal distribution and subsequently analyze the transformed values.

Table 1

Confidence (%)	80	90	95	99
η	1.28	1.64	1.96	2.58

Coefficient of Variation

The coefficient of variation (CV) is the standard deviation divided by the mean, i.e., $s/\bar{z}$. It is often multiplied by 100 and quoted as a percentage. The merit of the CV is that it expresses variation as pure numbers independent of the scales of measurement. It enables investigators and those reading their reports to appreciate quickly the degree of variation present and to compare one region with another and one experiment with another. The CV should not be used to compare variation in different variables, especially ones having different dimensions.

The CV is sensible only for variables measured on scales with an absolute zero. Otherwise the arbitrary choice of the zero affects it. Examples for which it should not be used are soil temperature in degrees Celsius (arbitrary zero at 273 K), color hue (which is approximately circular), and soil acidity on the pH scale (arbitrary zero equivalent to $-\log_{10}[H^+]$, with H^+ expressed in moles per liter).

For some soil properties, physics sets limits on the utility of the CV. For example, the minimum bulk density of the soil is determined by the physical structures that keep particles apart. Particles must touch one another, otherwise the soil collapses. For most mineral soils on dry land, a working minimum bulk density is approximately 1 g cm^{-3}. At the other end of the scale, the bulk density cannot exceed the average density of the mineral particles, approximately 2.7 g cm^{-3}. So the CV of bulk density is fairly tightly constrained.

The sensible use of the coefficient of variation for comparing two variables y and z relies on the assumption that they are the same apart from some multiplying factor, b, thus:

$$y = bz \qquad [7]$$

Then the mean of y is $\bar{y} = b\bar{z}$, its variance $s^2_y = b^2 s^2_z$, and its standard deviation is $s_y = bs_z$. From there, simple arithmetic shows that their CVs are the same. This principle offers a means of comparing variation by taking logarithms of the observations. Equation [7] becomes:

$$\log y = \log b + \log z \qquad [8]$$

The logarithm $\log b$ is a constant, and so the variances, $s^2_{\log y}$ and $s^2_{\log z}$, are equal, as are their standard deviations. The resulting measure of variation is therefore independent of the original scale of measurement.

The measure can be used to compare variation in two groups of observations. Consider again soil acidity. To compare the variation in acidity of a class A with that in another, class B, we treat the hydrogen ion concentration as the original variable, transform

it to pH, and compute the variances of pH. Whichever has the larger variance is the more variable, regardless of the mean. Further, we can make a formal significance test by computing $F = s^2_{\text{logy}}/s^2_{\text{logz}}$ and compare the result with F for N_y-1 and N_z-1 degrees of freedom.

Additivity of variances Variances are additive; those from two or more independent sources in an investigation sum to the total in the data. Their square roots, the corresponding standard deviations, are not. To obtain an average variation on the original scale of measurement from several sets of data, the arithmetic mean of their variances is computed, weighted as appropriate by the numbers of degrees of freedom, and then the square root of it is taken to give an 'average' or pooled standard deviation. This, divided by the mean, gives an average CV. More generally, the additive nature of variances confers great flexibility in analysis, enabling investigators to distinguish variation from two or more sources and estimate their components according to the design, as by the analysis of variance.

Statistical Significance

Significance in a statistical context means distinguishing a signal or the effects of some imposed treatment, or detecting differences between strata against a background of 'noise.' It is a matter of separating the variance due to the signal, treatments, or strata from that from other sources that are of no interest. The question being addressed is as follows: Given the magnitudes of the several components of variance, is the signal so strong or are the differences observed so large that they are highly unlikely to have occurred by chance? If the answer is 'yes,' then the result is said to be significant.

A significance test is prefaced by a hypothesis. This is usually that there is no real difference between populations or treatments and that any differences among the means of observations are due to sampling fluctuation. That is the 'null hypothesis,' often designated H_0, and the test is designed to reject it (not confirm it). The alternative, that there is a difference, is denoted either H_1 or H_A.

To judge, for example, whether two means differ, one computes from the sampling error, the probability, P, of obtaining the observed difference if the true means were identical, assuming that the form of the distribution is known. If P is small (conventionally <0.05), the null hypothesis is rejected, and the difference is judged significant. If P is large, then the null hypothesis is likely to be correct, but we have no measure of the probability that the two means are indeed identical; instead we take the view that we have too-little evidence to conclude that the difference observed applies to the population from which the sample has been drawn.

Mistaken conclusions can still be drawn as the result of significance tests. Mistakes can be of two kinds, denoted type I and type II. The first occurs when the null hypothesis is rejected on the basis of the sample evidence, i.e., a difference is declared significant when the populations are not different. The second is when the null hypothesis is accepted, i.e., there is insufficient evidence for a difference when the populations do differ.

The likelihood of drawing wrong conclusions can be diminished by increasing the sensitivity of the test, and that depends on the precision with which the means have been estimated, i.e., on their estimation variances or on the estimation variance of their difference. The latter is given by:

$$s^2_{\text{diff}} = \frac{s^2_{\text{W}}}{n_1} + \frac{s^2_{\text{W}}}{n_2} \qquad [9]$$

where n_1 and n_2 are the numbers of observations from which the means in classes 1 and 2 derive, and s^2_{W} is the variance within the classes, assumed to be common. If $n_1 = n_2$ then the variance of the difference is simply twice the estimation variance of the individual means.

Equation [9] shows two features. One is that the larger the variance is within the populations, the larger the variance between the means is and the less likely can a difference be established as significant. The second is that larger samples result in smaller variances and hence more sensitive comparisons. If the samples are large enough any soil can be established as different from almost any other for whatever property of interest.

The significance test is valuable in preventing false claims on inadequate evidence. Thus, a result might be summarized as:

> The mean measured pH of the topsoil was 5.7 compared with 6.7 in the subsoil; but because the samples were small (or because the variances were large) the difference was not statistically significant.

However, when a difference is deemed statistically significant because the null hypothesis is rejected, that does not mean that it is important or physically or biologically meaningful. For example, the difference between an observed mean pH of 5.7 in the topsoil and 5.9 in the subsoil would be of little consequence, whatever the probability of rejecting the null hypothesis. Also, while an investigator might regard a difference as significant only if $P \leq 0.05$, a reader may be willing to recognize one for which $0.05 \leq P < 0.1$

or, more stringently, only if $P \leq 0.01$. It is to some extent a matter of personal choice, and if the standard errors are reported then readers can reach their own judgments.

Note finally that the null hypothesis is highly implausible when horizons and different types of soil are being compared; they are different.

Transformations

It is often desirable to transform data to their square roots, or logarithms, or by other more elaborate functions. One reason for doing so is to obtain a new variate that approximates some known distribution, preferably normal (Gaussian) so that the usual parametric tests of significance can be applied.

The most serious departure from normality usually encountered with soil data is skewness, i.e., asymmetry, as in Figure 3a. The normal distribution is symmetric, its mean is at its center (its mode), and the mean of the data estimates this central value without ambiguity. The mean of data from a skewed distribution does not estimate the mode, nor does the median (the central value in the data). The meaning of the statistics can be uncertain therefore. A second feature of skewed data is that the variances of subsets depend on their means. If the data are positively skewed (again the usual situation) then the variances increase with increasing mean. This is undesirable when making comparisons. Third, estimation is 'inefficient' where data are skewed; that is, the errors are greater than they need be or, put another way, more data are required to achieve a given precision than would be if the distribution were normal. Transforming data to approximate normality overcomes these disadvantages. We achieve symmetry and hence remove ambiguity concerning the center. We stabilize the variances, and we make estimation efficient. The second of these is perhaps the most important.

No real data are exactly normal; all deviate more or less from normality. We have therefore to decide whether to transform them. This is best done by judicious exploration of the data aided by graphic display.

If a histogram looks symmetrical it can have superimposed on it a normal curve computed from the mean and variance of the data. The normal curve has the formula:

$$y = \frac{1}{\sigma\sqrt{2\pi}} \exp\left\{-\frac{(z-\mu)^2}{2\sigma^2}\right\} \qquad [10]$$

where y is the probability density. Scale it to fit the histogram by multiplying by the number of observations and by the width of the bins. If the curve fits well then there is no need to transform the data.

If the histogram is skewed then the skewness coefficient, γ_1, can be computed in addition to the mean and variance. This dimensionless quantity can be obtained via the third moment of the data about their mean:

$$\gamma_1 = \frac{1}{NS^3} \sum_{i=1}^{N} (z_i - \bar{z})^3 \qquad [11]$$

A symmetric histogram has $\gamma_1 = 0$. Values of γ_1 greater than 0 signify positive skewness, i.e., long upper tails to the distribution and a mean that exceeds the median, which is common. Negative values of γ_1 signify negative skewness and are unusual.

If γ_1 is positive and less than 0.5 then there should be no need to transform the data. If $0.5 < \gamma_1 \leq 1$ then it might be desirable to convert the data to their square roots; and if $\gamma_1 > 1$ a transformation to logarithms is likely to give approximate normality.

The following example illustrates the situation. The data, which are summarized in Table 2, are 433 measurements of available phosphorus, P, in the topsoil. Their skewness coefficient is 3.95, i.e., they are strongly positively skewed, and this is apparent in their histogram (Figure 3a). Transforming to logarithms makes the histogram (Figure 3b) more-nearly symmetric, and, as the skewness in the logarithms is now only 0.34, the transformation seems satisfactory. Further, the normal curve appears to fit well.

Figure 4 shows how the transformation stabilizes the variances. In Figure 4a the variances of subsets of 44 from the full set of data on phosphorus are plotted against the means. Evidently, the variance increases strongly with increasing mean. Converting the data to their logarithms produces a result in which there is virtually no relation (Figure 4b).

These simple functions change only the general form of the distribution; they do not change the detail.

Table 2 Summary statistics of 433 values of available phosphorus measured in a survey of topsoil. Values of χ^2, with 18 df are added for the hypothesis that the data or their logarithms are from a normal distribution

	Scale	
Statistic	*P (mg l^{-1})*	*Log$_{10}$P*
Mean	4.86	0.546
Variance	26.52	0.1142
Standard deviation	5.15	0.338
Skewness	3.95	0.23
χ^2_{df18}	368.2	26.7

Normalizing the detail requires a more elaborate, normal score transform.

Analysis of Variance

The analysis of variance is at once one of the most powerful and elegant techniques in statistics. Its basis is that variances are additive and that the total variance in a population is the sum of the variances contributed by two or more sources. Working from the design of an investigation, it analyzes the data by separating the contributions from those sources and estimating the variances in them. Designs vary from the simple to highly complex, but all embody the same principle.

Here, two of the simplest designs are considered, such as appear in Figure 2. An investigator wants to know how manuring improves crop yield in the field. He or she has several (k) treatments, e.g., nothing (O), dung (D), industrial waste (W), and a complete artificial (NPK) fertilizer (F). The researcher replicates each m times by assigning them completely at random to plots of equal size. Figure 2a shows how the experiment might be layed out with $m = 5$ replicates. The investigator applies the treatments, grows the crop, and measures the yield at harvest, designated z.

The total variance in the yields in the experiment, s_T^2, comprises variance from two sources, namely that between the treatments, s_B^2, and that within them, s_W^2, and $s_T^2 = s_B^2 + s_W^2$. The total variance is estimated by Eqn [4]. The variance within any one treatment is estimated by the same formula but for only those data in that treatment. Pooling estimates for all treatments gives s_W^2. To complete the analysis, a quantity B can also be computed:

$$B = \frac{1}{k-1}\sum_{i=1}^{k} n_i(\bar{z}_i - \bar{\bar{z}})^2 \qquad [12]$$

where n_i is the number of plots in the ith treatment, $\bar{z}_i$ is the mean of the ith treatment, and $\bar{\bar{z}}$ is the general mean of the data. The computations are set out in Table 3. Finally, the analysis leads to a test of significance. The ratio $F = B/W$ is computed, the distribution of which has been worked out and tabulated for degrees of freedom $k-1$ in the numerator and $N-k$ in the denominator. If F exceeds the tabulated value at probability $P = 0.05$ (or $P = 0.01$ or $P - 0.001$, according to choice), the treatments are judged to have produced significant differences.

In the simple experiment illustrated in Figure 2a, all n_i are equal to 5, so that n_i can be replaced by $n = 5$, and $N = mk = 5 \times 4 = 20$. Things do not always go as planned, however, and if some of the plot yields are lost then the n_i can vary from treatment to treatment; and the more general formulae in Table 3 will take care of that.

The soil might vary across the experiment systematically, so that there is trend, or in an apparently random way at a coarse scale. This variation could swell the residual variation and so mask that due to the treatments. It can be taken into account by blocking. The m replicates are now arranged in m blocks such that in each block every treatment appears once and once only. Figure 2b shows an example in which five blocks are laid out side by side. The analysis follows the same procedure as in Table 3 except that there is an additional line for the blocks in which the sum of squares is that of deviations from the block means (Table 4). The residual sum of squares is diminished by this quantity, and, although the residual degrees of freedom are also diminished, the residual mean square, i.e., the residual variance, is usually less, and the experiment more sensitive therefore.

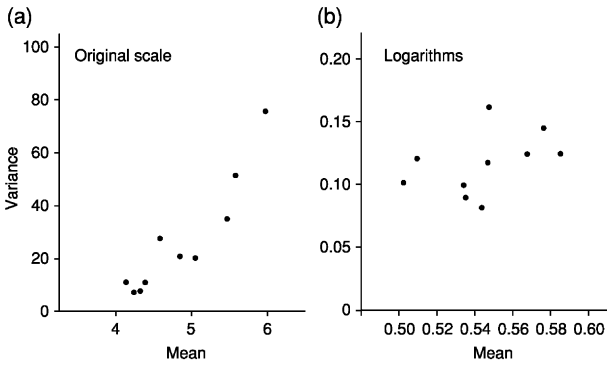

Figure 4 Graphs of variance against mean for 10 subsets of 44 phosphorus data (a) on the original scale in milligrams per liter and (b) after transformation to common logarithms.

Table 3 Table for the analysis of variance for a completely randomized design with a single classification

Source	*Degrees of freedom*	*Sums of squares*	*Mean square*	*F*
Treatments	$k-1$	$\sum_{i=1}^{k} n_i(\bar{z}_i - \bar{\bar{z}})^2$	$\frac{1}{k-1}\sum_{i=1}^{k} n_i(\bar{z}_i - \bar{\bar{z}})^2 = B$	B/W
Residual	$N-k$	$\sum_{i=1}^{k}\sum_{j=1}^{n_i}(z_{ij} - \bar{z}_i)^2$	$\frac{1}{N-k}\sum_{i=1}^{k}\sum_{j=1}^{n_i}(z_{ij} - \bar{z}_i)^2 = W$	
Total	$N-1$	$\sum_{i=1}^{k}\sum_{j=1}^{n_i}(z_{ij} - \bar{\bar{z}})^2$	$\frac{1}{N-1}\sum_{i=1}^{k}\sum_{j=1}^{n_i}(z_{ij} - \bar{\bar{z}})^2 = T$	

Table 4 Table for the analysis of variance for a balanced randomized block design with a single set of treatments

Source	*Degrees of freedom*	*Sums of squares*	*Mean square*	*F*
Treatments	$k-1$	$\sum_{i=1}^{k} n_i(\bar{z}_i-\bar{\bar{z}})^2$	$\frac{1}{k-1}\sum_{i=1}^{k} n_i(\bar{z}_i-\bar{\bar{z}})^2 = B$	B/W
Blocks	$m-1$	$\sum_{l=1}^{m} n_l(\bar{z}_l-\bar{\bar{z}})^2$	$\frac{1}{m-1}\sum_{l=1}^{m} n_l(\bar{z}_l-\bar{\bar{z}})^2 = M$	
Residual	$(k-1)\times(m-1)$	$T(N-1)-B(k-1)-M(m-1)$	$\frac{T(N-1)-B(k-1)-M(m-1)}{(k-1)(m-1)} = W$	
Total	$N-1$	$\sum_{i=1}^{k}\sum_{j=1}^{n_i}(z_{ij}-\bar{\bar{z}})^2$	$\frac{1}{N-1}\sum_{i=1}^{k}\sum_{j=1}^{n_i}(z_{ij}-\bar{\bar{z}})^2 = T$	

In soil survey, different classes of soil replace treatments. In the simplest cases, each class is sampled at random, and the n_i are rarely equal, either because it is difficult to obtain equal representation or because sampling is deliberately in proportion to area so as to maintain a fairly constant density. Effectively the classes are weighted in proportion to the areas they cover. $F = B/W$ can still be computed, and tested for significance, but, as above, this is less interesting than the differences between the means.

The variance between treatments or classes, s_B^2 can be obtained from B. The latter combines variation both from between treatments or classes and within them:

$$B = ns_B^2 + s_W^2 \qquad [13]$$

if $n_i = n$ for all i. Rearranging then gives:

$$s_B^2 = (B - s_W^2)/n \qquad [14]$$

If the n_i are unequal then n is replaced by n^*, given by:

$$n^* = \frac{1}{k-1}\left(N - \frac{\sum_{i=1}^{k} n_i^2}{N}\right) \qquad [15]$$

and:

$$s_B^2 = (B - s_W^2)/n^* \qquad [16]$$

Fixed Effects, Random Effects, and Intraclass Correlation

The value s_B^2 obtained as above estimates $\sum_{i=1}^{k}(\mu_i - \mu)^2/(k-1)$, where μ_i is the expected value of treatment or class i, and μ is the expected value in the whole population. In designed experiments, in which the effects are fixed by the experimenter, s_B^2 is of little interest. In soil survey, however, where it is often a matter of chance which classes are actually sampled, the differences $\mu_i - \mu$ are subject to random fluctuation. In this event, s_B^2 estimates the variance, σ_B^2, among a larger population of means and is termed a 'component of variance,' which is of considerable interest.

The between-class variance expressed as a proportion of the total variance, $\sigma_B^2 + \sigma_W^2$, is the intraclass correlation, ρ_i:

$$\rho_i = \frac{\sigma_B^2}{\sigma_B^2 + \sigma_W^2} \qquad [17]$$

which is estimated from the analysis of variance table by:

$$r_i = \frac{s_B^2}{s_B^2 + s_W^2} = \frac{B - W}{B + (n^* - 1)W} \qquad [18]$$

The intraclass correlation has a theoretical maximum of 1 when every class is uniform. In practice there is always some variation within classes, and so ρ_i never attains 1. The minimum of ρ_i is zero, when $s_W^2 = 0$. The calculated estimate of ρ_i can be negative, because $B < W$, and is usually best explained by sampling fluctuation.

Covariance, Correlation, and Regression

The relations between two variables can be expressed by correlation and regression.

Covariance

The covariance of a pair of variables, y and z, is estimated from data in a way analogous to the estimation of the variance, Eqn [4], by:

$$\hat{c}_{y,z} = \frac{1}{N-1}\sum_{i=1}^{N}\{y_i - \bar{y}\}\{z_i - \bar{z}\} \qquad [19]$$

where $\bar{y}$ and $\bar{z}$ are the means of y and z, respectively. Covariance is not easy to envisage, especially if y and z have different dimensions. The relation may be standardized by converting it to correlation, below.

Correlation

The correlation between two variables, strictly the linear correlation, or the product–moment coefficient of linear correlation, is a dimensionless quantity, usually denoted by ρ for the population parameter. Its estimate, r, is obtained from the covariance by:

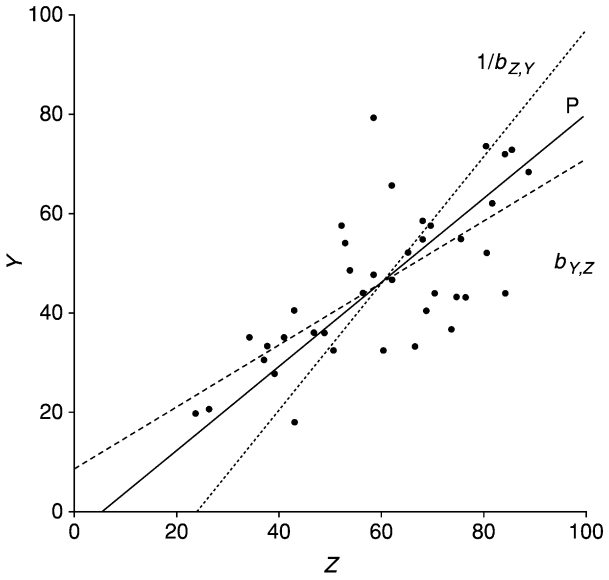

Figure 5 Scatter graph showing the relations between two variables Y and Z for which the correlation coefficient, r, is 0.699. The symbols are the observed values, the solid line, labeled 'P,' is the principal axis, with gradient 0.844, equivalent to an angle of 40.1° to the horizontal. The dashed line shows the regression of Y on Z, with gradient $b_{Y,Z} = 0.621$; and the dotted line shows that of Z on Y, for which $b_{Y,Z} = 0.788$, giving it a gradient of approximately $1/b_{Z,Y} = 1.269$.

$$r_{y,z} = \frac{\hat{c}_{y,z}}{\sqrt{s_y^2 s_z^2}} \qquad [20]$$

where s_y^2 and s_z^2 are the estimated variances of y and z. The coefficient was proposed by Karl Pearson, and for that reason it is often called the 'Pearson correlation coefficient.'

The coefficient is effectively a standardized version of the covariance. It measures the extent to which the data, when plotted as one variable against the other in a scatter graph, depart from a straight line (see Figure 5). It may vary between +1, signifying perfect positive correlation, and −1, for perfect negative correlation. Intermediate values indicate departures from the straight line, as in Figure 5, for which $r = 0.699$. In general, positive values of r indicate the tendency of y and z to increase together, whereas negative values arise when y increases as z decreases. A value of zero represents no linear relation.

Notice that the statistic refers specifically to linear correlation. The relation between two variables might be curved; the absolute value of r would then be necessarily less than 1 regardless of any scatter about the curve.

When the data, y_i, z_i, $i = 1, 2, \ldots, N$, are from a sample, then $c_{y,z}$ and $r_{y,z}$ estimate corresponding population parameters, $\mathrm{cov}_{y,z}$ and $\rho_{y,z}$. If the data can be assumed to be drawn from a bivariate normal distribution then one can test r for significance. One computes Student's t with $N - 2$ degrees of freedom:

$$t_{N-2} = \frac{r\sqrt{N-2}}{\sqrt{1-r^2}} \qquad [21]$$

The probability of this value's occurring on the null hypothesis that $\rho = 0$ can then be computed or looked up in a table of t.

Spearman rank correlation Where the distributions of the underlying variables are far from normal, the Pearson coefficient can be replaced by the Spearman rank correlation coefficient, usually denoted r_S. The values of each variable are ranked from smallest to largest and given new values 1, 2, ..., N. The correlation coefficient is then computed by applying eqns [19] and [20]. Alternatively, one may take the differences, d_i, $i = 1, 2, \ldots, N$, between the ranks and compute:

$$r_S = 1 - \frac{6\sum_{i=1}^{N} d_i^2}{N(N^2-1)}. \qquad [22]$$

Many soil variables observed in the field, such as grade of structure and frequency of mottles, are recorded as rankings rather than measured. In these circumstances the correlations between them can be expressed by the Spearman coefficient, whereas the Pearson coefficient would be inappropriate. Also, in these circumstances, tied ranks in any large set of data are inevitable, and Eqn [22] must be elaborated. The coefficient can be calculated in various ways, but from Eqns [19], [20], and [22] can be derived:

$$r_s = \frac{\sum_{i=1}^{N}(y_i-\bar{y})^2 - \sum_{i=1}^{N} T_{i,y} + \sum_{i=1}^{N}(z_i-\bar{z})^2 - \sum_{i=1}^{N} T_{i,z} - \sum_{i=1}^{N} d_i^2}{2\sqrt{\left\{(y_i-\bar{y})^2 - \sum_{i=1}^{N} T_{i,y}\right\}\left\{(z_i-\bar{z})^2 - \sum_{i=1}^{N} T_{i,z}\right\}}} \qquad [23]$$

in which:

$$T_i = \frac{t_i(t_i^2-1)}{12} \qquad [24]$$

where t_i is the number of observations tied at rank i.

For small samples, r_S is somewhat less sensitive than the Pearson coefficient in that larger values are necessary to establish statistical significance.

Regression

Regression treats the relation between two variables in a somewhat different way by designating one of them, y, as depending on the other, z, represented by the equation:

$$y = \beta_0 + \beta_1 z \quad [25]$$

The underlying rationale is often physical. For example, How is the soil's strength changed by additions of gypsum? Known amounts of gypsum can be added to the soil, the resultant changes in strength measured, and from the data how much on average the strength is changed by each increment in gypsum added can be estimated. The Gauss linear model can be adopted for this purpose:

$$y_i = \beta_0 + \beta_1 z_i + \epsilon_i \quad [26]$$

where y_i is the value of the random dependent variable, Y, here strength, in unit i, z_i is that of the independent variable, added gypsum, and ϵ_i is random error term that is uniformly and independently distributed with variance σ_ϵ^2. The quantities β_0 and β_1 are parameters of the model and are estimated as follows:

$$\hat{\beta}_1 = \frac{\hat{c}_{y,z}}{s_z^2} \quad [27]$$

and:

$$\hat{\beta}_0 = \bar{y} - \hat{\beta}_1 \bar{z} \quad [28]$$

Equation [27] gives the rate at which strength changes in response to increments in gypsum. The quantity $\hat{\beta}_0$ in Eqn [28] is the intercept at $y = 0$ and is likely to be of subsidiary interest. Together $\hat{\beta}_0$ and $\hat{\beta}_1$ may be inserted into Eqn [25] for predicting unknown values of Y if we know those of z:

$$\hat{y} = \hat{\beta}_0 + \hat{\beta}_1 z \quad [29]$$

The procedure minimizes the sum of the squares of the differences between the measured values y_i, $i = 1, 2, \ldots, N$, and those expected from Eqn [25], $\hat{y}_i$:

$$s_{Y,z}^2 = \frac{1}{N-2} \sum_{i=1}^{N} (y_i - \hat{y}_i)^2 \quad [30]$$

A somewhat different situation is common in soil survey. In it we sample the soil without knowing in advance what values we shall obtain for the variables of interest. For example, we may measure both cation exchange capacity, CEC, and clay content, and we may regard CEC as depending in a physical sense on clay content. The data on both variables now contain random components, and for this reason we designate them with the capital letters, Y and Z, respectively. We may express the relation as the regression of CEC on clay and estimate the parameters in the same way as for the Gauss linear model. In doing so we assign all the error to CEC and minimize the sum of squares, $s_{Y,Z}^2$, as in Eqn [30]. The purpose is now prediction, i.e., prediction of CEC, knowing the clay content. We could equally well compute the regression of clay on CEC. The roles of Y and Z are reversed, and we minimize:

$$s_{Z,Y}^2 = \frac{1}{N-2} \sum_{i=1}^{N} (z_i - \hat{z}_i)^2 \quad [31]$$

where:

$$\hat{z} = \hat{\beta}_0' + \hat{\beta}_1' y \quad [32]$$

The primes attached to $\hat{\beta}_0'$ and $\hat{\beta}_1'$ signify that these quantities refer to the regression of Z on Y, and that they are different from those for the regression of Y on Z. In other words, the line defined by Eqn [29] differs from that defined by [32], as **Figure 5** shows. The correct line to choose depends on which variable is to be predicted. To predict y from z, Eqn [29] is used; to predict z from y, Eqn [32] is used.

STOCHASTIC ANALYSIS OF SOIL PROCESSES

Introduction

Quantitative field-scale descriptions of water flow and chemical transport in the unsaturated (vadose) zone are essential for improving the basic understanding of the transport process in near-surface geological environments, and for providing predictive tools that, in turn, will be used to predict the future spread of pollutants in these environments. One of the distinctive features of a natural formation at the field scale is the spatial heterogeneity of its properties that affect flow and transport. This spatial heterogeneity is generally irregular; it occurs on a scale beyond the scope of laboratory samples and has a distinct effect on the spatial distribution of solutes, which results from transport through the formation. A fundamental question is that of how to develop predictive models that may incorporate the impact of field-scale spatial variability of the formation properties on vadose-zone flow and transport.

Modeling Flow and Transport in Unsaturated, Heterogeneous Soils

The starting point in modeling soil water flow is the uncertainty in the soil properties that affect flow and transport (because of their inherently erratic nature and the paucity of measurements). This uncertainty generally precludes the use of the traditional, deterministic modeling approach for the prediction of flow and transport on the field scale. In an alternative approach, uncertainty is set in a mathematical framework by modeling the relevant soil properties as random space functions (RSFs). As a consequence, the flow and transport equations are of a stochastic nature, and the dependent variables are also RSFs. The aim of the stochastic approach, therefore, is to evaluate the statistical moments of the variables of interest, given the statistical moments of the formation properties. In general, this is a formidable task and usually its scope is restricted to finding the first two moments. To simplify matters, it is common to treat each of the soil properties, as well as the various flow-controlled attributes, denoted by $p'(\mathbf{x})$, where $\mathbf{x}=(x_1,x_2,x_3)$ is the spatial coordinate vector, as stationary, characterized at second order by a spatially invariant mean, $P=<p'(\mathbf{x})>$, and a covariance, $C_{pp}(\mathbf{x}',\mathbf{x}'')=<p(\mathbf{x}')p(\mathbf{x}'')>$, in which $p(\mathbf{x})=p'(\mathbf{x})-P$, that depends on the separation vector $\boldsymbol{\xi}=\mathbf{x}'-\mathbf{x}''$, and not on $\mathbf{x}'$ and $\mathbf{x}''$ individually.

Under unsaturated flow conditions, the analysis is further complicated by the fact that the relevant flow parameters – hydraulic conductivity, K, and water capacity, C, which depend on formation properties – depend also on flow-controlled attributes in a highly nonlinear fashion. Consequently, under variably saturated conditions, the evaluation of the effects on flow and transport of spatial variations in the formation properties is extremely complex; it requires several simplifying assumptions regarding the constitutive relationships for unsaturated flow, the flow regime, and the spatial structure of the formation heterogeneity.

The focus here is on transport of conservative, nonreactive, nonvolatile solutes, under steady flow and in the absence of plant roots. Furthermore, the emphasis is on formations, for which the spatial distribution of their properties can be modeled by a unimodal distribution with a spatial correlation structure characterized by a covariance with a single, finite-length scale. It should be emphasized, however, that the theoretical framework described here can serve as a basis for more complicated situations, including transient water flow, transport of reactive solutes, and multiple-length scale, heterogeneous formations.

Quantification of solute transport in partially saturated, heterogeneous porous formations may be accomplished with a two-stage approach, which combines a stochastic continuum description of the steady-state flow with a general Lagrangian description of the motion of an indivisible particle of a passive solute that is carried by a steady-state flow. The first stage involves relating the statistical moments of the probability density function (PDF) of the velocity to those of the properties of the formation, while the second stage involves relating the statistical moments of the particle displacement PDF to those of the velocity PDF.

Stochastic Analysis of the Flow

A first-order perturbation approach is used here in order to obtain the first two statistical moments of the PDF of flow-controlled attributes, i.e., the pressure head, ψ, the log-unsaturated conductivity, $\log K$, the water flux vector, $\mathbf{q}'$, the water saturation, Θ, and, concurrently, those of the Eulerian velocity vector, $\mathbf{u}'$, for given statistics of the formation properties. The following assumptions are made:

1. The heterogeneous formation has a three-dimensional structure with axisymmetric anisotropy, and the flow domain is variably saturated and unbounded;
2. The local steady-state unsaturated flow obeys the Darcy law and continuity, which, if local isotropy is assumed, reads:

$$q_i'(\mathbf{x}) = -K(\psi,\mathbf{x})\frac{\partial\varphi(\mathbf{x})}{\partial x_i}$$
$$\frac{\partial q_i'(\mathbf{x})}{\partial x_i} = 0 \quad i = 1,2,3 \qquad [1]$$

where q_i' $(i=1,2,3)$ is the water flux vector, $\varphi = -x_1 - \psi$ is the hydraulic head, x_1 is directed vertically downward, and the Einstein summation convention is used in eqn [1] and elsewhere;
3. The local relationships between K and ψ (considered here as a positive quantity) and Θ and ψ are nonhysteretic and are given by the Gardner–Russo model, i.e.,

$$K(\psi,\mathbf{x}) = K_s(\mathbf{x})\exp[-\alpha(\mathbf{x})\psi] \qquad [2a]$$

$$\Theta(\psi,\mathbf{x}) = \left\{\exp\left[-\frac{1}{2}\alpha(\mathbf{x})\psi\right]\left[1+\frac{1}{2}\alpha(\mathbf{x})\psi\right]\right\}^{2/(m'+2)} \qquad [2b]$$

where K_s is saturated conductivity, $\alpha = \lambda^{-1}$ is a parameter of the formation, λ is the macroscopic capillary length scale and m′ is a parameter, selected here as $m' = 0$;
4. Both $\log K_s$ and $\log\alpha$ are multivariate normal (MVN) RSFs, ergodic over the region of interest, characterized by constant means, $F = E[\log K_s]$ and $A = E[\log\alpha]$, and by covariances $C_{ff}(\boldsymbol{\xi})$ and $C_{aa}(\boldsymbol{\xi})$, respectively, and cross-covariance, $C_{fa}(\boldsymbol{\xi})$ given by:

$$C_{pp}(\xi) = \sigma_{p*}^2\exp(-\xi') \qquad [3]$$

where f and a are the perturbations of $\log K_s$ and $\log\alpha$, respectively, $p = f$ or a, $p^* = f$, a, or fa; $\boldsymbol{\xi}' = (\mathbf{x}-\mathbf{x}'')/\mathbf{I}_p$, is the scaled separation vector, $\xi' = |\boldsymbol{\xi}'|$; σ_f^2 and σ_a^2, and $\mathbf{I}_f = (I_{f1},I_{f2},I_{f3})$ and $\mathbf{I}_a = (I_{a1},I_{a2},I_{a3})$ are the respective variances and correlation scales of $\log K_s$ and $\log\alpha$, σ_{fa}^2 is the cross-variance between perturbations of $\log K_s$ and $\log\alpha$, and $\mathbf{I}_{fa} = 2\mathbf{I}_f\mathbf{I}_a/(\mathbf{I}_f+\mathbf{I}_a)$;
5. The porosity, ϕ is constant and uniform throughout the formation.

Use of the aforementioned assumptions under ergodic conditions, by elimination of $\mathbf{q}'$ from eqn [1], expression of the various parameters and variables on the right-hand side (RHS) of eqn [2a] in terms of means and perturbations, i.e., $\log K_s = F+f$, $\log\alpha = A+a$, $\psi = H+h$, and use of the Taylor expansion with first-order terms retained, gives the first-order perturbation approximation of the steady flow equation as:

$$\frac{\partial^2 h}{\partial x_i^2} - \Gamma(2J_i - \delta_{1i})\frac{\partial h}{\partial x_i} - J_i(J_i - \delta_{1i})\Gamma a + J_i\left(\frac{\partial f}{\partial x_i} - \Gamma H\frac{\partial a}{\partial x_i}\right) = 0, \quad i = 1,2,3 \qquad [4]$$

where $\Gamma = \exp(A)$ is the geometric mean of α, $J_i = \partial(-H - x_1)/\partial x_i$ $(i=1,2,3)$ is the mean of the head-gradient vector and δ_{1i} $(i=1,2,3)$ is the Kronecker delta.

On the assumption that the flow is gravity-dominated, i.e., the mean pressure-head gradient is zero so that the mean head-gradient, J_i, is given by $J_i = \delta_{i1}$ $(i=1,2,3)$, the exact solutions of eqn [4] in terms of the (cross-)spectral relationships between the RSFs of f, a, and h, which are obtained by using Fourier–Stieljes integral representations, are:

$$\hat{C}_{hh}(\mathbf{k}) = \frac{k_1^2[\hat{C}_{ff}(\mathbf{k}) + \Gamma^2H^2\hat{C}_{aa}(\mathbf{k}) - 2\Gamma H\hat{C}_{fa}(\mathbf{k})]}{k^4 + \Gamma^2k_1^2} \qquad [5]$$

$$\hat{C}_{hf}(\mathbf{k}) = \frac{k_1(\Gamma k_1 - j'k^2)[\hat{C}_{ff}(\mathbf{k}) - \Gamma H\hat{C}_{fa}(\mathbf{k})]}{k^4 + \Gamma^2k_1^2} \qquad [6]$$

$$\hat{C}_{ha}(\mathbf{k}) = \frac{k_1(\Gamma k_1 - j'k^2)[\hat{C}_{fa}(k) - \Gamma H\hat{C}_{aa}(\mathbf{k})]}{k^4 + \Gamma^2k_1^2} \qquad [7]$$

where j' is the imaginary unit, $\mathbf{k} = (k_1,k_2,k_3)$ is the wave number vector, $k = |\mathbf{k}|$, and the inverse Fourier transform of the covariance of the formation properties, $C_{pp}(\boldsymbol{\xi})$ (eqn [3] with $p = \log K_s$ or $\log\alpha$), is given by:

$$\hat{C}_{pp}(\mathbf{k}) = \frac{\sigma_p^2 I_{p1}I_{p2}I_{p3}}{\pi^2(1 + I_{p1}^2k_1^2 + I_{p2}^2k_2^2 + I_{p3}^2k_3^2)^2} \qquad [8]$$

In a similar way, if the variables on the left-hand-side (LHS) of eqns [1] and [2b] are expressed in terms of means and perturbations, i.e., $\mathbf{q}' = \mathbf{Q}+\mathbf{q}$ and $\Theta = S+s$, respectively, and the Taylor expansion is used with first-order terms retained, the (cross-) spectral relationships between the RSFs of f, a, h, and s, and f, a, h, and q_i $(i=1,2,3)$, which are obtained by using Fourier–Stieljes integral representations, are:

$$\hat{C}_{ss}(\mathbf{k}) = B^2\{\hat{C}_{hh}(\mathbf{k}) + H^2\hat{C}_{aa}(\mathbf{k}) + H[\hat{C}_{ha}(\mathbf{k}) + \hat{C}_{ah}(\mathbf{k})]\} \qquad [9]$$

$$\hat{C}_{sh}(\mathbf{k}) = B[\hat{C}_{hh}(\mathbf{k}) + H\hat{C}_{ha}(\mathbf{k})] \quad [10]$$

$$\hat{C}_{sf}(\mathbf{k}) = B[\hat{C}_{hf}(\mathbf{k}) - H\hat{C}_{fa}(\mathbf{k})] \quad [11]$$

$$\hat{C}_{sa}(\mathbf{k}) = B[\hat{C}_{ha}(\mathbf{k}) - H\hat{C}_{aa}(\mathbf{k})] \quad [12]$$

$$\begin{aligned}\hat{C}_{q_{ij}}(\mathbf{k}) = K_g^2\{&\delta_{1i}\delta_{1j}[\hat{C}_{ff}(\mathbf{K}) + (\Gamma H)^2\hat{C}_{aa}(\mathbf{k}) + 2\Gamma H\hat{C}_{fa}(\mathbf{k})] \\ &+ \delta_{1i}[(\Gamma + j'k_i)(\hat{C}_{fh}(\mathbf{k}) + \Gamma H\hat{C}_{ah}(\mathbf{k}))] \\ &+ \delta_{1j}[\Gamma - j'k_j)(\hat{C}_{hf}(\mathbf{k}) + \Gamma H\hat{C}_{ha}(\mathbf{k})] \\ &+ (\delta_{1i}\delta_{1j}\Gamma^2 + k_i^2)\hat{C}_{hh}(\mathbf{k})\} \quad i,j = 1,2,3 \end{aligned} \quad [13]$$

where $B = (1/4)\ \Gamma^2 H\ \exp[-(1/2)\Gamma H]$, $K_g = \exp(Y)$ is the geometric mean conductivity, and $Y = F - \Gamma H$ is the mean of log$K$. Note that because $\psi = H + h$ is a function of water saturation, the (cross-)spectra $\hat{C}_{mn}$ $(\boldsymbol{k})$ (m, $n = f$, a, h, s; eqns [5–7] and [9–13]) depend on saturation. This dependence, however, is omitted for simplicity of notation. Furthermore, for $H \to 0$ (and $\Gamma \to 0$), the RHS of eqns [9–12] vanish, while eqns [5], [6], [7], and [13] reduce to their counterparts associated with steady flow in saturated formations.

The (cross-)covariances, $C_{mn}(\xi)$ associated with the (cross-)spectra $\hat{C}_{mn}(\mathbf{k})$ (m, $n = f, a, h, s$; eqns [5–13]), are then calculated by taking the Fourier transform of the respective $\hat{C}_{mn}(\mathbf{k})$, i.e.:

$$C_{mn}(\boldsymbol{\xi}) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \exp(j'\,\mathbf{k}\cdot\boldsymbol{\xi})\hat{C}_{mn}(\mathbf{k})d\mathbf{k} \quad [14]$$

Scaled forms of the pressure-head covariance, $C'_{hh}(\boldsymbol{\xi}) = C_{hh}(\boldsymbol{\xi})/I_{yv}^2\sigma_y^2$, independent of water saturation, Θ, are illustrated graphically in **Figure 1** as functions of the scaled separation distance in the direction parallel to the mean flow, $\xi'_1 = \xi_1/I_{yv}$ (**Figure 1a, c**), and in the direction perpendicular to the mean flow, $\xi'_2 = \xi_2/I_{yv}$ (**Figure 1b, d**), for selected values of the length-scale ratios, $\eta = \lambda/I_v$ and $\rho = I_h/I_v$, where $I_v = I_{f1} = I_{a1}$, and $I_h = I_{f2} = I_{f3} = I_{a2} = I_{a3}$. Here σ_y^2 and $I_{yv} = I_{y1}$ are the Θ-dependent, log$K$ variance and correlation length-scale in the vertical direction, respectively, given by:

$$\sigma_y^2 = \sigma_f^2 + \Gamma^2H^2\sigma_a^2 - 2\Gamma H\sigma_{fa}^2 - \Gamma^2\sigma_h^2 \quad [15a]$$

$$I_{yv} = \frac{\sigma_f^2 I_{f1} + \Gamma^2H^2\sigma_a^2 I_{a1} - 2\Gamma H\sigma_{fa}^2 I_{fa1} - \Gamma^2\int_0^\infty C_{hh}(\xi_1,0,0)d\xi_1}{\sigma_f^2 + \Gamma^2H^2\sigma_a^2 - 2\Gamma H\sigma_{fa}^2 - \Gamma^2\sigma_h^2} \quad [15b]$$

and $\sigma_h^2 = C_{hh}(0)$ is the variance of the pressure-head perturbations.

Note that the correlation length-scales, I_v and I_h, determine approximately the distances, parallel and perpendicular to the mean flow, respectively, at which property variations cease to be correlated. On the other hand, the macroscopic capillary length-scale,

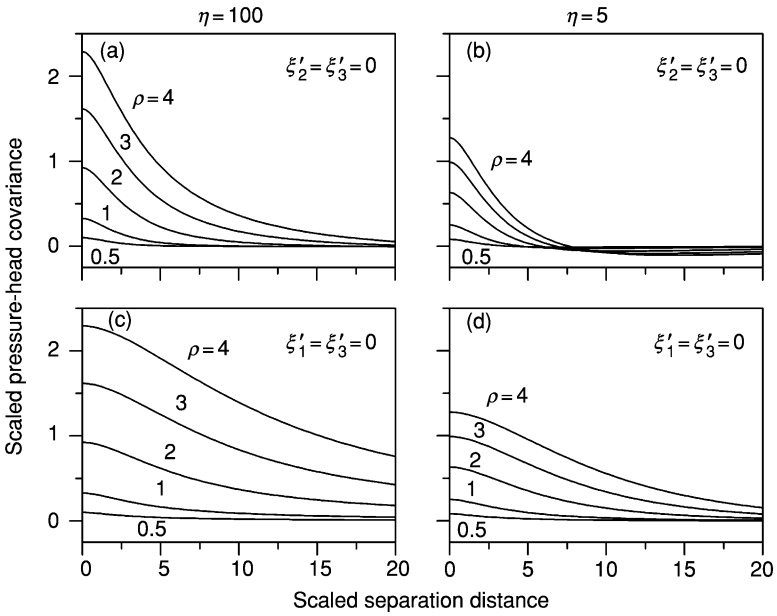

Figure 1 Scaled pressure-head covariance, C'_{hh}, independent of mean water saturation, S, as a function of the scaled separation distance parallel, ξ'_1 (a and b), and perpendicular, ξ'_2 (c and d) to the direction of the mean flow, for selected values of $\rho = I_h/I_v$ (the numbers labeling the curves), for various values of $\eta = \lambda/I_v$, and for $\nu = \sigma_a^2/\sigma_f^2 = 0.2$, $\sigma_f^2 = 0.5$, $\sigma_{fa}^2 = 0$, $I_{yv} = 0.2$ m, $Q/\phi S = 1$m day^{-1}, and $J = (1,0,0)$.

λ, determines the relative magnitude of the capillary forces in unsaturated flow; it may be regarded as a natural length-scale of the unsaturated soil. The results depicted in Figure 1 show that, for given variability in the soil properties, both the magnitude and the persistence of the pressure-head variability increase with increasing ρ and η. Furthermore, the persistence of the pressure-head variability in the direction perpendicular to the mean flow is larger than that in the direction of the mean flow, particularly when both ρ and η are relatively large. This can be explained as follows: when the mean flow is vertical and I_v is kept constant, an increasing ρ expresses an increase in the size of the typical flow barriers in a direction normal to the mean flow; on the other hand, an increasing η expresses an increase in the macroscopic capillary length-scale, λ, i.e., a transition from a coarse-textured soil material, associated with negligible capillary forces to a fine-textured soil material, associated with significant capillary forces. Consequently, as ρ increases, the streamlines are deflected less easily; similarly, as η increases, the lateral head perturbation gradients increase. In other words, increasing stratification and capillary forces are expected to enhance the lateral dissipatation of water and, concurrently, to enhance the variability in the pressure head.

In Figure 2, principal components of the scaled flux covariance tensor, independent of S, i.e., $q'_{ii}(\boldsymbol{\xi}') = Cq_{ii}(\boldsymbol{\xi}')/\sigma_y^2 Q^2$ $(i = 1,2,3)$, where $Q = |\mathbf{Q}|$, are depicted as functions of $\xi'_1 = \xi_1/I_{yv}$, for selected values of the length-scale ratios, $\eta = \lambda/I_v$ and $\rho = I_h/I_v$. Note that because of the assumption of axisymmetric anisotropy, and for $J_2 = J_3 = 0$, $q'_{22}(\boldsymbol{\xi}) = q'_{33}(\boldsymbol{\xi})$. Figure 2 shows that the longitudinal component of the scaled flux covariance tensor is much larger than its transverse components, and also that both the magnitude and the persistence of the transverse components of the flux covariance tensor may be greater in fine-textured soil material. However, in such soil, the magnitude of the longitudinal component of the flux covariance tensor increases and its persistence decreases. On the other hand, soil stratification may increase the persistence of the longitudinal and the transverse components of the flux covariance tensor, may decrease the magnitude of the longitudinal component, and may either increase (for $\rho < \pi/2$) or decrease (for $\rho > \pi/2$) the magnitude of the transverse components of the flux covariance tensor.

The behavior of the principal components of the flux covariance tensor depicted in Figure 2 is explained on the same basis as above, i.e., when the mean flow is vertical and I_v is kept constant, an increasing ρ expresses increasing size of the typical flow barriers in a direction normal to the mean flow, while an increasing η expresses increasing capillary forces. Consequently, $q'_{11}(0)$ approaches unity at the small ρ limit, $\rho \to 0$ (which implies heterogeneity in the horizontal directions only) and decreases with increasing ρ, vanishing at the large ρ limit, $\rho \to \infty$ (which implies a perfectly stratified formation), while $q'_{ii}(i = 2, 3)$ are nonmonotonic functions of ρ with a maximum at

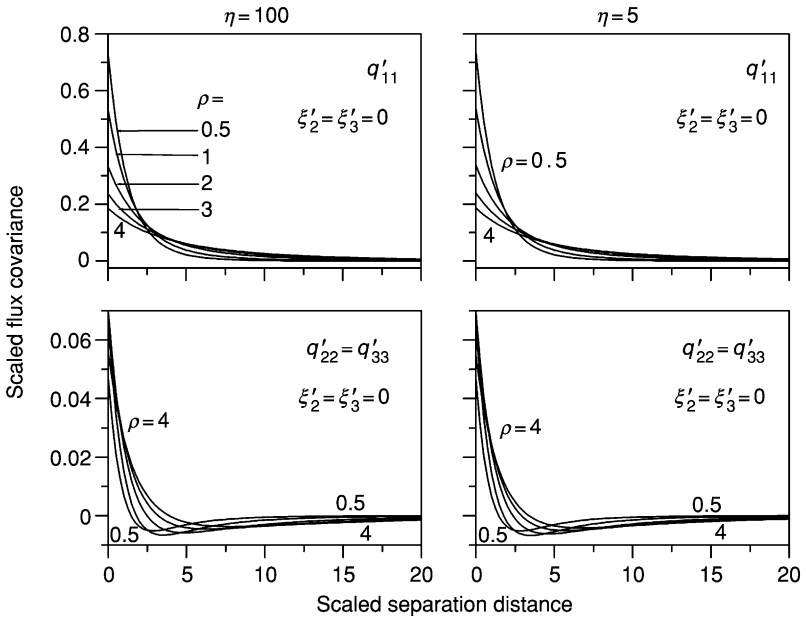

Figure 2 Principal components of the scaled flux covariance tensor, q'_{ii}, $i = (1,2,3)$, independent of mean water saturation, S, as a function of the scaled separation distance parallel to the direction of the mean flow, ξ'_1, for selected values of $\rho = I_h/I_v$ (the numbers labeling the curves), for various values of $\eta = \lambda/I_v$, and for $\nu = \sigma_a^2/\sigma_f^2 = 0.2$, $\sigma_f^2 = 0.5$, $\sigma_{fa}^2 = 0$, $I_{yv} = 0.2$m, $Q/\phi S = 1$m day^{-1}, and $J = (1,0,0)$.

$\rho = \pi/2$, that vanishes at the small ρ limit, $\rho \to 0$ and at the large ρ limit, $\rho \to \infty$. On the other hand, $q'_{ii}(0)$ $(i = 1,2,3)$ increases with increasing η.

When the mean flow is aligned with the x_1-axis only, the first term on the RHS of the Fourier transform of eqn [13] vanishes for $i,j = 2,3$, while both its second and third terms vanish at $\xi_1 = 0$ and $\xi_1 \to \infty$. Furthermore, the last term is antisymmetric in ξ_1. Consequently, integration of the principal components of the flux covariance tensor along the ξ_1-axis, when performed up to $\xi_1 \to \infty$, yields $\int_0^\infty Cq_{11}(\boldsymbol{\xi})d\xi_1 = Q^2\sigma_y^2 I_{yv}$ and $\int_0^\infty Cq_{ii}(\boldsymbol{\xi})d\xi_1 = 0$, $(i = 2$ to $3)$, irrespective of the value of ρ or η. Hence, the decrease in $q'_{11}(0)$ with increasing ρ and decreasing η must be compensated for by an increase in the separation distance over which $q_1(x_1)$ and $q_1(x_1 + \xi_1)$ are positively correlated. Consequently, the persistence of $q'_{11}(\xi_1)$ increases with increasing ρ and decreasing η. On the other hand, for $i = 2$ or $i = 3$, the increase in the separation distance over which $q_i(x_1)$ and $q_i(x_1 + \xi_1)$ are positively correlated with increasing ρ and η must be compensated by an increase in the separation distance over which $q_i(x_1)$ and $q_i(x_1 + \xi_1)$ are negatively correlated. Hence, the persistence of $q'_{ii}(\xi_1)$ $(i = 2,3)$ increases with increasing ρ and η.

Stochastic Analysis of the Transport

A first-order perturbation approach is used here in order to obtain the first two statistical moments of the PDF of the one-particle-trajectory for given statistics of the Eulerian velocity vector, $\mathbf{u}'(\mathbf{x})$, and, concurrently, for given statistics of the formation properties. In a general Lagrangian framework, the transport is described in terms of the motion of indivisible solute particles which are convected by the fluid. If pore-scale dispersion is neglected, the trajectory of a solute particle is related to $\mathbf{u}'(\mathbf{x})$ by the fundamental kinematic relationship:

$$\frac{d\mathbf{X}'}{dt} = \mathbf{u}'(\mathbf{X}') \quad \text{for} \quad t > 0; \mathbf{X}' = \mathbf{a} \quad \text{for} \quad t = 0 \qquad [16]$$

where t is time, and $\mathbf{X}' = \mathbf{X}'(t,\mathbf{a})$ is the trajectory of a particle which is at $\mathbf{X}' = \mathbf{a}$ when $t = 0$.

In order to relate the statistical moments of the PDF of the one-particle trajectory to those of the velocity PDF, the following assumptions are employed: (1) Lagrangian and Eulerian stationarity and homogeneity of the velocity field; (2) given statistics of the velocity field; (3) small fluctuations of the particle displacement about the mean trajectory; and (4) large Peclet numbers, i.e., local dispersion is omitted.

Under the aforementioned assumptions, for ergodic conditions and for a particle of a solute injected into the flow field at time $t = 0$ and location $\mathbf{x} = \mathbf{a}$, the solution of eqn [16] is:

$$\mathbf{X}'(t,\mathbf{a}) = \mathbf{a} + \mathbf{U}t + \int_0^t \mathbf{u}'(\mathbf{a} + \mathbf{U}\tau)d\tau \qquad [17]$$

where $\mathbf{U} = <\mathbf{u}'(\mathbf{x})>$ is the mean Eulerian velocity vector.

For fixed $\mathbf{a}$, the first two moments of $\mathbf{X}'$ (eqn [17]), the mean, $<\mathbf{X}'(t)>$ and, by a first-order approximation in the velocity variance, the covariance tensor, $X_{ij}(t) = <X_i(t)X_j(t)>$, $(i,j = 1,2,3)$, of the one-particle displacement at time t, where $\mathbf{X} = \mathbf{X}' - <\mathbf{X}'>$ is the fluctuation, are given by:

$$<\mathbf{X}'(t)> = \mathbf{U}t \qquad [18a]$$

$$X_{ij}(t) = 2\int_0^t (t - \tau)C_{u_{ij}}(\mathbf{U}\tau)d\tau \qquad [18b]$$

Here $C_{uij}(\boldsymbol{\xi}) = <u_i(\mathbf{x})u_j(\mathbf{x} + \boldsymbol{\xi})>$, $(i,j = 1,2,3)$, the velocity covariance tensor, where $u_i(\mathbf{x}) = u_i'(\mathbf{x}) - <u_i'(\mathbf{x})> = q_i(\mathbf{x})/\phi S - Q_i s(\mathbf{x})/\phi S^2$ is the velocity fluctuation, is given by:

$$C_{u_{ij}}(\boldsymbol{\xi}) = \frac{K_g^2 \delta_{1i}\delta_{1j}}{\phi^2 S^4} C_{ss}(\boldsymbol{\xi}) + \frac{C_{q_{ij}}(\boldsymbol{\xi})}{\phi^2 S^2} - \frac{K_g^2}{n^2\phi^3}\left[- \delta_{1i}\delta_{1j}[C_{sy}(\boldsymbol{\xi}) + C_{sy}(-\boldsymbol{\xi})] - \delta_{1j}\frac{\partial C_{sh}(\boldsymbol{\xi})}{\partial \xi_i} + \delta_{1i}\frac{\partial C_{sh}(-\boldsymbol{\xi})}{\partial \xi_j}\right] \qquad [19]$$

where $C_{sy}(\boldsymbol{\xi})$ is the cross-covariance between perturbations of $\log K$ and Θ given by:

$$C_{sy}(\boldsymbol{\xi}) = C_{sf}(\boldsymbol{\xi}) - \Gamma C_{sh}(\boldsymbol{\xi}) - \Gamma H C_{sa}(\boldsymbol{\xi}) \qquad [20]$$

Eqns [18a] and [18b] are of a general nature, consistent with the linearization of the flow equation. Furthermore, because the soil properties, $\log K_s$ and $\log\alpha$ are MVN, $\log K$, ψ, and Θ are also MVN. Consequently, the velocity is MVN, and, by eqn [17], the one-particle trajectory, $\mathbf{X}'(t)$, is also MVN at any time. This means that, generally, the PDF of $\mathbf{X}'(t)$ satisfies the Focker–Planck equation and the expected concentration satisfies the classical convection dispersion equation. Furthermore, under ergodic conditions, the one-particle trajectory statistical moments eqn [18], can be equated with those of the spatial moments of the resident concentration, $c(\mathbf{x};t)$ (defined as the mass of the solute per unit volume of aqueous solution) of a plume. For a passive solute which lies at $t = 0$, within a finite volume V_0, the ith coordinate of the centroid of the solute plume, $X_i^e(t)$, and the

moment of inertia of the plume with respect to the x_i-axis, $X^e_{ii}(t)$ $(i=1,2,3)$, are:

$$X^e_i(t) = M^1_i(t) = <X_i(t)> + \frac{C_s X'_i(t)}{S} \qquad [21a]$$

$$X^e_{ii}(t) = \left\{M^2_i(t) - [M^1_i(t)]^2\right\} = X_{ii}(t) - \left[\frac{C_{sX'_i}(t)}{S}\right]^2 \qquad [21b]$$

where $M^N_1(t)$, $N=1$, 2, are the first and the second normalized spatial moments of the distribution of $c(\mathbf{x};t)$ in the ith coordinate, $<X_i(t)>$ and $X_{ii}(t)$ are the principal components of eqns [18a] and [18b], respectively, and $C_{sXi}(t) = <X_i(t)s(0)>$ is the cross-covariance between perturbations of the ith component of $\mathbf{X}'$ and water saturation, Θ.

It is clear from eqn [21] that, because Θ is spatially variable, the velocity $\mathbf{u}'(\mathbf{x}) = \mathbf{q}'(\mathbf{x})/\phi\Theta(\mathbf{x})$ is not divergence-free, i.e., $\mathrm{div}[\mathbf{u}'(\mathbf{x})] \neq 0$. Consequently, $X^e_i(t)$ differs from $<X_i(t)>$ by the correction factor $C_{sXi}(t)/S$. This implies time dependence of the effective solute velocity, $v^e_i = \mathrm{d}(X^e_i)/\mathrm{d}t = U_i + C_{sui}(\mathbf{U}t)/S$, where $C_{sui}(\boldsymbol{\xi}) = <u_i(\mathbf{U}\tau)s(0)>$ $(i=1,2,3)$ is the cross-covariance between perturbations of the ith component of the Eulerian velocity vector, $\mathbf{u}'$ and water saturation Θ, given by:

$$C_{su_i}(\boldsymbol{\xi}) = \frac{K_g}{\phi S^2}\left[-\delta_{1i}C_{ss}(\boldsymbol{\xi}) + \delta_{1i}SC_{sy}(\boldsymbol{\xi}) - S\frac{\partial C_{sh}(\boldsymbol{\xi})}{\partial \xi_i}\right] \qquad [22]$$

On the other hand, if the second term on the RHS of eqn [21*b*] is regarded as a second-order term which can be neglected as a part of the first-order approximation, then $X^e_{ii}(t)$ and the effective macrodispersion, $D^e_{ii}(t) = (1/2)\mathrm{d}[X^e_{ii}(t)]/\mathrm{d}t$ are not affected by the fact that $\mathrm{div}[\mathbf{u}'(\mathbf{x})] \neq 0$, and are identical to their counterparts, $X_{ii}(t)$ and $D_{ii}(t)$, the principal components of eqns [18b] and [23] below, respectively.

Note that, from a physical point of view, the ratios $X_{ij}(t)/2t$ $(i,j=1,2,3)$ may be regarded as apparent dispersion coefficients, that, for $t\to\infty$, tend to the macrodispersion tensor, $D_{ij}(t)$, $(i,j=1,2,3)$ given by:

$$D_{ij}(t) = \frac{1}{2}\frac{\mathrm{d}X_{ij}(t)}{\mathrm{d}t} = \int_0^t C_{u_{ij}}(\mathbf{U}\tau)\mathrm{d}\tau \quad (i,j=1,2,3) \qquad [23]$$

In the case of the velocity covariance tensor eqn [19], the first term on the RHS of eqn [19] depends only on the variability of the water saturation, Θ, while the second term on the RHS of eqn [19] depends only on the variability of the water flux, $\mathbf{q}$. The third term on the RHS of eqn [19] represents the effect on the velocity of the interaction between the Θ and the $\mathbf{q}$ heterogeneities. Inasmuch as the term $\delta_{1i}\delta_{1j}[C_{sy}(\boldsymbol{\xi}) + C_{sy}(-\boldsymbol{\xi})]$ is negative and $|\delta_{1i}\delta_{1j}[C_{sy}(\boldsymbol{\xi}) + C_{sy}(-\boldsymbol{\xi})]| > -\delta_{1j}[\partial C_{sh}(\boldsymbol{\xi})/\partial\xi_i] + \delta_{1i}[\partial C_{sh}(-\boldsymbol{\xi})/\partial\xi_j]$, all three terms on the RHS of eqn [19] contribute to the variability in velocity, and, concurrently, to macrodispersion (eqn [23]). Note that when the mean flow is aligned with the x_1-axis only, i.e., $\mathbf{J} = (J_1,0,0)$, the first and third terms on the RHS of eqn [19] vanish for $i=j=2$ or 3. In other words, in this case the transverse components of the velocity covariance tensor (eqn [19]) and, concurrently, those of the macrodispersion tensor (eqn [23]), are independent of the spatial variability of Θ and are only influenced by its mean value, $S = <\Theta(\mathbf{x})>$. Note also that when the formation is saturated (i.e., when $H\to 0$ and $S\to 1$), and when Γ approaches its small limit, $\Gamma\to 0$, the first and third terms on the RHS of eqn [19] vanish; consequently, eqn [19] and, concurrently, eqn [23] reduce to their counterparts associated with steady flow in saturated, three-dimensional heterogeneous formations.

Scaled forms of the principal components of eqn [23], $D'_{ii} = \phi S D_{ii}/Q\sigma^2_y I_{yv}$, $(i=1$ to $3)$, are presented graphically in **Figure 3**, as functions of the scaled travel time, $t' = tQ/\phi S I_{yv}$, for selected values of mean water saturation, S, and the length-scales ratios, $\rho = I_h/I_v$ and $\eta = \lambda/I_v$. Note that because of the assumption of axisymmetric anisotropy, and for $J_2 = J_3 = 0$, $D'_{22}(t) = D'_{33}(t)$. **Figure 3** suggests that the longitudinal component of the scaled dispersion tensor is much larger than its transverse components, particularly in formations in which $\rho \leq 1$. Note that for $\mathbf{J} = (J_1,0,0)$, because of the first and the third terms on the RHS of eqn [19], D'_{11} is saturation-dependent, while $D'_{ii}(i=2,3)$ are not.

The behavior of the principal components of eqn [23] demonstrates the combined influence of the formation heterogeneity, the capillary forces and water saturation on solute spreading under unsaturated flow. This arises directly from their effects on the velocity covariance (eqn [19]). For given $\nu = \sigma^2_a/\sigma^2_f$, S, ρ, and η, and when $\mathbf{J} = (J_1,0,0)$, the time behavior of $D'_{ii}(i=1,2,3)$ describes a continuous transition from a non-Ficksian to a Ficksian regime, i.e., they grow monotonously and linearly with t' at small t' $(t' \ll 1)$. As t' increases, however, the behavior of D'_{ii} $(i=2,3)$ is completely different from that of D'_{11}. The latter is a monotonically increasing function of t', approaching a constant value at the large t' limit, $t'\to\infty$, while $D'_{ii}(i=2,3)$ are nonmonotonic functions of t', vanishing at the large t' limit.

Figure 3 suggests that in unsaturated flow, solute spreading is expected to increase with diminishing

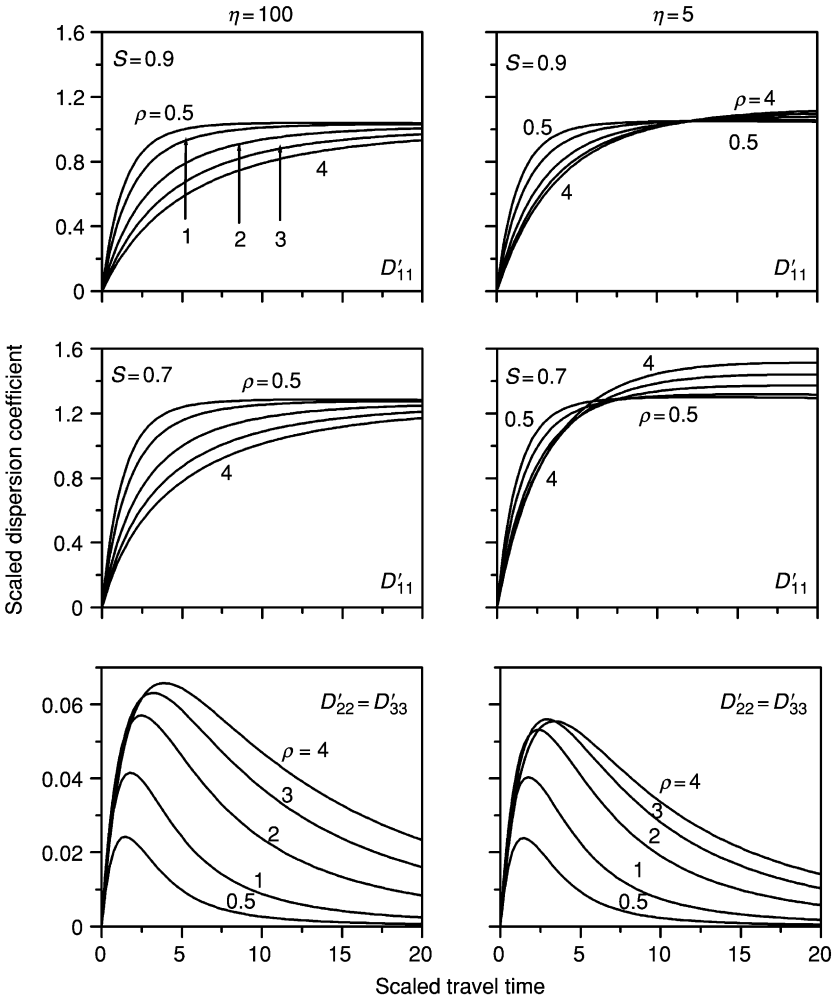

Figure 3 Principal components of the scaled macrodispersion coefficient tensor, D'_{i1}, $i=(1,2,3)$, as a function of the scaled travel time, t', for selected values of $\rho = I_h/I_v$ (the numbers labeling the curves), for various values of mean water saturation, S and $\eta = \lambda/I_v$, and for $\nu = \sigma_a^2/\sigma_f^2 = 0.2$, $\sigma_f^2 = 0.5$, $\sigma_{fa}^2 = 0$, $I_{yv} = 0.2$m, $Q/\phi S = 1$m day^{-1}, and $J=(1,0,0)$. Note that D'_{ii} ($i=(2,3)$) are independent of S.

water saturation. This is particularly so when the variances ratio, $\nu = \sigma_a^2/\sigma_f^2$, increases. Increasing stratification is expected to enhance solute spreading in the transverse directions in formations of both fine-textured and, especially, coarse-textured soil materials. On the other hand, increasing stratification is expected to reduce solute spreading in the longitudinal direction in formations of relatively fine-textured soil materials. In formations of relatively coarse-textured soil material, however, at a relatively small distance traveled, increasing stratification is expected to diminish solute spreading in the longitudinal direction while the converse is true when the travel distance exceeds a few log$K$ correlation length-scales. Furthermore, the travel distance required for the principal components of the macrodispersion tensor to approach their asymptotic values may be exceedingly large, particularly in relatively wet formations with significant stratification and with coarse-textured soil material that is associated with small capillary forces. Hence, in many practical situations of vadose-zone transport, the typical travel distance may be small compared with the travel distance required for the solute plume to reach its asymptotic, Ficksian behavior.

Summary

Before concluding, it is worthwhile emphasizing the limitations of the approach presented here. One limitation is due to the small-perturbation, first-order approximations of the velocity and the displacement covariance tensors, as a consequence of which the results are formally limited to formations with σ_y^2

smaller than unity. Other limitations stem from the fact that the calculations, which rely upon the assumption of ergodicity, are also restricted to conditions of constant mean-head gradient. The assumptions regarding the spatial structure of the formation (exponential covariance with axisymmetric anisotropy), the statistics of the relevant formation properties, and the flow-controlled attributes (statistically homogeneous), the local flow regime (steady-state flow), the local constitutive relationships for unsaturated flow (Gardner–Russo model), and the transport (Lagrangian stationarity, the neglect of both the fluctuations of the particle displacement about the mean trajectory and pore-scale dispersion), might also limit the applicability of the results of this approach. Nevertheless, the results of the first-order perturbation analysis are sufficiently reliable to indicate appropriate trends.

Most of the stringent assumptions of the first-order perturbation approach may be relaxed by using a numerical approach, which, in general, combines a statistical generation method that produces realizations of the heterogeneous formation properties in sufficient resolution, with an efficient numerical method to solve the partial differential equations that govern flow and transport in heterogeneous, variably saturated formations. However, the complexity and high degree of nonlinearity of such flow, compounded by the serious numerical problems which may be encountered when dealing with steep, spatial-head gradients, and the requirement that grid blocks must be much smaller than the length scale of the heterogeneity, all lead to a numerical problem of extreme difficulty which might demand a formidable computational capacity. This might substantially limit the capability of the numerical approach to solve flow and transport problems on a large, field scale.

List of Technical Nomenclature

$\boldsymbol{\alpha}$	Gardner–Russo parameter (m^{-1})
$\boldsymbol{\Gamma}$	Geometric mean of α (m^{-1})
$\boldsymbol{\delta}$	Kronecker delta (dimensionless)
$\boldsymbol{\eta} = \boldsymbol{\lambda}/I_{yv}$	Scale ratio (dimensionless)
$\boldsymbol{\Upsilon}$	Water saturation (dimensionless)
$\boldsymbol{\lambda}$	Macroscopic capillary length scale (m)
$\boldsymbol{\nu} = \boldsymbol{\sigma}_a^2/\boldsymbol{\sigma}_f^2$	Variance ratio (dimensionless)
$\boldsymbol{\xi}$	Separation distance vector (m)
$\boldsymbol{\xi}'$	Scaled separation distance vector (dimensionless)
$\boldsymbol{\rho} = I_h/I_v$	Length-scale ratio (dimensionless)
$\boldsymbol{\sigma}_p^2$	Variance of p' (units of p'^2)
$\boldsymbol{\tau}$	Dummy variable of integration (s)
$\boldsymbol{v}^e$	Effective solute velocity vector (ms^{-1})
$\boldsymbol{\phi}$	Porosity ($m^3\,m^{-3}$)
$\boldsymbol{\varphi}$	Hydraulic head (m)
$\boldsymbol{\psi}$	Pressure head (m)
$\mathbf{a}$	Coordinate vector of a point in V_0 (m)
a	A perturbation and mean of $\log\alpha$ (dimensionless)
$B = (1/4)\Gamma^2 H$	$\exp[-(1/2)\Gamma H]$ (m^{-1})
c	Resident concentration ($kg\,m^{-3}$)
$\mathbf{C}_{mn}$	(Cross-)covariance between perturbations m and n (units of $m \times n$)
$\hat{\mathbf{C}}_{mn}$	(Cross-)spectra between perturbations m and n (units of $m \times n$)
$\mathbf{C}_{q_{ij}}$	Flux covariance tensor ($m^2\,s^{-2}$)
$\mathbf{C}_{u_{ij}}$	Velocity covariance tensor ($m^2\,s^{-2}$)
$\mathbf{D}$	Macrodispersion tensor ($m^2\,s^{-2}$)
$\mathbf{D}'$	Scaled macrodispersion tensor (dimensionless)
D_{ii}^e	ith component of effective macrodispersion ($m^2\,s^{-1}$)
f, F	Perturbation and mean of $\log K_s$ (dimensionless)
h, H	Perturbation and mean of ψ (m)
$\mathbf{I}_p$	Correlation scale of p'(m)
I_v, I_h	Vertical and horizontal components of $\mathbf{I}_p$(m)
I_{yv}	Vertical correlation scale of $\log K$(m)
$\mathbf{J}$	Mean head-gradient vector (mm^{-1})
j'	The imaginary unit (dimensionless)
K	Unsaturated conductivity (ms^{-1})
K_g	Geometric mean of K (ms^{-1})
K_s	Saturated conductivity (ms^{-1})
$\mathbf{k}$	Wave number vector (m^{-1})
M_i^N	Nth normalized spatial moment in the ith coordinate (m^N)
$m = a, f, h, s$	(Units of a, f, h, or s)
m'	Parameter (eqn [2b]) (dimensionless)

$n = a, f, h, s$	(Units of a, f, h, or s)
$p' = f$ or a	(Dimensionless)
$p^* = f$, a, or fa	(Dimensionless)
$\mathbf{q}$, $\mathbf{Q}$	Perturbation and mean of $\mathbf{q}'$ (ms^{-1})
$\mathbf{q}'$	Water flux vector (ms^{-1})
q'_{ij}	Scaled flux covariance tensor (dimensionless)
s, S	Perturbation and mean of water saturation (dimensionless)
t	Time (s)
t'	Scaled value of t (dimensionless)
$\mathbf{u}$, $\mathbf{U}$	Perturbation and mean of $\mathbf{u}'$ (ms^{-1})
$\mathbf{u}'$	Eulerian velocity vector (ms^{-1})
V_0	Initial volume of the solute body (m^3)
$\mathbf{X}'$	Particle displacement vector (m)
X_{ij}	Particle displacement covariance tensor (m^2)
X_i^e	ith coordinate of the centroid of the solute plume (m)
X_{ii}^e	Moment of inertia of the plume with respect to the x_i-axis (m^2)
$\mathbf{x}$	Spatial coordinate vector (m)
$<\mathbf{X}>$ $\mathbf{X}$	Mean and perturbation of $\mathbf{X}'$ (m)
y, Y	Perturbation and mean of log$K$ (dimensionless)

STRESS–STRAIN AND SOIL STRENGTH

S K Upadhyaya, University of California–Davis, Davis, CA, USA

Concept of Stress

The concept of stress is the most fundamental concept of continuum mechanics and elasticity theory. When a body is subjected to external forces, it experiences deformation (strain) and stress. Consider a rectangular, parallelepiped-shaped volume element, ABCDEFGH, oriented such that its face BCGF is perpendicular to the X_1 axis; the face CDHG is perpendicular to the X_2 axis; EFGH is perpendicular to the X_3 axis; and where $X_1X_2X_3$ represents a right-handed Cartesian coordinate system such that the X_3 axis is vertical (Figure 1). Let ΔF_1, ΔF_2, and ΔF_3 respectively represent forces acting on these surfaces. Then the force per unit area acting on these surfaces (i.e., T_1, T_2, and T_3, respectively) as the size of the surface shrinks to zero can be represented by:

$$T_1 = \Delta F_1/(\Delta_2\Delta_3) \qquad [1a]$$

$$T_2 = \Delta F_2/(\Delta_1\Delta_3) \qquad [1b]$$

$$T_3 = \Delta F_3/(\Delta_1\Delta_2) \qquad [1c]$$

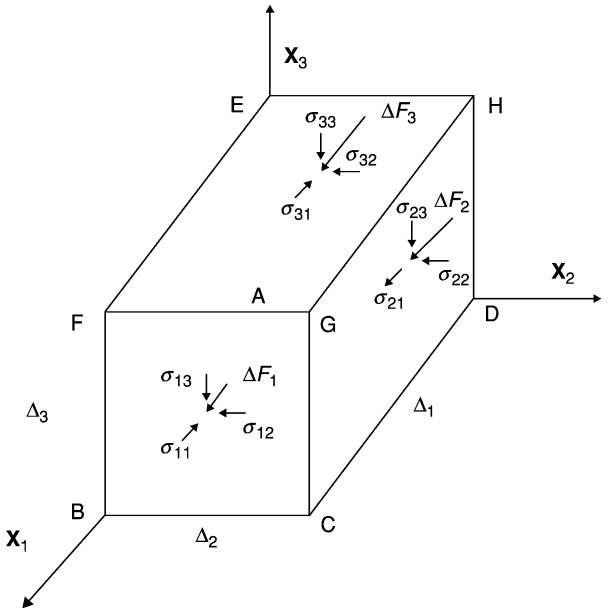

Figure 1 Components of a stress tensor.

in the limit Δ_1, Δ_2, and Δ_3 approach zero. In Eqns [1a]–[1c], Δ_1, Δ_2, Δ_3 are the linear dimensions of the volume element in X_1, X_2, and X_3 directions, respectively.

These three vectors can be decomposed along the coordinate axis as follows:

$$T_1 = \sigma_{11}\mathbf{i}_1 + \sigma_{12}\mathbf{i}_2 + \sigma_{13}\mathbf{i}_3 \qquad [2a]$$

$$T_2 = \sigma_{21}\mathbf{i}_1 + \sigma_{22}\mathbf{i}_2 + \sigma_{23}\mathbf{i}_3 \qquad [2b]$$

$$T_3 = \sigma_{31}\mathbf{i}_1 + \sigma_{32}\mathbf{i}_2 + \sigma_{33}\mathbf{i}_3 \qquad [2c]$$

where $\mathbf{i}_1$, $\mathbf{i}_2$, and $\mathbf{i}_3$ are unit vectors along the coordinate axes X_1, X_2, and X_3, respectively. The components of these stress vectors T_1, T_2, and T_3, form the elements of the stress tensor $[\boldsymbol{\sigma}]$, which is written as:

$$[\boldsymbol{\sigma}] = \begin{bmatrix} \sigma_{11} & \sigma_{12} & \sigma_{13} \\ \sigma_{21} & \sigma_{22} & \sigma_{23} \\ \sigma_{31} & \sigma_{32} & \sigma_{33} \end{bmatrix} \qquad [3]$$

The diagonal terms of this stress tensor are known as 'normal stresses' and the off-diagonal terms are known as 'shear stresses.' Figure 1 shows the various components of the stress tensor. As is usual in soil mechanics, compression is considered to be positive. Moreover, the subscripts of stress tensor component $\boldsymbol{\sigma}_{ij}$ are chosen so that the first subscript, 'i,' indicates the direction of the surface normal on which the stress component acts and the second subscript, 'j,' indicates the direction along which the stress component is directed. Thus σ_{13} indicates that this stress component acts on the surface whose normal is along the X_1 axis (i.e., BCGF) and σ_{13} is directed in the X_3 direction. In the absence of body couples, $\sigma_{ij} = \sigma_{ji}$, thus making the stress tensor symmetric. (Body couples, or distributed moments within the body, arise from the action of an electric field on polarized matter or the action of a magnetic field on magnetized particles. Such couples are not a concern in most mechanics problems and are ignored here.)

The first invariant of the stress tensor (the sum of the diagonal terms or the trace of the stress tensor, which does not change under a coordinate transformation) is related to the hydrostatic, spherical, or octahedral normal stress. It is given by:

$$J_1 = \mathrm{tr}(\sigma) = \sigma_{11} + \sigma_{22} + \sigma_{33} = 3\sigma_h = 3\sigma_{oct} \qquad [4]$$

where J_1 is the first invariant of the stress tensor, σ_h is the hydrostatic stress, and σ_{oct} is the mean octahedral normal stress. Mean pressure or bulk stress, p, is given by the mean of the diagonal elements, i.e.:

$$p = \sigma_h = \sigma_{oct} \quad [5]$$

The stress tensor can be decomposed into two parts in the following manner:

$$\begin{bmatrix} \sigma_{11} & \sigma_{12} & \sigma_{13} \\ \sigma_{21} & \sigma_{22} & \sigma_{23} \\ \sigma_{31} & \sigma_{32} & \sigma_{33} \end{bmatrix} = \begin{bmatrix} p & 0 & 0 \\ 0 & p & 0 \\ 0 & 0 & p \end{bmatrix} + \begin{bmatrix} \sigma_{11}-p & \sigma_{12} & \sigma_{13} \\ \sigma_{21} & \sigma_{22}-p & \sigma_{23} \\ \sigma_{31} & \sigma_{32} & \sigma_{33}-p \end{bmatrix} \quad [6]$$

The first tensor on the right-hand side is known as the 'hydrostatic' or 'spherical stress tensor,' and the second tensor is known as the 'deviatoric stress tensor' [S]. The second invariant of the stress tensor is related to the octahedral shear stress, τ_{oct}, and is given by:

$$J_{2D} = 1/6[(\sigma_{11}-\sigma_{22})^2 + (\sigma_{22}-\sigma_{33})^2 + (\sigma_{33}-\sigma_{11})^2] + \sigma_{12}^2 + \sigma_{23}^2 + \sigma_{13}^2 \quad [7]$$

where we have utilized the fact that the stress tensor is symmetric. The relation between octahedral shear stress, τ_{oct}, and J_{2D} is given by:

$$\tau_{oct} = [2/3\, J_{2D}]^{1/2} \quad [8]$$

This second invariant of the deviatoric stress tensor or the related quantity τ_{oct} plays an important role in describing the yield behavior in soil mechanics. In some cases the third invariant of the deviatoric stress tensor is also used to represent the yield behavior, such as in the extended Drucker–Prager yield criteria.

Principal Stress

For the symmetric version of the stress tensor $[\boldsymbol{\sigma}]$ given in Eqn [3], which is associated with the coordinate system shown in Figure 1, it is always possible to locate a set of mutually orthogonal planes along which all shear stress components will be zero, leaving only the normal components of the stress tensor. These normal components of stress tensor are known as principal stresses, the planes are called principal planes, and the normal vectors associated with these planes are known as principal axes or directions. If the principal axes are taken as the reference axes, then the stress tensor given in Eqn [3] becomes:

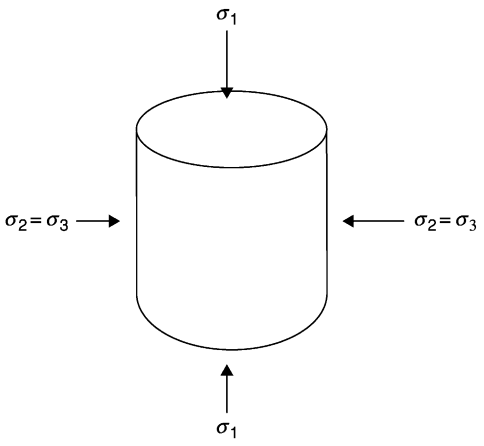

Figure 2 Cylindrical state of stress in soil mass.

$$[\boldsymbol{\sigma}] = \begin{bmatrix} \sigma_1 & 0 & 0 \\ 0 & \sigma_2 & 0 \\ 0 & 0 & \sigma_3 \end{bmatrix} \quad [9]$$

where σ_1, σ_2, and σ_3 are known as 'principal stresses.' The largest (in magnitude) of the principal stresses is known as the 'major principal stress,' the smallest one is known as the 'minor principal stress,' and the other one is known as the 'intermediate principal stress.' In terms of principal stresses, the second invariant of stress tensor and τ_{oct} become:

$$J_{2D} = 1/6[(\sigma_1-\sigma_2)^2 + (\sigma_2-\sigma_3)^2 + (\sigma_3-\sigma_1)^2] \quad [10]$$

For example, consider a cylindrical body of soil under a triaxial loading situation, as shown in Figure 2. For this case, σ_1, and $\sigma_2 = \sigma_3$ are the principal stresses. This example will be used throughout this discussion. The mean hydrostatic stress and the octahedral shear stress are given by:

$$p = (\sigma_1 + 2\sigma_3)/3 \quad [11]$$

$$\tau_{oct} = \left(\frac{2}{3}J_{2D}\right)^{1/2} = \frac{\sqrt{2}}{3}(\sigma_1 - \sigma_3) \quad [12]$$

In soil plasticity theory, often the deviator stress $q = (\sigma_1 - \sigma_3) = (3J_{2D})^{1/2}$ is used to describe shear behavior, and mean hydrostatic pressure, p, is used to describe volumetric compression.

Effective Stress

In soil mechanics usually effective stress rather than the total stress is used in constitutive relationships. For saturated soils, effective hydrostatic pressure, p_{eff}, is defined as the difference between the total

hydrostatic stress, p_t, minus the pore-water pressure, u_w (i.e., $p = p_{eff} = p_t - u_w$). For unsaturated soils the effective pressure is a function of soil suction or soil-moisture tension. The effective stress in unsaturated soils may be represented by:

$$p_{eff} = p_t - u_a + \chi(u_a - u_w) \qquad [13]$$

where u_a is pore air pressure and χ depends on water content. Often it is taken as a fraction of unit cross-sectional area of soil occupied by water. However, this is problematic from a continuum mechanics and thermodynamic point of view. There is a need to treat unsaturated soil as a four-phase medium consisting of air, soil particles, water, and 'contractile skin' which separates air from water. Instead of using a single effective stress as given in Eqn [13] to define the stress state of soil, it is possible to use two different stress-state variables: net stress $(p_t - u_a)$ and matric suction $(u_a - u_w)$. The additional stress-state variable, matrix suction, is related to soil-moisture content through the soil-water release characteristic, which is regarded as an important constitutive function.

A total stress approach has been used to determine critical state parameters for unsaturated, agricultural soils. This method is acceptable as long as it is recognized that the material parameters are treated as a function of soil-moisture content. Unsaturated agricultural soils can be modeled in terms of total stress as long as the effect of unsaturated conditions is duly recognized. Thus the effective hydrostatic pressure, p_{eff} (i.e., $p = p_{eff}$), is used for saturated soil, and total pressure, p_t (i.e., $p = p_t$), is used for unsaturated soil.

Concept of Strain

When a body is subjected to external forces, it experiences deformation. The ratios of these deformations to the respective original dimensions are known as 'strain.' Thus, if a slender rod of length L is subjected to a uniaxial compressive load, its length will decrease, leading to a compressive strain of $\epsilon_a = u/L$, where u is the decrease in length (Figure 3). This is known as the 'Cauchy strain.'

This concept can be easily extended to three dimensions. Just as in the case of stress, it is possible to represent the strain experienced by any body under the generalized external forces in terms of a strain tensor, $[\boldsymbol{\epsilon}]$ as follows:

$$[\boldsymbol{\epsilon}] = \begin{bmatrix} \epsilon_{11} & \epsilon_{12} & \epsilon_{13} \\ \epsilon_{21} & \epsilon_{22} & \epsilon_{23} \\ \epsilon_{31} & \epsilon_{32} & \epsilon_{33} \end{bmatrix} \qquad [14]$$

where each ϵ_{ij} is known as a normal strain if $i = j$ and known as a shear strain if $i \neq j$. If there are no body

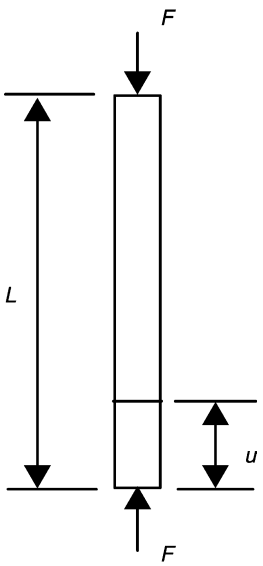

Figure 3 A slender rod under compressive axial strain.

moments, then $\epsilon_{ij} = \epsilon_{ji}$. This gives six strain components for a three-dimensional case. The subscripts 'i' and 'j' have the same implications as they did in the case of the stress tensor described above. If strain levels are small, these strain components can be expressed as:

$$\epsilon_{11} = \frac{\partial u_1}{\partial x_1}; \quad \epsilon_{22} = \frac{\partial u_2}{\partial x_2}; \quad \epsilon_{33} = \frac{\partial u_3}{\partial x_3}$$
$$\epsilon_{12} = \frac{1}{2}\left(\frac{\partial u_1}{\partial x_2} + \frac{\partial u_2}{\partial x_1}\right); \quad \epsilon_{13} = \frac{1}{2}\left(\frac{\partial u_1}{\partial x_3} + \frac{\partial u_3}{\partial x_1}\right);$$
$$\epsilon_{23} = \frac{1}{2}\left(\frac{\partial u_3}{\partial x_2} + \frac{\partial u_2}{\partial x_3}\right) \qquad [15]$$

where u_1, u_2, and u_3 and deformations of the body along three mutually orthogonal, rectangular coordinate system axes such as those in Figure 1. It is a common practice in engineering to use engineering shear strains, γ_{ij}, which are related to ϵ_{ij} as follows:

$$\gamma_{ij} = 2\epsilon_{ij} \qquad [16]$$

The first invariant of the strain tensor, $I_1 = \text{tr}\ (\epsilon) = \epsilon_1 + \epsilon_2 + \epsilon_3 = \epsilon_v$, is known as the 'volumetric strain.' Just as in the case of stress tensor, it is possible to decompose the strain tensor into two parts as follows:

$$\begin{bmatrix} \epsilon_{11} & \epsilon_{12} & \epsilon_{13} \\ \epsilon_{21} & \epsilon_{22} & \epsilon_{23} \\ \epsilon_{31} & \epsilon_{32} & \epsilon_{33} \end{bmatrix} = \begin{bmatrix} \epsilon_v/3 & 0 & 0 \\ 0 & \epsilon_v/3 & 0 \\ 0 & 0 & \epsilon_v/3 \end{bmatrix} + \begin{bmatrix} \epsilon_{11} - \epsilon_v/3 & \epsilon_{12} & \epsilon_{13} \\ \epsilon_{21} & \epsilon_{22} - \epsilon_v/3 & \epsilon_{23} \\ \epsilon_{31} & \epsilon_{32} & \epsilon_{33} - \epsilon_v/3 \end{bmatrix} \qquad [17]$$

The first tensor on the right-hand side is the volumetric strain tensor and the second one is the deviatoric strain tensor. The second invariant of the strain tensor, I_{2D}, is of particular interest and is given by:

$$I_{2D} = 1/6[(\epsilon_{11} - \epsilon_{22})^2 + (\epsilon_{22} - \epsilon_{33})^2 + (\epsilon_{33} - \epsilon_{11})^2] + \epsilon_{12}^2 + \epsilon_{23}^2 + \epsilon_{13}^2 \quad [18]$$

In engineering practice, a closely related term, 'octahedral shear strain,' is used and is given by:

$$\gamma_{oct} = \left[\frac{2}{3} I_{2D}\right]^{\frac{1}{2}} \quad [19]$$

Principal Strain

For the symmetric version of the strain tensor given in Eqn [14], which is represented in the $X_1X_2X_3$ coordinate system, it is always possible to find a set of three mutually perpendicular planes along which all shear-strain components will be zero. The directions normal to these planes are known as principal strain axes. In terms of the principal strains, the strain tensor reduces to:

$$[\boldsymbol{\epsilon}] = \begin{bmatrix} \epsilon_1 & 0 & 0 \\ 0 & \epsilon_2 & 0 \\ 0 & 0 & \epsilon_3 \end{bmatrix} \quad [20]$$

where ϵ_1, ϵ_2, and ϵ_3 are principal strains. In terms of these principal strains, the second invariant of the deviatoric strain reduces to:

$$I_{2D} = 1/6[(\epsilon_1 - \epsilon_2)^2 + (\epsilon_2 - \epsilon_3)^2 + (\epsilon_3 - \epsilon_1)^2] \quad [21]$$

For the example problem, shown in Figure 2, $\epsilon_2 = \epsilon_3$. Under these conditions, the volumetric strain becomes:

$$\epsilon_v = \epsilon_1 + 2\epsilon_3 \quad [22]$$

and the octahedral shear strain becomes:

$$\gamma_{oct} = \left[\frac{2}{3} I_{2D}\right]^{\frac{1}{2}} = \frac{\sqrt{2}}{3}(\epsilon_1 - \epsilon_3) \quad [23]$$

In soil plasticity, ϵ_v and ϵ_s (the latter of which is given by $2/3\ (\epsilon_1 - \epsilon_3) = \sqrt{2}\gamma_{oct}$) are often used to represent soil behavior.

Void Ratio and Volumetric Strain

Often volumetric strain is represented in terms of changes in void ratio, e, which is defined as the ratio of total pore space to the total volume of individual solid particles, i.e.:

$$e = \frac{V_0}{V_s} \quad [24a]$$

where V_0 is the total volume of voids and V_s is the total volume of solid particles. The volumetric strain ϵ_v is related to the changes in the void ratio by the following equation:

$$d\epsilon_v = -\frac{de}{1 + e_i} \quad [24b]$$

where e_i is the initial void ratio. Note that the negative sign in Eqn [24b] is owing to the sign convention that treats compressive strain as positive.

Constitutive Laws

The constitutive law has been defined as a general functional relationship between stress, strain, and their rates, i.e.:

$$f(\sigma, \dot{\sigma}, \epsilon, \dot{\epsilon}) = 0 \quad [25]$$

where $\dot{\sigma}$ and $\dot{\epsilon}$ represent stress and strain rates, respectively. For static equilibrium conditions, the most general linear relationship between stress and strain tensors takes the following form:

$$[\boldsymbol{\sigma}] = [\mathrm{C}][\boldsymbol{\epsilon}] \quad [26]$$

where [C] is a fourth-order tensor, known as 'material property tensor,' since it relates two second-order tensors. For homogeneous, elastic material, the material property tensor consists of 81 elements. However, symmetry of stress and strain tensors, and strain energy considerations reduce the number of independent constants required to 21. If this discussion is limited to isotropic elastic materials, only two independent material constants are required to relate stress and strain. The Young modulus, E, and Poisson ratio, ν, are usually selected as material properties to represent elastic isotropic behavior. With reference to Figure 4a, which shows a rod under uniaxial loading, the following are definitions for the Young modulus and Poisson ratio:

$$E = \frac{\sigma_1}{\epsilon_1} \quad [27a]$$

$$\nu = -\frac{\epsilon_3}{\epsilon_1} \quad [27b]$$

Now consider a component under a general state of stress. If we consider the principal stress and strain as shown in Figure 4b, then the strain component ϵ_1 is caused by the direct stress, σ_1, as well as two transverse stress σ_2 and σ_3 due to the Poisson effect. Similar arguments hold for strain components ϵ_2 and ϵ_3.

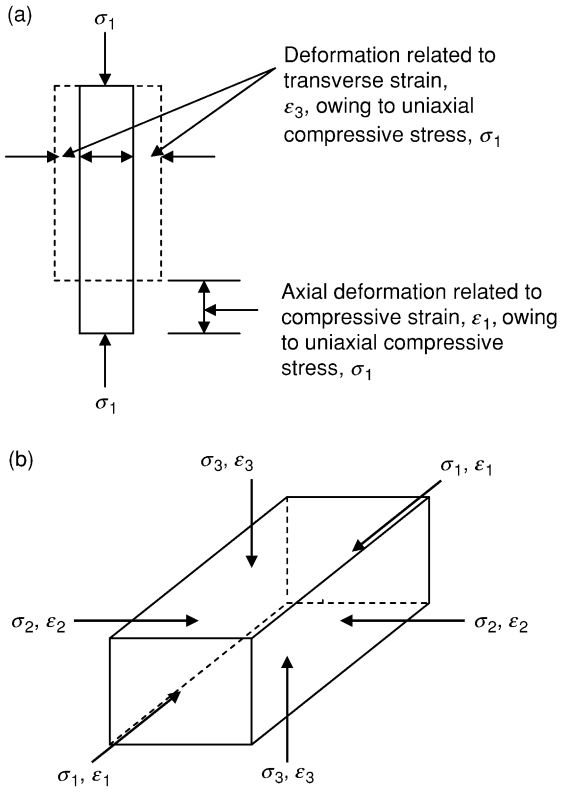

Figure 4 Behavior of (a) a rod under uniaxial loading and (b) a prismatic member under general loading.

Therefore:

$$\epsilon_1 = \frac{1}{E}\sigma_1 - \frac{\nu}{E}\sigma_2 - \frac{\nu}{E}\sigma_3 \qquad [28a]$$

$$\epsilon_2 = \frac{1}{E}\sigma_2 - \frac{\nu}{E}\sigma_3 - \frac{\nu}{E}\sigma_1 \qquad [28b]$$

$$\epsilon_3 = \frac{1}{E}\sigma_3 - \frac{\nu}{E}\sigma_1 - \frac{\nu}{E}\sigma_2 \qquad [28c]$$

Moreover, summing Eqns [28a]–[28c]:

$$\epsilon_1 + \epsilon_2 + \epsilon_3 = \epsilon_v = \frac{(1-2\nu)}{E}(\sigma_1 + \sigma_2 + \sigma_3) = \frac{3(1-2\nu)}{E}p \qquad [29]$$

where $\epsilon_v = \epsilon_1 + \epsilon_2 + \epsilon_3$ is the volumetric strain and $p = (\sigma_1 + \sigma_2 + \sigma_3)/3$ has been substituted (see Eqns [4] and [5]). Alternately Eqn [29] can be written as:

$$p = \frac{E}{3(1-2\nu)}\epsilon_v = K\epsilon_v \qquad [30]$$

where $K = E/3(1-2\nu)$ is known as the 'elastic bulk modulus.'

It is always true for an axisymmetric case such as cylindrical loading that $\sigma_2 = \sigma_3$. Subtracting Eqn [28c] from [28a]:

$$\epsilon_1 - \epsilon_3 = \frac{1+\nu}{E}(\sigma_1 - \sigma_3) \qquad [31a]$$

As mentioned earlier, $\epsilon_1 - \epsilon_3 = 2/3\ \epsilon_s$ and $\sigma_1 - \sigma_3 = q$. Therefore, Eqn [31a] becomes:

$$q = 3\left\{\frac{E}{2(1+\nu)}\right\}\epsilon_s = 3G \cdot \epsilon_s \qquad [31b]$$

where $G = E/2(1+\nu)$ is the shear modulus.

In soil mechanics, elastic bulk modulus, K, and shear modulus, G, are usually chosen as material parameters. If the symmetric properties of stress and strain tensors are utilized, Eqn [26] can be rewritten in terms of material parameters, K and G, as:

$$\begin{Bmatrix}\sigma_{11}\\ \sigma_{22}\\ \sigma_{33}\\ \sigma_{12}\\ \sigma_{23}\\ \sigma_{13}\end{Bmatrix} = \begin{bmatrix} K+\frac{4G}{3} & K-\frac{2G}{3} & K-\frac{2G}{3} & 0 & 0 & 0\\ K-\frac{2G}{3} & K+\frac{4G}{3} & K-\frac{2G}{3} & 0 & 0 & 0\\ K-\frac{2G}{3} & K-\frac{2G}{3} & K+\frac{4G}{3} & 0 & 0 & 0\\ 0 & 0 & 0 & 2G & 0 & 0\\ 0 & 0 & 0 & 0 & 2G & 0\\ 0 & 0 & 0 & 0 & 0 & 2G \end{bmatrix} \begin{Bmatrix}\epsilon_{11}\\ \epsilon_{22}\\ \epsilon_{33}\\ \epsilon_{12}\\ \epsilon_{23}\\ \epsilon_{13}\end{Bmatrix} \qquad [32a]$$

Sometimes it is useful to represent strain in terms of stress (i.e., inverse of Eqn [32a]). This inverse relationship is given by Eqn [32b]:

$$\begin{Bmatrix}\epsilon_{11}\\ \epsilon_{22}\\ \epsilon_{33}\\ \epsilon_{12}\\ \epsilon_{23}\\ \epsilon_{13}\end{Bmatrix} = \begin{bmatrix} \frac{1}{3G}+\frac{1}{9K} & \frac{1}{9K}-\frac{1}{6G} & \frac{1}{9K}-\frac{1}{6G} & 0 & 0 & 0\\ \frac{1}{9K}-\frac{1}{6G} & \frac{1}{3G}+\frac{1}{9K} & \frac{1}{9K}-\frac{1}{6G} & 0 & 0 & 0\\ \frac{1}{9K}-\frac{1}{6G} & \frac{1}{9K}-\frac{1}{6G} & \frac{1}{3G}+\frac{1}{9K} & 0 & 0 & 0\\ 0 & 0 & 0 & \frac{1}{2G} & 0 & 0\\ 0 & 0 & 0 & 0 & \frac{1}{2G} & 0\\ 0 & 0 & 0 & 0 & 0 & \frac{1}{2G} \end{bmatrix} \begin{Bmatrix}\sigma_{11}\\ \sigma_{22}\\ \sigma_{33}\\ \sigma_{12}\\ \sigma_{23}\\ \sigma_{13}\end{Bmatrix} \qquad [32b]$$

For the example problem of cylindrical state of stress, Eqns [30] and [31b] apply. These equations can be written in a matrix form as follows:

$$\begin{Bmatrix} p \\ q \end{Bmatrix} = \begin{bmatrix} K & 0 \\ 0 & 3G \end{bmatrix} \begin{Bmatrix} \epsilon_v \\ \epsilon_s \end{Bmatrix} \quad [33a]$$

Alternatively:

$$\begin{Bmatrix} \epsilon_v \\ \epsilon_s \end{Bmatrix} = \begin{bmatrix} \frac{1}{K} & 0 \\ 0 & \frac{1}{3G} \end{bmatrix} \begin{Bmatrix} p \\ q \end{Bmatrix} \quad [33b]$$

From Eqns [33a] and [33b], it is clear that volumetric and shear behavior are completely decoupled.

Material Behavior under Load

Response of a material to external loading can be linear-elastic, nonlinear-elastic, rigid-perfectly plastic, elastic-perfectly plastic, or elastoplastic. Figure 5 shows these responses.

Soil rarely exhibits a linear-elastic behavior (Figure 5a). A nonlinear-elastic constitutive relationship (Figure 5b) can be used to describe soil loading behavior along a particular loading or unloading path with reasonable accuracy. However, it is not a good indicator of soil behavior under wide varieties of loading and unloading conditions (i.e., general loading–unloading conditions). Rigid-perfectly plastic (Figure 5c) and elastic-perfectly plastic (Figure 5d) models are sometimes used in soil analysis, particularly in limit equilibrium analysis. Figure 5e represents a typical metal bar under uniaxial tension. Often, soil exhibits similar behavior under isotropic compression as well as triaxial compression. In the case of metals, when a specimen is loaded in a uniaxial direction, it usually exhibits a linear elastic behavior until the yield point (point A) is reached on its stress–strain curve. After yield it will further deform if loaded to a point B. If the specimen is now unloaded, it will usually follow an unloading path such as BCD. When the load is completely removed, it will not have recovered its original length but will have a permanent deformation or plastic deformation. If this specimen is reloaded, it may follow a path such as DEB, during which the material usually exhibits elastic behavior. At point B it will yield again and follow path BF. Unloading–reloading curves are generally close to each other, and the area under the curve BCDE represents hysterisis loss. Since point B corresponds to a higher stress level than point A, this type of material is often called a 'work-hardening' material. Note that beyond point B, along path BF, both elastic and plastic deformations will occur. If the specimen is unloaded and reloaded at point F it may trace an unloading–reloading curve FGHI similar to the curve BCDE. As mentioned earlier, soil exhibits similar behavior (overconsolidated soil may show a distinct hump) except that it seldom shows linear elastic behavior even when loaded from a stress-free, undeformed state. During unloading–reloading conditions, soil usually exhibits logarithmic (nonlinear) elastic behavior until the yield point is reached.

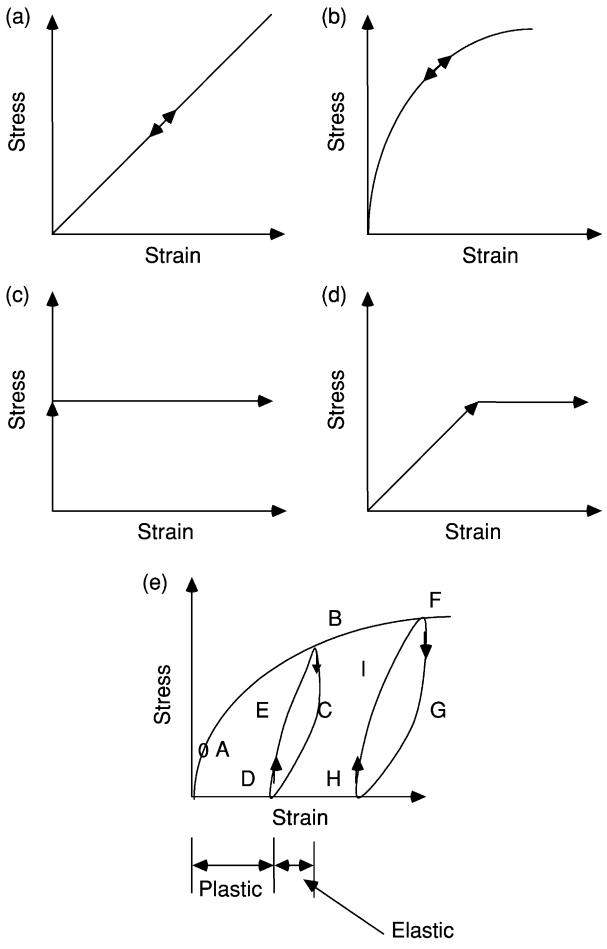

Figure 5 Idealized stress–strain curves for materials: (a) linear-elastic; (b) nonlinear elastic; (c) rigid-perfectly plastic; (d) elastic-perfectly plastic; (e) and elastoplastic behavior.

Nonlinear Elastic Behavior

In principle, it is possible to model the stress–strain behavior of soil using nonlinear elastic models for specific loading paths and conditions. Nonlinearity implies that the elastic parameters are no longer constants but depend on the states of stress and strain of the soil. For these conditions usually an incremental analysis is conducted using tangent moduli values: tangent bulk modulus, K_t, and tangent shear modulus, G_t. Figure 6 shows graphically the significance of tangent moduli. For the case of nonlinear elastic constitutive models, Eqns [32a] and [b] can be written in an incremental form to account for nonlinear behavior as follows:

$$\begin{Bmatrix} d\sigma_{11} \\ d\sigma_{22} \\ d\sigma_{33} \\ d\sigma_{12} \\ d\sigma_{23} \\ d\sigma_{13} \end{Bmatrix} = \begin{bmatrix} K_t + \frac{4G_t}{3} & K_t - \frac{2G_t}{3} & K_t - \frac{2G_t}{3} & 0 & 0 & 0 \\ K_t - \frac{2G_t}{3} & K_t + \frac{4G_t}{3} & K_t + \frac{2G_t}{3} & 0 & 0 & 0 \\ K_t - \frac{2G_t}{3} & K_t - \frac{2G_t}{3} & K_t + \frac{4G_t}{3} & 0 & 0 & 0 \\ 0 & 0 & 0 & 2G_t & 0 & 0 \\ 0 & 0 & 0 & 0 & 2G_t & 0 \\ 0 & 0 & 0 & 0 & 0 & 2G_t \end{bmatrix} \begin{Bmatrix} d\epsilon_{11} \\ d\epsilon_{22} \\ d\epsilon_{33} \\ d\epsilon_{12} \\ d\epsilon_{23} \\ d\epsilon_{13} \end{Bmatrix} \quad [34]$$

and the inverse relationship is given by:

$$\begin{Bmatrix} d\epsilon_{11} \\ d\epsilon_{22} \\ d\epsilon_{33} \\ d\epsilon_{12} \\ d\epsilon_{23} \\ d\epsilon_{13} \end{Bmatrix} = \begin{bmatrix} \frac{1}{3G_t} + \frac{1}{9K_t} & \frac{1}{9K_t} - \frac{1}{6G_t} & \frac{1}{9K_t} - \frac{1}{6G_t} & 0 & 0 & 0 \\ \frac{1}{9K_t} - \frac{1}{6G_t} & \frac{1}{3G_t} + \frac{1}{9K_t} & \frac{1}{9K_t} - \frac{1}{6G_t} & 0 & 0 & 0 \\ \frac{1}{9K_t} - \frac{1}{6G_t} & \frac{1}{9K_t} - \frac{1}{6G_t} & \frac{1}{3G_t} + \frac{1}{9K_t} & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{1}{2G_t} & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{1}{2G_t} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{1}{2G_t} \end{bmatrix} \begin{Bmatrix} d\sigma_{11} \\ d\sigma_{22} \\ d\sigma_{33} \\ d\sigma_{12} \\ d\sigma_{23} \\ d\sigma_{13} \end{Bmatrix} \quad [35]$$

For the triaxial, cylindrical-loading example problem, Eqn [35] takes the following form (cf. Eqn [33b]):

$$\begin{Bmatrix} d\epsilon_v \\ d\epsilon_s \end{Bmatrix} = \begin{bmatrix} 1/K_t & 0 \\ 0 & 1/(3G_t) \end{bmatrix} \begin{Bmatrix} dp \\ dq \end{Bmatrix} \quad [36]$$

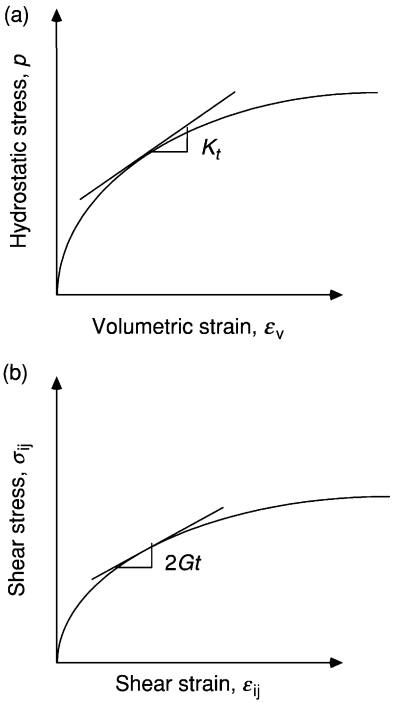

Figure 6 Stress–strain relationship for nonlinear elastic, isotropic material: (a) hydrostatic stress versus volumetric strain; (b) shear stress versus shear strain.

Variable-Moduli Models

Since both K_t and G_t are expected to be a function of stress and strain state of soil, these two tangent moduli can be represented as some explicit function of stress and strain, or stress and strain invariants. These are known as 'variable-moduli models' and many have been proposed for soil. One such model is:

$$K_t = K_0 + K_1 \cdot p \quad [37]$$

and

$$G_t = G_0 + G_1\sqrt{J_{2D}} \quad [38]$$

where K_0 and G_0 are the initial bulk and shear moduli, respectively, and K_1 and G_1 are stress-related material parameters. Here the tangent bulk modulus is assumed to depend on the mean hydrostatic stress and the tangent shear modulus is assumed to depend on the second invariant of the deviatoric stress tensor.

For the example problem using Eqns [36], [37], and [38], the following differential equations are obtained:

$$d\epsilon_v = \frac{dp}{(K_0 + K_1 p)} \quad [39]$$

$$d\epsilon_s = \frac{dq}{3(G_0 + G_1' q)} \quad [40]$$

where $G_1' = G_1/\sqrt{3}$, since $q = \sqrt{3J_{2D}}$.

Upon integration, Eqns [39] and [40] yield:

$$\epsilon_v = \frac{1}{K_1} \ln\left(\frac{K_0 + K_1 p}{K_0}\right) \quad [41]$$

$$\epsilon_s = \frac{1}{3G_1'} \ln\left(\frac{G_0 + G_1' q}{G_0}\right) \quad [42]$$

Under certain circumstances, this model allows the tangent shear modulus to become negative; but, in reality, material would have failed before this happens. From Eqn [42] it is clear that $\epsilon_s \to -\infty$, as $(G_0 + G_1' q) \to 0$. A modification of Eqn [39] is often used to describe the nonlinear elastic behavior of soil before it yields. If K_0 is zero, integration of Eqn [39] gives:

$$\epsilon_v = \frac{1}{K_1} \ln(p) + C$$

or:

$$e = e_i - \frac{(1 + e_i)}{K_1} \ln(p) = e_i - \kappa \ln(p) \quad [43]$$

where e_i is the void ratio at an initial pressure of 1 kPa, κ is the logarithmic bulk modulus which is related to K_1 and e_i (i.e., $\kappa = (1 + e_i)/K_1$). Eqn [43] is commonly used to describe the elastic behavior of soil. For normally consolidated soil (i.e., path A in Figure 7), isotropic compression is also described by a similar equation of the type:

$$e = \Gamma - \lambda \ln(p) \quad [44]$$

where Γ and λ are soil parameters. Eqns [43] and [44] are graphically represented in Figure 7.

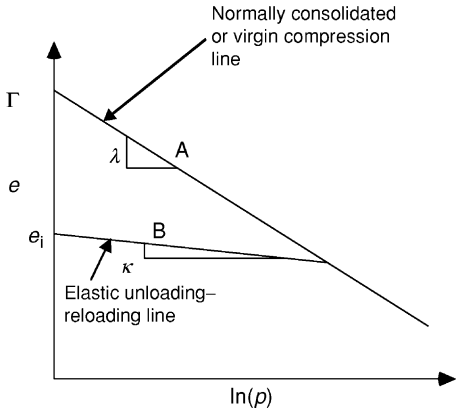

Figure 7 Isotropic consolidation for normally consolidated soil (curve A) and elastic unloading and reloading line (curve B).

The three soil parameters κ, λ, and Γ are used in describing soil behavior in the Cam-clay critical-state model (see the section Critical-State Soil Mechanics, below). Note that both κ and λ are associated with variable-moduli models that represent nonlinear behavior of soil in isotropic compression of normally consolidated soils and unloading–reloading characteristics of soils.

Duncan and Chang model

A well-known, hyperbolic-type stress–strain relationship has been proposed by Duncan and Chang. This model uses the tangent Young modulus and Poisson ratio. It assumes that the stress difference q is a hyperbolic function of axial strain. Figure 8 shows a typical stress–strain curve for both sandy and clayey soils.

This stress–strain curve can be represented by:

$$q = \sigma_1 - \sigma_3 = \frac{\epsilon}{a + b\epsilon} \quad [45]$$

where a is related to the initial tangent modulus ($E_i = 1/a$) and b is related to the asymptotic value of stress difference, $(\sigma_1 - \sigma_3)_{ult}$ ($(\sigma_1 - \sigma_3)_{ult} = 1/b$). It was found that compressive strength of soil at failure was always slightly smaller than this asymptotic stress value. The asymptotic value can be related to compressive failure stress by a factor, R_f, i.e.:

$$(\sigma_1 - \sigma_3)_f = R_f (\sigma_1 - \sigma_3)_{ult} \quad [46]$$

Combining Eqn [45] with [46]:

$$(\sigma_1 - \sigma_3) = \frac{\epsilon}{\left[\frac{1}{E_i} + \frac{\epsilon R_f}{(\sigma_1 - \sigma_3)_f}\right]} \quad [47]$$

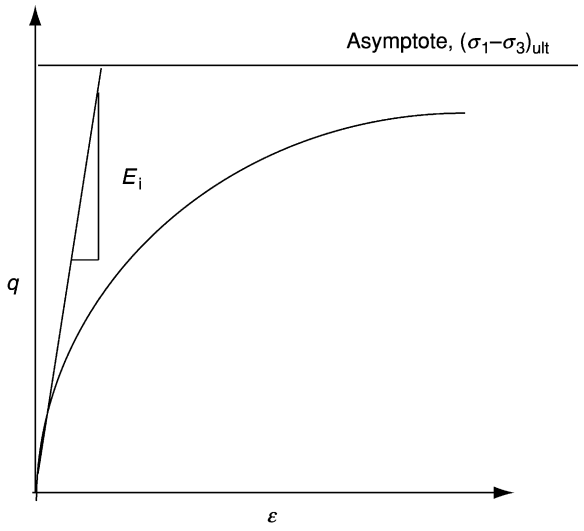

Figure 8 Variation of stress difference or deviator stress q as a function of axial strain ϵ.

The response of many soils depends on the confining pressure for a given stress path. Duncan and Chang used a relationship proposed by Janbu to represent initial tangent modulus as a function of confining stress as follows:

$$E_i = K' p_0 (\sigma_3 / p_0)^n \quad [48]$$

where K' and n are empirical constants, p_0 is the atmospheric pressure, and σ_3 is the minor principal stress. Moreover, the compressive pressure at failure in terms of the Mohr–Coulomb failure criterion is: funny initial moe

$$(\sigma_1 - \sigma_3)_f = \frac{2c\ \cos(\phi) + 2\sigma_3\ \sin(\phi)}{1 - \sin(\phi)} \quad [49]$$

where c is cohesion and ϕ is soil internal angle of friction. The tangent Young modulus can be obtained by differentiating Eqn [47] with respect to axial strain, i.e.:

$$E_t = \frac{\partial(\sigma_1 - \sigma_3)}{\partial \epsilon} \quad [50]$$

Eqns [47]–[50] show that:

$$E_t = (1 - R_f S)^2 E_i \quad [51]$$

where S is the fraction of mobilized stress strength and is given by:

$$S = \frac{(\sigma_1 - \sigma_3)}{(\sigma_1 - \sigma_3)_f} \quad [52]$$

or

$$E_t = \left[1 - \frac{R_f(1 - \sin(\phi))(\sigma_1 - \sigma_3)}{2c\ \cos(\phi) + 2\sigma_3\ \sin(\phi)}\right]^2 K' p_0 \left(\frac{\sigma_3}{p_0}\right)^n \quad [53]$$

This expression involves five parameters. It is relatively easy to implement such models into numerical analysis techniques such as the finite element technique (FEM), and a constant value of the Poisson ratio can be used. It should be noted that although these models can be readily incorporated into numerical analysis, the path dependency of the parameters used limits their widespread use. Since plastic strain dominates soil behavior following yield (point A in Figure 5), soil behavior can be better represented by elastoplastic models.

Elastoplastic Behavior of Soil

As mentioned previously, once the material yields (point A in Figure 5), there will be some irrecoverable (plastic) deformation. There are two important aspects of plastic behavior of materials: (1) a yield criterion, and (2) postyield behavior.

Yield Criteria

When the material arrives at a certain state of stress under the action of an external load, it may permanently lose the ability to regain its original dimensions for any further increase in that load. The relationship between various stress components at this limiting situation (transition from elastic to plastic region) is expressed in terms of a scalar function, f, known as the yield criterion, i.e.:

$$f = f(\sigma_{11}, \sigma_{22}, \sigma_{33}, \sigma_{12}, \sigma_{13}, \sigma_{23}) \quad [54]$$

For isotropic materials, this criterion can be expressed in terms of principal stresses or stress invariants as follows:

$$f = f(J_1, J_2, J_3) \quad [55]$$

Hydrostatic stress seldom plays a role in metal failure, therefore the yield criterion given in Eqn [54] is usually expressed only in terms of stress invariants of the deviatoric stress tensor as:

$$f = f(J_{2D}, J_{3D}) \quad [56]$$

where J_{3D} is the third invariant of the deviatoric stress tensor. J_{3D} is not dealt with here, since most of the widely used yield criteria are represented in terms of J_{2D} only. The well-known von Mises yield criterion depends on J_{2D} as follows:

$$J_{2D} = \frac{\sigma_y^2}{3} \quad [57]$$

where σ_y is the yield stress under uniaxial load. Another widely used yield criterion is the Tresca yield criterion, which is given by:

$$\sigma_1 - \sigma_3 = \sigma_y \quad [58]$$

Although, for the case of the cylindrical triaxial loading (i.e., the example problem), both von Mises and Tresca yield criteria reduce to the same equation, since $J_{2D} = (\sigma_1 - \sigma_3)^2/3$ (cf. Eqn [10]), in general these two yield criteria differ from each other.

Unlike for metals, the yield criterion for geologic materials depends on the first invariant of the stress tensor or the hydrostatic pressure. This is because these types of materials exhibit internal friction, which results in frictional forces that increase with normal load. The well-known Mohr–Coulomb failure criterion is a yield function that accounts for internal friction within the soil mass. This yield criterion is commonly expressed as:

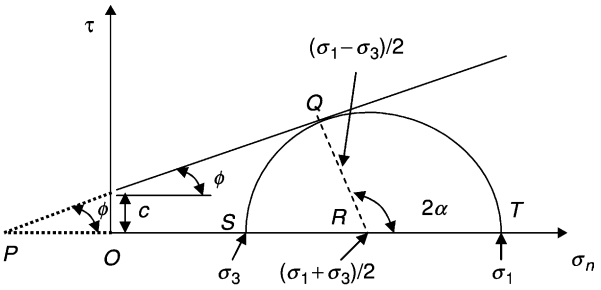

Figure 9 Mohr–Coulomb failure criterion for geologic materials. Point O is the origin of the coordinate axes, *R* is the center of the Mohr circle, *S* and *T* are intersection points of the Mohr circle with the normal stress axis, *Q* is the point of tangency between the Mohr circle and Mohr–Coulomb failure line, *P* is the point of intersection of the Mohr–Coulomb failure line with the normal stress axis.

$$\tau_{\max} = c + \sigma_{\mathrm{n}} \tan(\phi) \qquad [59]$$

where $\tau_{\max}$ is the maximum shear stress; σ_{n} is the normal stress; c is cohesion; and ϕ is the soil internal angle of friction. Figure 9 is a graphical representation of the Mohr–Coulomb failure criterion superimposed on a typical Mohr circle. Eqn [59] can also be written in terms of principal stress as:

$$\sigma_1 = \sigma_3 \tan^2\alpha + 2c \tan\alpha \qquad [60]$$

where α is $45^\circ + \phi/2$. It should be noted that, for frictionless materials (i.e., $\phi = 0$), the Mohr–Coulomb failure criterion reduces to the Tresca yield criterion. The Mohr–Coulomb yield criterion is difficult to implement in three-dimensional applications, because the yield surface is an irregular hexagonal pyramid with sharp corners (mathematical singularities). A generalization, known as the 'Drucker–Prager yield criterion,' that results in a yield surface in the form of a smooth right circular cone is commonly used in modeling granular materials. This yield criterion is expressed in terms of stress invariants as follows:

$$\sqrt{J_{2\mathrm{D}}} - \alpha J_1 - k = 0 \qquad [61]$$

where α and k are related to internal angle of friction and cohesion. Figure 10 shows a plot of the Drucker–Prager yield criterion in the $\sqrt{J_{2\mathrm{D}}}$ versus J_1 plane. For purely cohesive soils, α is zero and the Drucker–Prager yield criterion reduces to von Mises yield criterion.

Hardening Cap

Many geologic materials experience almost continuous plastic deformation from the very beginning of loading. Thus if a mass of soil previously loaded to point B in Figure 10 is unloaded along path BA and then loaded even hydrostatically (i.e., $\sigma_1 = \sigma_2 = \sigma_3 = p$) along the J_1 axis, it will deform elastically until it is loaded to point C, and any further loading leads to plastic deformation. The continuous curved surface, which is assumed to join the Drucker–Prager fixed-yield surface smoothly at point C, is called the 'hardening cap.' As the material is loaded to point E along the hydrostatic axis, the hardening cap is pushed out to location DE, thus extending the elastic region from OPBC to OPDE. In essence, the material has become harder under unloading and reloading. Thus, if the soil mass is loaded along an arbitrary path EFG after the hydrostatic loading to E, the soil will behave elastically up until it reaches a stress state defined by point F. Further loading will cause the soil to deform plastically until it reaches point G on the fixed failure surface defined by the Drucker–Prager yield condition. A state of stress above the line PG is not attainable according to this yield criterion. This idea of hardening caps has been incorporated in the development of an unified theory of soil mechanical behavior that links volume changes, stress state, and yielding into a single framework called the critical-state soil mechanics.

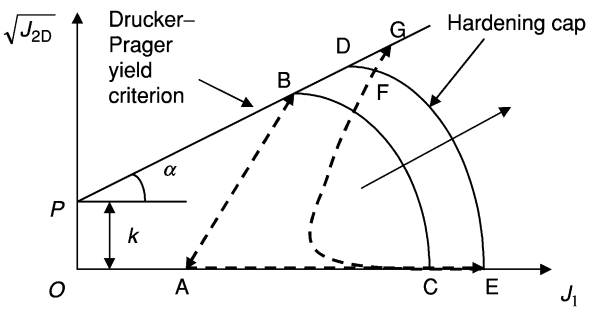

Figure 10 Drucker–Prager yield criterion with hardening caps.

Postyield Behavior

Upon yield, soil mass undergoes plastic deformation. The total strain can be decomposed into elastic and plastic strain, i.e.:

$$\epsilon_{\mathrm{ij}} = \epsilon^{\mathrm{e}}_{\mathrm{ij}} + \epsilon^{\mathrm{p}}_{\mathrm{ij}} \qquad [62]$$

where $\epsilon^{\mathrm{e}}_{\mathrm{ij}}$ is the recoverable elastic strain and $\epsilon^{\mathrm{p}}_{\mathrm{ij}}$ is the permanent plastic deformation. The elastic strain can be determined based on a constitutive relationship such as in Eqn [35]. The plastic strain is determined using the concept of plastic potential and flow rule.

Plastic potential and flow rule The plastic potential, g, is assumed to be a scalar function of the state of stress within the soil mass (i.e., $g = g(\sigma_{11}, \sigma_{22}, \sigma_{33}, \sigma_{12}, \sigma_{13}, \sigma_{23})$). The direction of the plastic strain is

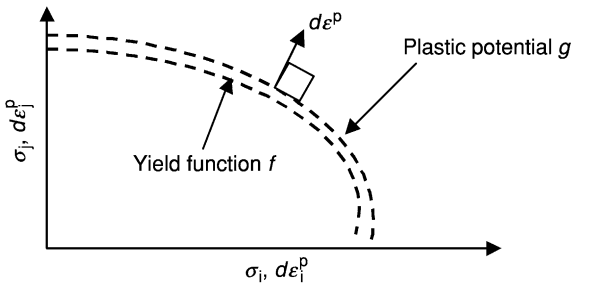

Figure 11 Plastic potential and yield function for a material governed by the associative flow rule.

defined by a flow rule. According to the flow rule, the incremental plastic strain vector is oriented in the direction of the normal to the yield potential (Figure 11). This condition is known as 'normality rule.' Using this definition, the plastic strain is given by:

$$\epsilon_{ij}^p = \chi \frac{\partial g}{\partial \sigma_{ij}} \qquad [63]$$

where χ is a positive scalar multiplier or loading index. For some materials, the plastic potential g is assumed to be the same as the yield function f. These materials are said to follow the associative flow rule; materials for which the plastic potential differs from the yield function are said to follow the nonassociative flow rule.

Hardening law An additional concept that is necessary to describe the plastic behavior completely is the hardening law. The hardening law describes the growth of yield function or hardening cap as the material undergoes plastic deformation (e.g., the rule for the growth of the hardening cap from BC to DE in Figure 10). A hardening parameter, h, is often included in the yield function to describe the changes in the yield function with plastic flow, i.e.:

$$f = f(\sigma_{11}, \sigma_{22}, \sigma_{33}, \sigma_{12}, \sigma_{13}, \sigma_{23}, h) \qquad [64a]$$

Critical-State Soil Mechanics

The critical-state concept is based on the observation that when a soil sample is subjected to increasing shear loading, it will yield and undergo plastic deformations (both volumetric and shear) and finally arrive at a critical volume, after which its volume remains unchanged, although its shape continues to change. The Cam-clay model for the elastoplastic behavior of wet clay includes this critical-state concept while accounting for the stress and volume changes during yielding. A slightly modified version of this original model has been used widely in numerical simulation studies. Here this 'modified Cam clay model' is considered for the particular case of a triaxial loading of a cylindrical soil sample to keep the mathematical treatment relatively simple. The hydrostatic stress ($p = (\sigma_1 + 2\sigma_3)/3$), shear stress ($q = (\sigma_1 - \sigma_3)$), and void ratio ($e$) are used as the state variables in developing the model.

Figure 12 graphically represents the soil behavior in the modified Cam-clay model. Figure 12a shows the variation of void ratio as a function of the hydrostatic pressure. Curve ABCD is the normal consolidation line (NCL) under hydrostatic loading. Curves EB and FC are elastic unloading–reloading curves (URL). The NCL and URL curves are mathematically represented by Eqns [43] and [44]. Figure 12b is the representation of NCL and URL in the void ratio versus $\ln(p)$ plane (cf. Figure 7). Figure 12c shows the critical-state line (CSL) and the elliptical yield surface, OPQ, that is hypothesized by the modified Cam-clay model in the q–p plane. The major axis of the ellipse coincides with the hydrostatic stress axis and is equal to $(p_0/2)$, which is the hardening parameter, h. The critical-state line is assumed to pass through the origin with slope M in the q–p plane and intersects the yield surface at point P. When the soil arrives at the critical-state line, it undergoes no more volume change, i.e., $d\epsilon_v$ is zero. This requirement along with the normality condition can be used to show that point P is directly above the center of the elliptical yield surface. Therefore the coordinates of this point are $(p_0/2, Mp_0/2)$, and $(Mp_0/2)$ is the minor axis of the ellipse:

$$\frac{\left(p - \frac{p_0}{2}\right)^2}{\left(\frac{p_0}{2}\right)^2} + \frac{q^2}{\left(\frac{Mp_0}{2}\right)^2} = 1 \qquad [64b]$$

Multiplying by $(Mp_0/2)^2$ and simplifying:

$$M^2[p(p - p_0)] + q^2 = 0 \qquad [64c]$$

Figure 12d is a three-dimensional (3-D) representation of the modified Cam-clay model which shows that the critical-state line is a space curve, the projection of which is a straight line on the q–p plane.

Modified Cam-Clay Constitutive Relationship

The following relationships are developed using the associative flow rule (i.e., plastic potential is the same as the yield function). The elastic portion of the total strain is given by Eqn [36], i.e.:

$$\begin{Bmatrix} d\epsilon_v^e \\ d\epsilon_s^e \end{Bmatrix} = \begin{bmatrix} 1/K_t & 0 \\ 0 & 1/(3G_t) \end{bmatrix} \begin{Bmatrix} dp \\ dq \end{Bmatrix} \qquad [65]$$

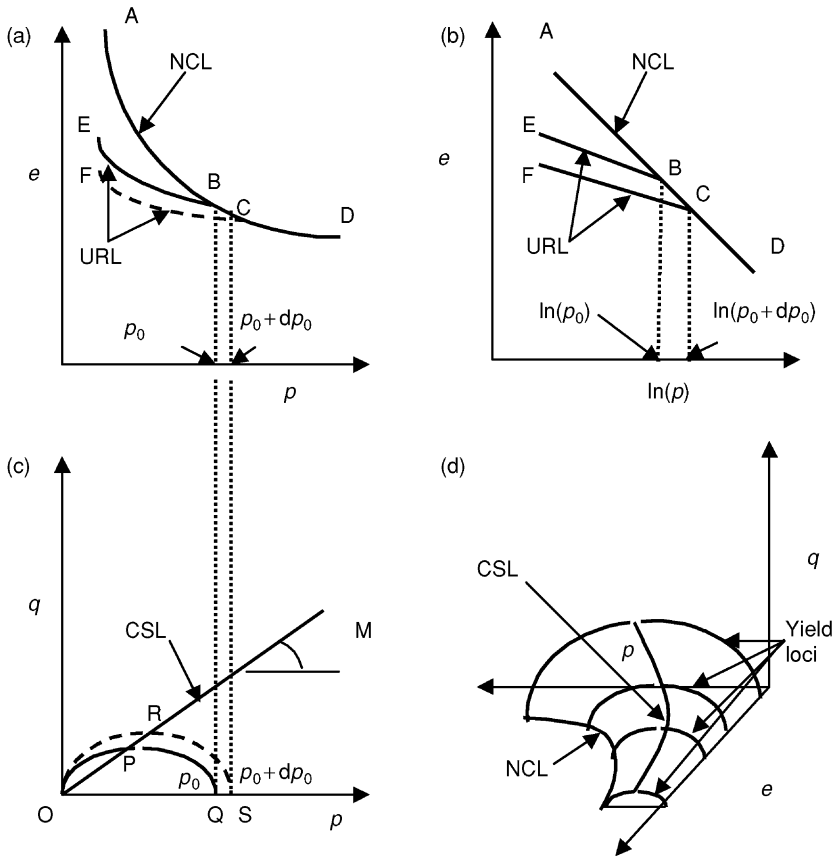

Figure 12 Modified Cam-clay model with elliptical yield surface: (a) deformation in the *e*-*p* plane; (b) deformation in the *e*-ln(*p*) plane; (c) behavior in the *q*-*p* plane; and (d) three-dimensional representation of the model. NCL, normal consolidation line; URL, unloading–reloading line; CSL, critical-state line.

where superscript 'e' represents elastic strain components. The plastic strain components are given by:

$$\mathrm{d}\epsilon_{\mathrm{v}}^{\mathrm{p}} = \chi \frac{\partial g}{\partial p}$$
$$\mathrm{d}\epsilon_{\mathrm{s}}^{\mathrm{p}} = \chi \frac{\partial g}{\partial q} \qquad [66]$$

where superscript 'p' stands for plastic strain components. Because of the assumption of associative flow, the plastic potential, g, is the same as the yield function, f. The elliptical yield function described in the previous section is given by (cf. Eqn [64c]):

$$f(p,q,p_0) = g(p,q,p_0) = M^2[p(p-p_0)] + q^2 = 0 \qquad [67]$$

Eqn [67] can be used to obtain an expression for loading index, χ, as follows. Taking the total differential of Eqn [67]:

$$\mathrm{d}f = \mathrm{d}g = \frac{\partial f}{\partial p}\mathrm{d}p + \frac{\partial f}{\partial q}\mathrm{d}q + \frac{\partial f}{\partial p_0}\mathrm{d}p_0 \qquad [68]$$

However, $\mathrm{d}p_0$, which is related to the size of the yield surface, i.e., changes in the hardening parameter, can be related to volumetric plastic strain using Eqns [43] and [44]. Referring to **Figure 12b**, from Eqns [43] and [44]:

$$e_0 = e_{\mathrm{i}} - \kappa \ln(p_0) \qquad [69a]$$

$$e_0 = \Gamma - \lambda \ln(p_0) \qquad [69b]$$

The elastic part of the volume change is related to that described in Eqn [69a], and the total volume change is related to that described in Eqn [69b]. Taking differentials of Eqns [69a] and [69b]:

$$\mathrm{d}e^{\mathrm{e}} = -\kappa \frac{\mathrm{d}p_0}{p_0} \qquad [70a]$$

$$\mathrm{d}e = -\lambda \frac{\mathrm{d}p_0}{p_0} \qquad [70b]$$

Therefore, the plastic part of the deformation is given by:

$$\mathrm{d}e^{\mathrm{p}} = \mathrm{d}e - \mathrm{d}e^{\mathrm{e}} = -(\lambda - \kappa)\frac{\mathrm{d}p_0}{p_0} \qquad [71]$$

From Eqns [24b] and [71]:

$$d\epsilon_v^p = -\frac{de^p}{1+e_i} = \left\{\frac{\lambda-\kappa}{1+e_i}\right\}\frac{dp_0}{p_0} \quad [72]$$

Eqn [72] can be solved for dp_0 as follows:

$$dp_0 = p_0\left\{\frac{1+e_i}{\lambda-\kappa}\right\}d\epsilon_v^p \quad [73]$$

Therefore, from Eqns [66], [68], and [73]:

$$\frac{\partial f}{\partial p}dp + \frac{\partial f}{\partial q}dq + \frac{\partial f}{\partial p_0}p_0\left\{\frac{1+e_i}{\lambda-\kappa}\right\}\chi\frac{\partial g}{\partial p} = 0 \quad [74]$$

Solving Eqn [74] for χ gives:

$$\chi = \frac{-\left(\frac{\partial f}{\partial p}dp + \frac{\partial f}{\partial q}dq\right)}{\frac{\partial f}{\partial p_0}p_0\left\{\frac{1+e_i}{\lambda-\kappa}\right\}\frac{\partial g}{\partial p}} \quad [75]$$

If $\eta = q/p$ is substituted as η, then for the Cam-clay model:

$$\frac{\partial f}{\partial p} = \frac{\partial g}{\partial p} = (M^2-\eta^2)p$$
$$\frac{\partial f}{\partial q} = \frac{\partial g}{\partial q} = 2\eta p$$
$$\frac{\partial f}{\partial p_0} = -M^2 p \quad [76]$$

where $p_0 = (M^2+\eta^2)p/M^2$ is substituted for from Eqn [67]. (From Eqn [67]: $f(p, q, p_0) = M^2\,[p\,(p - p_0)] + q^2 = 0$; therefore $M^2\,p^2 - M^2\,pp_0 + \eta^2\,p^2 = 0$, since $q = \eta p$; further simplification of this equation leads to $p^2\,(M^2+\eta^2) = M\,pp_0$, or $p_0 = (M^2+\eta^2)\,p/M^2$.) Substituting these partial derivatives in Eqn [75] and simplifying:

$$\chi = \left(\frac{\lambda-\kappa}{1+e_i}\right)\frac{(M^2-\eta^2)dp + 2\eta\,dq}{(M^2+\eta^2)(M^2-\eta^2)p^2} \quad [77]$$

Finally, from Eqn [66] and [76], upon simplification:

$$d\epsilon_v^p = \frac{(\lambda-\kappa)}{(1+e_i)(M^2+\eta^2)p}\left[(M^2-\eta^2)dp + 2\eta dq\right] \quad [78a]$$

$$d\epsilon_s^p = \frac{(\lambda-\kappa)}{(1+e_i)(M^2+\eta^2)p}\left[2\eta dp + \frac{4\eta^2}{(M^2-\eta^2)}\right] \quad [78b]$$

or in matrix form,

$$\left\{\begin{matrix} d\epsilon_v^p \\ d\epsilon_s^p \end{matrix}\right\} = \frac{(\lambda-\kappa)}{(1+e_i)(M^2+\eta^2)p}\begin{bmatrix} (M^2-\eta^2) & 2\eta \\ 2\eta & \frac{4\eta^2}{(M^2-\eta^2)} \end{bmatrix} \quad [79]$$

If the soil mass is within the elastic region, Eqn [65] can be used to compute elastic strain. However, if the soil mass has yielded and is undergoing elastic as well as plastic deformation, Eqn [79] can be used to obtain plastic strain while Eqn [65] provides the magnitude of the elastic strain. This model contains five soil parameters (κ, ν or G, λ, M, Γ). The first two parameters are related to the elastic behavior of soil mass whereas the last three parameters are related to the plastic behavior. Note that the parameter κ is related to soil bulk modulus K by the relationship, $\kappa = \frac{1+e_i}{\kappa}$, as shown previously.

Although the elliptic yield function represents the behavior of normally consolidated and lightly overconsolidated soils reasonably well, it overpredicts the strength of overconsolidated soils.

NSDL–AU Model

Based on numerous tests conducted using unsaturated agricultural soils at the National Soil Dynamics Laboratory (NSDL) and Auburn University (AU) in Alabama, USA, a model for plastic behavior of soils has been formulated, the NSDL–AU model, which is based on two key developments. The first is the development of a model to describe the hydrostatic compression of unsaturated agricultural soils. This equation for NCL differs from Eqn [43] and has the following form:

$$\bar{\epsilon}_v = (A + Bp)(1 - e^{-Cp}) \quad [80]$$

where $\bar{\epsilon}_v$ is the natural volumetric strain, $\ln(V/V_0)$, and A, B, and C are material parameters. Eqn [80] has been extended to represent cylindrical triaxial test results. The extended equation is given by:

$$\bar{\epsilon}_v = (A + Bp)(1 - e^{-Cp}) + \frac{\sqrt{2}}{3}D\frac{q}{p} \quad [81]$$

Note the use of $\tau_{oct} = \sqrt{2}/3\ q$ in this formulation. Moreover, this equation contains an additional material parameter, D. Eqn [81] represents the yield surface for unsaturated agricultural soils and is quite similar to the yield surface shown in **Figure 12d**. Furthermore, the model inherently contains a critical-state line. It should be noted that Eqn [81] represents plastic behavior of soil and does not account for any unloading–reloading action (i.e., elastic behavior). Most agricultural soils tend to be slightly overconsolidated and their deformation is primarily controlled by plastic deformation.

Composite Soil-Strength Parameters

Although the foregoing discussion treats mechanical behavior of soil from the veiwpoint of continuum mechanics, it has not been used widely by field researchers and practitioners due to its complexity and the difficulty in obtaining engineering soil parameters of undisturbed *in situ* soils. Devices such as cone penetrometers, and shear and sinkage devices have been developed to provide various measures of soil strength for use in tillage, traction, and soil-compaction studies. These devices provide soil-strength parameters that tend to depend on the geometry of the test device and type of loading applied. Moreover, these soil parameters often do not represent any single soil property, but are usually functions of several fundamental engineering properties of soil. Therefore soil parameters obtained using these devices are often called 'composite soil parameters'; e.g., penetrometers, shear-vane devices, and shear graphs. There are also various techniques used for determining soil stickiness, shatter resistance, and cutting resistance. The cone penetrometer is well-known among these devices because it is a simple device and very easy to use. Shear-vane devices and shear graphs have been used to obtain soil shear and sinkage parameters. They are useful in predicting tractive ability of wheels and tracks using a semiempirical approach.

Cone Penetrometer

Perhaps the most widely used device to measure soil strength in the field is the cone penetrometer. Although the cone penetrometer was developed to determine the mobility of off-road vehicles at the Waterways Experiment Station in Vicksburg, Mississippi, USA, it has been used to predict traction, draft requirements of tillage implements, and to quantify soil strength to indicate soil-compaction level and impedance to root growth. The most common form of this device consists of a polished steel cone, which is pushed against the soil and then the force of penetration is measured. The American Society of Agricultural Engineers (ASAE) has developed a standard (S313.3) that describes the geometry of a standard cone penetrometer, whereas a second standard (EP542) outlines the proper procedure for using this device.

Since the force needed to penetrate the soil is related to the geometry of the device, a cone with a base diameter of 20.27 mm and an apex angle of 30° is selected as the standard shape (Figure 13). For harder soil conditions, a smaller cone with a base diameter of 12.83 mm is used. A second key variable that influences the force of penetration is the penetration rate. ASAE Standard EP542 recommends a quasistatic rate of 1.83 m min^{-1}. Although it is difficult to control the insertion rate with handheld devices, hydraulically or electrically operated devices can be designed to operate at this standard speed. Force is usually measured using a load-sensing mechanism such as a load cell. Newer devices often include a depth-measuring sensor such as a potentiometer so that a soil penetration resistance profile can be obtained. The penetration resistance force is expressed as cone index, which is the ratio of the force to the base area of the cone. The soil cone index value obtained using a soil cone penetrometer is a composite value that depends on soil texture, bulk density, and moisture content. In terms of engineering properties of soil, it depends on cohesion, soil internal angle of friction, soil metal friction, and adhesion.

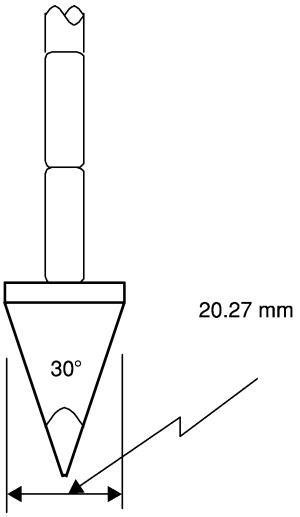

Figure 13 Standard cone penetrometer of the American Society of Agricultural Engineers.

One of the main concerns with the use of cone index to represent soil strength is its variability, especially in dry and cloddy conditions. ASAE standard EP542 recommends that at least 20 measurements must be taken near the field capacity of soil in a given location to obtain a representative measure of soil strength. With the advent of precision agriculture and the potential role of soil compaction in limiting water infiltration, drainage, and root growth, there is an increased interest in the cone penetrometer as a soil-strength mapping tool. Consequently, fully automated cone penetrometers with global positioning systems (GPS) to provide geographic position data are now commercially available.

Measurement of Soil Sinkage and Shear

Inadequacy of cone index values in representing soil characteristics relevant to tractive ability of wheels

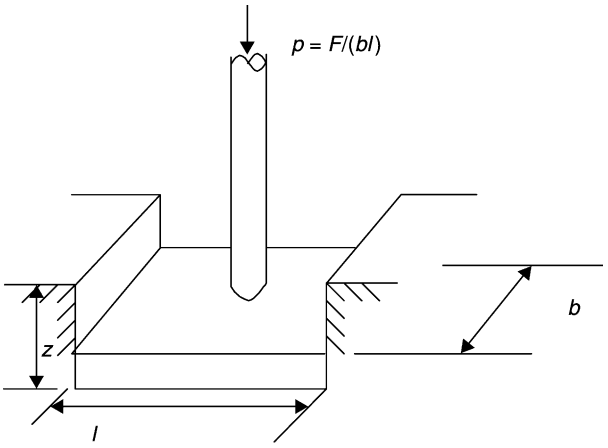

Figure 14 A rectangular sinkage plate.

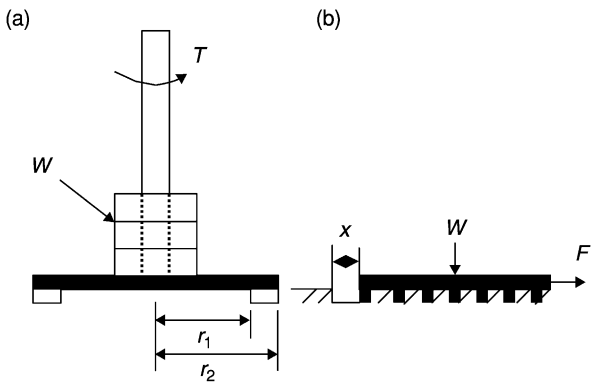

Figure 15 Soil-shear test devices: (a) shear ring; and (b) grouser plate.

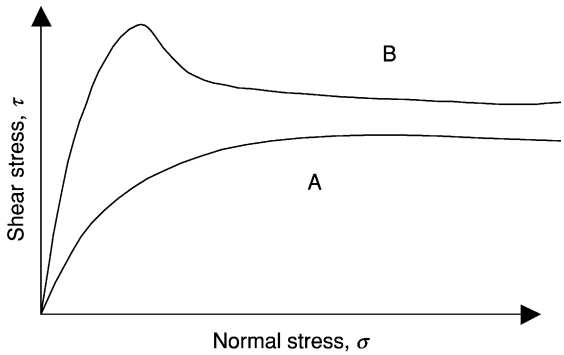

Figure 16 Shear characteristics of soil (A) normally consolidated or slightly overconsolidated and (B) overconsolidated.

and tracks has led to the development of sinkage and shear devices such as the bevameter.

Soil sinkage devices consist of either circular or rectangular plates that are pushed against soil, and their load deformation characteristics are recorded (Figure 14). The Bernstein equation is often used to relate applied load to soil deformation as follows:

$$p_s = kz^n \qquad [82]$$

where p_s is the applied compressive pressure, z is the soil sinkage, and k and n are constants. The sinkage parameter was found to depend on plate width by the following relationships:

$$k = \frac{k_c}{b} + k_\phi \qquad [83]$$

where k_c and k_ϕ are parameters related to soil cohesion and angle of internal friction, respectively, and b is the minimum plate dimension. Since the parameter n in Eqn [82] is usually not an integer, units of k are not straightforward. An alternate formulation that overcomes the problem of dimension of k is:

$$p = k_r \left(\frac{z}{b}\right)^n \qquad [84a]$$

and:

$$k_r = (k_1 + k_2\, b) \qquad [84b]$$

where k_1 and k_2 are once again parameters related to soil cohesion and angle of internal friction, respectively. Note that the unit of k_r in Eqn [84a] is the same as that of pressure. These plate sinkage relationships have been used to model rolling resistances of wheels and tracks.

Shear characteristics of soil such as cohesion and angle of internal friction have been used to model the tractive ability of wheels and tracks and soil cutting by tillage tools. Torsional shear devices (shear vane, shear cone, shear ring, shear graph) and rectangular grouser plates are often used to measure soil-shear characteristics. Figure 15 shows a circular shear head and a rectangular grouser plate. The maximum shear stress at a specific normal load, W, on a torsional device as shown in Figure 15a is given by:

$$\tau = \frac{3T}{2\pi(r_1^3 - r_2^3)} \qquad [85]$$

where T is the torque and r_1 and r_2 are the radii of the shear vane.

The original bevameter used a shear device similar to the one shown in Figure 15a. A recent development includes an instrumented soil test device that uses a grouser plate, sinkage plate, and a standard cone to obtain soil shear, sinkage, and cone index data. Figure 16 shows the shear characteristics of soil measured using a shear test device. The curve A in Figure 16 is a representation of a normally consolidated or slightly overconsolidated soil. The

curve B is a typical response of an overconsolidated soil. Most agricultural soils behave as shown in curve A, which can be represented by the empirical equation:

$$\tau = \tau_{max}(1 - e^{-x/k_s}) \quad [86]$$

where τ_{max} is the maximum shear stress, k_s is the soil-shear modulus, and x is the soil deformation in the direction of shear stress.

Moreover, the Mohr–Coulomb criterion (cf. Eqn [59]) can be used to represent τ_{max}. Note that $\tau_{max} = F/A$ and $\sigma_n = W/A$, where A is the plate area. If the shear test is repeated at two different values of the normal load, W, both c and ϕ can be determined.

Some Recent Developments

Increased interest in precision agriculture within the last decade has led to the investigation of causes of yield variability within a field. One factor believed to influence crop yield is soil compaction, since it has a direct impact on soil hydraulic conductivity. As mentioned previously, the cone penetrometer is the soil-strength measuring device that is being used increasingly to map soil compaction level. Since it is a highly variable point measurement, numerous cone index values are needed to obtain proper representation of a field. This limitation of the cone penetrometer has led to the development of alternative devices that can measure and map soil strength in a continuous manner. One such device consists of a texture–soil-compaction sensing system that consists of a simple tine that is instrumented with a load cell to measure soil-cutting force. It also incorporates a dielectric-based soil-moisture sensor, because soil-moisture content influences soil-cutting force significantly. The soil-cutting force, F, is a function of soil bulk density, ρ, texture, ξ, and moisture content, θ, when the device is operated at a constant speed and operating depth; i.e.:

$$F = f(\rho, \xi, \theta) \quad [87]$$

Based on the field measurements the soil-cutting force was determined as:

$$F = g(\rho, \xi) * e^{-c\theta} \quad [88]$$

where c is an empirical constant. The unknown function $g(\rho, \xi)$ is 'texture/soil compaction index' (TCI). Therefore, TCI is given by:

$$TCI = F/e^{-c\theta} \quad [89]$$

Note that this TCI value depends on both soil bulk density and texture. Since texture is a static property in the absence of cut-and-fill operation, TCI values can be used as an indicator of soil-compaction level. The TCI sensor has been interfaced to a differential global positioning system (DGPS) to obtain soil-strength maps of tomato fields and correlate them to tomato yield. The field test results indicate that, although the TCI sensor works reasonably well, it is not helpful in locating the compact layer within the soil mass. As of 2003, active research is currently in progress to develop a compaction profile sensor, which can measure the compaction level of soil with depth. Successful development of such a real-time soil-compaction profile sensor may contribute to the development of site-specific tillage (tilling only where there is a need to loosen soil) and limit tillage depth to the hardpan depth.

Introduction

The term 'structure' of a granular medium refers to the spatial arrangement of solid particles and void spaces. In materials such as coarse sands and gravels, the particles are loosely bound and tend to arrange themselves in closely packed, minimum-energy configurations (Figure 1a). Most soils, however, tend to exhibit a hierarchical structure. That is, primary mineral particles, usually in association with organic materials, form small clusters or 'first-order aggregates.' These in turn form larger clusters or 'second-order aggregates,' and so on, as illustrated schematically in Figure 1b.

Aggregate hierarchy in soils is reflected not only in increasing aggregate size with each successive level, but also in the predominant mechanisms by which particles in aggregates are bonded together; i.e., aggregates at different hierarchical levels tend to bond together by different mechanisms. Hence, the term 'structure' in soil science generally carries a connotation of bonding mechanisms in addition to geometrical configuration of particles.

Without hierarchical structure, medium- and fine-textured soils such as loams and clays would be nearly impermeable to fluids and gases, and at 'typical' moisture contents would possess a mechanical strength prohibitive to growth of plant roots and soil organisms. Thus, structure plays a crucial role in the transport of water, gases, and solutes in the environment, and in transforming soil into a suitable growth medium for plants and other biological organisms. Physical appearance of structured vs unstructured 'puddled' soil is shown in Figure 2.

This article briefly describes different hierarchical levels of soil structure, and dominant processes and mechanisms through which structural bonding occurs. Also discussed are statistical models and geometric scaling concepts used to describe the hierarchical system as a whole. A final section summarizes the dynamics of structure in tilled soils. Useful books and reviews on soil structure are listed at the end.

Hierarchical Levels of Soil Structure and Bonding Mechanisms

A fairly broad consensus exists for classifying soil aggregates into two main hierarchical categories, microaggregates (<250 μm diameter) and macroaggregates (>250 μm diameter). The microaggregates are typically subdivided into subclasses, <2 μm, 2–20 μm, and 20–250 μm. Salient properties of these aggregate categories are summarized below, and illustrated schematically in Figure 3. Comparison of aggregate size scales with other characteristic soil dimensions is presented in Figure 4.

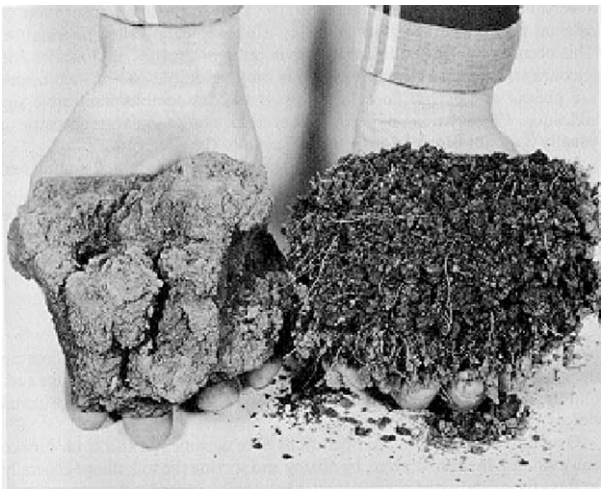

Figure 2 Photograph of structured soil and the same soil in a 'puddled' state where structure has been mostly destroyed. Courtesy of the USDA Natural Resources Conservation Service.

Microaggregates less than 2 μm in Diameter

These appear to be initially formed by flocculation of clay particles into domains or quasicrystals (Figures 3 and 5). Particularly in very small aggregates (<0.2 μm), most organic matter appears to be absorbed only onto external surfaces of the quasicrystals. Thus, bonding between particles in soil quasicrystals is governed by essentially the same van der Waals and electrical double-layer phenomena that produce quasicrystals in simple clay–water systems. Exclusion of organic matter from internal quasicrystal surfaces appears quite pronounced in montmorillonitic soils where clay particles exhibit a strongly oriented, mutually parallel structure (regions marked 'T' in Figure 5), and to a lesser extent in soils with illitic or kaolinitic mineralogy and correspondingly less-ordered domains. Very small microaggregates are highly resistant to mechanical disruption, typically requiring several minutes of ultrasonic dispersion, often with the aid of an oxidizing agent.

In a next hierarchical level, quasicrystals and other mineral particles coalesce around central bonding nuclei of highly processed organic materials of humic and polysaccharide nature. The clay domains and other mineral particles on the outside of these microaggregates protect the inner organic core against access by microorganisms. Figure 5 shows pockets of polysaccharide material (P) surrounded by clay tactoid coatings (T). The humic and polysaccharide materials typically consist of multiple strands and functional groups, which provide many

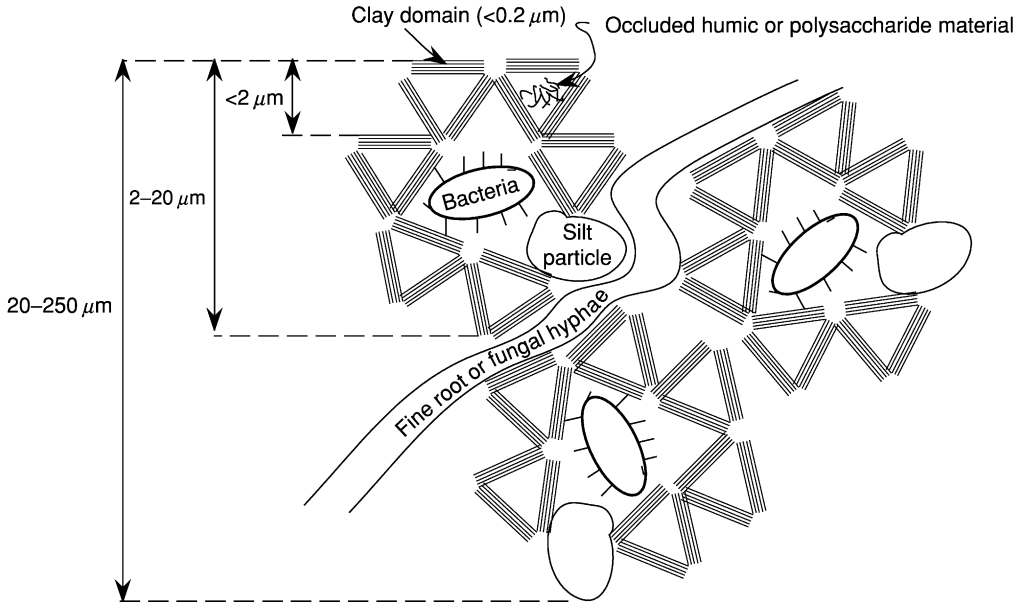

Figure 3 Schematic diagram of a hierarchical system of microaggregates illustrating special characteristics of each class.

sites for bonding with the mineral surfaces. Since the predominant electrical charge of organic polymers at 'normal' soil pH values is usually negative, bonding with negatively charged inorganic colloids is largely achieved through 'bridging' by multivalent cations such as Ca^{2+}, Fe^{3+}, Al^{3+} and their hydrous oxides, which are able to complex with both mineral surfaces and organic functional groups (Figure 6 and Table 1). In highly weathered soils with abundant variable-charge minerals, ligand exchange between mineral surfaces and organic functional groups can produce particularly strong bonds. This is particularly notable in Oxisols, characterized by extremely strong micro-porous microaggregates resulting in a characteristic bimodal pore-size distribution (Figure 7).

In order for microaggregates to form effectively in soil, organic binding materials must be finely distributed throughout the soil, rather than deposited in isolated pockets. Particularly effective mechanisms appear to be *in situ* biosynthesis of organic materials by microorganisms associated with extensive networks of fine roots with high turnover rates, such as under grass vegetation.

Microaggregates tend to form slowly in soils, but once formed they also degrade slowly, even under unfavorable soil management systems. Organic substances in microaggregates have been observed to remain stable for hundreds and in some cases even thousands of years. Among the stabilized organic materials are enzymes that may contribute to processes such as N mineralization and herbicide degradation. The amount of carbon 'sequestered' in soil microaggregates constitutes a substantial fraction of the total amount organic carbon on Earth. This has

stirred much interest in the impact of soil structure management on atmospheric CO_2.

Microaggregates 2–20 μm in Diameter

These are formed from oriented clay domains, microaggregates $<2\,\mu$m in diameter, and/or coarse clay and fine silt particles, which coalesce around a central core of hyphal fragments and bacterial cells or colonies (Figures 3 and 5). Bonding is effected by microbial materials such as polysaccharide synthesized by the bacteria and hyphae. The outer layer of clay domains and microaggregates protects the bacteria from organisms such as nematodes and protozoa, which are too large to penetrate the outer layer. Thus, up to 40–60% of the microbial biomass in soil has been found associated with microaggregates 2–20 μm in diameter.

Like $<2\,\mu$m aggregates, 2–20 μm aggregates are very resistant to mechanical disruption, sometimes resisting up to 5 min of ultrasonic dispersion.

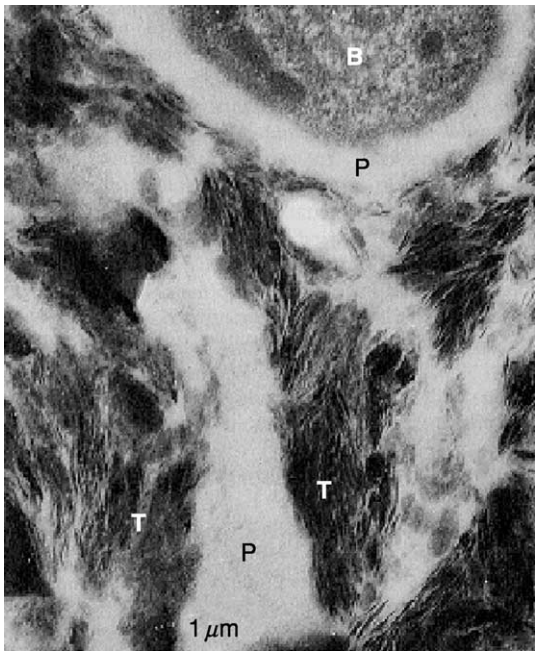

Figure 5 Micrograph of a $<2\,\mu$m microaggregate showing clay tactoids (T), occluded polysaccharide material (P), and bacterial capsule (B) surrounded by polysaccharide material. Reproduced with permission from Foster RC (1978) In: Emerson WW, Bond RD, and Dexter AR (eds) *Modification of Soil Structure*, p. 104. Chichester: Wiley.

Microaggregates 20–250 μm in Diameter

These are formed largely by particles or aggregates $<20\,\mu$m in diameter, bonded by polysaccharide material around central nuclei of fine roots and fungal hyphae, which may or may not be subsequently completely degraded by soil microorganisms. Bonding is generally strong enough that the aggregates are stable to slaking upon direct immersion of air-dry soil into water. Micrographs of two such aggregates are shown in Figure 8.

Macroaggregates (greater than 250 μm Diameter)

General properties of macroaggregates and their dynamic nature in soil management systems Due to their effect on size of the largest soil pores, these aggregates are very influential in determining macroscopic soil properties such as mechanical strength,

hydraulic conductivity, and aeration status. They are also the aggregates most susceptible to breakdown under stresses due to tillage, compaction, raindrop impact, or wetting-induced slaking.

Macroaggregation seems primarily caused by reorientation and binding of clay particles and microaggregates by fine roots and hyphae, and further cementation by extracellular polysaccharides. Associations between extensive fine root systems and vesicular arbuscular mycorrhizal (VAM) fungi, which produce large amounts of polysaccharide, appear particularly effective in forming macroaggregates. Saprophytic fungi also stabilize aggregates, particularly when substrates such as combinations of straw and manure are added to the soil. Algal filaments, covered with slimy gels, have also been observed to be effective. It is often difficult to distinguish between the relative importance of binding by fine plant roots and fungal hyphae because, particularly in the case of VAM fungi, fungi and root growth are often positively

correlated. What does seem fairly clear is that plant species with large systems of fibrous roots, associated with VAM hyphae that secrete large amounts of polysaccharide gel, are effective stabilizers.

Bonding by polysaccharides apparently does not occur uniformly throughout macroaggregates, but rather primarily in the larger cracks or pores (15–50 μm in diameter), precisely where aggregates are most likely to rupture. Due to this efficient placement of bonds, even small increases or removals of polysaccharide can cause large increases or decreases in macroaggregate stability. Polysaccharides in large pores are more accessible to degradation by microorganisms than in microaggregates, so they are relatively labile and sensitive to changes in management.

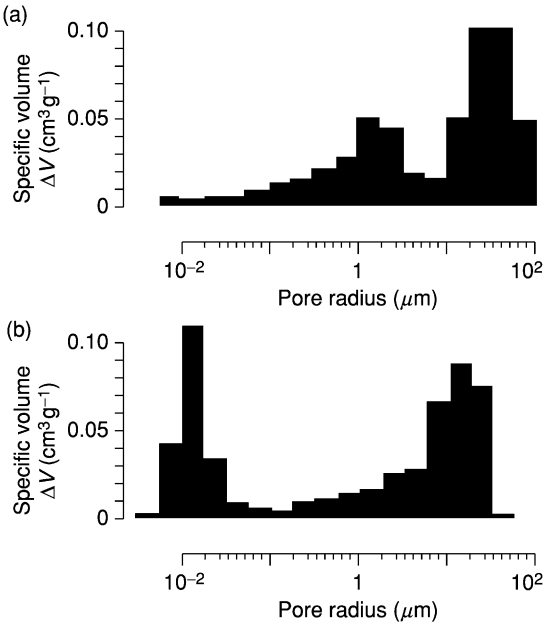

Figure 7 Pore size distribution for (a) silty soil and (b) an oxisol obtained by mercury porosimeter. Adapted from Bartoli F, Dutartre Ph, Gomendy V, *et al.* (1998) In: Baveye PJ, Parlange JV, and Stewart BA (eds) *Fractals in Soil Science*, p. 220. Boca Raton, FL: CRC Press, with permission.

Because labile polysaccharides constitute only a small fraction of the total amount of soil organic matter, it is not surprising that total soil organic matter content does not always correlate well with macroaggregate stability. This is particularly true shortly after sudden changes in management, where changes in total organic matter may be minimal but significant changes may have occurred in the network of fine roots, fungal hyphae, and associated polysaccharides, with associated rapid changes in aggregate stability. For example, Figure 9 shows that, after changing from continuous corn to an alfalfa cropping system, soil organic carbon accumulation lagged behind aggregate formation. In such situations, measurements of labile polysaccharide or related parameters are often better indicators of trends in macroaggregate stability than is total organic matter content (Table 2).

In cases where total soil organic matter content does correlate positively with macroaggregate stability, management has often been stable over long periods of time, e.g., continuous forest, pasture, or tillage. The high correlation probably reflects not only aggregate stabilization by organic matter, but also organic matter stabilization by aggregates. For a given type of soil management, correlation between organic matter and structural stability can be highly

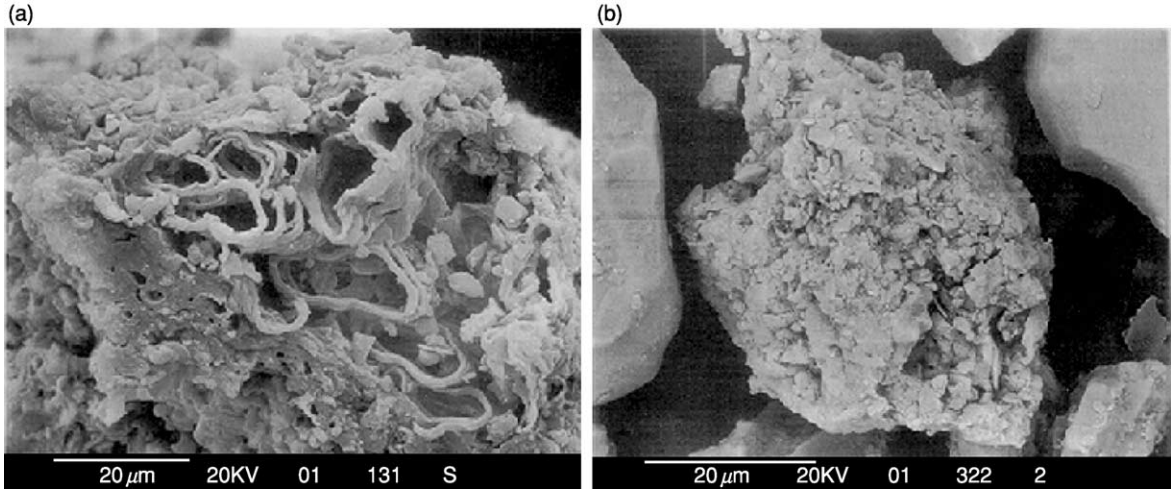

Figure 8 Micrographs of 20–250 μm aggregates showing (a) partly decayed vascular bundle surrounded by inorganics; (b) aggregates with elongated void running from top left to bottom right, with no remnants of plant anatomy evident. soil-dependent, with texture playing a major role. In many cases a certain threshold level of organic matter is necessary before macroaggregates begin stabilizing (Figure 10). The threshold value tends to increase with increasing soil clay content, suggesting that a critical amount of organic matter per unit mineral surface area must be exceeded in order for effective aggregation to occur.

Earthworm casts Earthworm casts are the indurated soil material surrounding channels left in the soil by earthworms. Casts are initially quite unstable, since they are essentially puddled soil emitted from the earthworm's gut. Stability comes later, as a result of microbial interaction with organic materials mixed with soil in the gut. Fungal hyphae also contribute to cast stability, but probably originate from fungi outside the casts since fungi are strict aerobes that cannot survive inside the earthworm gut. When disrupted by tillage or mild shaking in water, earthworm casts generally break down into macroaggregate-sized fragments, and thus are often classified as macroaggregates.

Casts provide stability to earthworm channels, which over time under zero-tillage conditions may occur in such numbers as to contribute significantly to soil hydraulic conductivity and aeration status. An important property of these channels is their continuity, which makes them particularly effective as preferential flow conduits. Tillage disrupts continuity of earthworm channels, rendering them largely ineffective for transport.

Role of Wetting and Drying on Soil Structure Development

A key element in the development of soil structure is the cyclic pattern of wetting and drying of field soils.

When wet soils dry, particles are drawn together by negative pressures or suctions that develop in the pore water. Microscopically, this promotes clay orientation and interparticle bonding. Macroscopically, the soil as a whole shrinks or decreases in volume, causing the development of crack networks and surfaces of weakness between neighboring soil elements. These to a large extent define the boundaries of soil aggregates, particularly macroaggregates, and form continuous channels that facilitate water infiltration and gas movement.

The extent of soil cracking depends primarily on the intensity of drying, and on the amount and type of soil clay minerals. Soils with large amounts of 2:1 clay minerals, such as vertisols, are notorious for networks of large shrinkage cracks. At the other extreme, soils with predominantly nonexpandable clay minerals, such as oxisols, exhibit very little shrinkage and cracking behavior. This to a large extent explains the characteristic 'massive' soil structure of oxisols, manifested by a lack of visually distinct macroaggregate boundaries.

If crack networks extend to the soil surface, as is usually the case in untilled soil, then water infiltration during rainfall events occurs preferentially down these cracks until swelling causes the cracks to seal up again. Dispersed clay in the infiltrating water may be deposited at crack boundaries as water infiltrates the

surrounding aggregates, forming clay skins or 'cutans' on the aggregate surfaces. Also, since the soil at crack surfaces is the first to wet during infiltration events, soil displacements during wetting may result in shearing or 'smearing' of these surfaces. Such shear zones, or 'slickensides,' are particularly notorious in vertisols.

Characterization of Soil Structure Based on Visual Assessment

Visual Inspection of Soil Aggregates

A routine component of soil surveys is the description of soil macroaggregates based on visual examination. The criteria used in this classification scheme are type or shape, class or size, and grade or distinctness. Different structure types are illustrated in Figure 11, and further details are given in Table 3.

A certain amount of subjectivity exists in deciding the precise category for a given soil structure, particularly with respect to shape and grade. Nevertheless, the classification system has been used successfully for grouping soils according to structure-related properties such as permeability and preferential flow of solutes. This is largely due to the fact that aggregate morphology is related to morphology of the interaggregate void spaces where most water and solute transport takes place. For example, blocky

Table 2 Sensitivity of various chemical indices in relation to changes in aggregate stability over time

Previous cropping history	*Aggregate stability (MWD, mm)*	*Organic C (%)*	*Acid-hydrolyzable carbohydrate (%C)*	*Hot water-extractable carbohydrate ($\mu g\ C^{-1}$)*	*Microbial biomass C ($\mu g\ C\ g^{-1}$)*
18-year pasture	2.7	3.2	0.35	208	1018
4-year pasture[a]	2.5	2.5	0.26	169	890

and prismatic macroaggregates are often bounded by networks of large, continuous cracks, whereas interaggregate void spaces for granular or crumb structures are smaller and more finely distributed.

Image Analysis

Examination of photographs of soil crack patterns, or of thin sections, has long been used to obtain detailed information on the shape of aggregates and their spatial organization in relation to interaggregate void spaces. This has become increasingly feasible with the advent of powerful yet low-cost digital image acquisition and analysis technology. Three-dimensional image analysis is also possible using techniques such as computer-aided tomography.

Mathematical Models of Soil Structure

Aggregate Size Distributions

A common method for characterizing soil structure involves measuring the size distribution of soil fragments or 'aggregates' produced by a specified fragmentation method. The distributions are often fitted to two-parameter probability models such as in Table 4. In many cases one of the two parameters is nearly constant. For example, for 'fractal' distributions, the fractal dimension D may be relatively constant. Likewise for log-normal and Weibull distributions, the geometric standard deviation σ and exponent λ, respectively, often do not vary much. In such cases the distribution may be defined by specifying only the diameter X at some fixed probability P, or a probability-weighted diameter or 'mean weight diameter' defined over some fixed probability interval (P_1, P_2) as:

$$\mathrm{MWD} = \int_{P_1}^{P_2} X(P)\,dP \qquad [1]$$

Pore Size Distributions

Pore size distributions may be determined by microscopic examination of thin sections, or inferred indirectly from moisture release characteristics or mercury intrusion porosimetry. The latter two methods are based on the capillary relation between equivalent cylindrical pore radius (r) and gauge pressure head (h) at which liquid will just enter or recede from the pore:

$$r = 2\sigma\cos\Phi/\Delta\rho g h \qquad [2]$$

Here ρ is liquid density, σ is solid–liquid surface tension, g is the gravitational constant and Φ is the solid–liquid contact angle. Equation [2] allows inferring the total volume of voids in radius interval $r + dr$ from the measured volume of liquid drained or intruded in the pressure head range $h + dh$. The pore-size histograms in Figure 7 are an example of distributions inferred by this method.

For the common case of liquid water in non-hydrophobic soils, where $\rho \approx 1\ \mathrm{g\,cm^{-3}}$, $\sigma \approx 71\ \mathrm{dyn\,cm^{-1}}$, and $\Phi \approx 0$, eqn [2] reduces to:

$$r = 0.15/h \qquad [3]$$

where r and h are expressed in cm.

Scaling Models of Soil Structure

Soil structure often exhibits certain similitude or 'scaling' properties, which greatly simplify its mathematical representation. Two types of scaling have received wide attention in soil science, fractal scaling and Miller scaling (in honor of the brothers E.E. and R.D. Miller, who developed the original concepts). Fractal scaling concerns similarities between hierarchical levels in a given soil, whereas Miller scaling deals with structural similarities between different soils. In both cases, the underlying assumption is that the structural elements being compared are similar

Table 4 Common cumulative probability functions used to characterize aggregate size distribution in soils

Distribution	*Functional form*	*Definition of variables*
Fractal	$P(x) = \left(\frac{X}{\sigma}\right)^{3-D}$	$P(x)$ = cumulative mass fraction X = aggregate diameter σ, D = constants
Log-normal	$P(x) = \frac{1}{\sigma\sqrt{2\pi}}\int_{-\infty}^{\ln X} \exp\left\{-1/2\left[\ln\left(\frac{X}{\mu}\right)\right]^2\right\} d\ln X$	$P(x)$ = cumulative mass fraction X = aggregate diameter μ,σ = constants
Weibull	$P(x) = 1 - \exp\left\{-\left(\frac{X}{\sigma}\right)^{\lambda}\right\}$	$P(x)$ = cumulative mass fraction X = aggregate diameter σ, λ = constants

geometrically, differing only in some characteristic dimension or 'length.'

Fractal scaling relations between hierarchical levels in a given soil Fractals may be defined, somewhat simplistically, as hierarchical porous or irregular objects composed of successively nested similar elements. To illustrate, a simple fractal object is shown in Figure 12. The lowest hierarchical level (Figure 12a) plays the role of reference element or 'generator.' A second hierarchical level (Figure 12b) is established by forming a larger cluster from the primary clusters. These in turn form a third hierarchical level (Figure 12c), and so on.

The filamentous fractal object in Figure 12 is similar in many ways to particle clusters formed during diffusion-limited flocculation. Other more compact fractal objects, like the one shown earlier in Figure 1b, are perhaps more representative of soil aggregates.

A property of these and many other self-similar objects is that the number of primary particles N required to form a given hierarchical level is a non-integer power law function of the characteristic length L (aggregate diameter) at that hierarchical level, i.e.:

$$N \propto L^D = L^{E-1+f} \qquad [4]$$

Here E represents dimensionality of the problem ($E = 3$ for three-dimensional space, and 2 for two-dimensional objects in the plane) and f is a fraction $0 > f \leq 1$. The parameter $D = E - 1 + f$ is often known as the fractal dimension. The fraction f increases with the degree of 'space-filling' of the given fractal object. For example, f has a value of approximately 0.465 for the open filamentous object in Figure 12, and a value closer to unity (0.658) for the more compact 'aggregate-like' structure in Figure 1b. In the case of complete space filling (such as squares formed by placing smaller squares edge to edge, cubes formed by placing smaller cubes face to face, etc.), $f = 1$ and eqn [4] reduces to the familiar Euclidean relation $N \propto L^E$.

A consequence of scaling property eqn [4] is that the number of particles per unit 'characteristic' bulk volume, N/L^E, varies as L^{f-1}, which is an inverse relation whenever $f < 1$. Consistent with this result, aggregate bulk density often decreases in linear log-log fashion with increasing aggregate size (Figure 13).

Analysis of pore spaces in certain fractal structures has yielded theoretical power law relations between volumetric water content θ and matric suction h. At least qualitatively, this agrees with the well known empirical Brooks–Corey relation:

$$\theta(h) = \theta_{sat}(h/h_e)^b \qquad [5]$$

where θ_{sat} is saturated water content, h_e is suction at air-entry and b is a soil-dependent constant.

Fractal scaling models have proved particularly useful for describing the geometry of complicated crack networks in soils.

Miller scaling relations between different soils In Miller scaling, no *a priori* assumption is made regarding fractal hierarchy within a given soil (although fractal scaling is allowed under certain conditions). All that is required is similitude between

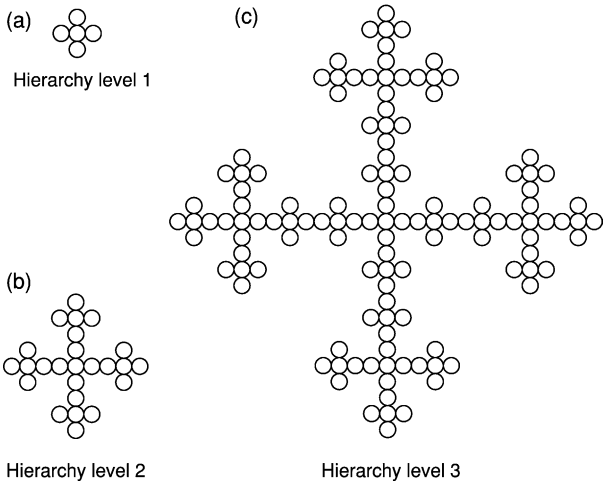

Figure 12 Self-similar filamentous objects of increasing hierarchical levels. Adapted with permission from Meakin P (1991) Fractal aggregates in geophysics. *Review on Geophysics* 29: 317–354.

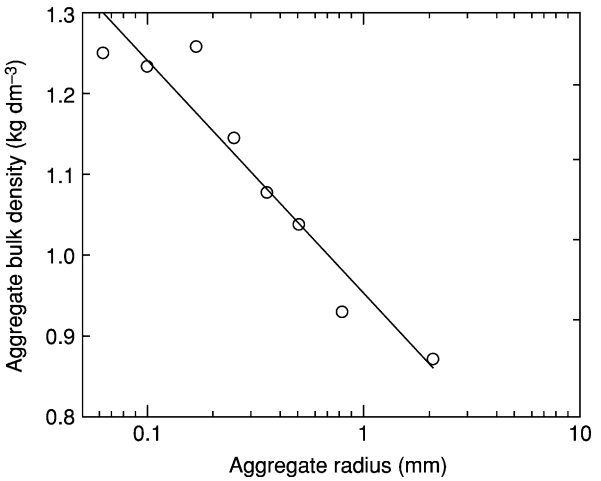

Figure 13 Bulk density of soil aggregates as a function of their radius. (Data from Chepil WS (1950) Methods of estimating apparent density of discrete soil grains and aggregates. *Soil Science* 70: 351–362, with permission.)

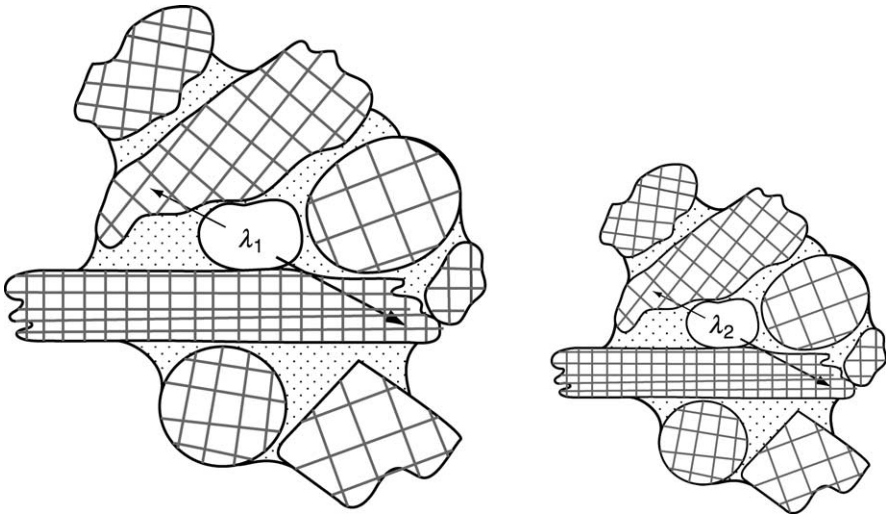

Figure 14 Illustration of two Miller similar soils with different characteristic lengths λ_1 and λ_2. After Miller EE and Miller RD (1956) Physical theory for capillary flow phenomena. *Journal of Applied Physics* 27: 324–332.

different soils, regardless of what the internal hierarchy may be.

In its strictest sense, Miller similitude assumes that the geometry of both elementary particles and their structural organization is identical across soils (Figure 14). Assuming dominance of capillary phenomena and creeping Newtonian fluid flow, this type of similarity imposes scale invariance on the dimensionless moisture release characteristic $\theta(h\lambda/\sigma)$ and the dimensionless hydraulic conductivity function $K(\theta)\eta/\lambda^2$, where K(θ) is hydraulic conductivity K at moisture content θ, η is fluid viscosity and σ is surface tension of the liquid–vapor interface. Miller similar soils always have identical porosity.

In practice, a weaker form of Miller similitude or 'generalized scaling' is often adopted, under recognition that it is usually the larger soil pores (i.e., those in upper hierarchical levels) that exhibit similitude and furthermore conduct most of the pore water. In generalized scaling, not only is the characteristic length λ of these large pores allowed to vary across soils, but also the soil volume fraction or 'effective' porosity P_e that they occupy. This is illustrated in Figure 15, where similarly shaped conducting or 'effective' structural units of different characteristic lengths λ_1 and λ_2 are embedded in a surrounding nonconducting soil matrix. For a given value of λ, the 'effective' porosity P_e is proportional to the number of elementary structural units per unit overall soil volume. Thus P_e may be considered a characteristic 'pore number' scaling factor, complementing λ which accounts for characteristic size. This contrasts with Miller similar soils, where λ is the only independent scale factor because P_e is always constant.

A consequence of generalized scaling behavior is invariance of the reduced moisture retention function $S_e(h\lambda/\sigma)$, where S_e is an 'effective' pore saturation defined as:

$$S_e = \theta_e/P_e = (\theta - \theta_o)/(\theta_{sat} - \theta_o) \qquad [6]$$

Here θ and θ_{sat} are the actual and saturated soil moisture contents, respectively, and θ_o is a 'residual' water content below which scaling relations no longer apply. θ_o may be considered as the water content when all the 'effective' structural units have drained and only the nonconducting matrix surrounding the 'effective' structural elements remains saturated. The parameter $\theta_e = \theta - \theta_o$ is known as the 'effective' water content and $\theta_{sat} - \theta_o$ is the effective porosity P_e.

Soils with invariant $S_e(h\lambda/\sigma)$ functions are frequently observed to have scale-invariant hydraulic conductivity functions $K(S_e)/\lambda_K^2$, where λ_K^2 is an empirical soil-dependent scale factor that may or may not correlate with the pore size scale factor λ. Only under strict Miller similarity does $\lambda = \lambda_K$.

Two fractal soils will also exhibit Miller scaling, if: (1) the shapes of the initial generating structures are the same in both soils, even though their characteristic lengths λ are different; and (2) both soils have the same number of hierarchical levels.

Structure of Tilled Agricultural Soils

Throughout history, modification of soil structure by tillage has played a central role in crop production. The tilled 'plow layer' plays a crucial role in determining plant growth and transport of gas, water, and

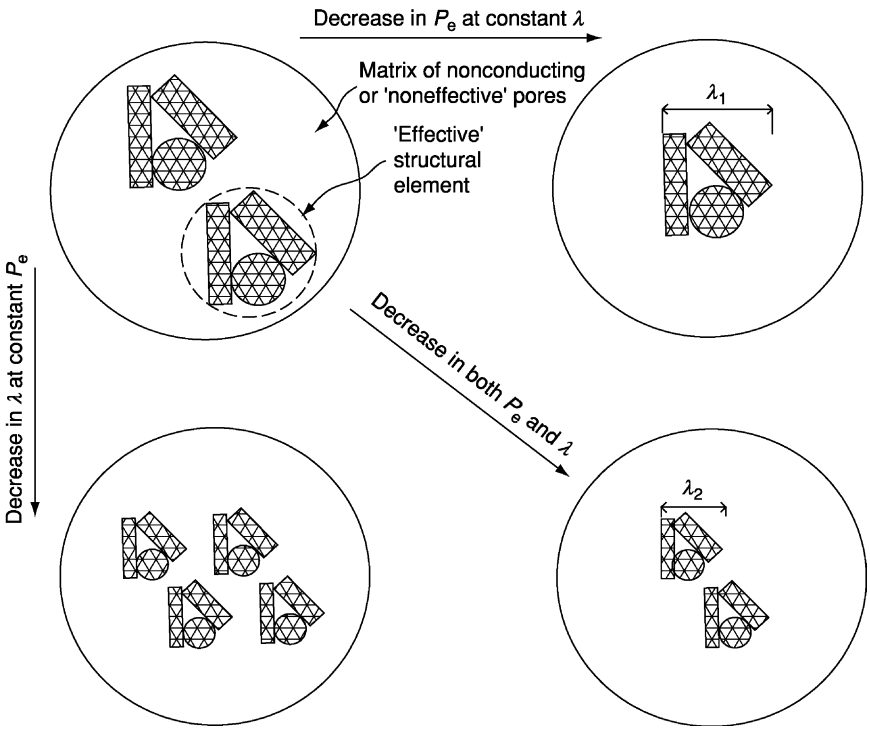

Figure 15 Illustration of four similar soils exhibiting generalized scaling.

chemicals in the environment. Thus, no review of soil structure would be complete without some discussion on structural dynamics in tilled soils.

Initial Soil Conditions Produced by Tillage: Soil Tilth

The structure or 'tilth' of freshly tilled soil is defined by the size and shape distribution, spatial arrangement, and internal structure of soil fragments produced by tillage. For a given soil and tillage implement, the tilth obtained depends primarily on soil moisture content at time of tillage.

Tillage under wet conditions, particularly in heavy-textured soils, generally results in large, plastically deformed fragments where internal structure may be seriously damaged or 'puddled.' Tillage of dry soils, on the other hand, generally results in minimal plastic deformation and structural damage, but undesirably large fragments may still be produced. The optimum soil moisture content for tillage is at some intermediate value, often close to the lower plastic limit, wherein maximum fragmentation occurs with little plastic deformation. Soils in this condition are said to exist in their most 'friable' state. Soils with predominantly large or intermediate pore sizes, associated with light texture or good structure or both, tend to be friable over fairly large ranges in moisture content. On the other hand, poorly structured fine-textured soils, particularly those dominated by high-activity clays, tend to present narrow moisture ranges for maximum friability.

Post-tillage Soil Structural Transformations

The loose structure produced by tillage tends to be highly unstable, so that under action of wetting and drying the soil resettles back toward a more stable structural state. The most important components of this resettlement process are crusting at the soil surface, and fracture and plastic deformation of aggregates deeper in the tilled layer.

Surface crusting of tilled soils The formation of thin (<2 mm) crusts at the soil surface, due to action of raindrops and sprinkler irrigation, is a common feature of cultivated soils throughout the world. Crusts are characterized by greater density, higher shear and tensile strength, finer pores and lower hydraulic conductivity than the underlying tilled soil. Important consequences are poor seedling emergence and increased runoff and erosion. A thin-section photograph taken from crusted soil is shown in Figure 16.

Crusting is thought to be a combined effect of two processes: (1) aggregate rupture caused by mechanical forces, such as raindrop impact and pore-air entrapment during rapid water infiltration; and (2) dispersion of clay particles. At low electrolyte concentrations, soils with Na^+-dominated exchange complexes tend to disperse spontaneously upon wetting. Ca^{2+}-dominated soils at low electrolyte concentrations may also disperse on wetting, but this

frequently requires additional mechanical energy input, such as by recent tillage or raindrop impact. Dispersion in both Na^{+}- and Ca^{2+}-dominated soils is reduced at high electrolyte concentrations, but to a much greater degree in the Ca^{2+}-dominated case.

Soils with 10–30% clay content, with at least traces of smectitic clay and high amounts of silt, seem to be the most prone to crusting. Clay contents >30% tend to stabilize aggregates against disruption, whereas at <10% clay not enough fine material is present for dispersion to have significant effects.

Efforts to control crusting mainly involve ground cover to reduce raindrop impact, and chemical application to control dispersion and stabilize aggregates. Commonly used chemicals are moderately soluble Ca^{2+}-salts such as gypsum that maintain high Ca^{2+} concentrations in solution, together with polymers such as polyacrylamides (PAM) that interact with clay surfaces to promote flocculation and aggregation.

Fracture and plastic deformation of aggregates during wetting and drying cycles At depths greater than several millimeters in the plow layer, soil is not subject to direct raindrop impact, and wetting occurs more gradually and under greater tensions than in the surface layer. Thus, the mechanisms governing soil structural changes are different from the surface layer. The main mechanisms appear to be aggregate fragmentation due to differential soil swelling during water infiltration, and plastic deformation of wet aggregates due to concentrated shear stresses at interaggregate points of contact.

Wetting-induced aggregate fragmentation seems to increase with increasing soil shrink–swell potential. The most extreme and familiar manifestation is the 'self-mulching' of vertisols, wherein large soil clods completely break down to small fragments after only one or two wetting and drying cycles (Figure 17a). Other heavy-textured soils with lesser clay activity manifest the same phenomenon, but generally require more wetting and drying cycles to achieve comparable amounts of fragmentation (Figure 17b,c).

Plastic deformation of aggregates occurs when shear stresses at interaggregate contact points exceed the plastic yield strength (dependent on water content) of the soil material. The result is a gradual flattening and coalescence of interaggregate contact points (Figure 18), tending toward a state where aggregate boundaries disappear and the soil reaches its original

isotropic structure. The main causes of the concentrated stress at interaggregate contact points are believed to be overburden pressure and capillary forces due to water menisci between adjacent aggregates.

Long-Term Effects of Tillage

In the short term, tillage produces a loose soil structure conducive to plant growth and water infiltration. However, when intensively tilled soil is allowed to reconsolidate through the above mechanisms over an extended period, it often reaches a state of greater compactness than if it had never been tilled at all, typically requiring years in the undisturbed state to recover its original (pre-tillage) structure.

The Notion of Structural Quality and the Nonlimiting Water Range

An important question is: what constitutes a 'good' or 'poor' soil structure for plant growth? These attributes pertain to the general notion of structural quality. Such a notion is difficult to quantify, because plant growth in soils is strongly influenced by a number of structure-related physiological stress factors, such as soil aeration, mechanical impedance, and water availability, all of which vary in different ways with changing soil water content. For example, aeration stress is greatest at high water content, and decreases as the soil dries out, whereas stresses associated with water availability and mechanical impedance tend to increase with decreasing water content. Soil structure acts as a modifier of these relationships, by increasing or reducing the severity of each stress factor at a given soil water content.

Optimum soil physical conditions for plant growth generally reside within some intermediate range of water content where none of the stress factors is limiting. This range is known as the nonlimiting water range (NLWR). Plants growing in soils with a wide NLWR have a lesser probability of experiencing stress during their growth cycle than those growing in soils with a narrow NLWR. The NLWR has been proposed as a simple, measurable indicator of soil physical conditions or structural quality. In this framework, soils with a wide NLWR are said to have good structure, whereas those with a narrow NLWR are considered poorly structured.

Summary

The proper study of soil structure includes the definition of its essential nature, its role in the environment, methods of its characterization, and processes involved in its development and degradation. Especially important are the role and dynamics of soil structure in agricultural ecosystems, primarily because it is in these ecosystems that soil structure is most influenced by, and in turn influences, human management. Simple mathematical models of soil structure have proved useful in explaining hydrological and other macroscopic phenomena in soils.

SUBSOILING

R L Raper, USDA–ARS, Auburn, AL, USA

Published by Elsevier Ltd.

Introduction

'Subsoil' refers to the stratum of soil immediately below the surface soil or topsoil. Often this layer is overlooked, as most land management is focused on the topsoil, which can be altered drastically by tillage and other practices. However, the subsoil can have a large impact on a soil's potential productivity. If this layer of soil is extremely dense, roots may not penetrate, rooting volume will be decreased, nutrient uptake will be reduced, and plants may become susceptible to drought; also, water may not be able to infiltrate into the subsoil, thus limiting available water for plant growth and increasing surface runoff and potential soil erosion. Disrupting the subsoil to allow proper water infiltration and root growth may be necessary for optimum plant response.

'Subsoiling' refers to the process of soil tillage performed by a tool inserted into the soil to a depth of at least 350 mm. Tillage conducted by a narrow tool inserted to a more shallow depth is sometimes referred to as chisel plowing and is mostly used to loosen or level the soil surface and prepare a seedbed. Although tillage has been performed for several thousand years at a shallow depth, subsoiling is a relatively new operation, having only been performed since vehicles have excessively compacted the soil through their large mass and frequent traffic. Prior to the twentieth century, the ability to till deeper than just a few centimeters was not possible due to a lack of tractive force, nor was it necessary, because compaction due to repeated vehicle traffic had not yet been caused. In addition, naturally dense subsoils (e.g., hardpans, fragipans) require such treatment to allow proper root growth and drainage.

Shallow soil compaction caused by natural processes or field equipment can usually be alleviated by chisel plowing to shallow depths. However, if compaction penetrates deeper, more radical measures such as subsoiling may be necessary. This deeper compaction is often caused by repeated trafficking of the soil surface with large vehicle loads. In some locations, natural processes can lead to deep compaction, which can restrict root, water, and air movement in the soil.

Currently, subsoiling is practiced on a routine basis throughout the world. Many soils respond positively to subsoiling, resulting in yield improvements. Tillage tools used for subsoiling vary widely and result in differences in residue draft force requirements, remaining on the soil surface, and belowground soil disruption.

Measurement of Subsoiling

Determining when to subsoil requires some measurement of soil compaction. Cone index is the most accepted measure of soil compaction and has been used to determine when roots are restricted and can no longer expand into soil. This term is defined as the force required to insert a standard 30° cone into the soil. When values of cone index approach 1.5–2 MPa, root growth becomes limited and plants can start suffering the ill effects of soil compaction. After subsoiling, however, cone index values as low as 0.5 MPa are commonly found down to the depth of tillage (Figure 1).

Benefits of Subsoiling

The most obvious benefit of subsoiling is the disruption of deep, compacted subsoil layers. If soil compaction is excessive in these layers, roots cannot

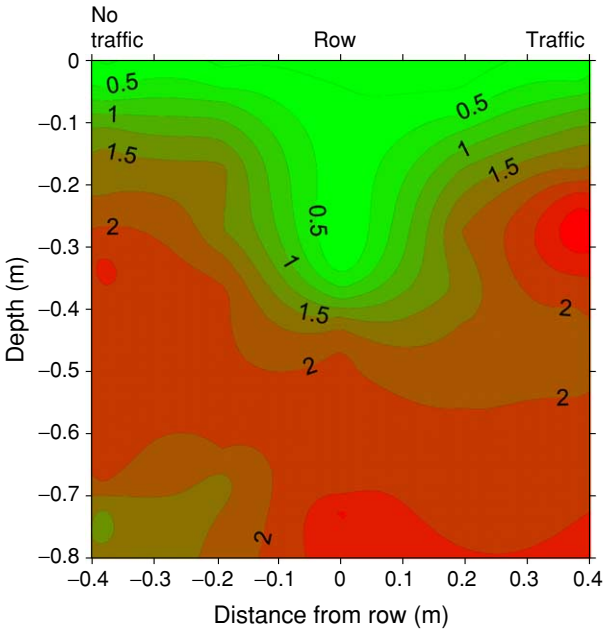

Figure 1 Cone index (mega pascals) isolines of soil showing location of nontrafficked row middle, row, and trafficked row middle. Minimal values of cone index are colored green and are shown near the center of the graph, representing root extension down to 0.3 m. Severely compacted zones are particularly evident under the trafficked row middle at the 0.3-m depth.

penetrate and are restricted to shallow depths. During times of drought, plants grown in a compacted soil are immediately susceptible, as their roots are confined to shallow zones that do not contain adequate soil moisture. Subsoiling excessively compacted soils lossens the soil for root growth, the depth of which is increased, so the plants are better able to withstand periods of drought.

Coupled with the increased root growth is the improved infiltration that usually accompanies subsoiling. Rainfall that previously exceeded infiltration capacity can be stored in the subsoil. The loosened soil provides pathways into the soil for rainfall to move quickly, instead of ponding on the soil surface and eventually evaporating or running off. Larger amounts of soil moisture may then be available to the plant during the growing season when moisture may otherwise be limited.

Increased numbers of macropores are also found after subsoiling. Even though some of these pores disappear as the soil reconsolidates, many stay open and provide increased storage of water and oxygen for plant roots. However, it is important that subsequent vehicle traffic be minimized to achieve long-lasting effects of subsoiling. Some research has reported that benefits of subsoiling are lost by the second pass of a vehicle tire. This could mean that subsoiling might not benefit a crop if traffic from a primary tillage operation and a planting operation were allowed to stray too close to the subsoiled channels. Maintaining the loosened soil profile and the increased storage capacity for water could be extremely valuable to plant roots during temporary summer droughts.

Ultimately, crop yields may improve from subsoiling, although the amount of improvement is difficult to estimate, because soil type, soil condition, plant species, and climate all have large effects. Many soils have shown benefits of being subsoiled; however, the amount of relative benefit may be offset by the expense of performing the operation. Some coarse-textured soils (sandy-to-loamy), which compact easily and require minimum tillage forces for subsoiling, show significant yield improvements when subsoiled. Some fine-textured soils are not economically subsoiled due to the lack of a yield improvement or because of the high draft forces necessary for subsoiling.

Subsoiler Design

Tillage tools used for subsoiling vary greatly in design and use. The individual vertical members that contact the soil and provide disruption are referred to as shanks. Their design varies greatly depending upon purpose, geographical location, soil type and depth of use.

Prior to 1950, most subsoiler shanks were straight, with a slight forward projection angle. However, research near the end of that decade recognized that other shapes, including curved and elliptical subsoiler shanks, can provide reduced draft forces in some soil types and soil conditions (Figure 2). Eventually, parabolic shanks became widely used and accepted as reducing draft forces. Some studies, however, have found that straight shanks mounted at an aggressive forward angle have reduced tillage draft when used in sandy soils. One negative effect of using curved shanks is that these shanks are designed to operate at a particular depth. When curved shanks are operated at depths either shallower or deeper than their intended depth, draft can increase, probably due to soil bodies that build up in front of the shanks, resulting in 'soil-on-soil' friction in contrast to the lesser 'metal-on-soil' friction (Figure 3).

Some subsoilers disrupt the soil in a symmetric manner, leaving equally disturbed soil on either side of the subsoiler as it moves in a forward direction. However, in the mid-1970s, the bentleg subsoiler was developed, which was designed to disturb the soil in a nonsymmetric manner. This shank is bent to one side by 45°, with the leading edge rotated forward by 25°.

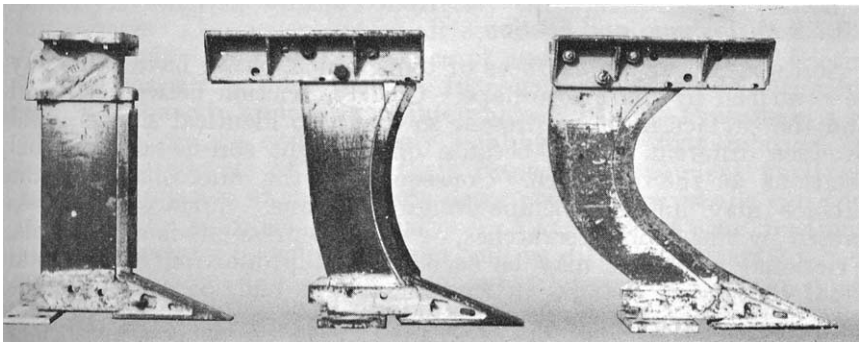

Figure 2 Straight, slightly curved, and deeply curved subsoilers, as tested in the 1950s. (Reproduced with permission from Nichols ML and Reaves CA (1958) Soil reaction to subsoiling equipment. *Agricultural Engineering* 39: 340–343.)

Figure 4 Side (left) and front (right) view of a bentleg subsoiler.

As the shank is traveling forward, it contacts the soil over a 216-mm width, which is substantially larger than any of the nonbentleg subsoilers. The main advantage of the bentleg subsoiler is its ability to pass through the soil leaving the surface relatively free of disturbance. For this reason, many producers have adopted this form of tillage as a method of alleviating soil compaction while maintaining large amounts of residue on the soil surface (Figure 4).

The bentleg subsoiler is commonly thought to require larger amounts of draft energy than traditional subsoilers. However, several studies have shown that comparable draft forces are generated for the bentleg subsoiler and traditional subsoilers if they are operated at similar depths.

Several other methods have been advocated for reducing draft on agricultural vehicles or increasing belowground disruption. These include vibrating the subsoiler, rotating the subsoiler shanks, placing a wing on or behind the subsoiler shank, using multiple shanks placed immediately behind each other and operating at different depths, or using a rolling coulter. Many of these experimental methods have shown promise and are undergoing further refinements, but none have been adopted by the agricultural machinery industry as of 2003.

Force Required for Subsoiling

Subsoiling requires a great amount of tillage energy. Based on experimental data obtained throughout the USA, the American Society of Agricultural Engineers' (ASAE) Standard D497.1 gives the following equation for calculation of draft force for subsoiling:

$$D = F_{\mathrm{i}}\left[A + C(S)^2\right]WT \qquad [1]$$

where D is implement draft (in newtons), F is dimensionless soil texture adjustment, i is fine (1), medium (2), or coarse-textured (3) soil, A and C are machine-specific factors, S is field speed (in kilometers per hour), W is number of rows or tools, and T is tillage depth (in centimeters).

Many factors influence draft forces of subsoiling and are represented in Eqn [1]. Soil texture certainly has a very large effect on draft force, with the factor F_{i} ranging from 0.45 for coarse-textured soils to 1.0 for fine-textured soils. (Coarse-textured soils are described as being sandy soils, medium-textured soils are described as being loamy soils, and fine-textured soils are described as being high in clay content.) Speed is also considered to be one of the most important factors. Because speed has a large effect on draft force, most subsoiling operations are conducted at relatively low speeds. The number of subsoiler shanks is also important, with the draft force increasing proportionally for each additional shank being pulled through the field.

One factor that is easily overlooked and that appears last in the equation is tillage depth. Often producers set their subsoiler depth at the deepest position that the tractor can pull. The subsoiler will only be moved upward toward the soil surface when excessive draft is sensed; after this area of excessive soil strength is passed, the original depth of subsoiling will be returned to. However, recent research reports that optimum yields are achieved when the depth of tillage is targeted to the depth of the root-impeding layer. Here, subsoiling energy is only expended to the problematic depth without wasting it by tilling too deeply. Also, excessive depths of subsoiling may increase compaction at these depths, as pressure from vehicle traffic could be propagated downward to depths below the tillage zone. As tillage is conducted more deeply every year, compaction moves downward through loosened soil horizons.

Eqn [1] only gives an approximate mean range (±50%) for subsoiler draft force, as many differences

can exist between subsoilers. One difference that is commonly found between subsoiler shanks is tip design. For Eqn [1], factors *A* and *C* have been designated as 226 and 1.8 for narrow points, but as 294 and 2.4 for 30-cm winged points. The effect of the point is to increase the draft force substantially, while increasing belowground disruption.

Management Practices

Subsoilers have been used mostly to totally disrupt entire fields or severely compacted parts of fields, especially headlands where turning and excessive trafficking has occurred. V-frame subsoilers have typically been designed with subsoiler shanks positioned closely over the width of operation (**Figure 5**). Their width is set so that the disrupted zone from a shank intersects the disrupted zone from nearby shanks. The compacted portion of the field or the entire field is loosened using this method of subsoiling with little consideration for future field activities. However, some producers subsoil at a slight angle to the previous year's rows so that excessively trafficked lanes of the field are mostly removed. Another reason for conducting the subsoiling operation at an angle is that it ensures that an entire row would not be missed if an error in subsoiler positioning occurred or if a shank were bent or broken and did not adequately disrupt the soil. Secondary tillage is normally required to prepare the soil surface for planting after a complete subsoiling disruption operation.

As many producers have begun to realize the benefits of maintaining an adequate surface-residue cover, they have become concerned that the subsoiling operation may bury excessive amounts of crop residue. To avoid this, one method that has been widely adopted is called 'strip-tillage' or 'in-row subsoiling.' This process involves subsoiling directly beneath the row. A single shank is pulled through the soil directly beneath each row to loosen the soil only in close proximity to the crop. Tillage energy is not wasted on loosening zones between rows that are not necessary for crop roots. Areas between rows are mostly left undisturbed with full residue coverage. One significant difference between strip-tillage and subsoiling as conducted by a V-frame subsoiler is the condition of the soil as it is left by the implement. Strip-tillage implements usually include a method of closing the subsoiling slot left by the shank to prepare a seedbed because planting may immediately follow the strip-tillage operation (**Figure 6**).

When to Subsoil

The frequency of subsoiling is dependent primarily upon the particular cropping system and the soil's needs. In some areas of the world, benefits of subsoiling have been found up to 10 years later. However, in the southeastern USA, most research indicates that this tillage operation could be performed every other year without limiting yields. To a large degree, it depends upon the management system that is put in place following the subsoiling operation. When

Figure 5 V-frame subsoiler used for complete disruption of soil compaction.

Figure 6 Strip-tillage subsoiler used for subsoiling beneath rows. Note closing wheels, which prepare the seedbed for planting.

controlled traffic and in-row subsoiling are both used, a soil may be able to withstand the compaction forces generated by traffic on the soil surface. The forces that tires place on the soil surface in the row middles will not propagate sideways into the row area, because the hardened soil in the row middles will be able to withstand the traffic without deformation. This process is likened to tires running on cement pads which are located between rows in the field. As long as the tires are kept on the cement pads, little compaction occurs under the rows. The loosened soil beneath the rows will be able to maintain their loose structure for longer periods of time and may not need to be subsoiled as often. Even when subsoiling is performed, the shank runs in soil that was previously loosened and not recompacted and the subsoiling forces are reduced. New automatic steering systems that enable precise control of the tractor as it passes through the field could enhance the adoption of controlled traffic as a management tool and could reduce the need for annual subsoiling (Figure 7).

Figure 7 Crops grown in a controlled-traffic system, where subsoiled zones beneath rows are kept separate from compacted zones between rows. Note deep rooting beneath rows.

Because of the large energy requirements necessary for subsoiling, some producers subsoil only a portion of their field during a year. The next year, they alternate and till other parts. This incremental approach is continued until the entire field has been subsoiled and the operation begins again. This type of rotation may provide enough overall loosening of the soil to enable good productivity. However, if deep tillage is not performed during a year that had a moisture-limiting condition, yield reductions could occur. To reduce overall risk from drought effects on their crops, many producers who must subsoil do it on an annual basis.

What time of year to subsoil is largely dependent upon the producer's schedule. Many producers subsoil in the autumn after their harvest is complete. Subsoiling at this time of the year can be efficient, because farmers have several months to prepare for planting the next season's crop. Waiting until spring to subsoil can delay planting if adverse weather conditions exist. Subsoiling can also remove compaction and rutting caused by the harvesting process, which can excessively traffic the field with very large loads (usually defined as greater than 10 Mg per axle) from

the harvesting or transport equipment. Subsoiling in the autumn can also be helpful due to the ability to have a loosened soil profile during winter months when rainfall is greater for many climatic regions. This loosened soil profile has increased surface roughness and increased infiltration, which enables more rainfall to penetrate and to be stored for future crop use.

Many producers who practice in-row subsoiling wait until spring to subsoil. They subsoil immediately before planting to give the crop the maximum benefit from the subsoiling operation. Combination planters and subsoilers have been produced for a one-pass operation. Producers who typically use this cropping system subsoil on an annual basis because their soils recompact very easily. Measurements made in the southeastern USA have shown that subsoiling conducted in the autumn does not provide adequate soil loosening necessary for optimum crop yields due to the soil's natural ability to reconsolidate over the winter months.

There is one disadvantage to subsoiling in the spring: occasionally when the subsoiling operation is closely followed by planting, a problem can develop relating to the proper emergence of seedlings. Intense rainfall events can cause the subsoiling channel to settle quickly and move the seed downward within the loosened zone. Replanting the crop may be necessary if the seeds have been excessively covered by soil.

Another consideration for deciding when to subsoil is the moisture content of the soil. Maximum disruption of the soil profile is usually provided when the soil is extremely dry, in contrast to subsoiling when the soil is almost saturated. However, subsoiling forces increase dramatically when soil is dry, and adequate tillage or tractive energy may not be available. A reasonable compromise seems to be to recommend subsoiling when soil moisture is near the permanent wilting point, but soil drying has not progressed to the point of the hygroscopic coefficient, when soil moisture is in vapor phase (i.e., soil moisture is bound tightly to soil solids and little is available for plant use). Some research indicates that little difference in soil disruption is measured between soil moisture of the hygroscopic coefficient point and that of permanent wilting point. However, the difference in tillage forces required for subsoiling between these two soil conditions can be significant.

Maintaining Surface-Residue Coverage

Consideration also has to be given to the amount of soil-surface disruption. Often producers are concerned with trying to reduce draft forces and they forget about leaving the soil in a smooth condition appropriate for planting. Also, efforts should be made to ensure that an adequate amount of crop residue is not buried by the subsoiling operation. This may be especially important to fragile residues when a crop such as soybean is followed by subsoiling. Research results also indicate that subsoiling when soil is near the hygroscopic coefficient causes maximum disturbance to the soil surface. Subsoiling near the permanent wilting point disrupts the soil surface less and probably results in less residue burial. Properly choosing a subsoiling shank that minimally disturbs crop residue and then operating it at the correct soil moisture and at a proper speed results in minimal surface disturbance and maximum subsurface disruption.

Even though most research on subsoiling has targeted force reduction, some early observations of the soil surface indicated that the overall effect of shank design had little effect on soil breakup. However, recent research indicates that bentleg subsoilers typically do a better job of maintaining surface residue than subsoilers, which are used for complete disruption. Consequently bentleg subsoilers have been readily adopted for use in many conservation tillage systems.

Subsoiling in Irrigated Fields

When irrigation is available, yield responses to subsoiling are less obvious. Increasing plant rooting depth by subsoiling may not be important, as the plants are likely to obtain all of their moisture through irrigation water. There are two advantages of using subsoiling with irrigation: the first is the ability of the soil to store additional moisture after subsoiling so less frequent irrigation is necessary; the second is that not all parts of a field respond positively to irrigation. Lower-lying areas of irrigated fields that are poorly drained show yield increases when subsoiled.

Subsoiling in Perennial Crops

Most subsoiling operations are conducted in row-cropping agriculture, although many other crops may experience potential benefits from this operation. In many forest locations a subsoiling operation is typically conducted before pine seedlings are planted. The subsoiling operation is conducted by large, single-row plows pulled either by bulldozers or log-skidders (Figure 8). Usually, this operation is conducted every 3 m and the trees are planted soon after the operation is completed. Several advantages are seen from subsoiling prior to forestry planting, for example: (1) pine tree seedlings gain from having

Figure 8 Subsoiling plow used for forest tillage to prepare soil before tree planting. Note backward sweep of subsoiler shank, which is used to allow the implement to pass over tree stumps.

compacted soil disrupted, enabling roots to penetrate to depths adequate for soil moisture; (2) the forest soil surface is smoother and more easily accessible to machinery; and (3) there is economic benefit from having the trees machine-planted rather than hand-planted.

Fields where other nonannual crops are grown such as pastures, vineyards, orchards, and fields used for sugar cane production that are prone to repeated heavy machinery traffic are frequently subsoiled prior to planting. After they are planted, the crops may be in place for many years and the opportunity for loosening is reduced. Subsoiling can be performed after the crop is established, but it is not advisable: plant growth and yields may be detrimentally affected due to excessive root pruning, potentially followed by periods of drought.

Considerations Before Subsoiling

Even though it may be possible to subsoil a field to remove compaction, care should be exercised before this potentially expensive operation is performed. Once soil is loosened by subsoiling, it will easily recompact if traffic is applied in the same area. Research indicates that two passes of a tractor in the subsoiled area will cause the soil to return to its previous state prior to subsoiling. If traffic is controlled, however, the benefits of subsoiling can be long-lasting.

Using a cover crop has been shown in some locations to replace the need for subsoiling. Winter cover crops are able to increase infiltration of winter rainfall and assist with water storage for use by the main cash crop the following summer. Evaporation of soil moisture is also hindered by the residue cover provided by the winter cover crop, even persisting several months later during summer months. The increased amount of soil moisture present under the cover crop reduces the overall soil strength and allows the plant roots to continue to grow downward. However, cover crops are not advisable under all climate and soil conditions, and subsoiling may still offer increased crop response in severely compacted soils.

The overall management of the production system should be examined to determine whether the soil compaction that is being alleviated by subsoiling is natural or whether it is traffic-induced. If it is natural, then subsoiling may have to be performed on an annual basis to give plants the maximum benefit of the operation. However, if a portion of the compaction is machine-induced, adoption of controlled traffic or a cover crop may enable the subsoiling operation to be performed less frequently.

Producers should be aware that some soils may not respond positively to subsoiling even though they may appear to be compacted. Yield improvements may not be realized in soils that are not severely

compacted or are not in need of subsoiling. Even some soils that are compacted may have adequate plant growth due to the presence of old root channels or significant earthworm activity and may not be improved significantly by subsoiling.

Summary

Subsoiling is a necessary tillage process for many fields used for crop production. Subsoiling disturbs the soil down to at least 350 mm and provides for increased rooting in soils compacted by either natural causes or by vehicle traffic. The potential success of subsoiling varies depending upon the design of the shank, the timing of the operation, the crop, the soil, and management decisions. Ongoing research is aimed at a better understanding of subsoiling so that producers can determine whether their soils might benefit from this tillage process.

Introduction

The average sulfur (S) content of the earth's crust is estimated to be between 0.06 and 0.10%. It is usually ranked as the 13th most abundant element in nature. Sulfur occurs in soils in organic and inorganic forms, with organic S accounting for more than 95% of the total S in most soils from the humid and semihumid regions. The proportion of organic and inorganic S in soils samples, however, varies widely according to soil type and depth of sampling. It is usually somewhat lower in subsurface than in surface soils.

Although it is well known that S in soils is present mainly in organic combinations, very little is known about the identities of these S compounds. The inorganic S fraction in soils may occur as sulfate (SO_4^{2-}) and compounds of lower oxidation state such as sulfide (S^{2-}), thiosulfate ($S_2O_3^{2-}$), tetrathionate ($S_4O_6^{2-}$), polysulfides (S_n^{2-}, where $n > 10$), sulfite (SO_3^{2-}), and elemental S (S^0). The last four are detected in soils treated with elemental S or certain pollutants. In well-drained, aerated soils, most of the inorganic S

normally occurs as sulfate, and the concentrations of reduced S compounds are generally 1%. There are several forms of sulfate in soils. These include easily soluble sulfate, adsorbed sulfate, insoluble sulfate, and sulfate coprecipitated (cocrystallized) with $CaCO_3$. Under anaerobic conditions, particularly in tidal swamps and poorly drained or waterlogged soils, the main form of inorganic S in soils is sulfide and, often, elemental S.

Carbon–Nitrogen–Phosphorus–Sulfur Relationships

Significant information is now available on the relationships between C, N, P, and S in soils around the world. Unlike P, which can be present in significant proportions as organic and inorganic combinations, inorganic N and S values are very small relative to organic forms of these elements in soils. Therefore, often the relationships between organic C, total N (instead of organic N), organic P, and total S (instead of organic S) are reported. Significant variation can occur in the C:N:P:S ratios of individual soils, but the mean ratios for groups of soils from different regions are similar. Agricultural soils, in general, have a mean C:N:P:S ratio of approximately 130:10:1.3:1.3. Soils under native grass have ratios of the order of 200:10:1:1. Peat and organic soils have intermediate ratios of approximately 160:10:1.2:1.2. These ratios are shown in Table 1 for six Brazilian surface soils and six Iowa surface soils.

Sources of Sulfur in soils

Minerals Sources

Many S-containing minerals occur in nature. The main S-bearing minerals in rocks and soils are present in two states: (1) as sulfate, such as in gypsum ($CaSO_4 \cdot 2H_2O$), anhydrite ($CaSO_4$), epsomite ($MgSO_4 \cdot 7H_2O$), and mirabilite ($Na_2SO_4 \cdot 10H_2O$); or (2) as sulfide, such as pyrite and marcasite (FeS_2), sphalerite (ZnS), chalcopyrite ($CuFeS_2$), cobaltite (CoAsS), pyrrhotite ($Fe_{11}S_{12}$), galena (PbS), arsenopyrite ($FeS_2 \cdot FeAs_2$), and pentlandite $(Fe,Ni)_9S_8$.

Fertilizers Sources

There are many fertilizer materials, both liquid and solid, which are used to supply S to growing crops. The S source selected for any particular situation is determined by the crop to be grown, the S level of the soil, the cost of the material, and the ease with which its use can be fitted into a particular fertilizer program.

Atmospheric Sources

Rainfall and the atmosphere constitute a third important source of S in soils. It is estimated that in the USA more than 25 million tons of SO_2 or 13 million tons of S are emitted annually into the atmosphere. Most of these amounts are derived from combustion of fossil fuels, but industrial processes such as ore smelting, petroleum-refining operations, and other such sources contribute approximately 20% of

the total S emitted into the atmosphere. Another major source is volcanic activity around the world.

Chemical Nature of Organic Sulfur in Soils

Understanding the nature and properties of the organic S fractions in soils is important, because these compounds govern the release of plant-available S. Even though much of the organic S compounds in soils remains unidentified, three broad groups of S compounds are recognized. These groups have been classifed according to the nature of the reagents used or according to the groups of S compounds attacked by the reagents. Thus, three distinct groups of S-containing compounds have been identified (Figure 1):

1. Organic S that is not directly bonded to C and is reduced to H_2S by hydriodic acid (HI). This fraction is believed to be largely in the form of sulfate ester with C–O–S linkages. Examples of substances that contain these linkages include arylsulfate, alkylsulfates, phenolic sulfate, sulfated polysaccharides, choline sulfate, and sulfated lipids. Other organic sulfates could be present as sulfamates (C–N–S) and sulfated thioglycosides (N–O–S). On average, approximately 50% of the total organic S in humid and semihumid regions is present in this form, but it can range from 30 to 60% (Table 2). Values as high as 95% have been reported for Iowa subsoils. Unless otherwise indicated, the HI-reducible S includes the inorganic SO_4^{2-} fraction (Table 3);
2. Organic S that is directly bonded to C (C–S) and is reduced to inorganic sulfide by Raney Ni (50% each of Ni and Al powder) in an alkaline medium (NaOH). This fraction is believed to consist largely of S in the form of S-containing amino acids such as methionine and cysteine. Its concentration in soils ranges from 10 to 30% of the total organic S (Tables 2 and 3);

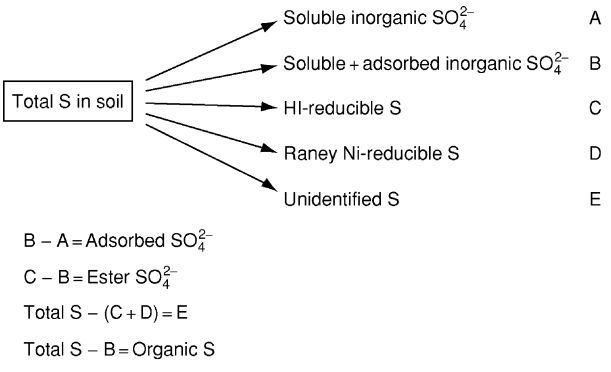

Figure 1 Organic and inorganic sulfur fractions in soils.

3. Organic S that is not reduced by either of the reagents employed in estimation of fractions 1 and 2. This unidentified fraction is inert to HI and Raney Ni. It is generally in the range of 30–40% of the total organic S (Tables 2 and 3). It is very stable, because it resists degradation by caustic chemical reagents; therefore, this fraction is of little importance as a potential source of S for plants.

Inorganic Sulfur in Soils

Inorganic S in soils may occur as sulfate and as compounds of lower oxidation states such as sulfide, polysulfides, sulfite, thiosulfate, and elemental S. In well-drained, well-aerated soils, most of the inorganic S normally occurs as sulfate, and concentrations of reduced S compounds are barely traceable, if present at all. The concentration of soluble SO_4^{2-} is estimated after extraction with 0.01% LiCl or 0.15% $CaCl_2$ solution, and the concentration of the soluble plus the insoluble fraction is estimated after extraction with a $Ca(H_2PO_4)_2$ solution containing 500 mg P l^{-1} (Table 2).

Fate of Inorganic Sulfate in Soils

The inorganic sulfate in soils may occur as water-soluble salts that can be leached from soils, adsorbed by soil colloids, or insoluble forms. Soil chemical properties such as pH, type of clay, and presence of cations are important factors in governing the leaching and adsorption of SO_4^{2-} in soils. The mechanism of SO_4^{2-} adsorption by soils involves coordination with hydrous oxides, exchange on edges of silicate clays, and molecular adsorption. Both the water-soluble and adsorbed SO_4^{2-} are available to plants. Under anaerobic (waterlogged) conditions, SO_4^{2-} is reduced to S^{2-} and precipitated as metal sulfide. This process is biological in nature.

Leaching losses

The movement of sulfate in soils determines the magnitude of losses of S in drainage water. Transport of sulfate within a soil profile is influenced by its concentration in soil solution, its reaction with the solid-phase components, and movement, velocity, and pattern of water movement within the soil. The relative magnitude of, and interactions among, these factors determines the physicochemical fate of the sulfate released from mineralization of organic S or added to soils as fertilizer, crop-residue decomposition, irrigation waters, and atmospheric deposition. From the information available on sulfate losses with percolating water, the following conclusions can be drawn:

1. Losses of SO_4^{2-} are reduced by cropping and are less with rooting and perennial crops than with annual crops;
2. Leaching losses of SO_4^{2-} are greatest when monovalent ions such as K^+ predominate; next in order are the divalent ions such as Ca^{2+} and Mg^{2+}, and leaching losses are minimal when soils are acid and appreciable concentrations of Fe and Al hydrous oxides are present;
3. Under comparable soil and cropping conditions, the amount of SO_4^{2-} removed from the soil profile is generally directly related to the amount of leachate;
4. Sulfate adsorption would lead to more rapid and complete removal of Cl^- from acid soils;
5. Sulfate losses increase with liming or amendment with phosphate;
6. Sulfate losses are less when the S fertilizer is banded than when broadcast.

Complete separation of the influence of physical and chemical soil properties on transport of sulfate is not possible, because several factors affect the distribution of an ion such as sulfate in the soil pores. These include: (1) the electric field surrounding the individual soil particles, and (2) the magnitude of the repulsive (or attraction) forces which are dependent on the mineralogy and chemical composition of the solid phase, and the pH and salt content of the aqueous phase.

Losses of S by leaching vary widely: some drainage water contains more S than the rain supplies, even though little or none is added in fertilizer. The extra quantity may be deposited directly on plants and soils from the atmosphere or released from soil organic matter or minerals. Expressed in kilograms of sulfur per hectare, the annual losses from unfertilized fields by drainage water in the state of Illinois range from 1.5 to 65 kg S ha^{-1}, in Germany they average 33 kg S ha^{-1}, in Europe and North America they average 15 kg S ha^{-1}, in South America they average 4.5 kg S ha^{-1}, and in some areas of Australia they are less than 1 kg S ha^{-1}. It has been estimated that between 3 and 32 kg S ha^{-1} is lost by tile drainage in the state of Iowa. In general, the annual loss from soils by leaching varies from insignificant amounts to as much as 320 kg S ha^{-1} from soils treated with S fertilizers.

Sulfate Adsorption by Soils

Soils vary widely in their capacity to adsorb sulfate. Because sulfate adsorption occurs at low pH values (less than 6), its adsorption is negligible in most agricultural soils ($pH > 6$). Its adsorption in subsurface acid horizons plays an important part in contributing to S requirement of crops; conserving S from excessive leaching, and in determining S distribution in soil profiles. Sulfate adsorption is a reversible process and is influenced by a number of soil properties. These include:

1. *Clay content and type of clay mineral*. Sulfate adsorption usually increases with clay content of soils. Kaolin minerals retain more sulfate than montmorillonite clays;
2. *Hydrous oxide of Al and Fe*. Hydrous oxides of Al, and to a lesser extent of Fe, show marked tendencies to retain sulfate, especially the former in certain soils;
3. *Soil horizon or depth*. Most soils have some capacity to adsorb sulfate. The amounts of sulfate adsorption in surface horizons may be low but are often greater in lower soil horizons due to the presence of more clay and Fe and Al oxides;
4. *Soil pH*. Sulfate adsorption in soils is favored by strong acid conditions. It becomes almost negligible at $pH > 6$;
5. *Sulfate concentration and temperature*. The amount of sulfate adsorbed is concentration- and temperature-dependent. The amount of sulfate adsorbed is in kinetic equilibrium with sulfate concentration

in solution. Temperature has a relatively small effect on sulfate adsorption by soils;

6. *Effect of time*. Sulfate adsorption increases with the length of time it is in contact with soil;

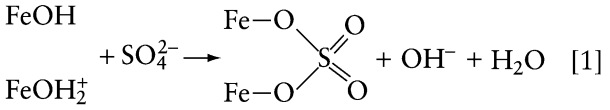
7. *Presence of other anions*. Sulfate is weakly held by soils. The retention decreases in the following order: hydroxyl > phosphate > sulfate = acetate > nitrate = chloride. Phosphate will displace or reduce the adsorption of sulfate;

8. *Effect of cations*. The amount of sulfate adsorbed is affected by the associated cation or by the exchangeable cation following the order: $H^+ > Sr^{2+} > Ba^{2+} > Ca^{2+} > Mg^{2+} > Rb^+ > K^+ > NH_4^+ > Na^+ > Li^+$. Both the cation and the sulfate from the salt are retained, but the capacity of adsorption of sulfate is different from that of the associated cation.

Mechanisms of Sulfate Adsorption by Soils

Several mechanisms have been proposed for adsorption of sulfate by soils.

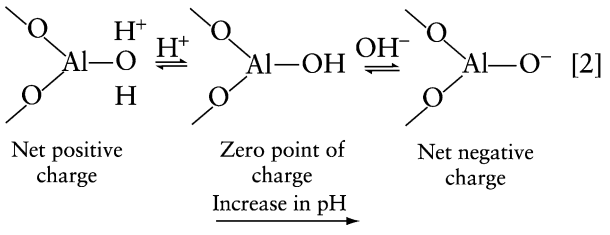
Coordination with hydrous oxides In acid soils sulfate adsorption essentially involves the chemistry of Fe and Al. The hydrous Fe and Al oxides tend to form coordination complexes due to the donor properties of oxygen. The adsorption involves the replacement of two surface OH groups (or OH_2^+) by one SO_4^{2-}. The two O atoms of the SO_4^{2-} are each bound to a different Fe^{3+}, resulting in a binuclear bridging surface complex:



[1]

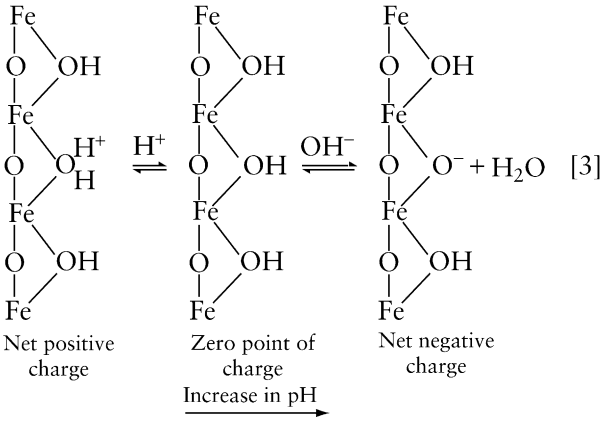
This reaction has been demonstrated to occur on the surfaces of goethite (α-FeOOH), and, because soils contain Fe oxides, it is assumed that a similar reaction takes place in soils under acid conditions.

The effect of pH on SO_4^{2-} adsorption by hydrous oxides in soil must consider the zero point of charge (the pH at which the change on the surface is zero). Deviation from this pH value involves protonation or deprotonation of Al oxides:



[2]

A similar protonation or deprotonation of Fe oxides is possible:



[3]

The positively charged Al and Fe hydrous oxides adsorb the SO_4^{2-} ions.

In addition to the mechanisms described above, homoionic Al-saturated clay coated with hydrated oxides R (Fe and Al) may adsorb sulfate ions as follows:

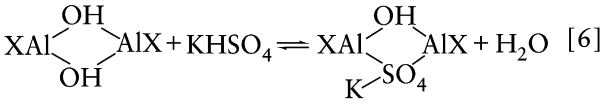
$$ {}^{y}K^+ + Al_x\text{—clay} + {}^{y}H_2O \longrightarrow Al_x(OH)_y^{Ky}\text{—clay} + {}^{y}H^+ \quad [4] $$

$$ SO_4^{2-} + R_x(OH)_y\text{—clay} \longrightarrow R_x[(OH)_{y-z}(SO_4)_z]\text{—clay} + {}^{z}OH^- \quad [5] $$

In this mechanism, it is assumed that K ion adsorption sites developed from the exchange and/or hydrolysis of Al on the clay surface. As a result of this hydrolysis, some Al ions are released into the solution. At the same time sulfate ions replace the OH ions from R(OH) coating on clay and substitutes for them. The replaced OH ions in turn react with H ions. According to this mechanism, whether the pH of the system increases or decreases depends on the relative rates of the two reactions: Al hydrolysis and OH ion exchange. It has been demonstrated that sulfate ion adsorption increases when sulfate-adsorbing soils are coated with Fe and Al oxides.

The adsorbed sulfate ions may be replaced by other anions of greater penetration (coordination) ability such as PO_4^{3-}. This has been demonstrated by displacing the adsorbed SO_4^{2-} from surface soils by application of phosphate fertilizers.

Exchange on edges of silicate clays This exchange presumably involves replacement of OH^- by SO_4^{2-} in terminal octahedral coordination with Al. The general effects and mechanism are similar to that discussed above for Al and Fe hydrous oxides. The following type of reaction can occur with both hydrated Al oxides and the Al layer kaolinite:



[6]

Molecular adsorption This mechanism is less understood than the others described above. It implies that SO_4^{2-} is adsorbed by some mechanism by which the associated cation is retained by soils. This mechanism has been referred to as 'salt' adsorption, 'molecular' adsorption, and imbibition.

Sulfur Transformations in Soils

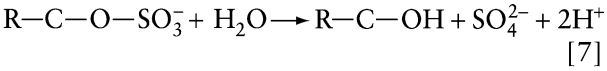
The transformations of S in soils are many and varied (i.e., oxidation, reduction, volatilization, decomposition and mineralization of plant and microbial residues), and often the changes are cyclic S changes from inorganic to organic forms (immobilization) and back again by living organisms.

Mineralization

The conversion of an element from organic form to an inorganic state as a result of microbial activity is termed 'mineralization.' As is the case with carbon and nitrogen, organic S in soils is mineralized to inorganic forms, mainly SO_4^{2-}, the form taken up by plant roots. The mechanisms involved in this transformation, however, are not clear. It appears that microorganisms are involved in this process, where they obtain their energy from the oxidation of carbonaceous materials in soils. During this process organic S is mineralized. Some of the mineralized S is used for synthesis of new microbial cell materials (immobilization), because the portion not required for synthesis is released as inorganic S. Mineralization and immobilization occur simultaneously in soils whenever organic material is undergoing microbial decomposition. The effect of temperature on the rate of N and S mineralization in 12 Iowa surface soils is shown in Table 4.

Sources of mineralizable S It is believed that ester sulfates in soils are the main sources of S mineralization in soils. However, carbon-bonded S (C–S) cannot be excluded, because this fraction contains the amino acids methionine, cystine, and cysteine, which can be converted to inorganic sulfate under aerobic conditions. The information available suggests that this form of S in soils can be a source for plant uptake.

Role of arylsulfatase in S mineralization Because a large proportion of the organic S in soils appears to be present as ester sulfate, it seems reasonable to expect that some organic S is mineralized by the action of arylsulfatase enzyme; indeed, this enzyme has been detected in soils. This enzyme catalyzes the hydrolysis of ester sulfate, releasing sulfate for plant uptake. The reaction is as follows:



[7]

Table 4 Comparison of rates of nitrogen and sulfur mineralization in Iowa surface soils; soil glass-bead columns were incubated at 20°C or 35°C and the mineral N and S produced were determined after leaching every 2 weeks with 0.01 mol l^{-1} KCl for a total of 26 weeks

Reproduced from Tabatabai MA (1984) Importance of sulphur in crop production. *Biogeochemistry* 1: 45–62.

Pattern of sulfate release Because the opposing reactions of mineralization and immobilization can occur simultaneously, different patterns of SO_4^{2-} release have been observed, depending on the energy materials available for the microorganisms (Figure 2):

1. Immobilization of S during the initial stages of incubation followed by SO_4^{2-} release;
2. A steady linear release of SO_4^{2-} over the whole period of incubation;
3. A rate of release that decreases with incubation time.

The pattern of SO_4^{2-} release is not related to any specific soil properties, but is apparently caused by adjustment of the microbial populations to the incubation conditions and to the availability of the initial substrates.

Factors affecting sulfur mineralization Because S mineralization is microbiological in nature, any variable that affects microbial growth should affect S

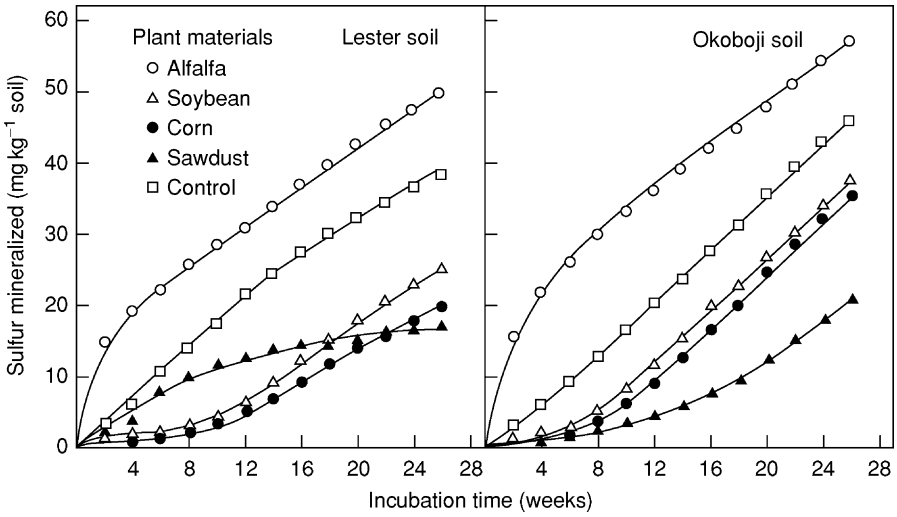

Figure 2 Effect of crop-residue treatment on sulfur mineralization in soils. (Reproduced from Tabatabai MA and Al-Khafaji AA (1980) Comparison of nitrogen and sulfur mineralization in soils. *Soil Science Society of America Journal* 44: 1000–1006.)

mineralization. Therefore, temperature, moisture, pH, and the availability of nutrients are most important.

Oxidation of Elemental S in Soils

Elemental S is one of the main sources of S added to soils. Before it can be untilized by crops, however, elemental S has to be oxidized to sulfate. Elemental S is oxidized in soils by chemical and biochemical processes, and a number of factors affect these processes. Microbial reactions dominate the processes. The microorganisms involved in oxidation of elemental S in soils belong to three groups: (1) chemolithotrophs (e.g., members of the genus *Thiobacillus*); (2) photoautotrophs (e.g., species of purple and green S bacteria); and (3) heterotrophs, which include a wide range of bacteria and fungi. Those listed in groups (1) and (2) are mainly responsible for oxidation of reduced S compounds in aerobic soils. Phototrophic bacteria are the predominant organisms responsible for oxidizing S^{2-} at the soil–water interface in flooded soils and in the rhizosphere of rice plants. The major reduced forms of inorganic S found in elemental S-treated soils are S^0, S^{2-}, and the oxyanions $S_2O_3^{2-}$, $S_4O_6^{2-}$, and SO_3^{2-}. These anion are oxidized, ultimately to SO_4^{2-} (Figure 3). The reactions involved in oxidation of elemental S in soils seem to be as follows:

$$S^0 \longrightarrow S_2O_3^{2-} \longrightarrow S_4O_6^{2-} \longrightarrow SO_3^{2-} \longrightarrow SO_4^{2-} \quad [8]$$

It is not clear whether these reactions are biochemical, occurring as a result of microbial processes in soils, or whether some of the intermediate products formed are the results of abiotic reactions. This is

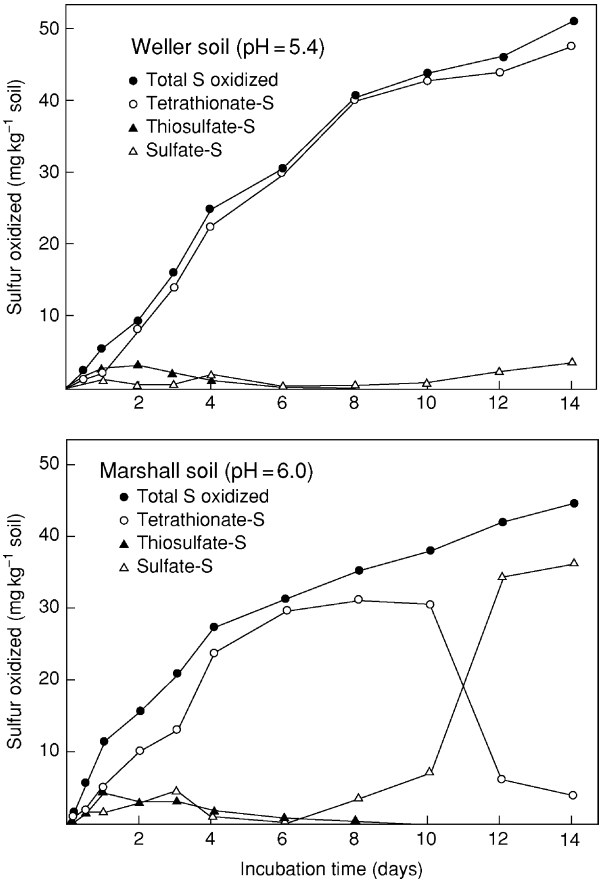

Figure 3 Amounts of thiosulfate-, tetrathionate-, and sulfate-S produced in two Iowa surface soils (Weller and Marshall soils) amended with elemental S (200 mg S kg^{-1} soil) and incubated at 30°C for various times. (Reproduced from Nor YM and Tabatabai MA (1977) Oxidation of elemental sulfur in soils. *Soil Science Society of America Journal* 41: 736–741.)

especially important in the case of the intermediates $S_2O_3^{2-}$ and $S_4O_6^{2-}$.

The enzyme rhodanese (thiosulfate-cyanide sulfotransferase; EC 2.8.1.1) catalyzes the conversion of the intermediate $S_2O_3^{2-}$ to SO_3^{2-} as follows:

$$S_2O_3^{2-} + CN^- \longrightarrow SO_3^{2-} + SCN^- \qquad [9]$$

Several factors affect of rate of oxidation of elemental S in soils. These include: (1) particle size: the finer the particles, the faster the reaction, which is because of the increase in surface area with decreasing particle size; (2) temperature: the higher the temperature, the greater the reaction rate (Figure 4); this is true between 10°C and 40°C; (3) time of contact with soil: the longer the reaction, the more the oxidation (Figure 5); and (4) effect of pH: the oxidation appears to be faster in alkaline than in acid soils.

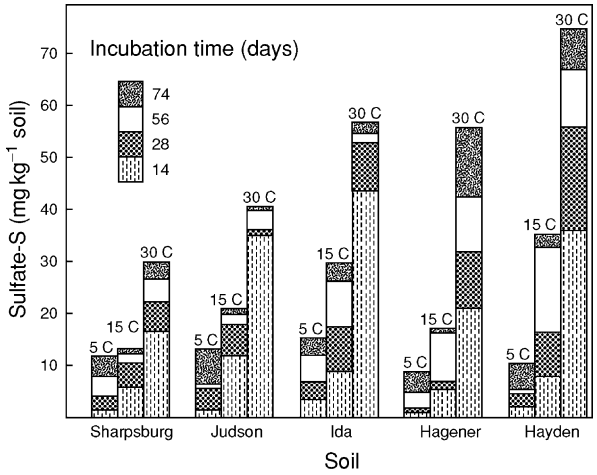

Figure 4 Effects of temperature and time of incubation on oxidation of elemental S (100 mg S kg^{-1} soil) in soils. (Reproduced from Nor YM and Tabatabai MA (1977) Oxidation of elemental sulfur in soils. *Soil Science Society of America Journal* 41: 736–741.)

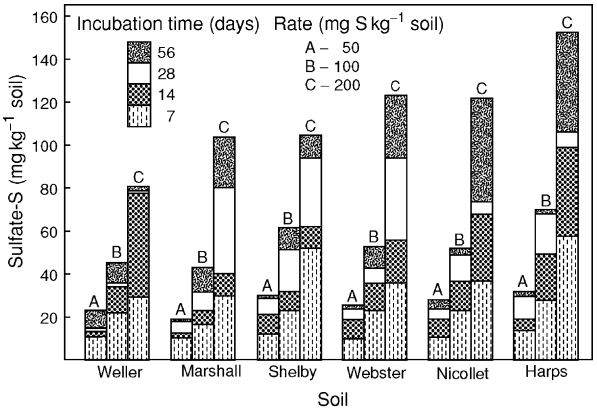

Figure 5 Effects of application rate and time of incubation on oxidation of elemental S in soils. The values for Weller and Marshall soils treated with 200 mg S kg^{-1} soil include the amounts of thiosulfate- and tetrathionate-S produced during 7 days and 14 days of incubation.

Reduction of Sulfate in Waterlogged Soils

The reduction of sulfate to H_2S is a process that occurs mainly by anaerobic bacteria; thus, it occurs only in anaerobic soils. This process is not important in aerobic agricultural soils, except perhaps in anaerobic microsites in soil aggregates. However, it is a major reaction in S cycling in waterlogged soils or periodic flooding, especially when in soils containing readily decomposable plant residues such as alfalfa (*Medicago sativa*). Bacterial reduction of sulfate involves either an assimilation or dissimilation process. In the former process, sulfate is reduced to the thiol (–SH) group of organic compounds for protein synthesis. In the latter process, the reduction leads to production of H_2S under very low redox potential (E_h) values. Under normal conditions, however, H_2S is not volatilized from soils, because it precipitates with Fe^{2+}, Mn^{2+}, Cu^{2+}, Cu^+, and/or Zn^{2+} present in soils. In the case of Fe^{2+}, it forms ferrous sulfide (FeS), and pyrite (FeS_2) is formed in severely reducing conditions by the reduction of sulfate to S^{2-} by the bacteria *Desulfovibrio desulfuricans*, which reacts with FeS to produce FeS_2.

Volatilization of S Compounds from Soils

Relative small amounts, if any, of S-containing gases, including H_2S, are released from aerobic agricultural soils, even when such soils are waterlogged. Substantial amounts of H_2S are released, however, from salt-marsh soils. Several gases are released from soils when treated with animal manures, sewage sludges, and protein-rich plant materials such as alfalfa, especially under waterlogged conditions. These include carbon disulfide (CS_2), which results from decomposition of the amino acids cystine and methionine; carbonyl sulfide (COS), released during decomposition of thiocyanate and isothiocyanate; and methyl mercaptan (CH_3SH), dimethyl sulfide (CH_3SCH_3), and dimethyl disulfide (CH_3SSCH_3), which result from decomposition of methionine-containing materials.

Biological Transformations

Introduction

In soil, sulfur exists in a variety of forms, some of which are beneficial to the environment, and other forms that are typically considered pollutants. The wide array of oxidation states and forms of sulfur results in a rich diversity of biological transformations involving this important element. These transformations are critical for many basic ecological processes such as plant growth, but also influence the movement of environmental contaminants.

The biological transformations of sulfur can be divided into four major classes: (1) oxidation; (2) reduction; (3) assimilation; and (4) mineralization (Figure 1). In addition, microbial metabolites can chemically fix or solubilize inorganic S compounds. The first two classes are related to the acquisition of energy for growth and the last two are typically related to nutrient acquisition. For energy acquisition, sulfur can act as an electron acceptor, an electron donor, and sometimes both at the same time. Sulfate (SO_4^{2-}) acts as an electron acceptor and is reduced to S^{-2} by a group of bacteria known as sulfate-reducing bacteria. These bacteria grow in the absence of oxygen. In contrast, S^{-2} can act as an electron donor and is oxidized by a group of bacteria known as sulfur oxidizers. These bacteria grow in the presence of oxygen. Interestingly, some bacteria can disproportionate sulfur, i.e., ferment sulfur. In this reaction, one of the two sulfur atoms, present in thiosulfate as S^{-1}, acts as an electron donor and the other sulfur atom, present as S^{+5}, acts as an electron acceptor.

The last two classes of sulfur transformation are directly linked to the nutritional status of the cell. Mineralization is a transformation in which organic sulfur contained in a growth substrate is released in a mineral form such as sulfate. In contrast, assimilation is a process is which sulfur present in the environment is incorporated into biomass. In the former case, the mineralized sulfur is available for other organisms to use, whereas in the latter the assimilated sulfur is no longer available to other organisms. Each of these transformations of sulfur has important side-effects on the environment. The mineralization of sulfur provides sulfate, which can potentially stimulate sulfate-reducing bacteria that play important roles in the arsenic and mercury biogeochemical cycles. The oxidation of reduced sulfur by sulfur oxidizers results in acid mine drainage, one of the primary detrimental impacts of mining.

The Global Sulfur Cycle

The global cycle of sulfur begins with sulfur volatilized largely as dimethylsulfide from marine algae, marshlands, mud flats, plants, and soil entering the atmosphere. This dimethylsulfide is converted photochemically to methanesulfonic acid, which then deposits on to the Earth and is rapidly converted by bacteria to carbon dioxide and sulfate. This sulfate

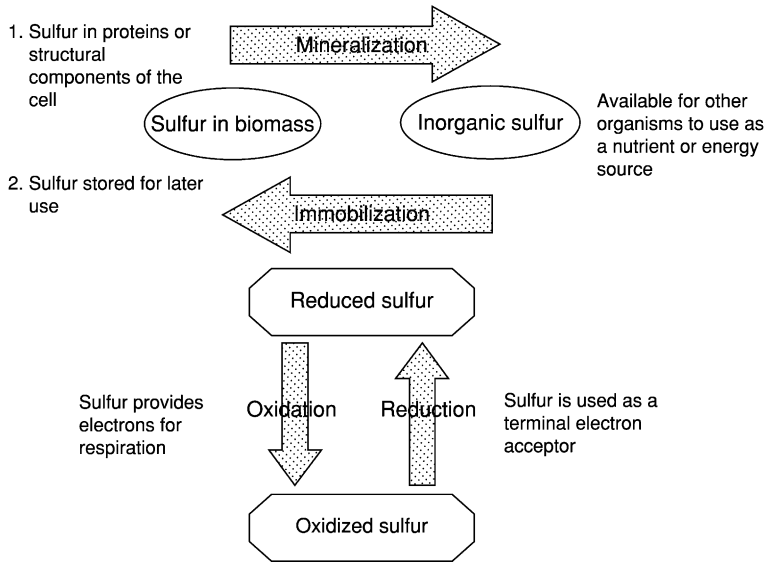

Figure 1 The four principal biological transformations of sulfur.

is assimilated by plants and immobilized into compounds like sulfoquinovosyl diacylglycerol, or alternatively the sulfur is released back to the atmosphere as dimethylsulfide. As plants die, bacteria metabolize the immobilized sulfur present in plant biomass and either immobilize this sulfur into their biomass or release it as sulfate for uptake by plants. In addition to this natural sulfur cycle, human activities have at least doubled the input of sulfur to terrestrial systems. Approximately 1.5×10^{11} kg S per year is deposited due to atmospheric pollution, largely in the form of sulfuric acid (sulfate), with small amounts of sulfite and biosulfite also being deposited. This deposited sulfate can either be used by bacteria as a terminal electron acceptor or assimilated by organisms requiring sulfur as a nutrient. Despite this recent disruption of the global sulfur cycle, the sulfur levels present in soil are largely due to pedogenic factors like climate, vegetation, and parent material. As a result, sulfur levels in soil range from 0.002 to 10%: most of this sulfur, 90%, is found in organic form.

The Biological Availability of Sulfur

Although 90% of sulfur in soil is present as organic sulfur, much of this organic S is not available for assimilation or dissimilation by microorganisms and plants. Microorganisms need to convert the organic sulfur in soil into sulfate before plants can take up the sulfate as a nutrient. This conversion of sulfate from organic sulfur is the end result of a complicated biogeochemical cycle. Sulfur enters the soil ecosystem and is converted and assimilated by microorganisms into their biomass. Predators then consume these bacteria and excess sulfur is released into the soil solution. The sulfur released into the soil solution is available for uptake by other organisms or plants. However, the predators do not mineralize all the S present in prey organisms and, as a result, a small fraction of S enters what is termed the 'resistant' pool of organic S present in soil (Figure 2). This resistant pool of organic S is found is large polymers that are in close association with clays. These large polymers resist microbial attack because it is not energetically favorable for microbes to attack these polymers. There are three distinct pools of sulfur in soil: (1) inorganic sulfate that is readily taken up by plants and microbes alike; (2) short-lived organic sulfur compounds like taurine and cysteine which are

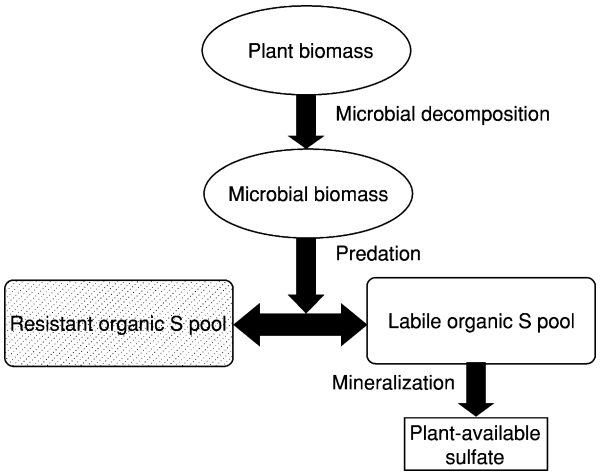

Figure 2 The different sulfur pools present in soil and their relationship to plant-available sulfur.

mineralized by microorganisms and either released as sulfate or incorporated into biomass; and (3) long-lived resistant organic sulfur polymers found in soil humus. Microbial transformations are the primary process by which sulfur is transferred between the pools of readily available, young organic sulfur and old organic sulfur. These transformations are discussed below.

Mineralization

Almost exclusively, microorganisms mediate sulfur mineralization. By definition, mineralization is the metabolic conversion of an organic form of an element to an inorganic form. Mineralization processes can be divided into cell-mediated or extracellular enzymatic processes. Cell-mediated mineralization occurs by oxidative decomposition under aerobic conditions or by desulfurization under anaerobic conditions. In cell-mediated mineralization, S present in carbon-containing compounds is mineralized as organisms consume the carbon to obtain energy. Thus, if there is more S in the substrate than the organism requires, the S will be mineralized and released to the environment. If there is not enough S, then any released S is consumed and immobilized by the organism. The break-even point for mineralization can be calculated based on the C:S ratio of the substrate, the C:S ratio of the organism, and the yield coefficient, i.e., how much of the consumed C is incorporated into biomass. As a general rule of thumb, if the C:S ratio of a substrate is 200 or less, then S is released. If the C:S ratio is greater than 400, then S is not going to be released because the microorganisms require the S for their own biomass. In this latter case, organisms rely on a second, enzymatic method of mineralization to obtain the sulfur essential for growth.

Enzymatic mineralization involves extracellular enzymes, such as arylsulfatases, released by the microorganism. These enzymes, once released from cells, will hydrolyze sulfate esters present in the soil. This process releases sulfate into the soil solution for use by the cells. The activity of these enzymes depends on a wide range of soil factors with reaction rates varying by a factor of 4 between different soils. These enzymes attack the vast amount of S present in the soil as organically bound S. Organic S in soil constitutes more than 90% of the total S present in soils. This organic S can be grouped into carbon-bonded S and organic sulfates. Organic sulfates, which comprise between 30 and 75% of sulfur in soil, typically include compounds such as sulfate esters (C-O-S), sulfamates (C-N-S), and sulfated thiogylcosides (N-O-S), and it is this form of sulfate that enzymatic mineralization processes attack.

Mineralization processes are biological transformations of sulfur that are intimately linked to cellular growth. Thus, factors that influence microbial activity, such as moisture, temperature, or plant growth, will influence mineralization. Increasing the growth of microorganisms by either adding a carbon source or plant growth typically results in reduced mineralization.

Assimilation

Assimilation is the process of converting inorganic sulfur into organic sulfur present in an organism. This assimilatory process is intimately linked to mineralization. In fact, these two processes, assimilation and mineralization, occur simultaneously. If the net effect is to release inorganic sulfate then this is termed mineralization; if instead the net effect is for the sulfur to be incorporated into the biomass, then this is termed assimilation. Thus, the first step of many assimilation processes is the conversion of sulfur into a form that can be incorporated into biomass. Taken alone, such steps might be considered mineralization processes but we term them assimilatory processes if: (1) the sum of the steps is to incorporate sulfur into biomass and (2) they are induced by sulfur limitation, suggesting that the organism is using the process to obtain sulfur. There are different biological assimilatory transformations that can occur depending on what form the available sulfur is in. For inorganic SO_4^{2-}, an enzyme called adenosine triphosphate (ATP) sulfurylase mediates the reaction between sulfate and ATP and sulfate to form adenosine-5′-phosphosulfate (APS) (Figure 3). In turn, this APS is transformed by APS kinase with another ATP molecule to form adenosine-3′-phosphate-5′-phosphosulfate (PAPS). This high-energy molecule reacts with PAPS reductase and two sulfhydryl groups to form sulfite, and sulfite is reduced by $NADPH_2$ to form sulfide which is incorporated into L-cysteine by *O*-acetylserine sulfhydrylase.

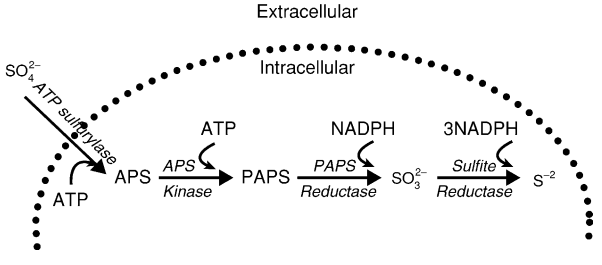

Figure 3 Assimilation of inorganic sulfur by bacteria. See text for a complete description of the reactions involved and definition of abbrevations. The sulfide produced is incorporated into cysteine by cysteine synthase.

This pathway will efficiently scavenge excess sulfate present in the soil solution that organisms require. So much so, that in the presence of an energy source, added SO_4^{2-} S is quickly incorporated into the organic fraction of the soil biomass and later found in the fulvic acid fractions. However, sulfate is not commonly found in soil solution and organisms have developed other pathways to assimilate sulfur for their metabolic needs.

Aromatic sulfonates, SO_3^{1-} groups bound to aromatic rings, can also serve as a sulfur source for assimilation. This assimilatory pathway is controlled by a genetic cluster called the 'sulfate-stimulation-induced stimulon' that encodes three distinct gene clusters, *asf*, *ssu*, and *ats*. Together these three genes control the assimilation of S by bacteria in soil. The *ats* gene cluster is responsible for the binding of aromatic sulfonates and transportation into the cell. The *ssu* genes encode for the cleavage for the C-S bond by a monooxygenase. The *asf* gene cluster provides the reducing equivalents from the oxidation of NADH necessary to assimilate aromatic sulfonates. The overall result of this pathway is the production of sulfite, which reacts with PAPS reductase to form sulfide, as described above. Alkane sulfonates are also a source of sulfur for assimilation. For most alkane sulfonates the pathway is very similar to that described above, with the exception that the transport mechanisms differ. There is a distinctly different pathway for taurine, involving an α-ketoglutarate-dependent dioxygenase which oxidizes both taurine and α-ketoglutarate to release sulfite. This pathway is regulated by *Tau*D and is specific for taurine, with little activity seen for other alkane sulfonates.

Sulfate esters are assimilated by the action of a group of enzymes termed 'arylsulfatases.' These enzymes are broadly grouped by their pH optima, with alkaline sulfatases having a pH optimum of 8.3–9.0 and acid sulfatases having a pH optimum of 6.5–7.1. In essence, these enzymes hydrate the S-O bond and release sulfate, which can then be assimilated by the pathway described above for sulfate. These assimilatory processes should be clearly differentiated from processes that use organo-sulfur compounds as a C and energy source. Organo-sulfur assimilation genes are regulated by the sulfate-stimulation-induced stimulon, which in turn is regulated by levels of cysteine, thiosulfate, and sulfite present in the cell. The presence of these compounds inside the cell will downregulate the sulfate-stimulated-induced genes and thereby repress expression of assimilatory enzymes. This is a logical regulatory control, since if there is excess cysteine and sulfate present in the cell, the cell likely does not need to assimilate sulfur.

Sulfur Oxidation

Many organisms, such as chemoautotrophs and photoautotrophs, use sulfur as a source of energy. This occurs by oxidizing S^0 to SO_3^{2-} and finally to SO_4^{2-} and in the process stripping six electrons from sulfur and using oxygen or nitrate as a terminal electron acceptor. A great variety of thiobacilli can perform these reactions. Some thiobacilli are chemoautrophs (only able to use S as an energy source), others are facultative chemoautotrophs (able to use C as an energy source if necessary) and some are mixotrophs (able to use C and S as an energy source at the same time). Most thiobacilli require the presence of oxygen but some, such as *Thiobacillus denitrificans*, can use nitrate as a terminal electron acceptor. Similarly, some thiobacilli can use Fe^0 in addition to sulfur as an electron donor.

The research on the importance of thiobacilli on sulfur oxidation comes largely from pure culture studies. The actual situation in soil involves a wide diversity of organisms. There are gliding sulfur oxidizers, including bacteria, the cells of which are arranged in trichomes, that show a gliding motion on the substrate. The most important members of this group in relation to S-oxidation in soils are species of *Beggiatoa*, bacteria that participate in sulfide oxidation in the root zone of rice. All strains of *Beggiatoa* deposit sulfur in the presence of H_2S. Phototrophic bacteria, such as *Chromatium* and *Chlorobium*, also play an important role in sulfide oxidation in rice paddy soil, but not in aerobic agricultural soils. A number of nonfilamentous, chemolithotrophic sulfur-oxidizing bacteria, such as *Sulfolobus*, *Thiospira*, or *Thiomicrospira*, have also been isolated from special habitats, but the importance of these bacteria in S oxidation in soils has yet to be determined. Some thiobacilli, such as *Thiobacillus denitrificans*, can oxidize sulfur or thiosulfate and use nitrate as an electron acceptor. Other aerobic bacteria, such as *Arthobacter*, *Bacillus*, and *Pseudomonas*, oxidize sulfur in soil during their normal metabolism of oxidizing organic compounds in soil and using oxygen as a terminal electron acceptor. These reactions have not been characterized but it is thought that this is occurring as a side reaction to the primary transformations being carried out by these organisms. In the soil ecosystem, it is widely assumed that thiobacilli are the dominant sulfur oxidizers but this view is based on the observation that if you add elemental sulfur to soil, the numbers of thiobacilli increase. However, no consistent correlation between S-oxidation rates and the prevalence of thiobacilli has been demonstrated, except in very broad terms. In general, it is assumed that initially heterotrophs oxidize elemental sulfur

until the pH is low enough that oxidation of sulfur chemoautotrophs is energetically favorable and then thiobacilli dominate. Thus, under energy-limiting conditions in an environment dominated by dissolved, reduced sulfur compounds with little organic matter, thiobacilli will dominate. In contrast, in a soil in which there are significant amounts of organic matter and less reduced sulfur, heterotrophs will dominate.

Disproportionation of Sulfur

In the latter part of the twentieth century, investigators discovered that not only can bacteria oxidize and reduce sulfur, but they can also disproportionate it. Disproportion reactions are best likened to a fermentation in which one portion of a molecule acts as an electron donor and the other, an electron acceptor. Bacteria are able to disproportionate thiosulfate by oxidizing the sulfur atom in thiosulfate that carries a +5 charge such that it now carries a charge of +6. This +6 sulfur is released as SO_4^{2-}. Simultaneously, bacteria oxidize the other sulfur atom in thiosulfate that carries a −1 charge such that it now carries a charge of −2. This −2 sulfur is released as hydrogen sulfide:

$$S_2O_3^{2-} + H_2O \rightarrow SO_4^{2-} + HS^- + H^+ \qquad [1]$$

This metabolic process has immense implications for the global sulfur cycle since typically in sediments sulfate predominates in the upper layers and sulfide in the lower layers. Hence, this metabolic reaction reveals an entirely new and, up until then, unsuspected ecological niche which is responsible for up to 60% of the thiosulfate transformations in sediment. Since then, other bacteria have been found that can disproportionate sulfonates such as taurine to sulfate and sulfide. The bacteria capable of this organic sulfur disproportation reaction form a new species called *Desulfonispora* since it appears that it is a distinct group of organisms that is capable of this reaction.

Reduction of Sulfur

The reduction of sulfur can occur for two reasons: assimilation and dissimilation. The assimilation pathway has been discussed above – bacteria convert sulfate to sulfide for inclusion in amino acids such as cysteine. Dissimilatory sulfate reductase refers to a process whereby sulfate is used as a terminal electron acceptor. Sulfate-reducing bacteria use such an enzyme, which allows them to oxidize organic substrates such as lactate, malate, and ethanol, and use sulfate as a terminal electron acceptor. Hence, these bacteria are primarily found in environments where there is little or no oxygen and live off the fermentation end products produced by other bacteria.

Sulfate-reducing bacteria catalyze the following process:

$$SO_4^{2-} + 5H_2 \rightarrow H_2S + 4H_2O \qquad [2]$$

Since hydrogen sulfide is extremely toxic, these organisms require some sort of metal to react with the hydrogen sulfide produced and precipitate as a nonsoluble metal sulfide. In soil, this metal is typically iron, with FeS being precipitated around areas of sulfate-reducing bacterial growth and activity. The reaction catalyzed by sulfate-reducing bacteria reaches an optimum at an E_h of −300mV at a pH of 7. These conditions are typically reached as one enters the highly anaerobic zone. Typically, terminal electron acceptors are depleted in the following order: oxygen, nitrate, nitrite, manganite, iron, sulfate, and finally, carbon dioxide. Thus, there are many alternative electron acceptors that will be used by a microbial community before sulfate is reduced. Despite this limitation, sulfate-reducing bacteria and activity are commonly found in soils, sediments, polluted water, oil-bearing strata, and shales.

Sulfate-reducing bacteria can implement an alternative survival strategy if sulfate levels in the water are too low to be used. The H^+ produced by organic matter oxidation is transferred directly to a methanogen which then consumes that H^+ to reduce CO_2 and produce methane. Because the methanogens keep the partial pressure of hydrogen so low, the sulfate-reducing bacteria can use this mechanism to obtain energy from organic matter degradation even when there is not enough sulfate around for them to transform to sulfide.

Sulfur Transformations and Environmental Quality

The biological transformations of sulfur can lead to significant environmental problems in the soil. The enzyme sulfate-reducing bacteria use to transfer methyl groups can also accidentally methylate mercury to form methylmercury. Sulfate-reducing bacteria have been identified as one of the primary causes of the increased mercury accumulation in many ecosystems because methylmercury is the form of mercury that most readily accumulates in food chains. Typically, this reaction occurs in anaerobic, lowland soils where the activity of sulfate-reducing bacteria is closely linked to methylmercury production. However, sulfate-reducing bacteria can also mitigate environmental pollution through the production of metal sulfides by the following reaction:

$$M^{2+} + S^{2-} \rightarrow MS \quad [3]$$

Sulfate-reducing bacteria like *Desulfovibrio* spp. can form sulfides of Sb, Co, Cd, Fe, Pb, Ni, and Zn during the reduction of sulfate. The extent of metal sulfide genesis depends on many factors, such as the amount of sulfate present and the relative toxicity of the metal ion. In nature, this toxicity is reduced when the metal ions are adsorbed on clays or complexed with organic matter.

The oxidation of metal sulfides in soil involves both chemical and microbial processes and, as a result, is a more complex process than is the oxidation of S^0 Chalcocite (Cu_2S), chalcopyrite ($CuFeS_2$), galena (PbS), pyrite (FeS_2), and nickel sulfide (NiS) are just a few examples of metal sulfides that are subject to microbial transformations. For example, the biological oxidation of pyrite (FeS_2) can follow one of two pathways. The first result follows a series of oxidation steps, described in eqns [4–7]. The second mechanism of pyrite oxidation involves thiosulfate as an intermediate but in the end requires the oxidation of elemental sulfur to sulfate by *Thiobacillus*. These biotic oxidations are responsible for the formation of acid mine drainage and acid soil formation in surface mine spoils. First, ferrous sulfate is formed as the result of an abiotic oxidation step:

$$2FeS_2 + 2H_2O + 7O_2 \rightarrow 2Fe_2SO_4 + 2H_2SO_4 \quad [4]$$

This reaction is then followed by the bacterial oxidation of ferrous sulfate, generally by *T. ferrooxidans*:

$$4FeSO_4 + O_2 + 2H_2SO_4 \rightarrow 2Fe(SO_4)_3 + 2H_2O \quad [5]$$

This reaction occurs chemically but can be accelerated 10^6–10^8 times by thiobacilli. This bacterial oxidation of ferric ion plays an important role in the bioleaching of metal sulfides in the environment because it cycles the iron between +2 and +3 and the iron is then free to oxidize sulfide minerals abiotically.

Subsequently, ferric sulfate is reduced and pyrite oxidized by a strictly chemical reaction:

$$Fe_2(SO_4)_3 + FeS_2 \rightarrow 3FeSO_4 + 2S^0 \quad [6]$$

$$2S + 6Fe_2(SO_4)_3 + 8H_2O \rightarrow 12FeSO_4 + 8H_2SO_4 \quad [7]$$

The elemental sulfur produced is finally oxidized by *T. thiooxidans*, and the acidity produced helps the whole process to continue.

$$2S^0 + 3O_2 + 2H_2O \rightarrow 2H_2SO_4 \quad [8]$$

Note the net production of 10 molecules of H_2SO_4 during the process.

Although several sulfur-oxidizing thiobacilli and heterotrophs can be isolated from acid sulfate soils in which pyrite is being oxidized, they appear not to play an important role in the process, with the exception of *T. ferrooxidans*. The biological oxidation of sulfides and other reduced S compounds can have severe consequences for the environment. For example, acid mine drainage contaminates several thousand kilometers of streams in the Appalachian coal-mining region of the USA.

Conclusion

There is a large amount of sulfur present in soil and most of it is found in a form susceptible to biological transformations. These transformations include mineralization, assimilation, oxidation, and reduction. Recently, anthropogenic activity has impacted the sulfur cycle by increasing the deposition of sulfate in the form of acid rain and by exposing more sulfur to oxidation during mining operations. The four basic transformations discussed in this article influence the fate of the movement of sulfur in terrestrial and aquatic ecosystems and the environmental impact of anthropogenic activities altering the sulfur cycle.

Introduction

Sulfur(s) is considered either the fourth most important nutrient element, after N, P, and K, for plant growth, or the sixth, after C, H, O, N, and P, for protein composition. In addition to these six, there are 15 other elements that are essential for the growth of some plants. These are Ca, Mg, K, Fe, Mn, Mo, Ni, Cu, B, Zn, Cl, Na, Co, V, and Si. Not all these elements are essential for all plants, but all have been shown to be essential for some plants.

S has been recognized as an essential element for plant growth and development for more than 200 years. In 1859 Liebig was aware of the close relationship between N and S in many plants. The ancient Romans and Greeks demonstrated the beneficial use of gypsum ($CaSO_4 \cdot 2H_2O$) as a fertilizer. The history of the use of S fertilizers may be divided into three periods: (1) the first period is the reign of gypsum (1760–1845); during this period, gypsum was used widely and its beneficial effect was generally overestimated; (2) the second period is the reign of superphosphate (1845–1905), during which the need for S fertilization was ignored and the use of gypsum was discouraged by agronomists; (3) the third period is the Renaissance, or Modern period. The use of gypsum as a fertilizer in modern times can be traced back to the middle of the eighteenth century. A field trial with gypsum applied to a clover field was reported in Switzerland in 1768. Application of gypsum increased the yield of clover by more than two-fold.

Interest in fertility-related aspects of the S cycle is increasing, because S deficiencies in agronomic crops are observed with increasing frequency. Sulfur fertilization is now required for many crops around the world. Several factors are responsible for the increased need of S fertilization. These include: (1) increased use of high-analysis fertilizers that contain little or no S, (2) increased crop yields, (3) decreased use of S as a pesticide, (4) more intensive cropping, and (5) decreased gain of atmospheric S by soils and plants as a result of decreased combustion of coal and other S-containing fuels.

Sulfur Requirements of Crops

The importance of S in crop production is obvious, because plants require S for synthesis of essential amino acids and proteins, certain vitamins and coenzymes, glucoside oils, structurally and physiologically important disulfide linkages and sulfhydryl groups, and activation of certain enzymes.

Sulfur is absorbed by plant roots almost exclusively as the sulfate ion, SO_4^{2-}. Typical concentrations of S in plants range from 0.1 to 0.4%. As with N, much of the SO_4^{2-} taken up by plants is reduced in plants, and the S is found in –S–S– and –SH forms. Sulfate-S in large concentrations may occur in plant tissues and cell sap. Normally, S is present in equal or lesser concentration than phosphorus in such plants as wheat, corn, beans, and potatoes, but in greater concentrations in alfalfa, cabbage, and turnips. Generally, agronomic crops require about the same amount of S as they do for P.

Although the S content of plants varies depending on the supply available, some crops have greater S requirement than others. An average yield of forage crops removes 17–50 kg S ha^{-1}, and the cereal grains generally remove more than 30 kg ha^{-1}. Other crops such as cabbage, turnip, and alfalfa have a particularly high requirement for S. Such crops commonly need from 45 to 70 kg S ha^{-1}. One of the crops that require a very high amount of S is sugarcane. A yield of 224 tons ha^{-1} removes approximately 100 kg S (Table 1).

Another factor that affects the S requirement of plants is the available N. S and N are closely associated in protein synthesis, thus S requirements vary with the supply of N to crops. Therefore, when S becomes limiting for plant growth, addition of N does not increase the yield or protein concentration of plants.

The N:S ratios of many crops at their maximum yields have been assessed. Alfalfa requires 1 part of S for every 11–12 parts of N to ensure maximum production, while wheat, corn, beans, and sugarbeet leaf blades require 1 part of S for every 12–17 parts of N. The N:S ratios of grains such as oats and barley are 13:1 and 9:1, respectively.

Crop plants obtain their S requirements from a number of sources. These include: (1) soils, crop residues, and manures; (2) irrigation waters; (3) rainfall and the atmosphere; and (4) fertilizers and soil amendments. The order of importance of each of these sources varies with the type of crop, location, and management practices. The effects on S requirements are particularly marked in nonindustrialized areas where soil supplies are already low and additions from precipitation are being further reduced by shifts in energy sources (burning coal for energy production).

Functions of Sulfur in Plants

Sulfur has numerous functions in plant growth and metabolism. Among those are the following:

Table 1 Sulfur content of crops

Crop	Yield (tons ha^{-1})	Total S content (kg ha^{-1})
Grain and oil crops		
Barley	5.4	22
Corn	11.2	34
Grain sorghum	9.0	43
Oats	3.6	22
Rice	7.8	13
Wheat	5.4	22
Peanuts	4.5	24
Soybeans	4.0	28
Hay crops		
Alfalfa	17.9	45
Clover grass	13.4	34
Bermuda grass		
Common	9.0	17
Coastal	22.4	50
Brome grass	11.2	22
Orchard grass	13.4	39
Pangola grass	26.4	52
Timothy grass	9.0	18
Cotton and tobacco		
Cotton (lint + seed)	4.3	34
Tobacco		
Barley	4.5	21
Flue cured	3.4	50
Fruit, sugar, and vegetable crops		
Beets		
Sugar	67	50
Table	56	46
Cabbage	78	72
Irish potatoes	56	27
Onions	67	41
Oranges	52	31
Pineapple	40	16
Sugarcane	224	96

Reproduced from Terman GL (1978) *Atmospheric Sulfur – The Agronomic Aspects.* Technical Bulletin no. 23. Washington, DC: The Sulfur Institute.

1. It is required for the synthesis of S-containing amino acids, cystine, and cysteine, and methionine, which are major components of proteins;

2. It is required for the synthesis of important metabolites, including coenzyme A, biotin, thiamine, or vitamin B_1, glutathione, sulfolipids;

3. It is a vital component of ferredoxin, a type of nonheme Fe–S protein present in chloroplasts. This is involved in photosynthesis, nitrite reduction, sulfate reduction, the assimilation of N_2 by roots of nodule bacteria and free-living N_2-fixing soil bacteria, and in mitochondrial electron transport;

4. It is an essential component (as cysteinyl, a–SH group) of the active sites of many enzymes;

5. Although it is not a component of chlorophyll, it is required for its synthesis by plants;

6. It occurs in volatile compounds responsible for the characteristic taste and smell of plants in the mustard and onion families.

Sulfur in Soils

Soil as a living system is a dynamic ecosystem supporting the life of microorganisms, plants, and animals. As is the case with carbon and nitrogen, S is continuously being cycled between organic and inorganic forms, resulting in synthesis and degradation of a variety of S compounds. The reactions and the nature of the S compounds formed depend on the environmental conditions of the soil. These include aeration, water content, pH, presence and absence of metal ions, tillage systems applied, crop residues incorporated, liming, type of crops, and crop rotations used.

The relative proportion of inorganic and organic forms of S in soils varies with the soil type, depth of sampling, cropping system, season, and soil conditions (field-moist or air-dried). No direct chemical method is available for determination of total organic S in soils, and this is normally determined from the difference between total S and inorganic S determined separately. The inorganic S fraction is small, ranging from 2 to 6% of the total S in soils from the humid and semihumid regions. This is normally present as inorganic SO_4^{2-} in well-aerated soils. In calcareous soils, much of this fraction is occluded by precipitate of calcium carbonate, leading to a smaller fraction of the total S in organic combinations. Similarly, because of lack of percolating water, inorganic SO_4^{2-} accumulates in surface layers of arid soils in the form of gypsum, leading to a small fraction of organic S in such soils. Organic S concentration decreases with depth in the soil profile, and this decrease is associated with a decrease in organic C, except in soils where organic matter accumulates in subsurface or B horizons such as podzolic soils.

The chemical nature of soil organic matter in soils is important, because this is the reservoir that supplies SO_4^{2-} to plants. Even though complete chemical forms of S soil organic matter are not completely characterized, three broad groups of S compounds are recognized. These are:

1. Hydriodic acid-reducible S. This fraction consists of organic S that is reduced to H_2S upon boiling with hydriodic acid (HI) under N_2 gas. This form of S is bonded to a carbon atom through an oxygen atom (i.e., ester sulfate, C–O–S). Examples of such forms of S are phenolic sulfate, sulfated polysaccharides, choline sulfate, and sulfated lipids. On average, approximately 50% of the organic S in soils is in this form; it can range from 30 to 60%, and values as high as 95% have been reported for some Iowa subsurface

soils. It is mineralized to SO_4^{2-} through the enzyme arylsulfatase, as follows:

$$R\text{–}O\text{–}SO_3^- + H_2O \xrightarrow{\text{Arylsulfatase}} R\text{–}OH + HSO_4^- \quad [1]$$

2. Carbon-bonded S. This fraction consists of S atoms directly bonded with carbon atoms (i.e., C–S). This form of S is hydrolyzed by Raney Ni (50% each of Al and Ni powder) under alkaline conditions (NaOH). When treated with HCl, this mixture releases the S atoms in the form of H_2S. Sulfur-containing amino acids, cystine and methionine, are the main components of this fraction, which accounts for approximately 20–30% of the soil organic S. Other S-containing compounds such as sulfoxide, sulfones, sulfenic, sulfinic, and sulfonic acids, and S-containing heterocyclic compounds are also constituents of this fraction;

3. Inert or residual S. This fraction is the organic S that is not reduced by either of the reagents described above. This fraction represents approximately 30–40% of the total organic S in soils. Because this fraction is resistant to drastic chemical treatment, it is of little importance as a source of S for plants.

Sources of Mineralizable Sulfur in soils

It is believed that both HI-reducible and carbon-bonded S fractions of soil organic S are sources of SO_4^{2-} for plant uptake.

Organic Nitrogen and Sulfur Relationship in Soils

The presence of large concentrations of organic S in surface soils is indicated by the close relationship between organic N and S. In many of the soils studied in North America and other parts of the world, the mean ratio of organic N:S is approximately 8:1. But, this ratio may range from 5:1 to 13:1 (Table 2). The ratio appears to be the same for virgin soils and their cultivated counterparts (Table 3), suggesting that the organic forms of these elements mineralize in about the same ratio as they occur in soil organic matter. However, results of some studies indicate that organic S in soils is depleted faster than that of organic N.

As is true of N, when land is first cultivated, the S content of the soil declines rapidly and an equilibrium level is reached which is influenced by climate, cultural practices, and soil type. At the equilibrium level, soil organic matter essentially ceases to act as a source of S for plant growth. Before reaching this equilibrium, however, the rate of S mineralization is so slow that it cannot cope with the plant's need for this element. This results in the appearance of S-deficiency symptoms on the plants. Because S is a mobile element in plants, the S-deficiency symptoms appear on the older leaves. Recent studies indicate that lack of S to meet plant's requirements may not only reduce yields, but it can reduce quality (reduction of the amino acids cysteine and methionine in protein) in grain legumes by changing gene expression of storage proteins in developing seeds.

Sulfur Availability Indexes

It is generally accepted that S is taken up by plants in the SO_4^{2-} form. Studies involving nutrient culture experiments have shown that low-molecular-weight organic-S compounds are utilized by plant. But, the availability of soil organic S depends primarily on its mineralization, which, in turn, depends on climatic factors such as temperature and moisture, and on the chemical nature of organic S present in soils.

Assessment of the plant-available S in soils is complicated by the fact that, in addition to soils, several other sources contribute to the S needs of plants. These sources include S in rainfall and irrigation

water, S in the atmosphere, and S in fertilizers and pesticides. Of the sources of S, the contribution of S in rainfall and direct absorption by soils and plants from the atmosphere are the most difficult to evaluate. In addition, both plants and soils absorb SO_2, and most likely other S gases, directly from the atmosphere. For example, studies in Wisconsin in the early 1970s, by using radioactive ^{35}S, have shown that under optimal yield 14% of the S in alfalfa (*Medicago sativa* L.) is derived from atmospheric sources.

There is no general agreement on the best methods for using an index of plant availability. The procedures used fall into one of the following two groups: (1) plant analyses and (2) soil analyses. The use of plant analysis for assessing S nutrition of plants is based on the notion that an essential element should be present in the plant as a concentration just sufficient for unrestricted plant growth.

Numerous methods and procedures have been proposed for evaluation of the plant-available S in soils. These methods include extraction with water, extraction with various salts or acid solutions, S mineralization during incubation, microbial growth, and plant growth and composition. The concentration of S removed by the various extractants normally falls in one of the following groups: (1) readily soluble sulfate, (2) readily soluble and some of the adsorbed sulfate, and (3) readily soluble and some of the adsorbed sulfate and some of the organic S.

Incubation procedures for assessing plant-available S paralleling those used in the estimation of available N have met with little success, because precise determination of the small amount of inorganic SO_4^{2-} released during incubation is difficult. In addition, the amount of S mineralized during incubation is affected by the presence or absence of plants.

Sulfur Requirement of Plants

The requirement of S or any other nutrient by crops is defined as "the minimum content of that nutrient associated with the maximum yield" or "the minimum rate of the uptake of the nutrient associated with maximum growth rate." The first definition refers to that the total amount of the element in the crops (normally expressed in kilograms per hectare) or the concentration of the element in the plant or plant part. The second definition is related to the minimum concentration of the element taken up from the soil or nutrient solution that is associated with the maximum growth. Information on the S content of crops is useful in estimating the S-fertilizer requirement.

Both the uptake and requirements for S differ greatly among plant species, among cultivars within species, and with the stage of development of the crop. Assessment of the S requirement of crops is more complicated than that of any other nutrient. That is because: (1) there are several S sources for plants, (2) each source has a different efficiency for its utilization by crops, (3) S has limited reuse within the crop, and (4) relatively large concentrations of S can be accumulated within the crop. The supply of S during the growing period can be changed by the atmospheric conditions and precipitation, impurities in fertilizers, addition of pesticides, and mineralization of organic S in soil organic matter. In spite of the difficulties associated with assessment of S status on crops, several approaches have successfully been used for this purpose. These include: (1) chemical soil tests, (2) a number of plant-tissue chemical analyses, and (3) crop-deficiency symptoms. The first of these approaches is the most commonly used.

Sulfur Metabolism in Plants

S metabolism in plants is very complex. The significant steps are as follows: (1) sulfate is 'activated,' that is, enzymatically converted to adenosine-5′-phosphosulfate (APS) and 3′-phosphoadenosine-5′-phosphatsulfate (PAPS). In plants, APS functions as substrate for SO_4^{2-} reduction and as a precursor of PAPS, while PAPS acts as the SO_4^{2-} donor in the formation sulfate esters (organic sulfates); (2) the

activated sulfate is reduced; (3) reduced S is incorporated into cysteine; (4) the cysteine-S is transferred into methionine and other essential compounds; (5) methionine is transferred into S-adenosylmethionine, which is a methyl ($-CH_3$) donor and a precursor of important non-S-containing compounds; and (6) cysteine and methionine are incorporated into proteins. Sulfate transport in plants is inhibited by structurally related compounds or ions such as SO_3^{2-}, $S_2O_3^{2-}$, $S_2O_5^{2-}$, SeO_4^{2-}, CrO_4^{2-}, MoO_4^{2-}, and WO_4^{2-}. Studies have shown that SeO_4^{2-} is a competitive inhibitor of SO_4^{2-} transport in plants.

Sulfur-Containing Materials Added to Soils

A number of materials added to soils contain S. These range from animal manures to sewage sludge, crop residues, and irrigation water. The S concentration in waste materials and irrigation water varies with the sources and quality of the material. Therefore, knowledge of the composition of such materials is needed before its application or use on soils.

Fertilizers

Many sources of S-containing fertilizer are available, most of which are old and established sources of S. Their behavior in soils is determined by the chemical nature of the S atom and the reactions involved when added to soils. The following are examples of dry fertilizer containing sulfur:

1. Ammonium sulfate. This compound is widely used as a source of N, but $(NH_4)_2SO_4$ contains 21% N in the ammoniacal form and approximately 24% of S in the SO_4^{2-} form;
2. Single superphosphate. This compound has been manufactured by the fertilizer industry since 1850. It contains approximately 8% of P. It is produced by reacting sulfuric acid (H_2SO_4) with phosphate rock. The reaction is:

$$3[Ca_3(PO_4)_2] \cdot CaF_2 + 7H_2SO_4 = 3Ca(H_2PO_4)_2 + 7CaSO_4 + 2HF \quad [2]$$

3. Ammonium phosphate sulfate. This is essentially a mixture of monoammonium phosphate and ammonium sulfate. The most common of these products contains 16% N, 8% P, and 13% S;
4. Gypsum. Large quantities of gypsum ($CaSO_4 \cdot 2H_2O$) are produced as a by-product of manufacturing concentrated phosphate fertilizer. It is a low-analysis fertilizer (13–14% S in the by-product forms and 18.6% S in the pure form);
5. Elemental S. When added to soils, elemental S is converted to SO_4^{2-}. The reactions involved are affected by particle size (the finer the particles, the faster the reaction rate), temperature, moisture and aeration, soil pH, soil type and properties, fertilizer interaction, characteristics of the elemental S, rate and placement, and time of application. The reactions involved are:

$$S^0 \longrightarrow S_2O_3^{2-} \longrightarrow S_2O_6^{2-} \longrightarrow SO_3^{2-} \longrightarrow SO_4^{2-} \quad [3]$$

6. Sulfur-bentonite. This product consists of 90% of elemental S and 10% of bentonite. When this material is added to soils, the bentonite imbibes moisture, causing the granules to disintegrate, releasing very fine S particles, which are rapidly converted to SO_4^{2-};
7. Elemental sulfur suspension. This material is made of finely ground elemental S (40–60% of S^0) and a small amount of attapulgite clay. It can be applied directly to soils or mixed with other fertilizer materials;
8. Phosphate-elemental sulfur materials. This material is a mixture of elemental S and mono- or diammonium phosphate. It is a source of S and P for plants;
9. Other dry S-fertilizer mixtures are available; these include urea-ammonium sulfate, ammonium nitrate–ammonium sulfate, and potassium sulfate mixtures;
10. Urea–S. This material contains 20% of S and 36% of N. It has excellent physical properties and easy to handle.

Fluid fertilizers containing sulfur include:

1. Ammonium thiosulfate. This compound is a clear solution containing 26% of S and 12% of N. It is the most commonly used S fertilizer. This material can be used for direct application to soils and in irrigation waters;
2. Ammonium-polysulfide. Polysulfides are used as fertilizers, as soil conditioners, and for treatment of irrigation waters to improve percolation into soils. Ammonium polysulfides are used for all these purposes. When added to soil, the polysulfide is changed to colloidal S and sulfide. Calcium polysulfide is marketed as soil conditioner and for treatment of irrigation water. The reaction involved is:

$$CaS_6 + H_2O + CO_2 = H_2S + CaCO_3 + 4S^0 \quad [4]$$

3. Ammonium bisulfite. This is a clear liquid, low-analysis fertilizer, containing 17% of S and 8.5% of N. It has a strong odor of SO_2 and is marketed to a very limited extent;

4. Urea-sulfuric acid mixtures. Two grades of this material are available on the market. One grade contains 10% of N and 18% of S, and the other contains 28% of N and 9% of S. Because this material is highly acidic (pH between 0.5 and 1.0), it is essential that all application equipment is made from stainless steel and extreme precautions must be taken in handling the material.

In addition to the S-containing materials described above, aluminum sulfate is added to soil for soil acidification. Acid soil is required for plants such as azaleas and camellias. When added to soils, the reaction is:

$$Al_2(SO_4)_3 + 6H_2O = 2Al(OH)_3 + 3H_2SO_4 \quad [5]$$

When using any of the above materials, the user should adhere to the recommendations provided by the manufacturer in terms of safety, rate of application, method and time of application, and storage conditions.

Sulfur in the Atmosphere

The atmosphere is an important compartment of the S cycle for agricultural crops and forest ecosystems. Sulfur gases and aerosols are found in the atmosphere of urban, rural, and remote areas. The sulfur species in the atmosphere range from oxidized forms such as sulfur dioxide (SO_2) and sulfate (SO_4^{2-}) to reduced forms such as hydrogen sulfide (H_2S), carbonyl sulfide (COS), dimethyl sulfide ($(CH_3)_2S$, and carbon disulfide (CS_2). These are derived from natural and anthropogenic sources. The lifetimes of the S compounds in the atmosphere range from a few hours to many years and can be found in various chemical forms from the troposphere to the stratosphere. The relationship between atmospheric S and the terrestrial ecosystem is very complex. To understand the interactions, the following information is needed: (1) the rate and chemical forms of S entering the atmosphere, (2) the chemical transformations occurring in the atmosphere, (3) the transport from the emission sources to the receptor (plant), (4) the amount and rate of transfer to soil and plants, and (5) the impact on crop production. The natural sources of S in the atmosphere include: (1) volcanic activity, (2) input from ocean spray, (3) bacterial decomposition of plant material in soils, and (4) animal manure and sewage sludge. Man-made sources include: (1) combustion of S-containing fossil duels (coal, oil, and gas), and (2) reduced S gases released from many industrial processes (e.g., pulp mills).

Atmospheric S gases are absorbed by plants, surface water, and surface soils or deposited in precipitation in the SO_4^{2-} form which, in turn, is absorbed by plants, retained in soils, or leached through groundwater.

Sulfur in Precipitation

Sulfur in the atmosphere occurs in gaseous, solid, and liquid form, with transformation among the different forms accomplished by chemical, biological, and photometric processes. As is the case with N, S is highly transitory among these forms in air and water. The reactions involved in these transformations determine the concentration of S in precipitation, which, in turn, affects its presence in surface and groundwater, with ultimate impact on soils and plants.

The data available on S content of rainfall indicate wide variation by geographic locations. Expressed in kilograms of sulfur per hectare, the annual addition of S in precipitation in North American ranges from 0.5 to 14. In many areas, most of this (approximately 60–80%) additional S is deposited during the crops' growing season. Laboratory and greenhouse experiments have shown that many soils of the USA do not contain sufficient plant-available S to meet the crops' requirements, yet no S-deficiency symptoms have been reported. This is because, in many areas, uptake of atmospheric SO_2 and of that in precipitation can compensate for the soil S deficiency. Indeed, it has been demonstrated that sunflowers can use SO_2 and H_2S as their only source of S without their normal growth being affected.

SURFACE COMPLEXATION MODELING

S Goldberg, USDA–ARS, Riverside, CA, USA

Published by Elsevier Ltd.

Introduction

Adsorption is the process through which ions are removed from solution and accumulate at a solid surface. The ion accumulation takes place at the interface between the surface and the solution forming a two-dimensional structure. If adsorption continues and leads to a three-dimensional structure, the process is called precipitation. The general loss of ions from solution to a surface is called sorption.

Adsorption can occur either specifically or nonspecifically. Specific adsorption occurs when ions have a high affinity for the surface and it results in the formation of inner-sphere surface complexes. Inner-sphere surface complexes are complexes that contain no water molecules between the adsorbing ion and the surface functional group. Examples of surface functional groups are reactive hydroxyl groups on oxide or clay minerals and carboxyl or phenol groups on organic matter. Such surface functional groups are a source of solid surface charge since they undergo dissociation and/or protonation reactions as a result of changes in solution pH. Specific anion adsorption occurs via ligand exchange where the adsorbing ion replaces a reactive surface hydroxyl from the surface functional group. Nonspecific adsorption is dominated by electrostatic attraction and results in outer-sphere complex formation or in adsorption in the diffuse ion swarm. Adsorption in the diffuse ion swarm is the weakest type of adsorption since the ion does not attach to a specific surface functional group but remains free in the aqueous solution, neutralizing surface charge only by its proximity to the charged solid surface. Outer-sphere surface complexes are also formed through nonspecific adsorption and contain at least one water molecule between the adsorbing ion and the surface functional group.

A model is a simplified representation of reality that considers only those characteristics of the system that are pertinent to the problem at hand. A chemical model provides a description of a chemical system consistent with its chemical properties while simultaneously being as simple and as chemically correct as possible. The ideal chemical model is realistic, effective, comprehensive, and predictive. A realistic model conforms to accepted theories of chemical behavior, an effective model closely describes experimental observations, a comprehensive model applies to a wide range of experimental conditions without modification, and a predictive model can be applied to various different chemical conditions.

Description of Models

Surface complexation models are chemical models that give a molecular description of adsorption phenomena using an equilibrium approach. Analogous to complex formation in solution, surface complexation models define surface species, chemical reactions, equilibrium constants, mass balances, and charge balances and their molecular features can be given thermodynamic significance. One of the major

advancements of surface complexation models is consideration of the charge on both the adsorbing ion and the solid adsorbent surface. Surface complexation models constitute a family of models having many common characteristics and adjustable parameters. The models differ in their structural representation of the solid–solution interface, i.e., the location and surface configuration of the adsorbed ions.

Surface Configuration of the Solid–Solution Interface

Members of the surface complexation model family include the two-pK models: constant capacitance, diffuse-layer, triple-layer. Two-pK models are based on a reactive surface functional group, SOH, that undergoes both protonation and dissociation:

$$\mathrm{SOH} + \mathrm{H^+} \leftrightarrow \mathrm{SOH_2^+} \qquad [1]$$

$$\mathrm{SOH} \leftrightarrow \mathrm{SO^-} + \mathrm{H^+} \qquad [2]$$

hence the term two-pK model.

Comparable models can be written based on the one-pK concept. So far, the one-pK model has been developed based on the Stern model. In the one-pK model, surface functional groups carry either one or two protons, SOH and $\mathrm{SOH_2}$, respectively. Surface charging can be represented with one reaction:

$$\mathrm{SOH^{1/2-}} + \mathrm{H^+} \leftrightarrow \mathrm{SOH_2^{1/2+}} \qquad [3]$$

The location and surface configuration of the adsorbed ions for the various surface complexation models are presented in Figure 1. In the constant capacitance model and the diffuse layer model all surface complexes are inner-sphere and are located in a single surface plane (Figure 1a, b). The diffuse-layer model includes a diffuse layer that commences at the d-plane and extends into solution. In the triple-layer model ions forming inner-sphere surface complexes adsorb in the surface o-plane and ions forming outer-sphere surface complexes adsorb in a β-plane located between the o-plane and the d-plane (Figure 1c). In the representation of the one-pK model based on the Stern model indicated in Figure 1d, protons and hydroxyls form inner-sphere surface complexes

located in the o-plane; all other ions form outer-sphere surface complexes and are located in the d-plane.

Surface Complexation Reactions

In the two-pK models chemical reactions for inner-sphere surface complexation are eqns [1], [2], and:

$$\mathrm{SOH} + \mathrm{M^{m+}} \leftrightarrow \mathrm{SOM^{(m-1)}} + \mathrm{H^+} \quad [4]$$

$$2\mathrm{SOH} + \mathrm{M^{m+}} \leftrightarrow \mathrm{(SO)_2M^{(m-2)}} + 2\mathrm{H^+} \quad [5]$$

$$\mathrm{SOH} + \mathrm{L^{l-}} + \mathrm{H^+} \leftrightarrow \mathrm{SL^{(l-1)-}} + \mathrm{H_2O} \quad [6]$$

$$2\mathrm{SOH} + \mathrm{L^{l-}} + 2\mathrm{H^+} \leftrightarrow \mathrm{S_2L^{(l-2)-}} + 2\mathrm{H_2O} \quad [7]$$

$$\mathrm{SOH} + \mathrm{L^{l-}} + 2\mathrm{H^+} \leftrightarrow \mathrm{SHL^{(l-2)-}} + \mathrm{H_2O} \quad [8]$$

where M is a metal ion of charge m^+ and L is a ligand of charge l^-. Surface complexes can be monodentate or bidentate. In monodentate complexation one bond is formed between the adsorbing ion and the surface functional group. Bidentate complexes contain two bonds between the adsorbing ion and two surface functional groups. Equations [4] to [7] are used in the constant capacitance model. In the diffuse-layer model, reaction [8] is used in place of reaction [7] since bidentate complexes for adsorbed anions have not been considered.

The following chemical reactions for outer-sphere surface complexation are considered in the triple-layer model in addition to eqns [1], [2], and [4] to [7]:

$$\mathrm{SOH} + \mathrm{M^{m+}} \leftrightarrow \mathrm{SO^-} - \mathrm{M^{m+}} + \mathrm{H^+} \quad [9]$$

$$\mathrm{SOH} + \mathrm{M^+} + \mathrm{H_2O} \leftrightarrow \mathrm{SO^-} - \mathrm{MOH^{(m-1)}} + 2\mathrm{H^+} \quad [10]$$

$$\mathrm{SOH} + \mathrm{H^+} + \mathrm{L^{l-}} \leftrightarrow \mathrm{SOH_2^+} - \mathrm{L^{l-}} \quad [11]$$

$$\mathrm{SOH} + 2\mathrm{H^+} + \mathrm{L^{l-}} \leftrightarrow \mathrm{SOH_2^+} - \mathrm{LH^{(l-1)-}} \quad [12]$$

$$\mathrm{SOH} + \mathrm{C^+} \leftrightarrow \mathrm{SO^-} - \mathrm{C^+} + \mathrm{H^+} \quad [13]$$

$$\mathrm{SOH} + \mathrm{H^+} + \mathrm{A^-} \leftrightarrow \mathrm{SOH_2^+} - \mathrm{A^-} \quad [14]$$

where C^+ is the cation and A^- is the anion of the background electrolyte.

In the one-pK models, chemical reactions for surface complexation are eqn [3] and:

$$\mathrm{SOH^{1/2-}} + \mathrm{M^+} \leftrightarrow \mathrm{SOH^{1/2-}} - \mathrm{M^{m+}} \quad [15]$$

$$\mathrm{SOH^{1/2-}} + \mathrm{M^{m+}} + \mathrm{H_2O} \leftrightarrow \mathrm{SOH^{1/2-}} - \mathrm{MOH^{(m-1)}} + \mathrm{H^+} \quad [16]$$

$$\mathrm{SOH_2^{1/2+}} + \mathrm{L^{l-}} \leftrightarrow \mathrm{SOH_2^{1/2+}} - \mathrm{L^{l-}} \quad [17]$$

$$\mathrm{SOH^{1/2-}} + \mathrm{C^+} \leftrightarrow \mathrm{SOH^{1/2-}} - \mathrm{C^+} \quad [18]$$

$$\mathrm{SOH_2^{1/2+}} + \mathrm{A^-} \leftrightarrow \mathrm{SOH_2^{1/2+}} - \mathrm{A^-} \quad [19]$$

Equilibrium Constants for Surface Complexation

The equilibrium constants describing inner-sphere surface complexation in the two-pK models are:

$$K_+ = \frac{[\mathrm{SOH_2^+}]}{[\mathrm{SOH}][\mathrm{H^+}]}\exp[\mathrm{F}\Psi/RT] \quad [20]$$

$$K_- = \frac{[\mathrm{SO^-}][\mathrm{H^+}]}{[\mathrm{SOH}]}\exp[-\mathrm{F}\Psi/RT] \quad [21]$$

$$K_\mathrm{M}^1 = \frac{[\mathrm{SOM^{(m-1)}}][\mathrm{H^+}]}{[\mathrm{SOH}][\mathrm{M^{m+}}]}\exp[(\mathrm{m}-1)\mathrm{F}\Psi/RT] \quad [22]$$

$$K_\mathrm{M}^2 = \frac{[\mathrm{(SO)_2M^{(m-2)}}][\mathrm{H^+}]^2}{[\mathrm{SOH}]^2[\mathrm{M^{m+}}]}\exp[(\mathrm{m}-2)\mathrm{F}\Psi/RT] \quad [23]$$

$$K_\mathrm{L}^1 = \frac{[\mathrm{SL^{(l-1)-}}]}{[\mathrm{SOH}][\mathrm{L^{l-}}][\mathrm{H^+}]}\exp[-(\mathrm{l}-1)\mathrm{F}\Psi/RT] \quad [24]$$

$$K_\mathrm{L}^2 = \frac{[\mathrm{S_2L^{(l-2)-}}]}{[\mathrm{SOH}]^2[\mathrm{L^{l-}}][\mathrm{H^+}]^2}\exp[-(\mathrm{l}-2)\mathrm{F}\Psi/RT] \quad [25]$$

$$K_\mathrm{L}^3 = \frac{[\mathrm{SHL^{(l-2)-}}]}{[\mathrm{SOH}][\mathrm{L^{l-}}][\mathrm{H^+}]^2}\exp[-(\mathrm{l}-2)\mathrm{F}\Psi/RT] \quad [26]$$

where F is the Faraday constant, Ψ is the surface potential, R is the molar gas constant, T is the absolute temperature, and square brackets represent concentrations. The exponential terms are correction factors accounting for the effect of surface charge on surface complexation. Equations [20] to [25] are considered in the constant capacitance model where $\Psi = \Psi_o$. In the diffuse layer model, eqn [25] is replaced with eqn [26] and $\Psi = \Psi_d$.

Equilibrium constants for outer-sphere surface complexation in the triple layer model are:

$$K_{\mathrm{M}}^{3} = \frac{[\mathrm{SO^{-} - M^{m+}}][\mathrm{H^{+}}]}{[\mathrm{SOH}][\mathrm{M^{m+}}]} \exp[\mathrm{F}(m\Psi_{\beta} - \Psi_{\mathrm{o}})/RT] \quad [27]$$

$$K_{\mathrm{M}}^{4} = \frac{[\mathrm{SO^{-} - MOH^{(m-1)}}][\mathrm{H^{+}}]^{2}}{[\mathrm{SOH}][\mathrm{M^{m+}}]} \exp[\mathrm{F}((m-1)\Psi_{\beta} - \Psi_{\mathrm{o}})/RT] \quad [28]$$

$$K_{\mathrm{L}}^{4} = \frac{[\mathrm{SOH_2^{+} - L^{l-}}]}{[\mathrm{SOH}][\mathrm{H^{+}}][\mathrm{L^{l-}}]} \exp[\mathrm{F}(\Psi_{\mathrm{o}} - l\Psi_{\beta})/RT] \quad [29]$$

$$K_{\mathrm{L}}^{5} = \frac{[\mathrm{SOH_2^{+} - LH^{(l-1)-}}]}{[\mathrm{SOH}][\mathrm{H^{+}}]^{2}[\mathrm{L^{l-}}]} \exp[\mathrm{F}(\Psi_{\mathrm{o}} - (l-1)\Psi_{\beta})/RT] \quad [30]$$

$$K_{\mathrm{C}} = \frac{[\mathrm{SO^{-} - C^{+}}][\mathrm{H^{+}}]}{[\mathrm{SOH}][\mathrm{C^{+}}]} \exp[\mathrm{F}(\Psi_{\beta} - \Psi_{\mathrm{o}})/RT] \quad [31]$$

$$K_{\mathrm{A}} = \frac{[\mathrm{SOH_2^{+} - A^{-}}]}{[\mathrm{SOH}][\mathrm{H^{+}}][\mathrm{A^{-}}]} \exp[\mathrm{F}(\Psi_{\mathrm{o}} - \Psi_{\beta})/RT] \quad [32]$$

In the one-pK model the equilibrium constants for surface complexation are:

$$K_{\mathrm{H}} = \frac{[\mathrm{SOH_2^{1/2+}}]}{[\mathrm{SOH^{1/2-}}][\mathrm{H^{+}}]} \exp[\mathrm{F}\Psi_{\mathrm{o}}/RT] \quad [33]$$

$$K_{\mathrm{M}}^{1} = \frac{[\mathrm{SOH^{1/2-} - M^{m+}}]}{[\mathrm{SOH^{1/2-}}][\mathrm{M^{m+}}]} \exp[\mathrm{mF}\Psi_{\mathrm{d}}/RT] \quad [34]$$

$$K_{\mathrm{M}}^{2} = \frac{[\mathrm{SOH^{1/2-} - MOH^{(m-1)}}][\mathrm{H^{+}}]}{[\mathrm{SOH^{1/2-}}][\mathrm{M^{m+}}]} \exp[(m-1)\mathrm{F}\Psi_{\mathrm{d}}/RT] \quad [35]$$

$$K_{\mathrm{L}} = \frac{[\mathrm{SOH_2^{1/2+} - L^{l-}}]}{[\mathrm{SOH_2^{1/2+}}][\mathrm{L^{l-}}]} \exp[-l\mathrm{F}\Psi_{\mathrm{d}}/RT] \quad [36]$$

$$K_{\mathrm{C}} = \frac{[\mathrm{SOH^{1/2-} - C^{+}}]}{[\mathrm{SOH^{1/2-}}][\mathrm{C^{+}}]} \exp[\mathrm{F}\Psi_{\mathrm{d}}/RT] \quad [37]$$

$$K_{\mathrm{A}} = \frac{[\mathrm{SOH_2^{1/2+} - A^{-}}]}{[\mathrm{SOH_2^{1/2+}}][\mathrm{A^{-}}]} \exp[-\mathrm{F}\Psi_{\mathrm{d}}/RT] \quad [38]$$

Mass and Charge Balances

The mass balance expression for the surface functional group, SOH, in the two-pK models is:

$$\begin{aligned} S_{\mathrm{T}} = {} & [\mathrm{SOH}] + [\mathrm{SOH_2^{+}}] + [\mathrm{SO^{-}}] + [\mathrm{SOM^{(m-1)}}] \\ & + 2[(\mathrm{SO})_2\mathrm{M^{(m-2)}}] + [\mathrm{SL^{(l-1)-}}] + 2[\mathrm{S_2L^{(l-2)-}}] \\ & + [\mathrm{SHL^{(l-2)-}}] + [\mathrm{SO^{-} - M^{m+}}] + [\mathrm{SO^{-}} \\ & - \mathrm{MOH^{(m-1)}}] + [\mathrm{SOH_2^{+} - L^{l-}}] + [\mathrm{SOH_2^{+}} \\ & - \mathrm{LH^{(l-1)-}}] + [\mathrm{SO^{-} - C^{+}}] + [\mathrm{SOH_2^{+} - A^{-}}] \end{aligned} \quad [39]$$

The mass balance for the surface functional groups, SOH and SOH_2, in the one-pK model is:

$$\begin{aligned} S_{\mathrm{T}} = {} & [\mathrm{SOH^{1/2-}}] + [\mathrm{SOH_2^{1/2+}}] + [\mathrm{SOH^{1/2-} - M^{m+}}] \\ & + [\mathrm{SOH^{1/2-} - MOH^{(m-1)}}] + [\mathrm{SOH_2^{1/2+} - L^{l-}}] \\ & + [\mathrm{SOH^{1/2-} - C^{+}}] + [\mathrm{SOH_2^{1/2+} - A^{-}}] \end{aligned} \quad [40]$$

The mass balance represents a summation of all surface species considered in the particular surface complexation model.

The charge balance expressions for the two-pK models are:

$$\begin{aligned} \sigma_{\mathrm{o}} = {} & [\mathrm{SOH_2^{+}}] + [\mathrm{SOH_2^{+} - L^{l-}}] + [\mathrm{SOH_2^{+} - LH^{(l-1)-}}] \\ & + (m-1)[\mathrm{SOM^{(m-1)}}] + (m-2)[(\mathrm{SO})_2\mathrm{M^{(m-2)}}] \\ & + [\mathrm{SOH_2^{+} - A^{-}}] - [\mathrm{SO^{-}}] - [\mathrm{SO^{-} - M^{m+}}] \\ & - [\mathrm{SO^{-} - MOH^{(m-1)}}] - (l-1)[\mathrm{SL^{(l-1)-}}] \\ & - (l-2)[\mathrm{S_2L^{(l-2)-}}] - (l-2)[\mathrm{SHL^{(l-2)-}}] \\ & - [\mathrm{SO^{-} - C^{+}}] \end{aligned} \quad [41]$$

$$\begin{aligned} \sigma_{\beta} = {} & m[\mathrm{SO^{-} - M^{m+}}] + (m-1)[\mathrm{SO^{-} - MOH^{(m-1)}}] \\ & + [\mathrm{SO^{-} - C^{+}}] - l[\mathrm{SOH_2^{+} - L^{l-}}] - (l-1) \\ & [\mathrm{SOH_2^{+} - LH^{(l-1)-}}] - [\mathrm{SOH_2^{+} - A^{-}}] \end{aligned} \quad [42]$$

$$\sigma_{\mathrm{o}} + \sigma_{\beta} + \sigma_{\mathrm{d}} = 0 \quad [43a]$$

$$\sigma_{\mathrm{o}} + \sigma_{\mathrm{d}} = 0 \quad [43b]$$

where σ is the surface charge. The charge balances, eqns [41] and [42], represent the summation of all charge contributions in a particular plane of adsorption. All of the models consider charge balance in the surface plane, eqn [41]. Charge balance in the β-plane, eqn [42], is restricted to the triple-layer model. Charge balance eqn [43a] is considered in the triple-layer model while eqn [43b] is used in the diffuse-layer model. The charge balance expressions for the one-pK model are eqn [43b] and:

$$\sigma_o = \frac{1}{2}([SOH_2^{1/2+}] - [SOH^{1/2-}]) \quad [44]$$

Charge-Potential Relationships

All surface complexation models contain relations between surface charges and surface potentials. In the constant capacitance model the charge-potential relationship is:

$$\sigma = C\Psi \quad [45]$$

where C is the capacitance. The charge potential relationship for the diffuse layer model is:

$$\sigma_d = -(8\epsilon_o DRTI)^{1/2} \sinh(F\Psi_d/2RT) \quad [46]$$

where ϵ_o is the permittivity of vacuum, D is the dielectric constant of water, and I is the solution ionic strength. In the triple-layer model the charge potential relationships are eqn [46] and:

$$\sigma_o = C_1(\Psi_o - \Psi_\beta) \quad [47]$$

$$\sigma_d = C_2(\Psi_d - \Psi_\beta) \quad [48]$$

The charge-potential relationships for the one-pK model are eqn [46] and:

$$\sigma_o = C(\Psi_o - \Psi_d) \quad [49]$$

Obtaining Values of Adjustable Parameters

Surface Site Density

The total number of reactive surface functional groups, S_T is an important adjustable parameter in the surface complexation models and is related to the surface site density:

$$S_T = \frac{Sa10^{18}}{N_A} N_S \quad [50]$$

where S is the surface area, a is the particle concentration, and N_A is Avogadro's number. Experimental methods for determining surface site density include: tritium exchange, potentiometric titration, fluoride adsorption, and maximum adsorption. Values of this parameter can also be calculated from crystal dimensions or optimized to fit experimental adsorption data. Various determinations of surface site density vary by an order of magnitude; the lowest values are obtained from crystallographic calculations while tritium exchange yields the highest values. Uncertainty in the value of the surface site density is a major limitation in the use of surface complexation models since the ability of the models to describe adsorption is sensitively dependent on this value. To standardize surface complexation modeling, a fixed value of 2.31 sites nm^{-2} has been used for many natural materials. Applications of the diffuse-layer model to metal adsorption have split the total number of reactive surface functional groups into a 'strong,' S_s, and a 'weak,' S_w, set of adsorption sites. This approach greatly increases the number of adjustable parameters since each set of sites, S_i, has its own protonation, dissociation, and metal surface complexation constants.

Capacitances

Some values of capacitance (C in the constant capacitance and one-pK model and C_1 in the triple layer model) can be obtained graphically from slopes of protonation-dissociation constants versus surface charge. Alternatively, both capacitances, C_1 and C_2, in the triple-layer model can be obtained using an electrokinetic extrapolation technique. Capacitance values obtained experimentally usually exhibit great variability; therefore, capacitances have generally been optimized to fit the titration data.

Surface Complexation Constants

Values of the protonation and dissociation constants in the constant capacitance model and the triple-layer model can be obtained from the same graphs used to obtain values of capacitance. These constants can also be obtained by optimizing titration data using a computer program. Values of the surface complexation constants for ion adsorption are obtained using computer optimization. An advantage of computer optimization, in addition to ease of use, is that it yields bias-free parameters with standard deviations and quality-of-fit criteria. Individual optimized equilibrium constant values can be weighted to obtain overall best estimates of the parameter:

$$\overline{\log K} = \sum \frac{(1/\sigma_{\log K})_i}{\sum(1/\sigma_{\log K})_i} [\log K]_i \quad [51]$$

For the diffuse layer model a set of best estimates of $\log K$ are available for a variety of adsorbing cations and anions. The advantage of this data set is that the surface complexation constants are all self-consistent; i.e., all ion surface complexation constants were optimized using the same values of protonation-dissociation constants and surface site density. This is an important point since parameter values in the surface complexation models are interdependent. Additionally, since each surface complexation model contains a different set of assumptions for the solid–solution interface, surface complexation

constants from one model must not be used in any other model.

Applications to Ion Adsorption on Natural Samples

All surface complexation models were originally developed to describe charging behavior and ion adsorption of ions on oxide minerals. Various curves are commonly used to describe adsorption behavior: adsorption isotherms, adsorption edges, and adsorption envelopes. Adsorption isotherms describe ion adsorption as a function of equilibrium ion concentration, usually at fixed solution pH. Adsorption edges and adsorption envelopes both describe ion adsorption as a function of solution pH at a fixed total ion concentration. Adsorption edge is the term generally applied to cation adsorption, while the term adsorption envelope is used to describe anion adsorption.

The most commonly studied oxide surfaces with surface complexation models have been the iron oxides goethite and ferrihydrite. Subsequently, the models were extended to include adsorption on clay minerals, organic materials, and soil samples. In extending the models to natural samples certain approximations and modifications are necessary. In the application to natural systems, such as clay minerals or soils, the assumption is made that ion adsorption occurs through interaction with the hydroxyl groups at the edges of the clay particles. The effect of permanent negatively charged sites at the clay basal planes on this adsorption process is ignored. This simplification may not be appropriate, especially for anions whose edge adsorption may be affected by this negative charge.

The surface complexation models contain the assumption that ion adsorption takes place on one or at most two sets of reactive surface sites. This is clearly an oversimplification since even simple oxide minerals contain several sets of reactive hydroxyl groups. However, this simplification is necessary to maintain the number of adjustable parameters at a reasonable level. Natural materials such as soils are complex, multisite mixtures having a variety of reactive surface functional groups. Thus surface complexation constants determined for soils represent average composite values for all these sets of reactive surface functional groups.

Constant Capacitance Model

The constant capacitance model has been used to describe adsorption on silicon, aluminum, iron, and titanium oxides, kaolinite, montmorillonite, and illite clay minerals, plant cell walls, and soils. Adsorbing ions that have been investigated include the cation and metal ions: calcium, cesium, lead, copper, cadmium, zinc, nickel, cobalt, aluminum, iron, manganese, silver, mercury, lanthanum, europium, ytterbium, and the anions: phosphate, sulfate, arsenate, arsenite, selenite, selenate, borate, molybdate, silicate, fluoride, phthalate, salicylate, benzoate, citrate.

Examples of the fit of the constant capacitance model to trace metal adsorption edges are provided in Figure 2 for iron, lead, copper, and cadmium adsorption on silica. As for many trace metal cations, the amount of adsorption increases rapidly from 0 to 100% over a narrow pH range. The model is well able to describe these changes in adsorption for the four different metal ions. Figure 3 indicates the ability

Amsterdam: Elsevier Science.

of the constant capacitance model to fit adsorption envelopes for the anion, silicate, on to the iron oxide, goethite at various initial silicate concentrations. Silicate adsorption is nearly constant over most of the pH range. The model is able to describe the adsorption, including the pH dependence observed at the highest initial silicate concentration.

Applications of the constant capacitance model to soils have been restricted to anions: phosphate, selenite, borate, and molybdate. For the application of the model to selenite adsorption by soils, two sets of reactive surface functional groups were postulated; monodentate surface complexes were formed on one set of sites and bidentate surface complexes on the other. The model was initially applied to one Californian soil. As can be seen in Figure 4a, the fit of the model to the data is good. Subsequently, the model parameters obtained in fitting this soil were used to predict adsorption on additional Californian soils. Figure 4b shows that this prediction was qualitatively successful and indicates some predictive capability of the model for soils of somewhat similar chemical and physical characteristics.

An alternative approach has been developed for describing borate adsorption on soils. From the fitted surface complexation constants for a set of soils, a

general regression model was obtained that predicts the surface complexation constants for new soils from easily measured chemical parameters: surface area, organic carbon content, inorganic carbon content, and aluminum oxide content. These surface complexation constants were then used in the constant capacitance model to predict borate adsorption on the new soils. This approach constitutes a completely independent model evaluation that was able to predict borate adsorption on a diverse set of soils having a wide range of chemical properties, as indicated in Figure 5.

Diffuse-Layer Model

The diffuse-layer model has been used to describe adsorption on iron, aluminum, manganese, titanium, and silicon oxides, kaolinite, montmorillonite and biotite minerals, natural organic matter, bacterial cell walls, and sediments. Adsorbing ions that have been investigated include the cation and metal ions: calcium, strontium, barium, copper, nickel, zinc, cadmium, lead, cobalt, aluminum, chromium, silver, mercury, uranium and the anions: phosphate, sulfate, selenite, selenate, arsenate, arsenite, borate, chromate, fluoride, vanadate, thiosulfate, oxalate, phthalate, salicylate, benzoate, and fulvate.

The ability of the diffuse-layer model to describe metal adsorption edges is indicated in Figure 6 for lead adsorption on the iron oxide, hematite. The model was able to describe the data very well at three significantly different initial lead concentrations over a wide range of solution pH values. Figure 7 demonstrates the ability of the diffuse-layer model to fit

adsorption envelopes for the chromate anion on goethite. In order to fit the two intermediate chromate concentrations it was necessary to add a third chromate surface complex, [$SCrO_4^{3-}$]. With this addition, the model is well able to describe chromate adsorption at all initial chromate concentrations over a wide range of solution pH.

Applications of the diffuse-layer model to soil systems have not been carried out to date. Adsorption

of various metal ions has been investigated on a lignocellulose organic substrate extracted from wheat bran. In these applications, two sets of reactive surface functional groups are considered representing carboxylic and phenolic sites. Figure 8 presents the ability of the diffuse-layer model to describe copper adsorption edges on this organic material as a function of initial copper concentration $[Cu_{ini}]$, solution pH, and ionic strength, I. In this application, the model is fitted to the data for $[Cu_{ini}] = 2 \times 10^{-4}$ M, $I = 0.1$. The model parameters resulting from this optimization were then used to predict the remaining model results depicted in Figure 8. The diffuse layer model is well able to describe copper adsorption on this natural material.

Triple-Layer Model

The triple-layer model has been used to describe adsorption on iron, aluminum, manganese, and silicon oxides, kaolinite and smectite clay minerals, and soils. Adsorbing ions that have been investigated include the cation and metal ions: sodium, potassium, calcium, magnesium, lead, zinc, cadmium, copper, cobalt, silver, mercury, uranium, plutonium, thorium, neptunium, and the anions: chloride, nitrate, perchlorate, sulfate, selenite, selenate, arsenate, arsenite, molybdate, borate, chromate, silicate, fluoride, carbonate, oxalate, phthalate, salicylate, lactate, acetate, formate, and humate.

The ability of the triple-layer model to describe metal ion adsorption edges is depicted in Figure 9 for lead adsorption on goethite. In this application an inner-sphere surface complex is assumed. The triple-layer model was well able to describe lead adsorption at various initial concentrations as a function of solution pH. Figure 10 shows the fit of the triple-layer model to anion adsorption envelopes for selenate adsorption on the iron oxide, ferrihydrite. With the assumption of two outer-sphere surface complexes, the model describes the adsorption data quantitatively for four vastly differing initial selenium concentrations as a function of solution pH.

The triple-layer model was able to fit calcium, magnesium, and sulfate adsorption on a Brazilian oxisol and sulfate adsorption on an acidic forest soil. Molybdate adsorption on two Californian soils as a function of solution pH and ionic strength could be described using either an inner-sphere or an outer-sphere adsorption mechanism. The quality of the fit was slightly better with the inner-sphere adsorption mechanism. In this application it was assumed that aluminol groups on the clay edges are the reactive surface functional groups in the soils and that

surface complexation constants determined for reactive surface hydroxyls of aluminum oxide can be used to describe the surface complexation reactions undergone by these aluminol groups.

In a similar approach, surface complexation constants previously determined for the reactions undergone by aluminum-substituted goethite were used to describe chromate adsorption by two soils. It was assumed that only the iron sites on the aluminum-substituted goethite are involved in chromate

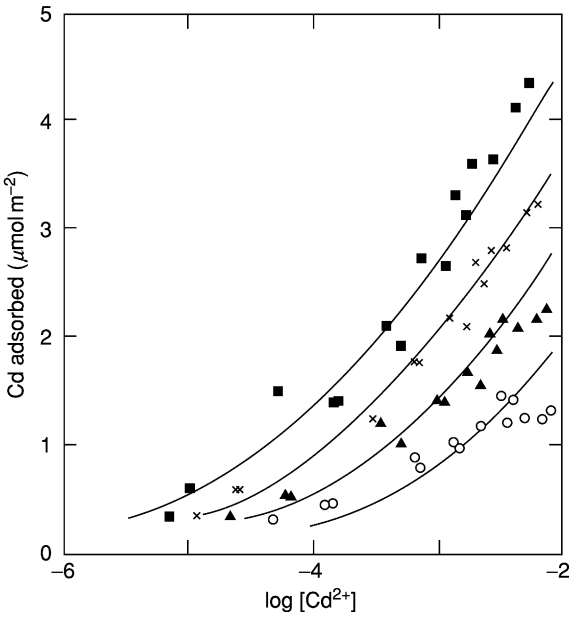

Figure 12 Fit of the one-pK model to cadmium adsorption on amorphous iron oxide. Model fits are represented by solid lines. pH ○ 7.0; ▲ 7.4; × 7.7; ■ 8.0. adsorption, forming monodentate outer-sphere surface complexes. The ability of the model to describe chromate adsorption on the two soils as a function of solution pH is indicated in Figure 11. The fit of the model on these heterogeneous materials is qualitatively correct.

One-pK Model

The one-pK model has been used to describe adsorption on iron and aluminum oxides. The vast majority of studies to date have used goethite as the adsorbent material. Adsorbing ions that have been investigated include the cations: potassium, calcium, cadmium, copper, and anions: phosphate, arsenate, selenite, sulfate, chromate, lactate, oxalate, malonate, phthalate, citrate, and fulvate.

The ability of the one-pK model to fit cation adsorption isotherms is indicated in Figure 12 for cadmium adsorption on hematite. The model was well able to describe cadmium adsorption at various solution pH values and initial cadmium concentrations. In this application, consideration of background electrolyte surface complexes was neglected. Figure 13 indicates the ability of the one-pK model to fit anion adsorption isotherms for phosphate adsorption on goethite. The model was well able to describe phosphate adsorption over a very wide range of solution pH values

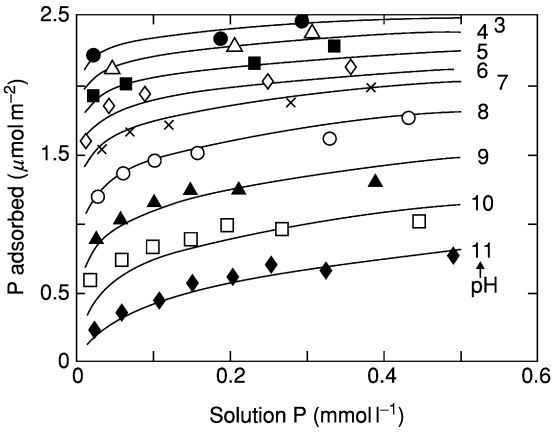

Figure 13 Fit of the one-pK model to phosphate adsorption on goethite. Model fits are represented by solid lines. and initial phosphate concentrations. In this application, a surface complexation constant for potassium adsorption was also optimized.

List of Technical Nomenclature

ϵ_o	Permittivity of vacuum [$C^2\,J^{-1}\,m^{-1}$]
σ	Surface charge density [$C\,m^{-2}$]
σ_β	Surface charge density in the β-plane [$C\,m^{-2}$]
σ_d	Surface charge density in the d-plane [$C\,m^{-2}$]
σ_o	Surface charge density in the o-plane [$C\,m^{-2}$]
$(\sigma_{logK})_I$	Standard deviation for logK of the Ith data set
Ψ	Surface potential [V]
Ψ_β	Surface potential in the β-plane [V]
Ψ_d	Surface potential in the d-plane [V]
Ψ_o	Surface potential in the o-plane [V]
A^-	Anion of the background electrolyte
a	Particle concentration [$g\,l^{-1}$]
C	Capacitance [$F\,m^{-2}$]
C_1	Capacitance between the o- and the β-plane [$F\,m^{-2}$]
C_2	Capacitance between the β- and the d-plane [$F\,m^{-2}$]
C^+	Cation of the background electrolyte
D	Dielectric constant of water
F	Faraday constant [$C\,mol^{-1}$]
I	Ionic strength
K_I	Equilibrium constant
L	Ligand
l^{l-}	Charge on the ligand
M	Metal ion
m^{m+}	Charge on the metal
N_A	Avogadro's number
N_S	Maximum surface site density [$sites\,nm^{-2}$]
R	Molar gas constant [$J\,mol^{-1}\,K^{-1}$]
S	Surface area [$m^2\,g^{-1}$]
SOH	Reactive surface hydroxyls bound to a metal ion S
S_s	High-affinity sites
S_T	Total number of reactive surface functional groups
S_w	Low-affinity sites
T	Absolute temperature [K]

SUSTAINABLE SOIL AND LAND MANAGEMENT

J L Berc, USDA Natural Resources Conservation Service, Washington, DC, USA

Introduction

The concept of sustainability has evolved to meet changing needs, changing realities, technological development, and new understanding of ecosystem functions. At any time in history it is likely that people have hoped to manage their land to sustain its productivity throughout their lifetime and for their offspring. In a new land with abundant resources, it is difficult to imagine depleting resources. Early national policy in the USA encouraged people to settle in the west, to claim the territory, and relieve population pressures in the east. If land was worn out, people could move to the western frontier. By the end of the nineteenth century, however, most of the land was settled, the frontier was 'closed,' and people could no longer count on more available land to replace worn-out land. Many families lacked sufficient knowledge, land, and water to sustain their livelihood on the land. Land was often pushed to produce crops that the soil and climate could not support. By the 1930s the nation was faced with much ruined and abandoned land in the east and a dust bowl and more abandoned farms in the west. From this ecological and human disaster came the public recognition of the need to help farmers and ranchers better balance long-term conservation needs and short-term economic needs so that agricultural production could be sustainable.

The Birth of Soil Conservation in US Agriculture

The vision of the early soil conservationists in the USA still inspires us today:

> Nature treats the earth kindly. Man treats her harshly. He overplows the cropland, overgrazes the pastureland, and overcuts the timberland. He destroys millions of acres completely. He pours fertility year after year into the cities, which in turn pour what they do not use down the sewers into the rivers and the ocean. The flood problem insofar as it is man-made is chiefly the result of overplowing, overgrazing, and overcutting of timber. This terribly destructive process is excusable in a young civilization. It is not excusable in the United States in the year 1938.
>
> *Henry A. Wallace, Secretary of Agriculture*
>
> Among the causes of this misuse of the soil and consequent waste of human resources, lack of knowledge on the part of individuals undoubtedly plays a large part. But even if all farmers thoroughly understood the consequences to themselves of the type of land use they are practicing and had perfect knowledge of soil-conservation techniques, a large number would still be unable to put the knowledge fully into practice. Social and economic limitations would prevent them from doing certain things they knew ought to be done.
>
> History is largely a record of human struggle to wrest the land from nature, because man relies for sustenance on the products of the soil. Yet too frequently man's conquest of the land has been disastrous: over extensive areas, his culture of the earth has resulted in extreme impoverishment or complete destruction of the soil resource on which he is dependent.... Conservation of the soil, in a national sense, requires the adoption of sound land-use principles and practices by agriculture as a whole. The attainment of this objective involves the widespread use of physical measures of land defense and the adjustment of certain economic and social forces tending to encourage exploitation of the soil.
>
> *Hugh H. Bennett, Chief, Soil Conservation Service, and W.C. Lowdermilk, 1938*
>
> Thou shalt inherit the Holy Earth as a faithful steward, conserving its resources and productivity from generation to generation. Thou shalt safeguard thy fields from soil erosion, thy living waters from drying up, thy forests from desolation, and protect thy hills from overgrazing by thy herds, that thy descendants may have abundance forever. If any shall fail in this stewardship of the land thy fruitful fields shall become sterile stony ground and wasting

> gullies, and thy descendants shall decrease and live in poverty or perish from off the face of the earth.
>
> *Walter Clay Lowdermilk, 1939*

W.C. Lowdermilk wrote this 'eleventh commandment' after reporting on the 'graveyard of empires' throughout the 'Old World,' where city after city was ruined not by climate change, but by the failure of their populations to conserve the soil and water resources from which they grew. His report, *Conquest of the Land Through 7000 Years*, was undertaken to help the USA in its struggle with the Dust Bowl and the gullied South. He warned that, if Americans failed to conserve their soil and water resources, the future of the nation would be at risk. He described erosion control and water management practices used at the time to increase water infiltration and reduce storm flow damage; and he called for improvement and adaptation of practices to address increasingly intensive land use.

The concept of sustainability in the 1930s focused on maintaining farm productivity to supply adequate food and fiber for the growing nation. Agricultural production was dependent on the inherent soil and water qualities of the land. Great progress was made during this era, with the introduction of contour cultivation, cover crops, and use of manure and crop rotations to restore soil nutrients and organic matter. The need for zoning, education, financial relief, and improved practices was recognized at the time to address holistically the roots of problems causing soil degradation and loss.

Emerging Agricultural Technology Shifts National Conservation Priorities

The synthetic fertilizer industry was in its early stages of development at the time of the beginning of soil conservation policy in the USA. Over the next generation, commercial nutrients began replacing crop rotations to maintain productivity. Water management at the watershed level was introduced, and soil drainage, irrigation, and land-leveling became major conservation efforts. By the late 1950s, more than 60 million hectares of farmland had been drained. Along with mechanization and new improved crop breeds, these technologies contributed to the doubling of crop and animal production between 1950 and the early 1990s. In this new technology frontier, the link between productivity and land quality was muted, and the impetus to conserve inherent soil productivity declined.

Erosion control was still encouraged to maintain the storage capacity of dams being constructed in watersheds throughout the country to prevent flooding and maintain adequate water supplies. The concept of 'tolerable soil loss' was developed in the 1950s from the perspective of the cost to the farmers of nutrients that would be lost from the eroded soil. The *1957 Yearbook of Agriculture: Soil* recommended that in the Corn Belt, depending on soil depth, mean annual soil losses should be less than 4.5–11 t ha^{-1} to avoid damaging the land or causing excessive silting on lower fields or in streams and reservoirs.

Nevertheless, erosion remained a major concern. The 1957 yearbook noted that "in the Great Plains alone, about 14 million acres not suited for permanent cultivation were cultivated in 1955. Much of this land offers low returns and is subject to severe erosion even in average years." The acreage damaged from erosion was equal to that damaged in the dust storms of the 1930s. Despite the long-term economic benefits to the farmer of conservation practices and because increasing numbers of farms were on rented land, long-term conservation investment was often not made.

The Conservation Reserve Program of the Soil Bank was established in 1956 to set aside cropland into soil-conserving crops such as grass and legumes for up to 10 years. By 1960 approximately 11.6 million hectares were enrolled. Objections from rural communities about disruptions to their economies caused by the enrollment of whole farms into this program caused it to be ended. The Agricultural Conservation Program, under which farmers received cost-share assistance for conservation, was made a permanent program in 1957. Conservation practices that were promoted included rotation cropping, terraces, shifts from row crops to pasture, improved grazing management, crop-residue management, and grassed waterways, as well as irrigation and drainage.

The importance of land-use planning and the use of the soil survey to develop land suitable for its intended purpose were introduced in the early 1960s. Concerns related to salt buildup in irrigated crops also emerged at that time.

Recognition of New Environmental Issues

The consolidation and specialization of farms, separation of crop from animal production, and increasing use of agrichemicals to manage production continued into the 1970s. No-till agriculture was introduced in conservation systems and helped to achieve conservation goals without relying on crop rotations or contour cultivation. Agricultural production systems today have further evolved, for example, incorporating genetically modified crops that tolerate herbicides used in reduced tillage. At the same time,

environmental awareness has grown. Soil and water quality are of concern not only for on-farm productivity, but also for human health on the farm, and in both rural and urban communities. The health of the ecosystem itself has been raised as a concern. However, public investment in conservation has not kept pace with these emerging conservation concerns.

The *1970 Yearbook of Agriculture, Contours of Change* noted that total conservation investment had not increased since 1962. A conservation-needs inventory was conducted, and it was found that almost two-thirds of cropland, pastureland, and rangeland needed conservation treatment; water pollution was severe.

In the *1983 Yearbook of Agriculture, Using Our Natural Resources*, erosion was cited as a national problem, despite 50 years of government programs to combat it. Concerns about maintaining farmland in agricultural production were discussed along with economic and environmental issues regarding irrigation and agrichemical use. Fish and wildlife habitat degradation resulting from reduced water levels from irrigation expansion, wetland conversion to cropland, planting fence row to fence row, and removing windbreaks was also raised. The advances of stubble-mulch and no-till management systems (developed in the 1950s) were discussed. Further, the Land Evaluation and Site Assessment system to aid land-use decision-making was introduced to support the 1981 National Farmland Protection Act, designed to slow urbanization of agricultural land.

The *1987 Yearbook of Agriculture, Our American Land* noted that, while technical assistance for conservation had remained stable since 1969, financial assistance declined by 77% between 1969 and 1985. New 'carrot and stick' provisions of the 1985 Farm Bill protected highly erodible land and wetlands through conservation compliance, and a new Conservation Reserve Program (CRP) removed approximately 15 million hectares of highly erodible cropland from production for 10 years.

Defining Sustainable Development

In 1987 The World Commission on Environment and Development (The Brundtland Commission) defined sustainable development as actions taken "... to meet the needs of the present without compromising the ability of future generations to meet their own needs." Agenda 21, The United Nations Programme of Action, developed at the 1992 Rio Earth Summit, declared:

> the destruction and degradation of agricultural and environmental resources is a major issue. Techniques for increasing production and conserving soil and water resources are already available but are not widely or systematically applied. A systematic approach is needed for identifying land uses and production systems that are sustainable in each land and climate zone, including the economic, social and institutional mechanisms necessary for their implementation.

The Agenda set the objective:

> To prepare and implement comprehensive policies and programmes leading to the reclamation of degraded lands and the conservation of areas at risk, as well as improve the general planning, management and utilization of land resources and preserve soil fertility for sustainable agricultural development.

In 1994, the US President's Council on Sustainable Development, Sustainable Agriculture Task Force, set forth the goal of management of agricultural activities to protect soil, air, and water quality, and biodiversity to increase agriculture's long-term productivity and profitability and enhance human health and well-being. The task force recommended that assistance to farmers be linked to voluntary implementation of farm and ranch plans for natural resource conservation in agricultural production. They also recommended implementation of land-use policies to preserve the prime land base for US agriculture.

The 1990 Farm Bill defined sustainable agriculture as:

> an integrated system of plant and animal production practices having a site-specific application that will, over the long term, satisfy human food and fiber needs; enhance environmental quality and the natural resources base upon which the agricultural economy depends; make the most efficient use of nonrenewable resources and on-farm/ranch resources; and integrate, where appropriate, natural biological cycles and controls; sustain the economic viability of farm/ranch operations; and enhance the quality of life for farmers/ranchers and society as a whole.

Policy Aspects

During the early 1990s, the US Department of Agriculture (USDA) also developed policy on sustainable development:

> The USDA is committed to working toward the economic, environmental, and social sustainability of diverse food, fiber, agriculture, forest, and range systems. USDA will balance goals of improved production and profitability, stewardship of the natural resource base and ecological systems, and enhancement of the vitality of rural communities. USDA will integrate these goals into its policies and programs, particularly through collaboration, partnerships and outreach.

In the 1991 yearbook, *Agriculture and the Environment*, Secretary of Agriculture Edward Madigan noted that national expenditure for pollution control increased fourfold from 1972 to 1990. Erosion had been greatly reduced by the CRP, and adjustments in the commodity programs in the 1990 Farm Bill were designed to encourage farmers to plant alternative crops and use crop rotations to reduce soil erosion and the use of agrichemicals. Advances in conservation tillage were reported, and associated environmental concerns such as increased application of agrichemicals were addressed.

A holistic, ecosystem-based concept of sustainable soil and land management was developed in technical and policy arenas throughout the decade. The Soil and Water Conservation Society published a collection of essays, *Soil Management for Sustainability*, in 1993. In it, the editors discussed applying agroecologic principles to farming to contribute positively to the quality of air, water, and soil resources and to meet the economic and social needs of the food and fiber producer. They offered the concept of farming according to the specific productivity and vulnerability of the soil in its immediate and larger landscape position.

In 1993, the National Research Council's Committee on Long-Range Soil and Water Conservation published *Soil and Water Quality, An Agenda for Agriculture*. Threats to soil resources were identified and criteria to guide soil management were recommended. The fate and transport of agricultural chemicals were analyzed to identify changes in farming systems required to improve water quality. Policy and program options to improve long-term conservation of soil and water quality were recommended. The committee identified these objectives for soil and water resource management: conserve and enhance soil quality as a fundamental first step to environmental improvement; increase nutrient, pesticide, and irrigation use efficiencies in farming systems; increase the resistance of farming systems to erosion and runoff; and make greater use of field and landscape buffer zones to capture otherwise uncontrolled off-site flow of agrichemicals.

The USDA released *Food and Agricultural Policy: Taking Stock for the New Century* in 2001. In the section on conservation and the environment, the report pointed out that, although soil erosion had declined by 40% over the previous 15 years, farmland was still losing 1.72 billion metric tons of soil every year. It stated that the array of conservation issues had grown with changes in the structure of agriculture, in farm practices, and in public concerns. Soil was recognized as an emerging challenge to manage as a national strategic asset. More than one-third (52.25 million hectares) of US cropland was reported to be in need of improved soil quality. It recognized that the biological, chemical, and physical processes that drive agricultural productivity cannot be bypassed with inputs. Soil degradation, such as compaction, crusting, salination, and loss of organic matter, needed to be addressed to maintain multiple soil benefits, including reduced runoff and erosion, increased carbon sequestration, and improved productivity and sustainability. The need to increase support for conservation on land in agricultural production was recognized, and innovative, market-based environmental benefits and/or stewardship policy tools were suggested.

The 2002 Farm Bill increased conservation on land in agricultural production and introduced a new program to pay farmers directly for the environmental benefits they produce with their conservation systems. The Farm Bill also directs a large portion of conservation resources to address environmental issues caused by livestock operations.

Sustainable and Organic Agricultural Systems

Sustainable agricultural systems strive to restore and enhance inherent soil qualities and productivity through improved conservation and management practices, while reducing use of commercial inputs. The USDA has supported a Sustainable Agriculture Research and Education Program since 1988. A number of colleges and universities throughout the USA have developed sustainable agriculture programs during this time frame.

Interest in organic agriculture has also grown dramatically. The production of organic food and fiber is largely dependent on building fertile, productive soils without the use of synthetic inputs. The public interest in agricultural production and products free of fertilizers and pesticides, expressed through the marketplace, both for human health and ecosystem health, has caused organic and sustainable production systems to flourish. US retail sales of organic agricultural products have increased by 20–25% each year since 1990 to US $7.8 billion in 2000, with global sales topping US $17.5 billion. US land in organic production grew from approximately one-quarter of a million hectares in 1992 to close to one million hectares in 2001. In 2002 the USDA National Organic Label Standard went into effect. This is expected to expand markets for organic products further.

Inventories and Assessment

Soil Loss

Soil losses recognized in the 1930s included both physical and chemical soil properties: loss of structure, loss of nutrients by crop removal and leaching, and loss of the soil itself through erosion by wind or water. Good conservation practices included primarily maintaining soil organic matter by crop rotations, cover crops, contour cultivation, and use of manure.

The 1937 appraisal of the 712.3 million hectares of agricultural land in the USA reported 114 million (16%) ruined or severely damaged by erosion, and another 314 million (44%) moderately damaged. Of the 168 million hectares of cropland then in production (1935 Census of Agriculture), 81 million were ruined, severely damaged, or had lost at least half of the topsoil, and erosion had begun on another 40.5 million hectares. Due to soil depletion from overgrazing of the 295 million hectares of rangeland in 1935 in the western USA, 239 million hectares (80%) were eroding more or less seriously, further reducing productive capacity.

Wind erosion was reported each year from 1954 to 1957 as damaging more than 6.1 million hectares each year, and destroying another 0.5–2 million hectares of crops. The annual cost of water-borne sediment damage in the mid-1980s was estimated between US $4 and 5 billion. The 1982 USDA National Resources Inventory (NRI) reported that 57.2% of nonfederal rural land needed conservation for erosion, drainage, irrigation management, or vegetative cover.

Changes in USDA conservation programs initiated in the 1985 Farm Bill created new progress in erosion control through the late 1980s into the 1990s. Conservation goals, however, were tied to earlier concepts of rates of tolerable soil loss (T), which emphasized farm-level economics more than ecosystem-wide sustainability. Conservation programs were targeted to the most highly erodible land, and ignored land that was eroding at close to T-values. Despite progress in controlling 'excess erosion,' the 1992 NRI reported that 82 755 000 ha of cropland and 23 661 000 ha of pastureland needed conservation treatment. The 1997 NRI reported that of the total 152 684 000 ha of cropland, 26 204 000 ha were eroding at more than

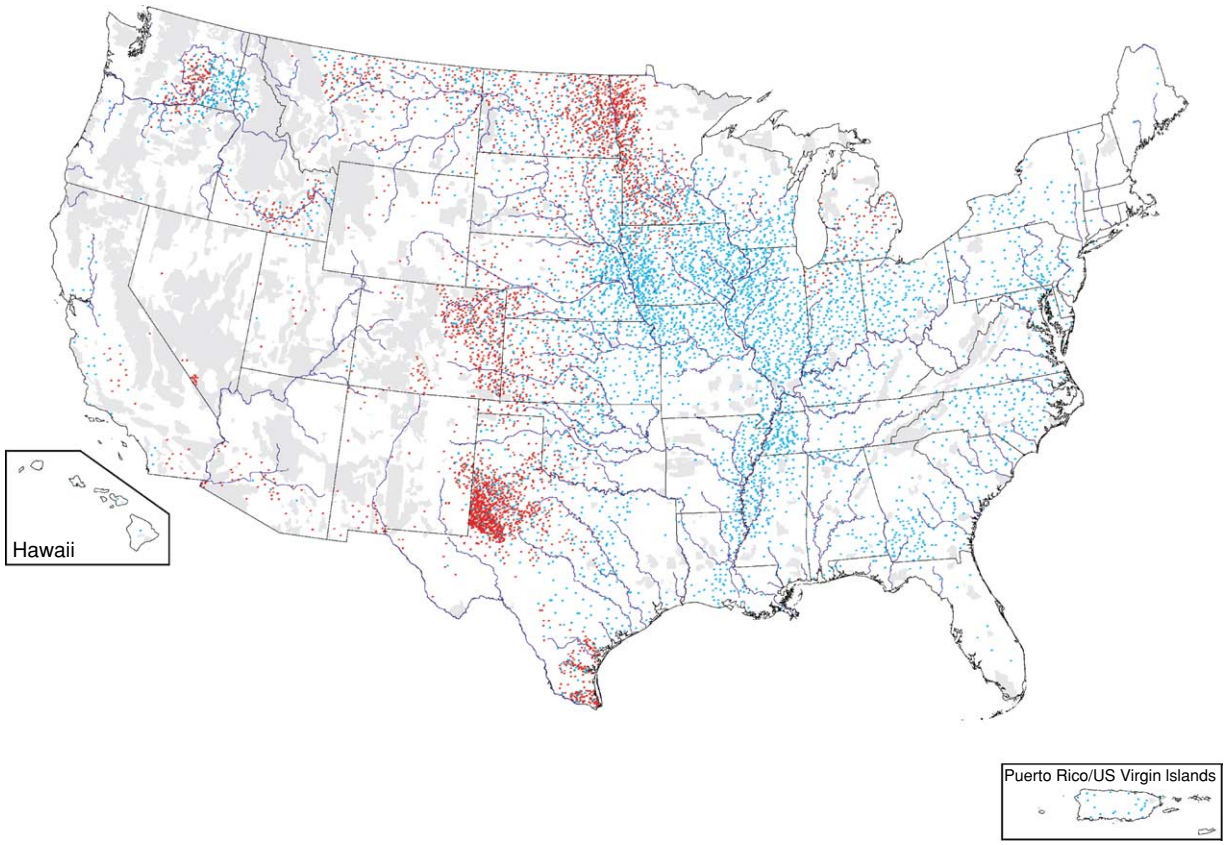

Figure 1 This dot map shows tons of erosion due to wind and water on cropland and Conservation Reserve Program land in the US. Each blue dot represents 970 million metric tons of mean annual erosion due to water. Each red dot represents 760 million metric tons of mean annual erosion due to wind. The combined erosion for the USA is 1.72 billion metric tons per year.

T owing to water erosion, and 19 372 000 ha of cropland were eroding at more than *T* owing to wind erosion (Figure 1).

Water Quality

Water pollution by nutrients or other agrichemicals from agricultural soils was not nationally recognized as a concern until the 1970s. From 1974 to 1981, river and stream water quality monitoring data showed that nitrate concentration increases were widespread nationally. From 1980 to 1989, the data showed that concentrations tended to decrease as often as they increased. These fluctuations are attributable to several farm economy crises during the period that severely curtailed application of purchased inputs. However, the cropland application of commercial nitrogen fertilizers continues to contribute to excess nitrogen in ground and surface waters. One example of the impact is the hypoxia, or 'dead' zone in the Gulf of Mexico, considered symptomatic of excessive nitrogen runoff (Figure 2).

From 1982 to 1992, commercial phosphorus consumption dropped 22% nationally, and river and stream monitoring data from 1982 to 1989 showed widespread declines in total phosphorus concentrations. However, increasing concentration of animal agriculture production systems resulted in increased localized problems associated with animal waste. As livestock production shifted to fewer, larger operations, more manure nutrients were spread on smaller areas. The number of counties without enough land to spread safely the manure generated within their boundaries increased significantly.

The 2002 Report, *State of the Nation's Ecosystems, Measuring the Lands, Water, and Living Resources of the United States*, evaluated chemical, physical, and biological conditions on US farmland. Approximately 20% of groundwater wells and 10% of stream sites on farmlands sampled by the US Geological Survey National Water Quality Assessment Program had nitrate concentrations that exceeded the federal drinking water standard (10 ppm or $10\,\mu g\,ml^{-1}$). About three-quarters of sampled farmland stream sites had phosphorus levels above the maximum concentration (0.1 ppm or $0.1\,\mu g\,ml^{-1}$) recommended to prevent algal growth in streams. More than 80% of the farmland streams had at least one pesticide above aquatic life guidelines and about 4% had one or more compounds that exceeded human health standards or guidelines. Approximately 60% of groundwater wells sampled in farmland areas had at least one detectable pesticide. It was noted that drinking water or aquatic standards or guidelines do not exist for approximately half of the 76 pesticides analyzed. In addition, mixtures of pesticides and intermittent high-concentration events are

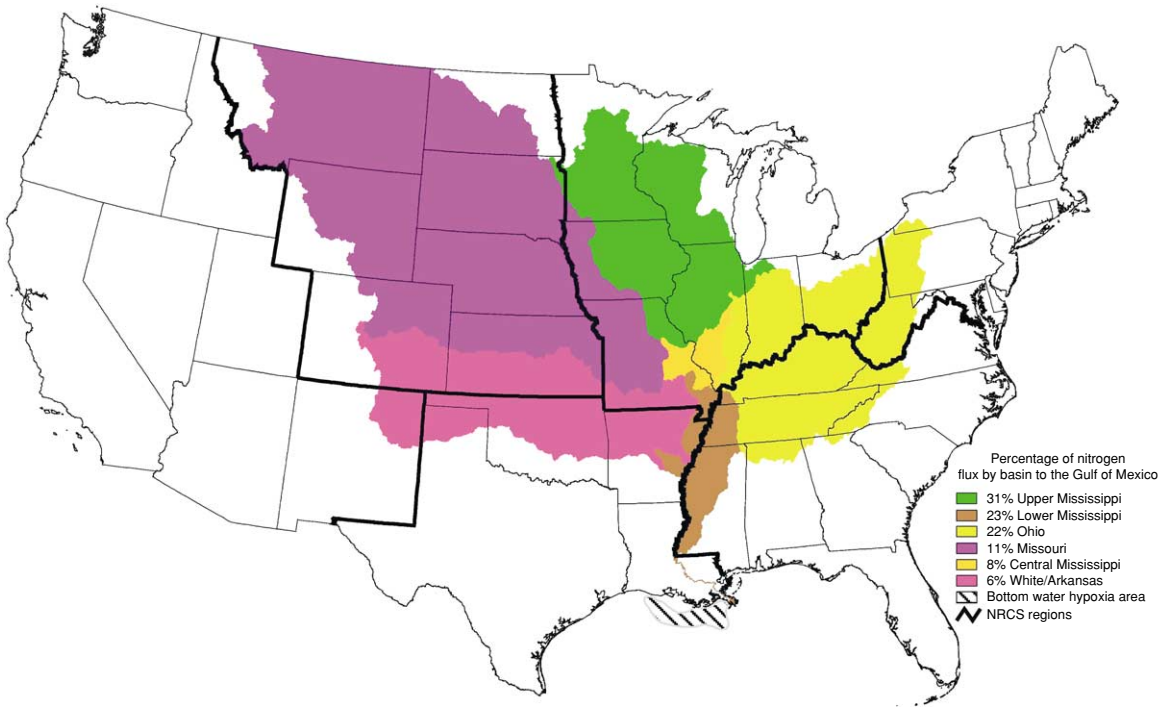

Figure 2 Areas where nitrogen leaves the soil and joins the water system, creating the 'bottom water hypoxia area' in the Gulf of Mexico. NRCS, Natural Resources Conservation Service.

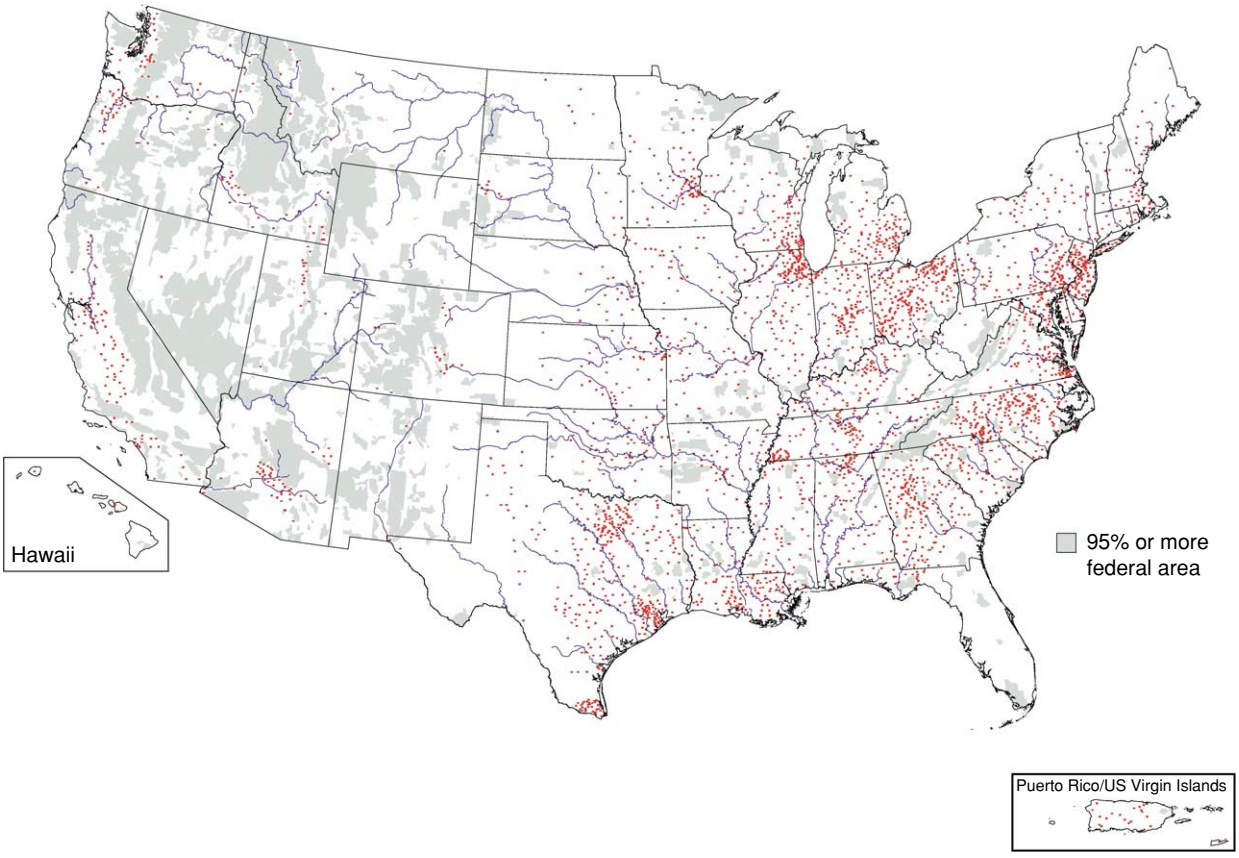

Figure 3 Of the 170 500 000 ha of cropland in 1982, 2 975 500 ha of prime farmland were developed for nonagricultural use between 1982 and 1997. Each red dot represents 810 hectares of newly developed land.

not covered or well understood. The report further identified the need for additional data and indicators to characterize soil organic matter, soil biology, and soil salinity.

Loss of Farmland

The loss of prime farmland to nonagricultural development emerged in the 1980s as a key concern to sustainable soil and land management. In 15 years, 8% of the 93 500 000 ha of prime farmland farmed in 1982 were lost, primarily due to nonagricultural development. This loss caused marginal land with less-favorable characteristics to be brought into production to meet agricultural demand. Production on marginal land requires more inputs and can create more negative offsite environmental impacts. A Federal Farmland Protection Program and state and county programs to preserve agricultural land were implemented and preserved about 0.5 million hectares of farmland by 2002, but the accelerating loss of agricultural land has not been significantly slowed (Figure 3).

Contributing to concerns about the supply of agricultural land is the recognition of the ecologic value of wetlands to sustain water quality, fish, and wildlife. Once considered a conservation practice, the drainage of wetlands is no longer supported or condoned. There is an effort to restore wetlands on agricultural lands, to achieve no net loss of wetlands in the USA. This puts further pressure on remaining croplands to provide the agricultural production demanded by increasing population throughout the world.

At the same time, the rising demand for and profitability of locally produced food, demonstrated by the growth of farmers' markets, 'pick-your-own' farms, and Community Supported Agriculture (contracts between farmers and consumers to supply farm production throughout the growing season for an annual fee), have helped to preserve some farmland, primarily located near urban consumers. These small, direct-market farms often use sustainable or organic production systems.

SWELLING AND SHRINKING

Introduction

After a century of study, hydrologic theory of non-swelling soils is applied routinely to irrigation and drainage, and to other problems of land and water management where quantitative insights and predictions relating to soil water and solute movement are required. By contrast, water movement in soils that change volume with water content is not well understood, and management of swelling soils remains problematic.

Difficulties arise because volume change complicates measurement of material balance, and both the liquid and the solid phases must be considered; volume change also introduces ambiguity, for example, in water profile measurements based on neutron probes when compared with, say, time-domain reflectometry, where the probes may 'float' with the solid phase. Then, swelling or shrinking accompanying soil water content change results in vertical displacement of the wet soil, which involves gravitational work and contributes an overburden component to the total potential of the soil water. In addition, the total flux of the water has a component advected with the moving solid as well as the water potential-driven, darcian flux relative to the solid. Finally, many swelling soils crack and the network of cracks provides

alternative, preferential pathways for rapid flow of water which prejudice application of theory simply based on darcian flow.

Swelling Soils

The Vertisol and the Histosol orders in Soil Taxonomy represent soils that change volume with change in water content. The Vertisols are the more significant, with great areas in India (approx. $7.9 \times 10^5\,km^2$), Australia (approx. $7 \times 10^5\,km^2$), and Sudan (approx. $5 \times 10^5\,km^2$), while China, Ethiopia, and the USA each have approximately $1.5 \times 10^5\,km^2$. They tend to be chemically fertile, but physically they are generally very intractable; very sticky when wet and strong when dry. Characteristically, they have high contents of smectite clay mineral. In Australia in the Murray Darling Basin alone, there are approximately $2.5 \times 10^5\,km^2$ of these soils. They represent approximately 10% of the basin and almost 50% of its irrigated soils, and they support irrigated and dryland crops which are currently worth more than A\$$1.5 \times 10^9$ annually.

The Histosols of concern include at least $10^6\,km^2$ of low-lying clay soils of marine or estuarine origin. These soils, which are mainly of the Hemist suborder, are characterized by permanently high water tables and the possible presence of sulfuric or sulfidic materials. They occupy low-lying positions of the landscape and many have been laid down over the past 10 000 years in the littoral zone of most continents and islands. Their natural water volume fraction may be higher than 0.8 and their bulk density may be as low as $0.2\,t\,m^{-3}$. They occupy areas of high and increasing agricultural and urban importance. Their development often involves consolidation and the sulfidic soils among them generate acid drainage.

The hydrology of these soils is not well understood, and neither is the reaction and 'chromatographic' chemistry associated with transfer of nutrients, or the residence and degradation of agricultural chemicals. The physicochemical consequences of oxidation of sulfides in the Histosols are also unclear.

In addition to soils, there are also particulate industrial and mining slurries that present local environmental problems. The physics of swelling soils has much to offer with respect to dewatering and consolidating these materials to rehabilitate the landscape; it also has much to offer in engineering soils to support built structures.

Volume change accompanying water movement is central to these activities and, in the case of the Histosols, oxidation of organic matter may also contribute significantly to irreversible volume change accompanying development. Present approaches to hydrology of swelling soils, however, are generally based in nonswelling soil theory; they rarely account for volume change and its consequences, and their use may result in significant errors in estimations of local water and solute flux, water balance, and aquifer recharge. The consequences of oxidation of part of the soil matrix, for example, on material balance estimates are rarely considered.

History

Schübler measured soil volume change in the early nineteenth century and Tempany provided a contemporary perspective early in the twentieth century. Tempany introduced the concept of the shrinkage curve and formally related linear and 'cubical' contraction of soil aggregates in relation to water loss. At the same time, anchored rods were used to measure profile swelling and water content change.

One-dimensional flow of water in soils that change volume with water content was first analyzed in a modern context by Terzaghi, who sought to describe soil consolidation following the imposition of loads associated with built structures. He perceived that the soil water initially carries an imposed load in a saturated soil, and that the soil gradually compresses as this load is transferred to the soil matrix when the water redistributes. Terzaghi thus associated consolidation with water flow and his approach anticipated that of Richards for rigid unsaturated soils, in being based on material continuity and the Darcy law. The outcome was a linear diffusion equation that Terzaghi solved using Fourier series. A decade later and independently, Nicholson and Childs applied a diffusion approach to water flow in clay soils in an agricultural context.

Terzaghi's presentation was obscure: papers still appear in civil engineering journals speculating on what he meant; and civil engineers did not appreciate his formulation and use of solid-based, space-like material coordinates. As a result, the theory was recast in physical space specifically identified with small strain behavior and Terzaghi's classic textbook discarded the material insights of the 1923 work. In 1960, however, Terzaghi's solid-based, space-like coordinates were explicitly reintroduced by McNabb to deal with soil consolidation. Raats and Klute and Smiles and Rosenthal independently developed this approach and the latter also experimentally tested it. In addition, Philip analyzed the one-dimensional problem using conventional spatial coordinates. He dealt well with mechanics of swelling, but his formulation was complicated and he subsequently abandoned it in favor of the simpler mathematics associated with the material approach.

Focus on water flow relative to the solid, described by the Darcy law, lay at the core of these analyses. It also emerged that, when the Darcy law was combined with material continuity using solid-based space-like coordinates, a flow equation analogous to the Richards equation resulted so, at least for one-dimensional problems, solutions to the Richards equation became transferable to flow in swelling systems.

Contemporaneously, chemical engineering schools in Japan and the USA working on filtration of very wet particulate suspensions and civil engineers working on soil consolidation identified similar approaches. Focus on flow of water relative to the solid, rather than solid movement relative to the water, also provides a unifying principle that extends the analysis to sedimentation in very wet particulate systems.

Elements of Theory

Water flow in unsaturated nonswelling soils is described by combining the Darcy law with an equation of continuity that accounts for the water in the system during steady and unsteady flow; the Richards equation results. These equations are formulated at the macroscopic scale and they apply to materials where the water potential and the hydraulic conductivity are well-defined functions of the water content.

Two distinct but complementary philosophies emerge to deal with soil profile volume change and the nature of flow in swelling soils. The first approach is mesoscopic and it focuses on behavior of individual soil-structural elements. It envisages water movement through macropores to or from these elements which then swell or shrink three-dimensionally to produce one-dimensional (vertical), macroscopic profile swelling or shrinkage. The approach is concerned with darcian or nondarcian flow in the fractures and three-dimensional volume change of aggregates, which ultimately results in vertical soil profile movement.

The second approach is macroscopic. It recognizes three-dimensional volume change of soil-structural units, but argues that the detail of this behavior is irrelevant and that we need concern ourselves only with the net one-dimensional, vertical volume change and flow that is observed macroscopically. It asserts that if the area of cross section is large enough and if there is no lateral net transfer of material from the control area, then behavior of structural entities beneath it may be described by a representative average vertical displacement. This approach is analogous to the Darcy scale approach to soil water movement in nonswelling soil, which also relates to volume averages and is agnostic about flow detail in individual pores and aggregates. It results in a one-dimensional analysis analogous to that of Richards.

Swelling and shrinking of individual structural elements need to be considered explicitly if the characteristic time of these mesoscopic processes approximates that of the macroscopic processes. In formulating a basic theory, it is presumed that, in general, they do not concur, and focus is on the macroscopic approach. That approach has been extensively tested with saturated materials and, to a lesser extent, with unsaturated soils. It exemplifies the principal issues of equilibrium and flow in a swelling material.

The practical challenges in applying the macroscopic approach are to:

1. Define a scale of discourse that permits meaningful measurements of macroscopic properties of the soil, such as water content and bulk density;
2. Meet Darcy-like requirements that the water potential and the hydraulic conductivity of the soil are well-defined functions of the water content.

To use the Richards equation, the potential and conductivity characteristics are again necessary but, in addition, a 'shrinkage curve' is needed to define the way the volume of soil per unit area of cross section, i.e., the elevation, changes with the soil water content.

Analysis is based on the material balance equations for the solid as well as the water, because both may be in motion relative to an observer, and on the Darcy law, which describes flow of water relative to the particles in response to a space gradient of total head. Both these elements are critical, but material balance must be retained even when the applicability of the Darcy equation is uncertain.

Material Balance in Swelling Systems

One-dimensional flow of water in a swelling system requires material balance equations for both the aqueous and solid phases:

$$\frac{\partial \theta_w}{\partial t} = -\frac{\partial F_w}{\partial z} \qquad [1]$$

$$\frac{\partial \theta_s}{\partial t} = -\frac{\partial F_s}{\partial z} \qquad [2]$$

where z is a distance coordinate, t is the time, F_w and F_s are the volume flux densities of the water and of the solid (cubic meters per square meter per second) relative to the observer, and θ_w and θ_s are the volume fractions of the water and solid. The volume fractions are defined per unit area of horizontal cross section of the soil and the reference volume includes the cracks.

Recognizing that the flux of water, seen by the observer, occurs relative to and with the moving soil solid:

$$F_w = u + \theta_w F_s/\theta_s = u + \vartheta F_s \quad [3]$$

where u is the volume flux of water relative to the particles, and the second term on the right describes transfer of water advected with the moving solid. The ratio of volume fractions, ϑ, is called the moisture ratio:

$$\vartheta = \theta_w/\theta_s = \theta_g \rho_s \quad [4]$$

with θ_g the water mass fraction (kilograms per kilogram) and ρ_s the specific gravity of the soil solid. In saturated soils, ϑ is equal to the void ratio, e.

Eqns [1], [2], and [3] may be manipulated to derive a material balance Eqn [5] for the water based on a solid-based, space-like material coordinate, $m(z, t)$, viz:

$$\frac{\partial \vartheta}{\partial t} = -\frac{\partial u}{\partial m} \quad [5]$$

For one-dimensional flow, the coordinate, $m(z, t)$, is formally defined by:

$$dm(z,t) = \frac{\partial m}{\partial z}dz + \frac{\partial m}{\partial t}dt = \theta_s dz - F_s dt \quad [6]$$

This definition of $m(z, t)$ satisfies the material balance Eqn [2] for the solid and reflects the distribution of the solid in space. Furthermore, $m(z, t)$ is independent of soil displacement that might accompany water content change and can be determined by integrating Eqn [6]. This integration is simplified if it is based on a surface, e.g., $z = 0$, where $F_s = 0$. In the absence of sedimentation or erosion, the soil surface provides such a datum. Then:

$$m = \int_0^z \theta_s dz - \int_0^t F_{s_{z=0}} dt = \int_0^z \theta_s dz = \int_0^z (\rho/\rho_s) dz \quad [7]$$

where m is the cumulative volume of solid, per unit area of cross section, measured from $z = 0$ or the cumulative oven-dried mass per unit area measured away from the soil surface and divided by ρ_s. Thus m is, for example, the cumulative amount of oven-dried solid per unit area measured from the top of a continuous field core sample taken for water content measurement. The final integral in Eqn [7] shows how m is related to the soil specific gravity profile, $\rho(z)$.

Flux Laws in Swelling Systems

The Darcy law describes flow of water relative to the solid in response to a space gradient of the total potential, Φ, of the water in the soil:

$$u = F_w - \vartheta F_s = -k(\theta_w)\frac{\partial \Phi}{\partial z} \quad [8]$$

in which the hydraulic conductivity, $k(\theta_w)$, is a function of the water content but also of the structure. Here it is identified as a function just of θ_w. In nonswelling soils the total potential, Φ, consists of a gravitational component and a capillary component, the latter arising as a result of the interaction of the water with the soil surfaces and their geometry. If Φ and its components are defined as work per unit weight of water, they have dimensions, L, and units meters of H_2O. The hydraulic conductivity, $k(\theta_w)$, then has dimensions LT^{-1} and units meters per second.

Defined this way, Φ is identical to the engineer's hydraulic head. Specifically:

$$\Phi = z + p_w \quad [9]$$

with the gravitational head, z, the elevation of the point of concern in the soil above a convenient datum, and p_w the pressure in the water relative to the pressure of the ambient gas phase measured with a manometer. Eqn [9] applies to both swelling and nonswelling materials. In unsaturated, nonswelling soils, the pressure head, p_w, is negative and reflects only the capillary potential.

Water Potential in a Swelling Soil

The components of Φ in swelling systems have been considered from a thermodynamic perspective and mechanistically. The latter approach argues that Φ represents the work involved in transferring unit weight of water from a reference flat surface of water at atmospheric pressure to a swelling material at some height, z, relative to that reference. Thus Φ is the sum of:

1. The gravitational potential, z, representing elevation of the element of water from the datum to the height z;
2. The unloaded matric or capillary potential, ψ, representing interaction between the water and the soil solid surfaces and their geometry;
3. The overburden potential, Ω, representing vertical displacement of the wet soil accompanying unit change in water content at z.

If the soil is saturated, unit change in water content produces unit change in elevation of the soil and, if the volume of the system is parameterized by the void ratio, e, this implies that $de/d\vartheta = 1$. If the soil is unsaturated, $de/d\vartheta$ tends to be less than 1, unit change in water content does not produce unit height change, and the work involved in elevating the wet profile is

less than it would be in the saturated case. The total potential, Φ, is then defined by the equation:

$$\begin{aligned}\Phi &= z + p_w = z + \psi + \Omega \\ &= z + \psi + \alpha\left(\int_z^T \gamma dz + P\right)\end{aligned} \quad [10]$$

The unloaded capillary potential ψ is the potential a tensiometer would measure at the existing moisture ratio in the absence of overburden. In Eqn [10], γ is the wet specific gravity of the soil, P is any static load on the soil surface, and α reflects the degree to which the soil is elevated by unit change in water content. In a saturated soil, $\alpha = 1$; when the soil is unsaturated $1 \geq \alpha$; and in a nonswelling soil, $\alpha = 0$. In civil engineering contexts, P may be very important, but we neglect it here without any loss of generality. Notice that, in Eqn [10], p_w includes the overburden component and may be positive.

The overburden, Ω, is related to the civil engineers' effective stress according to the equation

$$\Omega = \alpha\sigma = \sigma' + p_w \quad [11]$$

in which σ is the total normal stress and σ' is the effective or interparticle stress. Comparison of Eqns [10] and [11] shows that $\sigma' = -\psi$, and hence is related to ϑ through $\psi(\vartheta)$.

The nature of α has generated some controversy. At one time civil engineering practice equated it with the slope of the shrinkage curve. A more correct but more complicated definition followed some argument in which it was accepted that α must be a value of $de/d\vartheta$ averaged from zero load to that actually experienced at the point in question. The mathematical consequences of this definition are cumbersome, however, and it seems to be agreed that the civil engineering approximation remains the most practicable way forward.

It has been argued that, because the manometric pressure, p_w, is measurable, while ψ, an 'unloaded' capillary potential, is experimentally inaccessible, the water content should be defined as a function of p_w rather than ψ. The world remains indifferent to the issue. Figure 1 compares water content profiles and components of the total potential of the soil water for idealized nonswelling and swelling soils.

Potential Gradient

It suffices that the driving force in the Darcy equation is the space gradient of hydraulic head (or total potential), which is the sum of the manometric pressure (which may be negative relative to atmospheric pressure) plus a gravitational component relative to a convenient height datum. In this approximation, and if $\vartheta(\psi)$ is single-valued, $\partial\Phi/\partial z$ from Eqn [10] becomes:

$$\begin{aligned}\frac{\partial\Phi}{\partial z} &= \frac{\partial}{\partial z}\left(\psi + z + \alpha\int_z^T \gamma dz\right) \\ &= \theta_s\left(\frac{\partial\psi}{\partial m}\right) + (1 - \alpha\gamma) \\ &\quad + \theta_s\left(\frac{d\alpha}{d\vartheta}\right)\left(\int_m^0 \gamma/\theta_s dm\right)\left(\frac{\partial\vartheta}{\partial m}\right)\end{aligned} \quad [12]$$

In Eqn [12], the second equality on the right-hand-side is derived by differentiating the first equality by parts, and using the definition of m, i.e., $dm/dz = \theta_s$ to eliminate z.

Darcy Law and Hydraulic Conductivity

Substitution of the last of Eqns [12] in the Darcy law, in m-space, yields:

$$\begin{aligned}u = -k(\theta_w)\theta_s\Bigg(&\left(\frac{\partial\psi}{\partial m}\right) + \left(\frac{1 - \alpha\gamma}{\theta_s}\right) \\ &+ \left(\frac{d\alpha}{d\vartheta}\right)\left(\int_m^0 \gamma/\theta_s dm\right)\left(\frac{\partial\vartheta}{\partial m}\right)\Bigg)\end{aligned} \quad [13]$$

In Eqn [13], $k(\theta_w)\theta_s = k_m$ is identified as a 'material' hydraulic conductivity. Philip derived this equation 30 years ago, while Sposito derived the same equation from thermodynamic considerations.

The hydraulic conductivity, k_m, has conventionally been treated as a material characteristic parameterized by ϑ. However, it must be a function of both the structure, parameterized by e as well as the water content, ϑ, in a swelling material. No difficulty arises in saturated swelling systems where $e = \vartheta$, but, when $e > \vartheta$, the hydraulic conductivity must be represented by a surface, $k(e, \vartheta)$. This issue has escaped analysis hitherto and the magnitude of the effect needs to be established.

Flow Equation

Substitution of Eqn [13] in Eqn [5] yields an equation analogous to the Richards equation for a nonswelling soil. For saturated clays subject to large, constant imposed loads, gravity can be neglected and $\alpha = 1$. This latter condition characterizes many important practical chemical engineering situations. Numerical methods have been used to solve the full equation together with a nonlinear shrinkage curve to illustrate the solution for flow in unsaturated marine clays.

The principal physical differences, which distinguish equilibrium and flow in saturated swelling systems from those in nonswelling soils, arise from the overburden effect in these systems. Overburden

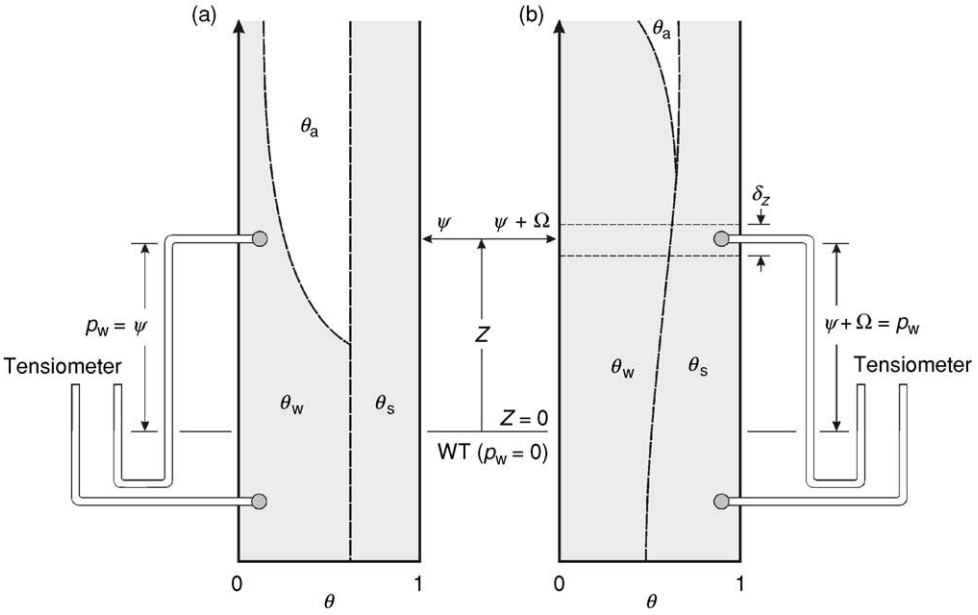

Figure 1 Comparison of the vertical, static equilibrium water content profiles in nonswelling soils (a) and swelling soils (b) in contact with a free water surface at atmospheric pressure. The *z*-coordinate is positive upwards, with its origin at the free water surface, and θ_w, θ_s, θ_a are the volume fractions of the water, solid, and air; they sum to unity. In the swelling soil, θ_s increases with depth toward some maximum density determined by the weight of the wet soil it supports and the water table height. A corresponding decrease is observed in θ_w. Desaturation in a swelling soil above the water table represents cracks and then desaturation of aggregates. The components of total potential, Φ, of the water in the two systems differ. Thus the arrows show the steps in transferring unit amount of water from the free water surface, WT, to the system at elevation *z* above it. Defined per unit weight of water, *z* is then the gravitational potential relative to the free water surface at WT; and p_w the pressure a manometer measures when inserted at height *z*. The manometric pressure is equal to ψ, the 'capillary' potential in the nonswelling soil, but is the sum of an unloaded 'capillary' or moisture potential and the overburden potential, Ω, which arises because of the vertical displacement of the wet profile, δz, that must accompany insertion of the water at height *z*. In the saturated region, unit displacement accompanies insertion of unit amount of water. In the unsaturated region of the swelling soil, the vertical displacement is less than unity. At static equilibrium, the manometer/tensiometer water level must have the same elevation as the water table. Reproduced from Smiles DE (2000) Hydrology of swelling soils: a review. *Australian Journal of Soil Research* 38: 501–521 (corrigendum 40: 1467).

reverses (and diminishes) the effect of gravity in systems where $\rho_s > 1$:

1. Infiltration into these systems resembles capillary rise in nonswelling soils;
2. Steady upward flow of water proceeds more readily in swelling than nonswelling soils;
3. Static equilibrium water-content profiles in the saturated region are drier at the bottom than at the top, in contrast to profiles in nonswelling soils;
4. The period of time for which a 'gravity-free' analysis applies to transient flow may be greatly extended;
5. The shape of the $\psi(\vartheta)$ characteristic together with a relatively weakly varying $k_m(\vartheta)$ often results in a material moisture diffusivity that decreases with increasing water content, so desorption in muds and slurries resembles absorption in nonswelling soil.

Overview

Water flow accompanied by volume change remains one of the most challenging areas of porous material physics. Some areas of application have been well tested, at least in one-dimensional flow, and theory has been usefully applied to a number of unit processes in chemical engineering and to consolidation in civil engineering. Examples of unit processes include filtration under constant pressure and constant rate conditions and effects of filter membranes that significantly resist flow. They also include centrifugation and centrifugal filtration of wet particulate slurries. Some of these analyses are based on well-known solutions of the Richards equation, but some required and tested solutions that had not previously been available in soil science. Constant-rate filtration and filtration through an impeding membrane exemplify the latter class of problem. Most of this work has involved saturated systems.

In soil science, however, one-dimensional theory remains incomplete and its test is uncertain. Curiously, it represents a bridging problem between well-founded and tested analysis of flow in unsaturated nonswelling systems and that in saturated swelling ones. In fact, Eqns [1]–[13] apply equally well to swelling and nonswelling materials, although application of the concepts and terminology of swelling soil theory to nonswelling soils is unusual. Thus, both 'limiting' systems are described well by the Richards equation and both demand that $\psi(\vartheta)$ and $k_{\mathrm{m}}(\vartheta)$ be well defined, although the swelling system requires a shrinkage curve also. The consequences of volume change in unsaturated soils, however, remain the challenge. It is useful to identify some important issues of concern.

Scale of Discourse

Because of the size of the structural units in swelling soils, the scale of discourse that permits application of an approach analogous to the approach of Richards for nonswelling soils, where properties represent measurable spatial averages, is much larger than is generally the case in nonswelling soils. As a result, the scale of measurement of water content and water potential requires careful consideration and it may be that many current methods fail to provide appropriate volume averages at the scales involved. The existence of cracks need not complicate measurement, however, provided the cracks are included in the representative volumes and areas of cross section. Water content defined per unit amount of solid, consistent with a solid-based, space-like coordinate, is a preferred basis for water balance in these soils. This convention ensures that volume change does not prejudice estimates of water content change.

Material Balance and Coordinates

In addition to requirements that material properties be consistent with the scale of the space-like coordinate if integral quantities such as the profile water content are to be interpreted without ambiguity, differences over time will be incorrect if the change in volume of a profile is ignored. Volume change accompanying water content change is irrelevant and material balance is exact, however, if the water content is expressed per unit amount of soil solid (mass or volume) and 'space' is defined as the cumulative amount to soil solid per unit area, measured, for example, from the soil surface. This approach extends to organic soils where the organic matter is being oxidized and to acid sulfate soils where drainage consolidates the profile as well as removing organic matter. The 'irreducible' mineral content of the soil provides a secure reference frame in these circumstances. It also provides an appropriate basis for intrinsic expression of the concentrations of water, organic matter, or sulfide.

Observations of consistent systematic behavior of heavy clay soils over almost 1000 days confirm that α of the soil profile is relatively constant at approximately one-third and is thus consistent with three-dimensional normal volume change of the soil aggregates. The effect is not greatly depth-dependent and permits quite accurate estimate of the soil water balance from surface displacement measures.

Water Flow

Water flow in swelling systems generally occurs in response to a space gradient of the total head. At the same time, preferential flow in macropores of cracked soils may dominate flow in the early stages of heavy rain or flood irrigation when the soil is very dry. Both phenomena and their relative importance have been considered in the mesoscopic analysis of flow, although a general approach has yet to be formulated. In addition, laboratory measurement must recognize and mimic the constraints experienced by swelling field soils, and procedures common in civil engineering may be obligatory in laboratory studies of flow and volume change in these soils. Early theory tended to identify these constraints carefully. Some recent experiments have been less careful and experimental artifacts inconsistent with theory have prejudiced analyses.

Multidimensional Flow

Application and test of theory have been confined largely to one-dimensional flow and volume change, although a long-available, three-dimensional analysis has also been used in some approximate analyses. Cracked systems have also been dealt with by using a single parameter to characterize the transversely isotropic deformation of the solid phase and combining this with one-dimensional, vertical flow of the aqueous phase. Experiments that model the constraints on, and test theory of, multidimensional flow remain elusive, however.

Measurement

Problems of measurement and its interpretation are endemic. For example, there has been concern about tensiometry and its interpretation in swelling systems with anisotropic constraints which have not been resolved. There is great need for laboratory and field measurement, with specific focus on noninvasive measurement of the time course of the spatial distributions of solid, liquid, and gaseous phases in the soil.

In the laboratory, civil engineers in particular systematically use equipment such as triaxial consolidation cells that are designed to characterize volume change with well-defined constraints in engineering soils. Their terminology and theory may not always be familiar to soil scientists but the technology offers much to soil physics. At the same time, many soil physical principles are unfamiliar to engineers, but each subdiscipline can learn from the other to the ultimate benefit of both.

Water Retention and Hydraulic Conductivity Functions in Unsaturated Swelling Soils

Both the water retention and hydraulic conductivity functions in swelling systems still present significant challenges for resolution. In relation to water retention, four parameters, e, ϑ, p_w, and P, of which three are independent, characterize an unsaturated, swelling porous material. The relations $e(P, \vartheta)$ and $p_w(P, \vartheta)$ have been preferred, mainly because of the wealth of experimental data that exists in relation to $e(P, \vartheta)$; this approach results in the notion of an unloaded moisture potential, as shown in Eqn [10]. The nature of the hydraulic conductivity function remains to be resolved. For nonswelling soils, hydraulic conductivity seems to be a nonhysteretic function of the volumetric water content, θ_w, with the fixed volume fraction of the solid, θ_s, as a parameter. Analogy suggests that the hydraulic conductivity, k, for an unsaturated swelling system must be similarly defined in a $k-e-\vartheta$ diagram. Few, if any, data are available to illustrate the nature of this surface. At the same time, there is an extensive data set for saturated montmorillonite in equilibrium with a range of solution salt concentrations. These data confirm that $k_m(\vartheta)$ is not unique in pure clays but reflects colloid structures associated with the cation suite and concentrations with which the clay is in equilibrium. At the same time, these data reveal strong unifying benefits across systems of different solution salt concentrations, when k is related to ψ. These observations await systematic study and explanation.

Summary

Water flow in swelling soils is described within a macroscopic, one-dimensional theory because field volume change, in the large, is vertical. The theory accounts for material balance of both the solid and liquid phases of the system, both of which tend to be in motion. It also recognizes that the total flux of water has a darcian component relative to the solid as well as a component advected with the moving solid. The theory identifies an overburden component of the water potential in addition to those due to gravity and capillarity. Material properties required by the approach require unambiguous measurement at the scale of application. Several issues of theory and measurement remain unresolved and skills currently available in civil and chemical engineering would benefit the science greatly.

List of Technical Nomenclature

α	Load factor
γ	Specific gravity of wet soil
θ_s	Volume fraction of solid
θ_w	Volume fraction of liquid
ϑ	Moisture ratio
ρ	Soil specific gravity
ρ_s	Soil solid specific gravity
σ	Total stress (L)
σ'	Effective stress (L)
Φ	Total water potential (L)
ψ	Capillary potential (L)
Ω	Overburden potential (L)
e	Void ratio
F_s	Volume flux density of solid (LT^{-1})
F_w	Volume flux density of water (LT^{-1})
k	Hydraulic conductivity (LT^{-1})
k_m	Material hydraulic conductivity (LT^{-1})
m	Solid-based space-like coordinate (L)
p_w	Manometric pressure (L)
t	Time (T)
u	Volume flux of water relative to particles (LT^{-1})
z	Vertical distance and gravitational potential (L)

TEMPERATE REGION SOILS

E A Nater, University of Minnesota, St. Paul, MN, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

A multiplicity of definitions for temperate regions exist, with a central concept that these regions have continental climates with significant seasonal differences in temperature. The US Department of Agriculture–Natural Resources Conservation Service (USDA–NRCS) defines temperate regions, and hence temperate region soils, as having mesic, thermic, or hyperthermic temperature regimes; iso regimes (those experiencing less than a 6°C annual difference in soil temperature at 50 cm depth) are normally excluded. Although aridic and xeric moisture regimes are often considered to occur in temperate regions, mainly subhumid (ustic) and humid (udic and perudic) temperate region soils are discussed here.

Temperate regions, and hence temperate region soils, fall mainly in the mid- to lower-latitude regions of the globe. The length and temperature of the growing season are sufficient for growth of annual grain and oilseed crops. In humid and subhumid temperate regions, precipitation is sufficient for growth of crops without irrigation, though there may be a dry season toward the end of the growing season in the drier parts of this region, thus necessitating early-maturing crops such as winter wheat. The majority of lands cultivated by intensive, mechanized agricultural practices occur in temperate regions.

Temperate regions are bounded by boreal regions, where soil temperatures are lower and the growing season is shorter, and by tropical regions, where temperatures are warmer and frosts rarely, if ever, occur. Humid and subhumid temperate regions are bounded by arid regions, where moisture is insufficient to support the growth of most crops without irrigation, and Mediterranean regions, where the majority of precipitation occurs during the cool season and the growing season is generally very dry. Overall, temperate regions constitute almost 40% of the Earth's ice-free terrestrial surface (Table 1).

State Factors

Climate

Climate is the initial bounding parameter for any discussion of temperate regions. Temperate regions encompass gradients in both moisture and temperature, but also in atmospheric moisture deficit, which has profound effects on evapotranspiration and consequently on soil moisture status and soil properties. In addition, the relative timing between annual temperature cycles, wet and dry cycles, and atmospheric moisture deficit are also important determinants for the plant communities that thrive in these landscapes. Climate strongly influences the development of soil properties, both directly through its effect on soil moisture status and indirectly through its effect on organisms.

Other factors being equal, soils in wetter parts of the region tend to have deeper sola and experience stronger leaching, lower base saturation, losses of

soluble salts, gypsum, and carbonates, and higher rates of mineral weathering. Soils in drier parts of the region, particularly those with high seasonal atmospheric moisture deficits, tend to have shallower sola, less leaching, and consequently higher base saturation, and are more likely to have accumulations of secondary carbonates and gypsum. Salts more soluble than gypsum tend to accumulate only in hydrologic discharge areas in these regions, though their accumulation is more common in aridic moisture regimes. Drier soils also tend to have lower rates of mineral weathering.

Likewise, soils in warmer parts of the region tend to be more weathered, have lower base saturation, and typically have less organic matter accumulation in the A horizon due to increased rates of organic matter decomposition. Increases in soil temperature enhance the rate of many chemical and biochemical pedogenic processes, particularly soil mineral weathering. Typically, a 10°C increase in temperature will produce a two- or three-fold increase in the rate of many biochemical reactions.

Soils in cooler parts of the region tend to have less mineral weathering, higher base saturation, and higher organic matter contents in the A horizon. These trends are reinforced by the occurrence of large areas of younger parent materials in the cooler parts of the region due to direct or indirect effects of continental glaciation, and also by the fact that the soil surface may be frozen for a significant portion of the year in colder climates, thus reducing the duration of action of many biologically and hydrologically driven pedogenic processes.

The balance between precipitation (or, more correctly, infiltration) and evapotranspiration controls the balance between leaching and chemical precipitation, and thus accumulation of carbonates, gypsum, and more soluble salts. Where precipitation exceeds evapotranspiration, leaching of relatively soluble materials occurs as water in excess of field capacity can move out of the system in response to gravity. Over time, leaching will remove all soluble salts, carbonates, and gypsum from soils, even those formed on carbonate bedrock.

Where precipitation is less than evapotranspiration, soil moisture status is less likely to exceed field capacity, and less water is available to be transported out of the solum. Consequently, carbonates, gypsum, and soluble salts will be moved downward in the profile with the wetting front, but may not be leached entirely out of the solum. Over time, horizons of carbonate, gypsum, or even soluble salts may form under horizons that have lost most, if not all, of the carbonates, gypsum, or soluble salts by leaching. Because of their high solubility, and hence mobility, salts more soluble than gypsum are easily removed from soils.

This simple analysis should be taken only as a rough guide; episodic precipitation events, snow melt, noncoincidence of precipitation and high evapotranspirative demand, and even bypass flow may all produce significant leaching even when annual total precipitation is much less than evapotranspiration.

Parent Materials

Because of their large areal extent, temperate region soils encompass a broad array of parent materials, ranging from residuum to glacially derived sediments to loess, alluvium, and colluvium. Although this broad array exists, a few generalities can be observed.

In the colder parts of temperate regions, particularly in the northern hemisphere, a significant proportion of parent materials were derived either directly or indirectly from processes associated with late Quaternary glaciation. Many of these soil landscapes formed on glacial drift, glaciofluvial, or glaciolacustrine sediments. Extraglacial areas near glacial margins were strongly affected by periglacial processes and may have experienced extensive wind erosion or fluvial reworking. Still other landscapes, often far removed from the glacial margins, were blanketed by thin-to-thick loess deposition derived mainly from riverine sediment sources associated with the wastage of continental ice sheets. Landscapes formed on recent glacial sediments have deranged (disconnected) drainage networks with numerous closed depressions and poor internal drainage.

In warmer parts of the region, soil landscapes not affected by recent glaciation or loess deposition form mainly on residuum, alluvium, or colluvium. Properties of these parent materials are closely related to local bedrock sources and thus may vary widely from one region to another. Soil landscapes in warmer temperate regions may show considerably more development and weathering due to the more stable nature of the surfaces, the longer duration of their exposure to pedogenic processes that alter them, and warmer soil temperatures. These landscapes generally have evolved highly dissected, well-connected, dendritic surficial drainage networks with few closed depressions.

The majority of andic parent materials are associated with continental margins, and particularly the Pacific rim. Restriction of this discussion to humid and subhumid temperate regions eliminates xeric, Mediterranean climates strongly affected by oceanic thermal masses, and thus effectively excludes nearly all of the soils dominated by andic parent material. The remaining parent materials, then, were derived from crystalline rocks.

Organisms

The majority of landscapes in humid and subhumid temperate regions are dominated by one of two ecosystem types: prairie or steppe, and deciduous or mixed deciduous–coniferous forest.

Low-relief landscapes, particularly in the drier parts of the region, are dominated by prairies or steppes, which range from shortgrass prairies, with a significant annual grass component in drier temperate regions, to tallgrass prairies, dominated by perennial bunch grasses in wetter temperate regions. Prairies can withstand and more readily regenerate from frequent fires than most forests can. Fires started in low-relief landscapes are often windswept and can cover very large areas, whereas higher-relief landscapes tend to slow or stop the spread of fires.

Deciduous or mixed deciduous–coniferous forests are also common in humid and subhumid temperate regions, particularly in areas of higher relief. They transition to coniferous or broadleaf evergreen forests in the warmer parts of the region, and to coniferous forests near the boreal region border.

Other ecosystem types such as spruce bog or fen, and savanna, are interspersed within temperate regions, but the prairie and forest general types predominate. Bounding this region are chaparral or desert scrub ecosystems in more arid regions; savanna, chaparral, or annual grasslands in Mediterranean regions; coniferous forests in boreal regions; and broadleaf evergreen forests or savannas in the tropics. These ecosystem types strongly affect soil properties.

The formation of thick, dark, organic-rich A horizons (mollic epipedons) is common under grassland- or savanna-type vegetation. Grasses have a deep, fibrous root distribution and a rapid root turnover rate (approximately one-third of grass roots die and are replaced annually) which, in combination, produce significant inputs of organic matter at depth, requiring no translocation to move the organic matter deep into the solum. In addition, the efficient base-cycling present in grassland ecosystems leads to high base saturation, a requirement for mollic horizon classification. Soils with mollic epipedons typically do not have identifiable E horizons owing to the lack of strong leaching in subsurface horizons and to the depth of the A horizon which masks them if present. Notable exceptions occur in Albolls, where distinct albic E horizons are present, often bisecting the mollic epipedon into a surficial and a subsurface portion.

Deciduous and mixed deciduous–coniferous forests typically have roots that are distributed much closer to the soil surface and have a much lower root-turnover rate. The majority of organic inputs in forests are from leaf litterfall, which occurs at the soil surface. Incorporation of leaf litter into the soil requires the activity of worms or other invertebrates. Where leaf materials are not incorporated, the soil typically develops a thin-to-thick layer of partially decomposed organic materials at the soil surface, termed the forest floor or the litter layer. This O horizon can be several centimeters thick and usually rests on an underlying E horizon formed by eluviation of clays and chelation, and subsequent leaching of iron and other coatings from the surface of silt and clay grains in the matrix. It may also rest on a thin A horizon. If earthworms or other invertebrates incorporate the forest floor into the underlying mineral soil horizons, then a relatively thin, light-colored A horizon (ochric epipedon) is typically observed. Introduction of nonnative earthworm species into forested landscapes in the northern USA has all but eliminated the thick O horizons once commonly observed in many forests.

Likewise, B horizon development is also strongly related to the organism factor. B horizon development is often minimal in prairie soils. Many have no B horizon at all (A/C morphology) or else have cambic B horizons that display a moderate degree of development. Older, more well-developed prairie soils may have argillic or natric horizons, but they are not nearly as common under prairie as they are under forests. Several factors tend to inhibit clay dispersal and movement in prairie soils, including the presence of organic coatings in the A horizon that tend to bind clays together; higher exchangeable Ca contents and higher pH generally present in grasslands, which promote flocculation; and the lack of stemflow common to deciduous forests, which tends to concentrate a high proportion of the precipitation falling on a tree directly under its bole, thus producing a localized effect similar to greatly increased precipitation.

Soils formed under deciduous or mixed deciduous–coniferous forest typically display prominent B horizon development. Argillic horizons are commonly observed under forest, with kandic horizons present in the more highly weathered soils or in those that formed on acidic parent materials; spodic horizons occur in coarse-textured soils dominated by coniferous or other vegetation that contributes large amounts of soluble fulvic acids to the soil surface.

Soils under coniferous forests may have spodic B horizons, resulting from podzolization processes. Coniferous leaf litter is more acidic than that of most deciduous forests and releases large quantities of fulvic acids, which are soluble in acidic environments. These organic compounds can chelate Fe, Mn, and Al from metal (hydr)oxide coatings on the soil

grains. In relatively coarse-textured soils, the fulvic acid–metal chelates are transported with the soil solution as long as they remain soluble, producing a distinct E horizon where metal (hydr)oxides have been removed. The chelated metals are deposited and accumulate lower in the profile due to changes in pH or other factors, producing distinctive red or black horizons of accumulation of Fe, Mn, and Al chelates.

Topography

Soil properties and soil-landscape relations are strongly affected by topography, in large part because topography exerts significant control on soil moisture relations and on erosional and depositional processes. There is a clear interaction between rates of infiltration and precipitation that strongly influences these relationships. Where the infiltration rate is lower than the rate of precipitation, runoff will occur. Runoff will be minimal on relatively flat summit positions due to their low slope, thus maximizing time for infiltration to occur. Runoff increases on shoulder and backslope positions, where slopes are higher, thus decreasing infiltration. These landscape positions are also the most susceptible to erosion by water due to the higher runoff and steeper slopes. Water and materials transported from the upper landscape positions accumulate on footslope and toeslope landscape positions. These are often the wettest landscape positions and are sites for deposition of eroded sediments. In more arid regions, they may also be sites for accumulation of soluble salts leached from higher landscape positions.

Soils in summit positions often show relatively more development than soils in other landscape positions due to increased infiltration and limited erosion in the summit position. These soils typically have deeper sola and are more leached than other soils in other landscape positions.

Infiltration into soils on shoulder and backslope landscape positions is proportionally lower than on summits due to increased runoff. Soils in these landscape positions are generally less developed than others in the same landscape, owing in part to their lower effective moisture status and to erosion. Erosion in these landscape positions is high because of the steeper slopes and the volume of runoff that occurs on them. These soils usually have limited B horizon development, thinner A horizons, and shallower sola than soils at the summit.

Soils in footslope and toeslope positions accumulate water and materials that were transported from above. In drier climates, these soils may show the greatest degree of development because they receive the most water. In wetter climates, footslope and especially toeslope landscape positions may be seasonally or permanently saturated. They may also be sites for accumulation of eroded sediments or soluble salts. Often the sola are very thick owing to addition of eroded materials.

If the rate of infiltration exceeds that of precipitation, runoff will not occur. If soil moisture exceeds field capacity, it will move in response to gravity. Depending on the presence or absence of subsurface strata or horizons that restrict the flow of water, water will either move downward to groundwater or may move laterally through the soil or underlying sediments by throughflow or lateral flow. Far more detailed hydrologic analyses are available now using digital terrain modeling and flownet analyses.

Landscape drainage patterns can significantly affect soil landscapes and the catenary relationships between soils. They have less effect on soils in upper landscape positions, more in lower landscape positions.

Relatively young landscapes typically have poorly dissected, deranged drainage patterns, where surficial connectivity is limited, drainage is mostly internal, and numerous closed depressions exist that collect water during the wet season and form seasonal-to-permanent depressional wetlands with hydric soils and wetland vegetation. This is particularly true in glacial landscapes, where the hummocky terrain commonly associated with glacial drift produces numerous closed depressions. The hydrology of landscapes with deranged drainage patterns is often quite complex. Soil properties are strongly affected not only by landscape position, but also by position with respect to recharge or discharge hydrology. Soils in footslope and toeslope positions are generally saturated for significant periods during the year and experience alternating reducing and oxidizing environments. The soils commonly have high organic matter contents and display a variety of redoximorphic features. Wetland rims may be water discharge sites and can sometimes contain significant salt, gypsum, or carbonate accumulations.

As landscapes evolve and mature, their surficial drainage patterns become more highly dissected, intersecting and draining closed depressions. They develop dendritic drainage patterns that have higher-order streams, increasingly more surficial connectivity, and fewer closed depressions. Lakes, ponds, and depressional wetlands are less common. The landscapes have more surficial and less internal drainage.

Significant differences between deranged and dendritic landscapes occur in the footslope and toeslope positions. In deranged landscapes, toeslopes are typically seasonal or permanent wetlands, with high concentrations of poorly decomposed organic materials, at least seasonal anaerobic conditions, and accumulation of erosional materials. Footslope

morphologies may be quite different depending on the hydrologic flow associated with them.

Recharge hydrology (soil water moves vertically to the groundwater) in wetlands is associated with leaching of soluble materials and removal of colloids from horizons or soils. Argillic horizon formation is a common result of recharge hydrology. Discharge hydrology (water moves from the groundwater table to or near the soil surface) is associated with chemical precipitation and is best observed in semiarid regions where wetland rims may display high salt concentrations resulting from capillary rise from saline groundwaters. Seasonal flow reversals are also common.

In dendritic landscapes, footslope and toeslope landscape positions often terminate in or near seasonal-to-perennial streams or alluvial floodplains that seasonally accumulate sediments. These landscape positions may also experience seasonal or permanent saturation, but it is less common than in deranged drainage systems.

Soils subjected to seasonal-to-permanent flooding or saturation can develop strongly anaerobic conditions because the rate of oxygen diffusion in the aqueous phase in soils is much lower than it is in the gas phase. If oxygen demand in the soil, generated mainly by root and microbial respiration, exceeds the rate of oxygen diffusion into the soil, reducing conditions can develop. Reduction requires both saturation of the soil and sufficient microbial activity to deplete oxygen from the soil so that alternate electron acceptors such as Fe^{3+} become favored. Saturation for insufficient duration or when microbial respiration is very slow (low soil temperatures or lack of suitable microbial substrate) will not produce sufficient oxygen demand in soils to consume free oxygen and thus will not produce reducing conditions or redoximorphic features.

Reducing conditions can lead to the dissolution of Fe and Mn (hydr)oxides, transport of reduced Fe^{2+} and Mn^{2+} with soil solution, and reprecipitation of Fe and Mn (hydr)oxides in other locations in the soil where pH and redox conditions favor precipition. Both Fe^{3+} and Mn^{4+} (hydr)oxides are very insoluble; the reduced forms (Fe^{2+}, Mn^{2+}), however, are very soluble in the aqueous phase and thus can be transported with the soil water and either removed entirely from a location in the soil, thus producing redox depletions, or moved to a different zone or region in the soil, where they are reoxidized to form redox concentrations. Because even small amounts of Fe and Mn coatings can mask the color of the underlying soil matrix, their removal provides a clear visual indicator of redoximorphic processes.

Saturated soils typically have higher organic matter contents than soils in more aerobic environments due to lower rates of organic-matter decomposition under anaerobic conditions. Histic epipedons may develop over mineral soil surfaces under these conditions. If the duration of saturation extends throughout most of the year, Histosols (organic soils) may develop.

Age

Soil age refers to the time since exposure of a surface and, as such, is a measure of the length of time a soil or soil landscape has been affected by pedogenic processes. Soil surfaces in whole regions may be exposed by processes such as continental glaciation or loess deposition, or over much smaller areas as a result of smaller-scale processes such as hillslope erosion or deposition.

Initially, soil properties strongly reflect the properties of the parent materials on which they form. Over time, they are altered by pedogenic processes and, given sufficient time, may little resemble their initial condition. Formation of horizons takes periods ranging from a few hundred years (formation of A horizons) to millennia (argillic, spodic, calcic horizons), to hundreds of thousands or even millions of years (oxic horizons).

Mineral fractions in young soils are derived from the parent materials and are largely unaltered. As soils age, mineral weathering occurs and secondary minerals begin to form. Over time the mineral fraction may be significantly altered from its initial state and be more closely related to weathering products controlled by thermodynamic stability fields. Over sufficiently long periods of time, soils with relatively different parent materials may end up with relatively similar mineralogies and compositions. Kaolin group minerals, which form by intense weathering of primary silicate minerals, often dominate the clay mineral fraction in highly weathered soils. In high-intensity, highly leached, base-poor environments, less thermodynamically stable clays such as illites and smectites are removed by chemical weathering and disappear entirely from older landscapes unless protected by microenvironments that are more suitable for their stability.

Effects of Humans

Humans also affect soils and their properties, particularly through agricultural and construction activities, but also through more subtle means. Temperate region soils have undergone extensive change due to the high density of intensive, mechanized agriculture. Agricultural tillage has caused accelerated erosion on many landscapes by leaving soil surfaces poorly protected against raindrop impact. Tillage and agricultural drainage of wetlands or seasonally wet soils have increased aeration of the solum and enhanced the rate of organic matter oxidation, releasing vast

quantities of CO_2 to the atmosphere. Many agricultural soils in temperate regions have lost more than 50% of their precultivation organic matter contents, with resultant losses in tilth and native fertility. Soil acidification is another widespread effect, resulting both from atmospheric deposition of nitric and sulfuric acid related to fossil fuel burning, but also from the application of nitrogen fertilizers.

Classification

Table 1 provides a generalized view of the areal extent of soils by US taxonomic order. The definition of 'temperate region' used in Table 1 is broadly defined to include both aridic and xeric moisture environments.

The dominant soil orders in temperate regions, as broadly defined, are Entisols and Aridisols, which comprise 27.7% and 22.3% of the total area, respectively. Other common orders include Inceptisols (10.4%), Alfisols (9.4%), Mollisols (8.7%), and Ultisols (6.6%). Nonsoil surfaces (shifting sands and rock) make up almost 10% of the total area of temperate regions. The remaining orders in toto constitute approximately 6% of the region.

Similar data portraying the areal extent of soil orders only in humid and subhumid temperate regions are not readily available. Because of the uncertainties in distribution of many of these orders between humid and subhumid and aridic and xeric moisture regimes, it is difficult to provide accurate relative distributions of these orders. However, some trends in soil distribution in these regions can be estimated from knowledge of soil distributions in aridic and xeric moisture regimes. Excluding soils from aridic moisture regimes would eliminate all Aridisols and nearly all of the shifting sands, along with large areas of Entisols. All of these soils and/or terrestrial surfaces are common in aridic moisture regimes. Mollisols, Vertisols, and Oxisols are also present in aridic moisture regimes, but constitute a smaller proportion of the total areas. Alfisols and Inceptisols are, by definition, excluded. It is more difficult to make generalizations about the areal extent of soil orders in xeric moisture regimes as compared to humid and subhumid temperate regimes, as all of the orders common to one region are also present in the other, though in varying proportions. The only clear distinction is that the majority of Andisols are located along coastal margins, particularly around the Pacific Rim; excluding xeric moisture regimes from the discussion would effectively exclude nearly all Andisols also.

For the most part, humid and subhumid temperate regions are dominated by Inceptisols, Entisols, Alfisols, Mollisols, and Ultisols. Other orders are present but generally constitute a smaller relative portion of humid and subhumid temperate regions.

Some general trends for the distribution of soil orders in humid and subhumid temperate regions follow. Alfisols and Ultisols are mainly associated with forested landscapes and Mollisols with prairies. Ultisols occur in warmer, wetter, and more stable landscapes of the region where soils have weathered more and base saturations are consequently lower. Alfisols are more common under forests in cooler, drier climates and younger landscapes where weathering, leaching, and removal of bases is not as extensive. Spodosols occur near the boundaries with boreal and tropical regions, where they are much more common.

Entisols and Inceptisols are interspersed throughout the region on erosional or depositional landscape positions, particularly shoulder and backslopes, where soil development is limited or new parent materials have been exposed or deposited. They are also common in wetter portions of the landscape where soil development processes are slow. Histosols occur in closed depressions and other very poorly drained landscape positions, particularly in glaciated regions, where closed depressions abound. Vertisols develop in clayey soils with high shrink–swell clays and seasonally wet and dry periods. They are common in alluvial and lacustrine settings, or form on decomposing shales, and are more common in the drier portions of the region.

List of Technical Nomenclature

Deranged drainage	Drainage patterns characterized by a lack of surficial connectivity and the presence of numerous closed depressions. Typically associated with relatively young landscapes
(Hydr)oxides	A term used to describe, in aggregate, oxides, hydroxides, and oxyhydroxides of metals, particularly iron and manganese, in soils. Used particularly when one is referring to materials which may fall in any of those three classes

All taxonomic terms and soil diagnostic horizon terms are from USDA–NRCS *Soil Taxonomy*.

Introduction

The practical application of equilibrium and non-equilibrium concepts to the hydrostatics and hydrodynamics of soil water in laboratory and field environments depends on the ability to measure relevant potentials. In unsaturated soils, the matric and gravitational potentials are usually regarded as the hydraulically important energy components. A tensiometer is a device used to measure the matric potential, ψ_m, the component of the soil water chemical potential that is directly dependent on water content. When the local soil gas-phase pressure differs from that of the reference pressure (usually taken as the local atmospheric pressure), the tensiometer reading also includes this difference as an additional air pressure potential. Thus, the tensiometer most generally equilibrates to the sum of the matric and air pressure (pneumatic) potentials, also referred to as the tensiometer potential. In addition, tensiometers can be sensitive to shrinking and swelling of soils. For simplicity, this discussion will be restricted to conditions where the soil gas phase is in equilibrium with the atmosphere, and soil volume changes are negligible, such that the tensiometer equilibrates simply with the soil matric potential.

The basic components of a tensiometer consist of a porous tip or cup, an internal cavity, and a device to measure pressure within the cavity (Figure 1). The water-saturated porous boundary (the tensiometer tip or cup) is placed in contact with soil. This permits exchange of soil water between the region of interest and the tensiometer cavity until equilibrium is reached. Thus, the measurement of matric (or capillary) potential is generally achieved through determining the pressure of a fluid phase within the tensiometer, after equilibrium with the surrounding soil has been established. If the water table rises up to or above the tip, the tensiometer provides a measurement of the local pressure potential rather than the matric potential. Because most tensiometers rely on measuring the pressure of liquid water inside the tensiometer body, the lowest attainable equilibrium reading is imposed by the vapor pressure of water. Although this suggests that the lower operational limit ranges from -100 to -95 kPa for temperatures ranging from 5 to 35°C, a practical lower limit of approximately -85 kPa is commonly encountered because of exsolution of gases (air). The lower operating limit should be taken into account in selecting the porous tensiometer tip. Hydrophilic ceramics are most commonly used, but water-wettable porous glass, stainless steel, plastic, cloth, and even paper are used for tensiometer tips in various applications. The air-entry value of the porous tip is the gauge pressure at which the air phase displaces water-filled pores. Thus, when the matric potential decreases

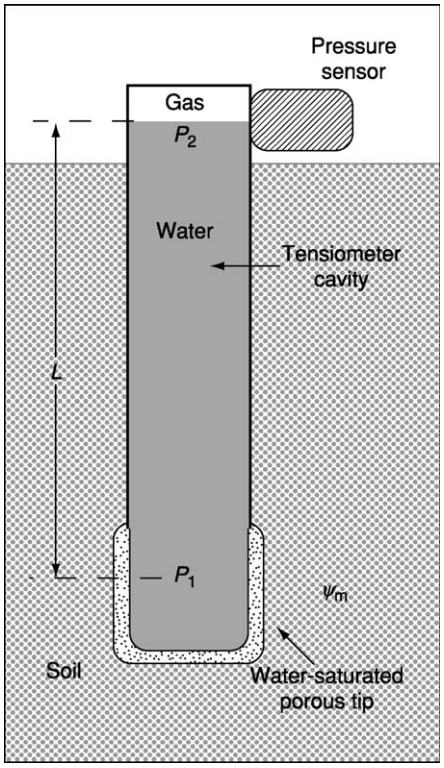

Figure 1 Basic components of a tensiometer. When significant, the hydrostatic pressure difference acting over the vertical distance L between the measurement point and the tensiometer tip must be accounted for. P_1, gauge pressure at elevation of interest.

(becomes more negative) such that its magnitude is larger than the air-entry value, air leaks in through the tip, causing the tensiometer to fail. Ceramics with air-entry values of approximately −100 kPa are typically used for tensiometer tips in field applications. More permeable ceramics with lower-magnitude air-entry suctions (e.g., −50 to −5 kPa) are used in some laboratory applications.

The original tensiometers, developed in the early twentieth century, consisted of a water-filled porous interface connected to a manometer. Since introduction of these early instruments, a wide variety of tensiometer designs have been developed. In field applications, tensiometers are used for irrigation scheduling, characterization of flow in soil profiles and deeper unsaturated sediments, and monitoring of contaminated soils. In the laboratory, tensiometers are used in soil physics, agricultural, and vadose-zone hydrologic research.

Equilibrium

By measuring the pressure of a fluid phase within a tensiometer, a measurement of the soil matric potential is obtained. The reliability of this measurement depends on establishing local equilibrium between the tensiometer and the soil, and on the condition that the matric potential is within the instrument's operational range, criteria that are discussed later. Equilibrium between the soil water and tensiometer can be viewed mechanically as a balance between capillary and adsorptive forces retaining water in the soil, and the hydrostatic pressure (suction) of water within the tensiometer. More generally, net exchange of soil water between the tensiometer (system) and soil (reservoir) occurs until differences in soil water chemical potential vanish. At this state, the gauge pressure in the tensiometer at the elevation of interest (denoted P_1 in Figure 1) is equal to ψ_m. When the pressure is recorded at an elevation different from that of the tensiometer tip, a hydrostatic correction is applied. In the example shown in Figure 1, $\psi_m = P_2 + \rho_w g L$, where ρ_w is the density of water, and g is the acceleration due to gravity. The time necessary to attain such equilibrium is generally determined by hydraulic properties of the soil, the soil–tensiometer contact, and response characteristics of the tensiometer.

Response Time

The time required to attain soil–tensiometer equilibrium depends on two basic factors: the rate of soil water transfer, and the change in tensiometer pressure per unit mass of soil water exchanged. These two factors can be parameterized in terms of the tensiometer–soil conductance and tensiometer gauge sensitivity. The overall conductance is determined by the (saturation-dependent) soil hydraulic conductivity, hydraulic contact between the soil and tensiometer tip, and the conductance of the tensiometer tip. Here, only the strictly tensiometer-dependent factors of tip conductance and gauge sensitivity will be addressed. In order to obtain a tensiometer reading rapidly that accurately reflects the local soil matric potential, it is desirable to maximize both the tip conductance and the gauge sensitivity. As shown below, the product of these two parameters is equal to the inverse of the instrument's response time.

The tensiometer conductance, K, is a measure of the volumetric rate that water can flow at through a tensiometer tip per unit hydraulic potential difference. When the potential difference (outside minus inside of the tensiometer) is expressed in terms of hydraulic head, K has dimensions of (L^2T^{-1}). The preferred maximization of K in order to shorten tensiometer response times can be achieved through increasing the permeability and bulk area of the porous tip, and decreasing the thickness of the tip. Each of these strategies is subject to constraints. Increasing the permeability of the tip material is achieved by

increasing its characteristic pore-size (since permeability scales to the square of pore diameter), and narrowing its pore-size distribution. However, the extent to which the characteristic pore-size can be increased is severely limited by the fact that the air-entry pressure is inversely proportional to pore-size. Thus more permeable tensiometer tips will not permit measurements of lower (more negative) matric potentials. The bulk surface area of the ceramic can be increased in order to provide more area through which soil water is exchanged. This option is limited when spatially resolved measurements of potential distributions are needed, and when constraints are associated with installation (labor and/or disturbance of soil profiles). The final option available for increasing the tensiometer-tip conductance involves decreasing the thickness of the porous ceramic or membrane. Compromised mechanical integrity imposes the primary limit on this option. In addition, thinner membranes may require more structural support to minimize flexing in response to pressure changes. This latter effect compromises the tensiometer's sensitivity.

The change in a tensiometer's pressure reading per unit volume (V_w) exchange of soil water defines its gauge sensitivity, S. When the pressure reading is expressed in head ($h(L)$) units, S has dimensions of (L^{-2}). Different types of pressure indicator have vastly different gauge sensitivities. Assuming the tensiometer cavity is rigid and completely water-filled, a pressure transducer can provide $S > 10^9\,m^{-2}$. In contrast, a simple water manometer (practical only for low-magnitude ψ_m measurements) has $S = dh/dV_w = A^{-1}$, where A is the cross-sectional area of the manometer tube. A 2-mm inner-diameter water manometer thus has a sensitivity of $3 \times 10^5\,m^{-2}$. Improving the sensitivity of manometer-based tensiometry through decreasing A is limited due to also increasing the uncertainty of the contact angle-dependent capillary rise (water) or capillary depression (mercury). Although the aforementioned values span a very wide range, most mechanical (Bourdon tube vacuum gauge) and electronic pressure transducers used in tensiometry have S in the range of 10^7–$10^9\,m^{-2}$. It should be noted that, because gases are highly compressible, the presence of air within tensiometers decreases S. The S associated with a gas cavity of volume V is equal to $P(\rho_w g V)^{-1}$, where P is the absolute pressure of the gas. Thus, a 1-cm^3 volume of air inside a tensiometer will allow S to be no greater than $10^7\,m^{-2}$, even when a much more sensitive pressure transducer is used to obtain that pressure reading.

The tensiometer's response time, τ, indicates how rapidly the instrument equilibrates with its environment when the rate of soil water exchange is controlled by the tip conductance (rather than the soil or soil–tensiometer contact). Under such conditions of tensiometer-limited response, the time parameter is related to K and S through $\tau = (KS)^{-1}$. The rate at which the tensiometer reading R relaxes towards its equilibrium value R_{eq} is then proportional the instantaneously magnitude of disequilibrium:

$$\frac{dR}{dt} = -\frac{(R - R_{eq})}{\tau} \quad [1]$$

In most tensiometers, τ is practically constant over the operational range, such that R_{eq} is approached according to:

$$\frac{R - R_{eq}}{R_0 - R_{eq}} = e^{-t/\tau} \quad [2]$$

where R_0 is the initial tensiometer reading. Thus τ is equal to the time require to diminish the difference between an arbitrary initial reading and the equilibrium reading to e^{-1} (approximately 37%) of the original discrepancy. By $t = 5\tau$, the tensiometer reading is within 1% of R_{eq} relative to the original discrepancy. Although tensiometers relying on pressure transducers or vacuum gauges have τ-values in the range of fractions of seconds to seconds, much slower responses are obtained in most applications due to low, unsaturated hydraulic conductivity of the soil and poor tensiometer–soil hydraulic contact.

Range of Applications

Given the wide variety of environments in which it is desirable to have information on matric potentials, it is worth addressing limitations in ranges of tensiometer applications as well as approaches that have been developed to diminish or circumvent limitations. Here, lower ranges in matric potential, tensiometry in deep unsaturated zones, and temperature-related problems are briefly discussed.

Although water-filled tensiometers have a lower practical limit of about -85 kPa, much lower matric potentials can be measured with osmotic tensiometers. In an osmotic tensiometer, a polymer solution within the tensiometer body equilibrates with soil water through a semipermeable membrane (ideally impervious to the polymer). The polymer solution equilibrates at a positive gauge pressure (in order to compensate for water potential lowering resulting from interactions with the polymer), thereby avoiding negative gauge pressure limitations of conventional tensiometers. Problems arising from high sensitivity to thermal fluctuations and slow leakage of the polymer have severely limited use of osmotic tensiometers, but recent advances may lead to wider interest in this alternative.

Interest in flow through deep unsaturated soils and sediments has grown over the past two decades, and this has necessitated the development of deep tensiometry methods for field applications. Use of a conventional field tensiometer with a water-filled column to provide the hydraulic connection between the buried tensiometer tip and the pressure gauge at the soil surface (Figure 1) permits a decreasing range of matric potential measurement with deeper installations because of the elevation-dependent hydrostatic pressure decrease. Such a conventional tensiometer used for depths greater than about 8 m will permit little to no useful measurements of matric potentials, because the upper section of the column exists at low absolute pressure and rapidly becomes filled with water vapor. Approaches used to circumvent this problem eliminate use of the water-filled column and rely instead on either burying pressure transducers at or near the depth of the tensiometer tip or use of an air-filled column. The latter option is not as suitable for monitoring transient flow conditions, since the air-filled cavity imparts low gauge sensitivity, hence a low response time.

Temperature variations in the field have long been known to make interpretation of tensiometer readings difficult. The phenomenon is complex and often sensitive to instrument design, since thermal effects on volume changes of tensiometer components and fluids can be substantial. This can be especially problematic when instrument sensitivity is high and the overall tensiometer–soil conductance is low. Keeping all instrument components below the soil surface (where maximum temperature variations occur) can diminish temperature-induced changes in tensiometer readings. When tensiometers are used in field locations exposed to freezing temperatures, protection from damage by ice formation is necessary. This can be accomplished to an extent by adding methanol or antifreeze to the water in the tensiometer, or by burying the instrument below the depth of soil freezing.

List of Technical Nomenclature

ρ_w	Density of water ($kg\,m^{-3}$)
τ	Response time (s)
ψ_m	Matric potential (Pa)
g	Acceleration due to gravity ($m\,s^{-2}$)
h	Head (m)
K	Conductance ($m^2\,s^{-1}$)
L	Length (vertical) (m)
P	Pressure (Pa) or (kPa)
R	Reading (tensiometer) (kPa)
S	Sensitivity (gauge) (m^{-2})
t	Time (s)
V	Volume (cm^3) or (m^3)

TERRACES AND TERRACING

G R Foster, Bryan, TX, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Terraces are runoff management structures used to control soil erosion by water. All terraces are topographic modifications of hillslopes. Terraces reduce rill and interrill erosion by shortening the overland flow path (slope) length or reducing effective landslope steepness. Some terraces reduce net erosion by depositing a portion of eroded sediment on the hillslope. Terraces capture runoff and convey it off the hillslope without causing excessive erosion. Captured runoff increases soil moisture and thus crop production. Terraces are designed, installed, and maintained to fit local climate, soil, topography, and crop management in accordance with available resources, preferred land use, and other socioeconomic factors.

Benefits and Limitations

Terrace systems are highly effective at preventing excessive rill erosion, eliminating ephemeral gully erosion, reducing sediment yield, conserving soil moisture, protecting landscape quality, and increasing land value.

Terraces are topographic modifications that require soil displacement to construct them. They work best on deep soils, such as loess soils. Terraces require a significant investment to build and maintain. Farming with terraces may be inconvenient, and they may limit the choice of farming practices. Terrace systems that do not fit local conditions can be worse than no terraces at all.

Runoff and Erosion on Hillslopes without Terraces

Runoff begins as overland flow spread uniformly around the hillslope. Overland flow is terminated by draws (concentrated flow areas) on the landscape where flow becomes channelized. These draws are formed during landscape evolution. Figure 1 illustrates these flow paths.

Soil erosion by water on the overland flow areas is known as rill and interrill erosion. Rill erosion is the detachment of soil particles by surface flow, and it occurs in a series of rills, which are small, parallel channels a few tens of millimeters wide. Location of rills is determined by soil surface microtopography. Interrill erosion occurs on interrill areas, which is the space between rills. Interrill erosion is detachment of soil particles by raindrop impact. Detachment is the separation of soil particles (sediment) from the soil mass. Deposition is the accumulation of sediment on the soil surface. Sediment load is the amount of the sediment that is transported downslope. Most downslope sediment transport is by surface runoff. Detachment increases sediment load in a downslope direction, while deposition decreases sediment load.

Erosion in concentrated flow areas is known as concentrated flow erosion. This erosion is also known as ephemeral gully erosion if tillage fills the channels and runoff reforms the channels during each cropping cycle. Rills are obliterated by tillage. Rills are typically reformed in different locations depending on the soil-surface microtopography left by tillage. Ephemeral gullies always occur in the same location because of the dominance of landscape macrotopography.

Types of Terraces

The major types of terraces are gradient, parallel-impoundment, bench, and ridge. Most terrace systems involve runoff interceptors that collect the overland flow and redirect it around the hillslope. Most terrace systems include water-conveyance structures that receive the intercepted flow and convey it to low points on the hillslope.

Gradient Terraces

Construction Gradient terraces use an embankment and associated channel to intercept overland flow and direct it around the hillslope. Flow from the terraces is discharged into a protected channel that conveys the flow downslope, as illustrated in Figure 2. These terraces are typically used on hillslopes less than 10% in steepness. Gradient terraces are constructed tens of meters apart and typically use low embankments and shallow channels so that the entire area can be farmed with tractors and wide farm

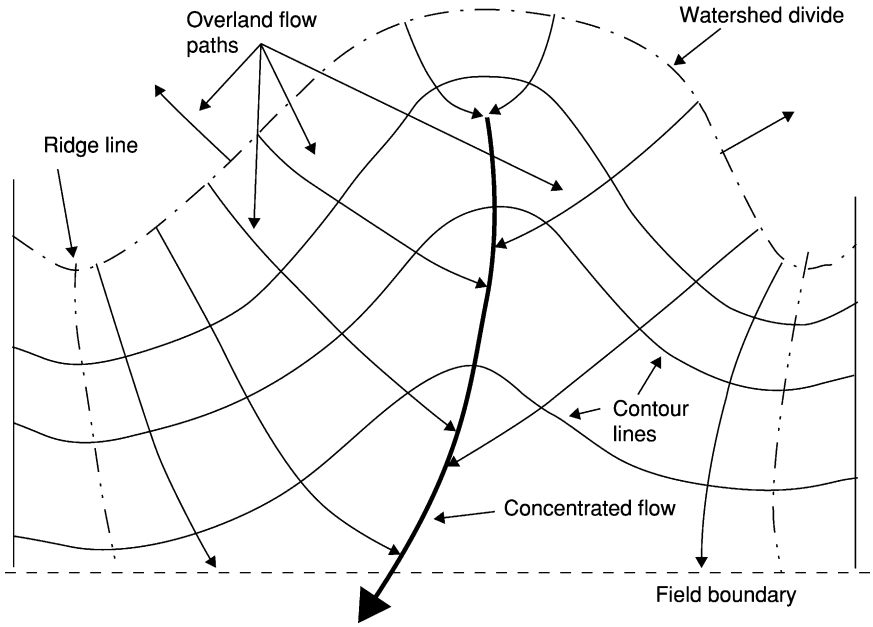

Figure 1 Overland flow and concentrated flow paths on a typical hillslope without terraces.

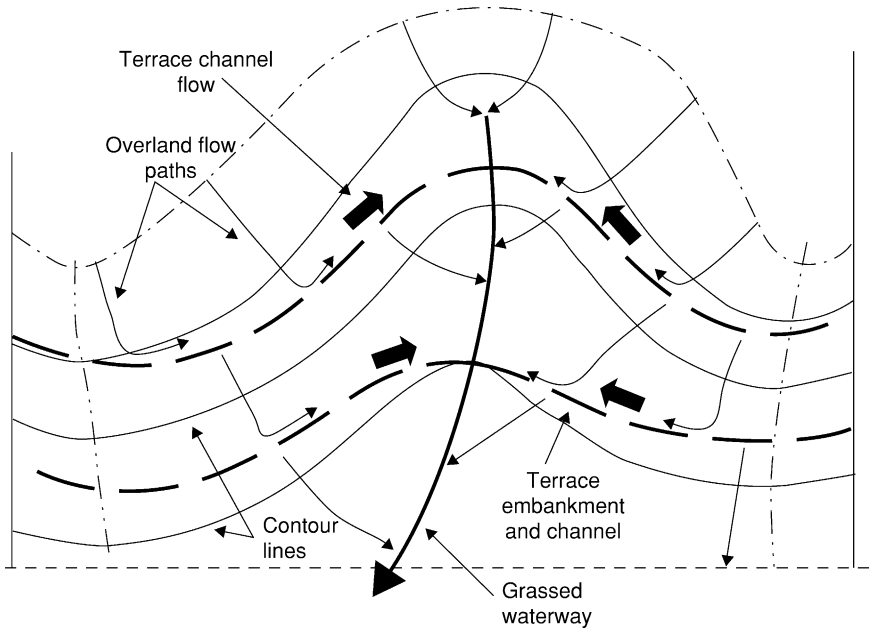

Figure 2 Overland flow and concentrated flow paths on a typical hillslope with gradient terraces on a uniform grade.

equipment. These terraces are referred to as broad-base terraces. Gradient terraces can be constructed with road graders, earthmovers, special terracing machines, and plows used in farming. Cuts and fills are balanced to minimize construction costs and the soil depth that is disturbed. Deep cuts expose subsoil and reduce crop production.

Gradient terraces shorten the 'slope length' of the overland flow path. Rill and interrill erosion vary approximately with the square root of slope length. Adding two gradient terraces to a 100 m slope length creates three slope lengths of 33 m minus the distance from the center of the terrace embankment to the upper edge of the terrace channel as illustrated in Figures 2 and 3. These terraces reduce rill and interrill erosion by ~40%.

Spacing Terraces are spaced to avoid excessive rill erosion. Equations for terrace spacing have been developed based on field experience. A rule of thumb is

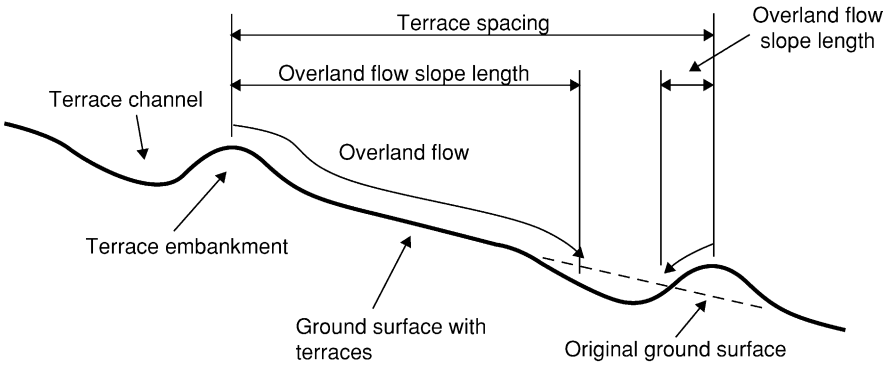

Figure 3 Terrace embankment and channel cross section for a broad base terrace.

that rill erosion is excessive when average annual rate for rill and interrill erosion exceeds 15 t ha^{-1} year^{-1}. Terrace spacing is decreased where rainfall amount and intensity are high and where the soil has a low infiltration rate, both of which produce high runoff rates. Terrace spacing is also decreased on steep hillslopes. High runoff rates and steep slopes increase runoff erosivity and the potential for rill erosion. Terrace spacing is decreased for soils that are susceptible to rill erosion.

Vegetative cover including plant stems, roots, and residue, and soil surface roughness reduce runoff erosivity. Terrace spacing is based on the most vulnerable period for rill erosion during a cropping cycle, which is often the seedbed preparation period, especially for clean-tilled row crops such as maize or soybean.

Terrace spacing can also be based on the average annual soil erosion rate estimated using erosion prediction technology such as the Revised Universal Soil Loss Equation (RUSLE). The terraces are spaced so that the estimated erosion rate on the inter-terrace interval is less than the soil loss tolerance value assigned to the site-specific soil. Soil loss tolerance values range from about 4 to 11 t ha^{-1} year^{-1}, based on the degree that erosion is judged to harm a particular soil.

Contouring, a practice where the direction of tillage and crop rows is on the contour around the hillslope, reduces rill and interrill erosion by about 50% on mild slopes. Contouring fails when runoff erosivity becomes too great. The failure location is known as the critical slope length, which is computed with RUSLE. Terrace spacing should not exceed the critical slope length.

Deposition and sediment delivery Gradient terraces also control erosion by deposition in the terrace channel. Deposition occurs when the sediment load reaching the channel from the inter-terrace area is greater than transport capacity of the flow in the channel. Transport capacity in the channel increases in direct proportion to increases in channel grade and channel flow rate. If transport capacity in the channel is greater than the incoming sediment load, no deposition occurs.

Sediment delivery ratio (SDR) is the ratio of the sediment load leaving the terrace channel to the incoming sediment load from the inter-terrace area. The sediment delivery ratio is about 0.2 and 0.4 for terraces on a 0.2% and 0.5% grade, respectively, in clean-tilled row crops. If terrace grade is greater than about 1.0%, no deposition occurs (as a rule of thumb).

Deposition also depends on sediment characteristics. Less very fine sediment is deposited than coarse sediment. Sediment eroded from most cropped soils is a mixture of primary particles and aggregates (conglomerates of primary particles). Silt-textured soils (e.g., 5% clay, 87% silt, 8% sand) are poorly aggregated and produce a high proportion of fine sediment particles. An SDR value for a silt soil might be 0.34. A silt loam soil (e.g., 15% clay, 65% silt, 20% sand) produces sediment having a balanced mixture of primary particles and aggregates. The SDR for that soil might be 0.26. A high sand soil (e.g., 4% clay, 6% silt, 90% sand) is eroded mainly as large, easily deposited primary particles. The SDR might be 0.12. In contrast, a high clay soil (e.g., 60% clay, 20% silt, 20% sand) erodes as sediment having a significant amount of very fine primary clay particles. The sediment also has a large fraction of large aggregates that are readily deposited. The easily deposited aggregates make up for the large fraction of primary clay in the sediment that is not readily deposited. The SDR for the clay soil is 0.24, about the same as for the silt loam soil. Clay is a bonding agent such that a large fraction of the sediment eroded from high clay soils is large aggregates.

Periodic maintenance is required to clear terrace channels of deposited sediment to maintain flow capacity. Otherwise, flow overtops the terrace and causes serious gully erosion that requires major

repairs. Deposited sediment removed from the terrace channel is spread over the field near the terrace to replace soil loss by erosion and soil displaced by the terrace construction. The ridges and channels are maintained so that farming over them can continue. Placing the deposited sediment on the terrace ridges makes them too high.

Only partial credit is given to deposition caused by terraces as soil saved relative to protecting the entire hillslope, because the deposition is on a relatively small area. Also, the deposition is remote from the location on the hillslope that produced the sediment. Erosion can degrade source areas even though much deposition occurs downslope. The credit given to deposition as soil saved decreases as terrace spacing increases because the fraction of the total area benefited by deposition decreases. No credit is given for deposition for terraces spacing greater than 100 m. A maximum credit of one half is given for spacing closer than 30 m. Very little credit is given for deposition that occurs in terraces located near the bottom of the hillslope.

Outlet channels Gradient terrace systems include outlet channels that collect flow discharged at the outlet of the terrace channels and convey the flow downslope. These channels must be well protected to prevent gully erosion. Flow in them is erosive because of a steep channel grade. Typically, these channels are grassed waterways. Rock can be used to line outlet channels where the flow is especially erosive. A major benefit of terrace systems is the elimination of ephemeral gully erosion, but this important benefit is not realized if stable outlet channels are not provided.

The capacity and stability of terrace and outlet channels are based on a design storm with a 24 h duration that occurs with a return period of 10 years, referred to as a 10 year-24 h storm. Runoff is computed based on the condition during the cropping cycle that produces the most runoff. Channel flow capacity is based on the condition that provides the greatest hydraulic resistance, e.g., unmowed grass in outlet channels and heavy residue cover in terrace channels. Channel stability is based on the condition when the channel is most vulnerable to concentrated flow erosion, e.g., freshly mowed grass in outlet channels and tilled seedbed in terrace channels.

Moisture conservation Gradient terraces are used in low precipitation regions to conserve soil moisture and increase crop production. A level terrace grade is used and the bottom of the terrace channel is widened to increase water capture and expand the benefited area (*See* **Water Harvesting**).

Parallel-Impoundment, Underground-Outlet Terraces

A terrace system suited for farming with wide equipment is one where the terraces are nearly parallel. Uniform-grade terraces are difficult to farm because the terraces are not parallel. Wide equipment does not work well when crossing terraces and tends to destroy them. Parallel terraces, illustrated in Figure 4,

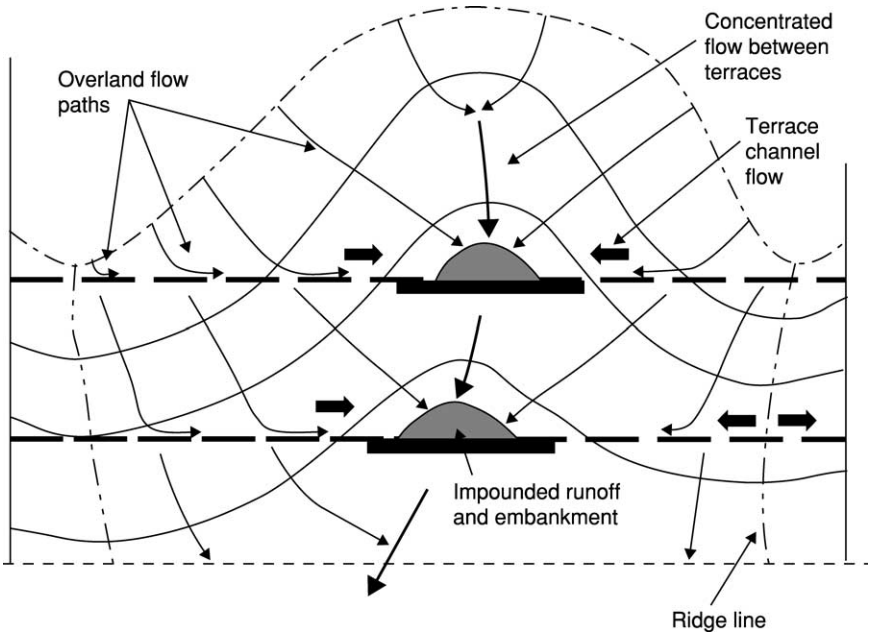

Figure 4 Overland flow and concentrated flow paths on a typical hillslope with parallel-impoundment, underground-outlet terraces.

require that grade varies along the terraces. Parallel-impoundment terraces are highly effective at controlling sediment yield and reducing ephemeral gully erosion, and are convenient to farm with large equipment. These terraces are less effective than gradient terraces at controlling rill and interrill erosion. Parallel-impoundment terrace systems include overland-flow interceptors, impoundments, and underground water-conveyance systems.

Overland-flow interceptors The overland-flow interceptors for parallel terraces are essentially the same as the embankments and channels used with gradient terraces. The slope lengths for the overland flow paths with a gradient terrace system are generally uniform along the terrace. However, the slope length of overland flow varies along parallel terraces. Slope lengths vary from essentially zero to the slope length of the natural landscape if the terraces are spaced far apart.

Channel grade varies along parallel terraces. The grade is zero where the channels cross a ridge and is steepest between the ridge and the impoundment in the draw. Deposition occurs uniformly along a uniform grade terrace channel, but deposition only occurs in parallel terrace channels where channel grade is sufficiently flat. Maximum channel grade is limited to ensure that no concentrated flow erosion occurs in the terrace channels. Terrace embankments and channels are relocated uphill to reduce terrace channel grade. The terrace spacing and hydraulic design procedures used for gradient terraces are also used to design parallel terraces.

Impoundments Impoundments located across the draws on the hillslope receive the flow from the overland-flow interceptors. These impoundments are sized to retain the runoff from a 10 year-24 h storm assumed to occur when runoff potential is greatest. The impoundment size is increased to store the sediment that will accumulate over the design life of the impoundment, usually 10 years. Maintenance can be performed periodically to remove and spread the deposited sediment over the hillslope to extend the life of the impoundments.

Runoff is retained in the impoundment to provide time for sediment to be deposited by settling to the bottom. Twenty-four hours is usually sufficiently long for most of the sediment to be deposited. The retention time is kept short to minimize inundation of crops and to speed drying so that farming operation can resume with minimal inconvenience.

Impoundment terraces very efficiently trap sediment. For example, an impoundment terrace will trap ~94% of the sediment eroded from a silt loam soil on the inter-terrace area for an SDR of 0.06. The SDR values for sediment eroded from sand, silt, and clay soils are 0.01, 0.07, and 0.14, respectively. The order of sediment delivery ratios among the soil textures differs from the SDR order for gradient terraces. This difference results from the sediment being continuously added along the gradient terrace channel, while the sediment is added to the impoundment at a point. Also, deposition mechanics in still water differ from deposition mechanics in channel flow.

The embankments for these impoundments are often so high that they cannot be crossed with farm equipment, which removes a portion of the field from crop production. The embankments are constructed with a steep backslope, illustrated in Figure 5, to minimize this loss. Dense grass is used on the backslope to prevent erosion. A bulldozer is used to construct the embankments.

Water-conveyance system Water is drained from the impoundments using a perforated riser pipe that projects above the floor of the impoundment. Water enters the riser and falls vertically into an underground pipe. Discharge rate is controlled using an orifice in the bottom of the riser to provide the desired retention time. Water flows from the riser into an underground pipe that runs up the draw and collects flow from all the terraces that cross that particular draw. A perforated underground pipe is sometimes used to provide subsurface drainage in the draw where seepage can collect.

Bench Terraces

Bench terraces reduce steep hillslopes to ones that are effectively flat. Bench terraces consist of a steep non-erodible section and a flat or nearly flat bench that is cultivated, as illustrated in Figure 6. The most impressive example of bench terraces is in China, where steep, highly erodible land is farmed. Reducing the effective landslope from 30% to 1% decreases erosion by ~99%.

Flat bench terraces are used in low rainfall areas to capture rainfall to increase soil moisture and crop production. Reduced runoff also reduces soil erosion (*See* **Water Harvesting**).

Flat benches with vertical backslopes Among bench terraces, flat benches with vertical backslopes provide the greatest land area for cultivation. However, constructing vertical walls for bench backslopes requires considerable resources. Vertical walls are easiest to construct if the wall is not high. However, a low wall results in a narrow flat bench area, which limits the cropping-management practices and size of equipment that can be used on the benches. A well-designed

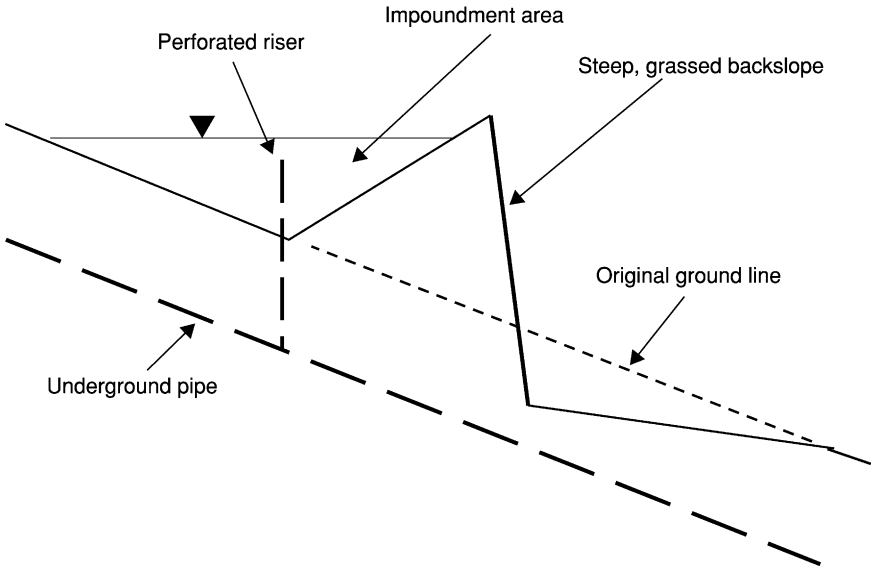

Figure 5 Impoundment embankment cross-section for an underground-outlet terrace.

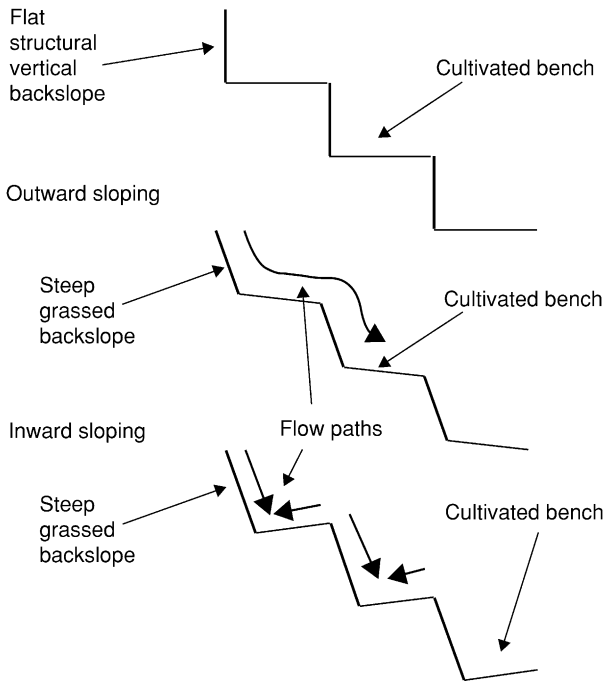

Figure 6 Types of bench terraces.

water-conveyance system is included with the terrace system to collect excess water and convey it downslope in stable channels.

Outward-sloping benches An alternative bench terrace system has a steep, grassed backslope (1:1 slope) and a relatively flat bench (less than 2%) wide enough (e.g., 3 m) to accommodate mechanically powered equipment. The bench can be outward or inward sloping. If the bench is outward sloping, as illustrated in Figure 6, overland flow originates at the top of the hillslope and cascades down the slope. Erosion is low because the grass essentially prevents erosion on the steep backslope, and erosion is low on the nearly flat bench.

While bench terrace systems theoretically perform well with water cascading from one terrace to the next, runoff must be carefully controlled to avoid concentrated flow and gully erosion. Maintaining bench terraces with the front edge perfectly on a level grade so that runoff flows uniformly over the bench edge is difficult. Also, the grass cover on the steep backslope must be well maintained to prevent areas where gully erosion can begin. Runoff should be collected at regular intervals downslope and brought to nonerodible channels that convey the runoff downslope.

Inward-sloping benches Inward-sloping benches, illustrated in Figure 6, eliminate the cascading flow down the slope. Each bench and its backslope are individual watersheds. The outer edge of the bench is left higher than the back edge so that runoff flows back toward the hillslope. The only runoff in each bench watershed is from the rainfall that falls directly on that watershed. The benches can be put on a slight grade around the hillslope so that runoff flows around the hillslope at the base of the backslopes to nonerodible collection channels that convey the runoff downslope.

Inward-sloping bench terraces have less rill and interrill erosion than do outward-sloping bench terraces. However, the difference is not great because at

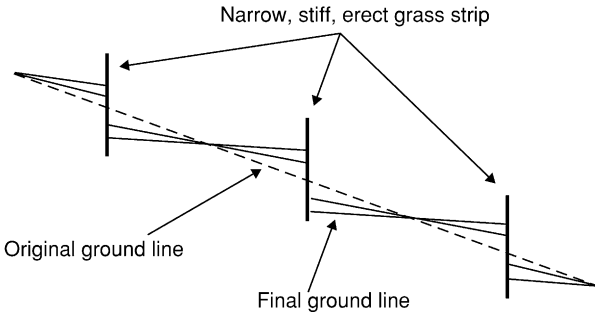

Figure 7 Narrow, stiff grass strips enable erosion and deposition to create bench terraces.

1% slope steepness and less, most of the erosion is caused by interrill erosion, which is not affected by slope length. For example, reducing slope length from 50 m to 3 m results in only a 20% reduction in erosion for a 1% steep slope.

Naturally formed benches Soil must be mechanically moved to construct the terraces described above. Permanent, narrow grass strips can be used to let nature build bench terraces. Narrow, approximately 0.5 m wide, strips of dense erect, stiff grass are planted very carefully on the contour. These dense strips slow the overland flow to cause deposition in backwater ponded on the upper side of the grass strip. Over time, the hillslope slowly evolves as illustrated in Figure 7. Reducing steepness from 10% to 2% for a 10 m hillslope segment by rotating the segment about its midpoint requires 0.35 m of erosion at the segment's upper end and 0.35 m of deposition at the segment's lower end. Approximately 100 years is required for this adjustment assuming that all sediment eroded on the segment's upper portion is deposited on the segment's lower portion, an average annual erosion rate of 50 t ha^{-1} $year^{-1}$, and a specific soil bulk density of 1.3. The process is often slow. However, an immediate benefit is that the grass spreads the runoff so that rill erosion is reduced for a few meters downslope from the strip.

Ridge Ridges and beds on the contour around the hillslope are actually a set of small terraces where the slope length is half the spacing of the ridges. The slope length of the overland flow is the distance from the top of the ridge to the middle of the furrow between the ridges. Almost all of the erosion on the ridges is interrill erosion because of short slope lengths.

The furrows between the ridges act like terrace channels. A flat furrow grade, less than 2% for clean-tilled row crops, deposits much of the sediment eroded on the ridges. Deposition in the furrows is given full credit, as soil saved protects the entire hillslope because the deposition is very near to the source of the sediment.

To function as terraces, ridges must be sufficiently high to avoid overtopping and be carefully constructed and maintained to ensure that they perform well. Erosion from failed ridges can be greater than if ridges had not been used. Overtopping in a local area is like a dam break. Failures cascade downslope, resulting in serious ephemeral gully erosion. Maintaining a sufficient height along the ridge and avoiding adverse furrow grades that pond water prevent overtopping in localized areas.

Ridges are most effective when arranged perfectly on the contouring. Maximum moisture is retained for crop utilization. When ridges overtop, the runoff flows over the ridges uniformly along the ridges if the ridges are perfectly level. The flow depth will be very shallow and much less erosive than if the runoff concentrates at low places and breaks over in a concentrated flow. Ridges perfectly on the contour reduce ephemeral gully erosion. When ridges are perfectly on the contour, the head of ephemeral gullies is further down the hillslope than if ridges and furrows are on a grade. Ridges and furrows on a slight grade concentrate overland flow far up the hillslope, which extends ephemeral gully erosion further up the hillslope than with ridges perfectly on the contour, as illustrated in Figures 8 and 9.

Straight-ridge alignment facilitates farming with large equipment. However, the furrow grade along straightened ridges is non-uniform, just as with parallel terraces. The grade must be sufficiently flat so that rill erosion does not occur in the furrows on areas adjacent to concentrated-flow areas. Runoff collects in these natural waterways and flows downslope. These concentrated-flow areas must be protected with a grass or another stable lining to prevent serious ephemeral gully erosion. If these concentrated-flow areas are not protected, ephemeral gully erosion can be greater with ridging slightly off the contour than with ridges directly up and downhill. However, wide grass waterways take land out of production, reduce farming convenience, and require significant maintenance.

Summary

Terraces are important structures used to safely convey runoff, control rill erosion, and prevent ephemeral gully erosion, especially on steep hillslopes with long slope lengths. Terraces are also used to conserve soil moisture and thus to increase crop production in low rainfall areas. Terraces intercept overland flow and redirect it around the hillslope where protected channels convey the runoff downslope.

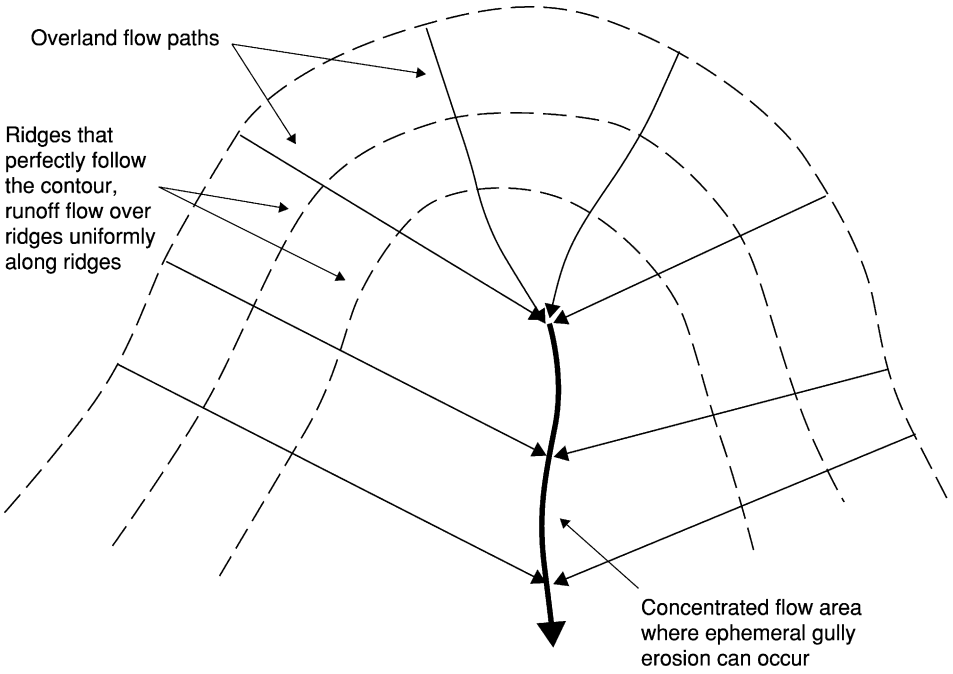

Figure 8 Overland flow paths and location of the head of ephemeral gullies when ridges are perfectly on the contour.

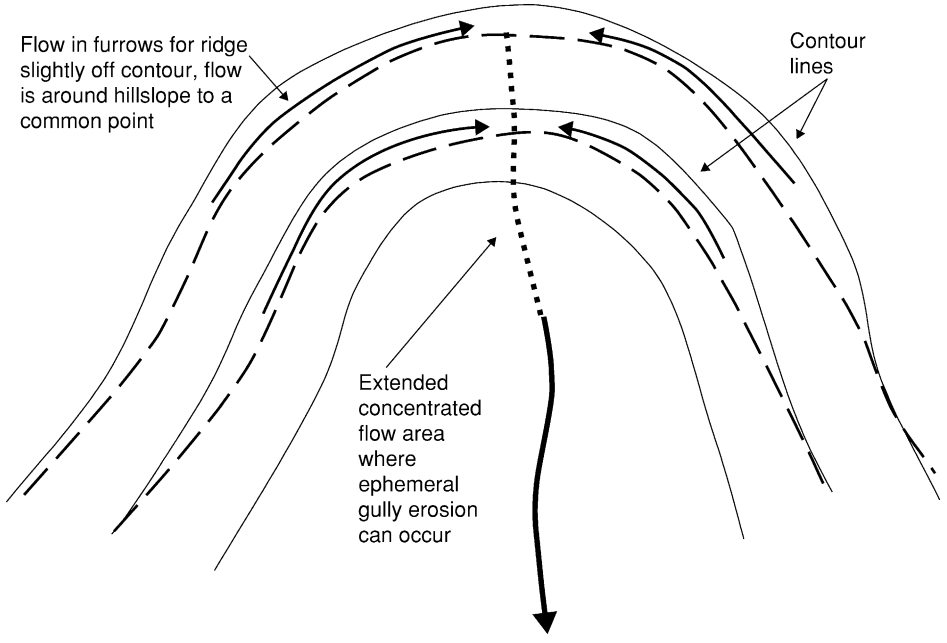

Figure 9 Overland flow paths and location of the head of ephemeral gullies when ridges are on a slight grade.

Terraces are used in a wide range of agroecosystems ranging from small plots farmed with human and animal power to large fields farmed with large machines. Terraces are best suited to deep soils where soil can be moved to create benches and ridges without seriously affecting the soil productivity. Terraces require significant resources of capital or labor to construct and must be maintained. Terraces on steep hillslopes in China graphically illustrate how terraces can be used to make maximum use of the landscape for crop production.

TESTING OF SOILS

A P Mallarino, Iowa State University, Ames, IA, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Soil testing is an important diagnostic tool for determining the nutrient needs of plants and for environmental assessments. Some soils are inherently deficient in plant nutrients. Other soils had sufficient levels of nutrients in the past, but removal with crop harvest has depleted the reserves. Thus, soil testing is widely accepted and used in most advanced crop-production areas of the world to determine fertilization needs for crops. Soil testing can also be used to identify application rates of waste materials containing nutrients or other elements that could harm the environment. Waste materials such as animal manures and industry by-products may provide various plant nutrients. However, high application rates to soils designed to dispose of the material at a low cost may result in nutrient loads that are harmful to plant, animal, or human health. Nutrient management regulations are being developed to address land application of waste materials. Soil testing is required in many regulations and management guidelines to assess environmentally harmful levels of certain elements and to determine limits to application rates.

Soils are tested routinely for the primary nutrients phosphorus (P), potassium (K), and nitrogen (N). In some regions, soils are also routinely tested for other primary nutrients such as calcium (Ca), magnesium (Mg), and sulfur (S), and for other nutrients required in very small amounts by crops such as boron (B), copper (Cu), iron (Fe), manganese (Mn), molybdenum (Mo), and zinc (Zn). Soils receiving waste materials are also tested for elements such as arsenic (As), cadmium (Cd), nickel (Ni), lead (Pb), mercury (Hg), and selenium (Se) among others.

Two of the primary plant nutrients, N and P, may have harmful effects on the environment when applied to soils in excessive amounts. Excessive N and P applications to agricultural fields and ineffective nutrient, soil, and water conservation practices are increasing nutrient pollution in many regions of the world. However, the basic concepts of soil testing also apply to other elements. Phosphorus is included with the group of elements with relatively low mobility in soils (Ca, Cd, Cu, Fe, Mg, Mn, Mo, Ni, Pb, and Zn among others). N, especially in the nitrate form, is included with the group of elements with greater mobility (which include B, Cl, S, and others). Important concepts include the meaning of a soil-test value, soil-testing quality, use of soil testing to determine economically optimum nutrient application rates, and use of soil testing for environmental assessments.

Soil-Test Extractants and Methodologies

Phosphorus Soil Tests

Soil tests for P and other elements have been developed based on an understanding of the chemical forms in which the elements exist in the soil and empirical work. In most soils, P is primarily associated with aluminum (Al), Fe, and Ca. P precipitation and/or adsorption to Fe and Al oxides generally predominates in acid (pH < 7.0) to neutral soils, whereas reactions with Ca predominate in soils with significant amounts of calcium carbonate. The degree and strength to which P is bound in soils are largely determined by the amount and types of Fe and Ca compounds present and by other soil properties such as pH, organic matter, clay mineralogy, and the amount of P currently present in the soil. The influence of Fe increases and that of Ca decreases as rainfall, temperature, and weathering increase. These factors are also important in determining the plant availability and solubility of other immobile elements.

Phosphorus soil-test methods for agronomic use employ dilute strong acids, dilute weak acids, complexing ions, and/or buffered alkaline solutions. Most tests have been developed to reflect the soil properties related to P sorption that predominate in a region. For example, the Bray P-1 test was developed for use in the acid-to-neutral soils of the north-central region of the USA; the Olsen (or sodium bicarbonate) test was developed primarily for use on calcareous soils of the same region; and the Mehlich-1 test was developed for the low cation-exchange capacity and highly weathered soils common to southeastern regions. The Mehlich-3 P extractant was developed more recently. It has been adopted because it is suitable for a wider range of soil properties than other P tests and also for other nutrients (such as K, Ca, Mg, Cu, Fe, and Zn).

Increasing concerns about nonpoint-source P pollution from agriculture has prompted questions about the suitability of agronomic soil P tests for environmental purposes. Several soil tests have been proposed as environmental soil P tests because they may provide better estimates of dissolved P delivery to water resources. Two of these tests are being evaluated extensively. One test based on FeO-impregnated paper uses a sink approach to extract soil-bound P that is most likely available to aquatic organisms. The other test is based on weaker desorption reactions and uses either deionized water or a diluted calcium-chloride solution to extract soil P. These tests are environmentally sound for laboratory use because few hazardous chemicals are needed.

Although the results of the different soil P tests are often highly correlated for soils with similar properties, the actual quantities extracted can differ greatly. For example, the Mehlich-3 test extracts 1.5 to 2 times the amount of P as the Mehlich-1 and Olsen tests. The FeO-impregnated paper environmental P test usually measures 4–10 times the amount of P measured by the water extractant. These observations highlight the importance of understanding the meaning of a soil-test value.

Nitrogen Soil Tests

The cycling of N in soils is different from other nutrients and requires a different soil-testing approach. More than 97% of N in soils is present in organic forms and is converted to inorganic forms available to plants mostly through microbial activity. The rate of N release from organic to inorganic forms is difficult to predict because it depends on temperature, moisture, aeration, organic matter type, soil pH, and many other factors. The predominant inorganic end-result of mineralization is nitrate-N. This N form is highly mobile in soils and is subject to loss by leaching and to gaseous losses through denitrification. Because of these factors, N fertilizer recommendations for crops are frequently made on the basis of crop yield potential coupled with an N-credit system and less frequently on the basis of soil testing. The N-credit system is based on empirical information of the effects of previous crops, several soil properties, and climate on crop response to N fertilization.

Soil testing for nitrate-N has been used for a long time in low-rainfall regions and is becoming more common in humid areas of the USA, mainly for maize production. In low-rainfall areas, where nitrate leaching potential is minimal, the amount of nitrate-N in the soil profile before planting crops can be credited directly against the N needs of the crop. In many humid regions, measurements of soil profile nitrate or ammonium before planting have been unreliable to predict N needs of maize. However, nitrate-N testing early in the growing season has been shown to provide an index of the soil N-supplying capability for maize. Soil samples are collected deeper than for other nutrients (usually from a 0- to 30-cm depth) after planting the crop and before plants reach a height of 15–30 cm.

The nitrate-N soil-test interpretation is usually complemented by consideration of the previous crop, rainfall during the 2- to 4-week period before collecting soil samples, and soil properties that influence nitrate leaching. As work on this type of testing for nitrate in humid regions continues, it is becoming a useful diagnostic tool to decrease N fertilizer rates and reduce potential N pollution of water resources. As with all soil tests, local or

regional field calibrations are being conducted to determine critical concentration ranges and fertilizer recommendations.

Calibration of Soil Tests for Crop Production

Soil tests seldom extract the total amount of nutrients or elements in a soil sample. Soil tests have been developed to measure a fraction of the total soil nutrient concentration that correlates with plant growth. Interpreting a soil-test value requires an understanding of the impacts on test results of the extractant used, method of soil sampling, sample handling, and the intended use for the result. The amount of nutrient measured by various soil tests can vary widely depending on the extractant used. Important extractant properties include the concentration of the chemical compounds and the reaction time with the soil. The method used to measure the nutrient after extraction may be important for some nutrients. For example, colorimetric methods usually measure only orthophosphate P, while other methods may also measure other P forms. Also, the same soil test may measure widely different amounts of nutrients in soils with contrastingly different chemical and (or) mineralogical properties. Extractants used and interpretations of results often vary depending on soil properties and the purpose of soil testing (for example, measurement of total, soluble, or plant-available concentrations).

A soil-test method useful for predicting crop response to fertilization should produce values that are well correlated with plant nutrient uptake and growth. Greenhouse and field research is conducted to determine which soil-test extractant is best suited for a given combination of soil, crop, and growing conditions. Accurate interpretations of soil-test results and appropriate fertilizer recommendations require that the relationship between the amount of a nutrient measured by a given soil test and the crop response to the added nutrient must be known. The process of determining the probability of crop response at a given soil-test value is known as soil-test calibration and must be determined by field experimentation. The calibration procedure usually involves growing a crop or various crops in soils representative of the region on which the test will be used and the application of various fertilization rates. The soils should have a broad range of soil-test values that include deficient, optimum, and above-optimum values.

The crop yield response can be expressed as an absolute value or as a value relative to the yield achieved without nutrient addition. As an example, Figure 1 shows the relationships between the relative or absolute yield increase of maize and the amount of P extracted by a soil test. Although the specific shape of the relationship between soil-test values and crop growth or yield can differ, the general response is fairly consistent. At low soil-test values, crop yield is limited by nutrient deficiency. As soil-test values increase, yield increases at a reduced rate until a maximum yield value. At higher levels, there is no longer a relationship between the soil-test values and yield. The maximum yield value can remain approximately constant for a wide range of soil-test values or can decrease at excessively high nutrient levels.

The soil-test value at which crop growth or yield reaches a maximum is called the soil-test critical concentration. This is the soil-test value that best separates soils where a positive crop yield response to an added nutrient is likely from those soils where a response is not likely. Various mathematical models can calculate different critical concentration values and some models are asymptotic to a maximum. There is no reasonable agronomic consideration that justifies a single critical concentration. Moreover, economic

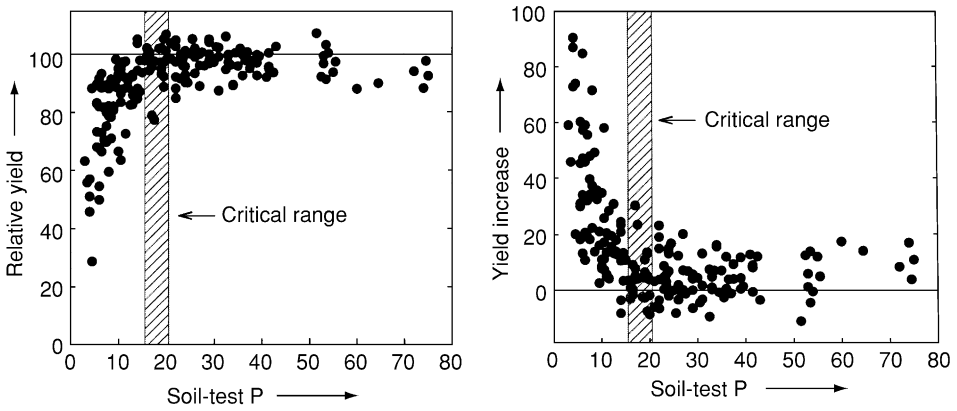

Figure 1 Example of the relationships between relative or absolute crop yield response and soil-test P values used for soil-test calibration.

considerations suggest that maximum economic yield perhaps should be the basis for determining critical concentrations instead of a physical maximum. Thus, critical concentration ranges are usually determined by using a combination of models and a variety of both agronomic and economic considerations. The soil-test response curve is often used to divide soil-test levels into several categories such as very low, low, optimum, high, or excessive.

A thorough understanding of crop response to nutrients and factors such as sampling date (season of the year), sampling method (mainly sampling depth), method of nutrient application (for example, band or broadcast), and application timing is needed to interpret soil-test results correctly. Also, other factors can influence crop growth (climatic factors, plant population, levels of other nutrients in the soil, and crop cultivars, among others). These factors may influence crop growth without affecting the amount of nutrient needed to produce a certain yield level or they may interact with soil nutrient levels.

Climatic factors are especially important for nutrients that are highly mobile in the soil, such as nitrate-N, B, Cl, and S. High nutrient mobility results from limited retention of nutrient chemical forms by soil organic or mineral constituents. High nutrient mobility results in more difficult soil-test calibrations and introduces more uncertainty when interpreting soil-test results. Levels of these nutrients in soil change markedly during the year as a result of changes in factors such as soil temperature and rainfall. Soil samples for relatively immobile nutrients (such as P, K, Ca, Mg, Cu, Zn) are often collected from the top 15–20 cm of soil, from where most of the nutrient uptake takes place. Other nutrient measurements, such as subsoil testing, are sometimes useful for the more immobile nutrients such as P or K but are more useful for mobile nutrients.

Calibration of Soil Tests for Environmental Purposes

The general concepts for soil-test calibration described for agronomic soil tests also apply to soil tests used for environmental purposes. With agronomic tests, the most important consideration is related to the meaning of a soil-test value for crop growth or yield. With environmental tests, the most important consideration relates to the meaning of a soil-test value for predicting environmental impacts. For several reasons, calibration and interpretation of soil tests used to predict potential environmental impacts are more complex than for agronomic uses. The most important reason is that a certain concentration of an element in the soil may have different impacts on the environment depending on the amounts absorbed by plants, amount retained by the soil, and potential delivery to environmentally critical areas. For example, soils with high clay content have a greater sorption capacity for P (and for other immobile elements) than coarse-textured soils, and a lesser amount of P is delivered as the distance from the source to channeled water flow increases. Establishment of nutrient loads that can result in unacceptable water-quality degradation will depend on factors such as the distance to a sensitive water body, the effectiveness of transport pathways for water and either total or dissolved nutrient fractions, and socioeconomic factors involving land or water use. A single, critical soil-test concentration range is unlikely to be found for nutrient impacts on the environment.

Not all areas of a field or landscape contribute equally to nutrient loss. For loss to occur, both a source of the nutrient and a mechanism for transporting it to water bodies or groundwater are needed. A key concept in effective management of nutrient pollution is to focus on the critical areas in which these two factors maximize the potential for loss. The P Index is an example of an assessment tool that considers soil-test values with other site-specific factors (such as hydrology, nutrient management, water-body proximity, and sensitivity to nutrient inputs) to determine the potential environmental risk of P levels in a field or parts of fields. The P Index includes source factors (soil-test values, as well as fertilizer and manure application rates, methods, and timing) and transport factors (such as soil erosion, surface runoff, subsurface drainage, and distance to streams or water bodies). Indexes are also being developed for N.

Agronomic soil-test methods designed to assess plant-available nutrients are sometimes used for environmental purposes. An effective environmental soil test should measure the nutrient forms most important to eutrophication or other negative environmental impacts. Eutrophication is a process whereby water bodies such as lakes, estuaries, or slow-moving streams receive excess nutrients that stimulate excessive aquatic plant or algae growth. This enhanced growth reduces dissolved oxygen in the water when dead plant or algae material decomposes, which causes ecosystem imbalances and may promote growth of toxic bacteria and unpleasant odor. Current research indicates that there are usually similar relationships between either agronomic or environmental soil P tests and dissolved P in surface runoff or subsurface drainage, except immediately after P additions. However, extending the concept of agronomic critical soil-test ranges to declare that nutrient concentrations above those needed for

optimum crop production will result in significant environmental impacts is not appropriate, because this ignores important aspects of nonpoint-source pollution. If soil tests are to be interpreted to predict the probability of nutrient pollution, calibrations relating soil-test results to specific measurements of environmental response (such as the concentration or load of P in surface runoff, for example) are necessary.

Quality of Soil Testing

Laboratory Quality Control

The quality of a laboratory soil-test result can be assessed on the basis of bias and precision. Bias refers to the deviation of the analytical result from the true value and measures accuracy of the result. Precision refers to the reproducibility of a given test value. A soil-testing laboratory could have good precision for a specific procedure but have bias in its results. A primary means of evaluating soil-test quality procedures as well as laboratory performance is through comparisons of tests performed on well-mixed subsamples of the same soil at different laboratories. In North America, a voluntary proficiency-testing program involving state and private laboratories was launched in the early 2000s to improve the quality of soil testing for agronomic purposes (the North American Proficiency Testing Program, NAPT). Results from this program indicate that, for example, the average variability of P tests is approximately 10–15% and that 65–70% of participating laboratories produced results within this level of variability. Variability is lower within any given laboratory. Data from the NAPT program indicate that precision levels for the P tests discussed are approximately 5–10% within each laboratory.

Soil Sampling for Soil Testing

For a soil-testing program to be effective, besides proper soil-test calibration and laboratory quality control, soil samples should be collected in a cost-effective manner and should accurately represent the nutrient levels in the area of interest. Sampling is a critical component of the soil-testing process because it usually represents the largest single source of error in soil testing. Many factors varying both spatially and temporally influence nutrient concentrations in soils. Sampling protocols must account for the great diversity in magnitude, structure, and spatial scale of nutrient variability present in agricultural fields and other ecosystems.

Soil nutrient variability within a crop field may be due to soil formation or management factors. Factors such as landscape position and soil parent material can cause great changes in soil texture, organic matter, drainage, and other properties. These properties affect nutrient levels directly through their influence on the amount of plant-available nutrient or indirectly though crop yield potential and, thus, the nutrient removal by crops. Variability caused by long-term history of management and land-use practices overlays that associated with soil-formation factors. The cumulative effects of nonuniform manure or fertilizer application are sources of potentially high soil-test variability. Proximity to livestock confinement areas, feed storage areas, and field boundaries are additional examples of historical factors that cause great variability in many fields. Small-scale variability usually predominates in fields with long histories of cropping and fertilizer or manure applications, especially when nutrients are applied using band methods. The challenge in these situations is to determine effective methods to delineate sampling areas within a field and the number of cores or borings needed for each composite sample to account for small-scale variability appropriately.

A variety of systematic and zone sampling approaches have been developed in different regions. The development of accurate and reliable global positioning technology, affordable geographic information systems, and variable-rate application equipment has led to widespread use of site-specific soil sampling approaches in North America. These sampling approaches are typically used to generate a soil fertility map to serve as an input to computer-controlled equipment for applying varying rates of one or more materials. One such approach is zone sampling, by which field subregions with more homogeneous properties than the field as a whole are delineated. Landscape position, soil color, soil mapping unit, and crop growth differences are examples of factors often used to help define management zones. Another site-specific approach involves systematic grid sampling, where soil-test patterns in a field are determined by means of a dense, systematic sample collection. A grid size of approximately 1 ha is most common today in the USA. Small-scale variability of P and K is so extreme in some fields that accurate within-field soil fertility mapping is impossible. Much uncertainty still exists regarding how best to perform site-specific soil sampling and generate accurate soil fertility maps.

Soil-test values may also change markedly with depth. This results from a combination of soil-forming and management factors and from the differential mobility of nutrients in soils. The elements with lower mobility tend to accumulate near the application point (often the most shallow soil layers), because they are more strongly retained by soil constituents than the more mobile nutrients. The tillage

system and the application method greatly influence vertical nutrient stratification. For example, the significant stratification of both P and K in no-till soils is well known, but deep nutrient application methods can reduce their concentration near the soil surface. Thus, the proper depth for soil sampling and its consistency are important considerations. Soil-test variability can also be the result of sampling-depth variability. Soil samples should be collected at the same depth used in the calibration research that serves as the quantitative basis for the soil-test interpretation and nutrient recommendations. Typically, this is a depth of 15–20 cm for the relatively immobile nutrients (such as P, K, Ca, Mg, Cu, Fe, Mn, Zn) and 30–60 cm for the more mobile nutrients (such as nitrate-N). However, the optimum soil-sampling depth varies with the objective of the soil testing. For example, soil sampling for predicting element loss with surface runoff may need to be shallower than for predicting uptake by plants or loss with subsurface drainage.

Use of Soil Tests to Determine Nutrient Loading Rates

Soil testing is becoming an established practice to determine whether environmentally unacceptable concentrations of plant nutrients or other elements are present in soils as a consequence of fertilization and waste applications. The term 'loading rate' implies that when excessive amounts of an element are applied to soils, it could be transported to environmentally critical areas and that the result may be harmful. Soils can be overloaded with a variety of nutrients, nonessential heavy metals, organic chemicals, and pathogenic organisms; and overloaded soils can affect the environment in various ways. For farmers and nutrient-management planners to make confident decisions about nutrient loading, soil tests must be able to predict loading rates and environmentally critical levels over a range of crops, soils, and environmental conditions.

In the USA and many European countries, regulatory initiatives are being established to mitigate water-quality problems associated with N and P water pollution. Other environmental efforts to which soil testing contributes include preventing nutrient toxicity to plants and protecting the food chain from accumulations of nutrients or elements harmful to animal and human health. These environmental problems usually occur at soil-test levels in excess of those required for optimal plant growth or as a result of clearly undesirable events (such as nutrient transport in floods or attached to eroded soil). Regarding phytotoxicity and feed or forage quality, soil tests have the potential to predict negative responses of plants to soils overloaded with a nutrient or nonessential elements.

Measurements and protocols for calibrating soil tests for environmental purposes are complex and are not well established. Soils can contribute to nonpoint-source pollution of water resources (mainly through erosion and surface runoff) even when soil-test levels are optimum for crop production. Nonincorporated surface applications of nutrient sources may result in high nutrient losses not correlated with soil-test levels. In this instance, nutrient transport may occur before any significant interaction between the nutrient source and the soil. A soil test alone does not permit accurate characterization of the risk of nutrient loss from soil to water. Estimates of the amount of nutrient directly lost from surface-applied materials are also needed. What happens between the field's edge and the surface water body, including the possibility for long-term retention of nutrients in buffer zones and any channel processes resulting in retention or release of nutrients, is a very important component of predicting loading rates. Complex diagnostic tools such as N and P risk indexes should be developed and tested for their efficacy to reduce nutrient pollution.

Summary

Soil testing is, and should be, an important component of more comprehensive environmental diagnostic tools. Researchers are attempting to define measurable parameters useful to improve estimates of the relationship between soil-test concentrations and loading rates to water resources. An example of such work is the ongoing international effort to develop better soil-testing procedures (including both methods of analysis and their interpretations) for N and P to identify watershed or field areas likely to contribute significant amounts of N and P to surface water and groundwater through erosion, surface runoff, or leaching. Growing evidence from field research demonstrates a strong relationship between soil-test values and concentrations of elements in surface runoff and subsurface drainage. However, local or regional calibrations are needed, because the relationships vary greatly across soil-test methods and soil properties. Moreover, the effective impact of a certain soil-test value on environmentally sensitive areas is strongly affected by the site hydrology and various transport mechanisms. Thus, if loading rate decisions regarding fertilizers or waste materials are made solely on the basis of soil-test concentrations, erroneous decisions will probably be made regarding potential element losses from fields. However, soil testing plays an important role

in optimizing crop production and protecting the environment.

Introduction

Soil consists of an assemblage of particles that differ widely in size and shape. Some particles are coarse enough to be seen easily with the naked eye, while others are so tiny they can only be seen with powerful electron microscopes. The term 'soil texture' is an expression of the dominant particle sizes found in soil and has both qualitative and quantitative connotations.

Qualitatively, 'soil texture' refers to the feel of soil material. A soil when rubbed by hand can have a feeling that ranges from coarse and gritty to fine and smooth. Experienced soil classifiers can press soil into their hands and tell its texture, coarse or fine, or gradations in between. The expressions 'light soil' and 'heavy soil' are frequently used to characterize the general physical behavior of different soils. A coarse-grained, sandy soil tends to be loose, well-aerated, and easy to cultivate, so it is called a 'light soil.' A fine-textured soil tends to absorb water easily and becomes plastic and sticky when wet, and tight, compact, and cohesive when dry, so it is called a 'heavy soil.' These terms are misleading, since coarse-textured soils are generally denser, having lower porosity, than fine-textured soils, and thus are heavier rather than lighter per unit mass. Table 1 shows the range of densities and porosities that can be found in soils of various textures.

Quantitatively, soil texture refers to the relative proportions of various sizes of soil particles, sometimes called 'size separates.'

Soil Particle Size: Measurements and Classification

The size of soil particles can vary over 6 orders of magnitude, ranging from large stones and rocks (greater than 0.25 m in size) to tiny, submicron clays (less than 0.0001 mm). The shape of soil particles also varies widely. Particle shape is often an indication of the mineral assemblage and the degree of soil weathering that has taken place. For beach sand, composed of quartz, particles are uniformly rounded and almost spherical. In contrast, most clay materials are far from spherical, many being platelets, looking more like playing cards (e.g., kaolinite) or tubes (e.g., halloysite) than marbles. In spite of the variation in shape, soil particles are sized according to their 'effective' particle diameter. Because of the huge size range, no single method can be used to measure particle diameters. Measurements are typically made with tape or ruler for large particles (boulders or cobbles) of more than a few centimeters in diameter, with sieves for particles as small as approximately

Table 1 Range of values found in bulk densities and associated properties for soils of various textures

Description	*Bulk density*[a] *($g\,cm^{-3}$)*	*Porosity*[b] *($cm\,cm^{-3}$)*	*Void ratio*[c] *($cm\,cm^{-3}$)*
Clay	1.20	0.54	1.17
Loam	1.40	0.49	0.96
Sand	1.60	0.39	0.64
Sandy loam[d]	1.90	0.28	0.39
Sandstone	2.12	0.20	0.25

[a]Bulk density, mass of solids per total volume.
[b]Porosity, total volume of pores (liquid and gas phase) per total volume.
[c]Void ratio, total volume of pores (liquid and gas phase) per solid volume.
[d]Compacted subsoil.

0.05 mm and with a variety of sedimentation methods (e.g., pipet, hydrometer, laser light-scattering) for particles less than 0.05 mm.

Size Measurements

Size measurements depend on separating the soil into primary particles. Methods for soil analysis consist of disaggregating by washing, vibrating, or otherwise dispersing the soil into single units. Typically the larger particles are measured directly by tape, ruler, or calipers. Particles from 100 mm to 0.05 mm are sieved. Materials less than 2 mm are generally washed through a nest of screens for a given period of time after treating with some kind of soil dispersant such as sodium hexametaphosphate, which swamps the clay surfaces with sodium, causing dispersion of the clay materials and accelerating disaggregation. For tropical soils or soils with high organic, iron, or aluminum contents, special treatments are deployed to remove these binding agents and release the primary particles. Soils of volcanic ash origin are notorious for aggregation, and pretreatment by chemical or mechanical dispersion can significantly affect the amount of clay produced. In one test, researchers have demonstrated that the clay (less than 0.002 mm) content of a volcanic ash soil varies from 1% to 56% depending on the amount of pretreatment imposed on the sample. Some tropical soils consist largely of clay-size particles yet behave much like sands, in terms of their water-storage and related physical properties, because of the high degree of natural aggregation.

Fine Soil Measurements

Fine soil measurements rely on sedimentation of a soil suspension. The sample is stirred in water and dispersing agent, then the suspension is allowed to settle. Sampling is done at preselected times at a fixed depth in the suspension using either a pipet or hydrometer. Pipet techniques take a physical sample after a given settlement period, while hydrometer methods rely on estimates of effective densities of the settling particles. Knowing settlement depths allows for a straightforward calculation of the effective particle diameter. The Stokes law for viscous drag on a settling spherical object is combined with buoyant and gravitational forces to obtain the settlement rate. Combining forces and solving for the particle velocity yields:

$$v = d^2 g\,(\rho_p - \rho_w)/(18\eta) \qquad [1]$$

where d is equivalent particle diameter, g is gravity acceleration, ρ_p is particle density, ρ_w, is solution density, and η is solution viscosity.

Figure 1 shows the pipet method and Figure 2 shows a typical hydrometer used for soil-solution density measurements. This equipment is relatively inexpensive and readily available and, for routine analysis in soils, sedimentation, and engineering laboratories, the pipet and hydrometer are the standard tools for fine-fraction analysis. In recent years, the need for diagnostic tools in soil genesis and mineralogy have led to more sophisticated techniques being developed and tested. Laser light-scattering techniques are now being used in soil science more routinely to obtain size distributions of soil materials. Figure 3 shows the primary components of a laser light-scattering device.

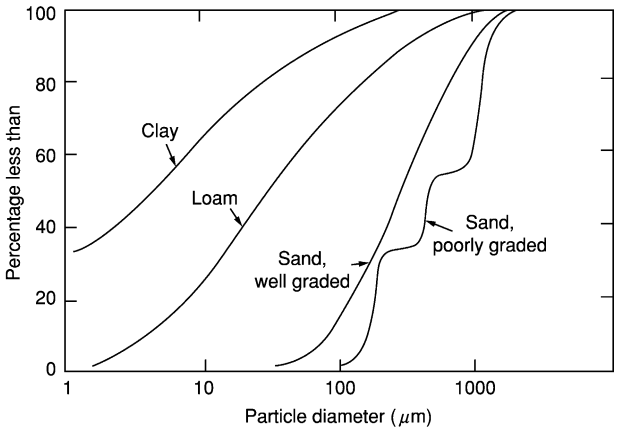

Figure 4 Particle-size distribution curves for several soil. (Adapted from Hillel D (1980) *Fundamentals of Soil Physics*. New York: Academic Press.)

Figure 4 shows particles-size distribution for a range of soils. All but the poorly sorted sand exhibit log-normal characteristics and might be considered fractal in nature. Much has been made about the fractal nature of particle-size distributions of soils and the possibility of relating the fractal dimension of the particle size to an equivalent pore-size distribution and then subsequently obtaining estimates of hydraulic properties from these parameters. In spite of this temptation, recent analysis suggests that many soils are actually multifractal, that is, they do not have the same fractal dimension over the entire particle-size range, so caution must be exercised in extrapolating fractal parameters beyond the range over which they might apply. Nevertheless, particle-size distribution curves are very useful and can help diagnose the origins of a soil as well as estimate numerous physical and chemical properties.

Figure 5 shows how various methods (sieving, sedimentation, and laser methods) are combined to obtain the size distribution of a soil sample. It appears that, with proper calibration and similar pretreatments (i.e., chemical and physical pretreatment), different methods can yield comparable results.

Size and Textural Classification Schemes

There are more than a dozen different schemes for classifying size separates. Figure 6 shows four of the more common schemes, including the size limits used in each scheme and the mesh numbers for the screens used in sieving the particles. Note that the size separates have arbitrary size limits, and for the most part the differences between schemes are relatively small, with division between the International Society of

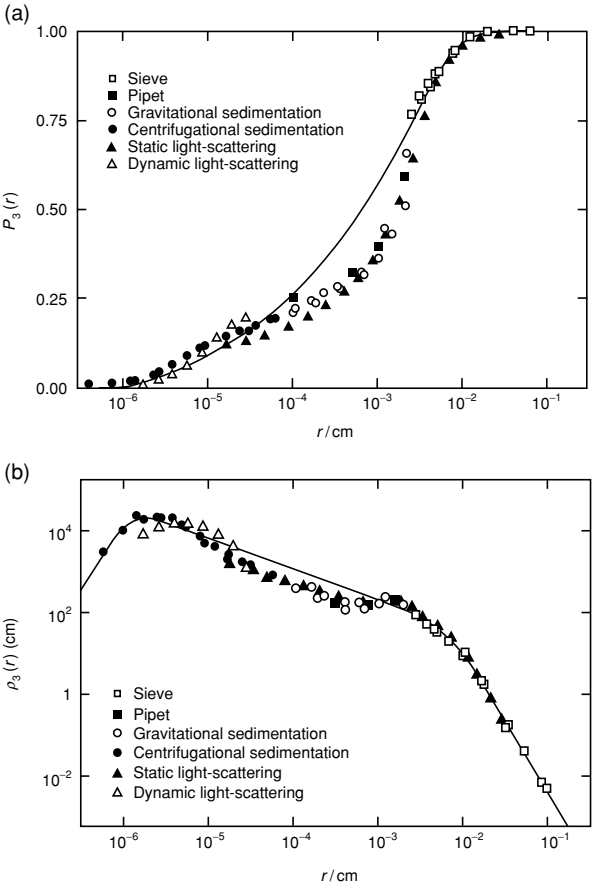

Figure 5 Cumulative mass distribution $P_3(r)$ (a) and number distribution density $\rho_3(r)$ for Buchberg soil as a function of particle radius for different measurement methods (solid lines represent empirical fit of three power-law functions). (Reproduced with permission from Wu Q, Borkovec M, and Sticher H (1993) On particle size distributions in soils. *Soil Science Society of America Journal* 57: 883–890.)

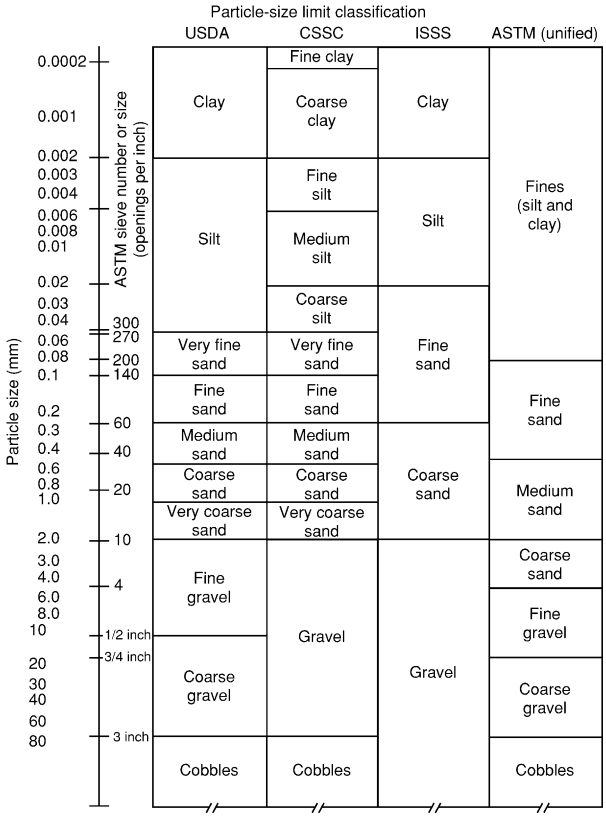

Figure 6 Particle-size limits according to several current classification schemes. USDA, US Department of Agriculture; CSSC, Canada Soil Survey Committee; ISSS, International Society of Soil Science; ASTM, American Society of Testing and Materials. (Adapted from Soil Survey Staff (1975); and McKeague JA (ed.) (1978) *Manual on Soil Sampling and Methods of Analysis*. Ottawa, Canada: Canadian Society of Soil Science.)

Soil Science (ISSS) and the US Department of Agriculture (USDA) classification being primarily the separation between the sand and clay fractions, with ISSS defining the uppermost silt limit at 0.02 mm and the USDA upper silt limit defined at 0.05 mm. Conversions from one system to another have been made and incorporated into user-friendly computer programs that translate one system readily into the another.

Textural Classification

Since soils rarely consist of one size range, textural classification is based on different combinations of size separates. The classification schemes that have been developed are as diverse as the applications for which the textural data are used. Two primary textural classifications are discussed, the universal classification scheme, used in engineering and adopted by the American Society of Testing and Materials (ASTM), and the USDA scheme that is widely used in agronomic science.

Universal classification (engineering) scheme Table 2 shows the engineering classification scheme used by the ASTM. In order to use this textural scheme, particle-size distribution is needed and certain engineering properties are required. From the size-distribution curve, the coefficient of curvature, C_c, can be obtained as:

$$C_c = (D_{30})^2/(D_{10} \times D_{60}) \quad [2]$$

where D_{60}, D_{30}, and D_{10} are the particle sizes corresponding to 60, 30, and 10% finer on the cumulative particle size distribution curve (Figure 7) and C_u, the coefficient of uniformity, is obtained as:

$$C_u = D_{60}/D_{10} \quad [3]$$

These properties are helpful in defining the types of gravel or sand that are present. C_u and C_c are shown in Figure 7 for a coarse soil. In this case, $C_u = 200$ and $C_c = 5.6$. If less than 5% of the sample passes the 200-mesh (0.075 mm) sieve, this soil is classed as a poorly graded gravel, GP. The other engineering properties are measures of the amount and type of fine materials present in the soil and are obtained from the liquid limit (LL) and plasticity index (PI). These properties (the so-called Atterberg limits) are obtained from standard methods and generally plotted on a PI versus LL diagram (Table 2). High LLs imply high clay content, and high PI implies the presence of swelling-type clays (e.g., smectites). Swelling clays such as smectites are typically more plastic than nonswelling clays (e.g., kaolinites). Kaolinitic clays are not plastic and grade out as materials that fall below the 'A' line on the PI versus LL curve (Table 2). In total, 16 different textural classes are used for engineering purposes, ranging from well-graded gravel (WG) to silts and clay (CH) and organic soils (PT).

USDA classification For agronomic and other soil-science applications, the textural designations are quite straightforward. It is assumed that the organic fraction is minimal and that only three size separates, sand, silt, and clay fractions, are being considered. In the USDA system, the fractions of the three size separates, sand (2–0.05 mm), silt (0.05–0.002 mm), and clay (0.002 mm) are plotted and 12 distinct textures are assigned according to the mix of separates (Figure 8). For the textural diagram, the assumption is:

$$m_d + m_t + m_y = 1 \quad [4]$$

where m_d is size fraction of sand, m_t is size fraction of silt, and m_y is size fraction of clay. Only two fractions are required to obtain texture from the textural triangle.

Table 2 Unified soil classification system, including plasticity chart

Criteria for assigning group symbols and names using laboratory tests[a]				*Soil classification*	
				Group symbol	*Group name*[b]
Coarse-grained soils more than 50% retained on No. 200 sieve	Gravels more than 50% of coarse fraction retained on No. 4 sieve	Clean gravels less than 5% fines[c]	$C_u > 4$ and $1 < C_c < 3$[e]	GW	Well-graded gravel[f]
			$C_u < 4$ and/or $1 > C_c > 3$[e]	GP	Poorly graded gravel[f]
		Gravels with fines more than 12% fines[c]	Fines classify as ML or MH	GM	Silty gravel[f,g,h]
			Fines classify as CL or CH	GC	Clayey gravel[f,g,h]
	Sands 50% or more of coarse fraction passes, No. 4 sieve	Clean sands less than 5%	$C_u > 6$ and $1 < C_c < 3$[e]	SW	Well-graded sand[i]
			$C_u < 6$ and/or $1 > C_c > 3$[e]	SP	Poorly graded sand[i]
		Sands with fines more than 12% fines[d]	Fines classify as ML or MH	SM	Silty sand[g,h,i]
			Fines classify as CL or CH	SC	Clayey sand[g,h,i]
Fine-grained soils 50% or more passes, No. 200 sieve	Silts and clays liquid limit less than 50	Inorganic	PI > 7 and plots on or above 'A' line[j]	CL	Lean clay[k,l,m]
			PI < 4 or plots below 'A' line[j]	ML	Silt[k,l,m]
		Organic	Liquid limit – oven-dried < 0.75 Liquid limit – not dried	OL	Organic clay[k,l,m,n] Organic silt[k,l,m,o]
	Silts and clays liquid limit 50 or more	Inorganic	PI plots on or above 'A' line	CH	Fat clay[k,l,m]

Use of Texture Data for Estimating Hydraulic Properties

Soil scientists use soil-texture information to make qualitative judgments about a number of physical properties, but, until recently, there have been limited attempts to use texture for quantitative assessments of soil properties. Because the division of particles into size classes is entirely arbitrary, it is not surprising that texture data do not generally relate directly to fundamental physical properties. For example, it is not easy to determine how much silt it takes to equal a unit of clay, or if silt and sand fractions have any effect on a particular soil property of interest. In addition, there are underlying issues of soil mineralogy, organic versus inorganic fraction, particle-shape factors, and aggregation that complicate matters, so that the use of particle size data often requires some degree of empiricism in relating to such things as water-retention characteristics or effective surface area.

A more fundamental approach for describing soil texture is to use a statistical description for the particle-size distribution. A basic property of soil is the mean effective particle diameter. Particle-size distributions tend to be log-normal or fractal, so the appropriate means and standard deviations are log means and log standard deviations. These can be computed as:

$$d_g = \exp\left(\sum_i m_i \ln d_i\right) \quad [5]$$

$$\sigma_g = \exp\left(\sqrt{\sum_i m_i (\ln d_i)^2 - (\ln d_g)^2}\right) \quad [6]$$

where d_g is geometric mean diameter (in micrometers), m_i is mass fraction of component i (in grams), d_i is mean diameter of component i (in micrometers), and σ_g is geometric standard deviation (in micrometers).

When sand, silt, and clay fractions are known, the geometric mean diameter and the geometric standard deviation can be estimated in terms of the silt and clay fractions by using the following expressions:

$$d_g = \exp(5.756 - 3.454\, m_t - 7.712\, m_y) \quad [7]$$

$$\sigma_g = \exp[33.14 - 27.84\, m_t - 29.13\, m_y - (\ln d_g)^2]^{1/2} \quad [8]$$

where m_t is mass fraction of silt and m_y is mass fraction of clay.

Table 3 shows typical silt and clay fractions, geometric mean particle diameter, and geometric standard deviation for the 12 textural classes of the USDA classification scheme as identified in Figure 7. The standard textural triangle (Figure 7) can be transformed into a diagram based on the geometric mean particle size and the geometric mean standard deviation. From such a construct, textures can be interpreted in terms of more quantitative relationships. Coarser-soil soils can be easily incorporated into such a scheme. The standard textural triangle ignores the soil fraction greater than 2 mm. Frequently there is a need to incorporate this fraction into the size distribution, particularly when hydrologic properties such as water retention and unsaturated hydraulic conductivity are of interest.

Table 3 Typical silt and clay fractions and geometric mean particle diameter and geometric standard deviation for the 12 US Department of Agriculture textural classes

Texture	*Silt fraction*	*Clay fraction*	d_g (μm)	σ_g (μm)
Sand	0.05	0.03	212	4.4
Loamy sand	0.12	0.07	122	8.7

Clay	0.20	0.60	1.5	22.8

Summary

Much effort has been expended in recent years to develop methods that relate particle-size distribution to pore size and subsequently to a host of other soil properties such as water retention and unsaturated hydraulic conductivity. While this is appealing, particularly when particle-size distribution data are available and other data are absent, this approach must be viewed with caution, because the particle-size distribution data obtained in most routine applications are at best empirical in nature. It needs to be pointed out that while particle-size distributions are important and offer what is often considered the most fundamental properties of a soil, the actual size distribution obtained from a laboratory analysis is almost always dependent upon the method used to obtain the particle-size distribution. As an example, researchers have found that some soils of volcanic ash origin have clay-sized particles that show great resistance to dispersion when subjected to gentle shaking but break down under high-energy source treatment. The chemical pretreatment and amount of mechanical work done on the soil are dictated by arbitrary decisions, so there is no absolute size distribution for a given soil. Because we are dealing with natural systems, we must rely on empirical methods and arbitrary limits and thus are constrained by the methods deployed to obtain size distributions and, resulting textural descriptions for soils.

THERMAL PROPERTIES AND PROCESSES

D Hillel, Columbia University, New York, NY, USA

Introduction

The soil temperature, as it varies in time and space, is a factor of primary importance in determining the rates and directions of soil physical processes and of energy and mass exchange with the atmosphere. Temperature governs evaporation and aeration, as well as the types and rates of chemical reactions that take place in the soil. Finally, soil temperature strongly influences biological processes such as seed germination, seedling emergence and growth, root development, and microbial activity.

Soil temperature varies in response to changes in the radiant, thermal, and latent energy exchange processes that take place primarily through the soil surface. The effects of these phenomena are propagated into the soil profile via a complex series of transport processes, the rates of which are affected by time-variable and space-variable soil properties.

Modes of Energy Transfer

In general, there are three principal modes of energy transfer: radiation, convection, and conduction. By radiation, we refer to the emission of energy in the form of electromagnetic waves from all bodies above 0 K. According to the Stefan–Boltzmann law, the total energy emitted by a body, J_t, integrated over all wavelengths, is proportional to the fourth power of the absolute temperature T of the body's surface. This law is usually formulated:

$$J_t = \epsilon\sigma T^4 \qquad [1]$$

where σ is a constant and ϵ is the emissivity coefficient, which equals unity for a perfect emitter (generally called a 'black body'). The absolute temperature also determines the wavelength distribution of the emitted energy. The Wien law states that the wavelength of maximal radiation intensity λ_m is inversely proportional to the absolute temperature:

$$\lambda_m = 2900/T \qquad [2]$$

where λ_m is in micrometers. The actual intensity distribution as a function of wavelength and temperature is given by Planck's law:

$$E_\lambda = C_1/\lambda^5[\exp(C_2/\lambda T) - 1] \qquad [3]$$

where E_λ is energy flux emitted in a given wavelength range and C_1 and C_2 are constants.

Since the temperature of the soil surface is generally of the order of 300 K (though it can range from below 273 K, the freezing point, to 330 K or higher), the radiation emitted by the soil surface has its peak intensity at a wavelength of approximately 10 μm and its wavelength distribution over the range of 3–50 μm. This is in the realm of infrared, or heat, radiation.

A very different spectrum is emitted by the sun, which acts as a black body at an effective surface temperature of approximately 6000 K. The sun's radiation includes the visible light range of 0.3–0.7 μm, as well as some infrared radiation of greater wavelength (up to approx. 3 μm) and some ultraviolet radiation ($\lambda < 0.3$ μm). Since there is very little overlap between the two spectra, it is customary to distinguish between them by calling the incoming solar spectrum 'short-wave' radiation, and the spectrum emitted by the Earth 'long-wave' radiation.

The second mode of energy transfer, called 'convection,' involves the movement of a heat-carrying mass, as in the case of ocean currents or atmospheric winds. An example more pertinent to soil physics would be the infiltration of warm waste water (from, e.g., a power plant) into an initially cold soil.

Conduction, the third mode of energy transfer, is the propagation of heat within a body by internal molecular motion. Since temperature is an expression of the kinetic energy of a body's molecules, the existence of a temperature difference within a body will normally cause the transfer of kinetic energy by the numerous collisions of rapidly moving molecules from the warmer region of the body to their neighbors in the colder region. The process of heat conduction is thus analogous to diffusion and, in the same way that diffusion tends in time to equilibrate a mixture's composition throughout, heat conduction tends to equilibrate a body's internal distribution of molecular kinetic energy – that is, its temperature.

In addition to the three modes of energy transfer described, there is a composite phenomenon which one may recognize as a fourth mode, namely latent heat transfer. A prime example is the process of distillation, which includes the heat-absorbing stage of evaporation, followed by the convective or diffusive movement of the vapor, and ending with the heat-releasing stage of condensation. A similar catenary process can also occur in transition back and forth

from ice to liquid water in soils subject to freezing and thawing.

Energy Balance for a Bare Soil

The radiation balance of a bare soil surface can be written:

$$J_n = (J_s + J_a)(1 - \alpha) + J_{li} - J_{lo} \quad [4]$$

Here J_n is the net radiation, that is, the sum of all incoming-minus-outgoing radiant energy fluxes; J_s the incoming flux of short-wave radiation directly from the sun and J_a the short-wave diffuse radiation from the atmosphere (sky); J_{li} the incoming long-wave radiation flux from the sky and J_{lo} the outgoing long-wave radiation emitted by the soil; and, finally, α is the albedo, or reflectivity coefficient, which is the fraction of incoming short-wave radiation reflected by the soil surface rather than absorbed by it. In the present context, all terms that do not pertain to the soil, namely J_s, J_a, and J_{li}, are disregarded.

The albedo α is an important characteristic of soil surfaces, and it can vary widely in the range of 0.1–0.4, depending upon the soil's basic color (whether dark or light), the surface's roughness, and the inclination of the incident radiation relative to the surface. In the short term, the albedo also depends on the changing wetness of the exposed soil. The drier the soil, the smoother its surface, and the brighter its color, the higher its albedo. To a certain extent, the albedo can be modified by various surface treatments such as tillage and mulching.

Apart from the reflected short-wave radiation, the soil also emits long-wave radiation. In accordance with eqn [1], the emitted flux J_{lo} depends primarily on soil surface temperature but is also affected by the soil's emissivity. This parameter, in turn, depends on soil wetness, but its range of variation is generally small, i.e., between 0.9 and 1.0.

The net radiation received by the soil surface is transformed into heat, which warms the soil and air and vaporizes water. We can write the surface energy balance as follows:

$$J_n = S + A + LE \quad [5]$$

where S is the soil heat flux (the rate at which heat is transferred from the surface downward into the soil profile), A is the 'sensible' heat flux transmitted from the surface to the air above, and LE is the evaporative heat flux, a product of the evaporative rate E and the latent heat per unit quantity of water evaporated, L.

The total surface energy balance (combining eqns [4] and [5]) is therefore:

$$(J_s + J_a)(1 - \alpha) + J_{li} - J_{lo} - S - A - LE = 0 \quad [6]$$

Conventionally, all components of the energy balance are taken as positive if directed toward the surface, and negative otherwise.

Conduction of Heat in Soil

The conduction of heat in solid bodies was analyzed as long ago as 1822 by Fourier, whose name is associated with the linear transport equations that have been used ever since to describe heat conduction. The first law of heat conduction, known as the Fourier law, states that the flux of heat in a homogeneous body is in the direction of, and proportional to, the temperature gradient:

$$q_h = -\kappa \nabla T \quad [7]$$

Here q_h is the thermal flux (i.e., the amount of heat conducted across a unit cross-sectional area in unit time), κ is thermal conductivity, and ∇T the spatial gradient of temperature T. In one-dimensional form, this law is written:

$$q_h = -\kappa_x \partial T/\partial x \quad \text{or} \quad q_h = -\kappa_z \partial T/\partial_z \quad [8]$$

Here $\partial T/\partial x$ is the temperature gradient in any arbitrary direction designated x, and $\partial T/\partial z$ is, specifically, the gradient in the vertical direction representing soil depth ($z = 0$ being the soil surface). The subscripts attached to the thermal conductivity term are meant to account for the possibility that this parameter may have different values in different directions (i.e., that it may be nonisotropic). The negative sign in these equations is due to the fact that heat flows from a higher to a lower temperature (i.e., in the direction of, and in proportion to, a negative temperature gradient).

Equation [7] is sufficient to describe heat conduction under steady-state conditions, that is, where the temperature at each point in the conducting medium is invariant and the flux is constant in time and space. To account for nonsteady (transient) conditions, we need a second law analogous to Fick's second law of diffusion. To obtain the second law of heat conduction, the principle of energy conservation in the form of the continuity equation is invoked, which states that, in the absence of any sources or sinks of heat, the time rate of change in heat content of a volume element of the conducting medium must equal the change of flux with distance:

$$\rho c_m \partial T/\partial t = -\nabla \cdot q_h \quad [9]$$

where ρ is mass density and c_m specific heat capacity per unit mass (called simply 'specific heat' and

defined as the change in heat content of a unit mass of the body per unit change in temperature). The product ρc_m (often designated C) is the specific heat capacity per unit volume, and $\partial T/\partial t$ is the time rate of temperature change. Note that ρ represents the total mass per unit volume, including the mass of water in the case of a moist soil. The symbol ∇ ('del') is the shorthand representation of the three-dimensional gradient. An equivalent form of eqn [9] is:

$$\rho c_m \partial T/\partial t = -(\partial q_x/\partial x + \partial q_y/\partial y + \partial q_z/\partial z)$$

where x, y, z are the orthogonal direction coordinates.

Combining eqn [9] with [7] gives the second law of heat conduction:

$$\rho c_m \partial T/\partial t = -\nabla \cdot (\kappa \nabla T) \quad [10]$$

which, in one-dimensional form, is:

$$\rho c_m \partial T/\partial t = \partial/\partial x(\kappa \partial T/\partial x) \quad [11]$$

Sometimes there is need to account for the possible occurrence of heat sources or sinks in the realm where heat flow takes place. Heat sources include such phenomena as organic matter decomposition, wetting of initially dry soil material, and condensation of water vapor. Heat sinks are generally associated with evaporation. Combining all these sources and sinks into a single term S, we can rewrite the last equation:

$$\rho c_m \partial T/\partial t = \partial/\partial x(\kappa \partial T/\partial x) \pm S(x,t) \quad [12]$$

in which the source–sink term is shown as a function of both space and time.

Volumetric Heat Capacity of Soils

The volumetric heat capacity C of a soil is defined as the change in heat content of a unit bulk volume of soil per unit change in temperature. Its units are calories per cubic centimeter per degree (Kelvin) or joules per cubic meter per degree. As such, C depends on the composition of the solid phase (mineral and organic constituents) of the soil, on bulk density, and on soil wetness (Table 1).

The value of C can be estimated by summing the heat capacities of the various constituents, weighted according to their volume fractions:

$$C = \sum f_{si} C_{si} + f_w C_w + f_a C_a \quad [13]$$

Here, f denotes the volume fraction of each phase: solid (subscripted 's'), water ('w'), and air ('a'). The solid phase includes a number of components subscripted 'i,' such as various minerals and organic matter, and the symbol Σ indicates the summation of the products of their respective volume fractions and heat capacities. The C value for water, air, and each component of the solid phase is the product of the particular density and the specific heat per unit mass (i.e., $C_w = \rho_w c_{mw}$; $C_a = \rho_a c_{ma}$; $C_{si} = \rho_{si} c_{msi}$).

Table 1 Densities and volumetric heat capacities of soil constituents (at 10°C) and of ice (at 0°C)

	Density ρ		*Heat capacity C*	
Constituent	*g cm^{-3}*	*kg m^{-3}*	*cal cm^{-3} K*	*J m^{-3} K*
Quartz	2.66	2.66×10^3	0.48	2.0×10^6
Other minerals (mean)	2.65	2.65×10^3	0.48	2.0×10^6
Organic matter	1.3	1.3×10^3	0.6	2.5×10^6
Water (liquid)	1.0	1.0×10^3	1.0	4.2×10^6
Ice	0.92	0.92×10^3	0.45	1.9×10^6
Air	0.001 25	1.25	0.003	1.25×10^3

Reproduced with permission from Hillel D (1998) *Environmental Soil Physics*. San Diego, CA: Academic Press.

Most of the minerals composing soils have nearly the same values of density (approx. 2.65 g cm^{-3} or 2.65×10^3 kg m^{-3}) and of heat capacity (0.48 cal cm^{-3} K or 2.0×10^6 J m^{-3} K). Since it is difficult to separate the different kinds of organic matter present in soils, it is tempting to group them all into a single constituent (with mean density of approximately 1.3 g cm^{-3} or 1.3×10^3 kg m^{-3}, and a mean heat capacity of approximately 0.6 cal cm^{-3} K or 2.5×10^6 J m^{-3} K).

The density of water is less than half that of mineral matter (approx. 1 g cm^{-3} or 1.0×10^3 kg m^{-3}); its specific heat is more than twice as large (1 cal cm^{-3} K, or 4.2×10^6 J m^{-3} K). Finally, since the density of air is only approximately 1/1000 that of water, its contribution to the specific heat of the composite soil can be neglected generally.

Thermal Conductivity of Soils

Thermal conductivity, designated κ, is defined as the quantity of heat transferred through a unit area of the conducting body in unit time under a unit temperature gradient. As shown in Table 2, the thermal conductivities of specific soil constituents differ very markedly (see also Table 3). Hence the space-averaged (macroscopic) thermal conductivity of a soil depends upon its mineral composition and organic matter content, as well as on the volume fractions of water and air.

Since the thermal conductivity of air is very much smaller than that of water or solid matter, a high air content (or low water content) corresponds to a low

thermal conductivity. Moreover, since the proportions of water and air vary continuously, κ is also time-variable. Soil composition is seldom uniform in depth, hence κ is generally a function of depth as well as of time. Unlike heat capacity, thermal conductivity is sensitive not merely to the volume composition of a soil but also to the sizes, shapes, and spatial arrangements of the soil particles.

The relationship between the overall thermal conductivity of a soil and the specific conductivities and volume fractions of the soil's constituents is very intricate, as it involves the internal geometry or structure of the soil matrix and the mode of transmission of heat from particle to particle and from phase to phase.

The dependence of thermal conductivity and diffusivity on soil wetness is illustrated in **Figure 1**. The influence of latent heat transfer by the diffusion of water vapor in the air-filled pores is proportional to the temperature gradient in these pores. It can be taken into account by adding to the thermal conductivity of air an apparent conductivity due to evaporation, transport, and condensation of water vapor (the so-called vapor-enhancement factor). This value is strongly temperature-dependent and rises rapidly with increasing temperature.

Because soil water potential depends on temperature, the development of a temperature gradient generally induces the movement of water as well as of heat. Hence techniques for measuring heat transfer through a soil sample based on steady-state heat flow between two planes maintained at a constant temperature differential involve the risk of changing the sample's internal moisture distribution and therefore its thermal properties. During the process of measurement, the soil near the warmer plane becomes drier, while that near the cooler plane becomes wetter. Early attempts to measure thermal conductivity failed to recognize this pitfall as they purported to maintain constant soil moisture conditions during prolonged, steady-state heat flow. Hence their results can only be considered approximations at best. While steady-state methods may be sufficiently accurate for measuring thermal conductivity of dry soils, short-term, transient heat-flow techniques are preferable, in principle, for moist soils.

Table 2 Thermal conductivities of soil constituents (at 10°C) and of ice (at 0°C)

Constituent	*mcal cm^{-1} sK*	*Wm^{-1} K*
Quartz	21	8.8
Other minerals (average)	7	2.9
Organic matter	0.6	0.25
Water (liquid)	1.37	0.57
Ice	5.2	2.2
Air	0.06	0.025

Simultaneous Transport of Heat and Moisture

The flows of water and of thermal energy under nonisothermal conditions in the soil are interactive phenomena: the one entails the other. Temperature gradients affect the moisture potential field and induce both liquid and vapor movement. Reciprocally, moisture gradients move water, which carries heat. The simultaneous occurrence of temperature gradients and of moisture potential gradients in the soil therefore brings about the combined transport of heat and moisture.

Two separate approaches to the combined transfer of heat and moisture have been attempted: (1) a

mechanistic approach, based on a physical model of the soil system, and (2) a thermodynamic approach, based on the phenomenology of irreversible processes in terms of coupled forces and fluxes. Though starting from different points of view, the two approaches have been shown to be related and, properly formulated, can be cast into an equivalent mold.

The mechanistic approach is based on the concept of viscous flow of liquid water under the influence of gravity and of capillary and adsorptive forces, and on the concept of vapor movement by diffusion. Local 'microscopic-scale' thermodynamic equilibrium between liquid and vapor is assumed to exist at all times and at each point within the soil. The general differential equation describing moisture movement in a porous system under combined temperature and moisture gradients for unidimensional vertical flow is, accordingly:

$$\partial\theta/\partial t = \nabla \cdot (D_T \nabla T) + \nabla \cdot (D_w \nabla\theta) - \partial K/\partial z \quad [14]$$

where θ is volumetric wetness, t time, T absolute temperature, D_T the water diffusivity under a temperature gradient (the sum of the liquid and vapor diffusivities), D_w the water diffusivity under a moisture gradient, K the hydraulic conductivity, and z the vertical space coordinate. The last term on the right-hand side is due to the gravity gradient and becomes positive if z is taken to be increasing downwards.

The heat transfer equation is, similarly:

$$C_v \partial T/\partial t = \nabla \cdot (\kappa \nabla T) - L\nabla \cdot (D_{w,vap} \nabla\theta) \quad [15]$$

Here C_v is volumetric heat capacity, κ apparent thermal conductivity of the soil, L latent heat of vaporization of water, and $D_{w,vap}$ diffusivity for heat conveyed by water movement (mostly vapor). Equations [14] and [15] are of the diffusion type, involving θ- and T-dependent diffusivities as well as gradients of both θ and T.

Taken together, eqns [14] and [15] describe the coupled transport of moisture and heat in soils. The assumption of local thermodynamic equilibrium links the vapor pressure p_v to the matric potential ψ by the following relation: $p_v = p_{vs}h = p_{vs}\exp(Mg\psi/RT)$, where p_{vs} is the saturated vapor pressure at the particular temperature T, h relative humidity, M molar mass, g acceleration due to gravity, and R the universal gas constant.

The approach based on the thermodynamics of irreversible processes formulates a pair of phenomenological equations in which the fluxes of moisture q_w and heat q_h are expressed as linear functions of the moisture potential (e.g., pressure) gradient dp/dz and the temperature gradient dT/dz:

$$\begin{aligned} q_w &= -L_{ww}(1/T)dp/dz - L_{wh}(1/T^2)(dT/dz) \\ q_h &= -L_{hw}(1/T)dp/dz - L_{hh}(1/T^2)(dT/dz) \end{aligned} \quad [16]$$

The four phenomenological coefficients occurring in these equations (L_{ww}, L_{wh}, L_{hw}, L_{hh}, relating water flow to the water potential gradient, water flow to the thermal potential gradient, heat flow to the water potential gradient, and heat flow to the thermal potential gradient, respectively) are unknown functions of p (or θ) and T. According to the Onsager theorem, the cross-coupling coefficients L_{wh} and L_{hw} are equal when the fluxes and forces are properly formulated. Thus, the number of coefficients that must be measured is reduced.

An apparent advantage of the irreversible thermodynamics approach is that it makes no *a priori* assumptions regarding the mechanisms of the transport phenomena formulated. Hence it would seem to be less restrictive than a physical theory whose validity

is constrained at the outset by its mechanistic assumptions. The disadvantage of this approach, however, is precisely its failure to address itself to, and provide insight into, the nature and internal workings of the phenomena considered.

Thermal Regime of Soil Profiles

In nature, soil temperature varies continuously in response to the ever-changing meteorological regime acting on the soil–atmosphere interface. That regime is governed by a regular periodic succession of days and nights, and of summers and winters. Yet the regular diurnal and annual cycles are perturbed by such irregular episodic phenomena as cloudiness, cold waves, heat waves, rainstorms or snowstorms, and periods of drought. Add to these external influences the soil's own changing properties (i.e., temporal changes in reflectivity, heat capacity, and thermal conductivity as the soil alternately wets and dries, and the variation of all these properties with depth), as well as the influences of geographic location, vegetative cover, and, finally human management, and one can expect the thermal regime of soil profiles to be complex indeed.

The simplest mathematical representation of nature's fluctuating thermal regime is to assume that at all depths in the soil the temperature oscillates as a pure harmonic (sinusoidal) function of time around an average value. Assume that, although soil temperature varies differently at different depths in the soil, the average temperature is the same for all depths. A starting time ($t = 0$) is chosen such that the surface is at the average temperature. The temperature at the surface can then be expressed as a function of time (Figure 2):

$$T(0,t) = T_{ave} + A_0 \sin \omega t \qquad [17]$$

where $T(0,t)$ is the temperature at $z = 0$ (the soil surface) as a function of time t, T_{ave} is the average temperature of the surface (as well as of the profile), and A_0 is the amplitude of the surface temperature fluctuation (the range from maximum, or from minimum, to the average temperature). Finally, ω is the radial frequency, which is 2π times the actual frequency. In the case of diurnal variation, the period is 86 400 s (24 h), so $\omega = 2\pi/86\,400 = 7.27 \times 10^{-5}\,s^{-1}$. Note that the argument of the sine function is expressed in radians rather than in degrees.

The last equation is the boundary condition for $z = 0$. For the sake of convenience, let us assume that at infinite depth ($z = \infty$) the temperature is constant and equal to T_{ave}. Under these circumstances, the temperature at any depth z is also a sine function of time, as shown in Figure 3:

$$T(z,t) = T_{ave} + A_z \sin[\omega t + \phi(z)] \qquad [18]$$

in which A_z is the amplitude at depth z. Both A_z and $\phi(z)$ are functions of z but not of t. They can be determined by substituting the solution of eqn [18]

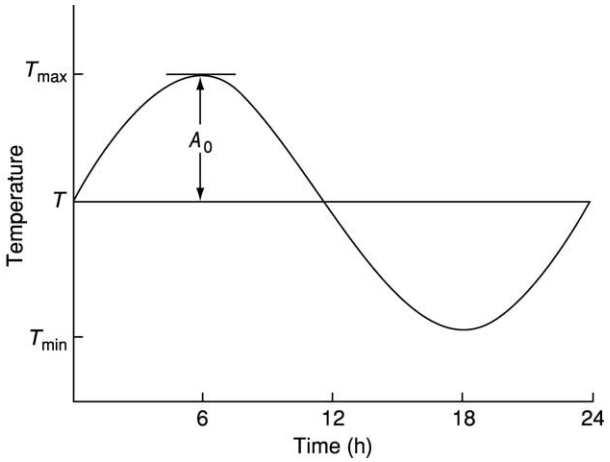

Figure 2 Idealized daily fluctuation of surface soil temperature, according to the equation: $T = T_{ave} + A_0 \sin(\omega t/p)$, where T is temperature, T_{ave} average temperature, A_0 amplitude, t time, and p period of the oscillation (in this case, p refers to the diurnal 24 h). (Reproduced with permission from Hillel D (1998) *Environmental Soil Physics*. San Diego, CA: Academic Press.)

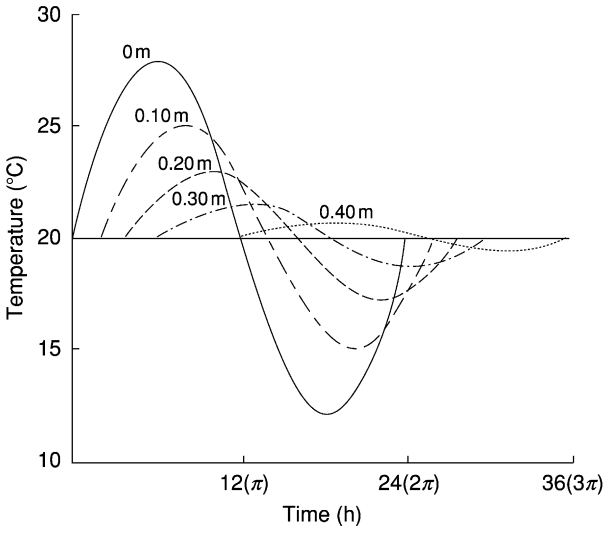

Figure 3 Idealized variation of soil temperature with time for various depths. Note that at each succeeding depth the peak temperature is damped and shifted progressively in time. Thus, the peak at a depth of 0.4 m lags about 12 h behind the temperature peak at the surface and is only about 1/16 of the latter. In this hypothetical case, a uniform soil was assumed, with a thermal conductivity of 1.68 $Jm^{-1}s^{-1}deg^{-1}$ (or 4×10^{-3} $cal\,cm^{-1}s^{-1}deg^{-1}$) and a volumetric heat capacity of 2.1×10^6 $Jm^{-3}deg^{-1}$ (0.5 $cal\,cm^{-3}deg^{-1}$). (Reproduced with permission from Hillel D (1998) *Environmental Soil Physics*. San Diego, CA: Academic Press.)

in the differential equation $\partial T/\partial t = \kappa(\partial^2 T/\partial z^2)$. This leads to the solution:

$$T(z,t) = T_{ave} + A_0[\sin(\omega t - z/d)]/e^{z/d} \qquad [19]$$

The constant d is a characteristic depth, called the 'damping depth,' at which the temperature amplitude decreases to the fraction $1/e$ ($1/2.718 = 0.37$) of the amplitude at the soil surface A_0. The damping depth is related to the thermal properties of the soil and the frequency of the temperature fluctuation as follows:

$$d = (2\kappa/C\omega)^{1/2} = (2D_h/\omega)^{1/2} \qquad [20]$$

At any depth the amplitude of the temperature fluctuation A_z is smaller than A_0 by a factor $e^{z/d}$, and there is a phase shift (i.e., a time delay of the temperature peak) equal to $-z/d$. The decrease in amplitude and increase in phase lag with depth are typical phenomena in the propagation of a periodic temperature wave in the soil (Figure 4).

The physical reason for the damping and retarding of the temperature waves with depth is that a certain amount of heat is absorbed or released along the path of heat propagation when the temperature of the conducting soil increases or decreases, respectively. The damping depth is related inversely to the frequency, as can be seen from eqn [20]. Hence it depends directly on the period of the temperature fluctuation considered. The damping depth is $(365)^{1/2} = 19$ times larger for the annual variation than for the diurnal variation in the same soil.

The annual variation of soil temperature down to considerable depth causes deviations from the simplistic assumption that the daily average temperature is the same for all depths in the profile. The combined effect of the annual and diurnal variation of soil temperature can be expressed by:

$$T(z,t) = T_{ave,y} + A_y[\sin(\omega_y t + \phi_y - z/d_y)]/e^{z/d_y} + A_d[\sin(\omega_d t + \phi_d - z/d_d)]/e^{z/d_d} \qquad [21]$$

where the subscripted indices y and d refer to the yearly and daily temperature waves, respectively. Thus $T_{ave,y}$ is the annual mean temperature. The daily cycles are now seen to be short-term perturbations superimposed upon the annual cycle. Vagaries of weather (e.g., spells of cloudiness or rain) can cause considerable deviations from simple harmonic fluctuations, particularly for the daily cycles. Longer-term climatic irregularities can also affect the annual cycle. The soil temperature profile as it varies seasonally is shown in Figure 4.

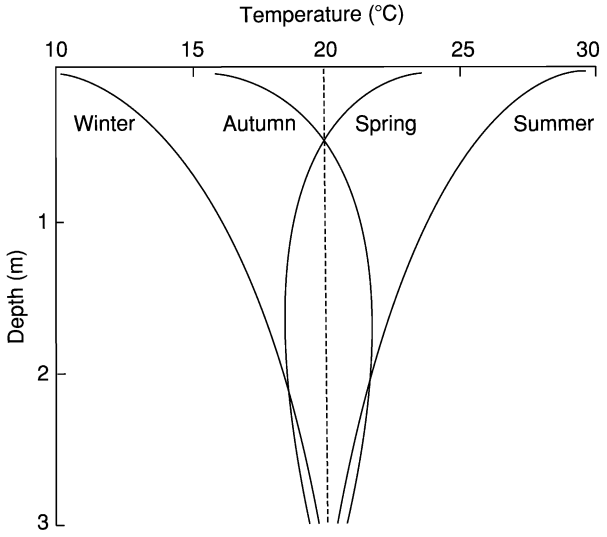

Figure 4 Soil temperature profile as it varies from season to season in a frost-free region. (Reproduced with permission from Hillel D (1998) *Environmental Soil Physics*. San Diego, CA: Academic Press.)

An alternative approach is possible, with fewer constraining assumptions. It is based on numerical rather than analytical methods for solving the differential equations of heat conduction. Mathematical simulation models relying on digital computers now allow soil thermal properties to vary in time and space (e.g., in response to periodic changes in soil wetness), so as to account for alternating surface saturation and desiccation and for profile-layering. They also allow various climatic inputs to follow more realistic and irregular patterns. The surface amplitude of temperature need no longer be taken to be an independent variable, but one that depends on the surface energy balance and thus is affected by both soil properties and above-soil conditions.

Other innovations of practical importance involve the development of techniques for monitoring the soil thermal regime more accurately and precisely than was possible previously. One such technique is the infrared radiation thermometer for scanning or remote sensing of surface temperature for both fallow and vegetated soils without disturbance of the measured surface. Knowledge of the surface temperature and its variation in time is important in assessing energy exchange between the soil and the overlying atmosphere, as well as in determining boundary conditions for within-soil heat transfer.

THERMODYNAMICS OF SOIL WATER

Introduction

The word 'thermodynamics' is derived from $\vartheta\epsilon\rho\mu$os (heat) and $\delta\upsilon\nu\alpha\mu\iota$s (force, power). It presents the science of all forms of energy and mass, including entropic ('waste') heat contained in the mass at ambient temperature. The origin of the word suggests that this branch of science deals with both the statics (equilibrium) and the dynamics (nonequilibrium) of energy and mass. Statics (classical thermodynamics) deals with the state of the system in which no heat or mass transfer occurs (this state is extremely rare in natural soils). Dynamics (nonequilibrium thermodynamics) deals with transport processes of mass and heat.

'Soil water' is often used interchangeably with the term 'soil moisture.' Here we distinguish between the two terms: 'soil water' indicating the chemical component H_2O in the soil and 'soil moisture' meaning the soil solution. Thermodynamics distinguishes the different chemical components in the system. It deals with the interaction between and transfer of these components and heat.

Classical (Equilibrium) Thermodynamics of Soil Water

The birth of thermodynamics is rather confusing. The founders tried to deal with such things as the effectiveness of steam engines (S. Carnot). R. Meyer, who was the first (in 1842) to publish the equivalence of work and heat, based his conclusion on his observations of the degree of 'redness' of human blood. No wonder that thermodynamics had a shaky start. The first mathematical formulation of the 'First Law of Thermodynamics' (the law of conservation of energy) came from Helmholtz and Joule in 1847. These scientists were dealing with systems that were 'on the move.' Yet the system had to be at equilibrium and the 'changes' had to be infinitesimally small and 'reversible' (meaning that the changes can be reversed without any loss of useful energy at the ambient temperature, or entropy production).

One would expect the First Law of Thermodynamics to equate integral values of the different forms of energy. Yet the equations always come in differential form first. At first only 'closed' systems were considered, implying that no mass could move into or out of the system. It was not until J. Willard Gibbs published his two great treatises, *The Equilibrium of Heterogeneous Substances* (in the *Transactions of the Connecticut Academy*, 1876 and 1878), that the 'system' was opened up and many of the mysteries of the previous 50 years were clarified. The *Transactions of the Connecticut Academy* were not widely read in Europe, and it was not until C.N. Lewis published his famous book in 1923, 20 years after Gibbs' death, that Gibbs' works became widely known. In the year of his retirement, Gibbs remarked that, during the 30 years of his teaching at Yale University, he estimated that only half a dozen of his students had benefited from his lectures.

We start with the integrated Gibbs equation:

$$E = U + \Psi = TS - PV + \sum_{i} \mu_i m_i + \sum_{i} \psi m_i \qquad [1]$$

where E is the energy of the system, U is the 'internal' energy, and Ψ is the energy derived from external force fields.

U consists of three 'blobs' of different forms of energy: the first one (TS) being the entropic energy (heat in the system at the ambient temperature T); the second one ($-PV$) being the energy the system has lost in order to create a volume, V, for itself to exist at the ambient pressure P; the third one being the sum of the chemical energy of each component (i) in the system, with m_i being the mass of component i and μ_i being the chemical potential of component i.

Ψ is derived from external force fields such as gravity or an electrical or magnetic field (in the gravity field $\Psi = gh$, g being the gravitational acceleration, and h the height above the reference level). If other forms of energy (such as kinetic energy or viscous stress energy) play a role in the transformations of energy, they should be added to eqn [1]. Although kinetic and viscous stress energy play a dominant role in energy transformations in the soil solution on the Navier–Stokes scale, on the Darcy scale they are almost always negligible and will therefore be ignored here.

The 'free' energy, G, was defined by Gibbs as:

$$G \equiv U - TS + PV = \sum_i \mu_i m_i \qquad [2]$$

Thus, μ_i is the specific (per unit mass) Gibbs free energy of constituent i.

The first expressions of the First Law were all in differential form, even after Gibbs 'opened up' the system:

$$\mathrm{d}U = T\mathrm{d}S - P\mathrm{d}V + \sum_i \mu_i \mathrm{d}m_i \qquad [3]$$

This is the differential form of the Gibbs equation. It is not trivial, because if one carries out the complete differentiation of eqn [1], one finds that, after subtraction of eqn [3] there is a 'leftover':

$$S\mathrm{d}T - V\mathrm{d}P + \sum_i m_i \mathrm{d}\mu_i = 0 \qquad [4]$$

This leftover is known as the Gibbs–Duhem equation.

From eqn [4] it follows that:

$$\mathrm{d}\mu_w = Sm_w^{-1}\mathrm{d}T - Vm_w^{-1}\mathrm{d}P + \sum_{(k\neq w)} m_k m_w^{-1}\mathrm{d}\mu_k \qquad [5]$$

This is the central equation in classical thermodynamics of soil water. It dictates how the chemical potential (specific Gibbs free energy) of water in the soil changes with the temperature, the pressure, and the composition of the soil solution.

The guiding principle is now that, when the system is in equilibrium, $\mathrm{d}\mu_w = 0$. The specific Gibbs free energy of water is the same everywhere, or, as far as water is concerned, there is no transport and no entropy production. In short, the water is at rest. The inverse statement, "when $\mathrm{d}\mu_w = 0$, the water is at rest," is not necessarily true and is not a fundamental principle of thermodynamics. It is possible that the last two terms of the right-hand side of eqn [5] (temporarily) balance each other, making $\mathrm{d}\mu_w = 0$, while both water and the solute are on the move and entropy is being produced. This is possible when 'leaky' semipermeable membranes are present. Heavy clay soils are excellent examples of leaky semipermeable membranes.

Therefore, the concept of the 'total' potential of the soil water (the sum of all the component potentials) is not very useful. When the whole system is at rest (complete equilibrium), then the total potential of the water is equal everywhere in the system.

But, when the total potential of the water is equal everywhere, this does not necessarily mean that the water is at rest. The gradient of the total potential is not the appropriate driving force in the flux equation of water. This will become clearer in the section on nonequilibrium thermodynamics, below.

The apprentice in thermodynamics often asks: "What is the practical use of all this?" Thermodynamics is still not a coherent, comprehensive science. Developments are still happening haphazardly. Some scientists, such as Clifford Truesdell, have complained bitterly about the inconsistencies and the lack of mathematical rigor, using words such as "thermodynamics was approached through detours in the fog of word-play." Here, only two of the practically useful results will be discussed.

The Tensiometer (and the Pressure Membrane Apparatus)

Early scientists such as L.A. Richards, G.H. Bolt, and M.J. Frissel, working on the thermodynamics of soil moisture, immediately realized that water in the soil is present in the soil solution and that the soil solution is never pure water. The soil solution contains dissolved salts and ions, as well as counterions, that is, a surplus of cations, necessary to counterbalance the surplus of electrons present in the lattices of clay particles. The electrical double layer acts as an osmometer and the counterions cause a volume element of the solution, close to a clay surface, to carry a volume charge. This gives the soil solution an additional opportunity to possess energy (in the presence of an electrical field). In addition, there are microforce fields acting on the solution that is in close proximity of solid surfaces (London–Van der Waals forces). All this implies that eqn [5] should contain a few more terms if the thermodynamic system were chosen on the Navier–Stokes scale.

The first requirement in soil physics is to formulate and assess the hydrostatics of soil water, i.e., establish

the characteristic relationships when the water is at rest. There are no 'membranes' in nature or in the laboratory that are semipermeable to heat. Thus, when a system is brought to equilibrium, the temperature will be the same everywhere. The energy level in the external force fields, such as gravity, can easily be established separately. In order to measure the energy level of soil water derived from internal force fields (menisci, electrical double layers, London–Van der Waals forces), it is now advantageous to bring the soil solution in equilibrium with either a compartment containing a solution that reflects the composition of the soil solution or one that contains pure water. There are membranes that are ('perfectly') semipermeable to all dissolved materials in the soil solution. In the latter case (using a perfect osmometer and measuring the hydrostatic pressure in the osmometer with respect to atmospheric pressure), the energy level of the soil water is measured at the ambient temperature and at the particular position in the external force field that results from all internal force fields plus all dissolved materials (the total osmotic pressure of the soil solution). In the former case, using a perfectly 'leaky' membrane such as the sintered ceramic cup (tensiometer cup) or a Visking membrane in a pressure plate apparatus, the solution inside the compartment (tensiometer cup) will reflect the composition of the 'free salts' in the soil solution and will show the 'equilibrium' solution. By measuring the hydrostatic pressure in a tensiometer with respect to atmospheric pressure, the energy level of all internal force fields is measured (including electrical double layers), excluding the free salt. This energy level is called the 'matric potential.' The counterions cannot equilibrate in the tensiometer cup. They act as internal miniosmometers and can be considered part of the matrix (the solid phase of the soil). Because most soils are quite 'leaky' as far as the exclusion of dissolved materials is concerned, the water in the soil moves largely as a solution. Therefore the gradient of the matric potential is the dominant driving force on the soil water (in addition to the force of the gravitational field). The imperfect semipermeability of a clay soil, causing osmotic pressure differences to drive the water, will be dealt with in the section Nonequilibrium Thermodynamics of Soil Water, below. The action of osmotic pressure gradients will then be formulated as 'capillary' osmosis and the imperfect semipermeability will be evaluated by the 'reflection coefficient.'

The Maxwell Relations and Their Use in the Hydrostatics of Swelling Soils

One of the many complaints about the lack of mathematical rigor lies in its origin: a closed pot on a bench in a chemistry laboratory. Temperature and pressure are allowed to change in steps, ΔT and ΔP, although only in small steps, δT and δP. But entropy production is not allowed and therefore the steps have to be infinitesimally small, dT and dP. They begin to look like a differential, but differential with respect to what? Time or space? Everything becomes cleaner when the denominator of the differential is specified. This first comes about, while still in the realm of classical thermodynamics, when a cross-differentiation is performed on the differential form of the Gibbs equation. This leads to the Maxwell relations, several of which can be constructed. Many more can be found after performing Legendre transforms on the Gibbs free energy. Most of the Maxwell relations are quite useless, but occasionally one finds a gem. One example is a Maxwell relation for shrinking soils. For many decades soil scientists have searched for an expression for the differential of the matric potential (tensiometer pressure), p, with respect to the load (or overburden pressure), P, at constant ratio of mass of water and mass of solids. Here, both the dependent and the independent variable are intensive variables. The appropriate Maxwell relation shows that the above differential is equal to the differential relationship between the void ratio (volume of voids per volume of solids), e, and the moisture ratio (volume of water per volume of solids) at constant load pressure, P. Here, both the dependent and the independent variable are extensive variables.

Thus:

$$\mathrm{d}p(\mathrm{d}P)^{-1} \text{ at constant } m_{\mathrm{w}}(m_{\mathrm{solids}})^{-1} = \mathrm{d}e(\mathrm{d}\vartheta)^{-1} \quad [6]$$

at constant P. This means that the behavior of the tensiometer reading can be predicted upon loading from the slopes of the shrinkage lines for different values of P. Because the shrinkage lines for different values of P are nearly parallel, one only needs to measure the unloaded shrinkage line in order to predict how the tensiometer reading changes when moving deeper into the soil profile or upon loading by machinery.

Nonequilibrium Thermodynamics of Soil Water

The thermodynamic 'system' is now chosen to be a unit volume element in the soil solution. All the extensive variables are expressed per unit volume. Subsequently, each of the terms of the differential form of the Gibbs equation (eqn [3]) are written as differentials with respect to time.

The mathematical sloppiness of classical thermodynamics disappears once the terms of the differential

form of the Gibbs equations are transformed into proper time differentials and the realm of nonequilibrium thermodynamics is entered.

Next, for each of the terms separately, an appropriate conservation (continuity) equation is constructed. The general form of such a conservation equation shows that the change of the content of the entity of concern, with time, is equal to the negative of the divergence of the flux of that entity (inflow minus outflow), plus or minus one or more source or sink terms. Thus, for the entropic energy term:

$$\mathrm{d}\left(SV^{-1}\right)\mathrm{d}t^{-1} = -\mathrm{div}\ j_s + \sigma \qquad [7]$$

where SV^{-1} is the entropy per unit volume of solution, j_s is the flux of entropy, and σ is the entropy production term. This latter term plays a central role in nonequilibrium thermodynamics. If all the processes and forms of energy are accounted for, nothing is counted twice, and all algebra is carried out correctly, then the entropy production term is nonnegative. As the absolute temperature is always positive, the energy dissipation term, $T\sigma$, must also be nonnegative. When σ and thus $T\sigma$ are zero, the system is at equilibrium and nothing moves. If anything moves, then entropy is produced, and σ and $T\sigma$ are positive. Energy is being dissipated; that is, energy is transformed from useful energy to waste energy (i.e., heat at the ambient temperature). This is the Second Law of Thermodynamics.

As the first term on the right-hand side of Eqn [3] is already multiplied by T, one finds, after replacing the time differentials of the different terms in Eqn [3] by the right-hand side of their appropriate conservation equations, the product $T\sigma$ as the source term of entropy conservation equation. After all the appropriate substitutions are made, the term $T\sigma$ is singled out (written explicitly) and the equation is then called 'the (energy) dissipation function.'

On the right-hand side of the dissipation function, one usually finds the sum of a number of products of fluxes and forces. One may reshuffle these forces and the fluxes, under the strict principles that the rules of algebra are carried out correctly and that nothing is forgotten or counted twice.

The resulting complete expression for the energy dissipation is then the sum of products of fluxes and conjugated forces:

$$T\sigma = -j_q(\mathrm{grad}\ T) - j^V(\mathrm{grad}\ H) - j^D(\mathrm{grad}\ \pi) - j^E(\mathrm{grad}\ E) \qquad [8]$$

where j_q is the caloric (Fourier) heat flux, j^V is the (Darcy) flux of the soil solution, j^D is the (Fick) diffusion flux, and j^E is the electric current (usually indicated by I). grad π is the gradient of the osmotic pressure, and grad E is the gradient of the electrostatic potential.

The primary forms of energy dissipation are the dissipation of heat, pressure, mixing, and electrical energy. If simple linear, homogeneous transport equations are constructed relating a flux to its conjugated flux (the one that is occurring in the same product), the transport equations of Fourier (1822), Darcy (1856), Fick (1855), and Ohm (1827) are obtained. The disciplines of physics and chemistry have long recognized that 'coupled' transport can occur. Examples of such coupled transport processes are osmosis, electro-osmosis, thermo-osmosis, the Peltier effect, etc. A coupled transport process takes place when a flux arises due to a nonconjugated force (that is, a force that occurs in a product other than the one in which the flux of concern occurs).

Nonequilibrium thermodynamics now postulates that each flux occurring in the energy dissipation function is a linear, homogeneous (no intercept) function of all forces occurring in the same equation for the total energy dissipation. Thus:

$$j_q = -L_{TT}(\mathrm{grad}\ T) - L_{TV}(\mathrm{grad}\ H) - L_{TD}(\mathrm{grad}\ \pi) - L_{TE}(\mathrm{grad}\ E) \qquad [9]$$

$$j^V = -L_{VT}(\mathrm{grad}\ T) - L_{VV}(\mathrm{grad}\ H) - L_{VD}(\mathrm{grad}\ \pi) - L_{VE}(\mathrm{grad}\ E) \qquad [10]$$

$$j^D = -L_{DT}(\mathrm{grad}\ T) - L_{DV}(\mathrm{grad}\ H) - L_{DD}(\mathrm{grad}\ \pi) - L_{DE}(\mathrm{grad}\ E) \qquad [11]$$

$$j^E = -L_{ET}(\mathrm{grad}\ T) - L_{EV}(\mathrm{grad}\ H) - L_{ED}(\mathrm{grad}\ \pi) - L_{EE}(\mathrm{grad}\ E) \qquad [12]$$

The 'phenomenological' coefficients in the transport equations [9–12] are indicated by the letter L with two subscripts, say K and M. The first one (K) indicates which entity is being transported. The second one (M) indicates which driving force causes the transport. The terms for which the coefficient has identical subscripts represent the 'straight,' well-known transport processes, the laws of Fourier (1822), indicated by L_{TT}, Darcy (1856), indicated by L_{VV}, Fick (1855), indicated by L_{DD}, and Ohm (1827), indicated by L_{EE}. All other coefficients are known as 'coupling' coefficients, representing 'coupling' processes. They come in pairs, a pair being indicated by L_{KM} and L_{MK}. The two coefficients of a pair are called 'twin' coefficients. They represent all possible coupling phenomena.

If the energy dissipation equation is complete and all algebra has been carried out correctly, then the two twin coefficients are equal:

$$L_{KM} = L_{MK} \quad [13]$$

Thus the matrix of coefficients in eqns [9–12] is symmetrical. In the above matrix there are six of these pairs of equal twins. These equalities are known as the Onsager reciprocal relations (ORRs).

The fundamental value of the procedure outlined above is that all possible forms of energy dissipation are accounted for, even if they have never been observed.

For soil physics these forms are extremely important. After the merciless denigration of the ORRs by Truesdell, soil physicists should rise up and accept the validity and the great practical usefulness of ORRs. The framework of the matrix of coefficients in eqns [9–12] is comparable, in nature but not quite in stature, to the periodic system as proposed by Mendeleyev. For his systematic framework, Onsager received the Nobel Prize in Chemistry (1968), but Mendeleyev never received this accolade. The first such prize in chemistry was awarded to Jacobus van't Hoff, even though Mendeleyev was still alive. The refusal by the Nobel Committee to award the prize to Mendeleyev continued until he died in 1907. The framework makes it possible, in case the measurement of a certain coefficient is difficult or expensive, to measure its twin, which often appears to be easier or cheaper to measure.

When building models for transport processes in clay soils, e.g., based on the electrical double-layer theory, these ORRs can be used to verify the correctness of the model: if the cross-coefficients are not equal, researchers can be assured that somewhere they have made a mistake.

The actual occurrence of a coupled transport process always relies on some kind of a selection mechanism, such as a mechanism that can select between molecules of different chemical nature, e.g., water and salts, or a mechanism that can select between 'hot' and 'cold' molecules, e.g., a liquid–gas interface. It should be noted that convection (advection) is never a selection mechanism.

The coupled transport processes are discussed here in pairs of twin phenomena and indicated by their (equal) coefficients:

- L_{TV} (thermofiltration) and L_{VT} (thermo-osmosis). Both these phenomena are very common in soils. The transport of heat due to a water potential gradient in the absence of a temperature gradient and the transport of water due to a temperature gradient in the absence of a water potential gradient are occurring constantly in the soil. In unsaturated soil they are due to evaporation and condensation (the selection mechanism here is the heat of vaporization–condensation). In saturated soils the magnitude of these phenomena is very small (the selection mechanism is now the heat of wetting). In frozen soils they are caused by freezing and melting (here the selection mechanism is the heat of freezing–melting and solidification–sublimation);
- L_{TD} and L_{DT} (thermodiffusive processes). These phenomena are known as, respectively, the Dufour effect and the Soret effect. The magnitude of these effects in soils is very small, but their occurrence is quite probable;
- L_{TE} and L_{ET} (thermoelectric processes). These phenomena are known as, respectively, the Peltier effect and the Seebeck effect. The magnitude of these phenomena in soils is small, but their occurrence is quite likely;
- L_{VD} (osmosis, also called capillary osmosis) and L_{DV} (reverse osmosis or salt sieving). These phenomena are very common in soils. The magnitude is directly related to the clay content of the soil. (The selection mechanism lies with the electrical double layer.) Clay particles expel negative ions, and therefore they expel dissociated salts (negative adsorption). The longstanding conflict as to whether the osmotic pressure (potential) should be added to the hydraulic potential of water to produce the 'total' potential of water, the gradient of which then serves as the driving force on the water, is here resolved. As the value of L_{VD} is almost always smaller then the value of L_{VV} (except for a perfectly semipermeable membrane), the concept of the total potential is useless. The ratio L_{VD} to L_{VV} is known as the 'reflection coefficient';
- L_{VE} (electro-osmosis) and L_{EV} (streaming current). These electrokinetic phenomena also find their cause in the existence of electrical double layers. The most commonly observed result of the effects is the streaming potential in clay soils;
- L_{DE} (electrophoresis) and L_{ED} (diffusion current). These phenomena, together with osmosis and reverse osmosis, electro-osmosis, and streaming current are extensively discussed in the literature. The magnitude of all six coefficients on the basis of electrical double-layer theory has been calculated.

Modern Development

The branch of science called 'nonequilibrium thermodynamics' is now split into two subbranches. The first one is now called 'linear nonequilibrium thermodynamics.' Indeed all transport equations presented

here are linear. This subbranch of science deals with processes that are 'not far from equilibrium.' The second subbranch is now called 'nonlinear nonequilibrium thermodynamics.' Its great proponent is Ilya Prigogine, who received the Nobel Prize in Chemistry for his work in 1977. This subbranch of science deals with 'violent' processes ('far away from equilibrium'), such as Liesegang rings and atom bombs. The natural transport processes in the soil are never violent, and, as long as the Darcy law (one of the primary energy-dissipating processes) holds, all coupling processes fall in the park of 'not far from equilibrium.' However, if there are cases where the Darcy law breaks down and turns into the nonlinear Forchheimer equation (that is, when the water in the soil becomes turbulent), soil physicists may have to turn their attention to this latest branch of thermodynamics.

TILTH

D L Karlen, USDA Agricultural Research Service, Ames, IA, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Tilth is defined as the physical condition of soil as related to its ease of tillage, fitness as a seedbed, and its promotion of seedling emergence and root penetration. It is also an important indicator of soil quality, because it relates to soil structure in terms such as 'mellowness' or 'friability.' Soils with poor tilth are described as appearing lifeless, resembling brick or concrete, or being cloddy. If soils with poor tilth have a high percentage of sand, they will often disaggregate or separate into their primary sand-, silt-, and clay-size particles with little or no tendency to bind together. Soils with poor tilth can also be massive and difficult to till, work into a suitable seedbed or seed. Soils with medium tilth are characterized as being

somewhat cloddy, with a tendency to 'ball up' and be 'rough pulling' (i.e., having a high draft or requiring a greater energy input) when worked into a seedbed. Soils with good tilth are described as being crumb-like, easy to slice (like cutting butter), and spongy. Defining the descriptive terminology for soil tilth is a challenging task for those specializing in soil management. Tilth is difficult, if not impossible, to quantify. A common description of this dilemma is that tilth is what all farmers can measure through the soles of their boots, but no soil scientist can define.

History of Tilth

The concept of soil tilth predates modern agriculture, but a clear definition has never evolved because of differing perceptions. For example, an old childhood story explaining the concept of soil tilth describes how, in his dying moments, an elderly man called his sons to his side to tell them that if they would dig diligently in the garden, they would find a hidden treasure. The sons did so, but alas, they found no treasure of silver or gold. The subsequent harvest from this much-worked garden, however, was so large that the father's meaning gradually dawned upon his sons and they realized the wisdom of his words. A sixteenth-century book entitled *Boke of Husbandry*, written to provide instructions for growing peas and beans, tells the farmer how to determine whether the soil is ready for planting. It states that he should walk on the plowed ground and:

> if it synge or crye, or make any noyse under thy fete then it is to wete to sowe; and if it make no noyse, and wyll beare thy horses, thanne sowe in the name of God.

In the 1930s, several authors described how climatic conditions and various soil-, crop-, and animal-management practices affected soil tilth. By sieving soil samples and separating the material into different sizes, they showed how freezing, drying winds, rainfall, tillage, animal compaction, and other management factors affected tilth. Eventually, 'soil tilth' was used as a 'blanket' term, describing all the soil conditions that determine the degree of fitness of a soil as an environment for the growth and development of a crop plant. Soil structure was identified as a key factor in determining soil tilth, because structure is a soil property that can be altered rapidly through tillage operations and changes in environmental factors such as rainfall or temperature.

Soil tilth gradually came to be recognized as a dynamic condition. As virgin grassland or forest soils are cultivated, the organic matter concentrations, base (cation) saturation, and porosity decrease, while bulk density increases. These changes reduce the granulation or tendency of the soil to form stable aggregates and gradually degrade soil structure. Declining soil tilth is associated with increased runoff, erosion potential, need for tillage to prepare an adequate seedbed, and fertilizer to sustain reasonable and profitable crop yields.

Soil-management research through the mid twentieth century focused on identifying basic properties and processes that affect soil structure and tilth (i.e., flocculation, cementing by organic and inorganic colloids, wetting and drying cycles, freezing and thawing, organic matter cycling, biological activity, and tillage). One result of these efforts was that, in 1959, the 86th US Senate passed Senate Document No. 59, confirming the need:

> to conduct basic research on the relation of the physicochemical nature of soils, the role of organic matter, the activities of microbes, and the effects of mechanical manipulation upon the structural attributes of soils; [directed] toward predicting the effects of soil management practices [and] providing an optimum environment for root growth of crops in different kinds of soils.

However, 30 years elapsed before the US Department of Agriculture (USDA) Agricultural Research Service established the National Soil Tilth Laboratory in Ames, Iowa. Significant progress has been made in understanding many of the scientific aspects of soil structure, organic matter cycling, activities of microorganisms, and effects of various soil- and crop-management practices. However, with regard to adoption of improved soil-management practices, economic pressures and political forces beyond the control of most farmers often contribute to declining soil tilth.

Soil Organic Matter and Tilth

Organic matter is one of the main factors affecting soil tilth because of its role in aggregation (**Figure 1**). Studies with disturbed and undisturbed soils show that, as organic matter increases, compaction decreases and there is more space for air and water exchange. The constant addition of organic matter throughout the soil profile is one reason why virgin grassland soils generally have excellent aggregation and structure. Those soils, especially in humid regions, generally have a high organic matter content, a high percentage of water-stable aggregates, and a structure that accommodates rapid plant growth with unlimited root proliferation. These soil characteristics occur because in humid regions grasses replace most of their roots and top growth each year. Also, when the aboveground plant material dies, it falls on the soil surface, where it is decomposed or mixed into the upper part of the soil by earthworms and other soil organisms. The dead

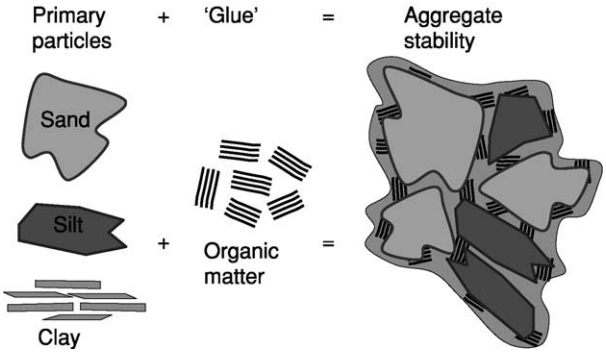

Figure 1 A conceptual illustration of soil aggregation, defined as the process whereby primary soil particles (sand, silt, and clay) are bound together, usually by natural forces and substances (glues) derived from root exudates, microbial activity, and other organic matter sources.

roots and plant residues provide a food source for fungal and bacterial decomposition processes, leading to the formation of soil aggregates, which modify effects of soil texture with regard to water and air relationships, and root penetration. Increased water-stable aggregation, annual proliferation of plant roots, and the associated wetting and drying cycles gradually develop a soil structure that is stable and, with good management, generally resists degradation.

The regular addition of organic materials can improve tilth by creating larger and more stable aggregates that are not easily eroded by wind or water. Organic matter, both as residue on the soil surface and as a binding agent for aggregates near the surface, strongly influences water infiltration, retention, and the potential for particle detachment and erosion. Surface residues intercept rainfall or irrigation water, and dissipate the energy before the drops hit the surface, detach soil particles through the splash, or begin to form a surface crust by filling the voids and cracks between the aggregates with fine particles. Organic materials on the soil surface also slow the water as it flows across the field, thus increasing opportunities for the water to infiltrate. Another characteristic of soils with good tilth is the presence of large channels or pore space between the water-stable aggregates. These channels greatly enhance the ability of soil to conduct water from the surface into the subsoil, where, because of enhanced root proliferation (another characteristic of good tilth), plants can subsequently use the water to support growth and development.

Soil-Management Effects on Tilth

Tilth, as an indicator of the physical condition of a soil, is strongly influenced by any soil management practice that quantitatively affects soil structure, aggregation processes, or soil organic matter cycling. Incorporating perennial crops into extended rotations, reducing tillage intensity and frequency, including cover crops, and optimizing nutrient and water management are among the most common practices that can be used to create the desired condition.

Surface mulch from crop residues, cover crops, animal manure, municipal sludge, leaves, or other carbonaceous sources provides both physical protection from raindrop impact and a food source for earthworms and other soil microorganisms. The surface mulch also moderates soil temperature and moisture extremes at the soil surface. If soils are left bare and exposed, surface temperatures can be very high, causing the soil to dry out. When this occurs, earthworms and other soil insects move deeper into the soil, leaving a surface zone that contains very few active organisms. Bacteria and fungi that live in thin films of water die or become inactive, slowing the natural process of organic matter cycling and aggregation.

Tillage Effects on Soil Tilth

Although tillage can improve tilth over the short term by loosening surface soil, disrupting crusts, and creating a more favorable soil–water–air environment for plants, it is also a primary cause for the long-term deterioration of tilth. The loosening process that often has positive short-term plant-production benefits has negative long-term effects, because it increases the rate of organic matter decomposition through chemical and microbial mineralization. This occurs because previously protected organic matter is exposed by the tillage and subsequently used as a food source by microorganisms. The loss of organic matter decreases aggregate stability, increasing the potential for surface crusting, poor seedling emergence, runoff, erosion, and other indicators of poor soil tilth (e.g., decreased infiltration of rainfall or irrigation water, decreased soil water retention, and decreased nutrient cycling). Tillage itself or the wheel traffic associated with the operations can further reduce the quality of tilth by increasing compaction. This reduces total pore space and frequently increases water-filled pore space, leading to reduced aeration, slower nutrient cycling, and a decreased volume of soil for plant root proliferation. These processes obviously occur in fields used for crop production, but they have similar negative effects on tilth at construction sites, in forests during logging operations, on campgrounds, athletic fields, or even desert areas where off-road recreational vehicles are allowed.

Tillage has been described as being 'addictive' for soils because of the vicious cycle that can be

established. Soils are tilled to disrupt surface crusts, compacted zones, or other real or perceived limitations to crop production. Doing so may provide short-term improvements in tilth and nutrient cycling, but these periods of improvement become shorter and shorter as more of the organic matter is lost through oxidation. Ultimately the soils may be 'burned out' and must either be abandoned until natural processes (e.g., wetting and drying; plant root proliferation, exudation, death, and decay; weathering) can restore the tilth or management practices (e.g., crop rotation, tillage, water management) are changed. As a result of these interactions, monitoring of soil tilth may provide a useful indicator of the sustainability of an agricultural system.

In situations where nitrogen is the most limiting factor, increasing nitrogen fertilization rates and therefore crop productivity has been shown to increase soil organic matter, even with moldboard plowing. However, without risking increased nitrogen leaching and potential water-quality degradation, development and adoption of reduced- or no-tillage agricultural practices can generally improve soil tilth even more by slowing organic matter decomposition, maintaining aggregate stability, and preserving soil structure. The critical management practice for these systems generally focuses on crop-residue management. Maintaining crop residues on the soil surface and the lack of loosening through tillage reduces dispersion of the surface aggregates by rainfall or runoff. By leaving crop stubble on untilled soil, the potential effects of wind erosion are minimized. Reducing or eliminating tillage also diminishes tillage erosion and keeps soil from being moved downhill by tillage tools.

Studies from around the world illustrate how tillage can affect soil tilth. In one study where direct drilling was compared with several methods of cultivation for wheat production, five soil series from southern England were examined. At each site, the tillage treatments had been in place for at least 4 years. The results showed that aggregates from the surface were more stable after direct drilling than after plowing. Most of the effects were attributed to a positive interaction between aggregate stability and organic matter content (i.e., two critical indicators of soil tilth). Direct drilling did decrease both aggregate stability and organic matter content in soils where grass had been grown before the treatments were imposed, but the decrease was less than that observed with plowing. Benefits of direct drilling were assumed to be greater root density in surface layers and less organic matter mineralization than in plowed soils. A similar response was observed in the USA when moldboard plowing and no-till crop-production practices were evaluated on land being taken out of the Conservation Reserve Program.

Extended Crop Rotations

Soil tilth is affected in two ways by incorporating forage or hay crops into an extended rotation. First, soil organic matter decomposition decreases because the soil is not being disturbed or tilled each year; second, grass and legume sods develop extensive root systems, part of which will naturally die each year, adding new organic matter to the soil. The dead roots provide a food source for fungal and bacterial decomposition processes, leading to the formation of soil aggregates and improved tilth.

To demonstrate the effect of perennial root systems on soil aggregation, researchers have compared aggregate size distributions for soils under continuous corn production with those where corn is grown in rotation with oat and meadow. The data show that, with continuous corn production, aggregate size is less than half that for corn grown in rotation. The studies also show that aggregation decreases slowly but consistently over a 7-year period of continuous corn production. In related studies, comparisons among crop sequences show that aggregation increases by switching to a corn–oat–meadow rotation after 11 years of continuous corn production. Also, it takes only 4 years of continuous corn production to decrease the aggregation established under either bluegrass or alfalfa to less than that found after 18 years of a corn–oat–meadow rotation. The highly significant correlation between crop yield and aggregate size confirms that soil tilth and productivity are both affected by crop rotation.

Cover Crops

Growing cover crops can improve soil tilth by decreasing erosion, increasing infiltration, and adding organic residues to the soil. These benefits are achieved because cover crops are often grown only during seasons when the soil is especially susceptible to erosion, although in orchards and vineyards the cover crops are frequently grown year-round. The leaves and stems of the cover crop intercept rainfall and dissipate its energy, while roots bind the soil and hold it in place. The amount of benefit from cover crops depends on the above- and belowground biomass and rooting structure of the plant being grown and the length of time before the soil is prepared for the next crop. For example, in the southeastern USA, crimson clover can be grown successfully as a cover crop prior to cotton. Initially planted in late autumn, the clover grows slowly throughout the winter and early spring, often reseeding itself for the next year

before the cotton crop is planted. In more northern areas such as the US Corn and Soybean Belt, where cold temperatures significantly shorten the growing season, warm-area crops such as crimson clover cannot survive. Oat, rye, and hairy vetch are some of the possible cover crops for the northern states of the USA, but the amount of protection against soil erosion and especially the amount of nitrogen supplied by the vetch are generally much less than in the southern USA. Also, in semiarid regions, where water is often the most limiting factor, growing cover crops may not be a viable management practice.

The quantity of organic residues returned to the soil by cover crops varies depending on plant species and the length of the growing season. Depending on temperature and moisture conditions, production can vary from less than 1000 kg ha^{-1} to more than 10 000 kg ha^{-1}. With low amounts of residue, there may be some detectable changes in active organic matter (e.g., particulate organic matter), but, because the material decomposes so rapidly, there generally will be no detectable change in total soil organic matter. However, a 5-year study in California, USA, has shown that growing a clover cover doubles total organic matter in the top 5 cm of soil (13–26 g kg^{-1}) and increases it by 2 g kg^{-1} at the 5–15-cm depth.

Additional benefits of cover crops include sequestering nutrients (especially nitrate N) so they cannot be leached below the crop root zone, supplying nutrients (usually N) to the following crop, suppressing weeds, breaking pest cycles, and providing habitat for beneficial insects and other fauna. However, before a farmer or land manager decides to grow a cover crop to maintain or improve soil tilth, it is important to determine the objectives. Is the main purpose to add available nitrogen to the soil or to provide large amounts of carbon? Is erosion control during the late autumn and early spring the primary goal? Does the soil have a compaction problem that needs to be alleviated? Will the combination of cover crop, climate, and water-holding capacity of the soil result in excess water depletion that adversely affects the primary crop? Once the primary purpose for growing a cover crop has been determined, decisions on plant species (i.e., legume or grass), the optimum date of planting, and when to eliminate the cover crop will be easier to make.

Evaluating Soil Tilth

Several factors can cause soil tilth to change, including tillage, compaction due to wheel traffic or grazing, reconsolidation due to rainfall or irrigation, and cultivation. Qualitative observations of surface crusts, cloddiness, poor seedling emergence, ponding, restricted plant rooting, soil organism diversity and population (especially earthworms), and increased runoff, erosion, or compaction have traditionally been used to evaluate soil tilth. Among the more quantitative measurements that have been used are aggregation (e.g., mean weight diameter, percentage of water-stable aggregates, or aggregate-size distributions), penetration resistance, infiltration rates, and crop performance.

Penetration resistance is measured most precisely with a penetrometer, although a stiff wire, spade, or tile probe can also be used. For precise measurements, the force required to push a rod with a cone-shaped tip through the soil to a known depth is recorded. To minimize the variation and provide the most quantitative data possible, measurements are taken 24–48 h after rainfall or irrigation so that the soil moisture content is relatively uniform throughout the measurement zone. Penetrometer data are also more reliable in nonstructured sandy or sandy loam soils. In general, if the resistance exceeds 2070 kPa (300 psi) the soil will be too hard for root penetration. Although it is not possible to be quantitative with a wire, tile probe, or spade, it is still possible to use these tools to observe soil structure and qualitatively describe soil tilth. If the soil has good tilth, it is fluffy and granular, and separates easily along the various structural planes of weakness. If the soil structure is massive or compacted, the tilth, by definition, is poor.

Measurements of infiltration rates with a rainfall simulator or other less-sophisticated tools (i.e., single- or double-ring infiltrometers) are also useful for evaluating soil tilth. These measurements are based on the time required for a known volume of water to enter the soil. If a soil has good tilth, water entry will be moderately fast for the first 5–10 cm of water. If water continues to enter at a very high rate, it could indicate that the soil has no ability to retain the water or that there are cracks, crevices, fractures, root channels, worm holes, or other macropores carrying the water away. If water enters the soil at an extremely slow rate or not at all, tilth is generally in a less-desirable condition, perhaps due to compaction or surface crusting. Under those conditions, rainfall and irrigation water usually runs off, increasing the potential for soil erosion and further degradation of soil tilth.

Tilth Indices

Efforts to develop a tilth index have been initiated to improve soil management and provide guidance for custom or prescribed tillage. The need for a tilth index was envisioned because even though an experienced person may be able to determine whether a soil has good tilth by sight and feel, there was no available method to measure or quantify it. Furthermore, if soil tilth can be quantified, it may be possible to measure

Table 1 Soil measurements and corresponding coefficients developed to compute a soil tilth index[a] for Mollisols and Alfisols in the Midwestern USA

Indicator	*Description*	*Tilth coefficient*
Bulk density	Mass per unit volume of dry soil	1.0, for $BD \leq 1.3\ g\ cm^{-3}$ $-1.5 + 3.87 \times BD - 1.5 \times BD^2$, for $1.3 \leq BD \leq 2.1\ g\ cm^{-3}$ 0.0, for $BD \geq 2.1\ g\ cm^{-3}$
Penetration resistance (cone index)	A measure of soil strength, indicating ease of root penetration, plant growth, and yield	1.0, for $CI \leq 1.0$ MPa $1.012 - 0.002 \times CI - 0.01 \times CI^2$, for $1.0 \leq CI \leq 10.0$ MPa 0.0, for $CI \geq 10.0$ MPa
Soil organic matter content	The organic fraction of soil excluding nondecayed plant and animal residue	1.0 for $OM \geq 50\ g\ kg^{-1}$ $0.59 + 0.122 \times OM - 0.008 \times OM^2$, for $10\ g\ kg^{-1} \leq OM \leq 50\ g\ kg^{-1}$ 0.70, for $OM \leq 10\ g\ kg^{-1}$
Aggregate uniformity coefficient	Shape of the grain-size (aggregate) distribution curve (all of equal size gives an AUC 1.0)	1.0, for $AUC \geq 5$ $0.348 + 0.245 \times AUC - 0.023 \times AUC^2$, for $2 \leq AUC \leq 5$ 0.75, for $AUC \leq 2$
Plasticity index	The difference in water content between the liquid limit and the plastic limit of a soil (cohesiveness)	1.0, for $PI \leq 150\ g\ kg^{-1}$ $1.02 + 0.0009 \times PI - 0.00016 \times PI^2$, for $150\ g\ kg^{-1} \leq PI \leq 400\ g\ kg^{-1}$ 0.80, for $PI \geq 400\ g\ kg^{-1}$

BD, bulk density; CI, cone index; UC, uniformity coefficient; OM, soil organic matter; PI, plasticity index; AUC, aggregate uniformity coefficient.
[a]Tilth index $= CF_{(BD)} \times CF_{(CI)} \times CF_{(UC)} \times CF_{(OM)} \times CF_{(PI)}$.

seasonal variation and to understand the subtle effects of soil- and crop-management practices such as conservation tillage or extended rotations.

The initial effort to develop an index assumed that tilth of a mineral soil could be characterized by examining bulk density, strength, aggregate characteristics, organic matter content, and consistency of a soil simultaneously. Bulk density, cone index (penetration resistance or strength), and an aggregate uniformity coefficient were chosen to reflect soil properties that respond to short-term manageable; organic matter content was chosen to reflect long-term management effects. The plasticity index was used as a measure of consistency, which reflects the relative ease with which a soil can be deformed or ruptured. This index relates to soil water properties and is strongly influenced by inherent soil characteristics (predominantly clay type and amount). These five measurements or indicators were also chosen because they can be measured easily in the field or with a routine soil test (e.g., for organic matter; see Table 1).

The search for a better tilth index continued with the addition of soil-water content. Concurrently, and with an even greater emphasis on the biological processes that affect tilth, the concept of soil quality has emerged as a strategy to quantify the effects of various soil-management practices on physical, chemical, and biological properties and processes occurring within the soil (*See* **Quality of Soil**). In the USA, the concept evolved during the 1990s, with two distinct areas of emphasis, education and assessment, both based on principles of soil science. Information sheets about the various indicators (or measurements) that can be used to evaluate soil quality, a *Soil Biology Primer* and *Guidelines for Soil Quality Assessment in Conservation Planning*, were among the educational materials developed for those with minimal knowledge of soil resources. For qualitative evaluation, scorecards were developed to provide farmers with a self-assessment of their current soil and crop management practices. The scoring is relatively simple (e.g., poor, fair, good) and generally based on observations of tilth, earthworms, runoff or ponding of water, plant vigor, ease of tillage, crop growth and development, and yield. Soil-quality test kits have been developed to provide semiquantitative indicator data and guidelines have been written to help interpret the data. A more comprehensive framework that uses scoring curves to interpret a full suite of potential indicators has been developed to provide a more comprehensive evaluation of soil tilth or soil quality. The most important aspect of these efforts is that quantitative methods for characterizing soil tilth do appear to be feasible and with further refinement may be useful for guiding soil and crop management decisions toward more sustainable land-use practices.

Summary

The concept of soil tilth is often easier for a farmer to recognize than for a scientist to describe. Traditionally, tilth has been described in many ways,

usually focusing on the physical condition of a soil and how it responds to tillage, functions as a seedbed, or affects seedling emergence and plant root growth and development. Soil tilth is strongly influenced by soil organic matter and soil structure. Soil management, especially tillage practices, cover crops, and crop rotations, often affects soil tilth because of its effect on soil organic matter. Soil scientists, ecologists, and agricultural engineers are continuing to evaluate different biological, chemical, and physical measurements or indicators that can be used individually or combined into index values to describe tilth quantitatively. That information may then help to improve soil-management practices through technologies such as no-tillage agriculture, the use of cover crops, and more diversified and extended crop rotations.

Introduction

The vital role of water in maintaining the life of the landscape requires the development of techniques to monitor and sustain water supply and its quality. Time-domain reflectometry (TDR) is a recently developed technology for use in soil and landscape processes, which has become widely used in highly diversified applications. Despite the importance of water and ionic solutes in the mass and energy balances of the soil profile, it has been only in the last 20 years that rapid, *in situ*, nondestructive measurement of soil water content and ionic solute concentration has become possible in the form of TDR. This is an electromagnetic (EM) technique using radar principles at radio frequency where estimates of water content and electrical conductivity of soil can be made separately from the same wave. The effect of the soil and water on the propagation velocity of the EM wave is analyzed to provide a reliable measure of the water content. The bulk electrical conductivity (EC) is determined from an analysis of the rate of decrease in amplitude during the propagation of the wave in soil. The principles of EM wave propagation are also used for the design of soil probes and to indicate the precision of measurements. The strong interaction between water content and electrical conductivity usually hinders the independent and separate determination of these properties in soil. This difficulty is overcome with TDR where both measurements are from the same sampled region and with the same EM wave.

Water molecules have unique electrical properties that determine the electrical properties of soil. Because of the strong dependence of soil electrical properties on the amount of water in a soil and on the quality of that water, electrical and electromagnetic measurements can be very useful for characterizing the soil water content. One method with which these properties can be measured is TDR. TDR can be thought of as one-dimensional radar using radio waves that propagate along a wave-guide. This wave-guide is constructed from parallel metal rods that are inserted in the soil. As radio waves travel through any material, the characteristics of the wave are continuously changed by the medium through which the wave is traveling. These changes in wave properties are measured by TDR and a wave equation analysis is used to estimate two electrical parameters

of the soil: dielectric permittivity (dielectric constant) and electrical conductivity. These properties are then used to estimate the water content and the electrical conductivity of the soil, respectively.

As the name implies, time-domain reflectometry relies on the measurement of the travel time of reflected waves. In this way, it is similar to other radar applications. In TDR, the wave velocity is measured by recording the time difference between the entry of a wave into the soil and the return of the reflected wave from the end of the TDR probe. Currently available TDR instruments operate in the range of radio frequencies (10 to 1000 MHz). In this frequency range, the dependence of the wave velocity on the water content is not strongly influenced by the electrical conductivity of the pore water or the electrical properties of the soil solids. This is supported by direct measurements made since the mid-1970s that show that, while other soil factors such as density, texture, temperature, and soluble salts affect the TDR wave velocity, their effects are less pronounced than are the effects of water content. That is, the soil water content is the most important soil factor affecting the travel time measured by TDR. This property of TDR makes the method very effective and efficient for the measurement of soil water content.

Soil salinity is an issue of great importance in regard to irrigation and agricultural production in arid and semiarid regions. It has long been realized that the electrical conductivity of pore water can be related to pore-water salinity. However, the bulk soil electrical conductivity is not solely dependent upon the concentration and composition of salts in solution. This property is also highly dependent on the soil texture, the temperature, and the water content. TDR can be used to infer the bulk electrical conductivity of a soil. The energy loss of the transmitted signal is related to the bulk electrical conductivity of the soil. This energy loss is determined from the relative amplitudes of the signal source and that of the wave reflected from the end of the probe. TDR has the advantage of simultaneously measuring both the water content and the bulk electrical conductivity in approximately the same volume of porous medium. Under some conditions, this information can be used to infer the bulk electrical conductivity, and thereby the salinity, of the pore water.

In the 20-plus years since TDR was first applied to soil measurements, the method has become a *de facto* standard for soil water content measurement and monitoring. The popularity of the method for environmental monitoring and research arises from a combination of its accuracy in a wide range of soils and its relative ease of use compared with many other available techniques. TDR provides real-time, *in-situ* soil water content measurements. Multiple soil probes can be incorporated into a switching network connected to a single instrument and data logger allowing for remote automated monitoring. For most soils, the accuracy of measurements of volumetric water content change is within $\pm 0.02\,m^3\,m^{-3}$ without the need for soil-specific calibration, and similar absolute water contents can be achieved with calibration. There is considerable flexibility in the design and placement of TDR probes, allowing users to modify water content measurement networks to conform to the requirements of any specific study. Finally, because TDR measures the volumetric water content, the data are directly applicable to hydrologic water balance analyses with no need for the measurement of supporting soil parameters such as bulk density.

Measurement of Soil Water Content Using TDR

Measuring the volumetric water content of a soil is difficult. As a result, methods have been developed that infer the volumetric water content based on the water potential, bulk electrical conductivity, or dielectric permittivity. The water potential–volumetric water content relationship is nonlinear and hysteretic. The bulk electrical conductivity depends on many factors in addition to the water content. In contrast, the bulk dielectric permittivity of a soil is highly correlated with the volumetric water content. For these reasons, recent advances in the development of indirect methods of measuring the volumetric water content have focused on methods that rely on the measurement of dielectric permittivity. TDR has long been used as a laboratory method to measure the dielectric permittivity of liquids. In an unrelated field, TDR has been widely applied to the location of faults in buried cables. However, it was not until it was demonstrated that a single correlation existed between the bulk dielectric permittivity and the volumetric water content for a wide range of porous materials that these two distinct uses came together to give rise to the TDR method for soil water content measurement. Over the past 30 years, TDR has been applied at many scales and under a broad range of conditions spanning agricultural and forestry environments and seasonal conditions from summer to winter. In addition, the method has been improved and modified.

Most TDR instruments launch a fast-rise voltage step (rise time <200 ps) along a transmission line that is connected to a probe that is inserted in the soil or medium of interest. The voltage pulse propagates as a planar EM wave, traveling in the soil and guided by the conductors that form the probe. The properties of

the soil that govern the propagation of the TDR pulse are described collectively by the propagation constant of the soil, from which velocity of propagation, v ($m\,s^{-1}$), and attenuation coefficient (α) are derived. The TDR instrument records and displays the voltage returning to the instrument as a function of elapsed time following the launch of the voltage pulse. This gives rise to a characteristic plot known as the waveform.

The waveform is a record of the voltage that arrives back at the instrument after being reflected from the end of the probe. Commonly, the returning voltage, V, is displayed as a normalized voltage, known as the reflection coefficient (ρ), as a function of time (t) (Figure 1, where $V/V_0 = 1 - \rho$), where V_0 is the voltage of the transmitted pulse. From the TDR waveform it is possible to determine both v and α. As discussed above, v is used to infer the volumetric water content while α is used to determine the electrical conductivity. A portion of the TDR step pulse travels a distance, L_{cable} (m), along the connecting cables to the probe and then reflects back to the instrument. A portion of the energy that enters the probe travels an additional distance, L (m), along the probe, and then travels the total distance back to the instrument. Taking the difference in these travel times to be t(s), the velocity of the wave can be determined from the known probe length, L, as:

$$v = \frac{2L}{t} \qquad [1]$$

From electromagnetic wave propagation theory, v is given in terms of relative dielectric permittivity and electrical conductivity of soil, which can be expressed as:

$$v = \frac{c}{\sqrt{\epsilon_{ra}}} \qquad [2]$$

where c ($= 3 \times 10^8\,m\,s^{-1}$) is the velocity of light and other EM waves in vacuum, and ϵ_{ra} is the apparent relative dielectric permittivity or apparent dielectric constant that controls the rate of propagation of the step pulse. Combining eqns [1] and [2] gives:

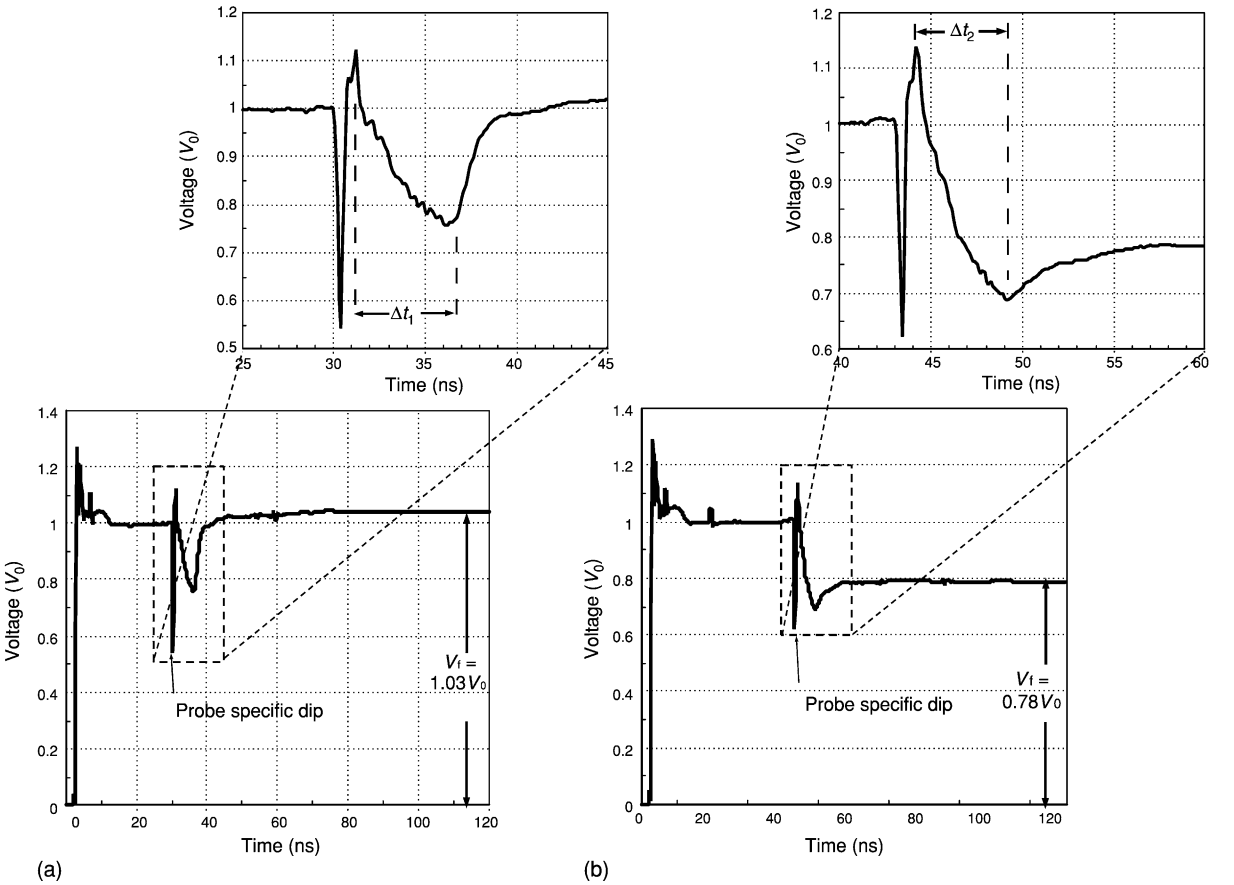

Figure 1 Two time-domain reflectometry curves from 20-cm probes in silty clay loam soil. The soils are at similar water content but the soil solution is more conductive in (b), giving a smaller return reflection and resulting lower V_f. In (a) $\theta_v = 0.304\,m^3\,m^{-3}$ and $\sigma_0 = 57\,mS\,m^{-1}$ and in (b) $\theta_v = 0.271\,m^3\,m^{-3}$ and $\sigma_0 = 95\,mS\,m^{-1}$.

$$\epsilon_{ra} = \left(\frac{ct}{2L}\right)^2 \quad [3]$$

More complete analyses of the EM wave equations show that ϵ_{ra} is primarily the result of the relative dielectric permittivity (real component) or dielectric constant of the soil, ϵ'_r. Also, ϵ_{ra} is affected to some extent by the electrical conductivity, σ_0 ($S\,m^{-1}$), the frequency of the signal, ω ($2\pi\,s^{-1}$), and the relative dielectric loss or imaginary component of relative dielectric permittivity, ϵ''_r. The effect of these factors on EM waves is expressed as:

$$\epsilon_{ra} = \frac{\epsilon'_r}{2}\left[1 + \sqrt{1 + \left(\frac{\epsilon''_r + \frac{\sigma_0}{\omega\epsilon_0}}{\epsilon'_r}\right)^2}\right] \quad [4]$$

where ϵ_0 is the dielectric permittivity of free space ($= 8.85 \times 10^{-12}\,F\,m^{-1}$). Most TDR applications in soil have assumed that $(\epsilon''_r + \sigma_0/\omega\epsilon_0)/\epsilon'_r << 1$, which leads to $\epsilon_{ra} \approx \epsilon'_r$. This assumption allows for the determination of the volumetric water content without prior knowledge of the bulk electrical conductivity.

The high relative dielectric permittivity of water imparts to wet soil a very strong dependence of ϵ_{ra} on the water content. The early laboratory work in TDR adopted an empirical approach, making no assumption about the 'state' of water in porous materials. Instead it related the TDR-measured ϵ_{ra} to the volumetric soil water content, θ_v ($m^3\,m^{-3}$), based on oven drying to 105°C. This early work gave a consistent empirical relationship between relative dielectric permittivity and volumetric water content for a wide range of soils and became a model for calibration of the TDR as a method for measurement of water content. Furthermore, it was found that the relationship is essentially independent of soil bulk density, texture, ambient temperature, and salt content, within the range of these parameters most often encountered. The equation now used widely for calibration is:

$$\theta_v = -5.3 \times 10^{-2} + 2.92 \times 10^{-2}\epsilon_{ra} - 5.5 \times 10^{-4}\epsilon_{ra}^2 + 4.3 \times 10^{-6}\epsilon_{ra}^3 \quad [5]$$

This relationship has extremely broad applicability, providing good descriptions for the water content of soils of widely varying properties, such as iron-rich volcanic soils, the unfrozen water content in frozen soils, soils with up to 50% gravel, oil shale waste, and crushed concrete. The widely obtained agreement between observations and eqn [5] has not been true for observations made in low-density soils, mineral soils with high organic or clay contents and artificial soils, such as glass beads. The widespread use of TDR has resulted in a number of applications in which eqn [5] cannot be used, and some effort has been devoted to finding alternative relationships between ϵ_{ra} and θ_v. However no relationship has emerged that shows more general applicability without the requirement for other supporting measurements (e.g., clay content, temperature).

Alternatives to empirically derived calibrations are often based on dielectric mixing models. The application and use of mixing models require varying levels of prior knowledge about the soil, such as porosity, density, and the relative dielectric permittivity of soil components. The application of mixing models for water content determinations has shown that 'square root' mixing models are most common. Such models are equivalent to a linear relationship between $\sqrt{\epsilon_{ra}}$ and the TDR travel time, t in eqn [3], which leads to a convenient linear calibration for water content. The linear relationship between θ_v and $\sqrt{\epsilon_{ra}}$ is supported by calibration data from numerous sources and is very similar to the polynomial expression in eqn [5] (Figure 2). Fitting a linear relationship where possible presents a significant improvement over fitting a

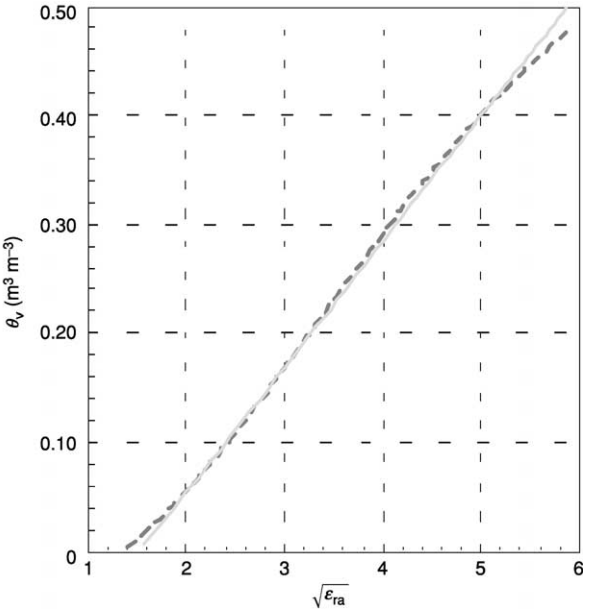

Figure 2 The similarity between eqn [5] (dashed line) and eqn [6] (solid line) over the water content range (0.05 to 0.45 $m^3\,m^{-3}$) applicable for most soils. Note the *x*-axis is $\sqrt{\epsilon_{ra}}$ and shows the linearity of eqn [6].

$$\theta_v = -5.3 \times 10^{-2} + 2.92 \times 10^{-2}\epsilon_{ra} - 5.5 \times 10^{-4}\epsilon_{ra}^2 + 4.3 \times 10^{-6}\epsilon_{ra}^3 \quad [5]$$

$$\theta_v = 0.115\sqrt{\epsilon_{ra}} - 0.176 \quad [6]$$

Reproduced with permission from White I, Knight JH, Zegelin SJ, and Topp GC (1994) Comments on ''Consideration of the use of time-domain reflectrometry (TDR) for measuring soil water content'' by Whalley WR. *European Journal of Soil Science* 45: 503–508.

polynomial calibration curve because there are only two parameters to define, making the fitting procedure much simpler. A linear regression of $\sqrt{\epsilon_{ra}}$ on θ_v gives rise to (Figure 2)

$$\theta_v = 0.115\sqrt{\epsilon_{ra}} - 0.176 \quad [6]$$

The constant term includes the electrical properties of the dry solids, primarily the bulk density and the relative permittivity of the constituent material. The slope coefficient in the first term on the right hand side embodies the effects of dissolved solutes and clay surfaces on the electrical properties of the water phase as seen by TDR. This slope changes relatively slowly as salt and clay contents increase. Clay and salt content do introduce some curvature to the relationship between $\sqrt{\epsilon_{ra}}$ and θ_v, indicating the importance of calibration checks to assure an appropriate calibration for high-resolution measurements and for unique soil conditions. Precise calibration equations become more important where absolute measures of water content are required as contrasted with differences or changes in water where more general calibrations usually suffice.

Instrumentation and Wave-Guides

The original and still widely used TDR instrument for soil was the portable cable-tester. This instrument displays the TDR waveform on a screen, allowing analyses to be performed and recorded manually. Alternatively, the data can be recorded and analyzed digitally on a personal computer (PC). Currently, a number of companies offer TDR instrumentation aimed directly at soil and environment studies. Most commercial instruments now offer automated analysis of the TDR waveform as a part of the basic instrument with network switching for multiple probes as an option. Most of these instruments make use of general calibration relationships that closely approximate eqns [5] or [6]. In addition, they allow for the calibration relationships to be customized for the desired soil characteristics.

One of the most important components of a TDR system is the soil probe or transmission line. The basic elements are the conductive components, often parallel metallic rods, which act as wave-guides. Currently the most common soil probes are of the parallel rod type, consisting of two or three parallel rods. These may vary in length from 0.1 to 1.0 m and with probe separations from 0.01 to 0.1 m. Probes that use bare metallic rods measure total water content along the path of the TDR pulse regardless of the distribution of water along this path. However, the distribution of electromagnetic energy is not uniform in the directions perpendicular to the rods. Furthermore, the distribution of energy depends on the number of rods, their diameters, and their separations. A rod separation to rod diameter ratio less than 10 is a practical rule of thumb for probe design. Further, the rod diameter should be large in relation to the dominant pore size, e.g., 10 times the dominant particle or aggregate size. We have found that 6-mm rods spaced at 50 mm have worked well in a variety of studies in tilled and untilled agricultural soil.

Many other probe configurations have come into current use, including profiling probes with the conductors mounted on opposite sides of a dielectric central core. The parallel wires mounted on a central core have been diversified to include a helical-wrapped pair on a single shaft probe and serpentine pathways on a plastic surface giving a surface probe. In all cases the energy density of the propagating wave decreases rapidly with distance from the conductors. Spatial weighting of the measurements in the cross-section perpendicular to the direction of wave propagation is a very important consideration, especially for probes that have nonmetallic components near the metal rods. Numerical analyses have been applied to the wave-equation response from parallel rod probes embedded in a porous medium. One aspect of this work was the definition of sample areas in the transverse plane that are not limited to predefined shapes, allowing for a more realistic description of the lateral sensitivity of different probe configurations. In general, TDR probes should be installed in a manner that minimizes variability of the water content within their sampling volume, especially in the direction that is transverse to the rods.

An important application of TDR relates to the measurement of shallow soil water content profiles. Three general approaches to water content profiling are depicted in Figure 3 using vertical and horizontal probes. In general, vertical rods (Figure 3a) give the most accurate measurement of cumulative water from the surface to the ends of the rods, regardless of the water content distribution with depth. Horizontal rods (Figure 3b) give higher resolution of the water content profile, with less accurate measurements of the total water stored to a given depth. It is possible to place probes depicted in Figure 3a and 3c at an angle off the vertical. Angled rods at say 45° give an optimal compromise between horizontal and vertical configurations. Another consideration is the potential for causing cracks in the soil or gaps around the rods. These features can have a significant impact on TDR measurements and on water movement, and vertical emplacements are most susceptible to these influences. In addition, water content profiles that are determined by the differencing of adjacent measurements (e.g., Figure 3a) introduce the error from both measurements, which can lead to a cumulative error

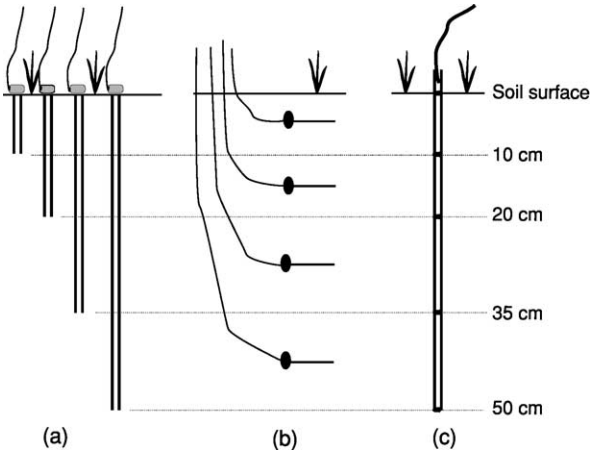

Figure 3 Three options for measurement of water content profiles. (a) Adjacent vertical; (b) horizontal; (c) segmented vertical. Probe lengths and intervals can be adjusted to the monitoring requirements. Installing probes in (a) and (c) off vertical results in a compromise between vertical and horizontal installation but optimizes the advantages from each. Reproduced with permission from Ferré PA and Topp GC (2002) Time domain reflectometry. In: Dane JH and Topp GC (eds.) *Methods of Soil Analysis Part 4 Physical Methods*. SSSA Book Series No. 5, Soil. Sci. Soc. Amer., Madison, WI.

as large as $\pm 0.03\,m^3\,m^{-3}$. On the other hand, horizontal rods require excavation for insertion at depth, which can also affect water movement. In addition, because the head of a horizontal probe is placed beneath the ground surface, it is important that it be watertight to avoid the influence of water entry. Practically, vertical rods are the simplest to install. However, their tendency to move vertically out of the soil during winter by the processes of frost-heave can be countered somewhat by the use of angled rods.

An alternative to the continuous-rod probes is the segmented probe depicted in Figure 3c. This probe configuration makes use of diode-shorting to achieve probe segmentation electronically and is available commercially. This probe is essentially a series of vertical probes placed in the same hole. As a result of its design, these probes provide both the water content profile and the total profile stored water from a single installation. Installation of this type of probe is of critical importance as any disturbance of the soil adjacent to the probe is in the most sensitive part of the measured region. Similarly, air gaps or preferential water flow along the probe will also affect measurements.

Impact of Salinity on Water Content Measurement

The explicit effect of the bulk electrical conductivity on TDR water content determinations has not been fully evaluated. Research is continuing with varied EM techniques to define conditions when the direct effect of bulk electrical conductivity (EC) results in unacceptable error in water content estimates. It appears, however, that the influence is very small for mineral soils having a clay content less than 50% and pore-water electrical conductivities less than $5\,dS\,m^{-1}$. For example, measurements in a soil of 55% clay gave an overestimate of water content of $0.014\,m^3\,m^{-3}$ due to the assumption that $\epsilon_{ra} = \epsilon'_r$. Typically, high EC conditions lead to difficulty in measuring the water content due to total extinction of the waveform through energy loss. This places a practical limit on the maximum length of TDR rods. However, to maintain acceptable water content accuracy, probe length should be at least 7.5 cm. If the EC is too high to use probes at least 7.5 cm in length, nonconductive rod coatings can be used to minimize the effects of signal loss. These coatings change the water content calibration and they should only be used when absolutely necessary.

Some of the limitations of TDR analysis and application may be addressed by a new approach to TDR waveform analysis. Standard analyses involve interpretation of the time of arrival of reflections. However, in addition to this time-based analysis, a TDR waveform can be analysed in the frequency domain using Fourier analysis. Conversion of TDR data into the frequency domain provides additional frequency-dependent information about the electrical properties of the soil and water. Frequency domain analyses of measurements made with 3-cm length probes may provide high-precision measurement of relative dielectric permittivity in saline soils where the time-domain analysis is not feasible. Further developments of this approach may extend the range of applicability of TDR.

Measurement of Bulk Electrical Conductivity Using TDR

As the TDR wave propagates through soil guided by the probe rods, its velocity is decreased by the presence of water. In addition, the magnitude of the wave is decreased by electrical losses associated with the bulk electrical conductivity of the soil, σ_0. The decrease in magnitude of the wave is expressed in the attenuation coefficient, α. It is possible to express σ_0 in terms of the values obtained from the TDR waveform (Figure 1):

$$\sigma_0 = \left(\frac{1}{120\pi L}\right)\left(\frac{Z_0}{Z_i}\right)\left(\frac{2V_0}{V_f} - 1\right) \qquad [7]$$

where Z_0 (ohms) is the characteristic impedance of the TDR probe (a factor of the probe geometry), Z_i is the output impedance of the TDR instrument, V_0 (volts) is the initial step voltage output and V_f is the

final voltage remaining after all multiple reflections from the probe, respectively. In practice, the quantity $(Z_0/120\pi LZ_i)$ is often treated as a calibration constant for the instrument, cable, and probe combination, which can be obtained from measurements in solutions of known EC. After the probe and TDR instrument have been characterized, the bulk EC is calculated from the value of V_f as the only independent variable at each measurement site or measurement time. Although the measurement is straightforward, it is important that V_f be determined well after all multiple reflections have returned and the TDR waveform has reached a final constant value.

The bulk EC measured by TDR has applications in research into solute transfer processes, particularly ionic solute breakthrough experiments. At a heterogeneous field site, using vertically installed TDR rods, solute mass flux measured with TDR was in good agreement with that obtained from solution samplers. The TDR-measured EC has been used to monitor nitrate levels in the field with a view to improving crop nutrient management and minimizing leaching to groundwater.

Impact of Water Content on Pore-Water Salinity Measurement

The EC of the soil solution is often desired for soil and environment studies, particularly in relation to soil salinity assessment or monitoring migration of polluting chemicals. The relationship between bulk EC and solution EC is strongly dependent on both the soil water content and the clay content of the soil. TDR offers the distinct advantage of measuring both water content and EC in the same sample and under identical conditions. Thus, TDR can be very useful for establishing both the water content and the pore-water EC simultaneously. TDR has been used in both direct and indirect approaches and to elucidate the relationship among water content, bulk EC, and solute EC. However, it is not always possible to determine the pore water EC if the water content varies along the TDR probes, as this will give a gradient of pore water EC along the probe.

Conclusion

In the 25 years since the early applications in soils, TDR has revolutionized the field measurement of soil water content. In 1991, a survey of soil physicists in four countries reported TDR was used one-third as often as gravimetric sampling and one-half as often as neutron moderation. It is most likely that TDR use had surpassed both these methods by the end of the 1990s, making it more ubiquitous than any other technique. The capability to log TDR data and the relatively nondestructive nature of the installations have allowed *in situ* monitoring, contributing to the much wider use of TDR. For water balance and water-use efficiency studies, TDR is particularly applicable because the probe designs and orientations can be chosen to meet a variety of conditions, such as agricultural row crops, drip irrigation patterns, and forested landscapes. Through the application of TDR in soil much has been learned about the soil's electromagnetic properties in the radio frequency range. This knowledge has assisted in the development of other electromagnetic techniques, such as ground-penetrating radar and remote sensing using either active or passive microwave radars. TDR is specifically valuable for 'ground-truthing' radar applications because both are interpreting measured EM properties of soil. As a consequence, TDR can be applied to defining the sampling regions of radar applications by appropriate choice of probe geometries for the TDR. Water content measurement by capacitance techniques has been accelerated recently, in part because appropriate frequencies and probe geometries were identified through TDR studies. Although capacitance devices are less expensive, they have not yet offered the ability to measure EC as can be done by TDR.

TDR is prominent among several emerging technologies being used to enable the long-neglected investigation of roots as the major agents of water and chemical transfer in soil. TDR water content measurements also improve the value and significance of other environmental parameters. For example, frequent measurements of temperature, water content by TDR, and oxygen concentrations in the rooting zone of maize can help to demonstrate when tillage and trafficking limit both O_2 supply and crop growth. Prior to TDR, measurements of O_2 supply for roots and other biota in the soil had not been possible. Time-domain transmissiometry (TDT), which is similar to TDR, has been combined with a soil penetrometer to measure both soil strength (compaction) and water content. The combination of sensors greatly enhances the value of the soil penetrometer as a diagnostic tool for soil compaction.

Regulations now play a leading role in the need to monitor soil contamination and harmful infiltration of contaminated solutions into groundwater. Cities in the USA such as Los Angeles, Tucson, Las Vegas, and Glendale are using TDR for such monitoring. Agencies from around the world have reported using TDR in environmental monitoring applications as diverse as nonaqueous liquid-phase concentrations (Sweden), subsurface pollutant detection (United Arab Emirates), changes in groundwater level and

crude oil thickness (USA), characterization of diesel-contaminated soil (Canada), and measuring water-table elevations within sidewalk systems (USA).

The application of TDR in soil is continuing to develop and diversify in ways that will enhance the value of TDR for soil and environmental monitoring. The analyses of spatial sensitivity within probes have facilitated designs for specific uses, often allowing combinations of TDR with other measurements such as with tensiometers and the cone penetrometer.

List of Technical Nomenclature

α	Attenuation coefficient
ϵ_0	Dielectric permittivity of free space ($F\,m^{-1}$)
ϵ_r	Relative dielectric permittivity (dielectric constant)
ϵ_r'	Real component of relative dielectric permittivity (dielectric constant)
ϵ_r''	Imaginary component of relative dielectric permittivity (relative dielectric loss)
ϵ_{ra}	Apparent relative dielectric permittivity (dielectric constant)
θ_v	Volumetric soil water content ($m^3\,m^{-3}$)
ρ	Reflection coefficient
σ_0	Electrical conductivity ($S\,m^{-1}$)
ω	Frequency of signal ($2\pi\,s^{-1}$)
c	Velocity of light ($m\,s^{-1}$)
L	Length (m)
t	Time(s)
V	Voltage (volt)
v	Propagation velocity of electromagnetic waves ($m\,s^{-1}$)
Z_0	Characteristic impedance of probe (ohms)
Z_i	Output impedance of instrument (ohms)

Introduction

Arid and semiarid soils occupy about one-third of the Earth's ice-free land surface. They are sources and sinks of atmospheric CO_2, sources and sinks (mainly sources) of global dust, and substrate that support high biodiversity of plants and animals. Arid and semiarid soils uniquely accumulate secondary minerals, such as calcite and gypsum, as the result of low rainfall and limited leaching. Because of sparse vegetative cover and high susceptibility to wind and water erosion, many arid and semiarid soils have low resistance and low resilience to disturbance. Hence land degradation (i.e., desertification) is common on most continents with arid and semiarid soils.

These dryland soils have been a factor of primary importance in human history. The oldest hominid fossils are found in east Africa in sediments with paleosols containing pedogenic carbonate indicating an arid or semiarid climate. The transition from hunting-and-gathering to agriculture took place in arid and semiarid Mesopotamia about 10 000 years ago. The production of surplus food on the floodplain soils of the Euphrates and Nile gave rise to early civilizations in Sumeria, Babylonia, and Egypt. Today several large urban centers are located on arid and semiarid soils around the world that have adequate groundwater or river water supplies. If irrigated, arid and semiarid soils are an important source of local and global food production. Still, most arid and semiarid land is sparsely populated, open, and often wilderness land.

Climatic Controls

The terms arid, deserts, semiarid, and steppes are used variously to describe dryland conditions. Arid (an adjective) describes a climatic condition of low rainfall – commonly taken to be less than 250 mm (10 in.) of mean annual precipitation (Figure 1a). Desert (a noun) is a region of the Earth's land surface within an arid climate. Likewise, semiarid is a climatic condition characterized by a mean annual precipitation between 250 and 500 mm (Figure 1a). A region of the Earth's surface within a semiarid climate is a steppe.

Closely linked to annual precipitation, and especially to soil moisture, is vegetation. The driest deserts are often barren of plant cover, but most deserts have scattered shrubs, cacti, forbs, and grasses. Though some steppe vegetation can occur in areas like the Badia of Jordan that receive as little as 100 mm of rainfall, generally steppe vegetation is characterized by higher amounts of rainfall in which short-grass prairie is bordered by desert vegetation on the arid side and tall-grass prairie, savanna, or woodlands on the subhumid side. Thus, by these definitions arid soils are synonymous with desert soils and semiarid soils are synonymous with steppe soils.

But to define deserts and steppes by precipitation alone is to ignore other important climatic variables, mainly temperature. One expression of the combined influences of both precipitation and temperature is the de Martonne aridity index based on the formula:

$$I_a = P_{mm}/(T^{\circ}C + 10) \qquad [1]$$

where the aridity index (I_a) is equal to the mean annual precipitation in millimeters (P_{mm}) divided by the mean annual temperature in degrees Celsius ($T^{\circ}C$) plus 10. According to this index, values below 5 characterize true deserts, values of approximately 10 demarcate dry steppes, values of about 20 represent prairies, and values above 30 typify forest. The boundary for the Chihuahuan desert of Mexico and the USA, for example, is based on an aridity index of 10 or lower.

The Köppen system also demarcates deserts and steppes as a function of both precipitation and temperature (Figure 1b). For example, some cold regions in the high latitudes of North America and Eurasia that get semiarid-amounts of precipitation are coniferous forest instead of steppes, and many cold

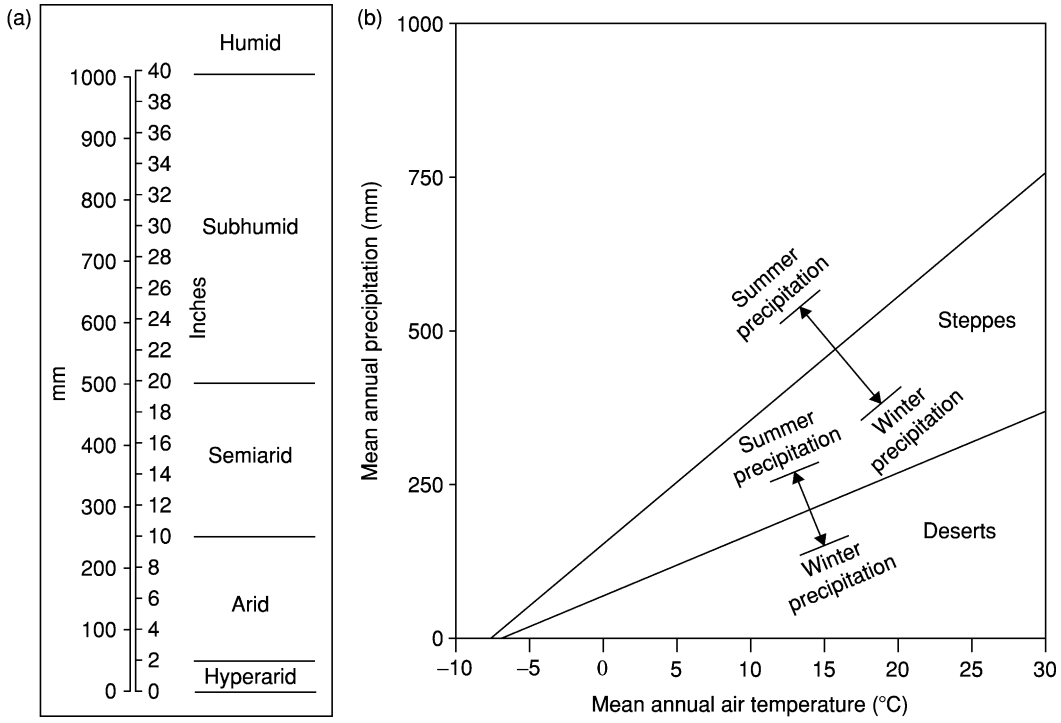

Figure 1 (a) Climate categories based on mean annual precipitation. (b) Desert and steppe boundaries as a function of both mean annual precipitation and temperature according to the Köppen system. Arrows show how boundaries shift according to whether precipitation falls mainly in the summer or winter.

areas that receive arid-amounts of precipitation are steppes instead of deserts.

Seasonality of precipitation is another climatic factor that affects desert and steppe boundaries. For a given mean annual temperature, the boundary of a steppe will extend into wetter climates if its precipitation falls mainly in the summer (Figure 1b). In other words, if precipitation falls in summer, the area of a steppe will be larger because summer evapotranspiration depletes soil moisture more thoroughly than winter evapotranspiration. Similarly, the size of a desert will be larger if its precipitation falls in the summer rather than in the winter.

Soil water potential is another way of defining boundaries of arid and semiarid soils. Soil moisture measured as soil water potential, which includes the influence of particle size and salts, is more important to vegetation than annual precipitation alone. The Soil Taxonomy system, for example, uses soil water potential to define moisture regimes as a criterion for classifying soils. The aridic moisture regime, for example, includes soils too dry to support nonirrigated crops, and is defined as soil that is moist (i.e., water held at tensions greater than −1500 kPa) for no more than 90 consecutive days when the soil temperature at a depth of 50 cm is above 8°C. Soils with the ustic and xeric moisture regimes are transitional between the aridic moisture regime and soils of humid climates that have the udic moisture regime. Semiarid soils occur within ustic and xeric moisture regimes, their drier subdivisions, and wetter subdivisions of the aridic moisture regime, namely, the aridic ustic, aridic xeric, xeric aridic, and ustic aridic regimes.

Processes of Soil Formation in Arid and Semiarid Soils

Water – its amount and depth-of-wetting – is the major driver that gives rise to differences between arid and humid soils. In humid soils >50% of the water entering the soil drains downward through the profile to groundwater. In arid soils, <10% flushes through the soil profile to the groundwater. A humid soil receiving 1300 mm of rain, for example, would have about 650 mm that percolated through its profile in a year. An arid soil receiving 200 mm would have <20 mm that percolated through its profile. Thus, nearly all water in arid soils and much water in semiarid soils enters and leaves via the soil surface. Notable exceptions are low-lying areas that receive runoff water (e.g., playas). In these topographic lows, soils are nonsaline because of deep leaching, if the water table is deep and the soils have high permeability. However, if the water table is shallow or soils have slow permeability, these topographic lows are zones of salt accumulation

As with humid soils, the processes of soil genesis (i.e., gains, transfers, transformations, and losses) operate in arid and semiarid soils, but the magnitude and direction of these processes are different. The shallow depth-of-wetting and incomplete leaching have a major impact on gains because authigenic minerals, such as calcite, silica, and gypsum, accumulate in the profile and give rise to the formation of calcic, petrocalcic, duripans, gypsic, and petrogypic horizons. Gains of dust are also important. Silicate clay dust, for example, contributes to the formation of argillic horizons, carbonate dust to the formation of calcic horizons, and gypsum dust to the formation of gypsic horizons. Gains of photosynthetic carbon in the form of soil organic matter are lower than in humid soils. But gains of photosynthetic carbon released as respired soil CO_2 that leads to HCO_3^- and $CaCO_3$ formation are higher than in humid soils.

Transfers of material down the profiles of arid and semiarid soils include illuvial clay, carbonate, and salts. Arid soils typically display a chromatographic pattern of an argillic horizon overlying a calcic horizon. If gypsum and soluble salts are also present, the profile can contain an argillic overlying a calcic overlying a gypsic overlying a salic horizon. Transfers of materials also occur up the profiles of some arid and semiarid soils. These include capillary rise of soluble material and particles moved upward by ants and termites. In some cases, desert pavements are formed by the upward movement of coarse fragments lifted by silts and fine sands that accumulate beneath them.

Important transformations in arid and semiarid soils include rock disintegration resulting from the crystallization of salts, thermal fluctuations, and chemical weathering. Other transformations involve the decomposition of organic matter and formation of clay minerals, such as palygorskites and sepiolites. The formation of kaolinite is common in parent materials containing feldspars. Losses are mainly in the form of erosional truncation of soil horizons.

Factors of Soil Formation in Arid and Semiarid Soils

The five soil-forming factors interact in assorted ways to produce arid and semiarid soils (Figure 2). Climate, especially water supply, is the defining factor. Water is not only the agent for mineralogical gains, transformations, and transfers, it is also essential for nutrient supply and direct use by vegetation. Vegetation, in turn, has a feedback link to soil by adding organic matter, translocating ions via bioaccumulation, and providing ground cover that protects the soil from erosion. Vegetation is also linked to animals by being their food supply, while animals are linked to vegetation by herbivory and seed dispersal (Figure 2). Animals affect soil by bioturbation – humans alone move about 40 GT of soil per year. Soil, in turn, affects animals by providing habitat, which is important for nematodes, gastropods, earthworms, crustaceans, mites, spiders, ants, termites, mice, moles, rabbits, gophers, birds, foxes, badgers, deer, bear, and even humans in some places of the arid world.

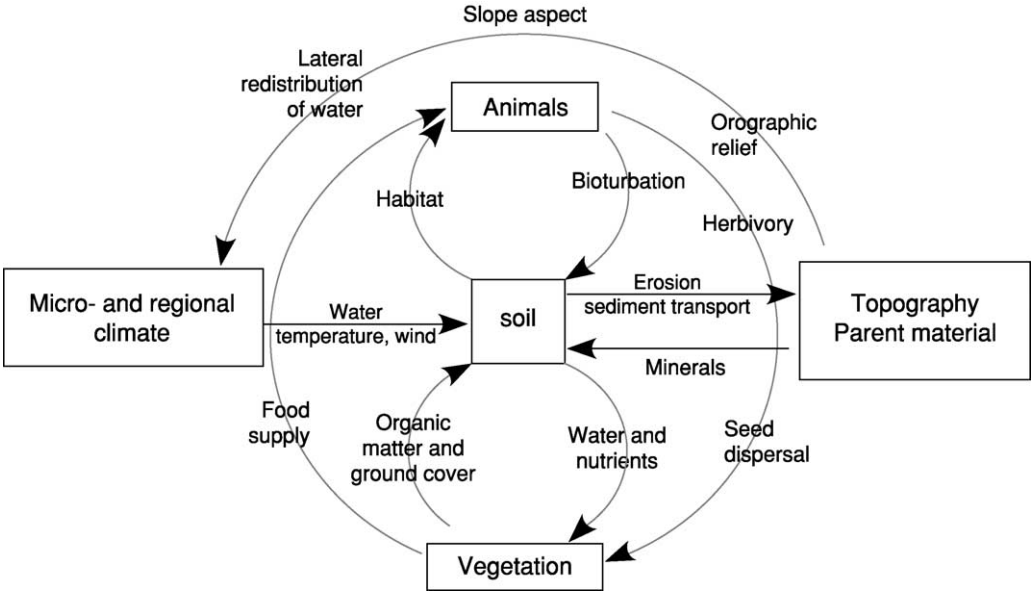

Figure 2 Illustration of the links among the soil-forming factors of climate, biota (vegetation and animals), topography, and parent material. The fifth factor, time, affects all of the illustrated links in proportion to the duration that the factors operate.

Parent material and topography are the main factors of the geologic setting that affect arid and semiarid soils. Parent material has a direct link to soil as a supplier of mineral detritus. Topography has its link to soil by its influence on regional climate at the orographic scale and by its influence on microclimate (resulting from slope aspect and laterally redistributed water) at the local scale. Over the long term, climate through its effects on soils alters the configuration of the landscape by erosion and sediment transport (Figure 2).

Properties of Arid Soils

Arid soils have surface horizons with several unique characteristics. Many arid soils, for example, are covered by desert pavement that overlies vesicular A and E horizons. Other arid soils are covered by salt efflorescence in areas where shallow groundwater has risen by capillarity and evaporated at the surface. Still other arid soils are covered by microbiotic crusts or by blankets of aeolian sand or silt. Nearly all arid soils have lower amounts of organic matter than their more humid counterparts. For classification purposes, the surface horizon (i.e., epipedon) that is ubiquitous for arid soils is the ochric epipedon. Other epipedons of arid soils with much smaller occurrences are the mollic, anthropic, and in very rare cases of grass sod over shallow basalt, the histic.

Subsurface horizons of arid soils are uniquely different from subsurface horizons of humid soils in some instances, yet similar in other instances. Subsurface horizons in arid soils that are uniquely different include horizons dominated by calcium carbonate, secondary silica, gypsum, and soluble salts, while horizons common to both arid and humid soils include those with weak structural and color development and accumulations of illuvial clay and sesquioxides. Diagnostic horizons unique to arid soils include the calcic, petrocalcic, duripan, gypsic, petrogypsic, natric, and salic horizons (Figure 3). Diagnostic horizons found in both arid and humid soils include the cambic, argillic, and in rare cases, the oxic.

In addition to diagnostic horizons, other soil properties, such as vertic, andic, lithic, climatic, anthropogenic, depth to groundwater, and particle-size characteristics are used to make taxonomic subdivisions in arid soils. At the highest taxonomic levels, arid soils include Leptosols, Gypsisols, Durisols, Calcisols, and Solonchaks in the World Reference Base (WRB) system; Desert gray brown, Desert takyr-like, Desert sandy, and Meadow desert soils in the Russian system; and Halosols and Aridisols in the Chinese system. In the Soil Taxonomy system, arid soils are classified as, in order of abundance, Aridisols, Entisols, Vertisols, Oxisols, and Andisols (Table 1). Moving dune fields also occupy large areas of deserts, especially in North Africa.

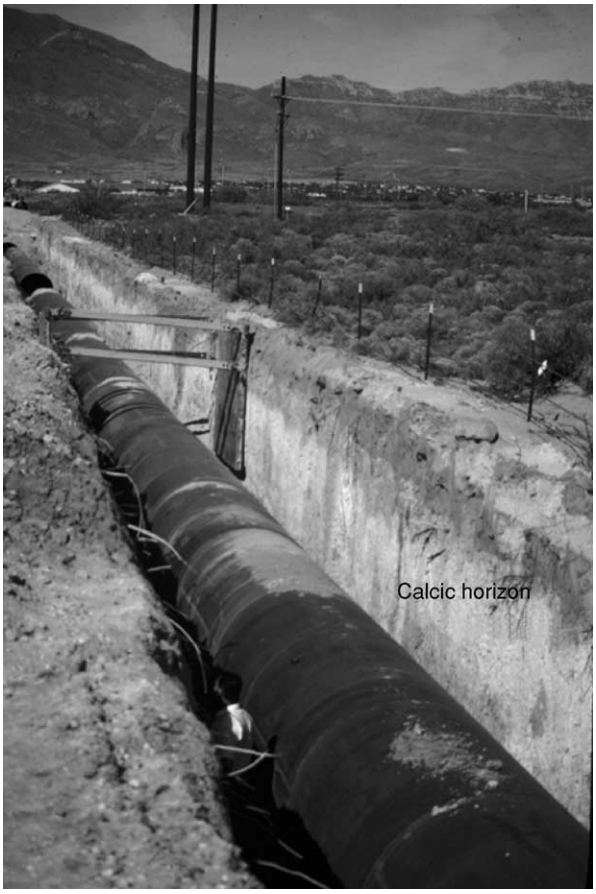

Figure 3 Calcic horizon in an arid soil in the Chihuahuan desert of North America. This site has an annual rainfall of 250 mm and an annual temperature of 16°C.

Properties of Semiarid Soils

Semiarid soils, owing to more rainfall and the homogenizing effects of greater vegetative cover, have surface horizons with more organic matter than arid soils and fewer unique features like desert pavements, vesicular horizons, and efflorescence. Although the ochric epipedon is still a common horizon of semiarid soils, the mollic epipedon is widespread and dominates the steppe areas that border tall-grass prairies.

Being transitional between arid and humid soils, semiarid soils have a large variety of subsurface horizons. As with arid soils, semiarid soils might have calcic, petrocalcic, duripan, gypsic, natric, and salic horizons. Yet, as with humid soils, semiarid soils might have albic, argillic, and kandic horizons as well as fragipans and plinthite.

[b] Entisols with the aridic (torric) moisture regime are designated at the great group level (e.g., Torripsamments and Torriorthents).
[c] The semiarid soils category contains some soils of subhumid climates (500–1000 mm annual precipitation) in cold regions and along coasts.
[d] Entisols with the ustic and xeric moisture regimes are designated at the great group level (e.g., Ustorthents and Xerofluvents).

Other diagnostic properties used to subdivide semiarid soils include redox, petroferric, vertic, andic, lithic, climatic, anthropogenic, particle-size, and groundwater characteristics. Classification of semiarid soils includes the Kastanozems, Chernozems, and Phaeozems in the WRB system; Meadow Chernozem-like, Meadow Chestnut, Semidesert Brown, and Semidesert Meadow Brown soils in the Russian system; and Isohumisols and Ferrallisols in the Chinese system. In the Soil Taxonomy system, semiarid soils are classified as, in order of abundance, Alfisols, Entisols, Mollisols, Inceptisols, Ultisols, Oxisols, Vertisols, and Andisols (Table 1).

Human Land Use of Arid and Semiarid Soils

Early civilizations arose in arid and semiarid Sumeria in the fourth millennium BC as irrigated agriculture on floodplain soils encouraged stable settlements, led to surplus food, and freed people to pursue specialized trades and to develop social order and cultural creativity. Similar cultural developments arose along rivers in other arid and semiarid climates, such as the Indus of ancient India and Hoang-Ho of ancient China. In the western hemisphere as well, societies developed in arid and semiarid climates, such as the Inca, Aztec, and Hohokan cultures.

Grazing of domesticated cattle, sheep, and goats has been the traditional land use of arid and semiarid soil away from the irrigated floodplains. Today, in addition to grazing, arid and semiarid soils have ecological and global biogeochemical properties important to humans. Arid and semiarid ecosystems have some of the highest biodiversity on Earth as grasses, cacti, shrubs, reptiles, birds, and mammals have adapted to wide and rapid shifts in temperature and moisture. Much of the carbon in the global carbon cycle, at least 800×10^{15} g, is stored as soil carbonate in arid and semiarid soils. The source of much of the local, regional, and global dust is from arid and semiarid soils.

Desertification, which is defined by the United Nations Convention on Desertification as 'land degradation resulting from climatic and human activities,' is a major issue of importance in arid and semiarid climates because desertification directly affects about one-sixth of the world's population in both developing and developed countries. Increasing human population and livestock pressures have accelerated desertification and caused shrubs to invade grasslands with subsequent erosion of exposed topsoil. Wind erosion is a major agent for desertification in arid and semiarid regions because it removes organic matter and fine mineral particles in A horizons that have important water and nutrient storage properties. Water erosion is also important, especially at the arid–semiarid boundary of about 250 mm of precipitation where erosion rates are commonly at their greatest.

Limited water supply is of paramount importance to expanding populations in arid and semiarid regions of North and South America, Australia, Africa, Asia, and the Middle East. In the western USA, for example, the drought did not move to the people, the people moved to the drought. While the lack of water threatens population growth in arid and semiarid regions, the lack of water is the natural state, and the state that imparted the unique properties to arid and semiarid soils. It is also the lack of water that makes arid and semiarid places some of the most open, least developed places on Earth, and some of the last 'wild' places for future generations to enjoy and study.

Humid Tropical

Introduction

Soils are the physical, chemical, and biological media at the upper surface of the Earth's land areas capable of accepting plant roots. A wide range of geologic materials, soil moisture, and temperature conditions

that differ regionally and among adjacent soils on local landscape positions provide for diverse suites of contrasting soils that interact differently with biological communities and human attempts to sustain food production within the humid tropics.

Humid Tropical Setting

Many climatic classifications have been published. The parameters of soil temperature and moisture regimes used to classify soils do not conform to general concepts of humid tropics. The following criteria, adopted by the National Cooperative Soil Survey in the USA, are most universally used when classifying soil.

Soil-Temperature Regimes of the Tropics

Mean annual soil temperatures are 2–4°C warmer than mean annual air temperatures. Soil-temperature regimes (STRs) are defined by two criteria, mean annual soil temperature and seasonal temperature difference (Figure 1). Seasonal soil-temperature difference is determined as the mean soil temperature of June, July, and August compared with the mean soil temperature of December, January, and February. Almost all of the soils within the geographic tropics have soil temperatures that seasonally differ by less than 6°C and are identified by the prefix 'iso' placed before the name of the mean annual soil-temperature regime. Except for a few soils near the northern and southern extremities of the geographic tropics in Africa, this one characteristic is the only soil property that is nearly universal with the concept of tropical soil. The practical aspect of this soil property is that seasonal soil temperatures seldom have to be considered when planting food crops.

Soils with mean annual soil temperatures of 22°C or higher are classified as isohyperthermic; soils with mean annual soil temperatures of 15–22°C are identified as isothermic. Freezing conditions are seldom a problem in the isothermic and isohyperthermic STRs. Higher elevations in tropical areas have isomesic STRs, with mean annual soil temperatures less than 15°C; crop growth is slow, night-time freezing is common, and even cold-tolerant crops such as potatoes seldom grow well where mean annual soil temperature is below 10°C.

Soil-Moisture Regimes of the Tropics

Soil-moisture regimes (SMRs) are defined to classify a soil's ability to supply water to plants without irrigation (Figure 2). In soils where the groundwater table is not reached by the roots of most crop plants, the SMR is determined by the seasonal distribution of rainfall in 'normal' years. Normal years are ±1 standard deviation of long-term means. Most food crops require a reliable supply of water for at least 90 consecutive days. To calculate SMRs, the mean monthly precipitation is compared with the calculated potential evapotranspiration. A soil-water balance is then constructed for the mean rainfall in the area. The duration of time during which water is normally available either from average rainfall or as stored available water in the soil during a period when soil temperatures are warm enough to grow the crop determines the SMR.

The perudic SMR has precipitation that exceeds potential evapotranspiration every month of normal years. Although this may seem desirable, these areas present weed, insect, and disease problems, and the constantly humid conditions make it difficult to harvest mature grain crops.

The udic SMR has fewer than 90 cumulative days when water is not available in the rooting zone in normal years. It is possible to grow food crops any time of the year without irrigation when the temperature is warm enough for that crop. Available water is less reliable during some part of the year, and farmers often select more drought-tolerant crops or may choose not to plant during that period, but perennial plants are adequately supplied with water throughout most years in most of the udic SMR areas.

The ustic SMR is borderline to the common concept of humid. In normal years, soils with an ustic SMR have at least 90 consecutive days when moisture is available, but more than 90 cumulative days when water is not available in the rooting zone. Natural vegetation is either seasonal rain forest or savanna. At least one crop can be reliably grown each year, and it is possible to grow two crops per year on some soils, but there is a seasonal dry period of 90 days or more when crop production is not possible without irrigation. The reliable dry season of the ustic SMR is a distinct advantage for weed and disease control and grain-crop harvest in isohyperthermic and isothermic STRs.

Soils that have a reliable moisture supply for fewer than 90 consecutive days in normal years have an aridic SMR and are excluded from the concept of humid tropics.

The above SMRs are used to classify only the well-drained upland soils. Groundwater often saturates the rooting zone of some soils within all areas of the humid tropics. These soils are identified as having an 'aquic soil moisture condition' and are commonly referred to as poorly drained soils. Soils with aquic soil-moisture conditions most often occur in areas adjacent to rivers and lakes or in broad, level

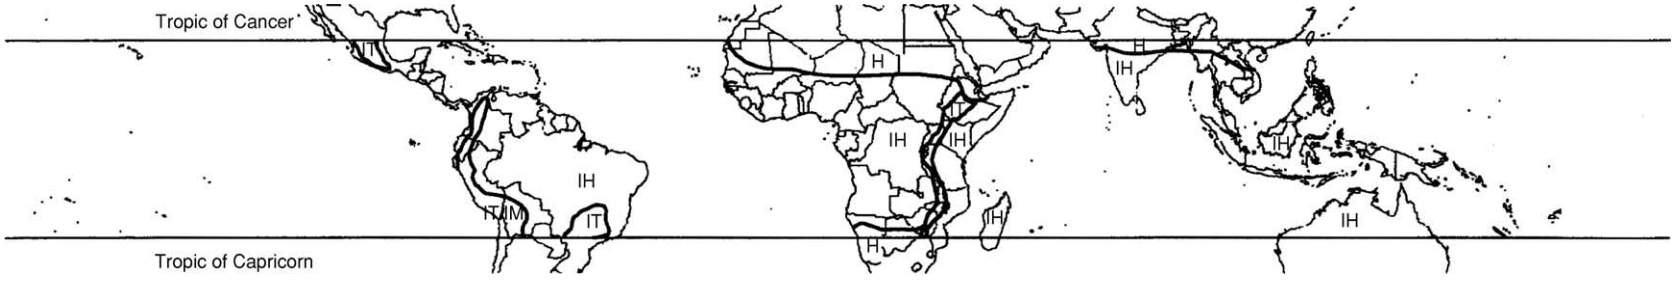

Figure 1 Generalized map of soil-temperature regimes in the tropics. IH, isohyperthermic; IT, isothermic; IT/IM, isohyperthermic and isothermic; H, hyperthermic.

landscapes. Soils with aquic soil-moisture conditions are saturated with water only during some part of the year. They are often seasonally utilized for subsistence food crops, but most require engineered drainage systems before commercial agricultural production is possible.

Chemical and Mineralogical Composition of Soils

Of the chemical elements needed for plant and animal physiology, only carbon, oxygen, hydrogen, nitrogen, and to some extent sulfur are derived from air and water. The other essential elements are obtained from the minerals in the soil. Mineralogical properties of soils are derived from the geologic material within which the soil is formed. An inadequate supply of any essential element limits plant growth. The most frequent limitations result from insufficient plant-available nitrogen, phosphorus, potassium, calcium, or magnesium.

Practically no nitrogen is present in soil minerals. Nitrogen enters the soil as ammonium and nitrate dissolved in rainwater or via fixation from the air by nitrogen-fixing microbes. Some nitrogen-fixing microbes in the soil are symbiotic and the nitrogen they extract from the air is incorporated into their legume plant host. Other nitrogen-fixing microbes are not symbiotic, and the nitrogen they extract from the air is incorporated into their cells. Nitrogen is concentrated in organic residues in the surface layers of soil. As organic residues decompose, inorganic forms of nitrogen are released into the soil solution and become available to growing plants, leach into the groundwater during periods of excessive rainfall, or return to the air as nitrogen gas during periods when the soil is saturated with water. Plant-available nitrogen contents in soil are transient and closely related to supplies of organic residue.

Phosphorus is present in only a few minerals. Iron and aluminum phosphates are extremely insoluble and do not release phosphorus rapidly enough for rapid plant growth. The release rate is so slow that soils with high iron and aluminum contents tend to absorb phosphate applied as fertilizer and decrease its availability to plants. Apatite, a more soluble calcium phosphate mineral capable of supplying plant-available phosphorus, is a common source of phosphorus and often present in limestone.

Potassium is present in mica and feldspar minerals. These minerals are rather easily decomposed in the soil environment and consequently are seldom present in materials that have been repeatedly transported and deposited on the land surface.

Calcium and magnesium are most abundant in carbonate minerals associated with limestone and some sandstone. Carbonate minerals are also relatively unstable when subjected to weathering and therefore are present only in recent geologic sediments, limestone and some sandstone.

Soil pH is a measure of the acidity or alkalinity of water in the soil and has a direct effect on how rapidly many of the essential elements are available to growing plants. In the absence of carbonate minerals, soils in the humid tropics are acid in reaction and only limited quantities of essential elements present in the soil are available for plant growth. Acid soils with pH values less than approximately 5.2 also have a concentration of aluminum ions that is toxic to some but not all crop plants. Additions of lime (finely ground calcium and calcium:magnesium carbonates) are desirable and often necessary to reduce or eliminate aluminum toxicity and increase the availability of the essential elements to most crop plants growing in acid soils.

The rate at which essential elements in the soil are available to plants is critical to understanding soil fertility. Plants extract the elements they need from the soil as inorganic ions in the soil solution. The amount of each essential element in the soil that is available to plants changes rapidly as the moisture content of the soil changes and also depends on the rate at which organic compounds decompose to release organically bound elements as available inorganic ions. Less than approximately 1% of the total amount of most essential elements in the soil is present in an available form. Plant species differ greatly in the rate at which they need to acquire essential elements for adequate growth. The rate at which nutrients become available influences natural plant communities and is directly related to human food production. Most human food crops require 90–120 days to mature. Food crops must have a rate of nutrient availability many times faster than required by native ecosystems. A high-yielding grain crop of rice, wheat, or corn must acquire approximately as much phosphorus in 90 days as trees acquire from the same area of land in more than 20 years. In addition, tree roots usually penetrate more deeply and exploit a larger volume of soil than food crops. Therefore, the concentration of available nutrient elements near the soil surface must be considerably greater to supply adequately the needs of a food crop than to support tree growth.

Humans harvest and transport their food crops to a domicile some distance from the site where the crop was grown. Often the seed portion of the plant is consumed and only the less nutrient-rich stems, leaves, and roots of the crop plant are returned to the soil as organic residue. Considerable amounts of

organic residues are required to fertilize a crop plant, because these residues decompose slowly to release inorganic ions for crop growth. The common practice of burning residues facilitates rapid crop growth by releasing organically bound nutrients.

Historically humans have populated areas of soil with high levels of mineral fertility. These are commonly igneous or volcanic materials of basic mineral composition, sedimentary rocks such as limestone rich in calcium, magnesium, and phosphorus, and recent flood plains frequently renewed by depositions of material derived from fertile geologic materials and eroded surface soil. Where the mineral composition of the soils contains only small amounts of essential elements and a large amount of slow-growing natural biomass is present, a system of food production known as slash and burn is practiced. Although some essential elements are volatilized and lost, fire is the primary method of rapidly decomposing organic material and creating a short time period when nutrients contained are rapidly available as inorganic ions. If there is enough biomass, at least one crop can be successfully grown in the 90 days after burning. If correctly done, burning also assures that the surface temperature of the soil becomes high enough to reduce weed competition by killing most weed seeds near the soil surface. A second and third crop is often possible before the available supply of essential elements is exported from the field as human food and the rate of nutrient availability is reduced to a point where crop yields are low and/or weeds become a major problem. After the farmer abandons that land, a succession of native communities that are able to grow with lower rates of nutrient flow from the soil invade the site. After some years, the slow-growing native vegetation acquires enough nutrients in its biomass that it can again be cut, dried, and burned to obtain a site for another brief sequence of crop plants. This method of nutrient-availability management has numerous variations among different indigenous cultures. Only low human population densities are sustained by slash-and-burn agriculture because of the long periods of time (usually between 10 and 30 years and inversely related to the mineral fertility of the soil) that must be allowed for natural vegetation to accumulate sufficient quantities of essential elements needed to fertilize a food crop after burning. Where domestic animals are allowed to graze large areas of native vegetation, essential elements concentrated in their excrements are often collected and used to fertilize small areas of food crops. In areas where infrastructure enables crops to be exported and essential nutrients imported as concentrated fertilizer, continuous food-crop production is practiced on even the most chemically infertile soils. Many combinations and variations of these strategies presently exist throughout the humid tropics.

Mineral and Chemical Grouping of Soils

Broad geographic areas of soils with similar mineral and chemical composition are outlined in Figure 3. Many localized areas of soils that differ significantly from those described in the following discussions are present within each identified area.

Reworked Sediments of Low Fertility

Unlike many areas in temperate latitudes, where soils form from material that has been loosened and deposited by massive glaciations in rather recent geologic times, many areas in the tropics have land surfaces that have been exposed to weathering, soil formation, and erosion for many geologic ages. In these areas the present soils have formed from material almost devoid of minerals that contain essential elements, and soil acidity renders the low quantities present only slightly available to plants. Soils formed from such materials are not only deficient in available forms of the major plant essential elements, but also often deficient in plant-available forms of copper, zinc, boron, and sulfur. The nutrient-poor natural biomass growing on such areas often contains inadequate amounts of essential nutrients for slash-and-burn agriculture. Without the importation of essential nutrients, human habitation is often nomadic and limited to small, isolated sites of more fertile soil.

The watershed uplands between the Amazon and Parana rivers in Brazil are representative of infertile reworked material. The soils form in thick deposits of material that has been weathered through several cycles of erosion and deposition. Quartz, kaolinite, gibbsite, and iron oxides are the predominant minerals. Content of essential elements is very low, and the majority of the soils are Oxisols (Ferralsols) (*Nomenclature of Soil Taxonomy* is used to identify soils and, where applicable, the corresponding units of the *Soil Map of the World* follow in parentheses) and, in very sandy sediments, equally infertile Quartzipsamments (Ferralic Arenosols). The most infertile of these soils, Acrustox (Acric Ferrosols), support sparse native vegetation of grass and low shrubs called 'cerrado' in Brazil. Each year wildfires burn extensive areas during the dry season of the ustic SMR. Attempts to graze the native vegetation often result in nutrient deficiencies in cattle. Extensive areas of these soils are now being utilized for mechanized agriculture with external sources of lime and fertilizer. In addition to wheat, soybeans, and other food crops, sugar cane for ethanol fuel production is grown.

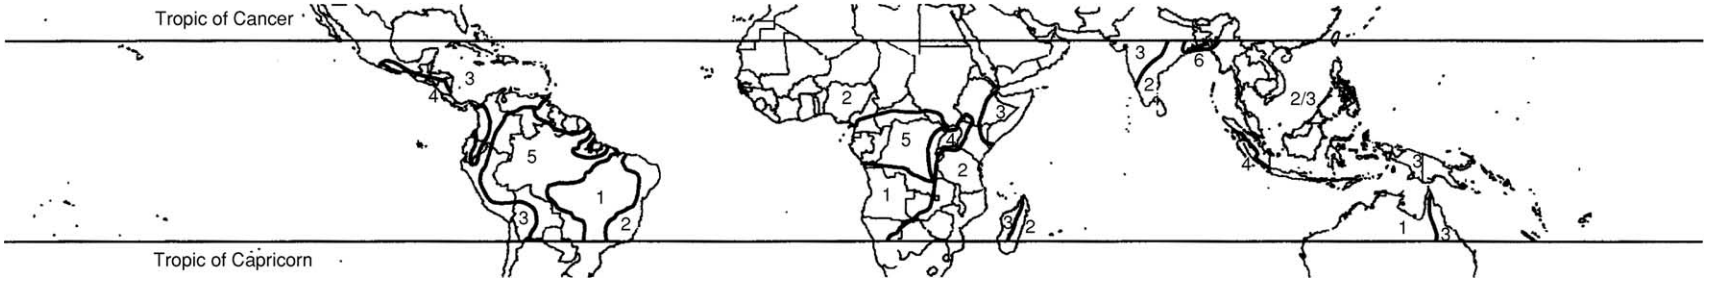

Figure 3 Generalized map of mineral and chemical soil regions in the tropics. 1, low-fertility sediments; 2, acid igneous rock; 3, limestone and other base-rich rock; 4, volcanic materials; 5, major river basins; 6, flood plains.

On inclusions of limestone, basalt, and sediments from these more fertile materials, Eutrustox (Rhodic Ferralsols) are present. These more fertile soils were naturally forested with seasonal deciduous forests that have been removed as farmers seek the more fertile soils for food-crop production.

Acid Igneous Rock

These areas are most extensive in Southeast Asia, parts of the eastern highlands in South America, West Africa, the central highlands of East Africa, and Eastern India. Ultisols (Acrisols) and Inceptisols (Cambisols) formed in these materials can be considered of moderate fertility but most commonly deficient in P and Ca. In most areas there are inclusions of more base-rich sedimentary rock where Alfisols (Luvisols) have formed. Most agriculture is limited to slash and burn unless infrastructure for markets and fertilizer exist.

Limestone and Other Base-Rich Rock

Where tectonic upheavals have exposed areas rich in carbonate and other nutrient-bearing rock, the soils are relatively rich in essential elements. Soils on the Deccan plateau of western India are fertile Vertisols (Vertisols) and Mollisols (Cambisols) formed in base-rich rock. The Andean chain along the west coast of South America and in Central America was formed by tectonic uplift and associated volcanic activity. Some of the uplifted materials are limestone, rich in carbonate, while other portions of the region are granite and schist, relatively poor in essential elements. Tectonic instability, steep slopes, and glaciers at the highest elevations have resulted in rapid erosion of surface materials and deposits of relatively fertile sediments in intermountain valleys of fertile Eutrudepts and Haplustepts (Eutric Cambisols).

Volcanic Material

A small proportion of the soils in humid tropical areas are formed in relatively nutrient-rich material derived from volcanic activity. Volcanic ash and basalt materials of various ages, including some recent volcanic activity, form Andisols (Andosols). Soils derived from volcanic ash and basalt historically have supported intense human settlement. Java, southern Sumatra, parts of the Philippines and other Pacific islands, Central America, the Andean mountains in South America and the Rift Valley in Africa are major areas of volcanic material. Many volcanic areas are mountainous and the higher elevations have isothermic or isomesic STRs where crop growth is reliable but cool temperatures slow crop growth at the higher elevations. Development and maintenance of roads are expensive due to the rugged relief, earthquakes, and volcanic activity. Transportation infrastructure is seldom reliable beyond local markets.

Major River Basins

The major river basins include the Amazon, Orinoco, and Paraguay river basins in South America, and the Congo basin in Africa (Figure 3). The basins are composed of sedimentary materials derived from surrounding uplands and mountains. The fertility of the soils reflects the mineral composition of the upland areas from which the sediments are derived.

The western portion of the Amazon basin and the central portion of the Congo basin have udic and perudic SMRs, while the eastern portion of the Amazon basin has an ustic SMR. Oxisols (Ferralsols) predominate in the Congo basin and eastern portion of the Amazon basin, where the sediments are derived from the Guyana and Brazilian shields. Ultisols (Nitosols) predominate in the western part of the Amazon basin, where the sediments are derived from the Andes and are slightly more nutrient-rich than those to the east. Both Ultisols and Oxisols are nutrient-poor, but inclusions of more nutrient-rich material are present. Alfisols (Luvisols and Eutric Nitosols) are formed in these more base-rich sediments in western Brazil and on the eastern boarders of the Congo basin. Many areas of these more chemically fertile soils are being cleared of forest vegetation for crop production and cattle grazing.

Some of the sediments in the basins are sandy. Soils formed in the sandy sediments are very infertile Quartzipsamments (Arenosols), where the water table is deep, or Spodosols (Podzols), formed where the water table is near the soil surface. It has been estimated that perhaps 10% of the Amazon basin has these kinds of soils. One major area of sandy soils is in the headwaters of the Rio Negro in the northwestern part of the basin, where it merges with the Orinoco watershed. Smaller areas of sandy soils are scattered throughout the basins, often detectable by coffee-colored 'black' waters of the rivers that drain these sandy watersheds.

Floodplains

Soils formed in river floodplain sediments and deltas are often fertile. The fertility is derived from eroded topsoil from the surrounding uplands. Where the mineral composition of the soil is relatively rich in essential elements, people are able to grow and harvest food with little or no attention to chemical fertilization. Crop yields are usually low but reliable. Most soils formed in floodplains are Entisols and Inceptisols, with aquic soil conditions (Gleysols). Despite the

physical dangers from flooding, human settlements are concentrated in these areas, attracted by the soil fertility and access to transportation afforded by the rivers. Road maintenance is extremely difficult where broad floodplains are prevalent. Most agriculture is subsistent unless the flooding hazards and periodic saturation can be controlled. Narrow areas of flood plains are present along coastlines and rivers throughout the humid tropics, but only a few areas are shown in Figure 3.

Organic Deposits

Organic remains accumulate in areas that remain saturated for most of the year, forming organic soils (Histosols). Histosols are present in many floodplain areas but contiguous areas are too small to outline in Figure 3. Cultivation is problematic and drainage systems are needed to aerate the soil and provide stable trafficking.

Human Utilization

The predominant soil limitation in humid tropical regions is low chemical fertility. Major areas of soil are formed from geologic material that contains very limited quantities of life-essential phosphorus, potassium, calcium, and magnesium. The most chemically infertile soils are present as uplands in the interiors of Africa and South America. Most of these soils are physically deep and have reliable moisture for one or two food-crops each year. The most infertile of these soils do not support enough natural biomass to sustain even slash-and-burn subsistence agriculture. Where rapid and reliable infrastructure has been developed, sustained commercial agriculture is now practiced. Reliable markets, fertilizer, lime, and fuel supplies are essential. A sufficient amount of phosphorus must be applied and mixed into the soil to saturate the iron and aluminum oxide surfaces to the extent that sufficient phosphorus becomes available before crops can be grown. Carbonate, in the form of crushed limestone, must be applied to raise the pH of the soil and inactivate the extractable aluminum. Nitrogen fertilizer is needed for nonlegume crops. Potassium is required for high yields, and small amounts of copper, zinc, boron, and molybdenum are needed in many areas. After an initial investment is made in altering the chemical conditions, fertilizer requirements are annually no greater than in other grain-growing soils around the world. Modern soil-testing technology is utilized to determine annual fertilizer formulations and rates. The physical stability of the inert soil minerals, a paucity of river systems that must be bridged, and the gentle topography aid in economical road construction in most parts of the region.

Somewhat less infertile soils with dense forest vegetation can be and are being used for slash-and-burn subsistence agriculture. The rate at which essential nutrients are released from the minerals is too slow to replenish those removed in rapidly growing food crops. The slow-growing forest vegetation that regenerates in abandoned fields can accumulate enough nutrients in its biomass that when cut and burned one or two food crops can be grown only every 10–30 years. These soils have the potential for more intense food crop production if chemically fertilized, which is seldom possible without a market infrastructure.

Human populations in the humid tropics are concentrated on soils formed from materials relatively rich in phosphorus, calcium, magnesium, and potassium. Such soils are primarily located in floodplains and deltas, in areas of volcanic activity, and in upland areas underlaid by limestone, base-rich igneous, and metamorphic rock.

Importing essential elements to compensate for those harvested in human food can increase crop yields from all soils. Applying animal and human wastes wherein the essential elements have been gathered from sites distant from the food-growing area is a partial solution in many cultures. However, the concentration of essential elements in organic residue and waste materials is low, transportation is difficult, and the rate at which the residues decompose to release inorganic ions for crop uptake is slow. Where commercial infrastructure is available, concentrated inorganic fertilizers have proven to be the most economical method of supplying nutrients harvested in human food.

Introduction

The importance of understanding unstable preferential flow processes cannot be overstated considering its relevance to crop irrigation, groundwater recharge, and vadose-zone transport of nutrients and contaminants. An important aspect of preferential infiltration is the residence time of water in the vadose zone, where contaminants and nutrients are degraded or exchanged in the media. The residence time is shorter for soils with preferential flow than without. Preferential flow can also be caused by macropores. Both types of preferential flow are similar in that the gravity force dominates sorptive processes. This article is concerned mainly with the unstable finger flow formation.

Conditions for Unstable Flow

Although the existence of fingered flow has been known since 1945, the practical importance of instability in stratified soils was not recognized prior to 1972, when Parlange and coworkers demonstrated that fingering can occur in a fine-over coarse-textured profile. In the early years, investigators were concerned with instabilities caused by gradients of temperature or solute concentration in miscible liquids. A few noticed that 'narrow tongues' formed in hydrophobic sands.

Several attempts were made in the 1950s and 1960s by Saffman and other researchers to relate the fingering in petroleum engineering to vadose-zone fingers; but this was problematic, because the first laboratory experiments used a viscous oil, glycerin, which was displaced by compressed air in Hele–Shaw cells. This is not an obvious analog to water displacing air in a stratified medium. As a consequence, viscosity became initially a dominant feature in many theories, although this is now known to be incorrect. This does not mean that some of the equations derived by Hele–Shaw cells cannot be properly reinterpreted. A necessary condition for instability, for water and air in a porous media, neglecting both viscosity and density of air, becomes:

$$K_s > Q \qquad [1]$$

where Q is the water flux imposed by the upper layer of fine material, and K_s is the saturated conductivity of water in the coarse layer underneath. The condition in eqn [1] is obviously necessary, because if Q was greater than K_s, the whole area would have to be saturated to carry the water and no finger would be present. It is a fundamental contribution of Hillel and coworkers to have noticed that eqn [1] is not constraining enough and that water entry in the coarse layer is associated with a 'water entry' suction for the water to penetrate the coarse layer. They further suggest that, upon rewetting, the water entry suction will be higher, resulting in drier fingers, leading to interesting hysteresis phenomena. In all cases, hysteresis is crucial by limiting lateral capillary diffusion of water which would otherwise remove the presence of fingers, as often happens in Hele–Shaw cells.

Finger Diameter and Structure

In early work in Hele–Shaw cells, the optimal width of the fingers was found by balancing the destabilizing effects of gravity and the stabilizing effect of surface tension. Finger width for soils were initially derived 'Green and Ampt soils,' with discontinuous wetting fronts. In the mid-1970s, Parlange and coworkers derived an expression for the finger

width, d, based on the analysis of Richards' equation, i.e., a diffuse front, yielding:

$$d = \pi \frac{S^2}{K(\theta - \theta_i)} \frac{1}{1 - Q/K} \quad [2]$$

where S is the sorptivity given by:

$$S_c^2 = \int_{\theta_i}^{\theta} D\left[\theta + \bar{\theta} - 2\theta_i\right] d\theta \quad [3]$$

where D is the soil-water diffusivity and θ_i is the initial water content, assumed small enough that the soil-water conductivity, K, at θ_i is negligible compared with its value at θ_c. The value of θ_c is a strong function of the initial water content and is not predicted by the theory. Equation [2] is valid for a two-dimensional finger in a slab chamber. In the field, where the fingers are three-dimensional π is replaced by 4.8.

Initially, for a soil initially dry, Parlange and coworkers assumed that θ_i in eqn [2] corresponds to saturation. However, fingers are rarely saturated in soils (as they are in a Hele–Shaw cells) and water content varies along the fingers. As shown in **Figure 1** the finger tip is the wettest (the red color) and it dries behind the finger. The moisture content, θ, varies with depth (measured from the interface between layers) according to the equation:

$$z = \int_{\theta_o}^{\theta} \frac{D d\bar{\theta}}{K - v(\bar{\theta} - \theta_i)} \quad [4]$$

where v is the constant downward speed of the fingers obtained after a short time, i.e., after all mergers have taken place and the fingers have reached a steady configuration. θ_o is the value of θ at $z = 0$ and, if we assume that the maximum value of θ corresponds to a water entry value θ_e, then eqn [4] gives:

$$vt = \int_{\theta_o}^{\theta_e} \frac{D d\theta}{K - v(\theta - \theta_i)} \quad [5]$$

which gives $\theta_o(t)$ when v and θ_e are known. In particular, when $t \to \infty$, θ_o approaches an asymptotic value $\theta_{o\infty}$ with:

$$K(\theta = \theta_{o\infty}) = v(\theta_{o\infty} - \theta_i) \quad [6]$$

When Q/K_c is negligible in eqn [2], we obtain a simpler equation for d:

$$d = \pi S_c^2 / K_c(\theta_c - \theta_i) \quad [7]$$

Note that both S_c^2 and K_c are inversely proportional to the viscosity; accordingly d is independent of viscosity. The influence of viscosity can be felt only through $[1 - Q/K_c]$ in eqn [2] and, thus, is irrelevant when fingering is important and Q/K_c is small.

Finally, for coarse sands, and as long as θ is not too small where the description of the Gardner–Ritsema soil-water conductivity is realistic:

$$K = K_c \exp \alpha(h - h_c) \quad [8]$$

where α is more or less constant and h is the matric potential. Then, eqn [3] shows that for a coarse sand:

$$S^2 \simeq 2(\theta - \theta_i) \frac{K_c}{\alpha} \quad [9]$$

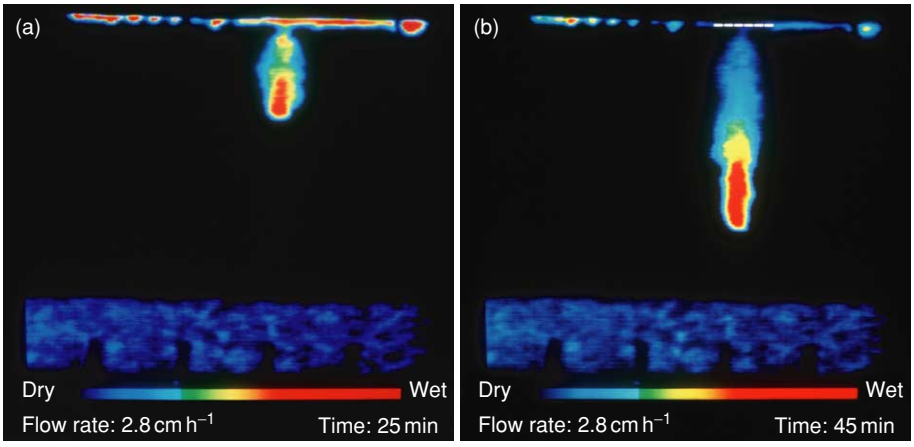

Figure 1 Finger formation in a coarse sand. Note that near the soil surface the distribution zone is visible. This zone carries the water from the rainfall that is uniformly applied at a rate of 2.8 cm h^{-1} to the one finger. Color indicates the moisture contents, with red the closest to saturation. Then the colors for decreasing moisture contents are: yellow, light green, light blue, dark blue, and black: (a) 25 min after water application; (b) 45 min after water application. Reproduced from Nektarios PA, Steenhuis TS, Petronic AM, and Parlange J-Y (1999) Fingered flow in laboratory golf putting greens. *Journal of Turfgrass Management* 3: 53–67.

Hence, we find the remarkably simple result:

$$d \simeq 2\pi/\alpha \qquad [10]$$

i.e., the dependence on θ_o and θ_i has disappeared. This explains why d is essentially constant in time and space and is inversely proportional to Gardner's α.

Note that, for water contents between θ_e and θ_o, all properties are measured on a drying curve of the matric potential. However, as the finger moves downwards within the sand, there is a very narrow zone at the finger tip where the water content increases rapidly, thus operating on a wetting curve, but reliable matric potential data are almost impossible to get in that region. Insight in this region was obtained by measuring reliable water contents down to the pore scale with neutron radiography. A 'dynamic' pressure, $h(\theta)$, was calculated based on Darcy's law by measuring the velocity of the finger, the distributed moisture content, and the unsaturated conductivity. The shape of the curve is similar to that which can be derived from earlier fingered flow experiments depicted in Figure 2 and is very much different from expected soil-water pressure relationships for the same soil. Although these effects are sometimes attributed to nonequilibrium effects, applying continuum results to the pore scale is problematic.

In fingered flow experiments where initial moisture content is varied, the finger size initially decreases when the moisture content increases from 0 to 0.005 $cm^3\,cm^{-3}$ and then later increases with increasing moisture content when it reaches the width of the chamber at 0.04 $cm^3\,cm^{-3}$ (Figure 3; note that the

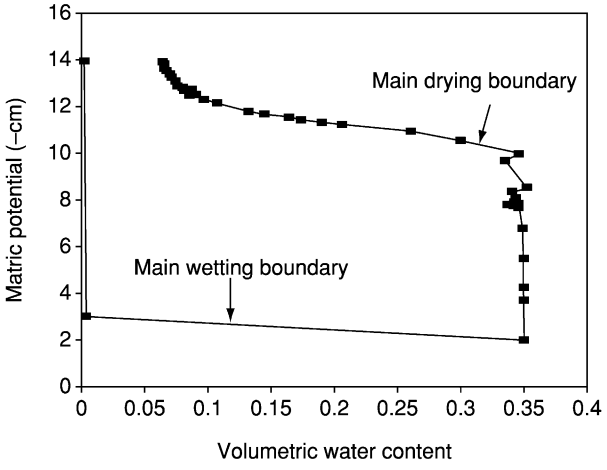

Figure 2 Nonequilibrium soil moisture curve obtained from fingered flow experiments. *h*, matric potential. Reproduced from Lin, Y, Steenhuis TS, and Parlange J-Y (1994) Closed-firm solution for finger width in sandy soils at different water contents. *Water Resource Research* 30: 951.

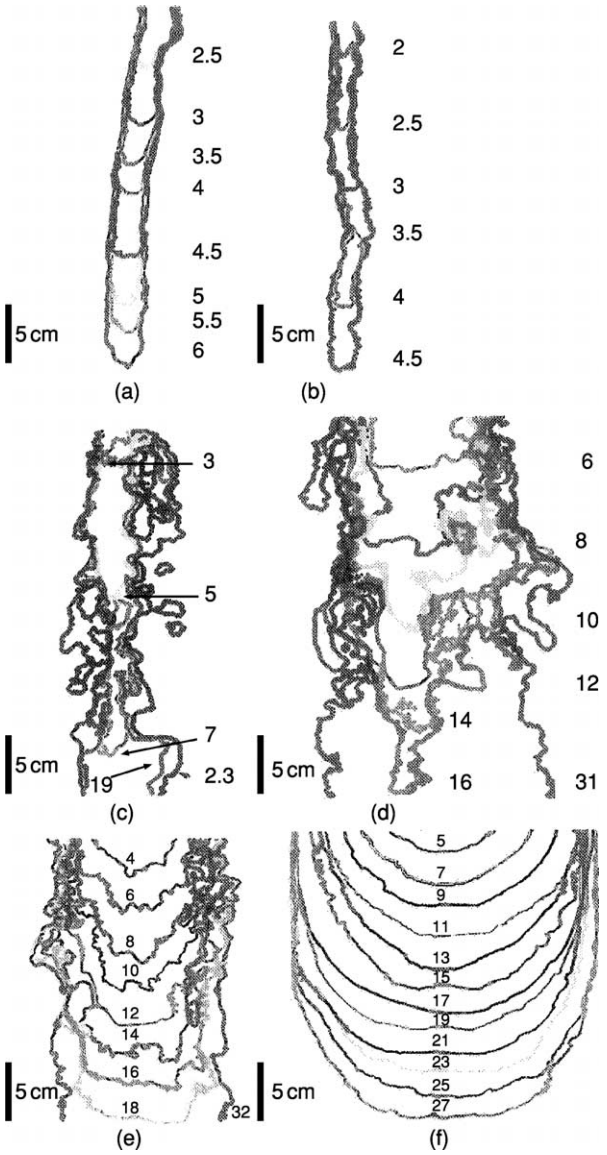

Figure 3 (a) Tracings of the totally dry sand. The sequence of tracings were taken every 30 s. The numbers accompanying the tracings are the minutes after infiltration started. A scale indicates 5 cm; (b) the advancing wetting front in the 0.01 $cm^3\,cm^{-3}$ moist sand. The infiltration front has a smaller width than in the totally dry case; (c) the advancing wetting front in the 0.02 $cm^3\,cm^{-3}$ initial moist sand pack. The tracings are depicted every 2 min. In addition, the latest tracing (after 23 min of infiltration) is shown; (d) advancing wetting fronts in the 0.03 $cm^3\,cm^{-3}$ moist sand. Two-minute tracings are shown until the front reached the bottom of the visible area. In addition, the tracing of the front is depicted when the infiltration was stopped (after 31 min); (e) advancing wetting fronts in the 0.04 $cm^3\,cm^{-3}$ initial moisture case. Two-minute tracings are shown until the front reached the bottom of the visible area. In addition, the front is depicted when the infiltration was stopped (after 32 min.); (f) the tracings of the wetting front when the chamber was imbibed from the bottom, or with a 0.04 $cm^3\,cm^{-3}$ (measured) initial moisture content. Tracings are depicted every 2 min. Reproduced with permission from Bauters TWJ, Dicarlo DA, Steenhuis TS, and Parlange J-Y (2000) Soil water content dependent wetting front characteristics in sands. *Journal of Hydrology* 231–232: 244–254.

surface induction zone is not shown). As θ_i increases, θ_c decreases rapidly and Q/K_c is not negligible in eqn [2] any more. Eqn [10] does not hold and d increases rapidly with θ_i.

The theory above applies only for a liquid, e.g., water or oil, and a gas, e.g., air. To extend the formula to the case of oil and water, it is necessary to obtain the dependence of the front velocity on its curvature. To obtain the dependence of the front velocity on curvature, the flow in the narrow diffuse region, ahead of it, must be analyzed, and to do so we must know the flow further ahead (here the pure oil). In the case of a gas, this presents no problem as it is assumed that the air can move freely ahead and does not affect the flow of water. Usually this will not be the case when oil is displaced by water, although it represents a limiting case.

The discussion has been limited, so far, to the movement of liquids. To include the transport of solutes, it is necessary to recall the physical configuration of the flow paths (**Figure 4**, where for clarity **Figure 1** has been redrawn schematically). The soil near the surface is more or less uniformly wet. This is the distribution zone in which water and solutes are funneled into the fingers of the conveyance zone below. The thickness of the distribution zone is that of the fine layer for layered soils and is of the order of the finger size for soils without such a layer. In the conveyance zone, all fingers move down with a velocity v. The number of fingers depends on the flow rate. For example, in **Figure 1** the flow rate is relatively low and only one finger is formed. In other experiments, where the flow rate is higher, several fingers form and, as a consequence, are spaced closer.

For the case when the initial concentration in the distribution zone is C_o, and the rainfall is solute-free, the concentration in the percolating water out of the distribution zone can be described as similar to a linear reservoir:

$$C = C_o \exp(-\lambda t) \quad [11]$$

where λ is the coefficient equal to q/w, q is the steady-state flow rate, w is the apparent water content of the distribution zone and equals $L(\rho k_d + \theta_s)$, d is the depth of the distribution zone, θ_s is the saturated moisture content, ρ is the bulk density of the soil, and k_d is the desorption partition coefficient. In case water is added with a solute concentration, C_o, the concentration in the water leaving the distribution zone is:

$$C = C_o(1 - \exp(-\lambda t)) \quad [12]$$

Equations [11] and [12] are equivalent to those used for sludge by the US Environmental Protection Agency in predicting the loss of metals from the incorporation zone.

It is reasonable to assume that the transport in the preferential flow paths of the conveyance zone can be described with the convective–dispersive equation, viz:

$$D\frac{\partial^2 C}{\partial x^2} - v\frac{\partial C}{\partial x} = \frac{\partial C}{\partial t} \quad [13]$$

where D is the dispersion coefficient, and v is the velocity of the solute and equals approximately $q/(\beta(\rho k_d + \theta))$, where β is the wetted fraction in the conveyance zone by fingers and θ is the moisture content. Using Laplace transforms, eqn [13] can be integrated subject to the boundary condition described in eqn [11], with no solutes initially present in the column, and for $4D\lambda/v^2 < 1$ as:

$$C = \frac{1}{2}C_o \exp(-\lambda t)\left[\exp\left\{\frac{vx}{2D}(1-a)\right\}\operatorname{erfc}\left(\frac{x - vta}{2\sqrt{Dt}}\right) + \exp\left\{\frac{vx}{2D}(1+a)\right\}\operatorname{erfc}\left(\frac{x + vta}{2\sqrt{Dt}}\right)\right] \quad [14]$$

where

$$a = \sqrt{1 - \frac{4D\lambda}{v^2}}$$

The last term can usually be neglected when x or t is sufficiently large, i.e., $(x + vta)/(4Dt)_{1/2} > 3$. For the boundary condition (eqn [12]), we can find the solution by superposition.

Note that in eqn [14], as discussed above, the velocity is a function of the soil properties and not of the flow rate. The number of fingers in the conveyance zone adjusts itself to facilitate the different flow rates. This has been demonstrated with a fingered

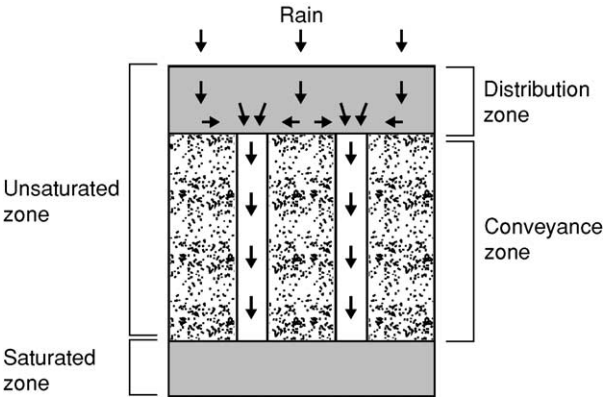

Figure 4 Schematic of the fingered flow process in the soil with preferential flow paths.

flow experiment that was carried out in the laboratory with 50-cm-long, 14-cm-diameter duplicate columns filled with coarse sand subjected to different intensities of steady-state rainfall. Chloride was applied at the surface as a pulse during each steady-state rainfall using different columns for different flow rates. The results are given as a function of cumulative flow (Figure 5a) rate and time (Figure 5b). In Figure 5a, the initial breakthrough of chloride takes more water for the high flow rate of 2 cm h^{-1} than for the low flow rate (0.3 cm h^{-1}). This is, obviously, a direct consequence of having a greater portion of the column wetted for the high flow rate. In Figure 5b, when chloride concentrations are plotted as a function of time, initial breakthrough for all three flow rates is approximately at the same time, clearly establishing that water and solute velocity is the same for the different flow rates. When the results are fitted to eqn [14], the solute velocity is, in all cases, approximately 35 cm h^{-1}, with no clear trend among the different flow rates, as expected.

In conclusion, it has become obvious in the last 25 years that, for soils in the field, preferential flow is the rule rather than the exception. Fingered flow is one of these types of preferential flow and can often be found above the primary coastal aquifers that are overlain by coarse-grained soils. Recognizing that these fingered flow paths can rapidly carry chemicals down to groundwater is a first step in keeping our aquifers clean for generations to come.

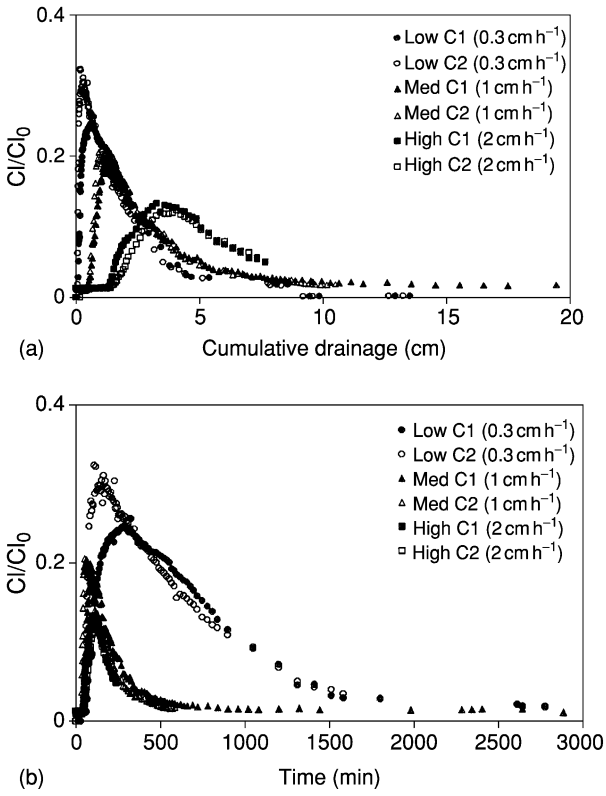

Figure 5 Chloride breakthrough curves (CBTs) for sand columns with a pulse application for three different flow rates of 0.3, 1, and 2 cm h^{-1} plotted: (a) as a function of cumulative drainage after application of the chloride pulse; (b) as a function of time after application of the chloride pulse. The experiment was carried out in duplicate with C1 and C2 indicating the two columns.

Introduction

Soils in urban and suburban areas are transformed by human activities. For several decades, soil surveys and research were largely focused on agricultural and forest lands, and intensively managed and disturbed soils were not much investigated as revealed by the white (nonmapped) areas representing cities on most soil maps. Urban soils are used for many purposes, including urban and industrial activities, forestry, and agriculture. They are characterized by a strong spatial heterogeneity resulting from the various inputs of exogenous materials and the mixing of original soil material. The basic functions of natural and extensively modified soils are essentially the same. The evolution of urban soils is controlled by the same factors as natural soils, but the human factor imposes extremely rapid transformation cycles in comparison with those dominant under natural conditions. They often hold pollutants that may be a threat to human health. Anthropogenic soils can be investigated at least in part with traditional soil survey approaches; however these methods must be properly adapted and new methodology must still be developed. It is only through a multidisciplinary approach that urban soils will be better understood and their use optimized to protect human health and the quality of natural resources, e.g., preventing groundwater contamination.

Definition

'Urban soils' is a class of Anthropic soils, a term already used in several classification systems. Urban soils are soils extensively influenced by human activities, found mostly but not only in urban areas. They include: (1) soils that are composed of a mixture of materials differing from those in adjacent agricultural or forest areas, and that may present a surface layer greater than 50 cm, highly transformed by human activity through mixing, importing, and exporting material, and by contamination; (2) soils in parks and gardens that are closer to agricultural soils but offer different composition, use, and management than agricultural soils; and (3) soils that result from various construction activities in urban areas and that are often sealed. According to this definition, urban soils are essentially under strong human influence in urban and suburban environments; they may exert a strong effect on human health, on plants and soil organisms, and on water infiltration. They are differentiated from other strongly influenced soils such as those found in quarries, mines, and mine tailings, and airfields away from cities. However, it is sometimes difficult to set a clear boundary between urban soils and agricultural soils (Figure 1).

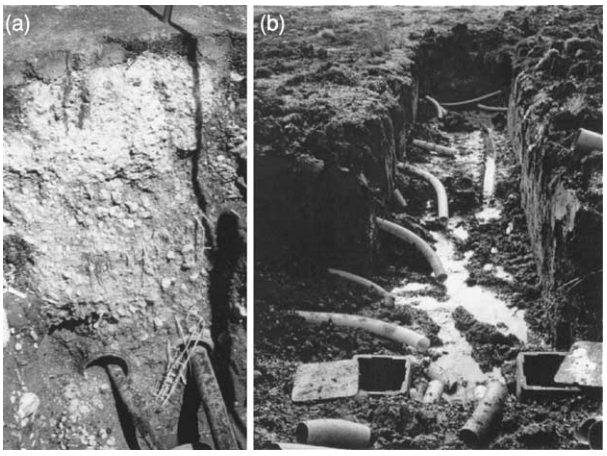

Figure 1 Urban soils and agricultural soils: (a) urban soil profile showing a sealed surface, imported soil materials, and electric wires; (b) agricultural soil profile showing strong perturbation induced by the incorporation of plastic drains.

Use of Soils in Urban Areas

In cities, soils provide support for infrastructure (buildings, roads, railways, parking lots, bridges), shelter for cables (electricity, telephone, television) and pipes of various size and composition (drinking water, wastewater, gas), and substrate for plants (isolated trees along streets, trees in public parks, and ornamental and edible plants in public and private gardens). They are also used for agricultural (horticulture, suburban agriculture, gardening), and industrial (buildings, mining, industrial waste disposal) production activities, and for recreation (stadiums, playgrounds). For centuries, the regions surrounding residential areas have been used for provision of construction materials and domestic waste disposal.

There are numerous soil types in urban areas as a result of these various uses, which differ in the intensity and duration of human impact. Human impact on urban soils may be light (e.g., urban forests) or, in contrast, maximal in developed built

areas (e.g., sealed and artificial soils). Therefore, soils in a city differ according to the degree of human transformation. In general, artificiality increases from the periphery to the center of the city, where original soils are often removed and replaced by anthropogenic materials. Older cities show the most modified soils, as they are generally constructed on their own waste materials that have accumulated over the years. For example, cities like Paris and Moscow are built on several meters of anthropogenic materials that hold remains of former human activities and materials.

Another main feature of urban soils is the high frequency of usage change with time. An example is the conversion of former industrial sites (now termed 'brownfield' sites) to new activities, including residential, public, and recreational activities. Such intensive changes are often dramatic and may cause problems for residents as a result of possible soil contamination. Landfills located at the periphery of cities are, knowingly or not, frequently converted to residential development as a result of the pressure of increasing urban population. This may result in increasing risks for residents from contamination through direct contact, inhalation, and/or consumption of garden produce.

Evolution of Soils in Urban Areas

As known from traditional soil science, a soil is the outcome of the evolution of a parent mineral material under the influence of climate, vegetation, topography, and time. Soils generally display a sequence of layers with an organically enriched surface horizon. Soil formation is generally a slow process that involves typically three main processes: weathering, transport, and accumulation. Differences in climatic conditions, parent rocks, and topography are at the origin of a wide range of soil types developed under natural conditions and, in general, the soil type can be deduced from knowledge of the conditions that have controlled its formation.

The three fundamental processes of formation (climate, parent rock, topography) and evolution of soils also apply to urban soils. However, urban soil formation is strongly influenced by the 'human factor' (Figure 2), which often creates a new 'parent rock' (e.g., debris from former buildings or industrial wastes), and modifies the conditions of its evolution through its influence on water circulation and composition in urban areas. The influence of the 'human factor' can also be interpreted in terms of soil formation and evolution: (1) weathering: transformation of the original material by mixing, compaction, or aeration of material layers; (2) transport: excavation of soil layers, leading to the partial or total elimination

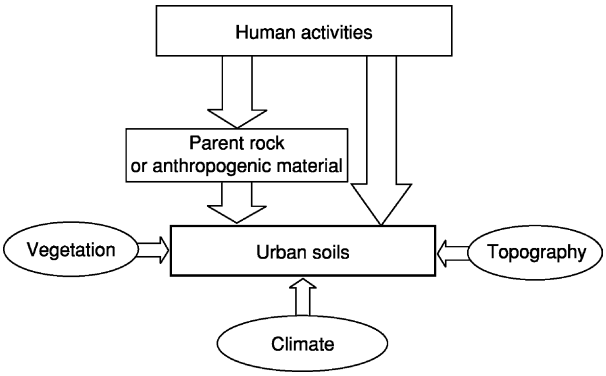

Figure 2 Urban soil formation and evolution.

of the original soil profile; and (3) accumulation: addition of exogenous materials from various origins (soil materials, minerals, technological compounds, and inert, organic, or toxic wastes). The kinetics of these processes are very rapid in comparison to natural processes, as a result of the increasing use of modern equipment, like tractors and bulldozers. A week or even a day is often the time scale required to modify completely the urban landscape. Heterogeneity in the landscape and in the soil may therefore change rapidly. Digging for new buildings, bringing in material from large distances for landscaping, disposing of rubbish, debris and topsoil for leveling and preparing the land for a new use often prevent any relation with the original parent material in the vicinity of the site being examined. Under such conditions, the natural weathering mechanism of soil formation does not play a great role if any, whereas transport and accumulation are predominant.

Another main feature of urban soils is the construction of barriers, e.g., sidewalk, which notably reduces the infiltration of water in soil, and increases its transport to streams, often causing flooding problems. Oxidizing conditions generally dominate in urban soils as a result of lack of water in the soil profile. However, soil compaction and leakage of drinking or wastewater from pipes may induce locally strong changes in redox and water flux conditions.

Composition and Heterogeneity of Urban Soils

The composition of soils in the cities depends largely on the nature of the materials in which they are developed. Coarse textures, with mostly sand and coarser material (rubble and gravel), generate great horizontal as well as vertical heterogeneity. This is a frequent characteristic of urban soils. Bulk density is generally low (<0.5) or very high (>1.60) as a function of the parent material. As an example, Figure 3 shows a soil

Figure 3 Soil profile in a twelfth-century urban area (Nancy, France).

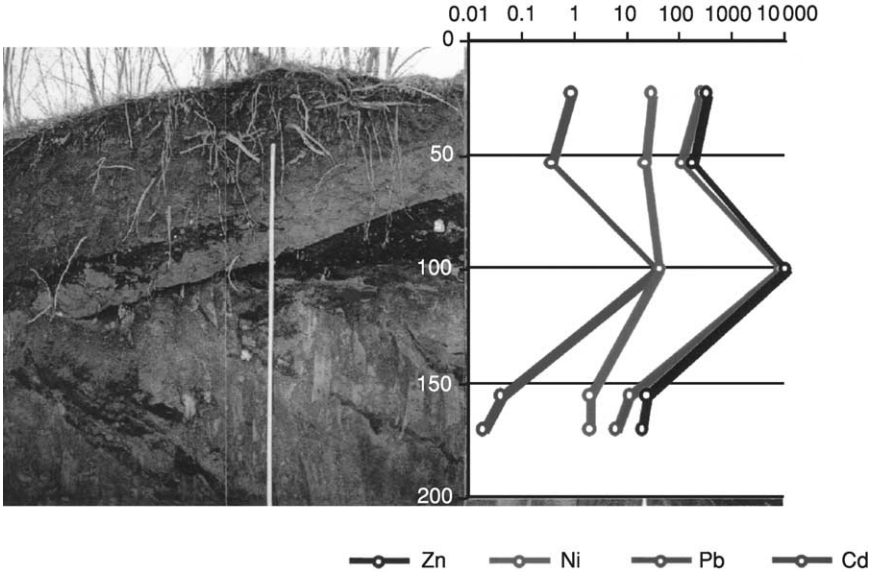

Figure 4 Soil profile and metal concentrations (mg kg^{-1}) in a former industrial site.

profile observed from a pit excavated for building construction in the city of Nancy, France. The soil exhibited a depth of more than 7 m and consisted of six distinct horizons. The three horizons at the bottom were the relic of a former agricultural soil. It presented a clear Ap horizon (15 cm) colored by organic matter, very compacted and weakly calcareous as a result of former agricultural practices or addition of calcareous construction material. The second horizon was not calcareous and offered a higher porosity with galleries of earthworms. The three upper horizons (0 to 1 m) were successive depositions of raw material. They were very heterogeneous and made of earthy material of sandy clay texture dominated by more than 80% of fine material. They were rich in organic matter and presented a brownish color. Numerous tree roots were present. The second horizon was strongly compacted and the third was characterized by the presence of building material of lighter density with fragments of dark gray schists coated with clayey sands.

Another example is given by a soil developed on a former industrial site (Figure 4). With the exception of the two upper horizons made of agricultural soil material brought in to facilitate the revegetation of the site, most of the material was of anthropogenic

origin, deposited during industrial activity and mixed and compacted at the closing of the factory. Many types of debris are present, including concrete, metal wires, slag, and industrial sand, each offering specific physical (density, porosity, mechanical resistance) and chemical properties (nutrients, metals, organic pollutants). In general, the analysis shows the high pH that is a common feature in anthropic soils, often as the result of alkalizing products mixed in the soil. Organic matter content may be high, and the C/N ratio is generally high because of the presence of organic material low in N, especially in industrial soil material; these high values are often due to contamination with oily wastes.

Soil Contamination in Urban Areas

Because of their diversified origin, urban soils may contain pollutants, the location, characteristics (including availability), and potential evolution of which must be established properly for future land use. Urban and suburban soils prompt a strong interest because of the growing public concern about the environment and human health. For example, urban horticulture provides a nonnegligible percentage of the food supply to large populations, especially in developing countries, and there is a need to improve this type of production while ensuring its safety, as well as addressing the issues related to a wide range of land uses. Also, in urban areas children are often in direct contact with soil material, and soil quality (pollutants, pathogens) in playgrounds may affect their health. Some urban soils, in particular those observed on brownfields where they were previously used as support for industrial production, may contain large amounts of mineral and organic pollutants that accumulated over time. The profile of the industrial site described above contains elevated amounts of some metals (Cd, Pb, and Zn), especially in the horizons made of industrial material, e.g., slag. Also organic contaminants (e.g., hydrocarbons, polychlorobiphenyls, herbicides) are commonly found in urban soils; polycyclic aromatic hydrocarbons (PAHs), a special class of hydrocarbons, some of which exhibit carcinogenic properties, are found in some former industrial sites (e.g., gasworks, coking plants). The soil shown in Figure 4 was also contaminated by lead and zinc (Pb and Zn), two metals widely present in urban areas (Table 1). An urban soil profile studied in the city of Nancy showed the influence of the material in place or brought in. These materials contributed to modifying the content of metals in the profile. The metal concentrations in the urban soil were lower than in the industrial site, but metals were present at significant concentrations in the upper horizon as a result of the various urban activities, including traffic and water runoff from zinc roofs.

Table 1 Concentration of metals in the profile of an urban soil (see Figure 3)

	Cd	Cu	Cr	Hg	Ni	Pb	Zn
Depth (cm)	($mg\,kg^{-1}$)						
20	0.67	66.2	65.0	2.00	28.3	415.1	325.7
175	0.08	11.8	39.5	0.04	24.5	28.4	50.4
199	0.75	41.0	59.7	0.06	50.0	21.4	119.3
215	0.26	20.2	44.7	0.04	28.6	26.6	70.4
294	0.11	15.0	54.0	0.02	32.6	24.3	63.4
725	0.03	5.8	25.7	0.02	13.4	26.0	32.1

Urban soils have different retention capacities for organic components, but their alkaline reaction often limits the mobility of heavy metals. In most urban soils, a pH shift to alkalinity constitutes an alkaline (carbonate) geochemical barrier in the topsoil. This barrier hinders the mobilization of heavy metals. Methods developed for agricultural soils (such as plant tests, selective extraction, microbiological and enzymatic tests) may be adapted for assessing the risk of transfer of pollutants to the food chain.

Garden soils

Gardens are a place of strong interactions between soils and human activities. In general, a very intensive form of agriculture is conducted, resulting in soils with high fertility and great diversity, deriving from the multiplicity of gardening practices. Soil quality (i.e., nutrient and pollutant content) in gardens is related to the quality of the parent materials, but through various inputs and modifications of the soil profile, the gardener is the most important factor in soil quality. Inputs range from traditional agricultural amendments and chemicals (manure, lime, pesticides, fertilizers) to domestic wastes and industrial amendments that may contain several inorganic and organic contaminants. In general, rates of amendment application are far higher than in traditional agriculture production, and garden soils tend to exhibit a deep upper horizon with a high concentration of organic matter and mineral nutrients, e.g., nitrogen and available phosphorus. In general, the organic matter content is directly related to the age of the garden. Therefore, the soil quality, hence fertility, of garden soils is as variable as gardening practices. This may be reflected by the biomass production of lettuce grown on various soil samples collected from a set of gardens (Figure 5). But pollutants may also accumulate in garden soils and be transferred to the food chain by direct consumption of vegetables.

Heavy metals tend to accumulate in garden soils and, in general, their concentration is on average twice that in agricultural soils, probably because of the input of various amendments to the garden soils (Figure 6). As for fertility, contamination is highly variable from one garden to another. This can be observed from the analysis of a set of soil samples collected from family gardens located in the Lorraine region (France) and in the nearby Saarland region (Germany) that showed a wide range of values, probably due to gardener practices and the proximity of industries. Soil physical properties and accumulation of heavy metals in the Ap horizon depend on parent material, substrates, and anthropogenic modifications. In Saarbrücken, only 18% of the garden soils were natural soils. Also metal concentration correlated well with soil fertility, as expressed by the total and available phosphorus contents (Figure 7). Finally, the content of heavy metals can be explained in decreasing order of importance by the age of the garden, previous use of the garden (including practices of the gardeners), natural concentration of metals in the soils, and atmospheric deposition.

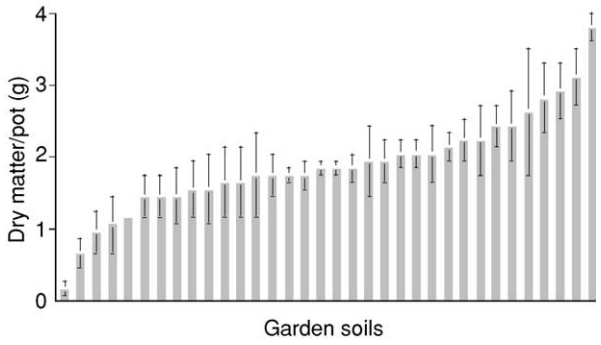

Figure 5 Biomass production of lettuce (*Lactuca sativa*) grown on a set of soil samples collected in family gardens in the Lorraine region (France).

Functions of Urban Soils

The link between soil functions and various soil properties such as substrate, texture, and humus content for soils at urban, industrial, and mining sites can be made using a set of indicators of soil quality such as those developed in Germany: rooting depth, wetting and aeration, nutrient status, and acid neutralization capacity. The high degree of surface sealing in urban soils limits the water partitioning that normally exists under natural conditions. Reduced seepage towards the subsurface causes high surface runoff and floods. Attempts are made to reduce this effect by increasing rainwater infiltration and groundwater recharge, and by reducing discharge by increasing water retention. Water and air supply in urban soils, an important feature for plant and tree growth, are controlled by bulk density, amount of medium, coarse, and very coarse mottles, organic matter content, and texture expressed as contents of clay, silt, and sand.

Urban soils are characterized by a great ecological heterogeneity, and show special distinctness of vegetation and fauna. They are habitats for plants and soil organisms, and for their filtering, buffering, and transforming of organic and inorganic pollutants. The root depth is, however, often limited due to abrupt horizon transitions, especially in the presence of a large percentage of coarse material (>2 mm). As a medium for plant growth, urban soil supports a large population of amenity vegetation in diversified habitats, including parks, gardens, roadsides, and turf areas. Much of the urban vegetation is cultivated, but there are also relics from natural vegetation or spontaneous infestation by opportunistic species.

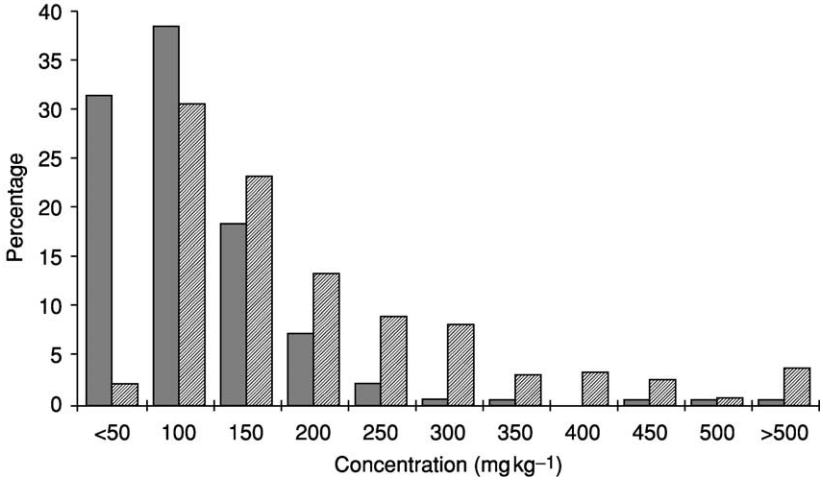

Figure 6 Frequency distribution of copper concentration in garden soils. ■ Regional soils ($n = 185$); ▨ garden soils ($n = 233$).

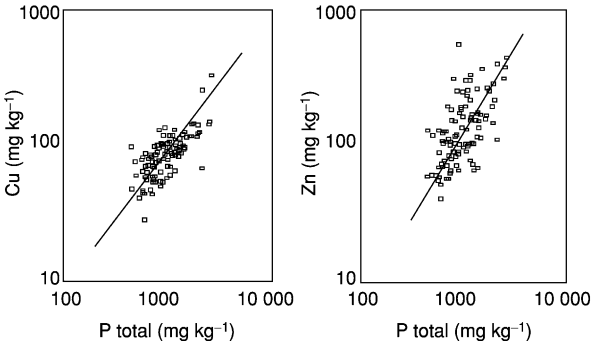

Figure 7 Relation between phosphorus and zinc and copper contents in garden soils.

The habitats may create stresses to vegetation survival: whereas normal root spread requires a circular soil disk preferably with a diameter equivalent to the crown spread and one meter deep, most urban tree roots are closeted in a narrow and shallow strip of substandard soil. In urbanized areas, roots of isolated trees are often sequestered in a restricted space; lateral room space is hindered, with a narrow strip, often less than 2 m, of poor-quality soil sandwiched between building foundations and highly compacted road material. The subsurface material quality is also often ignored. The presence of mortar, concrete, and asphalt attests to the widespread contamination of sites by construction debris that poses a physical hindrance to root development. Also the volume for water and nutrient storage is largely diminished.

Pedology and Archeology

Contrary to the situation in natural and slightly modified soils, e.g., agricultural or forest soils that most often display distinguishable horizons, a major challenge in urban soils, not only for their characterization, but also for determining their potential uses, is the heterogeneity of the layers associated with the fact that the latter are not always horizontal (Figure 3). Heterogeneity can also be very large within a single layer. This prompts a number of questions: what is an urban soil profile? What is an urban pedon? What area, both horizontally and vertically, is required for its description? What volume of soil is necessary for its characterization? How to describe the texture of urban soil, in particular the material coarser than sand? The presence of rubble may indeed confer special properties, and prevent some future uses of the soil.

Concepts must be properly developed in order to develop a suitable and useful classification scheme. Soil description involves the characterization of the successive layers with a specific composition. Urban soils are thus polycyclic soils composed by

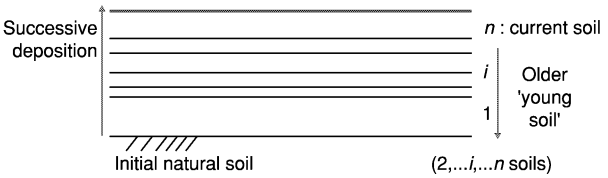

Figure 8 Urban soils in old cities are developed on waste material.

the superposition of several young soils (Figure 8). Using this approach, and as long as the human factor is clearly established, an urban soil survey is not strikingly different from a traditional soil survey: urban soils are the ultimate members of a continuum characterized by increasing human influence, and ranging from soils slightly or not affected by human influence (forests, rangeland) to agricultural lands and to urban soils where the human imprint is maximum, and where most natural features have often disappeared. For example, during early city development in previous centuries, when large machinery and transportation facilities were not available, rubble and debris were often disposed of at the site or at a short distance: cities were actually built on their own wastes. Therefore, the soils may contain layers or strata reflecting the processes that ruled the accumulation and such layers are the 'memory' of past activities: each layer corresponds to sedimentary materials representing an urban soil, generally poorly developed but significantly influenced by people.

Soils contain a large array of historical information, which has been proved very useful in understanding ecological and anthropological evolution. The materials brought about by human activities may also undergo pedological evolution leading to their significant transformation. In general, archeologists and pedologists have had only a few interactions in the past. Combining pedology and archeology by sharing research tools will increase our understanding of human evolution and help to predict better the problems connected to urban soils. Each layer of an urban soil contains products that are characteristics of the technological evolution of human societies. Combining archeology and pedology enables prediction of the location of some pollutants, such as heavy metals (Pb, Cu, Zn) and their fate in the profile.

Management of Urban Soils

The world is in the midst of a massive urban transition unlike that of any other time in history. In 1975, approximately one-third of the world's people lived in urban areas. By 2025, the proportion will have risen to almost two-thirds, which corresponds to more

than 5 billion people, mostly in developing countries. In developed countries, the population shift involves migration away from concentrated urban zones to large, sprawling metropolitan regions. Since the beginning of the twentieth century, the French population has increased considerably in cities, and it amounts to up to 70% of the population. In these large cities, as well as in smaller ones, green and open spaces play an important role as recreation areas, and they are the 'lungs' of urbanites. In the above context, characterizing the land that provides the infrastructure for these growing cities becomes particularly important. It is also a challenge: industrial and service businesses that are often located at the outskirts of the cities or in the suburbs near workers and employees are not particularly welcome amidst the new urban developments, and they are forced to move to a greater distance. This is favoring the emergence of brownfield sites, lands and buildings contaminated by previous industrial activities. Such areas are then recycled and often used for other human activities, that may present various risks for health. Waste disposal, especially the accumulation in landfills outside cities, creates similar concerns.

Within urban and suburban areas, soils are used as physical support for diverse anthropocentric activities and needs: infrastructure both at the soil surface and underground (e.g., roads, parking lots, railroads, pipes, sewers, ducts) and for buildings, sources (e.g., topsoil, landfill material from excavation) and sinks (e.g., dredged sediments, compost of organic urban wastes) of raw materials, food production, recreational activities (e.g., parks, landscaping), and memory and cultural heritage (e.g., cemeteries). Soil scientists have the expertise, as well as the social responsibility, to address issues related to these uses.

Introduction

The distinction between groundwater and the unsaturated zone is usually made within a hydrologic context that views water as the agent of change of the subsurface and the main driver for transport of chemicals between the atmosphere and groundwater. This region between the soil surface and groundwater table known as the vadose zone, involves a complex array of time-dependent, nonlinear physical, chemical, and biological processes, including interactions with groundwater and the atmosphere. The soil is the uppermost part of the vadose zone, subject to fluctuations in water and chemical content by infiltration and leaching, water uptake by plant roots, and evaporation from the soil surface. It is the most dynamic part of the subsurface, as changes occur at increasingly smaller time and spatial scales when moving from the groundwater toward the soil surface. Soil depth is usually controlled by the maximum rooting depth of plants (generally within a few meters of the soil surface). By contrast, the vadose zone may extend much deeper than the surficial soil layer and includes unsaturated rock formations and alluvial materials to depths of 100 m or more.

In the last few decades of the twentieth century, research interests in the deeper vadose zone have increased dramatically, instigated by a need to sustain quality of groundwater and maintain adequate resources for drinking water and ecologic purposes. Unquestionably, our society has negatively impacted the quantity and quality of its soil, water, and air resources. Chemical pollution generated by past agricultural, industrial, and municipal activities has contaminated soil and groundwater and surface-water systems worldwide. Unfortunately it continues to do so up to the present. Scientists and others are now increasingly aware that soil is a critically important component of the Earth's biosphere, not only because of its food-production function, but also as a safekeeper of local, regional, and global environmental quality. For example, management strategies in the vadose zone will offer the best opportunities for preventing or limiting pollution, and for remediation of ongoing pollution problems. Because chemical residence times in groundwater aquifers can range from a few years to thousands of years, their pollution is often essentially irreversible. Prevention or remediation of soil and groundwater contamination starts, therefore, with proper management of the vadose zone. Understanding the intricate processes in the vadose zone is a challenge because of the many complex nonlinear physical, chemical, and biological interactions that simultaneously control the transfer of heat, mass, and momentum between the atmosphere and the groundwater table.

Physical Processes

The physical characteristics of the vadose zone control such processes as natural or artificial recharge to deep groundwater and surface water–groundwater interactions. When considering the water budget of the vadose zone as a whole, many terms are similar and equally as important as those of a soil-water budget, with differences in measurement techniques mostly

predicated by differences in the spatial scale. Whereas typical soil-infiltration measurements are conducted over areas smaller than 1 m^2, estimates of infiltration rates over much larger areas and depths are required in the vadose zone, for which the assumption of one-dimensional flow is generally inadequate. Whereas the soil-water budget requires quantification of drainage, i.e., flow of water beneath the rooting zone (*See* **Drainage, Surface and Subsurface**), the water budget of the vadose zone includes net infiltration (*See* **Infiltration**), percolation, and recharge rates at large depths. 'Net infiltration' is generally defined as the water flux below the root zone that is not further influenced by evaporation or plant transpiration. 'Percolation rate' is defined as the net infiltration rate at any depth within the vadose zone, whereas 'recharge rate' defines the water flux into the groundwater across the groundwater table. Depth variations in percolation rates are caused by lateral flow and temporal variations in precipitation and evapotranspiration (*See* **Evapotranspiration**), whereas estimated rates are affected by measurement type. Specific vadose zone methods to estimate percolation and recharge rates include physically based methods that assume darcian water flow (*See* **Darcy's Law**) throughout the vadose zone, and tracer methods. The darcian methods generally require dedicated and highly specialized instrumention for large-depth measurements, but neglect fractured flow. Environmental tracer methods estimate percolation rate or age of water at a given depth based on *in situ* concentrations of natural tracers such as tritium, chloride, chlorine-36, and nonradioactive isotopes such as deuterium and oxygen-18, assuming that these are mass-conservative.

Accurate estimation of vadose zone water and solute fluxes is especially challenging in arid climates, where they are orders-of-magnitude smaller than in humid agricultural settings. However, because of these small flow rates, the relevant time scales of recharge rate can be orders-of-magnitude larger. A variety of methods have been reviewed, including detailed numerical modeling, to estimate percolation and recharge rates at Yucca Mountain, Nevada. The different methods were compared to study the potential and performance of Yucca Mountain as a repository site for high-level radioactive waste over time scales of 1000 years and longer (Figure 1). The mean water table depth is approximately 500 m, whereas the potential repository location is at a mean depth of 300 m below the land surface, within a densely welded and fractured tuff horizon. In February 2002, President George W. Bush endorsed a formal recommendation by the Department of Energy (DOE) for the Yucca Mountain to accept a total of approximately 85 000 metric tons of radioactive wastes.

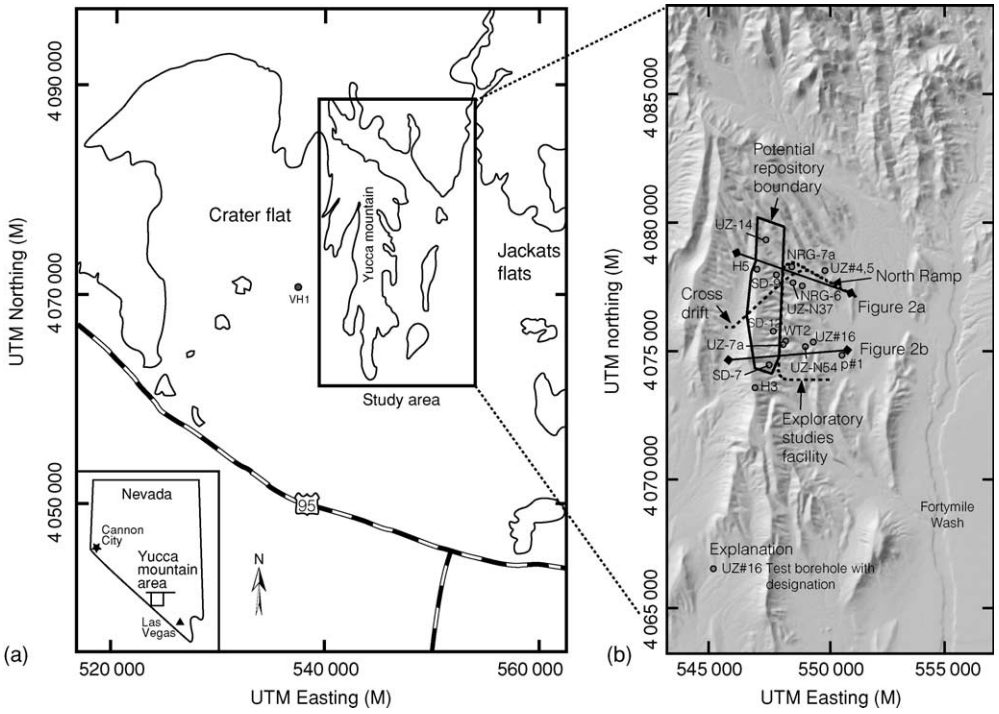

Figure 1 Location of (a) the Yucca Mountain area, Nevada, and (b) the study area. (Reproduced with permission from Flint AL, Flint LE, Kwicklis EM, Faryka-Martin JT, and Bodvatsson GS (2002) Estimating recharge at Yucca Mountain, Nevada, USA: comparison of methods. *Hydrogeology Journal* 10: 180–204.)

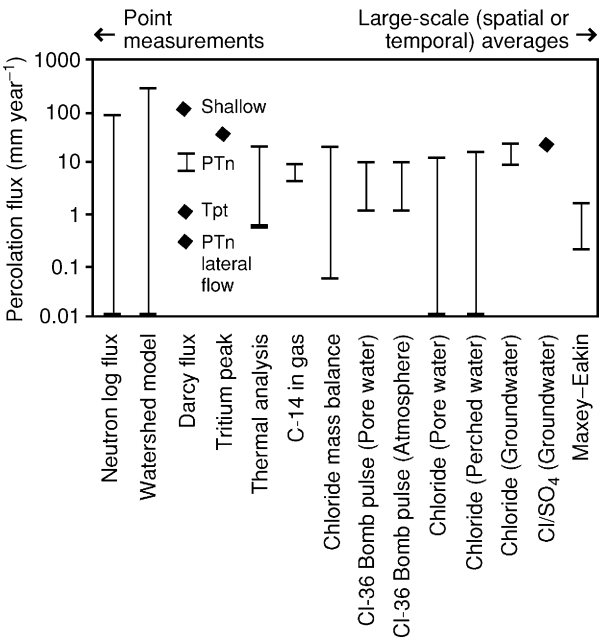

Figure 2 Comparison of percolation fluxes estimated by various methods. Bars represent ranges of estimates; points represent single estimates. PTn and Tpt indicate different hydrogeologic units of the Yucca Mountain site. (Reproduced with permission from Flint AL, Flint LE, Kwicklis EM, Faryka-Martin JT, and Bodvarsson GS (2002) Estimating recharge at Yucca Mountain, Nevada, USA: comparison of methods. *Hydrogeology Journal* 10: 180–204.)

Estimated percolation rates at Yucca Mountain vary between 0.5 and 20 mm year^{-1} (Figure 2), with differences in magnitudes controlled by variable precipitation, topography, soil depth, and highly variable, physical vadose zone properties, including fractures and faults. The different methods each yield percolation values typical of their specific space and time scales, with results complementing and partially overlapping each other. For example, shallow methods are representative for relatively small time scales, whereas rates estimated from the deep vadose zone and recharge measurement techniques are an integration of spatial mixing over much longer time scales.

Chemical Processes

The justification of vadose zone characterization and monitoring of contaminant transport arises from the simple observation that, for contaminants and microorganisms to reach the groundwater table, they must pass through the vadose zone first. Therefore, monitoring of the vadose zone and appropriate management practices using vadose zone concepts is a prerequisite for understanding and successfully preventing groundwater contamination. Much of the *Handbook of Vadose Zone Characterization and Monitoring* is devoted to current and emerging techniques for vadose zone measurement and monitoring of chemical and microbial pollutants. The general theories and concepts of chemical fate and transport in the vadose zone are largely identical to those occurring in soils. Therefore, the focus here is on the added complexities to which constituents are subjected as they move through the vadose zone. Most additional complications in vadose zone transport arise because of the much wider range in relevant space and time scales and the presence of preferential flow mechanisms (fractures, sediment, and rock beddings) that make it difficult to delineate transport networks for the larger vadose zone. Moreover, the increasing physical heterogeneity (*See* **Spatial Variation, Soil Properties**) and associated spatially variable soil moisture conditions and preferential flow mechanisms of the vadose zone affect geochemical and microbial reactions, resulting in spatial and temporal variations of concentrations and transport of which the implications have yet to be fully understood.

As dissolved solutes move through the vadose zone, various physical, chemical, and biological properties control their fate. In addition to diffusion and dispersion, the fate and transport of chemicals in the subsurface are influenced by sorption on to the solid phase and biological transformations. Diffusion and dispersion of the transported chemical are a function of both pore size distribution and water content. Mechanical or hydrodynamic dispersion is the result of water mixing within and between pores as a result of variations in the pore-water velocity. Increasing dispersivity values causes greater spreading of chemicals, thereby often also decreasing their peak concentration. Sorbed chemicals move through the vadose zone slower than noninteracting chemicals, with the degree of sorption largely depending on mineral type, specific surface area of the solid phase, and organic matter fraction. In addition, biogeochemical processes and radioactive decay affect contaminant concentration, for example by cation exchange, mineral precipitation and dissolution (*See* **Precipitation–Dissolution Processes**), complexation, oxidation–reduction reactions (*See* **Oxidation–Reduction of Contaminants**), and microbial biodegradation and transformations. Moreover, all of these processes depend on such environmental conditions as temperature, pH, water saturation, and redox status (*See* **Redox Potential**), including, their spatial variations.

The fate and transport of microorganisms (including pathogenic bacteria, viruses, and protozoan parasites) follow many similar processes to chemical compounds. For example, many microbes exibit

enhanced transport relative to the water solution as a result of electrostatic repulsion from negatively charged solid surfaces, as well as owing to size exclusion from smaller areas of the pore space. There is also evidence that biologically reactive solutes and bacteria preferentially adsorb to gas–liquid interfaces and may be subject to inferfacial adsorption–desorption processes. In addition, transport of microorganisms is controlled by their retention (such as filtration) in the porous matrix, which is a function of the size of the specific microorganisms, the water-filled pore size distribution, and pore-water velocity as well as concentration and ionic composition of the aqueous phase. As such, microbial biomass accumulation may reduce the porosity and alter the hydraulic properties of vadose zone soils. Additionally, inorganic, organic, and microbiologically active colloids with diameters between 0.01 and 10 μm can strongly adsorb otherwise immobile chemicals or microbes and thus facilitate their transport by acting as a mobile solid phase.

No better example of the complexities of vadose-zone transport can be illustrated than by highlighting progress made at the US DOE Hanford site in Washington State, toward measurement, characterization, modeling, and remediation of vadose zone contamination from leaking, high-level radioactive waste storage tanks. The subsurface fate of the nuclear waste is increasingly complex because of various potential preferential flow mechanisms occurring, such as fingered flow, tunnel flow, and flow associated with poorly sealed boreholes (**Figure 3**). Soon after World War II, the US Atomic Energy Commission built many 2.0- to 3.8-million-liter, carbon-steel single-shell tanks at the Hanford Site to store high-level waste generated from production of plutonium and uranium. Inventory studies show that more than 4 million liters of waste leaked from these tank farms into the surrounding vadose zone. The vadose zone at Hanford consists of permeable and poorly consolidated sands and gravels that are bedded but highly discontinuous in the lateral direction. Also, the vadose zone includes many sharp contrasts in texture between layers. The regional groundwater table at depths of 60–90 m below the surface discharges to the Columbia River, which flows adjacent to the Hanford site. Gamma logging data from approximately 140 dry wells (boreholes) surrounding the tanks shows contamination to depths of at least 40 m, probably mostly caused by preferential flow. The different preferential flow processes have caused widespread contamination of ^{137}Cs and other radionuclides, which otherwise would have been highly retarded. Fingered flow occurs because of density-driven flow, whereas tunnel flow is caused by zones of increased permeability around the tanks. The geologic complexities of the Hanford site, combined with man-made changes, have prevented adequate prediction of the transport of the various radioactive nuclides, even with the use of sophisticated multidimensional flow and transport models.

Whereas this example applies to point-source pollution, even more complications arise when responding to questions on nonpoint pollution of groundwater such as occurs through crop production by application of fertilizers (e.g., nitrates) and irrigation (e.g., salinity and toxic trace elements). Typically, using distributed modeling techniques, flow and transport

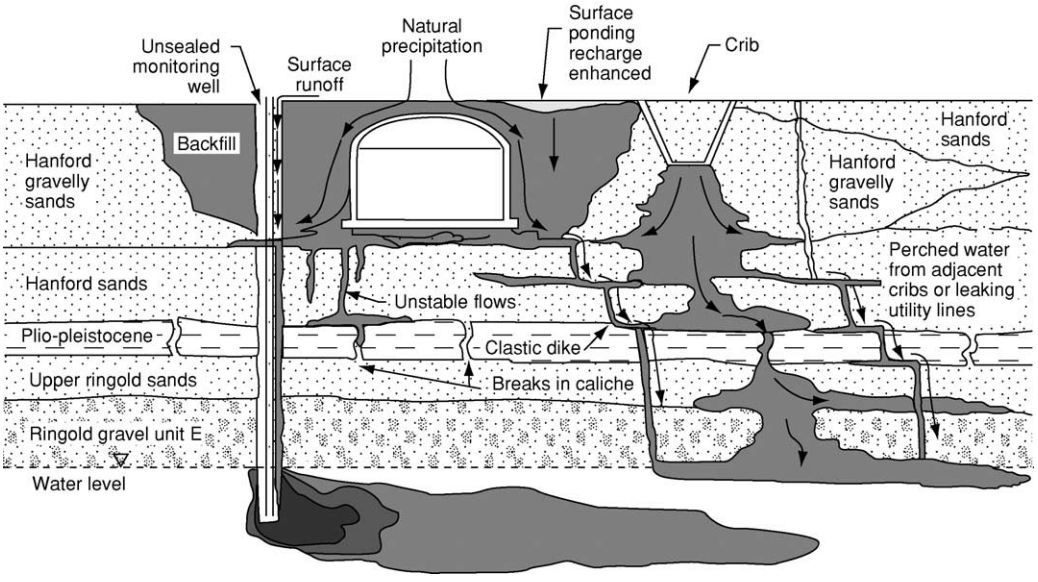

Figure 3 Conceptual model of fluid blow beneath single-shell tanks at the US Department of Energy's Hanford site.

are simulated for major characteristic units within a watershed or landscape (e.g., using soil map units, vegetation type, and slope). However, the connection and integration of the resulting simulation units within the watershed beg many questions of scale and associated nonlinearity effects. These nonlinear effects may be exacerberated when including chemical processes that are highly variable in space and time because of local soil variations in soil chemical composition, saturation, aeration, pH, redox status, and other factors. There is a need for interdisciplinary and multifaceted research approaches to improve the understanding of biological effects on soil chemical reactions and processes.

Biological Processes

In the soil environment, bioremediation and phytoremediation can be used to reduce vadose zone and groundwater contamination, by means of biological processes sustained by selected plants or microbes. Favorable environmental conditions of plant and microbial growth in soils and the vadose zone allow for bioremediation of contamination by inorganic and organic chemicals. Microbial processes mainly transform the parent chemical, thereby reducing its concentration, and by the formation of less-toxic metabolites, whereas plants can accumulate specific chemical species, e.g., through bioaccumulation of heavy metals in plant tissues. In addition, root water uptake by plants and trees can reduce leaching (*See* **Leaching Processes**) of water and salts below the rooting zone, thereby controlling percolation rates and contaminant transport through the vadose zone.

Differences between the microbiology of the vadose zone and the saturated zone are mostly caused by differences in water saturation, which affects the prevailing fluid fluxes and the availability of oxygen and other nutrients. With oxygen being the oxidizing agent for aerobic microorganisms, its supply may be limited in the deep vadose zones and/or in locally saturated (parched) areas. For most other nutrients, fluxes are controlled by the degree of water saturation and associated percolation rates and by organic matter supply rates. Consequently, nutrient availability is relatively abundant in the root zone and in humid climates, while their fluxes generally are limited in the vadose zones of arid climates. Although the vadose zone is generally unsaturated, local water-saturated inclusions may occur, promoting anaerobic microbiological processes, using electron acceptors other than oxygen, such as nitrate, Mn^{4+}, Fe^{3+}, or sulfate, depending on the redox status of the system. Irrespective of climate, the local nutrient supply in the vadose zone is at times predominantly controlled by diffusion to or from regions where transport is mainly by preferential flow through macropores (*See* **Macropores and Macropore Flow, Kinematic Wave Approach**) and cracks. Whereas, in general, microbial population density and activities are low in the vadose zone below the soil-rooting zone, their densities and activities can be orders-of-magnitudes higher at contaminated sites that facilitate microbial colonization. Microbes are generally located at air–water and water–solid interfaces; however, microbial heterogeneity is generally unpredictable, as it is conditioned by local variations in nutrient availability.

Enhanced microbial degradation (*See* **Pollutants:** Biodegradation) is generally achieved by gaseous nutrient deliveries of electron donors and acceptors to the contaminated sites, e.g., by bioventing through injection of air to simulate aerobic biodegradation of petroleum hydrocarbons (*See* **Hydrocarbons**). Microbial degradation of recalcitrant organic contaminants may require a secondary carbon supply, whereas other nutrients such as N and P are sometimes required. Inorganic contaminant concentrations of heavy metals or radionuclides can be reduced by microbes through their transformation (*See* **Metals and Metalloids, Transformation by Microorganisms**) to less-toxic states or by changing their mobility by using them as electron acceptors. A specific form of bioremediation is phytoremediation (defined as remediation through plants), which is mostly effective in near-surface soils. Many processes may contribute to phytoremediation (**Figure 4**), including specific root uptake followed by bioaccumulation and/or volatilization, and biodegradation in the rhizosphere (*See* **Rhizosphere**) sustained by root exudates and organic matter of decaying roots.

Certain plants have been adapted genetically to grow in soils containing toxic levels of metals. A classic example of this is the use of specific plants for the bioaccumulation of selenium, for example crop and grassland species. Research in selenium remediation methods accelerated in the 1980s after the discovery of high concentrations of Se in agricultural drainage water, followed by high mortality rates of grazing waterfowl at Kesterson Reservoir in Merced County, California. The specific advantage of crop or grassland plant species to remediate Se-laden soils is that these can be harvested and subsequently used as a Se supplement for Se-deficient forage or as an amendment for Se-deficient rangelands. Studies have demonstrated that grasses such as tall fescue can effectively take up Se if soils are supplemented with organic matter. Other successful examples include bioaccumulation of lead and other toxic metals, and radionuclides such as Cs, U, Cd, and Cr.

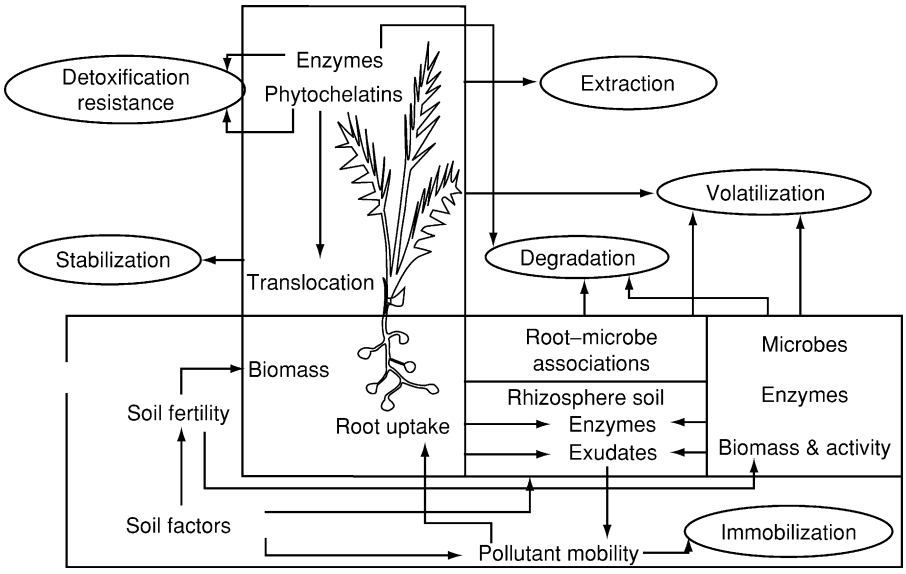

Figure 4 Simplified overview of soil–plant–microbe processes and interactions involved in phytoremediation. (Reproduced from Wenzel WW, Adriano DC, Salt DI, and Smith R (1999) Phytoremediation: a plant–microbe-based remediation system. In: Adriano DC, Bollag J-M, Frankenberger WT Jr, and Sims RC (eds) *Bioremediation of Contaminated Soils*, pp. 457–508. Agronomy Series No. 37. Madison, WI: American Society of Agronomy, Inc.)

There are many questions that need to be resolved before bioremediation techniques can be applied universally to a wide range of contaminant classes. Major issues revolve around the complex interactions between microbiological, geochemical, and hydrogeologic processes, the unpredictable local distribution of microsites, and the difficulty in supplying nutrients to these spatially distributed, contaminant-transforming microorganisms (*See* **Spatial Patterns**). In addition, successful bioremediation is controlled by the physical (e.g., soil moisture, temperature, oxygen diffusion) and chemical (e.g., organic matter type and content, soil adsorptive properties, availability of micronutrients) soil environment.

An additional example of mostly unknown territory occurs in the mixing zone between surface and subsurface water underneath streams, known as the hyporheic zone (HZ). This region of increased biochemical activity within the upper few centimeters of stream sediment affects the type and rate of material transformation as water moves downstream, thereby significantly changing stream-water composition and the stream ecosystem, as well as groundwater chemistry. Specific examples include the influence of oxygen supply to fish eggs buried in the HZ, the influence of particulate and dissolved organic matter on microbial activity and resulting stream-water chemistry, and the function of the HZ to denitrify, thereby ameliorating high-N stream load. There is a definite need to understand better the hydrology of the HZ and the coupling of hydrologic with biogeochemical processes, through dedicated interdisciplinary experiments and numerical modeling.

Scale Issues

For the past few decades, soil scientists have applied soil physical data to characterize flow and transport processes in large-scale, heterogeneous vadose zones, using measurement scales that are typically much smaller. For example, prediction of soil-water dynamics at the field scale is usually derived from the measurement of soil hydraulic properties from laboratory cores, collected from a limited number of sampling sites across large spatial extents. Soil parameters obtained from these small-scale measurements are included in numerical models with a grid or element size that is many times larger, with the numerical results extrapolated to predict large-scale flow and transport behavior. Because of the typical nonlinearity of physical properties, their use across spatial scales is inherently problematic. Specifically, the averaging of processes determined from discrete, small-scale samples may not describe the true soil behavior involving larger spatial structures. Moreover, the dominant physical flow processes may vary between spatial scales. Considering that soil physical, chemical, and biological measurements are typically conducted for small measurement volumes and that the natural variability of soils is enormous, the main question asked is how

small-scale measurements can provide information about large-scale flow and transport behavior. Answers to this question may require the estimation of appropriate, effective soil parameters for use in describing the behavior of pollutant plumes at the field or landscape scales.

A conceptual solution to the problem of scale issues of vadose-zone modeling might lie in considering the controlling effect of small-scale processes on larger-scale flow behavior. Hence, vadose zone properties are nonunique and scale-dependent, resulting in effective properties that vary across spatial scales and merely serve as calibration parameters in simulation models. Therefore, their accurate prediction in heterogeneous materials can only be accomplished using scale-appropriate measurements, including those that measure at the landscape scale.

Opportunities and Challenges

There are a number of opportunities that have come about in the past decade through experimental innovations and increasing environmental awareness. These opportunities include improved physical characterization of the vadose zone at larger spatial scales, which needs to be extended to chemical and biological measurements also.

First, it is becoming increasingly clear that there is a pressing need for subsurface observations and property-measurement techniques at spatial scales much larger than the usual laboratory or field-plot scale. The scale problem is extremely complex because of the general presence of large spatial and temporal variabilities of the soil physical, chemical, and biological properties in question. For example, at the heart of many hydrologic projects lies the need to understand better the flow and transport of water and associated chemical constituents into and through the vadose zone above an aquifer, and within a watershed. Hence, developmental work is needed on fundamental concepts and measurement technologies to establish appropriate soil parameters for use in theories or models describing the behavior of vadose zone water flow and pollutant plumes across spatial scales. In addition, appropriate measurement techniques and field experiments are needed to characterize effective field-scape and landscape-scale soil properties. In particular, we note the potential of using inverse methodologies perhaps in combination with rapidly improving invasive and noninvasive geophysical techniques, to infer *in situ* dynamic soil physical characteristics and the development of instruments that combine multiple measurements within a single device, thereby minimizing soil heterogeneity effects.

Second, although it is evident that large-scale characterization is needed, there is also increasing awareness within the scientific community that the physical, chemical, and biological processes in the vadose zone are controlled by mechanisms operating at the pore-size scale. Improved predictions of subsurface flow and transport will probably be a function of the development and application of innovative pore-scale modeling approaches (e.g., Lattice–Boltzmann, percolation, and related methods), and associated measurement techniques that operate at the microscopic level. Examples of the latter are nuclear magnetic resonance (NMR), computed tomography (CT), and spectromicroscopy.

Third, improved characterization and interpretation of subsurface processes will require increasing efforts toward an interdisciplinary partnership, integrating physical with chemical and biological processes. The soil physicist and/or vadose zone hydrologist must seek collaborations in other disciplines to ensure that different measurement types are collected and integrated to study more effectively and determine relationships between flow and transport processes at the microscale and in the laboratory, with ultimate application to the watershed scale. To achieve this goal, soil physics must be taught within the broader context of hydrology and the environmental sciences.

Introduction

The vadose zone consists of unsaturated porous media and rock extending from the surface soil to the groundwater table. This zone is characterized by a lack of water relative to other major Earth compartments such as the ocean, fresh water, aquatic sediments, and groundwater. Low nutrient availability, low water content, and low potential energy per unit volume of water, termed 'water potential,' constrain life in the deeper vadose-zone relative to the surface. However, the vadose zone harbors numerous and diverse microbes, including bacteria, fungi, protozoa, and viruses. Vadose-zone microbial ecology refers to the study of interactions between vadose-zone microbes and their environment. Generally, microbial population density, diversity, and total activity, as well as available nutrients, and moisture and temperature fluctuations, decline sharply with depth below surface soil. For example, relative to surface soil, culturable heterotrophic bacteria in the unsaturated subsurface are only one-tenth as numerous. Regardless, the integral mass of microbes along the depth profile is large, which accounts for the overall importance of vadose-zone microbes as catalysts in terrestrial nutrient-cycling, including pollutant biodegradation.

Definition of the Vadose Zone

The vadose zone is the Earth's terrestrial subsurface that extends from the surface to the regional groundwater table. As shown in Figure 1, the vadose zone includes surface soil, unsaturated subsurface materials, and a transiently inundated capillary fringe. The subsurface materials include partially weathered soils and unweathered parent material. The vadose zone may be very shallow (less than 1 m) or very deep (extending hundreds of meters or more), depending on the depth to the water table.

The vadose zone has low water content relative to the saturated zone below the water table and is therefore commonly referred to as the unsaturated zone. Above the capillary fringe, vadose-zone pore spaces are generally air-filled, with thin water films coating solid particles. Pore spaces become water-filled when rainfall percolates, followed by drainage and gradual drying. It is the relative lack of water and its

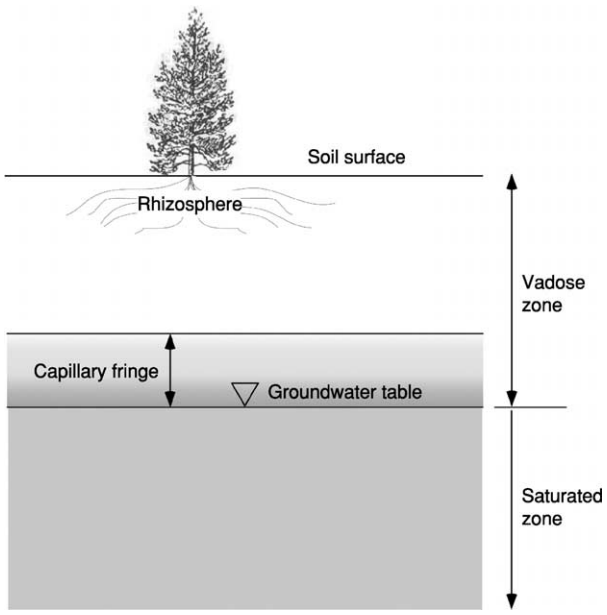

Figure 1 The vadose-zone profile.

transience, the complete lack of sunlight, and complex physical and chemical gradients that make the vadose zone an interesting and unique compartment for microbes.

Vadose-zone microbial ecology is the study of the microbes residing in the vadose zone, their interactions with each other, and their interactions with their surrounding environment. Compared with soil microbiology, a field for which a significant amount of agriculturally oriented research has been conducted, vadose-zone microbial ecology is a relatively young science. However, questions regarding the presence of microbes in the vadose zone, where they live, what they do, and how they do it are integral to the work of biogeochemists, environmental scientists, and engineers concerned with the fate of nutrients and pollutants.

Abundance and Distribution of Microbes in the Vadose Zone

Quantity Along a Depth Gradient

The abundance and distribution of microbes in the vadose zone are key parameters that need to be measured in order to understand vadose-zone microbial ecology. Abundance is studied by sampling (typically by aseptically coring through the face of a trench or vertically from the surface) and laboratory quantification at each depth interval sampled. Laboratory quantification of microbial abundance is performed using a variety of methods, including: directly counting eluted bacteria, culturing, measuring substrate uptake and/or mineralization, measuring total phospholipid fatty acids (PLFAs), measuring biomass carbon (C), quantifying extractable deoxyribonucleic acid (DNA), or counting using a most-probable-number (MPN) technique. Specific phylogenetic or functional groups of microbes can also be sensitively quantified using molecular biological approaches such as either fluorescence *in situ* hybridization (FISH) coupled with directly counting cells, or quantitative polymerase chain reaction (Q-PCR). Typically, each of these methods provides estimates of microbial abundance that are in general agreement with one another. Along a depth gradient (Figure 2), microbes tend to be most numerous in the surface soil, with their abundance declining sharply below the surface then reaching a nonzero plateau in the subsurface. The initial rate of decline with depth is more rapid in some vadose-zone systems than in others. Microbial population densities tend to increase in the capillary fringe and at the water table. In shallow vadose zones, the majority of the microbial biomass is in the surface material. In deeper vadose zones, microbial biomass densities are highest in the surface regions, but the total microbial biomass in deeper materials can be high due to the integration of sparser population densities across a large spatial area.

Generally, the number of culturable cells decreases more rapidly with depth than the number of total extractable cells. For example, by culturable counts, subsurface populations of heterotrophic bacteria may be one-tenth the size of surface populations, but, by direct counts, subsurface populations may be one-fifth the size of surface populations. In general, the

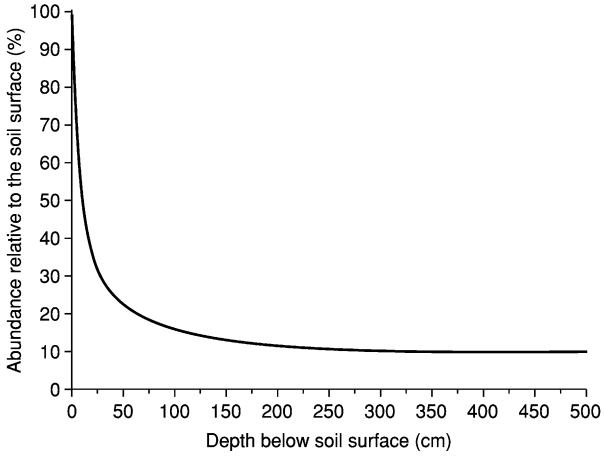

Figure 2 Typical depth trend of the vadose-zone constituents that are relevant to microbial ecology.

total numbers of culturable bacteria are higher in polluted vadose materials.

Protozoan population densities decline rapidly with depth below surface soil, which may be attributable to the concomitant decline in abundance of bacteria, their primary food source. Direct counts of fungal populations also decline with depth, but at a more dramatic rate than bacteria. Overall, total nonbacterial microbial biomass, including protozoa, algae, diatoms, and fungi, is lower than bacterial biomass in surface soils and decreases more dramatically with depth.

While the majority of soil microbial biomass is found in the surface horizons (Figure 1), where nutrients are most abundant (Figure 2), these horizons also experience extreme fluctuations in moisture and temperature which may result in significant temporal variability in population sizes. Microbial population sizes in the subsurface tend to experience a minimal degree of seasonal variation.

Distribution at the Meso- and Microscales

The distribution of microbes with depth through the vadose zone, as described above, is useful to know if we want to build large-scale mathematical models of microbially mediated processes in the vadose zone. However, there is also a secondary nature to microbial distribution which occurs at the meso-, and micro-, or perhaps 'microbe-' scales in soil. As depicted in Figure 3a, mesoscale variation in microbial abundances depends on the spatial distribution of bulk soil properties, including flow paths that preferentially conduct water through both surface and subsurface soils. Different microbial communities have been found along preferential flow paths as compared to the surrounding vadose material. In surface soils, preferential flow paths harbor more carbon and therefore more microbes; in the subsurface, this phenomenon is attenuated. At the microscale, the scale of individual pores, microbes are less active in the smallest pores where the diffusional resupply of nutrients is restricted. In contrast, larger, interconnected pores tend to contain more metabolically active microbes.

At the scale of individual microbes, which in some cases may be at the pore scale, there are at least three known possible configurations for microbial growth habits (Figure 3b). These configurations are mainly applicable to bacteria, the most abundant microbes in the vadose zone, but may also apply to other microbial particles, including fungal spores, viral particles, and protozoa. The distribution of filamentous fungi is generally a mesoscale phenomenon, because fungal hyphae can structurally, and physicochemically, bridge pores and particles. As shown in Figure 3b,

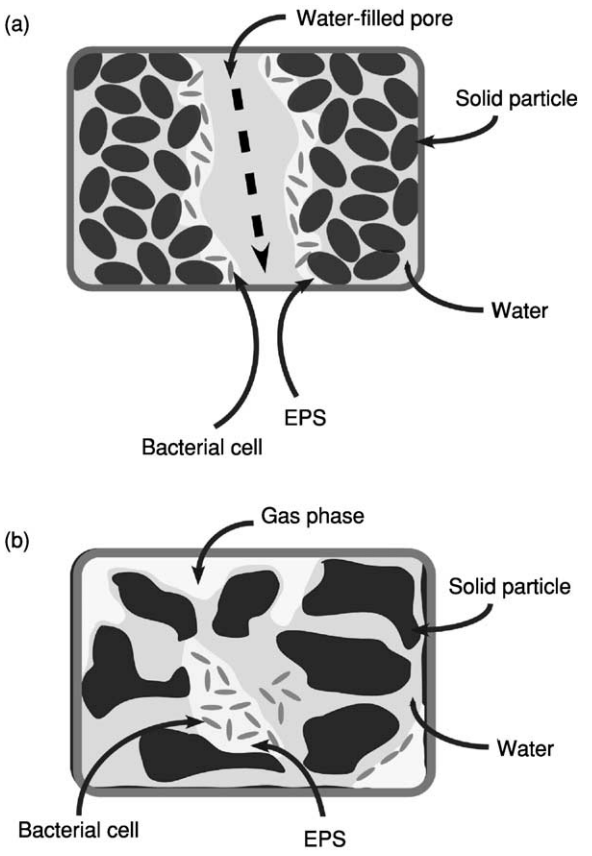

Figure 3 (a) Mesoscale and (b) microscale orientations of vadose-zone bacteria relative to other constituents, including extracellular polymeric substances (EPS) surrounding bacterial cells.

microbes can colonize the air–water interface, exist planktonically in water, or attach to surfaces and grow in biofilms consisting of cells and their associated expolymeric substances (EPS). The growth habit dictates movement: microbes at the air–water interface and in bulk water are mobile, but microbes embedded in EPS are relatively immobile. The growth habit also affects the availability of nutrients and the susceptibility to predation: microbes in EPS tend to be more protected from predation but often have reduced access to nutrients. Compared with what we know regarding gross microbial distributions at the macro- or depth-gradient scale, we know very little about microbial distributions at smaller scales and how specific configurations affect larger-scale vadose zone processes.

Diversity of Vadose Microorganisms

The microbes inhabiting the vadose zone are diverse taxonomically, metabolically, and morphologically. There are thousands of bacterial species (species richness) in a gram of surface soil. The proportional

representation of each taxonomic group (evenness) varies with depth within a vadose zone and between different types of vadose zones. For example, the overall abundance of Gram-positive bacteria has been shown to increase relative to Gram-negative bacteria along a vadose-zone depth profile, and there are lower fungal-to-bacterial ratios at depth than at the surface.

Taxonomic diversity is assessed with a range of techniques, including: the identification of culturable microbes, PLFA fingerprinting, fingerprinting based on 16S ribosomal DNA (rDNA), and the enumeration of different 16S rDNA sequences in a clone library. Metabolic diversity can be assessed by exposing serial enrichment cultures or microcosms to a variety of substrates and measuring the potential for substrate metabolism. Both taxonomic and metabolic diversity decline with depth through the vadose-zone profile, following the general trend depicted in Figure 2. In a related pattern, the number of dead and viable-but-nonculturable cells (VBNC) tends to increase with vadose-zone depth. Morphological diversity can be assessed by the microscopy of cultivated cells, but, as with any diversity assessment based on conventional laboratory culturing, the method may yield biased estimates of diversity because so few soil microbes (less than 1%) can be cultivated.

A fundamental question in vadose-zone microbial ecology is: How did the microbes, particularly those found at greater depths, get there? In part, diversity studies address this question by looking for similarities between the microbial community composition of the surface soil and that of the deeper vadose zone. If identical taxonomic groups are found at the surface and at depth, this suggests that microbes are transported downward through the vadose zone. If there are microbial groups found at depth that are unique from those at the surface, this suggests that microbes may have resided in the initial parent materials before the formation of the vadose zone. Generally, while there is overlap in the taxonomies of surface and deep vadose microbial communities, there are also unique groups.

Water is the main agent responsible for the inoculation of the subsurface by the surface. Thin water films in the vadose zone typically limit the transport of microbes through the profile. However, water and gas transiently advect and diffuse through soil pores. Preferential flow of water through certain pores causes these paths to have differing chemical and biological characteristics when compared with surrounding soil. Further, recharge of water to the vadose zone varies and, in turn, this leads to additional variations in pore chemistry and microbial communities along preferential flow paths. Overall, site hydrology is a key determinant of the abundance and types of microbes inhabiting the vadose-zone profile. However, at any given depth, the variability in microbial community composition and abundances can be high, and this heterogeneous distribution contributes greatly to microsite-level variation in microbial processes.

Activity of Vadose-Zone Microbes

Microbial metabolic activity declines with depth in the vadose zone, roughly paralleling the curve in Figure 2. The observed decline in activity with depth is related to the previously mentioned declines in microbial viability and abundance with depth. However, *in situ* activity is strongly affected by available nutrients. For example, *in situ* denitrification rates at depth in the vadose zone are generally much lower than the rates measured for surface soils (top 10 cm). The decrease in denitrification rates is partly a result of the low abundance of denitrifying bacteria, but is primarily a result of the low carbon availability in the deeper depths of the vadose zone. When subsurface vadose-zone samples are amended with nutrients, the activity per viable microbe in the subsurface is approximately the same as that in the surface.

Physiological markers of stress indicate that vadose-zone microbes are subject to starvation with increasing depth. Starvation is enhanced when water availability is low, because both the intrinsic physiology of microbes and the substrate availability to microbes are affected. Microbial biodegradation activity declines with depth, as shown with simple analysis of CO_2 evolution patterns. However, degradation rates can be as high or higher when either water or aqueous-phase nutrients are added to the vadose zone.

Measurements of enzyme activity are used to assess enzyme abundance in vadose-zone samples. Dehydrogenase, a useful measure of oxidative activity in all microbes, positively correlates with bacterial abundance, with dehydrogenase activity generally decreasing with depth below the surface. Other enzymes related to carbon, nitrogen, phosphorus, and sulfur metabolism show similar patterns. The low enzyme activity of deeper soils appears to be related to the low numbers of microbes and the low quantities of available nutrients.

Physical and Chemical Characteristics Affecting Vadose-Zone Microbial Ecology

The vadose zone is an open, multiphase system (Figure 3b) containing dissolved and undissolved solids (organomineral complexes and biomass), liquids

(water and nonaqueous-phase liquid pollutants), and gases (also known as soil gases). Open systems are inherently dynamic which, in the vadose zone, means that water, gases, and solutes are continuously being redistributed. The concept of chemical equilibrium in the vadose zone is only valid over short distances and short time scales. The ramification for microbes is that their local environment is in a state of continuous flux, due to either microbial metabolism or external environmental factors. Six key environmental factors are commonly cited as important to vadose zone microbial ecology: water availability, temperature, nutrient availability, oxygen, redox potential, and pH. Nutrient availability, redox potential, and oxygenation change with alterations in soil-water content: drying soil increases air-filled soil pore space, while wetting inhibits oxygenation and lowers redox potentials. Water is therefore considered to be a unifying environmental factor in the vadose zone.

Vadose-zone microbial ecology is affected by both soil-water potential and soil-water content (θ). Total soil-water potential (ψ) is defined as the potential energy per unit volume of soil and has two main components in the near subsurface: matric potential (ψ_m) and solute potential (ψ_s). In nonsaline soils, ψ_m is the dominant component of ψ. Total soil-water potential is related to the relative humidity of surrounding soil gas by:

$$\psi = \frac{RT}{V_w} \ln\left(\frac{\text{rh}}{100}\right) \qquad [1]$$

where R is the gas constant ($P - L^3/\text{mol} - T$), T is temperature (T), V_w is molal volume of water (moles per cubic liter), and rh is relative humidity (percentage).

As per eqn [1], ψ is negative when the rh is less than 100%. Alternatively, ψ is zero when the rh is equal to 100% (i.e., when water activity or $a_w = 1$). The vadose-zone environment may have a ψ equal to zero over a range of water contents that qualitatively span moist to fully saturated. For all $\psi = 0$ conditions, soil-water content indicates the degree to which pores are air-filled and thus oxygen-bearing. As soil dries, both θ and ψ decrease, but ψ is most relevant to microbial ecology. At approximately -0.25 MPa, vadose-zone bacteria become slightly nutrient-stressed, because the diffusional resupply of solutes is restricted. A total soil-water potential of -1.5 MPa is approximately the lower limit of what is physiologically tolerable to many surface soil bacteria, but filamentous fungi and actinomycetes are often more resilient to even lower water potential conditions. Vadose-zone microbes can adapt to be extremely desiccation-tolerant, as evidenced by the presence of viable microbes in deep, arid vadose zones where the total water potential is *c.*-50 MPa or less.

Water is an important physical environmental factor governing vadose-zone microbial ecology; temperature is another. For both water and temperature, average conditions vary from surface to subsurface. However, perhaps more importantly, both water content (and potential) and temperature are more variable in surface soils as compared to deep in the vadose zone. For example, temperature extremes are greatest at the soil surface but either increase or decrease (depending on the season) with depth to a constant temperature of around 20°C (*See* Figure 4 in **Thermal Properties and Processes**). Similarly, surface soils wet and dry frequently depending on the climate and season, yet subsurface soils are more stably moist or dry. In general, more stable temperature and moisture regimes at depth will select for vadose-zone microbial communities with narrower temperature and moisture optima and with lower tolerance for extreme or rapid fluctuations in environmental conditions.

The availability of nutrients to microbes in the vadose zone declines steeply with depth below the surface to low equilibrium values (**Figure 2**). In many vadose-zone environments, nutrients are more abundant in the surface soils because of plants and their contributions to soil nutrition. However, the textural composition of the vadose zone also changes with depth, affecting nutrient availability. For example, the percentage of clay, which controls the availability of exchangeable ions, typically decreases with depth. Further, the percentage of organic matter, which controls the abundance and availability of dissolved and available sorbed organic nutrients, also decreases with depth.

Soil gas composition affects redox status and aeration, and it often changes with depth through the vadose zone. For example, the oxygen content of soil gas in the subsurface is generally below the atmospheric concentration of 21%, often dropping to 15% or less. Also, CO_2 concentrations often range from 0.033% at the surface to as high as 4% or more at soil depths below 2 m. The CO_2 increase is due to the combined effects of microbial respiration and low rates of diffusional exchange between gases above- and below-ground. The high rates of CO_2 production and limited diffusional transport tend to increase alkalinity at depth, resulting in higher pHs in the subsurface compared with the soil surface. The unique gas conditions of the deeper soil depths facilitate the selection of microaerophiles and carboxyphiles.

The physical morphology of the vadose-zone particles is complex near the soil surface and more homogeneous in the subsurface (**Figure 4**). Undoubtedly,

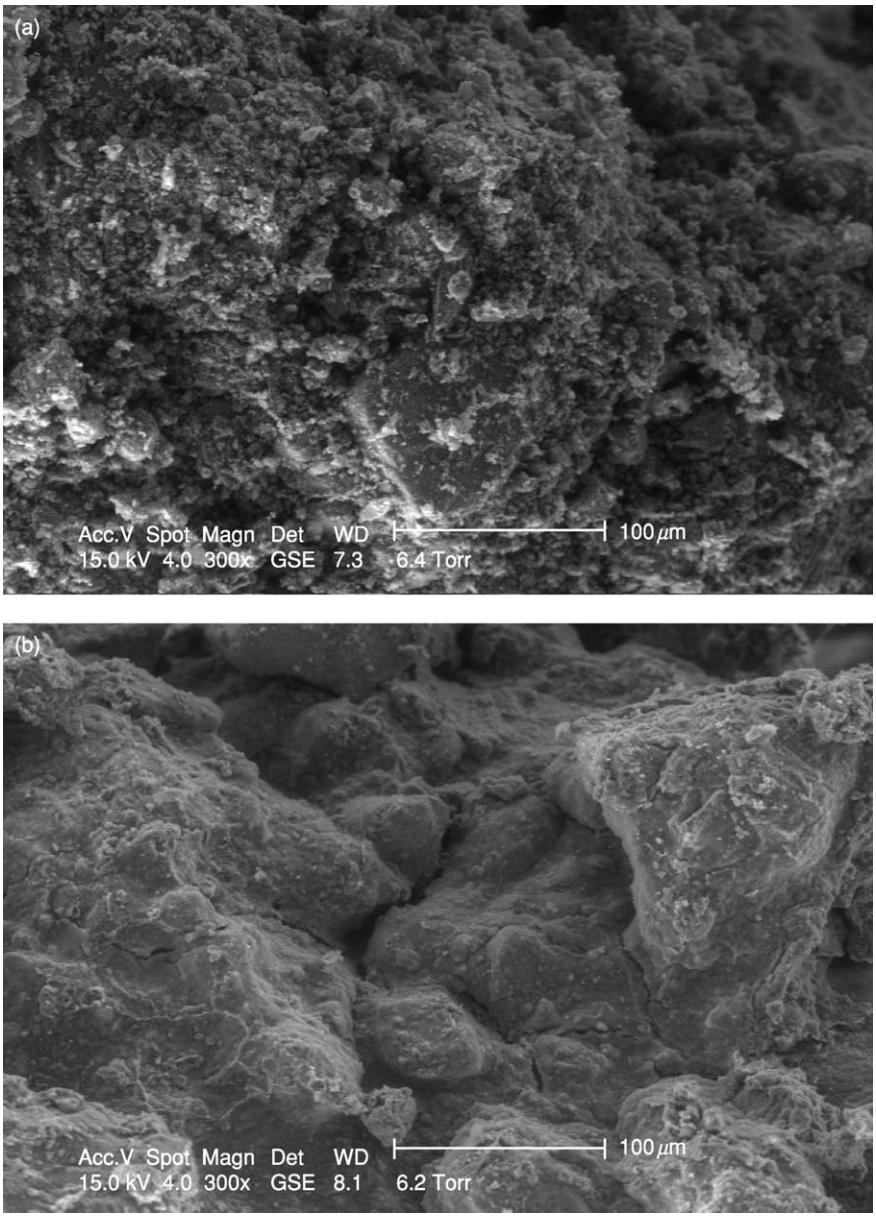

Figure 4 Environmental scanning electron micrographs of (a) surface and (b) subsurface vadose-zone materials at 300× magnification.

microbial growth and activity shape the physical appearance of vadose-zone particles and surfaces, but the relationship between gross surface textural morphology and microbial ecology is not yet quantified. Certainly, the physical composition of the vadose zone can influence the distribution and abundance of microbes: low-porosity rock such as basalt and higher-porosity sands and silts with low carbon content harbor fewer microbes as compared to buried soils (paleosols), which contain more organic carbon. Soil texture also influences the distribution of microbes, since higher clay contents are often associated with greater substrate availability due to the sorption of nutrients on to clay surfaces. However, at a given water content, soils with higher clay contents have lower soil-water potentials, restricting the rates of nutrient diffusion.

Modeling Vadose-Zone Microbial Processes

Mathematical models are useful for predicting the fate of nutrients and pollutants in the vadose zone. Although the vadose zone is not a well-mixed system, because of its heterogeneity it is sometimes modeled as a complete mix reactor where microbes are not

limited by diffusional or advective resupply of nutrients. In such cases, X, the concentration of growing microbes (n per cubic liter) increases according to a simple first-order relationship with respect to time:

$$\frac{dX}{dt} = \mu X \qquad [2]$$

where μ is specific growth rate (t^{-1}), where t is true.

Specific growth rate, for a particular microbe and for a given set of environmental conditions, varies with substrate concentration, as per the Monod equation:

$$\mu = \frac{\mu_{max} S}{K_s + S} \qquad [3]$$

where μ_{max} is maximum specific growth rate (t^{-1}), S is substrate concentration (per cubic milliliter), and K_s is substrate concentration at one-half μ_{max} (per cubic milliliter).

Equation [2] can be related to a change in substrate concentration over time by a yield coefficient, Y, where Y is mass of substrate utilized per mass of microbes. In that case, the rate of substrate depletion is:

$$\frac{dS}{dt} = -\mu X Y \qquad [4]$$

An equation that is analogous to eqn [3] but more applicable to substrate depletion by nongrowing microbes is the Michaelis–Menten equation:

$$v = \frac{v_{max} S}{K_m + S} \qquad [5]$$

where v is substrate depletion rate ($ml^{-3}\,t^{-1}$), v_{max} is maximum substrate depletion rate ($ml^{-3}\,t^{-1}$), S is substrate concentration (per cubic milliliter), and K_m is substrate concentration at one-half v_{max} (per cubic milliliter). Note that eqn [5] describes the variable v, whose units are different from the Monod specific growth rate, μ, because v describes the mass of substrate depleted per unit volume of catalysts (free enzymes or nongrowing microbes). When cells are nongrowing and do not experience mass transfer limitations:

$$\frac{dS}{dt} = -\frac{vX}{\rho_c} \qquad [6]$$

where ρ_c is microbial cellular density (per cubic milliliter).

Transport processes may limit the observed rate of microbial reaction in the vadose zone. At the scale of microbial biofilms (**Figure 5a**), the composite biofilm EPS and cells (**Figure 3a**) can significantly impede the diffusion of nutrients to biofilm bacteria. If we assume a steady state at that spatial scale, the

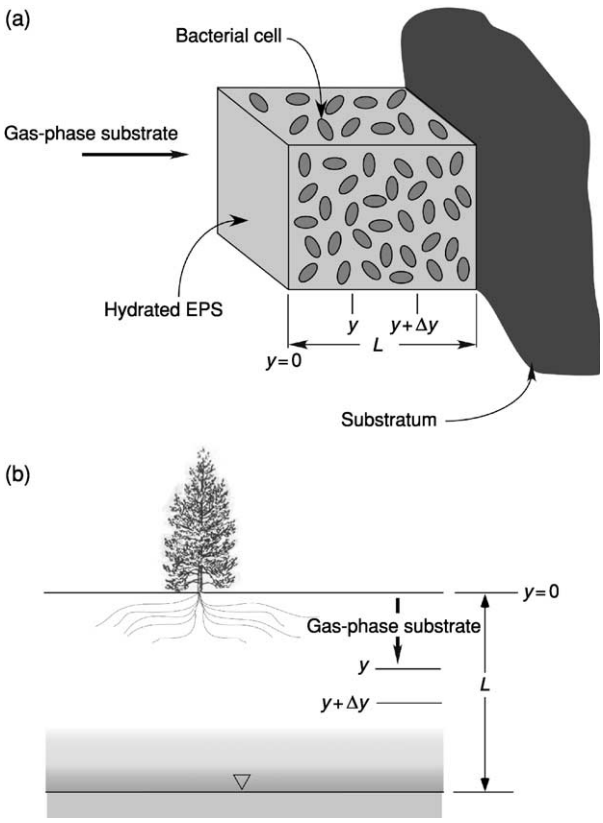

Figure 5 Idealized control volumes depicting (a) biodegrading bacterial biofilm and (b) the vadose-zone profile where, for modeling purposes, L is total depth, y is the distance into the system, and Δy is the change in distance. EPS, extracellular polymeric substances.

applicable differential equation that accounts for both diffusional substrate resupply and microbial reaction is:

$$D\frac{d^2S}{dy^2} = -\mu X Y \eta_i \qquad [7]$$

where D is effective diffusivity of limiting nutrient ($l^2\,t^{-1}$), y is distance along the axis of diffusion (L), and η_i is internal effectiveness factor, a dimensionless parameter that reduces microbial reaction to the rate constrained by diffusional rate limitation.

The boundary conditions for eqn [7] are: for $y = 0$, S is a maximum concentration occurring at the outside edge of the biofilm; and, for $y = L$, $dS/dy = 0$.

Equation [7] can be used to describe gas-phase substrate mass transfer and microbially mediated substrate reactions along a depth profile (**Figure 5b**), as long as the advection of gas through soil pores is relatively rapid and there are no rate-limiting sorption processes. Where mass flow through soil pores and/or sorption processes limit the rate of biogeochemical processes in the vadose zone, the

mathematical model includes explicit mass flow terms for the moving phase. Equations for describing mass flow of solution phase nutrients are typically based on the Darcy equation. Models of the latter kind will also include an applicable reaction term, e.g., eqn [4] or [6], if the purpose of the model is to describe the transport and fate of nutrients or pollutants.

Applications of Vadose-Zone Microbial Ecology

Pollutant Remediation

The vadose zone is frequently subject to pollution from either activities on the ground surface or below-ground leaking storage tanks. Depending on the physicochemical properties of the particular pollutant, the local environmental conditions, and the length of time following release, pollutants can be distributed through various regions of the vadose zone, as depicted in Figure 6. The vadose zone, either passively or actively, is frequently relied upon to attenuate pollutants that would otherwise migrate into groundwater. Active uses include leach fields for disposal of septic tank effluent and bioventing for the remediation of volatile organic pollutants. Passive uses rely upon the natural degradation capabilities of the vadose zone rather than an engineered system. Table 1 summarizes the various technologies that use the vadose zone to attenuate and remediate environmental pollution.

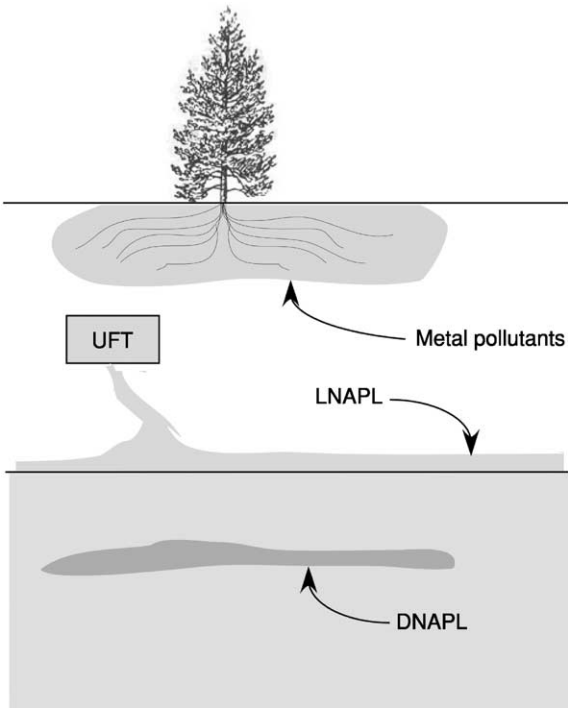

Figure 6 Profile of the polluted vadose zone depicting the orientation of a leaking underground fuel tank (UFT), light non-aqueous-phase liquid (LNAPL) and dense nonaqueous-phase liquid (DNAPL).

Pollution can alter vadose-zone microbial ecology. For example, sites used for waste disposal often have higher populations of culturable microbes and increased microbial activity relative to unimpacted sites. The effects of pollution on vadose-zone microbes and the effectiveness of microbial remediation depend on the characteristics of the specific pollutant and the nature of the microbial communities. Pollutant toxicity as well as bioavailability, i.e., the integrated mass transfer and biodegradation characteristics of the pollutant, are important determinants of the rate of pollutant bioattenuation in the vadose zone. Toxicity can be quantified in the laboratory using bioassays, but pollutants often occur in mixtures which have different toxicity characteristics to individual chemicals. Bioavailability largely depends on the physicochemical characteristics (e.g., solubility, partitioning characteristics, volatility) of the pollutant *in situ*.

The Vadose Zone as an Analog for Other Extreme Habitats

From the near surface to the extremely deep subsurface (several kilometers below the surface), the varying regions of subterranean Earth may physically and chemically mimic the harsh environments that exist on other planets. Although mostly beyond the scope of this chapter, a significant body of new knowledge has been gathered in the last two decades to confirm that microbes of varying taxonomies exist in the deep subsurface, living in high-temperature, high-pressure, and anoxic conditions. Much of the work that has generated the current knowledge of microbial ecology in the very deep subsurface has been funded by the US Department of Energy Subsurface Science Program. While much of that work has been focused on the microbiology of saturated zones, some research has been conducted on vadose-zone samples. Many questions in deep subsurface microbial ecology have been partly answered for specific sites, yet generalizable answers are still needed. How and when did microbes first inhabit deep vadose environments? How do they survive in environments that appear decoupled from aboveground primary productivity? What limits their proliferation: is it the lack of carbon or other nutrients, desiccation, unfavorable pH, and/or lack of terminal electron acceptors? Can subsurface microbiology reveal clues about the origins of life on Earth? Continued interest in these questions still fuels

Table 1 Selected waste treatment technologies and applications requiring vadose-zone microbes

Technology	*Application*	*Description*	*Comments*
Leach field	Septic tank effluent disposal	Organic and nutrient removal; effluent percolates from near-surface distribution pipes through underlying subsoil	Used frequently for rural domestic wastewater treatment; depending on percolation rates, nitrate and microbial pollutants may enter the groundwater
Phytoremediation	*In situ* bioremediation of metal and organic pollutants	Selected plants are cultivated in contaminated soil; plants sequester metals and enhance organic pollutant degradation in the rhizosphere	Low cost and high aesthetic value as compared to mechanical systems. Metal-enriched plant material requires special disposal; efficacy depends on the plant, pollutant, rooting depth, and extent
Bioventing	*In situ* bioremediation of volatile organic carbon pollutants	Air is piped belowground to enhance soil aeration, pollutant mobilization, and aerobic biodegradation	Used frequently for the remediation of refined petroleum that has leaked from underground storage tanks
Natural bioattenuation	Organic (volatile and semivolatile) and inorganic pollutant remediation	Natural physical, chemical, and biological processes distribute and possibly destroy waste; monitoring programs track performance	Used frequently, either intentionally or not; rate of remediation and pollutant fates are uncertain
Bioswale	Storm water	Storm water runoff collects in a constructed depression aboveground and percolates belowground, where dissolved and particulate pollutants are filtered	Used frequently in urban settings; depending on percolation characteristics, pollutants may enter groundwater directly. Sorption and biotransformation capacity for metals is uncertain
Land application	Disposal of treated wastewater	Effluent is applied by irrigation or spraying on to the soil surface and allowed to infiltrate for the removal of organic compounds and nutrients	Used for some domestic and livestock wastewater disposal; less effective in cold or wet climates. Pathogen distribution a potential problem when irrigating food crops

research in subsurface microbial ecology. Given that most of the biomass on Earth resides in the subsurface, it is imperative that we reach a better understanding of microbial life in the subsurface and the role of subsurface microbes in the Earth's biogeochemistry.

VOLCANIC SOILS

G Uehara, University of Hawaii, Honolulu, HI, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Molten magma extruded as liquid lava or ejected as cinders or ash from deep within the Earth adds to the variety of parent materials and soils we find on the landscape. Unlike their plutonic counterparts that cool and solidify slowly underground and are subjected to weathering only after uplift and erosion, volcanic rocks cool and solidify immediately upon exposure to the atmosphere. The faster cooling rate results in formation of glassy and finer rock textures in volcanic rocks so that plutonic and volcanic rocks with identical chemical composition can lead to formation of different soils. This is especially true for finely divided pyroclastic ejecta that cool even before they land. The porosity and texture of such cindery or ashy materials differ so greatly from those of other parent materials that glassy volcanic ash develops into soils that fall in the exclusive Andisol soil order.

In addition to rock texture and porosity, volcanic materials also vary in chemical and mineral composition. In fact it is the chemical composition of the magma that determines, to a large extent, the texture and porosity of the extruded material. Highly glassy and porous pyroclastic rocks are more common in high-silica magma that form acidic rocks than the less viscous, basic magma that erupt less explosively and produce basalitc lavas.

The higher viscosity of silicic magma results in the formation of steep-sided, cone-shaped volcanoes exemplified by Mount Fuji in Japan, whereas the basic, low-viscosity magma form broader, shield volcanoes exemplified by Mauna Loa in the island of Hawaii. Both types of volcanoes erupt pyroclastic materials and lava, but the silicic magma have more frequent explosive eruptions and produce more ash than the shield volcanoes. The 1980 eruption of Mount St. Helens in the USA illustrates the explosive nature of intermediate and silicic eruptions. Silicic eruptions often force nearby residents to evacuate the area, whereas sightseers flock to view molten lava pouring out from vents and fissures along rift zones of shield volcanoes.

The range of silica content of volcanic rocks is shown in Table 1. As silica decreases, the content of iron, magnesium, calcium, and sodium increases. These differences in chemical composition influence the rocks' susceptibility to weathering. In general, the basic rocks weather more rapidly owing to the ease with which sodium-, calcium-, magnesium-, and iron-bearing silicate minerals undergo hydrolysis and dissolution. The rate of weathering is even faster if the erupted material is ash.

Rock Weathering

As a rule, the weathering rate of volcanic rocks is influenced by its chemical composition, glass content, and particle-size distribution. Volcanic ash, for example, weathers very rapidly owing to its high glass content and high specific surface associated with smaller particle size. Volcanic glass, however, varies in chemical composition. Felsic glass is high in silicon, potassium, and sodium and is more resistant to weathering than mafic glass high in iron and magnesium.

Artifacts such as arrowheads made of obsidian show little sign of weathering even after centuries of burial, primarily because they are felsic in composition and have low surface-area-to-mass ratios. It is a different matter with ash particles, called shards, which geologists and soil scientists often use as stratigraphic markers and evidence of ancient volcanic eruptions. Shards have high surface-area-to-mass ratios so that volcanic ash particles still identifiable as shards after deposition and buried for thousands of years are more likely to be felsic, as mafic shards would long have been weathered to clay minerals.

Soil Formation

Any student of soil science who has walked over a lava flow or freshly deposited volcanic ash can sense

that soil formation on such materials would be rapid. Owing to the high porosity and large pores of most lavas and ash deposits, very little runoff occurs, and plants are able to establish themselves with relative ease. Nitrogen-fixing lichens are the first to colonize lava flows, and, under warm and humid climates, dense forests can cover lava fields in less than a century. In humid areas, the soils that first form are Folists of the Histosol order. Folists are well-drained Histosols that consist primarily of an organic surface horizon resting on rocks or fragmental materials. If the underlying rock is A'a lava the soil is often a Typic Udifolist, but if the rock is Pahoehoe lava the soil is commonly a Lithic Udifolist. This distinction between a Typic and Lithic Udifolist is crucial from an agricultural standpoint. A Typic Udifolist with its clinkery A'a substrate is ideal for use as orchards, but its Lithic counterpart, with an unbroken and smooth rock substrate, is not. Figure 1 shows papaya production on a Typic Udifolist.

In the case of volcanic ash, plants readily send roots deep on to the loose ash deposit, and rapid buildup of organic matter occurs throughout the rooting depth. The first recognizable soil would most likely be a Vitrand. As the name implies, the soil is an Andisol consisting mainly of unweathered glass fragments.

Folists and Vitrands do not remain unchanged for very long. While soils change little in a human lifespan, one can, given the right circumstances, understand how volcanic soils change with time. Such circumstances exist in the Hawaiian Islands which formed from the movement of the Pacific plate over a stationary hotspot. Islands that form from outpouring of lavas from the hotspot are displaced in a northeasterly direction, providing a chain of islands that is now the Hawaiian islands. The age of the rocks in the island chain ranges from 0.4 million years on the island of Hawaii to 5 million years on the island of Kauai. Ten of the 12 soil orders of Soil Taxonomy occur in the island chain. Unlike Folists and Vitrands that can form in less than a century, and are common on the youngest island of Hawaii, Oxisols and Ulitisols that require prolonged weathering and leaching to develop do not exist there. On Kauai, the oldest island, the opposite is true, wherein Oxisols and Ultisols dominate and Folists and Vitrands are nowhere to be found. The greatest diversity of soils is found on the island of Oahu, midway between Hawaii and Kauai. Here soils found on the old islands dominate, but young, posterosional volcanic eruptions have rejuvenated part of the landscape. A soil order that does not occur on the young islands, but peaks in the intermediate islands and slightly diminishes in abundance on the oldest island, is the Vertisol. The Vertisols form in valley floors on the dry, leeward side of the older islands. On the leeward side, rainfall is lower and the bases that accumulate in the valley floor provide the right conditions for smectite formation. Vertisols do not occur on the young islands because the valleys have not yet formed. In the oldest islands, Vertisols in the wetter zones lose their bases and eventually become kaolinitic.

Figure 1 Papaya production on a young volcanic soil, which was originally a Udifolist.

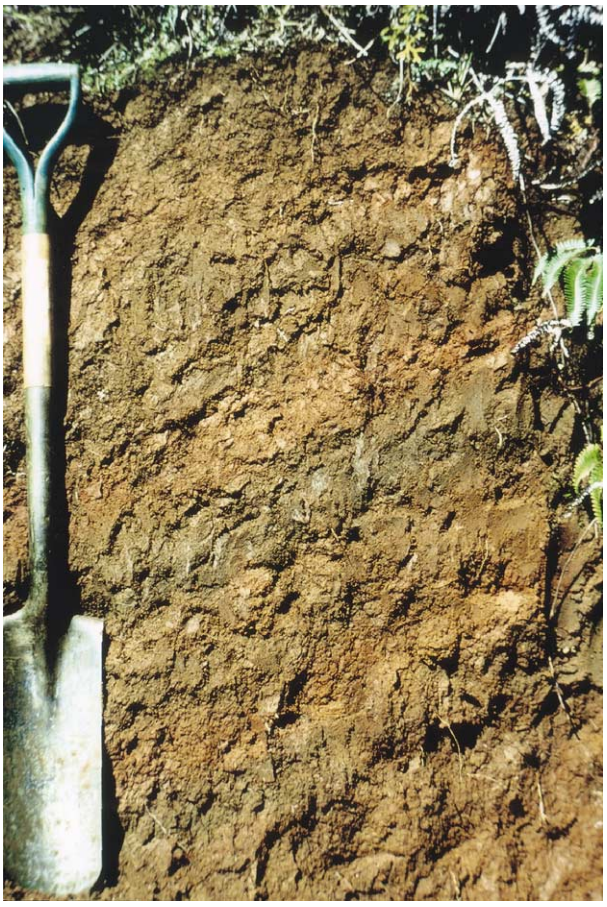

Figure 2 A highly weathered Andisol, an Acrudoxic Hydrudand.

The soils developed from volcanic ash age much faster. Vitrands quickly turn to Haplustands in the dryer zone and to Hydrudands in the wetter areas. The Hydrudands are some of the lightest soils in the world, with bulk densities less than $0.5\,cm^{-3}\,g$ and field water content by weight generally exceeding 100%. Owing to their porous nature, they are readily leached of bases and silica, leaving a residue high in hydrated iron and aluminum oxides. These highly weathered, prematurely old soils occur on the youngest islands (Figure 2).

Vertisols

A combination of basic parent material and low-leaching environment often serves as a necessary condition for Vertisol formation. Sediment deposited by streams and rivers cutting through basaltic rock often provides the first condition, and the semiarid tropics that circle the globe north and south of the equatorial humid tropics provide the second. The Vertisols of Sudan's Gezira region, situated between the White and Blue Nile, is such an example. There are no volcanoes in the Gezira, but the soils there owe their origin to the Blue Nile, which transports basaltic sediments from the highlands of Ethiopia to the Gezira. A similar situation exists in the experimental fields of the International Crop Research Institute for the Semi-Arid Tropics located near Hyderabad, India. The black Vertisols in the Hyderabad area sit side by side with red Alfisols to form a red-and-black soil complex. Here again, there are no signs of volcanoes nearby, for the Vertisols are products of sediment transported by water from basalts of the Deccan Flats.

In Table 2, the chemical composition and chemical properties of a Vertisol from Hawaii are shown. The Vertisols of the semiarid tropics are remarkably alike. Often referred to as tropical black earths, they have low organic carbon content and their dark color has been attributed to dark iron minerals and manganese coatings. Their chemical and physical properties are mainly determined by the high clay and smectite content.

Oxisols

A key feature of Oxisols is the low cation exchange capacity (CEC) of their clay. This condition is most likely to occur when the clay fraction is low in layered silicate clay and rich in iron oxides. Volcanic rocks low in silica and rich in ferromagnesium minerals weather rapidly to Oxisols under warm and humid conditions. While time and intense leaching can produce Oxisols from a variety of materials, volcanic materials, due to their porous nature, produce Oxisols with greater ease. The chemical composition and selected properties of an Oxisol formed from basic volcanic rock are shown in Table 3. The extreme weathering of the soil is indicated by its placement in the Acrudoxic subgroup and also by the rise in the $1\,mol\,l^{-1}$ KCl pH in the oxic horizons midway in the profile. In the oxic horizons the pH measured in $1\,mol\,l^{-1}$ KCl is higher than the pH measured in water, indicating that the net charge of the soil material is positive. Soils with these characteristics are infertile, but can be made productive with phosphorus fertilization, as well as liming with calcium silicate rather than calcium carbonate.

Ultisols

From a taxonomic standpoint, 'volcanic soil' is not a very useful term as a great variety of soils can have volcanic origins. Ultisols can form from volcanic rocks where rainfall is sufficiently high to leach bases, and conditions exist that favor activation and

illuviation of clay. It is not unusual to find two soil orders, in close proximity, forming from the same parent rock. Ultisols and Oxisols, for example, have developed synchronously on the same geomorphic surface on the volcanic island of Kauai in the Hawaiian Islands. The Ultisols, however, always occur on the knick points of the landscape, where soil creep activates and mobilizes clay along sheer planes in the subsoil. The chemical composition and properties of such an Ultisol are given in Table 4. The same shearing action leads to formation of Alfisols in drier locations, where leaching is less intense and basic cations are retained in the profile.

In climates where Ultisols dominate, water is plentiful but nutrients are in short supply, whereas, in semiarid regions where Alfisols predominate, the land is fertile but short of water.

Volcanic soils may have special meaning to people living in humid regions where soils that under normal circumstances would be Ultisols are maintained in an Alfisol-like condition by periodic additions of nutrient-rich ash from a neighboring volcano. The advantage of having an adequate supply of water and nutrients in contrast to having one or the other was, for our ancestors, the difference between being able to form creative, sedentary communities in contrast to simply surviving by hunting and gathering. Thus it may not be the soil itself but the presence of an active volcano nearby that makes volcanic soils what they are.

Andisols

If one had to choose a soil to represent the class of soils we call volcanic, it would be an Andisol. This is because all Andisols are volcanic soils, but the reverse is not true. Andisols have two characteristics which make them unique. They contain high amounts of short-range-order and noncrystalline materials, and have low bulk densities. Two short-range-order minerals commonly found in highly leached and weathered Andisols are allophane and imogolite. These minerals have high specific surfaces (approximately equal to $1000\,m^2g^{-1}$) and pH-dependent charge. The high specific surface of the inorganic colloids enables the soil to sequester large quantities of organic matter. The prefix 'Ando' on Andisol is the Japanese word for 'dark,' used to describe the low chroma of organic-rich volcanic ash soils of Japan. In Japan, where the ash is generally high in silica and low in iron, organic matter imparts a nearly black color to the soil. In Andisols developed from low-silica, high-iron and -magnesium ash, the iron oxide masks the black color of organic matter to produce a dark-brown soil (Figure 2).

The chemical composition and selected chemical properties of two Andisols, one developed in a perudic, and the other in an ustic moisture regime, are shown in Tables 5 and 6. Both soils are excellent agricultural soils, with the wetter soil requiring careful nutrient management and the drier soil requiring irrigation for profitable farming.

Human Interactions with Volcanic Soils

Our human ancestors may have avoided extinction and evolved by adapting to the diverse and ever-changing volcanic environment of the African Rift. The rich soil, constantly rejuvenated by sprinkling of volcanic ash, even today supports large herds of herbivores and their predators, and some of the highest nonurban human population densities in Africa.

When modern humans exited Africa through the Rift zone, then crossed Asia and the Bering Straits, they encountered the North, Central, and South American segment of the 'Ring of Fire' that circles the Pacific. Like the rich alluvial soils of the Nile, Tigris, Euphrates, and Indus rivers that enabled humans to shift their energies from hunting and gathering to creative endeavors, the fertile and well-watered volcanic soils of Central and South America provided the new settlers with the means to do the same.

Even today, the influence of volcanic soils on human society is evident. In Indonesia, for example, nearly half of its 200 million people live on the tiny volcanic island of Java. Efforts to move whole communities from Java to the larger and less densely populated neighboring islands have not been easy. Villagers accustomed to farming Andisols with characteristics similar to the one shown in Table 5 found it difficult to survive on Ultisols with features similar to those shown in Table 4.

Today science and technology enable farmers to understand and overcome soil constraints, but only a century ago soil fertility determined to a large degree outcomes of human interactions with the environment. Unfortunately this is still true in many developing countries, where science-based soil management practices have yet to be adopted. The volcanic soils of Africa, Asia, and Latin America that helped people in the past now need our help to perform and contribute to human well-being as they have in the past.

List of Technical Nomenclature

Acrodoxic Hydrudands — These are highly weathered soils derived from volcanic ash that occur in high-rainfall areas. The subsoil material contains more that 100% water on a weight basis and dries irreversibly when exposed to the atmosphere

Udifolists — These are well-drained organic soils that occur mainly in the high-rainfall areas of the Hawaiian Islands on forested lava flows

WAKSMAN, SELMAN A.

H B Woodruff, Soil Microbiology Associates, Watchung, NJ, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Selman A. Waksman, professor and research specialist at Rutgers University, the State University of New Jersey, USA, was a highly creative soil scientist. From the time of preparation of his senior college thesis in 1915 until his death in 1973 he specialized in the study of the microbes of the soil. During that 58-year period, he published 447 scientific reports. They covered the full range of the early development of soil microbiology, extending from the descriptive phases of the microorganisms of the soil to details of their physiology, from investigations of their influence on soil fertility to studies of their interactions together within soils. His research on the microbial associations led to a demonstration that soil microorganisms produce antagonistic agents. He proposed the name 'antibiotic' for such products. Certain of the antibiotics derived from soil microbes, for example streptomycin, discovered in his laboratory, have proven useful in the treatment of infections of humans, animals, and plants.

Selman Waksman was a prolific writer, publishing papers in a wide range of scientific journals, in several languages. He was author or co-author of 28 books. His *Principles of Soil Microbiology*, an 897-page volume, the first edition published in 1927, for years became the standard textbook of his field. He guided 78 students to graduate degrees. He was an inspiring lecturer. His presentations were filled with stories of his relationships with leaders of his field and were avidly followed by his students and by general audiences. He was beloved by his students, who spoke of him familiarly as 'The Old Maestro.' Waksman's name is generally included with Winogradsky, Omeliansky, Beijerinck, and the Americans Lipman and Thom in lists of the pioneers of soil microbiology.

Illustrative of the breadth of Selman Waksman's interests and the scope of his accomplishments is the quantitative record of his publications, written in association with his students. Fifty-eight were descriptive reports of the microbes of the soil, 53 of the enzymology and biochemistry of soil microbes, 11 on sulfur oxidation, 35 on peat, composts, and humus, 18 on microbes of the sea, 20 on taxonomy and methodology, eight on organic acids and fermentation products of molds, 18 on general physiology, and 31 were biographies and discussions on the philosophy of science. Finally, 195 were on antibiotics, including the announcement of 17 new antibiotics discovered in his laboratory.

Waksman was greatly honored, based on his productive career. By the time of his 80th birthday, he had received 22 honorary degrees, 12 from universities of Europe, Asia, and South America. He had been granted 63 prizes, awards, and medals. He was elected to the prestigious National Academy of Sciences, served as President of the American Society for Microbiology and was awarded the 1952 Nobel Prize in Physiology or Medicine.

What were the background, family, experiences, and education that led to such a creative career?

Selman Abraham Waksman was born 8 July, 1888 according to the old Russian calendar (now 22 July) in Novaia-Priluki, a small village in the Russian Ukraine. The villages and small towns of western Russia and Ukraine were populated by recently liberated serfs, who subsisted by small-scale farming and livestock husbandry, and by Jewish artisans and tradesmen who engaged in crafts, shop-keeping, and the processing and marketing of farm and forest products. These activities influenced the young child, and provided a motivation for his later decision to specialize in unraveling the chemistry of living things.

The inhabitants of Novaia-Priluki were poor. There was a rigid separation in culture and approaches to life between two groups, the Russian and the ethnic Jewish populations. The Jews stressed education, but a specialized religious education, directed by the synagogue Rabbinate, devoted almost exclusively to the Bible and the Talmud. The adult men spent much of their free time in study, discussion, and

arguments in their religious halls. Yiddish was their universal language, only a minority learning the intricacies of Hebrew and developing the ability to write in Russian. Waksman's mother was more accomplished than most. She vowed that her son Selman would become even more so, therefore she strove constantly to see that objective fulfilled.

No formal state schools existed in Novaia-Priluki. The sole opportunity for a broad education was private tutors, who either taught small groups or, if financial circumstances permitted, individual students. Waksman was taught privately. He learned the rudiments of language and mathematics and limited geography. He had an exceptional ability to memorize almost instantly anything read, thus progressed more rapidly than many of his student associates. Somewhat chagrined by the advantages offered him, compared to his friends, he, with some associates, organized a volunteer school, in which they passed on to economically deprived young folks the results of their studies. It was a most fortunate experience. It not only honed the lecturing skills Waksman exemplified later as a college professor, but provided the means whereby he could remove himself from the drudgery of mere subsistence.

Once he had sampled the full extent of educational opportunities available in his home town, Waksman moved to a larger town, Zhitomir, capital of a nearby prefecture. It had a Gymnasium for advanced studies, so accomplished teachers were available who would accept students for private study. From Zhitomir he progressed to an even larger city, Odessa, where highly qualified professors were located. In these locations at a distance from home, his prior experience as a volunteer instructor became significant. He offered himself as an instructor in the daytime, thus earning funds to cover living costs and tutors' fees, taking his own lessons during evening hours.

After years of study, at 22 years of age, Waksman felt qualified to take the 2-week extensive written and oral exams whose passage was required to obtain permission to enter a university. He did so, and passed.

Now that the essential qualification had been earned, entry into a university became possible. For Jews in Russia, however, that was very difficult to accomplish because of a quota system. Waksman realized that, graduating in Russia as a specialist in his chosen area, he would face few opportunities for employment. Therefore, he gave serious consideration to emigrating to the USA. Close relatives had done so and their letters contained descriptions of the opportunities for advancement that existed in America. The turning point came with the death of his mother. His father quickly remarried. Feeling that he no longer had a home to return to and with little opportunity available to advance in his objective for life work, he emigrated.

His port of entry to the USA was Philadelphia. Relatives, the Kornblatts, had advanced from tenant farmers to ownership of a farm specializing in poultry. They lived nearby in Metuchen, New Jersey. He joined them, working on the farm to earn his board. For the first time he became directly responsible for agricultural practices, obtaining best yields of vegetables and enhancing egg production.

The experience aiding the Kornblatts on their farm strengthened Waksman's intent to study the application of chemistry to biology. He applied to Columbia University in New York City to enter a premedical program, was accepted, but had no means to cover the costs involved. He visited nearby Rutgers College, at that time a private school that had associated with it federally supported Schools of Engineering and of Agriculture, supported financially through the Federal Morrill Land Grant Act, and the site of an agricultural experiment station supported by the state of New Jersey. There he met Jacob G. Lipman, professor of soil chemistry and microbiology, an excellent experimentalist and skilled leader, who was slated to become Director of the Agricultural Experiment Station. In Lipman, Waksman found his mentor. In soil microbiology he discovered the topic he had been striving toward all his life, providing him the opportunity to study the relationship of chemistry to living systems. He applied for a scholarship at Rutgers College, received one and became an undergraduate student, the sole person in his class majoring in soil microbiology.

Waksman was highly successful in his studies. Despite his limited knowledge of the English language, he received high grades. As he entered his senior year, he had already fulfilled most of the requirements for graduation. Therefore, a senior thesis became his prime objective for the year. His life as an experimentalist in the field of soil microbiology had begun.

The prior investigations in soil microbiology had been directed primarily toward individual organisms, the nitrogen-fixing rhizobia and azotobacter, or soil organisms that caused plant diseases. Waksman chose to apply a holistic approach to the topic. He enumerated the types of organisms existing in soils, defined the changes in numbers and types that occurred at different soil depths, among differing soil types, at different temperatures and moisture levels. From trenches he had dug on the college farm, using good aseptic techniques, he isolated and classified hundreds of organisms. At the end of his senior year, he tabulated his results. They were presented orally by his professor, Jacob Lipman, at a Society of American Bacteriologists meeting. An abstract of the talk was

published in the first issue of the newly established *Journal of Bacteriology*.

Highly appreciative of Waksman's ability to perform science independently, Lipman encouraged him to remain at Rutgers as a graduate student, working towards an MS degree in soil microbiology. He provided the financial wherewithal to make it possible. Waksman had become fascinated with the small, hard, slowly growing microbes that appeared almost universally in his agar platings of soils at high dilutions, often by count a dominant proportion of the soil population. They were known to others, but were very little studied. They had been generally ignored because of the smallness of their colonies and slowness of their growth. These microorganisms were the actinomycetes, the cells of which are typical of bacteria, approximately the same size in diameter, but in morphology filamentous, resembling the molds. Waksman decided to concentrate on them as an MS thesis objective and with an associate he isolated many, studying each in detail. When the isolates were typical of past descriptions, he applied the established species names, but often he found cultures that differed distinctly from previously known actinomycetes. He created names for these, often related to his personal experiences: *lipmanii* and *halstedii*, his favorite teachers; *rutgersensis* and *californicus*, his university and choice for his PhD education; *bobili*, the nickname for his wife.

Upon completion of his MS program, Waksman realized the need to enhance his knowledge of biochemistry, a special branch of chemistry, and to do so he accepted a student appointment to the Department of Biochemistry at the University of California in Berkeley. As subjects for his investigations there, he took with him a selection of the cultures isolated at Rutgers and with them concentrated on defining the enzymes they produced.

Upon receiving his PhD degree at Berkeley, Waksman was offered a position at Rutgers as a college instructor in soil microbiology, with simultaneous appointment as researcher in the Agricultural Experiment Station, at a small salary. He returned to New Brunswick and designed a graduate-level lecture program for soil microbiology. He continued his research studies on the actinomycetes and extended them to include the fungi and protozoa of the soil. For a few years he also worked part-time at a commercial concern to supplement his salary.

Assertive in his approaches, he came into conflict with recognized specialists in the field of soil microbiology. H.J. Conn of Cornell University was convinced that the fungi observed in soil platings were of little significance, that they were derived from wind-blown fungal spores. E.J. Russell in England, a member of the prestigious Rothamsted Experiment Station, had proposed that soil protozoa are controlling members of soil populations because they consume soil microorganisms as a source of nutrition. Waksman objected to both claims, did research to prove the correctness of his ideas, and, through his publications on soil microorganisms he became well-known in the field. He, with the aid of his students, greatly expanded the understanding of microbes of the soil, especially the actinomycetes. New students were attracted to his laboratory, as well as many non-degree-seeking visitors who desired to work several weeks or months conducting studies in association with him.

By 1924 Waksman had completed studies defining the nature of the common members of the soil population and he faced the question of an objective for his future program. To search for the answer, he chose to tour the well-known laboratories of Europe, to spend hours in conversation with specialists in his field and allied subjects. For 5 months he did so, visiting a variety of persons. Mostly, he was received with enthusiasm by those who appreciated his scientific record. Sometimes he had to negotiate an entry where unknown, but always he entered into detailed discussions, sometimes somewhat heated if he disagreed with accepted dogma. He had firmly fixed ideas about many chemical and biochemical processes, a few not in tune with current thinking, and he avidly promoted them.

Waksman came home thoroughly refreshed, convinced that his holistic approach to the study of soil microbes was correct. He had chosen the new objective of defining what the grand mixture of organisms present in soils was accomplishing. What products did they produce in the soil? How did they affect soil fertility? He became convinced that a significant factor in defining fertility was humus, the resistant organic matter resulting from the microbial attack on plant residues, composts, other organic substances that come into contact with soils. Using a system of analysis, dubbed proximate analysis, he followed the changes in organic matter in the soil, then followed the slower attack on humus itself by other microbes, causing its gradual breakdown. He became convinced that the resistant organic complexes in soils have fertility-defining significance.

He extended his studies to follow details of the microbial processes that occur during the composting of waste agricultural products. He also investigated the special geographic situations in which humus is broken down less rapidly than it is formed, resulting in the formation of peat bogs. Here, likewise, he stated his opinions assertively, which eventually brought him into conflict with members of the

chemistry section of his department. In contrast to his belief that humus is a significant substance in soil fertility, some chemists at Rutgers, led by the excellent experimentalist Jacob Joffe, differed. Joffe had previously been Waksman's associate in research on sulfur-oxidizing organisms and was co-discoverer with him of *Thiobacillus thiooxidans*. He and fellow chemists considered soils to be the equivalent of ion exchange substances, binding essential plant nutrients as they entered the soil, gradually releasing them to support plant growth, with the soil organic fraction being relatively insignificant for fertility. In many aspects, the arguments advanced by members of both sections of the department had validity, but their inability to come to an agreement led to a permanent subdivision of the Soils Department into two separate departments, Soil Chemistry and Soil Microbiology. Waksman was appointed chairman of the latter.

In his new capacity, Waksman had one professional associate, Robert Starkey, one graduate student position, and one technician funded permanently by the University and its associated Experiment Station. He greatly expanded his research program by receiving financial support from private funding agencies and occasionally by government grants. His work was also supplemented by accepting commercial support for projects with practical objectives that had relation to his ongoing programs. One that had special significance was support offered by Merck & Co., Inc., at that time a commercial concern in New Jersey especially interested in producing bulk chemicals for pharmaceutical and industrial uses. Merck directors felt the need to expand into organic acid manufacture and provided a fellowship to Waksman to investigate organic acid production by soil microbes. Initially, the effort was directed at fumaric acid, a product useful in the dry-cleaning industry. It was soon extended to citric acid, which was then being produced for the beverage industry by culturing *Aspergillus niger* in pure culture in large trays. Waksman and his students isolated from soils new highly efficient organisms that produced the desired acids. Because of close contacts with A.J. Kluyver of the Technische Hoogschool in Delft (Waksman's associate Robert Starkey had recently spent a sabbatical year in the Netherlands with him), Waksman became familiar with the value of cultivating molds aerobically for citric acid production by submerged culture on rotary shaking machines. With adequate oxygen available at all times, mold growth was far more rapid and it was much more dense in the shaken cultures than that obtained by the prior stationary culture techniques. This was an advanced method of culture for microbes, not only valuable in organic acid production but highly significant when Waksman extended his program utilizing submerged culture procedures into the antibiotic field.

Supplementing his broad attack on understanding the activities of microbes within the soil, Waksman became involved with many related activities. Much effort was spent in developing a classification system for the filamentous bacteria, commonly termed the actinomycetes. In 1943, he, with A.T. Henrici, proposed a new generic name *Streptomyces* for the frequently found spore-forming members of the order Actinomycetales. The new genus name became official and was included in Bergey's *Manual of Determinative Bacteriology.*

Waksman was consulted concerning the role of bacteria in initiating the fouling of ship bottoms with barnacles and other marine life. Because of the special wartime needs that developed soon thereafter, the project rapidly expanded and Waksman started summer residences at the Oceanographic Institution in Woods Hole, Massachusetts, supervising students there. For several years he applied the basic procedures of soil microbiology to investigation of the microbes of the sea, until the demands of the program required full-time supervisory effort, whereupon he resigned. Eighteen publications resulted from this scientific side excursion.

Waksman spoke frequently of threefold objectives for research in soil microbiology: first, defining the nature of the organisms present in soils; second, defining the microbiological processes that occur in soils that influence soil fertility; and, finally, elucidation of the interactions, both growth-promoting and growth-inhibiting, that occur among the multitudes of organisms that exist and interact together in soils.

Waksman's approach to the latter objective was based on observations he had made throughout his career. As early as 1923, Starkey and Waksman, in a paper describing results of their study of the microbiological changes that occur during recovery from partial sterilizations of soils, had stated: "Certain actinomycetes produce substances toxic to bacteria – around an actinomycete colony upon a plate a zone is found free from bacterial growth." They had seen such inhibitions as well as growth enhancements repeatedly when they plated soils. In 1938, Waksman decided it was appropriate to initiate a formal study of the interaction of microbes upon one another in soils. Three companion publications resulted. The first was a historical review of microbial interactions. The second, prepared with a student, covered antagonistic actions among microbes grown in the laboratory in artificial substrates. The third, with another student, covered interactions during the decomposition of plant residues. Waksman was fully prepared, therefore, to appreciate an experiment

reported the following year by Rene Dubos. Dubos, as a former Waksman student, had utilized the technique of soil enrichment at Rutgers to isolate cellulose-degrading organisms from the soil. Waksman had recommended him to Oswald Avery of the Rockefeller Institute for a project to find an enzyme capable of hydrolyzing the resistant mucoid capsule of the pneumococcus. Dubos had not only been successful in that endeavor, using the soil-enrichment procedure learned under Waksman, but had extended his studies, enriching soil with living cocci and from that enriched soil isolating a bacillus that killed cocci, including the pneumococci. The antibacterial agent responsible for the killing, which he named tyrothricin, was described in a 1939 publication. Waksman immediately encouraged his cooperators at Merck to aid Dubos by growing the tyrothricin producer in large quantities.

Waksman also saw the potential of the method as a means of discovering other important antibacterial agents. He decided to organize a project aimed at their discovery as products of actinomycetes. He assigned his university-supported graduate student to full-time study of microbial associations. Quickly, a new extremely active inhibitory substance was obtained from an actinomycete. It was crystallized in association with a Merck chemist. It was named actinomycin (Figure 1). Additional graduate students were enlisted to the task, supplemented by short-time visitors who arrived at the laboratory. The scientific publication describing actinomycin had resulted in intense newspaper publicity, attracting an even greater number of visitors than usual. Thus was organized an expanded program on antibacterial substances derived from soil microbes. When requested by an editor of an abstract journal to coin a name under which reports of such substances could be grouped, Waksman proposed the term 'antibiotic' and it became accepted worldwide.

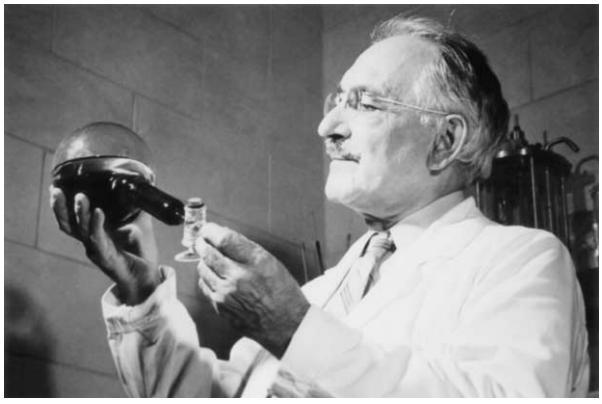

Figure 1 S.A. Waksman purifying actinomycin, his first antibiotic. (From the public files of Rutgers University, photographer unknown.)

The antibiotic discovered in Waksman's laboratory that has had greatest commercial significance is streptomycin, a broad-spectrum inhibitor, that investigators at the Mayo Clinic showed to be active against experimental tuberculosis infections in guinea pigs. Clinical trials of streptomycin soon followed. No effective therapeutic agent existed for human tuberculosis, therefore streptomycin quickly became the dominant approach for treatment of the disease, resulting in many striking cures, in spite of frequently expressed side-effects. Commercial production of streptomycin was initiated in America, initially by Merck & Co., Inc., but with conversion of the streptomycin product patent to a nonexclusive basis at Waksman's and Rutgers University's request, production was undertaken by several additional companies in the USA as well as abroad.

The commercial success of steptomycin led to an intensive search for improved antibiotic producers among the soil population, especially among actinomycetes, both at Rutgers and elsewhere. Many useful agents were found and actinomycete antibiotics have achieved great commercial value.

As the result of Waksman's prominence in the field of antibiotics and the success stories concerning streptomycin, his presence was sought constantly for advice and for the presentation of lectures, especially after he was awarded the Nobel Prize for Physiology or Medicine in 1952 for his studies on the microbes of the soil leading to the discovery of streptomycin. Students flocked to his laboratory, far more than budgets could support or for whom space was available. Waksman recommended, and the University assented, that the royalties earned from the sale of streptomycin, as well as other discoveries from his laboratory, be applied for the construction and support of a specialized Institute of Microbiology located on the Rutgers University campus. Its objective was not to be limited to research on microbes of the soil but to be applied to research on microbes broadly. Through the financial support of the royalties, the Institute of Microbiology was built and became fully staffed. Selman Waksman served as its first Director. In the Institute, important fundamental discoveries have been made and basic investigative work on microorganisms is continuing.

Supplementing this expanded activity, a research and teaching program in agricultural microbiology has been continued in Cook College, which is the successor name for the Rutgers University Agricultural College. Present in that college is a museum devoted to the development of the science of soil microbiology. It celebrates the organization in 1901 of a specialized Department of Soil Microbiology, the first such university department organized in the USA. Special

emphasis in the museum is given to Selman A. Waksman's creative leadership and to the honors accorded, including award of a Nobel Prize in 1952.

To honor Selman Waksman, in 1973 the name of the Institute for Microbiology at Rutgers University was changed to the Waksman Institute for Microbiology. For Selman A. Waksman, a dedicated research scientist for more than 50 years, and this author's mentor during the period when the first Rutgers antibiotics were discovered, the honor provided by the revised Institute name assures permanent recognition for his creative leadership in the field of soil microbiology.

Introduction

The land application of human wastes has been practiced for centuries. The benefit of the nutrients provided in these wastes has been recognized as a major benefit in crop production. However, because of the presence of pathogenic organisms in such wastes, the use of untreated wastes is no longer practiced in developed countries. The main objectives of land application of wastewater today are further effluent treatment, groundwater recharge, and provision of nutrients for agricultural crops. Land treatment is defined as the controlled application of wastewater onto the land surface to achieve a planned degree of treatment through natural physical, chemical, and biological processes within the plant–soil–water matrix. During land treatment of wastewater effluents, biological and chemical pollutants are removed by physical (settling, filtration), chemical (adsorption, precipitation), and biological (e.g., plant uptake, microbial transformation) processes.

Land-treatment systems are capable of reducing the levels of pathogenic microorganisms, biochemical oxygen demand (BOD), suspended solids, nutrients (nitrogen and phosphorus), toxic metals, and trace organics. Suspended solids are removed by filtration and sedimentation. Soluble organics are removed by microbial action in the soil. Nitrogen is removed by sedimentation-filtration (e.g., particle-associated organic nitrogen), adsorption to soil, volatilization (e.g., NH_4), uptake by crops, and biological denitrification. Phosphorus is removed by adsorption to soil particles, chemical precipitation, and uptake by vegetation.

There are three major land-treatment processes: slow rate, rapid infiltration, and overland flow. A comparison of the design features of these land-treatment

Table 1 General characteristics of the three methods used for land application of sewage effluent

	Application method		
Factor	*Low-rate irrigation*	*Overland flow*	*High-rate infiltration*
Main objectives	Reuse of nutrients and water Wastewater treatment	Wastewater treatment	Wastewater treatment Groundwater recharge
Soil permeability	Moderate (sandy to clay soils)	Slow (clay soils)	Rapid (sandy soils)
Need for vegetation	Required	Required	Optional
Loading rate	1.3–10 cm week^{-1}	5–14 cm week^{-1}	>50 cm
Application technique	Spray, surface	Usually spray	Surface flooding
Land required for flow of 10^6 l day^{-1}	8–66 hectares	5–16 ha	0.25–7 ha
Required depth to groundwater	Approx. 2 m	Undetermined	5 m or more
BOD and suspended solid removal	90–99%	90–99%	90–99%
N removal	85–90%	70–90%	0–80%
P removal	80–90%	50–60%	75–90%

processes is shown in Table 1 and Figure 1. Expected removals of BOD, nitrogen, and phosphorus are also shown in Table 1.

In recent years, rapid-infiltration and slow-rate systems have been studied most. Rapid-infiltration systems are seen as important in the recharge of drinking-water aquifers, and slow-rate systems as a means of crop production in the arid regions of the world. Because of the potential impact of contaminants on underground drinking-water supplies, the fate of trace organics and pathogens have received increasing attention where rapid infiltration is used to supplement groundwater supplies. Because of the transport of food crops around the world today, the fate of pathogens in slow-rate systems has also received more attention.

Types of Land-Treatment Processes

Slow-Rate Process

Slow-rate irrigation systems are the most frequently used land-treatment system. There are approximately 1200 systems in the USA. Slow-rate land treatment is the application of wastewater to a vegetated land surface, with the applied wastewater being treated as it flows through the plant–soil matrix. Some of the flow percolates to the groundwater and some is used by the vegetation. Off-site surface runoff of the applied wastewater is generally avoided in the design. Nitrogen is often the limiting factor in these systems because of strict standards for levels of nitrate in drinking water. In arid lands, salts at acceptable levels for crop production may be limiting. Usually sandy loams or clay loams are the preferred soil type.

In slow-rate systems, the soil can be as shallow as 0.3 m for grass crops, but 1.5 m is preferred for complete wastewater treatment. Retention of contaminants is a function of residence time of the wastewater in the soil and the degree of contact with the soil colloids.

BOD in most slow-rate treatment systems is applied at rates of less than 11 kg ha^{-1} day^{-1}, which is

an order of magnitude lower than the capacity of the soil. High-strength food-processing wastewater systems are loaded as high as $9500\,kg\,ha^{-1}\,day^{-1}$. The BOD reductions in most systems exceed 98%. Filtration through the soil results in removal of 99% or more of total suspended solids.

Nitrogen removal is achieved using a nitrogen balance that matches the expected removal plus a percolate nitrate nitrogen of less than $10\,mg\,l^{-1}$, which is the drinking-water standard in the USA. Slow-rate systems use forage crops to remove much of the applied nitrogen. To achieve the nitrogen uptake rates expected for the crop, excess nitrogen must be applied so that the crop can compete effectively with soil microorganisms for the available nitrogen. Biological nitrogen removal occurs by nitrification–denitrification. The loss due to denitrification depends on the BOD-to-N ratio and the soil temperature, pH, and moisture. Intermittent application, which is characteristic of slow-rate systems, serves to enhance nitrification followed by denitrification. Ammonia volatilization losses of 10% can be expected if the soil pH is greater than 7.8 and the cation exchange capacity is low (low absorption of ammonium by the soil). For soils with less than 2% organic matter, nitrogen storage in the soil can be a significant loss for the first 3–4 years of operation of the system. Eventually, equilibrium is reached and the net storage of nitrogen stops.

Phosphorus removal has been found to be generally around 98–99%. Removal is by formation of insoluble phosphates with metals at the soil surface.

The concern with pathogens in slow-rate systems is related to their potential for reaching the groundwater, contamination of adjacent surface waters, and contamination of the crop. The low rate of wastewater application usually limits the potential for groundwater contamination, and contamination of surface waters can be controlled by proper management and site selection. However, enteric viruses have been detected in groundwater beneath slow-rate systems when high rates of wastewater are applied to areas with high water tables. Food-crop contamination with pathogens easily occurs during furrow irrigation, but can be limited by drip irrigation and covering the soil surface with plastic sheeting.

Rapid-Infiltration Process

In rapid infiltration, most of the applied wastewater percolates through the soil and the treated effluent percolates through to the groundwater, where it may be collected in recovery wells for drinking water or irrigation. The wastewater is applied intermittently at high loading rates ($6–125\,m\,year^{-1}$) onto a permeable soil (e.g., sands or loamy sands). Application is usually in basins and vegetation is usually not planted. Recovery wells may be used to reclaim the treated water for irrigation or as a drinking-water source. The treatment potential of rapid-infiltration systems is lower than in slow-rate systems. Removal of nitrogen is generally low but may be enhanced by encouraging denitrification. Denitrification requires adequate carbon (as found in primary wastewater effluents) and low oxygen levels, necessitating flooding periods as long as 9 days, followed by drying periods of approximately 2 weeks. Climate and season will affect the intervals of flooding and drying due to their influence on microbial activity.

Typical BOD loadings for rapid-infiltration systems using municipal wastewater range from 27 to $175\,kg\,ha^{-1}\,day^{-1}$ with removals ranging from 74 to 96%. BOD loadings of industrial systems range from 112 to $676\,kg\,ha^{-1}\,day^{-1}$. Suspended-solids loadings of $112–224\,kg\,ha^{-1}\,day^{-1}$ or more require more frequent disking or scarifying of the infiltration basin surface to avoid plugging of the soil.

Nitrification–denitrification is the principal mechanism of ammonia and nitrogen removal from wastewater in rapid-infiltration systems. Ammonia adsorption also plays an important role in retaining ammonia in the soil long enough for biological conversion. Nitrification and denitrification are affected by temperature and the amount of organic carbon available. It has been found that nitrification rates of up to $67\,kg\,ha^{-1}\,day^{-1}$ can be achieved under favorable moisture and temperature conditions. Nitrogen removal is a function of detention time, BOD-to-N ratio, and anoxic conditions. Detention time is related to hydraulic loading rates through the soil profile. For effective nitrogen removal (80% or more), the loading rate should not exceed 3–4 cm. The BOD-to-N ratio needs to be 3:1 or more to ensure adequate carbon to drive the denitrification reaction. Secondary wastewater effluent will have a BOD-to-N ratio of approximately 1:1, while primary effluent usually has a BOD-to-N ratio of 3:1. To overcome the low BOD-to-N ratio in secondary effluent, a longer period of application (7–9 days) is necessary. Typical removal of total nitrogen ranges from 38 to 93%.

Phosphorus removal is accomplished by adsorption and chemical precipitation. The adsorption occurs quickly and the chemical precipitation occurs more slowly; removal typically ranges from 40 to 97%.

Removal of bacteria, helminths, and protozoan parasites is largely accomplished by filtration. Almost all are removed within a meter of the soil surface under unsaturated conditions. Virus removal is dependent upon adsorption to the soil surface; viruses have the potential to travel long distances under the

right conditions (50 m or more). The depth of the unsaturated or vadose zone is important in the degree of removal of viruses before the wastewater reaches the aquifer. Expected removals of virus should be 99% or more.

Overland-Flow Process

In overland-flow treatment, wastewater is applied at the upper reaches of grass-covered slopes of 2–10% grade and allowed to flow over the vegetated surface to runoff collection ditches. Typical slopes are 2–4% in grade and 36–45 m long. The overland-flow process is best suited to sites having relatively impermeable soils. The most suitable soils are clay or clay-loamy soils with a permeability equal to or less than $0.5\,cm\,h^{-1}$. About 50 overland-flow systems have been built in the USA. The wastewater is treated by a thin biofilm and plants as it flows down the slope. Removal of nitrogen is due to nitrification followed by denitrification, and uptake by the grass or other plants. Phosphorus removal is via adsorption and precipitation.

In municipal systems, the BOD loading rate typically ranges from 12.3 to $4\,kg\,ha^{-1}$. Biological oxidation accounts for the 90–95% removal of BOD normally found in overland-flow systems. A typical BOD concentration in treated runoff water is approximately $10\,mg\,l^{-1}$. Overland flow is effective in removing most suspended solids, with effluent total suspended solids between 10 and $15\,mg\,l^{-1}$.

The removal of nitrogen depends on nitrification–denitrification and the crop uptake of nitrogen. Denitrification can account for 60–90% of the nitrogen removed, with denitrification rates of $160\,kg\,ha^{-1}$. Phosphorus removal in overland-flow systems is limited to approximately 40–50% because of the lack of soil–wastewater contact.

Overland flow is not very effective in removing microorganisms. Fecal coliforms can be reduced by approximately 90% when raw or primary effluent is applied; however, minimal removal occurs when secondary effluents are applied. Enteric virus removals of up to 85% have been observed with overland flow.

Treatment Mechanisms

In the land application of wastewater, the soil is used as a treatment medium. Some substances pass through the soil and into the groundwater, some are utilized by growing plants, while others are retained almost indefinitely within the soil. Proper design of land-application facilities must relate the fate of pollutants to the properties of soil with which they may interact and minimize the fraction of contaminants passing through to groundwater. There are several separate-unit processes that can be adopted for removal of suspended solids, total dissolved solids, biochemical oxygen demand, nitrogen, phosphorus, and toxic substances. Waste-treatment mechanisms that occur in soils can conveniently be categorized as physical, chemical, and biological. Within each category, various processes act to remove or alter specific pollutants.

Filtration

As wastewater moves into and through soil pores, suspended solids are removed by mechanical filtration. The actual depth at which removal occurs varies with the size of suspended particles, soil texture, and the rate of application. The larger the hydraulic loading rate and the coarser the soil, the greater the distance required. However, when loading rates are such that much of the applied water is held in the soil, additional removal can occur as suspended materials settle or adhere to the surfaces of the soil particles. Some organic particles and some organisms such as worms and protozoa are large enough so that removal by simple blockage occurs. Both bacteria and viruses, however, are small enough that they can move through the soil pores. While filtration in the soil matrix limits the movement of most bacteria to a meter or less, viruses are too small to be affected, and filtration is not believed to play a significant role in their removal. In practice an organic mat or 'Schmutsdecke' forms at the soil surface, enhancing the removal of particulates. Suspended matter can evidently clog soil pores and thereby severely reduce the infiltration rate. In rapid-infiltration operations, flooding and drying cycles help restore infiltration rates. During flooding the infiltration rate is reduced over time. Drying of the Scmutszdecke results in its cracking and removal during the next infiltration event.

Adsorption and Precipitation

Chemical reactions among dissolved ions or compounds and interactions with the soil solid-phase alter the mobility of waste pollutants. Some dissolved constituents are retained within the profile indefinitely, while the movement of others is only temporarily restricted or unaffected. Two processes, adsorption and precipitation, account for most of the retention. Adsorption refers to the net effect of interactions between dissolved and particulate (i.e., viruses) matter of the soil and humus particles. Precipitation is the formation of an insoluble form of a substance that was originally in solution. Ion exchange is one type

of adsorption process. Anion exchange is of very minor importance in land-application systems. Phosphorus is the only anion appreciably retained in soils, though the primary mechanism is not anion exchange. The predominant ion exchange reactions in most soils in the USA involve cations and are related to the cation exchange capacity. In wastewater-treatment systems, the retention of dissolved cations depends largely on their concentration in solution entering the soil. Large concentrations overcome a higher degree of attraction of other cations toward the soil matrix. Many of the heavy metal cations such as zinc, copper, nickel, cadmium, mercury, lead, and chromium are present in wastewater at concentrations too low to be appreciably affected by cation exchange reactions. These cations seem to be incorporated into the soil solid-phase in a nonexchangeable form.

Chemical Reactions

Phosphorus and nitrogen are at least partially controlled by chemical mechanisms in the soil. The most important chemical mechanism for nitrogen removal is the reaction of positively charged ammonium ions with the soil cation-exchange complex.

Volatilization

Volatilization refers to the evaporation of chemical vapor from soil or water and its subsequent loss to the atmosphere. Many organic compounds are volatile in water, as are some nitrogen compounds (e.g., ammonia, nitrous oxide) generated from biological transformations. In addition, some inorganic chemicals (e.g., selenium compounds) may be rendered volatile through biological reactions. For a given chemical, the extent of volatilization is very dependent on the soil and atmospheric conditions. In general, volatilization is greatly reduced in soil compared with water, because the soil solid-phase retains the chemical mass, thereby reducing its vapor pressure. In addition, the soil can offer substantial resistance to the transport of the chemical from the soil profile to the surface, particularly if the soil is wet and little upward flow of water is occurring. In rapid-infiltration processes where the wastewater is ponded over the surface for prolonged periods of time, the primary route of volatilization loss is from the surface of the standing water. During the drainage cycle, when the soil becomes unsaturated, volatile constituents in solution near the surface can evaporate and escape to the atmosphere.

Ammonia present in wastewater is very volatile and vaporizes from the anhydrous form immediately upon exposure to air. Nitrite may be transformed anaerobically by biological denitrification to several gas species (primarily N_2O and N_2) when soil-water content is high and a source of organic carbon is present.

Biological Mechanisms

Soil microorganisms alter the waste constituents through organic matter decomposition, inorganic transformations, and nutrient assimilation. These processes are largely restricted to the upper meter of soil. The ability of soil microorganisms to decompose organic matter is a function of their population complexity. The diversity of microorganisms enhances the capability of soil to degrade a wide variety of organic substances; some prey on pathogenic bacteria and reduce the survival of viruses. The rate at which organic matter decomposition occurs and the exact nature of the intermediate and end products depend in part on the composition of the added organic matter in the wastewater. Soil factors, however, exert considerable control as well. The presence or absence of oxygen, more than any other single factor, determines the rate and end products. The oxygen status of the soil is a function of soil porosity, and properties that favor rapid transmission of water also favor oxygen movement unless the soil is completely saturated.

Decomposition proceeds most rapidly under aerobic conditions. Under aerobic conditions, up to 60% of the organic carbon may be respired by organisms as carbon dioxide in the initial stage of decomposition. Much of the rest is incorporated into microbial cells, and some of this is subsequently respired when the population declines. Through organic matter decomposition, nitrogen, phosphorus, sulfur, and a host of other trace elements are converted from organic to inorganic forms, i.e., mineralization. Many of the elements that are mineralized during organic matter decomposition are then subject to inorganic transformation in the soil and are assimilated by plants in overland-flow and irrigation-treatment systems. Vegetation thus functions as a sink where waste nutrients, most notably nitrogen and phosphorus, can be effectively immobilized. When harvested, vegetation plays an integral part in the renovation or 'treatment' of the applied wastewater.

Fate of Specific Contaminants

Metals and Trace Elements

Factors that affect the retention of trace elements by soils include soil texture, pH, soil organic matter, and contents of amorphous oxides of Fe, Al, and Mn. Most studies have a high capacity to attenuate the concentration of copper and lead. The retention of

other trace elements studied is best correlated with the clay content of free iron oxides of the soil. Capacities for attenuating the cationic elements (Cu, Pb, Be, Zn, Cd, Ni, and Hg) in soils tends to increase with their clay and iron oxide contents. For the anionic trace elements (SeO_3, VO_3, AsO_4, CrO_4), retention in the soil also increases with increasing clay and iron oxide content of the soils. In general, the solubility of the cationic trace-element species increases as the pH of the soil decreases. By contrast, the solubilities of anionic trace-element species in the soil tend to increase as the pH of the soil increases.

Metals and trace elements may be removed by a number of mechanisms during land application of wastewater. Those associated with suspended matter are retained at or near the soil surface. In rapid-infiltration systems, they accumulate in the colloid material in the surface-clogging layer, which eventually must be removed to restore infiltration. Smaller suspended particulates that can move through soil pores without becoming trapped are also attenuated by sorption to mineral surfaces in the soil matrix. For dissolved elements, ion exchange, precipitation, surface adsorption, and complexing with organic compounds are important. The principal mechanisms that immobilize dissolved trace elements in the wastewater within the soil appear to be absorption and precipitation. Most soils appear to have a high capacity to remove trace elements during land treatment of wastewater. The amounts of trace elements removed by crops are small compared with the amounts applied to the soils though application of wastewater (Table 2).

Because soil sorption may be finite for most trace elements, there may be long-term accumulation of metals in the soil. Groundwater concentrations of silver, barium, cadmium, cobalt, and chromium below the rapid-infiltration site at Hollister, California, have been unaffected by the additions of wastewater to the overlaying soil. However, manganese, nickel, iron, zinc, lead, and copper are above background levels. Soil samples taken at the Whittier Narrows infiltration facility after more than 20 years of operation have shown elevated levels of cadmium, chromium, copper, nickel, lead, and zinc in the top 60 cm, but not below that depth, suggesting that the soil has the capacity to remove metals for many more years of operation before groundwater is affected.

Organic Compounds

Organic compounds vary greatly in their mobility, volatility, and persistence in soil. In land-application systems, volatile compounds volatilize prior to application, and only soluble organic compounds enter the soil. The fate of the soluble compound depends on the degree to which it is chemically or biologically transformed during its passage through the system. Organic compounds degrade by hydrolysis, photodecomposition, or redox reactions. Microbial conversion occurs chiefly at or near the soil surface, where bacterial populations and organic carbon levels are high. Low organic carbon levels limit microbial action in the deeper regions of the vadose zone during treatment in rapid-infiltration systems. The travel time of an organic compound may be roughly estimated by its retardation factor in a given soil. The overall action of the chemical and microbiological processes transforming an organic compound moving through the soil may be crudely expressed as the half-life or degradation rate constant. The length of the half-life compared with the travel time can be used as an index of the potential for the compound to survive its contact and passage through the soil.

The dissolved organic carbon (DOC) in domestic, secondary-treated wastewater during rapid infiltration is reduced by 50% after passage of a few meters through the soil. DOC is primarily removed by microbial action during passage through the soil, with more than half being removed during passage through the top 8 cm of soil. With long residence

Table 2 Expected trace element removal by vegetation from wastewater-irrigated soils

times in the soil, aquifer DOC is reduced to 1 mg l^{-1} after 12–24 months.

Disinfection By-products

In most cases, wastewater is disinfected before land application with chlorine, chloramine, ozone, or ultraviolet light. In the case of chemical oxidizers, this results in the formation of disinfection by-products which may potentially be harmful to human health. Some of these compounds are listed in Table 3 along with their probable fate during land application of wastewater. In addition to known disinfection by-products, residual halogen is present when chlorine is used. This material may then appear as adsorbable organic halogen (AOX). Sorption processes do not play a significant role in their removal. Under anoxic conditions removal is probably based on co-metabolism and is related to the DOC that is needed as a substrate. Ozone disinfection of wastewater improves the biodegradability of refractory organic compounds and co-substrate concentration for AOX co-metabolism in soil columns. AOX removal in 1-m soil columns to which secondary effluent is applied averages 30%.

Endocrine Disruptors

Many endocrine-disrupting compounds are present in wastewater at trace quantities (i.e., estrogens, pesticides, polychlorinated biphenyls, phthalates, pharmaceuticals). Estrogens are probably the largest contributors to the endocrine-disruption activity in domestic wastewater, since daily urination adds estrogen to household wastewater. Humans are known to excrete between 10 000 and 100 000 ng l^{-1} of 17beta-estradiol per day. Synthetic estrogens such as 17alpha-ethinyl estradiol have been detected in wastewater and in surface waters affected by effluent discharge. Measurements of endocrine-disrupting compounds displaced by a fluorescent estrogen assay or cell proliferation assay have shown the reduction of endocrine disruptors during rapid infiltration. By cell proliferation assay, the estradiol equivalent value of 71 ng l^{-1} was found to be reduced to 13.7 ng l^{-1} after passage of 63 m through the vadose zone. The equivalent 17beta-estradiol activity measured by a binding assay was reduced by 97% after travel through the vadose zone to reach the aquifer. Since the study site had been in operation for more than 10 years, it seems unlikely that endocrine disruptors would ever break through the vadose zone.

Pharmaceuticals

There has been increasing concern about the fate of micropollutants originating from pharmaceuticals and active ingredients in personal-care products (e.g., soaps, deodorants) that are introduced into domestic wastewater. There is evidence that substances of pharmaceutical origin are not completely eliminated during wastewater treatment or biodegraded in the environment. At two rapid-infiltration sites in Arizona, neither ibuprofen nor naproxen or any other acidic drug were detected in groundwater wells downgradient of the infiltration basins (Table 4). These results indicate a high potential for degradation of anti-inflammatory and lipid-regulator drugs. However, antiepileptic, carbamazepine, and primidone drugs have been detected in all of the wells, suggesting that they are able to persist in soil-treatment systems.

Microorganisms

From the standpoint of acute diseases, microbial contaminants are of greatest concern during the land application of wastewater. Microorganisms are responsible for more than 90% of all waterborne outbreaks reported each year in the USA. Hundreds of different types of pathogenic microorganisms (i.e., bacteria, viruses, protozoa, helminths) are excreted in fecal material of infected hosts and these can find their way into municipal wastewater. The number of types of pathogenic microorganisms present in wastewater varies by location and over time at a given location. A variety of factors influence pathogen content of wastewater, including the incidence of the disease in the population, the season of the year, the economic status of the population, and water-use patterns. Diseases caused by waterborne organisms range from mild gastroenteritis to severe and life-threatening illness such as hepatitis, cholera, typhoid, paralysis, meningitis, heart disease, etc. New enteric pathogens are discovered almost yearly and the significance of new ones changes over time. *Cyclospora*

Table 4 Fate of pharmaceuticals after rapid infiltration

Use/origin	*Compound*	*Secondary-treated wastewater (mg l^{-1})*	*Detection in groundwater (ng l^{-1})*
Lipid regulator	Gemfibrozil	1235	Not detected
Antiepileptic	Carbamazepine	Not detected	455
	Primidone	110	115
Analgesic/anti-inflammatory	Ibuprofen	3380	Not detected
	Naproxen	6280	20
	Fenoprofen	35	Not detected
	Propyphenazone	20	15

and TT hepatitis virus are examples of new pathogens that have been recognized only recently, and the significance of caliciviruses (Norovirus) as a major cause of food-borne illness has only recently been recognized.

During land application of wastewater, pathogens are removed from the system by a combination of die-off (inactivation in the case of viruses) and physical filtration or adsorption by the soil or plant material. Pathogen removal by overland flow systems has been little-studied, but it is not expected to result in large reductions of enteric bacteria or viruses. Irrigation systems and rapid-infiltration systems have been studied more because of the potential for crop and aquifer contamination.

Transmission of food-borne illness by enteric pathogens due to irrigation with untreated wastewater has been well-established for more than 100 years. For this reason, irrigation with untreated wastewater for food, crops is usually forbidden. Wastewater to be used for food crop production should meet the same standards as drinking water and be intensely monitored. Thus almost all irrigation with wastewater is for the production of nonfood crops or fruit crops. However, recent outbreaks of disease associated with apples and raspberries caused by the parasites *Cryptosporidium* and *Cyclospora* suggest that only wastewater treated to potable standards should be used in any food crop production.

Factors controlling the survival of pathogens are shown in Table 5. Table 6 shows the range of reported survival times of selected enteric pathogens in the environment. Temperature is probably the most important factor controlling persistence of pathogens on plant material and soil. The die-off of pathogens increases as the temperature increases; however, under proper conditions (high humidity), some growth of bacterial pathogens may occur on the plants in the field. Rotavirus and enteroviruses appear to be inactivated very rapidly on irrigated grass under the conditions found in the arid southwestern USA. Poliovirus type one is inactivated at a rate of $0.06\,\log_{10}\,h^{-1}$ and rotavirus SA-11 at $0.04\,\log_{10}\,h^{-1}$ during the winter (4–10°C) in Arizona (USA). The rates of die-off during the summer are $0.37\,\log_{10}\,h^{-1}$ and $0.2\,\log_{10}\,h^{-1}$. It would appear that 8–10 h is needed during the summer and 16–24 h during the winter before inactivation of these viruses. *Salmonella* and other enteric bacteria can survive for several weeks on grass if sufficient organic matter and moisture is available. Helminth eggs such as *Ascaris* are

Table 5 Factors influencing enteric pathogen survival in soils

Factor	*Comments*
Temperature	Lower temperatures promote increased survival
Moisture content	Survival is decreased in drying soils. Increases may result in bacterial growth
pH	Survival is decreased pH extremes
Soil type	Survival influenced by chemical, textural, and mineralogical properties such as pH, exchangeable ion content, and water-retention capacity
Organic matter	Survival enhanced and growth of bacteria possible
Soil microflora	Survival is decreased in nonsterile soil
Salt species and concentration	Cationic type and ionic strength may influence survival
Soil surfaces	Survival may be enhanced by adsorption to soil particles
Saturation	Air–water interface under unsaturated conditions may enhance viral inactivation

Table 6 Survival of pathogens in soils

Organism	*Survival time (days)*
Coliforms	38
Fecal streptococci	26–77
Salmonellae	15–90
Salmonella typhi	1–120
Entamoeba histolytica cysts	6–8
Enteroviruses	8–175
Ascaris ova	Up to 2 years

believed to survive for 30–60 days, although they may survive many months in the soil itself.

Temperature also significantly influences the survival of enteric pathogens in soil. Poliovirus persists for 8 days in saturated sand and sandy loam soils at 4°C, whereas more than 175 days are required at 8°C. Survival of bacteria in soils is also favored by cold temperatures. However, freeze–thawing increases mortality of enteric bacteria and protozoa. *Cryptosporidium* may persist in soils for several weeks, although its survival time is reduced at temperatures above 35°C and if multiple freeze–thaw cycles in the soil take place. Extreme acidic or alkaline conditions (pH <6.0 or >8.0) tend to adversely affect the survival of both enteric bacteria and viruses in soil. Greater moisture also enhances survival of most enteric organisms in soil as does greater concentrations of organic matter in the wastewater.

Transport of microorganisms through the soil is influenced by many of the same factors that affect survival of microorganisms (Table 7). Because of their large size, bacteria, protozoan parasites, and helminths are usually removed within a meter or less of the soil surface. Because of their small size (20–200 nm), viruses have the potential to travel the greatest distances through soil. Removal largely occurs by adsorption to the soil surface and is influenced by the surface properties of the virus and soil. Electrostatic and hydrophobic interactions control the degree of adsorption. Transport is favored in sandy soils with a low clay content. Adsorption largely occurs near the soil surface because of the presence of iron oxides to which the negatively charged viruses readily adsorb. Transport is more limited under unsaturated conditions and at pH levels greater than 8.0. Organic matter in wastewater reduces adsorption because of competition for adsorption sites on the soil surface.

Table 7 Factors influencing microbial transport

Factor	*Comments*
Size of microorganism	Transport of bacteria and parasites is limited because of size in most agricultural soils
Adsorption	Major factor in limiting virus transport through soils. Also plays a role in bacterial transport
pH	Lower pH enhances adsorption
Salt species and concentration	Increased cation valency and ion concentration increase retention; low ionic strength promotes desorption and transport
Organic matter	Some organics (e.g., humic and fulvic acids) interfere with adsorption and cause desorption
Metal oxides	Virus adsorption to iron oxides occurs readily in soils
Hydraulic conditions and moisture content	Increase flow rates and saturated flow decrease adsorption

Introduction

Waste materials are produced by all societies. The nature of waste and the quantities requiring management vary according to both geographic and historical factors, largely because the definition of waste is governed by both political and economic considerations. Given that at the present time it is required that waste is managed to minimize possible pollution of water resources (drinking water and fisheries and/or recreation) and the atmosphere, disposal to land is the dominant procedure used in North America and Europe for the disposal of the residues left after recovery of potentially useful materials and energy. In other parts of the world, disposal to land is widespread, depending on local political, economic, and environmental factors.

The artificial process of disposal to land by landfill, land-raising, or land-spreading produces accumulations that may be as much as 30 m thick of organic matter derived from plants and animals, mineral matter (including glass), metals, and plastics. Once deposited, these materials are subjected to natural processes of decomposition, and in good practice the site is restored to a new use, through appropriate capping and revegetation. Disposal to land thus generates an artificial 'soil' profile that can affect root systems and that influences pore water and gas compositions in the unsaturated and saturated zones. To understand the consequences of land disposal on soil systems, in the broadest sense, it is necessary to understand the chemical processes that take place within landfill and how they change with time.

Municipal solid waste (MSW) is waste generated by urban populations and collected for disposal by municipal authorities. It is typically composed of putrescible waste from food production, distribution, and consumption, together with discarded consumer goods, packaging, and papers. It differs from industrial wastes that are specific to particular factories or processes and so have a focused impact requiring attention on a case-by-case basis. It differs from mine waste and demolition wastes, which are 'inert' through their lack of putrescible material (although important because of, for example, reactions involving sulfides or sulfates).

The amounts of MSW generated by the UK, the USA, and Japan are summarized in Table 1. This shows variation in the relative proportions of key waste types. Japan has little land available for landfill disposal, whereas land is abundant in the USA. Like all European countries, the UK has a very tightly regulated waste management system, coupled with shortage of land close to urban centers where there is considerable popular opposition to waste incineration.

MSW Composition and Degradation

The composition of municipal solid waste (Figure 1) is dominated by paper (33%) and putrescible waste (20%). Putrescible waste includes raw and cooked

Table 1 Amounts of waste produced annually in the USA, UK, and Japan, and relative proportions of methods of disposal (1995)

	USA	*UK*	*Japan*
Household waste (t year^{-1})	210	20	50
Landfill (%)	63	90	20
Incinerated (%)	16	5	75
Recycled/reused (%)	17	5	5

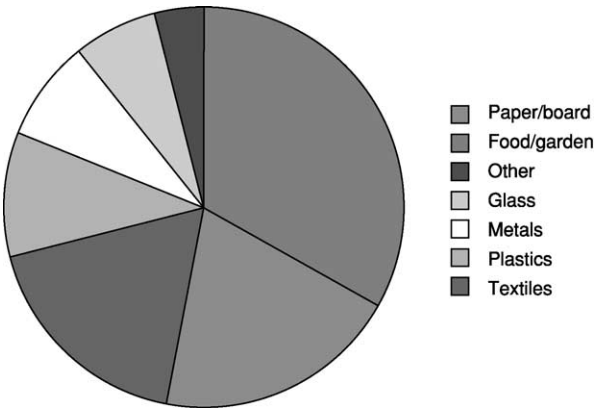

Figure 1 Approximate composition (percentage weight) of municipal solid waste (UK, 1992). (Data from Williams PT (1998) *Waste Disposal and Treatment*. Chichester, UK: John Wiley & Sons, Ltd.)

food waste and waste from domestic gardens or yards. It is composed of fats, carbohydrates and proteins, all of which decompose readily through microbial-mediated putrefaction. Paper waste is dominated by cellulose, with a significant mineral component (up to 25%) through the use of kaolin and calcite as paper-coating and -filling agents. Compared with putrescible waste, paper is relatively inert within a landfill and may not degrade for many years.

Within a landfill, waste is deposited ideally under dry conditions and is rapidly compacted and buried beneath a daily cover (often a local clay or an inert waste stream). Anaerobic conditions become established rapidly, and microbial degradation is dominated by communities of anaerobic bacteria. Although moisture ingress is minimized as far as possible, the inherent moisture content of the waste and some input from rainfall is sufficient to produce a liquid, 'landfill leachate,' that drains to the bottom of the waste pile. At the same time, microbial reactions within the leachate and on surfaces within the waste produce methane gas, which rises through the waste pile. Landfill management revolves around the control of both leachate and gas, to prevent harm that might arise from their escape, and to recover energy from landfill gas.

Typically, landfill gas is composed of approximately 66% methane and 34% carbon dioxide, with varying proportions of other gas species (Table 2). This 'end-member' composition is diluted with nitrogen from the atmosphere (oxygen having been consumed prior to the onset of anaerobic conditions). Reported landfill gas compositions may contain oxygen due to ingress of air to the sample prior to analysis. High levels of hydrogen sulfide are unusual, but may arise in circumstances where a site has received gypsum waste (especially plaster-based building products) or other sulfate-bearing industrial waste.

Landfill leachate composition varies according to the age of a landfill and the types of waste that have been deposited within it. Typical compositions are given in Table 3. The dominant cationic species

Table 2 Typical composition of landfill gas

Component	*Typical value (vol %)*	*Observed maximum (vol %)*
Methane	63.8	88.0

are ammonium, Na, K, Mg, Ca, and Fe. The dominant anionic species include chloride, bicarbonate, and organic acid anions. Leachates differ from surface waters and from most natural shallow groundwaters in having high ammonium and organic acid anion contents, sometimes as the dominant cation or anion, respectively.

Variation in landfill gas and leachate composition with time is shown in Figure 2. Atmospheric oxygen is consumed rapidly, and anaerobic conditions lead initially to the formation of hydrogen (during acetogenesis, which is the stage when ethanoate (acetate) is a dominant product of decomposition) and then methane (methanogenesis; which is the stage when methane is the dominant product of decomposition). Gas production peaks and then declines over periods of months to years (depending on local conditions). Over a similar period, leachate composition shows a major change as acetogenic conditions are replaced by methanogenesis. As organic acid anions are consumed quantitatively by microbial communities that produce methane, inorganic solutes also reduce to very low levels. Ammonium is not affected greatly by this change, remaining at 100- to 1000-mg l^{-1} levels.

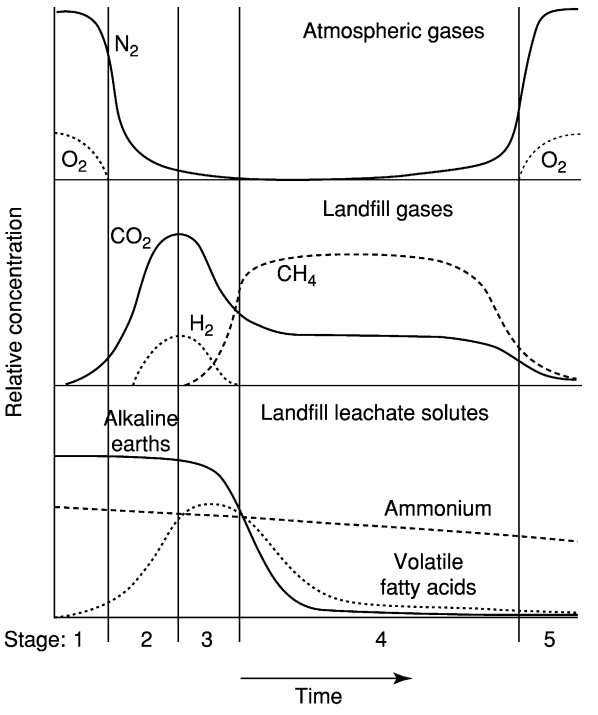

Figure 2 Changes with time in (a) atmospheric gases, (b) landfill gas, and (c) leachate composition (expressed relative to chloride). Stages 1 and 5 are dominated by aerobic conditions. Stages 2, 3, and 4 are anaerobic acidogenesis, acetogenesis, and methanogenesis, respectively. (Adapted from Rees JF (1980) The fate of organic compounds in the landfill disposal of organic matter. *Journal of Chemical Technology and Biotechnology* 30: 161–175; Robinson HD (1995) *A Review of the Composition of Leachates from Domestic Wastes in Landfill Sites*. Report CWM/072/95. Department of the Environment. London, UK: The Stationery Office.)

Microbial Reactions and Waste Degradation

The decomposition of the constituents of the putrescible fraction (proteins, lipids, and carbohydrates) is summarized in Figure 3. Initially, relative molecular masses are reduced through aerobic hydrolysis and anaerobic fermentation reactions that reduce chain length largely without destroying the characteristic functional groups, and that produce intermediate products that are readily water-soluble. Thus proteins degrade to give amino acids, carbohydrates yield simple sugars, and lipids form glycerol and long-chain fatty acids.

During the acetogenic stage, acetate is produced as an end-member of the degradation of amino acids (which also yield the ammonium ion) and long-chain fatty acids. The microbial communities responsible for the degradation of the fatty acids typically include two components in an obligate syntrophic relationship – one population oxidizes the volatile fatty acid anion, yielding hydrogen, and another reduces hydrogen or an inorganic species (sulfate, nitrate, or iron, all acting as electron donors). Examples of reactions known to occur for specific bacterial communities (e.g., *Syntrophobacter wolinii*

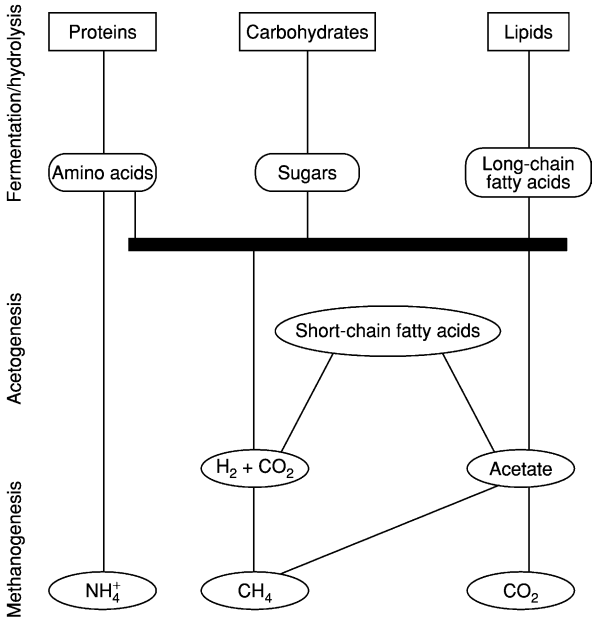

Figure 3 Schematic to summarize the decomposition of putrescible matter. (Adapted from Rees JF (1980) The fate of organic compounds in the landfill disposal of organic matter. *Journal of Chemical Technology and Biotechnology* 30: 161–175.)

Table 4 Examples of microbially mediated acetogenic reactions within landfill

	Microorganism	*Reaction*	ΔG_r^o *(kJ)*
Propionate-acetate	*Syntrophobacter wolinii*	$CH_3CH_2COO^- + 3H_2O = CH_3COO^- + H^+ + 3H_2 + HCO_3^-$	+76.1
Butanate-acetate	*Syntrophomonas wolfei*	$CH_3CH_2CH_2COO^- + 2H_2O = 2CH_3COO^- + H^+ + 2H_2$	+48.1
Sulfate reduction[a] *with oxidation of:*			
Hydrogen	*Desulfovibrio vulgaris*	$4H_2 + SO_4^{2-} + H^+ = 4H_2O + HS^-$	−152.2
Acetate	*Desulfobacter postgatei*	$CH_3COO^- + SO_4^{2-} = 2HCO_3^- + HS^-$	−47.6
Propionate	*Desulfobulbus* sp. or *S. wolinii* + *D. vulgaris*	$4CH_3CH_2COO^- + 3SO_4^{2-} = 4CH_3COO^- + 4HCO_3^- + 3HS^- + H^+$	−150.6
Methane	Species unknown in 1988; still controversial in 2003	$CH_4 + SO_4^{2-} = HCO_3^- + HS^- + H_2O$	−16.6

[a]Sulfate reducers can reduce nitrate to ammonium.

+ *Desulfovibrio vulgaris*) are summarized in Table 4. The 1:1 relationship for acetate and propionate that is observed in landfill leachates (Figure 4) appears to be characteristic of anaerobic systems of this type, as it is also observed for sedimentary waters (oil-field waters).

During the methanogenic stage, methane is produced in two ways once sulfate, nitrate, and iron in solution have been exhausted. First, decomposition of acetate in solution is facilitated by acetoclastic bacterial communities (e.g., *Methanosarcina barkeri*, *Methanosarcina mazei*, *Methanothrix soehngenii*). Secondly, methanogenic bacteria produce methane directly from hydrogen and carbon dioxide (or bicarbonate):

- General reaction (all methanogens except acetoclasts; syntrophic):

$$4H_2 + HCO_3^- + H^+ = CH_4 + 3H_2O$$
$$\Delta G_r^o = -135.6\,\text{kJ};$$

- Acetoclastic methanogenesis (*Methanosarcina barkeri*, *Methanosarcina mazei*, *Methanothrix soehngenii*):

$$CH_3COO^- + H_2O = CH_4 + HCO_3^-$$
$$\Delta G_r^o = -31.0\,\text{kJ}.$$

In all landfill leachates, the nature of the microbial community will be complex and variable in time as well as spatially. The production of methane is rarely homogeneously distributed throughout a landfill site, partly as a consequence of leachate-management procedures that mix leachates of different ages in separate parts of a landfill site.

Mineralogical Reactions Within Waste

The changes in the inorganic solute constituents of landfill leachates that are observed relate directly to mineralogical reactions that take place within the waste. These reactions can be predicted through use of the technique of geochemical modeling of landfill leachate compositions, in which a chemical analysis is recalculated to give thermodynamic concentrations of dissolved species, and then this information is used to calculate saturation indices (SI) for selected minerals. Those mineral species that have $SI > 0$ are predicted to precipitate, and those with $SI < 0$ are predicted to dissolve. Evidence that predicted mineral precipitation reactions take place can be obtained by determining the mineralogical composition of the suspended solids within leachate, or of scale that forms within leachate drainage and pumping systems.

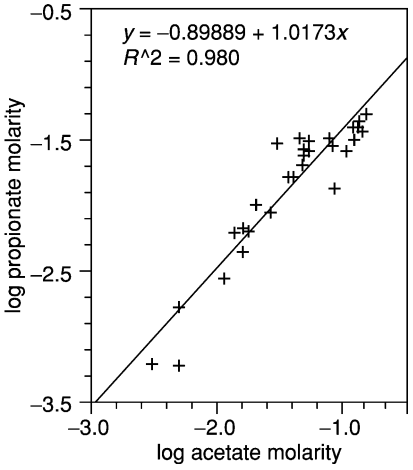

Figure 4 Relationship between acetate and propionate within landfill leachates. (Data from Manning DAC (1997) Acetate and propionate in landfill leachates: implications for the recognition of microbiological influences on the composition of waters in sedimentary systems. *Geology* 25: 279–281.)

Typically, landfill leachates have saturation indices for calcite and carbonate minerals that are greater than zero and so precipitation of calcite is predicted. Figure 5 shows the change in calcite SI with time, showing a general decrease with age. Also, calcite

saturation is observed over a wide range of pH values (Figure 6). Calcite precipitation is evident from the common observation that calcite forms scale within landfill leachate-management systems, and from the presence of calcite in a number of morphologies within leachate-suspended solids.

Silicate minerals typically show saturation indices greater than zero and so are predicted to precipitate. However, the ubiquitous presence of quartz and clays within waste- and landfill-containment systems means that newly precipitated silicate minerals cannot be recognized with confidence. Additionally, the very slow reaction kinetics of silicate mineral precipitation suggest that these minerals will not form within landfill systems under typical temperature conditions.

The recalculation of leachate compositions as activities allows mineralogical controls on leachate chemistry to be elucidated. Cation exchange reactions involving leachate and clay minerals clearly explain the distribution of K and ammonium in solution (Figure 7). Silica activities are tightly constrained to values consistent with a control by equilibrium between illitic and smectitic clays (Figure 8). These patterns are seen irrespective of the type of containment system used to hold the waste and instead relate

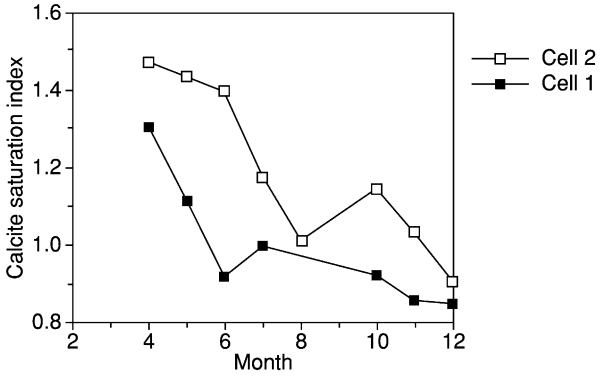

Figure 5 Variation in calcite saturation index calculated from leachate compositions for two landfill cells over time.

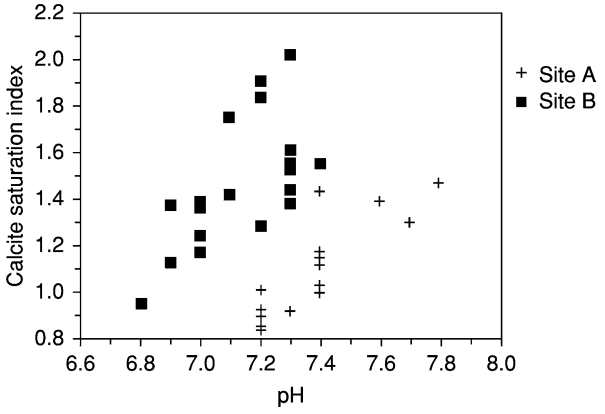

Figure 6 Variation in calcite saturation index calculated for leachate compositions with varying pH values.

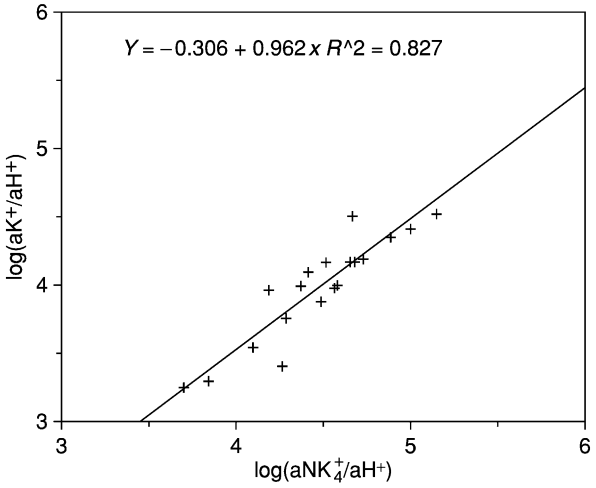

Figure 7 Ion activity diagram showing ammonium-to-hydrogen ion activity ratios $\log(aNH_4^+/aH^+)$, versus potassium-to-hydrogen ion activity ratios ($\log(aK^+/aH^+)$) for leachate data reported by Owen and Manning. A slope of 1 is consistent with mineral-controlled ammonium–potassium cation exchange. The term 'activity' refers to the thermodynamic concentration of the chemical species. (Adapted from Owen JA and Manning DAC (1997) Silica in landfill leachates: implications for clay mineral stabilities. *Applied Geochemistry* 12: 267–280.)

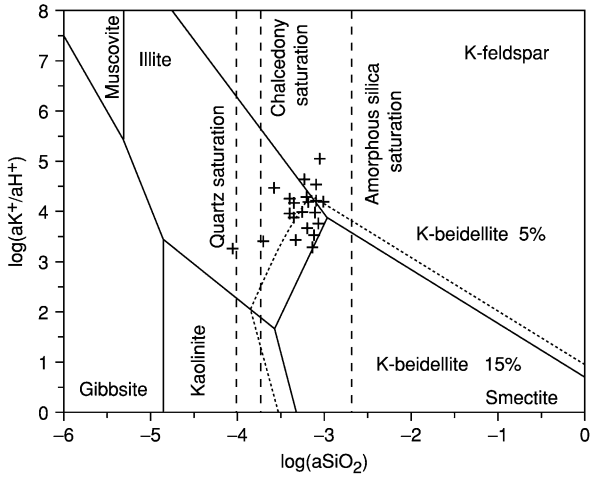

Figure 8 Ion activity diagram showing mineral stability fields calculated for soil minerals (including two smectite compositions: K-beidellite end-member, 5% (dashed) and 15% (solid)) as a function of potassium-to-hydrogen ion activity ratio ($\log(aK^+/aH^+)$) versus dissolved silica activity ($\log(aSiO_2)$), with activity ratios for landfill leachates. (Adapted from Owen JA and Manning DAC (1997) Silica in landfill leachates: implications for clay mineral stabilities. *Applied Geochemistry* 12: 267–280.)

to the nature of the minerals that are present within municipal waste as constituents of consumer goods. Sorbents such as animal litters are based on smectite–illite mixtures; clays within paper are kaolinite–illite mixtures.

Summary

Landfill disposal of municipal waste involves the artificial creation of an anaerobic environment in which degradation of putrescible matter and mineral reactions produce solutions and gases whose composition is controlled by natural processes analogous to those that take place in soils. Degradation products include methane and carbon dioxide, and calcium carbonate mineral precipitate. Clay minerals within waste control solution composition through cation exchange, and through the illite-smectite reaction.

List of Technical Nomenclature

–	pH (pH units)
ΔG_r^o	Gibbs free energy of reaction (kilojoules)
$\mu S\,cm^{-1}$	Conductivity (micro-Siemens per centimeter)
a	Activity
BOD_5	biochemical oxygen demand (5 days' incubation)
COD	chemical oxygen demand
kJ	Energy (kilojoules)
m	Molarity (moles per liter)
$mg\,l^{-1}$	Concentration (milligrams per litre)
TOC	total organic carbon
VFA	volatile fatty acids

WATER CONTENT AND POTENTIAL, MEASUREMENT

G S Campbell and C S Campbell, Decagon Devices, Inc., Pullman, WA, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Soil-water content is a measure of the amount of water (volume or mass) contained in a unit volume or mass of soil. If the measure is the volume of water per unit volume of soil, the water content is called the 'volume wetness.' If it is the mass of water per unit mass of soil it is called the 'mass wetness.' Mass wetness in soils is typically defined as the mass of water per unit mass of dry soil. Volume and mass wetness are related by:

$$\theta = \frac{\rho_b}{\rho_w} w \qquad [1]$$

where θ (cubic meter per cubic meter) is the volume wetness, w (kilogram per kilogram) is the mass wetness, ρ_b (kilogram per cubic meter) is the bulk density of the soil (mass of dry soil per unit volume) and ρ_w (kilogram per cubic meter) is the density of water (10^3 kg m^{-3}).

Soil-water potential is a measure of the potential energy per unit mass, volume, or weight of soil water, compared with that of pure, free water. It is the work required, per unit quantity of water, to remove an infinitesimal quantity of water from the soil to a pool of pure, free water. The energy of soil water responds to the hydrostatic or pneumatic pressure on the water, to the concentration of solutes in the water, to the forces that adsorb the water to the surfaces of soil particles, and to the position of the water in the gravitational field. The components of the water potential arising from these interactions are, respectively: ψ_p, the pressure potential; ψ_o, the osmotic potential; ψ_m, the matric potential; and ψ_g, the gravitational potential. The pressure and gravitational components can be positive or negative. The osmotic and matric components can only be negative.

Both water content and water potential must be known to characterize the status of water in soil. Water content tells how much water is there, but gives no information about the availability of the water for plant uptake or microbial activity, and no information about the direction of movement of the water. Water tends to move from regions of high potential to regions of lower potential. A gradient in water potential is the driving force for water flow. A plant or microbe is therefore able to obtain water from the soil as long as it can maintain an internal water potential below that of the soil. Since there is a limit to the lowest potentials attainable by living organisms, organisms may cease to be able to obtain water from soil when the soil still contains a substantial quantity of water.

The gravitational and pressure potentials are important for determining rates and directions of water flow when the soil is saturated or near saturation. Both are proportional to the distance from a reference plane to the soil location in question. They are therefore measured with a ruler. Our focus here will be on the other components of the water potential, the osmotic and matric, which are more difficult to measure.

Measurement of Water Content

Gravimetric Methods

Mass wetness is typically measured by oven-drying a sample. The mass wetness is the mass loss divided by the dry mass of the sample. Samples are typically dried for approximately 24 h at 105°C. Aside from errors in weighing, the two most serious errors come from loss of mass of nonaqueous volatiles in the sample and uncertainty in the point at which the sample is really 'dry.' Increasing or decreasing the drying temperature changes the mass loss, and this change can be substantial in some soils. Variation in oven humidity can also lead to some uncertainty. Typical errors are on the order of 0.005 kg kg^{-1}. There are a number of faster drying methods which give quicker results at the expense of some accuracy. Drying of samples in a microwave oven can decrease the time required for a measurement to approximately 20 min, while still giving acceptable accuracy for many purposes.

Mass wetness is frequently used in laboratory studies, but has little relevance in the field, where one is mainly interested in the ability of the soil to store water for later transpiration and evaporation. Here volume wetness is the relevant measurement. The only direct method for measuring volume wetness is to find the mass wetness, through oven-drying, of a sample of known volume. From the known volume and the soil dry mass, the bulk density is computed. The volume wetness is then obtained using Eqn [1]. Since this is a tedious and time-consuming

measurement and is subject to large uncertainty owing to the large spatial variation found in the field (*See* **Spatial Patterns**), volume wetness is often inferred from measurements of other soil properties. These include dielectric properties, thermal properties, and interactions with nuclear radiation.

Dielectric Properties

The relative dielectric permittivity of water is approximately 80 at microwave frequencies, while the permittivity of soil minerals, organic matter, and ice ranges from 3 to 5. A measure of soil permittivity is therefore strongly influenced by the amount of water present in the soil. One of two methods is typically used to measure the permittivity of the soil: time-domain reflectrometry (TDR) and capacitance. For the TDR method, parallel conductors are placed in the soil forming a transmission line, and one measures the time required for an electromagnetic pulse to traverse the transmission line, reflect from the distal end, and return along the same line. The speed of propagation of an electromagnetic disturbance in the transmission line is determined by the dielectric permittivity of the surrounding medium. It is computed from:

$$\epsilon = \left(\frac{ct}{2L}\right)^2 \qquad [2]$$

where c is the speed of light ($3 \times 10^8\,\mathrm{m\,s^{-1}}$), t is the time to traverse the transmission line, and L is the length of the transmission line. (*See* **Time-Domain Reflectometry**.)

TDR measurements obviously require very fast response circuitry. The time resolution must be on the order of 100 ps. Equipment with this kind of time resolution is necessarily expensive. When slower circuitry is connected to the transmission line and a voltage pulse applied through a resistor of value R, the transmission line acts like a capacitor, with the soil as the dielectric. The time constant for charging the capacitor (time to charge to 63% of its final voltage) is RC, where C is the capacitance of the probe. The capacitance is related to geometric factors and is directly proportional to the dielectric permittivity of the medium surrounding the probe. The charging time is therefore directly related to the soil permittivity.

The dielectric constant of the soil can therefore be measured by either method. TDR, however, due to its higher-frequency excitation, is less influenced by electrical conductivity of the soil. Since ice has a dielectric permittivity near that of soil minerals, dielectric methods measure unfrozen water content in frozen soil.

A number of sensors are available commercially, both for TDR and capacitance measurement of soil moisture. An example of a capacitance sensor is shown in Figure 1. Sensors of this type have been used extensively for the past 20 years or so. Since they measure the properties of the dielectric within the electromagnetic field of the probe or transmission line, it is important that a representative sample of the soil lie within the field of the sensor. Unfortunately, the field lies close to the surface of the sensor, so any air gaps or compaction around the sensor may adversely affect the measurement.

Thermal Properties

Both thermal conductivity and heat capacity of soil vary with water content. (*See* **Thermal Properties and Processes**.) The relationship with heat capacity is an easy one to use for determining water content. The water content can be computed from the volumetric heat capacity of soil (*See* Eqn [13] in **Thermal Properties and Processes**):

$$\theta = \frac{C - C_s\rho_b/\rho_s}{C_w} \qquad [3]$$

Here C, C_s, and C_w (joules per cubic meter per kelvin) are the volumetric heat capacities of the bulk soil, the soil minerals, and water; and ρ_b and ρ_s are the bulk and particle densities. Since C_w is typically about twice as large as C_s, changes in water content have a fairly large effect on C. If the bulk density of the soil is known and C is measured, all values on the right-hand side of Eqn [3] are known, so water content can be computed. Typically C is measured using a dual-needle thermal properties sensor. Figure 2 shows a typical dual-needle sensor.

Nuclear Methods

Gamma rays and neutrons both interact strongly with soil water. The methods used most widely for water-content measurement involve attenuation

Figure 1 An example of a capacitance soil-water content sensor. The circuitry to measure the capacitance is in the overmolded head of the probe. The capacitance sensor is in the blade and consists of parallel conductors sandwiched between insulating layers.

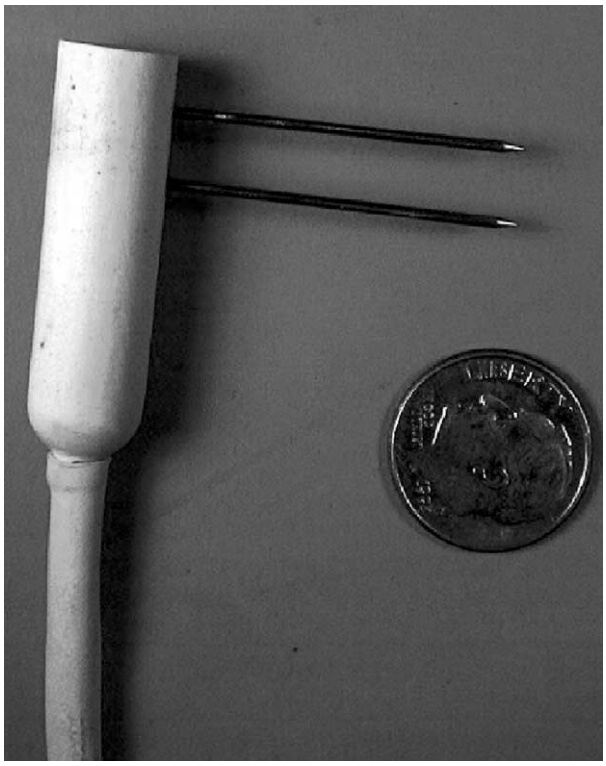

Figure 2 Dual-needle probe for measuring soil heat capacity. One needle contains a heater, the other contains a temperature sensor. The temperature rise in the temperature sensor resulting from a heat pulse to the heater is measured.

of transmitted gamma radiation and backscattering of neutrons, though neutron transmission and gamma backscatter have also been used. Gamma attenuation is typically a laboratory method. A soil column, 5–20 cm thick, is irridiated by a collimated beam of gamma radiation. Sources with appropriate energy levels are ^{137}Cs and ^{241}Am. The volume wetness is computed from:

$$\theta = \frac{\ln\left(\frac{I_d}{I_w}\right)}{\mu_w S} \qquad [4]$$

where I_d and I_w are the numbers of gamma photons passing through the dry and wet soil in unit time, respectively, μ_w is the mass attenuation coefficient for water, and S is the soil-column thickness. It is possible to determine the bulk density and the water content of a sample without measuring the gamma attenuation in the dry soil column by measuring the attenuation of two gamma beams having different energies.

Neutron scattering is a method for measuring volume wetness in the field. In a typical application, a neutron source such as ^{241}Am/Be is lowered into an access tube in the soil. The neutrons from the source initially have high energy, but, as they collide with low-atomic-mass nuclei (mainly hydrogen) in the soil, they slow and become 'thermal' neutrons, with energies typical of atoms at room temperature. These slow neutrons can be counted with a relatively simple detector. Since the main source of hydrogen nuclei in the soil is water, and since the number of scattered neutrons is proportional to the number of collisions with these hydrogen nuclei, there is a relationship between neutron count and water content:

$$\theta = a + b\frac{I}{I_{std}} \qquad [5]$$

where a and b are soil-specific empirical constants, I is the count in soil, and I_{std} is the count in a standard scattering medium. Neutron scattering is much less affected by air gaps around the sensor than are dielectric methods. The scattering volume for the neutrons varies with soil-water content from approximately 15 cm diameter in saturated soil to, e.g., 70 cm in dry soil.

Measurement of Water Potential

While the water potential concept is straightforward, no method exists for directly measuring the energy status of water in soil. All of the methods currently available equilibrate an external phase of some sort with the water in the soil and then measure the potential of the equilibrated phase. The sensing phase can be solid, liquid, or gas. Typical solid-phase sensors are heat-dissipation matric-potential sensors, gypsum blocks, dielectric matric-potential sensors, and filter paper. The tensiometer is a liquid-phase sensor. Thermocouple psychrometers and dew-point potentiometers are vapor-phase sensors.

Solid-Phase Sensors

For each of the solid-phase sensors, a porous matrix of ceramic, gypsum, or cellulose equilibrates with the soil matric potential. The water content of the matrix is then determined by weighing and drying (filter paper), measuring thermal conductivity (heat-dissipation sensor), electrical conductivity (gypsum block), or dielectric constant (dielectric sensor). From predetermined relationships between these measures of water content and matric potential, the measurements are converted to water potential.

Heat-Dissipation Matric-Potential Sensors

A heat-dissipation sensor is shown in Figure 3. It has a cylindrical, ceramic outer matrix that fully encases a stainless-steel needle. Inside the needle is an electrical resistor that runs the length of the probe

Figure 3 Heat-dissipation matric-potential sensor. The darker, upper part of the cylinder is the overmold, containing wires and connections. The lighter, lower part is the ceramic matrix, which equilibrates with the soil.

(typically 3 cm) and a temperature sensor, either a thermocouple or thermistor. To measure thermal conductivity, a known amount of current is passed through the resistor for a preset amount of time and data are collected on the temperature change (δT) over time (t). The thermal conductivity (λ_h) can be calculated from the slope (m) of the δT versus logarithm of time curve using:

$$\lambda_h \cong \frac{q}{4\pi m} \qquad [6]$$

where q is the power applied to the internal resistor (watts per meter). Because the ceramic matrix properties remain fixed, the thermal conductivity is a measure of the water content of the matrix, which, in turn, is related to the water potential of the soil. These sensors must be calibrated and, at midrange water potentials, have a strong temperature dependence. The heat-dissipation probe functions over an extremely wide range of water potentials (field capacity to air dryness).

Electrical Resistance Matric Potential Sensors

Electrical resistance sensors measure the electrical resistance between two electrodes packed in a granular (sand) or gypsum matrix to obtain water potential. As the sensor matrix comes into equilibrium with the surrounding soil, water fills the voids in the matrix. The increase in water causes the electrical resistance between the electrodes to decrease. The resistance of the sensor is related to the water content, and a value of water potential can be calculated using its predetermined relationship with water content. Electrical resistance sensors are the most inexpensive sensors available for measuring water potential, and this may be why they are also the most popular. They are easy to install and simple to automate for data-logging purposes; however, they are sensitive to changes in salinity and temperature. The largest pores in a gypsum matrix are still fairly small, so these sensors have very low sensitivity in wet soil.

Dielectric Matric-Potential Sensors

Dielectric matric potential sensors differ very little from the other solid-phase sensors discussed above. Instead of a heated needle or two electrodes, two or more wave guides are separated by a porous matrix. The wave guides measure the dielectric permittivity of the porous matrix. An empirical relationship between the matrix permittivity and matric potential is used to infer matric potential of the matrix, which is equal to the matric potential of the soil at equilibrium. The high accuracy of the dielectric sensor provides excellent resolution of water potential; in addition, careful selection of a matrix allows relatively quick equilibration in a wide range of soils. However, although dielectric sensors are not sensitive to temperature and salinity to the same degree as the electrical resistance sensor, they are not completely insensitive either.

Filter-Paper Method

The filter-paper method is a simple method for measuring water potential. A single disk of Whatman No. 42 filter paper is brought to equilibrium with a soil sample, which generally takes 2–3 days. The filter paper is then weighed and dried. The water content of the paper is used to calculate water potential using the relation:

$$\psi_m = -11w^{-3.68} \qquad [7]$$

where the relationship between the water content of the filter paper and its water potential in joules per kilogram is defined by the two constants, which are specific for the specified filter paper.

Tensiometer

The tensiometer equilibrates water inside a tube with the water in the soil matrix. The soil is separated from the water in the tube by a porous ceramic which is permeable to water and solutes, but not to soil colloids and air. When the water in the tube equilibrates with the soil water, the suction on

the water is equal to the soil matric potential. (*See* **Tensiometry**.)

Vapor-Pressure Methods

If soil water is allowed to come to temperature and vapor equilibrium with a vapor phase, the potential in the vapor phase becomes the same as that in the liquid phase. Since a vapor barrier is impermeable to solutes as well as soil colloids, the potential in the vapor phase is equal to the sum of the osmotic and matric potentials in the soil. The potential in the vapor phase can be determined by measuring its relative humidity. The Kelvin equation relates humidity and water potential:

$$\psi = \frac{RT}{M_w} \ln h \qquad [8]$$

where R is the gas constant, T is temperature (Kelvin) M_w is the molecular mass of water, and h is the relative humidity (a fraction, not a percentage). It is possible to measure h by measuring either the wet-bulb depression or the dew-point depression of the headspace air. For soil wet enough to sustain plant growth, the relative humidity is greater than approximately 0.99, so the psychrometer or dew-point meter must be extremely accurate and sensitive. A number of such devices are available which resolve changes in humidity of 0.0001 at these high humidities. Figure 4 shows a dew-point meter for water-potential measurement.

Water-Potential Units

Water potential has been expressed in a variety of ways and with a variety of units. As stated earlier, water potential is the potential energy per unit quantity of water, where the quantity is sometimes mass, sometimes volume, and sometimes weight. Potential energy per unit volume is dimensionally equivalent to pressure, so pressure units are often used; equivalent concentrations of ideal solute, relative humidity, and freezing point have also been used. Table 1 shows some of these units.

WATER CYCLE

D K Cassel and B B Thapa, North Carolina State University, Raleigh, NC, USA

Introduction

The water cycle is an endless process of water circulation on the planet Earth. Water is an essential constituent of all plants and animals, most of which contain more than 60% water, and many contain more than 95%. The planet Earth is dominated by the hydrosphere, which contains all of the Earth's water. Approximately 1.39 billion km^3 of liquid water is stored in depressions, primarily oceans, which occupy over 70% of the Earth's surface. Water is unique in many ways: it has a high heat capacity, high heats of vaporization and fusion, and can exist in solid, liquid, and gaseous phases at temperatures commonly encountered on Earth. The ease with which water can move from one phase to another in response to additions or losses of heat or energy allows water to move or cycle from one storage field to another.

Overview

Approximately 97% of the Earth's water is salty and is stored in oceans (Table 1). The remaining 3% is fresh water and, if uncontaminated, is considered to be potable and drinkable by animals and utilized by nonsalt-tolerant plants. Fresh water is stored primarily as ice in glaciers and icecaps, but also in groundwater, lakes, streams, and rivers. Water retained as soil moisture is a small fraction of the total, but is extremely important for the production of food and fiber. The amount of water existing in the gaseous state is relatively constant and is estimated to be 12 900 km^3.

Table 1 Estimate of global water distribution

Source	*Volume × 1000 km³*	*Total water (%)*	*Fresh water (%)*
Oceans	1 338 000	96.5	–

The water cycle, commonly called the 'hydrologic cycle,' is a conceptual model that relates to the transport of water to and from the various storage fields or pools on the Earth. Movement of water from one storage field to another depends on the energy sources available for the processes of evaporation, condensation, precipitation or deposition, runoff, infiltration, melting, and groundwater flow. It is estimated that 380 000 km^3 of water are recycled each year. Human recognition of this water-recycling process has led to the utilization of renewable (recycling) flowing water to generate hydroelectricity in many parts of the world. A given water molecule could follow an infinite number of pathways as it progresses through the various processes in the water cycle.

At the global scale (macro scale), the water-cycle model appears to be a simple process of evaporation and precipitation and is typically viewed as transport of water from oceans and lakes to land masses and back to oceans and lakes. The water, once on land, is eventually returned to the oceans in runoff water or as precipitation fed by water evaporated from the soil or transpired by plants. When considered at the regional scale, human intervention in the water cycle often exists, and the water-cycle model becomes more complicated. For example, in arid regions, in addition to precipitation, water previously stored in the groundwater might be 'mined' for domestic purposes, or water falling in another region might be transported to the arid region for domestic or commercial uses or to satisfy the transpiration demand to grow crops. Conversely, water in humid regions might be impounded in dams and transported by canal or pipeline to another region or watersheds.

The water cycle becomes even more complex at the local or field scale, and we often view it as the water balance. The individual mechanisms of water transport become more important at smaller scales. For example, at the local scale, a high percentage of the water might be transferred to the land by irrigation canals rather than by precipitation. Likewise, lateral subsoil transport of water from sloping fields might be the major mode of transport rather than runoff. In

many agricultural fields, a conscious effort is made to reduce or at least control runoff to allow more water to infiltrate and to control soil erosion. The soil moisture component of the water cycle may appear to be insignificant at the global scale (Table 1), but at the field scale it is elevated to primary importance in growing plants.

The quality of waters transferred by runoff, groundwater flow, and precipitation is an important consideration. Pollutant-laden runoff has significant negative impacts on aquatic habitats and decreases the usefulness of water for further use. As the population increases, not only is more water needed, but human activities tend to impair water quality as it continues to travel in the water cycle. Examples of water-quality impairment are the contamination of groundwater by organic and inorganic chemicals, and the fouling of lakes, streams, and oceans by rubbish and human and animal wastes. Acid rain due to sulfur, a by-product of some industrial operations, has damaged plant and animal habitats. These impacts on water quality can lead to health hazards and drastic environmental and economic impacts at the regional and local scales. Fortunately, the evaporation process in the water cycle purifies polluted water, allowing it eventually to reappear as fresh precipitation to be reused to support plant and animal life.

Water Cycle Processes

The water cycle is a conceptual model to describe the transfer and temporary storage of water among various storage fields or reservoirs. These reservoirs include lakes, streams, oceans, groundwater, soil moisture, glaciers, snowfields, the atmosphere, and the biosphere. Energy balance and the water cycle are closely linked. Water is transferred from one storage field to another by processes of evaporation, transpiration, sublimation, condensation, precipitation, infiltration, runoff, and groundwater flow (Figure 1). An estimate of the approximate residence time in various water reservoirs is given in Table 2.

Evaporation converts liquid water to the gaseous phase. Evaporation is a distillation process that leaves all impurities and contaminants behind in the soil or water body from which it evaporates. Evaporation of water requires a large quantity of energy, most of which comes from the Sun. The heat required to vaporize water is $540\,\mathrm{MJ\,kg^{-1}}$ at 373 K (101 kPa) and increases to $2.26\,\mathrm{MJ\,kg^{-1}}$ at 273 K. Evaporation occurs when the vapor pressure of the atmosphere is less than the vapor pressure of liquid water at the evaporating surface. The evaporation rate is controlled by the energy available, temperature, humidity, wind speed, and salinity of the water. On a global

scale, evaporation of water is most intense in the subtropical oceans, where solar radiation is relatively constant throughout the year and provides a constant energy source to vaporize water.

Sublimation is conversion of solid-phase water (ice) directly to the vapor phase without passing through the liquid phase. This process requires approximately 2.85 MJ kg^{-1}.

Transpiration is the conversion of water from liquid to gas as it passes through plant stomata, small openings on the undersides of leaves of vascular plants. The stomata of some plants have the ability to open and close. Transpiration is a passive process, being controlled by several factors. When soil water content is high (absolute value of soil water pressure is small), the transpiration rate of plants with extensive root systems tends to be controlled by the solar energy available. Wind tends to increase transpiration rate. In general, 99% of the water entering plant roots passes through the plant and is lost to transpiration.

The processes of evaporation and transpiration on a given area of land often occur simultaneously, and it is difficult to differentiate between the evaporative loss of water from the land surface and the transpiration loss by plants. In such cases the combined loss of water by these two processes is referred to as evapotranspiration. Generally, potential evapotranspiration exceeds precipitation from landmasses during the summer at middle and high latitudes.

Condensation is the process whereby water is converted from the gaseous phase to the liquid phase. This process releases a vast amount of heat. Condensation occurs when the atmospheric temperature cools below the point at which the relative humidity approaches 100%. When this condition is reached, condensation nuclei such as dust, smoke particles, or salts provide sites for water vapor to condense to form water droplets. These condensed water droplets form clouds or fog. The water droplets in the clouds continue to increase in size when the right conditions are encountered and eventually coalesce into ice crystals or a liquid. Condensation nuclei such as salts, e.g., NaCl, are hygroscopic, thus allowing water to condense at a relative humidity of less than 100%. As clouds form, air currents move them, thus dispersing the water vapor around the Earth. When clouds eventually encounter environmental conditions where they can no longer hold the moisture, they release some or part of it as precipitation. Another result of the condensation process is the formation of dew during summer and autumn nights, when the air temperature cools to the point where the relative humidity at the plant or land surfaces rises to 100%.

Precipitation is any aqueous deposit, whether in liquid or solid form, that develops in a water-vapor-saturated atmosphere and falls to land or water surfaces. In general, precipitation over continents tends to exceed evaporation, whereas over oceans, evaporation tends to exceed precipitation. Most precipitation forms from natural clouds, but most clouds exist without yielding precipitation. On the other hand, small precipitation events derived from water vapor emitted from smoke stacks are not uncommon. Precipitable water is the amount of water potentially available in the atmosphere for precipitation, usually measured in a vertical column that extends from the Earth's surface to the upper edge of the troposphere. In many clouds, water droplets and ice crystals are too small to overcome natural updrafts found in the atmosphere. Hailstones are formed by the continual thickening of ice crystals until they become heavy enough to overcome the updraft.

The distribution of rainfall reaching the soil surface can be modified by vegetation covering all or part of the soil surface. Deforestation in some regions of the world has changed the rainfall pattern. The amount of rainfall intercepted by vegetative cover depends on leaf density and the branching structure of the plants. Some of the water is evaporated directly from the vegetative surfaces, while some of it might drip from leaves or move by 'stemflow' down the leaves and stems to the soil surface.

The intensity, duration, and amount of rainfall events control to some degree the pathway water takes once it arrives at the soil surface. Rainfall intensity varies during a storm event. If the intensity is high, or if the duration is long, the likelihood is great that some of the water reaching the soil surface will run off. The energy associated with high-intensity rainfall increases the opportunity for soil erosion, a process that degrades productive soil as well as the quality of the runoff water.

Irrigation is the application of water to the soil, usually for the purpose of growing food or fiber. This very important process in the water cycle is human-imposed, but has tremendous impact on other processes in the water cycle. Approximately

40% of the world's food comes from irrigated land. One common source of irrigation is water diverted from large, constructed reservoirs. These reservoirs are often hundreds of kilometers away from the land being irrigated. Other sources of irrigation water are ponds, streams and rivers, and groundwater. Irrigation accounts for over 65% of the fresh water use, but, because of inefficiencies at various points in the irrigation process, less than half of that water reaches the plant roots. The remaining half is lost to evaporation during transport of water to the land to be irrigated, deep percolation, and runoff. Runoff water leaving the lower boundary or an irrigated field (irrigation return flow) often has a high salt content, thus reducing water quality of streams into which it drains. Irrigation water is applied to the soil by flooding, spraying, sprinkling, furrowing, and trickle methods. Groundwater resources continue to be depleted in some regions of the world due to pumping more water than is being recharged.

Infiltration is the process of water entry into the soil, generally by downward flow through the soil surface. Liquid water falling on the soil surface is temporarily stored on the surface, runs off, or infiltrates. The infiltrability, that is, the rate at which water enters the soil when water at atmospheric pressure is available at the soil surface, decreases with time. The infiltration rate of unsaturated soils is controlled by a number of factors, including the condition and cover of the soil surface, soil texture, pore-size distribution and porosity, soil water pressure or soil suction, soil structure, the rate at which water arrives at the soil surface, antecedent soil water content, and the permeability of underlying soil horizons. If a soil is saturated, water will not infiltrate because there is no pore space for it to enter. Coarse-textured soils usually have high infiltration rates unless they have high antecedent water contents. Fine-textured soils tend to have low infiltration rates, increasing the chances for water to run off. For some soils, water infiltrates along preferred pathways due to the presence of cracks and fissures, soil 'pipes,' and large pores created by animal or plant roots.

Runoff is excess water that does not infiltrate into the soil. When liquid water as precipitation or irrigation arrives at the soil surface at a rate that exceeds the soil's infiltration rate, the excess water is temporarily stored in small depressions on the soil surface. Once these depressions on sloping land are filled, additional water arriving at the soil surface that does not infiltrate is transported across the soil surface as runoff. Gravity provides the energy to transport runoff, or 'overland flow,' from higher to lower elevations. Overland flow occurs as sheet flow on the soil surface. Runoff water concentrates in rivulets or rills, waterways, and gullies, eventually emptying into streams and rivers, and finally into lakes and oceans. This runoff water provides energy that can transport detached soil materials in the processes of sheet, rill, and gully erosion. Flooding can occur if too much water runs off in a short time period. In some arid regions, land is set aside and managed to increase the amount of runoff water that is usually collected in reservoirs at lower elevations for various consumptive uses.

Drainage When soils become saturated or nearly saturated, the possibility that some of the water will continue to drain or percolate deeper into the soil or into the underlying water table increases. This process recharges ground water supplies and also provides 'base flow' water for streams and rivers. When irrigation is practiced, it is imperative that some water drains below the root zone to remove salts that are added to the soil in the irrigation water. Open ditches or buried drains carry the drainage water to a discharge outlet, where it is returned to a river or stream. Mobile chemicals present in the soil move in the percolating and drainage waters. Transport of chemicals has led to the contamination of groundwater, streams, rivers, and reservoirs throughout the world and is a continuing problem.

Environmental and Economic Implications of Water-Cycle Processes

Tremendous environmental impacts are associated with the processes in the water cycle. At the global scale, the geography of the entire world along with its many beautiful geologic features has been shaped primarily by the various components of the water cycle, without human intervention, acting over extended periods of time. For millions of years the water-cycle processes, driven and interacting with the energy-distribution patterns on the Earth's surface, have shaped Earth's surface. Geologic erosion, deposition of eroded and transported solids, the formation of rivers, lakes, and streams by runoff water, and the formation of wetlands in low areas are results of water-cycle processes. All of these processes result from a combination of ordinary and episodic events associated with the water cycle.

At the regional scale, one can only imagine the flooding that occurred as huge amounts of runoff water loosened and scoured minerals from higher elevations, transporting them to lower elevations to settle and eventually develop into sedimentary and metamorphic rocks. Phosphates, carbonates, and placer gold are but a few of the numerous minerals and chemicals that are mined that have been concentrated in certain regions throughout the world by

water-cycle processes. Similarly, very fertile alluvial flood plains, such as the Indo-Gangetic Plain in Asia, have developed.

Glaciation, a process that occurred in some regions of the Earth in the past and presently is ongoing in some regions, transports vast amounts of ice that scour and shape the surface features of the Earth. As glaciers melt, rivers, lakes, prairie potholes (closed depressions), wetlands, and numerous other features are formed. At the local scale, for example, the magnitudes of the individual processes of the water cycle for a prairie pothole in eastern North Dakota differ from those for land just a few hundred meters away. Surface runoff from land in the small, depressional watershed surrounding the pothole contributes to the water stored in the pothole, where it will be evaporated or percolate downward to the groundwater. On the other hand, runoff water from the nearby land outside the depressional watershed contributes its runoff to streams. This seemingly small difference creates great diversity in ecology within a distance of 100 m or less.

Extreme variation in the magnitude of one or more components of the water cycle, for example, precipitation, causes catastrophic events such as flooding or drought, although these two terms are defined in terms of norms as perceived by humans today. Yet flooding as a catastrophic event has occurred for billions of years and has been a key process in the formation of sedimentary rocks.

On a shorter time scale, vagaries in various processes of the water cycle have caused disasters for humans. In fact, humans have altered the water cycle at various scales for millennia, and currently the process of global warming, which is still a highly debated topic, is intimately linked with the water cycle. Impacts of global warming that have been predicted using models are shifts in temperature, rainfall distribution, and food production. These shifts are predicted to have greater impacts in some regions of the world than in others. Acid precipitation is another man-induced problem that affects the quality of water and is changing the ecology of large regions. Nitrogen and sulfur oxides released into the air as a result of industrial processes and fuel combustion are further oxidized and converted into nitric and sulfuric acids. These acids are washed from the air by precipitation. Acid precipitation refers to wet forms of acid pollution contained in rain, sleet, snow, fog, and vapor transport. Still another problem affecting the quality of water is the input of chemicals and heat that is discharged into stream waters. Excess nitrogen and phosphorus can lead to excessive algal growth. Siltation of lakes and rivers and accompanying fish kills are common occurrences.

Water in lakes and streams has a large impact on quality of life and the economy. Water for transportation led to the development of ancient and modern civilization. Water for industrial and domestic use is diverted from lakes, streams, and groundwater supplies. After the liquid water is used, much of it continues its travel in the water cycle as 'wastewater' discharged into streams and lakes. This water is reused further downstream for additional domestic and industrial applications. In some locations energy in the form of hydroelectricity is 'harvested' from the flowing water. Without this source of energy, many areas of the world could not have been developed. The use and reuse of water continue until the water eventually evaporates or reaches the ocean and then evaporates. The development of cities, industries, agriculture, and recreational parks are dependent on water as it passes along the various stages in the water cycle.

Land-Management Impacts

Human interventions in the 'natural' water cycle at many scales have occurred as a result of implemented land- and water-management (or mismanagement) practices. Several examples of the effects of management practices involving the water cycle at different scales, either directly or indirectly, follow. Intervention of the water cycle at the regional scale began in ancient times with the construction of irrigation canals that diverted water from one region to another, thus increasing the amounts of water applied to irrigated areas. The anticipated response of increasing food production by applying greater amounts of water to the lands was obtained. However, an unanticipated regional-scale response was that, in time, the soils became saline and were eventually abandoned for crop production. Failure to provide soil drainage led to the gradual increase in salt content of irrigated soils. Eventually, even salt-tolerant crops failed to grow. This undesirable salinization process was a direct effect of inadequate land and water management. Unfortunately, today we are still losing arable land due to salinization caused by inadequate drainage of irrigation water.

Another type of salinization problem, caused by modification of the water cycle as a result of changes in land management at the field or landscape scale, arose in the subarid Northern Great Plains (USA) due to the adoption of 'summer fallow.' Dryland small grain production was, and still is, common in this area even though precipitation in a typical year is often insufficient to produce a grain crop. The practice of summer fallow was developed to accumulate water in the soil profile, thereby using the precipitation occurring over a 2-year period to produce one

grain crop every 2 years. Typically, the soil was kept bare the year before planting the grain crop (year 1) so that water falling as precipitation during that year would infiltrate, thus increasing the amount of stored soil moisture. The grain crop planted in year 2 would derive benefit from the stored moisture in year 1 in addition to precipitation occurring in year 2. Use of this practice over decades gave rise to 'saline seeps.' In essence, summer fallow was inefficient in conserving water for the following crop. Much of the water evaporated from the soil surface in year 1. However, some of the water in higher-rainfall years percolated through the soil. This percolating water carried salts leached from underlying strata having high salt contents. When the drainage water encountered an aquatard, it moved obliquely downslope and eventually seeped from the hillside, causing excessively wet, salty nonarable soils at lower elevations.

As the human population increases, more and more land is being altered and subjected to different land uses. The land use changes have impacts on the processes of the water cycle, the scale of impact being dictated by the extent and nature of land management. Compaction of soils by farm and construction machinery, as well as human and animal footprints, decreases infiltration with a resultant increase in runoff. The eroded soil material from farmland and construction sites may include adsorbed hazardous chemicals. The construction of sedimentation basins to collect runoff water to allow solids removed in runoff water to settle out is a management practice that has arisen to help control the environmental degradation.

The construction of dams and ponds occurs at many scales and, regardless of scale, they cause some alteration of the magnitudes of the processes in the water cycle. The water that fills ponds and lakes impounded by dams arises from runoff waters, groundwater, seeps, and springs. The impounded water in farm ponds is often used for irrigation. At a regional scale, for example, some of the large dams constructed in California impound water that is transported hundreds of miles and used for domestic consumption, industry, and irrigation. In some regions of the world, so much water is diverted for irrigation and other human uses that rivers run dry for parts of the year. Rivers affected in this manner include the Yellow River in China, the Ganges in South Asia, and the Colorado in the United States. In addition, in many regions the groundwater supplies are being mined for irrigation and other uses at rates exceeding their recharge rates, resulting in dropping water tables.

Urbanization has drastically altered the water cycle at various scales. Precipitation falling on roofs of houses and buildings, on streets and highways, and paved parking lots near industries, schools, and shopping centers does not infiltrate the soil, but increases the runoff component of the water cycle. This stormwater runoff carries suspended solids and numerous chemicals, such as spilled petroleum products, and nitrogen and phosphorus fertilizers that degrade water quality and cause eutrophication. In addition, it is common for the increase in amount of runoff water to initiate or exacerbate downstream flooding. Following Hurricane Floyd in 1999, the state of North Carolina began a program to develop new flood plain maps for five river basins which incorporates changes in flood plain elevation caused by two decades of development.

Summary

Human life cannot exist without water: life originated in water, and civilization began near water; water is the shelter for many marine creatures; water fulfills human recreational needs. The importance of water in the world today cannot be overstated. In addition to being the major constituent of human life forms, water is a required input to produce food and clothing, manufacture products, transport people and products around the world, and produce a significant percentage of the world's energy.

Water molecules are in continuous motion and keep moving from one storage field to another. Liquid water in rivers moves downslope to the ocean, where solar radiation converts it to the gaseous phase, which in turn transports the water vapor back to the landmasses, where it condenses to form precipitation. The precipitation is divided into water that infiltrates the soil and runoff water that carries with it suspended solids, chemicals, pesticides, and organic and inorganic wastes. This endless cycle is called the water cycle or hydrologic cycle.

The total amount of water on Earth remains constant, but it is separated into different processes or pathways depending on environmental factors and human interventions. Thus processes such as evaporation, condensation, precipitation, infiltration, and runoff and subsurface water movement induce the transfer of the three phases of water. The evaporation processes can be viewed as a distillation process that purifies water, leaving impurities in the ocean, whereas runoff and percolation are water-polluting processes of the water cycle. The runoff process affects the quality of surface waters. Fish kills as a result of algal growth and eutrophication are primarily due to runoff generated in response to inappropriate land management, deforestation, and misuse of heavy machinery, chemical fertilizers, and pesticides.

Percolated water can leach undesirable chemical compounds below the rooting zone of plants and into drainage water or through the vadose zone into the groundwater. Even though the ocean serves as a huge sink for salts and pollutants, the contamination of streams, rivers, lakes, and groundwater resources poses a great threat to plant and animal health, the environment, the economy, and civilization.

WATER HARVESTING

D Hillel, Columbia University, New York, NY, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Definition

The term 'water harvesting' generally refers to the collection of rainstorm-generated runoff from a particular area (a catchment) in order to provide water for human, animal, or crop use. The water thus collected can either be utilized immediately, as for irrigation, or be stored in aboveground ponds or in subsurface reservoirs, such as cisterns or shallow aquifers, for subsequent utilization. As such, water harvesting is an ancient practice that has enabled some societies to subsist in semiarid and arid areas where other sources of fresh water (e.g., rivers, lakes, or aquifers) are scant or unavailable.

Surface Runoff

Whenever the rate at which rainwater is applied to the soil surface exceeds the rate of infiltration into the soil, the excess tends to accumulate over the surface. Where the surface is not perfectly flat and smooth, the excess water collects in depressions, forming puddles. The total volume of water thus held, per unit area, is called 'surface-storage capacity.' It depends on the geometric irregularities (roughness) of the surface as well as on the overall slope of the land (Figure 1).

Only when the surface storage is filled and the puddles begin to overflow can actual runoff begin. The term 'surface runoff' thus represents the portion of the water supply to the surface that is neither absorbed by the soil nor accumulates on its surface, but that runs downslope.

Surface runoff typically begins as sheet flow but, as it accelerates and gains in erosive power, it eventually scours the soil surface to create channels. There exists

a wide spectrum of channel geometries and flow patterns. On the one extreme is the thin, sheet-like runoff called 'overland flow.' It is likely to be the primary form of surface runoff from small areas or fields having little topographic relief. The next distinctive form of flow takes place in small channels called rills. The latter gather the overland flow in a continuous fashion along their length to form the lowest order of stream flow. As these small streamlets merge with one another, they form higher-order channels, called gullies, which collect concentrated tributaries as well as distributed (lateral) overland flows (Figure 2).

Runoff Control and Utilization

Uncontrolled runoff is never desirable, as it is likely to cause soil erosion on slopes as well as flooding and silting in bottomlands. In humid regions, where rainfall may be excessive, measures may be needed to ensure the safe routing and conveyance of the runoff. Such measures, called 'surface drainage,' include shaping the land and treating it so as to direct the runoff via protected (grassed or even concrete-lined) channels. In semiarid regions, by way of contrast, natural rainfall is barely sufficient for crops, hence farmers typically strive – by such means as terracing and mulching – to cause as much of the rainfall as possible to infiltrate the soil, and thereby to minimize runoff.

The situation is fundamentally different in arid (as distinct from semiarid) regions. In many arid regions, large tracts of land are basically unsuitable for conventional rainfed farming, owing to the paucity and instability of rainfall, the nature of the soil (too shallow, stony, or saline to permit cultivation), or the rough topography. From the point of view of farmers (though not of ecologists, who are concerned about an area's natural biota rather than about crop production per se), rain falling on such lands is almost totally lost – being insufficient either to recharge groundwater or to support an economically viable crop.

Most of the meager rainwater generally infiltrates the soil to a shallow depth only, and it is quickly returned to the atmosphere – either by direct evaporation from the soil or by transpiration from native vegetation. Occasional intense rainstorms may none the less generate runoff and cause sudden flash floods. Although runoff from any particular rainstorm may be high, under natural conditions the total seasonal runoff seldom exceeds 10% of the annual precipitation.

The possibility of controlling and even increasing the amount of surface runoff obtainable from such lands can be of great importance. Particularly where no other dependable water source is available, the runoff thus obtained may constitute the major supply of an inhabited area.

Ancient Methods

The art of inducing, collecting, and utilizing runoff has been practiced by desert-dwelling communities since antiquity, in such disparate regions as southwestern Asia, northern Africa, and southwestern North America. Remnants of extensive water-harvesting systems are found in these regions.

Highly noteworthy are the works of the ancient Nabateans, who inhabited the Negev Desert of southern Israel some 2000 years ago. They began as caravan drivers, conveying aromatic, spicy, and medicinal plant-products, as well as other precious objects of trade, from distant sources across the desert to the major population centers along the shores of the Mediterranean Sea. The Nabateans established stations along their trading routes, and these grew in time into permanent settlements and even into cities. To sustain their population in the desert environment, the Nabateans built extensive terraces and channels, and hewed out numerous cisterns. Remains of their cities (most notable among them being the city of Petra, in southern Jordan) can be visited today.

The first imperative of desert settlement was the provision of potable water for humans and livestock. This was done by means of cisterns, which are artificially constructed reservoirs filled with surface flows during infrequent rains. The early cisterns were undoubtedly leaky and inefficient. Building efficient cisterns became possible only with the advent of watertight plaster, made of burned and slaked lime. Also crucial was the ability to recognize suitable rock formations, such as soft marly chalk, which could be hewed out readily and was not as fissured and leaky as the hard limestone that is also prevalent in the same region. The Nabateans were also skilled at choosing appropriate sites for their cisterns and at ensuring that they could be filled with water annually.

Where cisterns could be located alongside natural streams, they were filled directly by flash floods. However, most cisterns in the Negev were built along the lower reaches of hillsides and depended on the direct collection of runoff from the higher slopes. Many hundreds of such cisterns were built in the Negev, and they are clearly discernible landmarks even today. A typical one resembles a giant necklace, with the glistening white pile of excavated rock appearing to hang like a pendant from the two collection channels that ring the hill and curve down its sides from opposite directions (Figure 3). To parched travelers through the desert, to whom these cisterns would beckon from afar, no sight could be more gladdening.

The application of water-harvesting techniques to enable farming in desert areas (that is to say, collecting runoff from sloping areas and using it to irrigate plots or tracts of flat land, where crops could be grown) has been called 'runoff farming.' In ancient times, stone dikes were constructed across tributary streambeds, thus forming a series of terraced fields. These fields were watered by flows arriving from the upper watershed of the stream, as well as from the adjacent hillslopes. The slopes were often divided into sections, the runoff from each of which was led by means of constructed channels to specific fields (Figure 4). The water retained and infiltrated in each field was then utilized by annual crops (e.g., wheat or barley) or by perennial crops (e.g., grapevines, olive trees, or other fruit trees).

Water Spreading

Another form of water harvesting, called 'water spreading,' consists of diverting flash floods from intermittent streams (known as *wadis* in the Middle East, *arroyos* in the American Southwest, and *dongas* in parts of Africa) on to adjacent tracts of land. It is a simple form of flood irrigation, controlled by dikes, check dams, or channels designed to direct and spread the expected flow. It is generally used to irrigate pastures and rangelands, but in places also to sustain groves of trees in arid areas.

Water spreading is typically practiced on small watersheds of a few square kilometers. In larger watersheds, the floods may occasionally be too violent or torrential to be controlled by simple diversion structures. In such cases, a more complex system may be required: the construction of dams designed not to retain the floods but merely to detain and regulate them, so as to provide farm units located downstream from the dam with controlled flows. Such dams, called 'detention dams,' are built across a stream in order temporarily to impound the flood. A large-diameter open pipe is laid through the dam to permit downstream flow at a predetermined rate, as through the drain of a bathtub. Thus, a flash flood that would normally last just a few hours is made to flow through the pipe and on to a series of fields for perhaps several days. The field dikes (made of compacted earth or stone) can then be built economically and safely to withstand floods of a known maximal intensity, so farming operations can be planned accordingly (Figure 5).

Runoff Inducement

The builders of runoff utilization systems in the Negev in ancient times had to contend with the paucity of natural runoff, and there is evidence that they actually strove to augment it. They developed techniques for inducing a greater portion of the rainfall to trickle downslope as runoff.

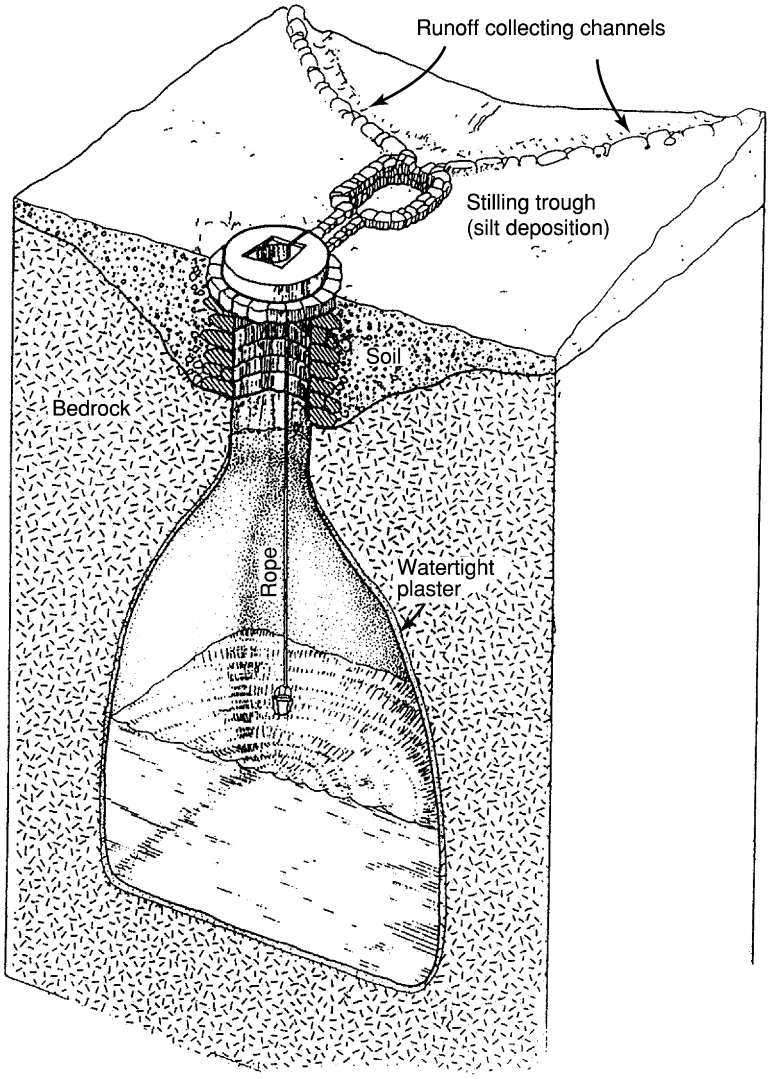

Figure 3 A typical hillside cistern excavated in the bedrock and filled by runoff from a sloping catchment. Reproduced from Hillel D (1982) *Negev: Land, Water, and Life in a Desert Environment.* New York: Praeger Publishers. © D Hillel.

Noticing that the soil had a natural tendency to crust, which was obstructed, however, by the desert's natural cover of loose gravel (commonly known as 'desert pavement'), the ancient inhabitants of the Negev region in southern Israel raked the stones off the surface in order to expose the finer soil material and to induce the formation of a surface seal. Even so, the ancient runoff farmers needed a water-contributing area approximately 20 times larger than the area to which water was directed for crop production. Similar techniques were used to collect runoff in cisterns for subsequent use as drinking water for humans and domestic animals (goats, sheep, and camels).

The importance of runoff inducement is greater than the mere increase in runoff yield that it may produce. The practice can also lower the 'runoff threshold' of a rainstorm, i.e., the minimal rainstorm (in terms of intensity, duration, and total amount of rain) needed to initiate runoff. This decrease in the threshold correspondingly increases the probability of obtaining runoff a sufficient number of times during the season to provide for the needs of domestic human use, as well as for agricultural or industrial purposes. This is especially important in view of the fact that most of the storms in an arid region result in light rains only, and that only a few storms (typically no more than two or three per season) are of sufficient intensity and quantity to yield runoff under natural conditions.

Still another climatic feature of arid regions that adds to the importance of runoff inducement is the interannual variability of rainfall. Most years provide less than the average (or mean) rainfall, and only a few anomalously rainy years skew the mean. (In statistical terms, mode and median rainfall tend to be less than the long-term mean rainfall.) In such regions, droughts are relatively frequent and may be very severe. In some years, there may be practically no

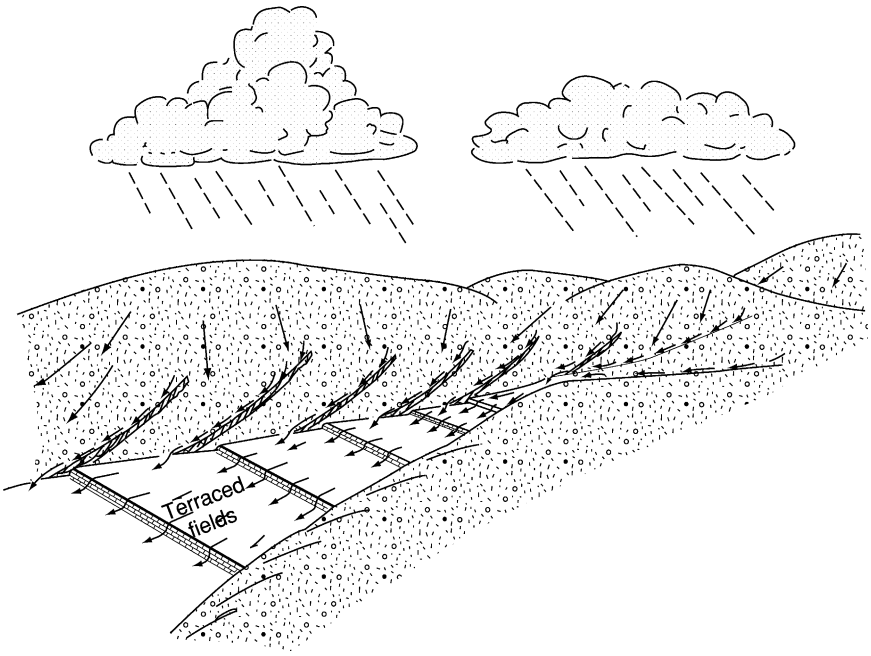

Figure 4 Ancient runoff farming in the Negev: water trickling off barren slopes was directed to terraced fields in the *wadi* bed. Reprinted from *Environmental Soil Physics*, Hillel D (ed.). Copyright (1998), with permission from Elsevier.

intense rainstorms and therefore no substantial natural runoff. Human enterprises dependent on the collection and utilization of runoff must therefore ensure, first of all, that there be a minimally sufficient water supply even in years of drought. Methods of runoff inducement can greatly contribute to this end.

Modern Methods

Modern technology holds the promise of more efficient runoff inducement than was possible in ancient times. The simplest, though generally most expensive, way to induce runoff is to cover the surface with an impervious apron of such materials as plastic, rubber, or aluminum sheeting, or by asphalt or concrete paving. A possibly more economical approach is to cause the soil itself to shed, rather than absorb, the rain. Runoff from natural surfaces can be increased several-fold by means of mechanical treatments (stone clearing, smoothing, and compaction), as well as by a variety of chemical treatments to encrust and stabilize the surface so as to prevent erosion of the runoff-contributing areas. Accordingly, the soil surface can be made water-repellent and relatively impermeable by treating it with sprayable clay-dispersants, sealers, and hydrophobic agents. The following series of treatments can be applied:

1. Eradication of vegetation and removal of surface stones, to reduce interception of rain and obstruction of overland flow, and to permit the formation of a continuous surface crust;
2. Smoothing of land surface, to obliterate surface depressions and prevent the retention of water in puddles;
3. Compaction of the soil top-layer to reduce its permeability. This can be done by means of a roller at optimal soil moisture content;
4. Dispersion of soil colloids to cause crusting, by means of sprayable solutions of sodic salts. This treatment pertains to soils that contain sufficient clay to be dispersible, but not so much as to exhibit marked shrinkage and cracking;
5. Impregnation of the surface with a sealing and binding substance such as an emulsion of asphalt that can form a water-repellent and stable coating.

With such methods, it is possible not only to increase the total yield per unit area of the watershed, but also to decrease the threshold of rain needed to form runoff and thus to increase the frequency of runoff supply and contribute to the efficiency and economic feasibility of agricultural and engineering systems designed to utilize runoff. In a desert with a seasonal rainfall of 250 mm, for instance, yields as high as 200 000 m^3 of water may be obtainable per square kilometer of treated area per season.

Several systems have been tried with respect to the size and arrangement of the contributing area in relation to water-receiving areas or reservoirs. A small watershed may be treated in its entirety so as to provide the maximal amount of water at the outflow

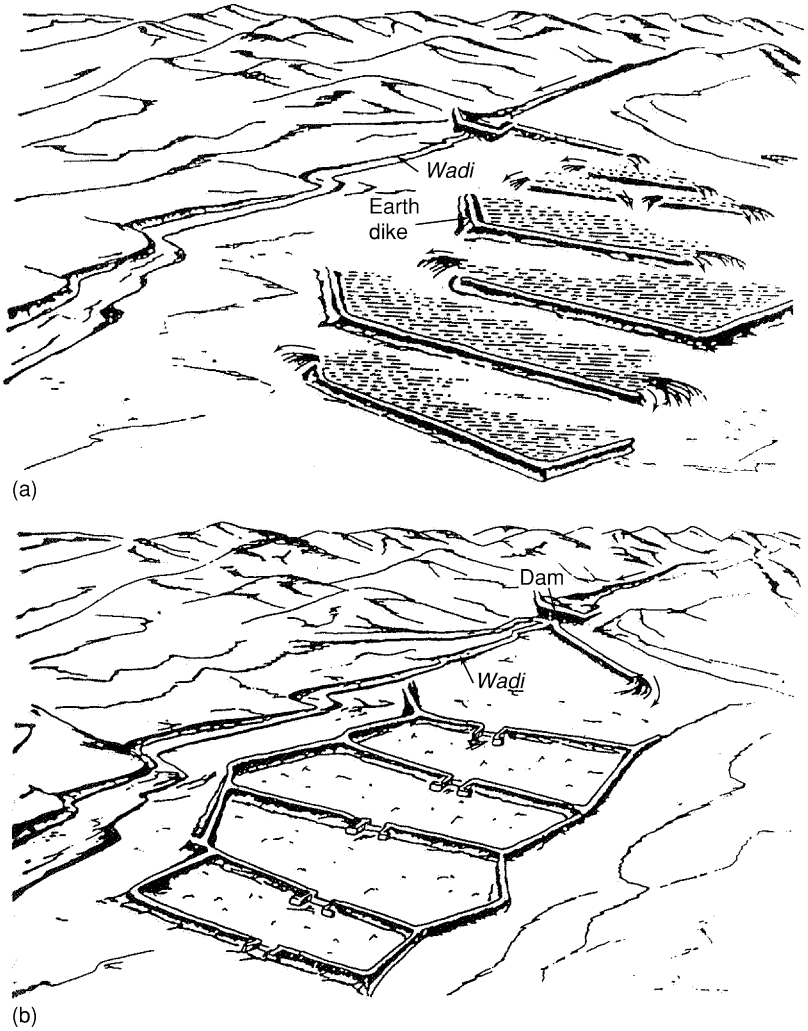

Figure 5 Two general methods of water spreading by diversion from an intermittent stream (a *wadi*) on to adjacent land: (a) diversion of an uncontrolled flow over unleveled land by means of a zigzag series of earthen dikes; and (b) diversion of a controlled flow from a detention dam to a series of level basins with concrete- or stone-lined spillways. Reproduced from Hillel D (1982) *Negev: Land, Water, and Life in a Desert Environment*. New York: Praeger Publishers. © D Hillel.

of the basin for conveyance to a pond or a series of irrigated fields. Another system of runoff farming may consist of strips treated to shed runoff, alternating with basins or areas treated to receive and absorb the runoff (Figure 6). A third possibility is to form microwatersheds, wherein each contributing area serves a single tree or row of plants.

In the ancient runoff-farming systems found in the Negev of Israel, the measured ratio of runoff-contributing areas to the runoff-receiving areas is generally between 30:1 and 20:1. In a region with a mean annual rainfall of 100 mm and a mean runoff yield of 10%, a 'runoff-to-runon' area ratio of 10:1 would double the effective water supply to an agricultural plot, a 20:1 area ratio would triple it, and a 30:1 ratio would quadruple it. The latter ratio would provide 400 mm (100 mm of rain plus 300 mm of runon) to a plot of arable land that would otherwise receive only 100 mm. (These data are hypothetical.) If using methods of runoff inducement can increase the mean runoff yield to approximately 50%, then the runoff-to-runon area ratio may be reduced to about

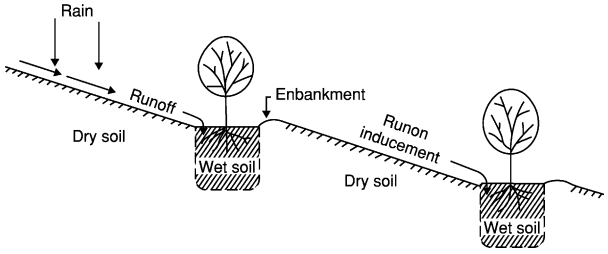

Figure 6 Schematic of a modern runoff-farming system. Reprinted from *Environmental Soil Physics*, Hillel D (ed.). Copyright (1998), with permission from Elsevier.

6:1 or even less. Moreover, the number of months or seasons without a minimally sufficient water supply (owing to the paucity of rain during a drought) would diminish and the entire system could thereby operate with a greater probability of success.

Introduction

Water status in soils is characterized by both the amount of water present and its energy state. Soil water is subjected to forces of variable origin and intensity, thereby acquiring different quantities and forms of energy. The two primary forms of energy of interest here are kinetic and potential. Kinetic energy is acquired by virtue of motion and is proportional to velocity squared. However, because the movement of water in soils is relatively slow (usually less than 0.1 $m\,h^{-1}$) its kinetic energy is negligible. Potential energy, which is defined by the position of soil water within a soil body and by internal conditions, is largely responsible for determining soil water status under isothermal conditions.

Like all other matter, soil water tends to move from where the potential energy is higher to where it is lower, in pursuit of equilibrium with its surroundings. The magnitude of the driving force behind such spontaneous motion is a difference in potential energy across a distance between two points of interest. At a macroscopic scale, we can define potential energy relative to a reference state. The standard state for soil water is defined as pure and free water (no solutes and no external forces other than gravity) at a reference pressure, temperature, and elevation, and is arbitrarily given the value of zero.

The 'Total' Soil Water Potential and its Components

Soil water is subject to several force fields, the combined effects of which result in a deviation in potential energy relative to the reference state, called the 'total soil water potential' (ψ_T) defined as: "The amount of work that an infinitesimal unit quantity of water at equilibrium is capable of doing when it moves (isothermally and reversibly) to a pool of water at similar standard (reference) state, i.e., similar pressure, elevation, temperature and chemical composition." It should be emphasized that there are alternative definitions of soil water potential using concepts of chemical potential or specific free energy of the chemical species water (which is different from the soil solution termed 'soil water'). Recognizing that these fundamental concepts are subject to ongoing debate, presented here are simple and widely accepted definitions which are applicable at macroscopic scales and which yield an appropriate framework for practical applications.

The primary forces acting on soil water held within a rigid soil matrix under isothermal conditions can be conveniently grouped as: (1) matric forces

resulting from interactions of the solid phase with the liquid and gaseous phases; (2) osmotic forces owing to differences in chemical composition of soil solution; and (3) body forces induced by gravitational and other (e.g., centrifugal) inertial force fields.

The thermodynamic approach, whereby potential energy rather than forces are used, is particularly useful for equilibrium and flow considerations. Equilibrium would require the vector sum of these different forces acting on a body of water in different directions to be zero; this is an extremely difficult criterion to deal with in soils. On the other hand, potential energy, mathematically defined as the negative integral of the force over the path taken by an infinitesimal amount of water when it moves from a reference location to the point under consideration, is a scalar (not a vector) quantity. Subsequently, we can express the total potential as the algebraic sum of the component potentials corresponding to the different fields acting on soil water as:

$$\psi_T = \psi_m + \psi_s + \psi_p + \psi_z \qquad [1]$$

where the component potentials ψ_i are discussed below.

ψ_m is the matric potential resulting from the combined effects of capillarity and adsorptive forces within the soil matrix. The primary mechanisms for these effects include: (1) capillarity caused by liquid–gas interfaces forming and interacting within the irregular soil-pore geometry; (2) adhesion of water molecules to solid surfaces due to short-range London–van der Waals forces and extension of these effects by cohesion through hydrogen bonds formed in the liquid; and (3) ion hydration and water participating in diffuse double layers (particularly near clay surfaces). There is some disagreement regarding the practical definition of this component of the total potential. Some consider all contributions other than gravity and solute interactions (at a reference atmospheric pressure). Others use a device known as a tensiometer to measure and provide a practical definition of the matric potential in a soil volume of interest in contact with a tensiometer's porous cup. The value of ψ_m ranges from zero when the soil is saturated to increasingly negative values as the soil becomes drier (note that $\psi_m = 0$ mm is greater than $\psi_m = -1000$ mm; in analogy, a temperature of 0°C is greater than −10°C). (*See* **Capillarity.**)

Applied theories for flow and transport in unsaturated porous media, particularly at low water content, commonly lump capillary and adsorptive forces without distinguishing individual contributions to the matric potential. Advanced frameworks simultaneously consider individual contributions of capillary and adsorptive forces for calculation of liquid–vapor interfacial configurations in angular pore spaces. The liquid–vapor interface is considered as a surface of constant, partial specific Gibbs free-energy (or matric potential) made up of an adsorptive component (A) and a capillary component (C):

$$\psi_m = A(h) + C(\kappa) \qquad [2]$$

with κ as the mean curvature of the liquid–vapor interface, and h as the distance from the solid to the liquid–vapor interface, taken normal to the solid surface (thickness of the adsorbed film). The capillary component C is given by the classic Young–Laplace equation:

$$C(\kappa) = \frac{-2 \cdot \sigma \cdot \kappa}{\rho} \qquad [3]$$

where κ is positive for an interface concave outward from the liquid, σ is the surface tension at the interface, and ρ is the density of the liquid. (*See* **Capillarity.**)

The adsorptive component in eqn [2] is attributed to two types of surface forces. The first kind includes long-range (>500 Å) electrostatic forces (e.g., diffuse double layer, DDL), and short-range (<100 Å) van der Waals and hydration forces, responsible for molecular interactions and structural changes in water molecules near the solid surface. The second kind is comprised of long-range forces due to the overlapping of two interfacial regions (e.g., mutual attraction between two clay platelets across a slit-shaped pore space). The combined effect of interfacial interactions results in a difference in chemical potentials between the liquid in the adsorbed film and the bulk liquid phase. This difference in chemical potentials may be expressed as an equivalent interfacial force per unit area of the interface, termed the 'disjoining pressure' (Π). The disjoining pressure is a function of liquid film thickness (h), and it can also be viewed as the difference between a normal component of film pressure, P_N (in equilibrium with the gaseous phase $P_N = P_G$), and the pressure in the bulk liquid phase, P_L:

$$\Pi(h) = P_N(h) - P_L = P_G - P_L \qquad [4]$$

The disjoining pressure is related to more conventional thermodynamic quantities such as Gibbs free energy. Gibbs free energy (G) per unit area of the interface may be defined on the basis of $\Pi(h)$ isotherms for constant pressure P_L, temperature T, and chemical (μ) and electric potentials of the liquid–gaseous and the liquid–solid interfaces as:

$$G(h) = -\int_{\infty}^{h} \Pi(h)\mathrm{d}h \qquad [5]$$

The value of $G(h)$ is equal to the work of thinning the film in a reversible isobaric–isothermal process from ∞ to a finite thickness h, with $\Pi(h) = -(\partial G/\partial h)_{T,\, P_L,\, \mu,\, \psi_g,\, \psi_s}$. The use of $\Pi(h)$ as the basic thermodynamic property is not a mere change of notation, but $\Pi(h)$ has advantages in cases where Gibbs thermodynamic theory is difficult to define, such as when interfacial zones overlap to the extent that the film does not retain the intensive properties of the bulk phase. The use of the disjoining pressure is advantageous from an experimental point of view because of the relative ease in accounting for different contributions (e.g., electrostatic effects).

The disjoining pressure is a sum of several components, similar to the concept of total soil water potential discussed above. The primary components of $\Pi(h)$ in porous media are: molecular, $\Pi_m(h)$; electrostatic, $\Pi_e(h)$; structural, $\Pi_s(h)$; and adsorptive $\Pi_a(h)$:

$$\Pi(h) = \Pi_m(h) + \Pi_e(h) + \Pi_s(h) + \Pi_a(h) \qquad [6]$$

$\Pi_m(h)$

The molecular component originates from van der Waals interaction between macro-objects (e.g., parallel clay plates). Various expressions, with $\Pi_m(h)$ often proportional to h^{-3}, were derived by Paunov *et al.* and Iwamatsu and Horii.

$\Pi_e(h)$

The electrostatic component of the disjoining pressure is calculated from the solution of the Poisson–Boltzmann equation for the DDL with appropriate boundary conditions. Approximate solutions are adequate for many applications, often with $\Pi_e(h) \propto h^{-2}$.

$\Pi_s(h)$

Some controversy exists regarding the origin of the structural component; some attribute it to changes in the structure (density) of water adjacent to solid surfaces and deformation of hydrated shells, while others attribute this force to the presence of a layer with a lower dielectric constant near the surface. Regardless of its exact origin, this component is responsible for the so-called hydration repulsion which stabilizes dispersion and prevents coagulation of some colloidal particles, even at high electrolyte concentrations: $\Pi_s(h) \propto h^{-1}$.

$\Pi_a(h)$

The adsorptive component of the disjoining pressure results from nonuniform concentrations in the water film due to unequal interaction energies of solute and solvent with interfaces in nonionic solutions. This is different to the nonuniform distribution of charged ions. This component of the disjoining pressure is likely to become very important for interactions between nonpolar molecules (e.g., NAPLs) which give rise to repulsive forces in the liquid film.

The form of the disjoining pressure isotherm $\Pi(h)$ is determined by the nature of surface forces. While the molecular component $\Pi_m(h)$ is always present, the influence of other components depends on surface properties, liquid polarity and its composition, and adsorption of dissolved components. The range of the electrostatic forces in dilute solutions of a 1:1 electrolyte (10^{-6}–10^{-7} mol l^{-1}) is in the range of 0.3–1.0 μm. Consequently, thick films of water and aqueous electrolyte solutions ($h > 500$ Å) are stable mainly through the $\Pi_e(h)$ component of disjoining pressure. The magnitude and contribution of $\Pi_e(h)$ primarily depend on the charges of the film and substrate surfaces. Dispersion forces become appreciable in the range $h < 500$ Å, and their influence is enhanced by large differences between the permittivity of the liquid and the solid. The forces of structural repulsion may come to play when the film thickness is less than 100 Å.

ψ_s is the solute or osmotic potential determined by the presence of solutes in soil water, which lower its potential energy and its vapor pressure. The effects of ψ_s are important when: (1) there are appreciable amounts of solutes in the soil; and (2) in the presence of a selectively permeable membrane or a diffusion barrier which transmits water more readily than salts. The effects of ψ_s are otherwise generally negligible when only liquid water flow is considered and no diffusion barrier exists. The two most important diffusion barriers in the soil are: (1) soil–plant root interfaces (cell membranes are selectively permeable); and (2) air–water interfaces; thus when water evaporates, salts are left behind. In dilute solutions the solute potential, also called the osmotic pressure, is proportional to the concentration and temperature according to:

$$\psi_s = -RT\,C_s \qquad [7]$$

where ψ_s is in kilopascals, R is the universal gas constant (8.314×10^{-3} kPa m^3/(mol K)), T is absolute temperature (Kelvin), and C_s is solute concentration (moles per cubic meter). A useful approximation which may be used to estimate ψ_s in kilopascals from the electrical conductivity of the soil solution at saturation (EC_s) in deciSiemens per meter (dS m^{-1}) is:

$$\psi_s \approx -36\,EC_s \qquad [8]$$

ψ_p is the pressure potential, defined as the hydrostatic pressure exerted by unsupported water that

saturates the soil and overlays a point of interest. Using units of energy per unit weight provides a simple and practical definition of ψ_p as the vertical distance from the point of interest to the free water surface (unconfined water table elevation). The convention used here is that ψ_p is always positive below a water table, or zero if the point of interest is at or above the water table. In this sense, nonzero magnitudes of ψ_p and ψ_m are mutually exclusive: either ψ_p is positive and ψ_m is zero (saturated conditions), or ψ_m is negative and ψ_p is zero (unsaturated conditions), or $\psi_p = \psi_m = 0$ at the free water table elevation. Note that some prefer to combine the pressure and matric components into a single term, which assumes positive values under saturated conditions and negative values under unsaturated conditions. Based on operational and explanatory considerations, we prefer to adopt the more commonly used separate components protocol.

ψ_z is the gravitational potential, which is determined solely by the elevation of a point relative to some arbitrary reference point, and is equal to the work needed to raise a body against the Earth's gravitational pull from a reference level to its present position. When expressed as energy per unit weight, the gravitational potential is simply the vertical distance from a reference level to the point of interest. The numerical value of ψ_z itself is thus not important (it is defined with respect to an arbitrary reference level) – what is important is the difference (or gradient) in ψ_z between any two points of interest. This value is invariant of the reference level location.

Soil water is at equilibrium when the net force on an infinitestimal body of water equals zero everywhere, or when the total potential is constant in the system. Though the last statement is a logical consequence of the definitions above, it is not strictly true. Constant total potential is a necessary but not a sufficient condition, and, for thermodynamic equilibrium to prevail, three conditions must be met simultaneously: (1) thermal equilibrium or uniform temperature; (2) mechanical equilibrium, meaning no net convection-producing force; and (3) chemical equilibrium, meaning no net diffusional transport or chemical reaction. In most practical applications, however, the macroscopic definition of the total potential and equilibrium conditions based on it are completely adequate.

The difference in chemical and mechanical potentials between soil water and pure water at the same temperature is known as the soil water potential (ψ_w):

$$\psi_w = \psi_m + \psi_s + \psi_p \qquad [9]$$

Note that the gravitational component (ψ_z) is absent in this definition. Soil water potential is thus the result of inherent properties of soil water itself, and of its physical and chemical interactions with its surroundings; whereas the total potential includes the effects of gravity (an 'external' and ubiquitous force field).

Total soil water potential and its components may be expressed in several ways depending on the definition of a 'unit quantity of water.' Potential may be expressed as (1) energy per unit of mass; (2) energy per unit of volume; or (3) energy per unit of weight. A summary of the resulting dimensions, common symbols, and units are presented in Table 1.

Only μ has actual units of potential; ψ has units of pressure, and h of head of water. However, the above terminology (i.e., potential energy expressions rather than units of potential per se) is widely used in a generic sense in the soil and plant sciences. The various expressions of soil water energy status are equivalent, with:

$$\mu = \frac{\psi}{\rho_w} = gh \qquad [10]$$

where ρ_w is density of water ($1000\,kg\,m^{-3}$ at 20°C) and g is gravitational acceleration ($9.81\,m\,s^{-2}$).

Measurement of Potential Components

Water Potential

A psychrometer (Figure 1) is commonly used for measurement of total water potential (ψ_w) in soils. The potential of the soil solution is in thermodynamic equilibrium with its ambient water vapor. Taking the vapor pressure above pure water at reference state ($\psi_w = 0$) as e_o, the vapor pressure (e) over a salt

Table 1 Units, dimensions, and common symbols for potential energy of soil water

Units	*Symbol*	*Name*	*Dimensions*	*SI units*	*CGS units*
Energy/mass	μ	Chemical potential	$L^2 t^{-2}$	$J\,kg^{-1}$	$erg\,g^{-1}$
Energy/volume	ψ	Soil water potential, suction, or tension	$ML^{-1}t^{-2}$	$N\,m^{-2}$(Pa)	$dyn\,cm^{-2}$
Energy/weight	h	Pressure head	L	m	cm

L, length; *M*, mass; *t*, time.

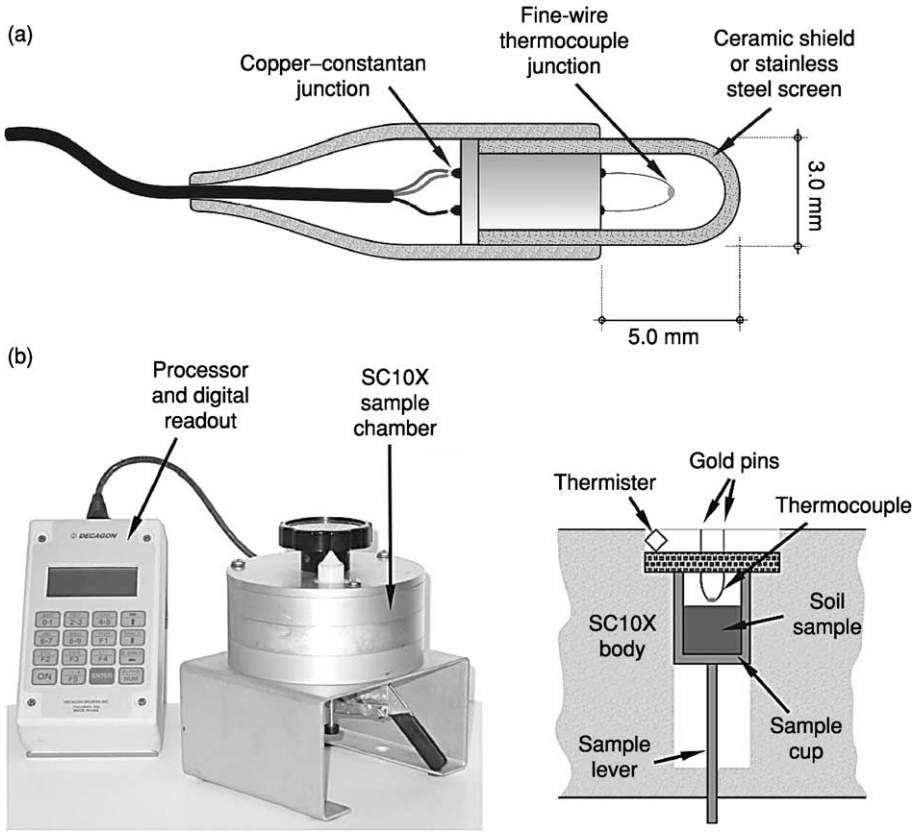

Figure 1 (a) A field psychrometer with porous ceramic shield (Wescor Inc., Logan, Utah, USA); and (b) SC10X sample chamber for psychrometric laboratory measurements of soil water potential (Decagon Devices Inc., Pullman, Washington, USA).

solution or soil water held in soil pores by matric forces is depressed relative to the reference state, i.e., $e < e_o$. A convenient measure obtained by the psychrometer is the relative vapor pressure of the ambient soil atmosphere, which is related to the water potential (ψ_w) of soil water through the well-known Kelvin equation:

$$\mathrm{RH} = \frac{e}{e_o} = \exp\left[\frac{M_w \psi_w}{\rho_w R T}\right] \qquad [11]$$

where e is water vapor pressure (kilopascals), e_o is saturated vapor pressure at the same temperature, M_w is the molecular weight of water ($0.018\,\mathrm{kg\,mol^{-1}}$), R is the ideal gas constant ($8.31\,\mathrm{J\,K^{-1}\,mol^{-1}}$ or $0.008314\,\mathrm{kPa\,m^3\,mol^{-1}\,K^{-1}}$), T is absolute temperature (Kelvin), and ρ_w is the density of water ($1000\,\mathrm{kg\,m^{-3}}$ at 20°C). Rearranging and taking a log-transformation of eqn [11] yields an expression for water potential ψ_w:

$$\psi_w = \frac{R T \rho_w}{M_w} \ln\left(\frac{e}{e_o}\right) \qquad [12]$$

The water potential in drier soils is lower such that fewer water molecules 'escape' into the ambient atmosphere, resulting in lower relative humidity (lower relative vapor pressure). Concentrated soil solutions having lower osmotic potentials have similar effect on reducing vapor pressure, as more water molecules are associated with hydrated salt molecules and are less free to 'escape' the liquid state. The inability to distinguish between matric and osmotic effects limits psychrometric measurements to soil water potential only. In some cases where the osmotic potential is negligible, psychrometric measurements are used to infer the matric potential.

Pressure Potential

Piezometers are commonly applied to measure ψ_p. A piezometer (Figure 2) is a tube that is placed in the soil to depths below the water table and that extends to the soil surface and is open to the atmosphere. The bottom of the piezometer is perforated to allow soil water under positive hydrostatic pressure to enter the tube. Water enters the tube and rises to a height equal to that of the unconfined water table. The elevation of the free water table is measured relative to the soil surface using a steel tape with bell sounder, or other electro-optic devices that indicate water table depth. The value of pressure potential

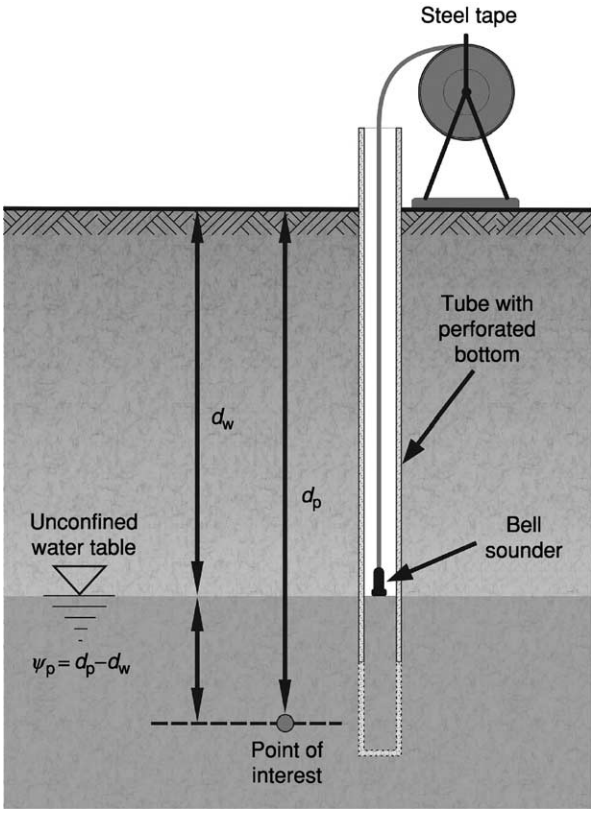

Figure 2 The concept of piezometer measurements.

expressed as energy per weight is simply the vertical distance from a point of interest to the surface of the free water table. Pressure potentials above the water table surface are always zero (nonzero pressure and matric potentials are mutually exclusive).

Matric Potential

Tensiometers or heat-dissipation sensors are commonly applied to measure soil matric potential. A tensiometer consists of a porous cup, usually made of ceramic and having very fine pores, connected to a vacuum gauge through a water-filled tube (Figure 3). The porous cup is placed in intimate contact with the bulk soil at the depth of measurement. When the matric potential of the soil is lower (more negative) than inside the tensiometer, water moves from the tensiometer along a potential energy gradient to the soil through the saturated porous cup, thereby creating suction sensed by the gauge. Water flow into the soil continues until equilibrium is reached and the suction inside the tensiometer equals the soil matric potential. When the soil is wetted, flow may occur in the reverse direction, i.e., soil water enters the tensiometer until a new equilibrium is attained. The tensiometer equation is:

$$\psi_m = \psi_{gauge} + (z_{gauge} - z_{cup}) \quad [13]$$

with ψ_{gauge} the reading at the vacuum gauge location and z indicating depth. The vertical distance from the gauge plane to the cup, expressed as a negative quantity, must be added to the matric potential measured by the gauge (ψ_{gauge}) in order to obtain the matric potential at the depth of the cup. This accounts for the positive head exerted by the overlying tensiometer water column at the depth of the ceramic cup. Note that using the difference in vertical elevation is appropriate only when potentials are expressed per unit of weight. Electronic sensors called pressure transducers often replace mechanical vacuum gauges. The transducers convert mechanical pressure into an electric signal which can be more easily and more precisely measured. In practice, pressure transducers can provide more accurate readings than other gauges, and in combination with data-logging equipment are able to supply continuous measurements of matric potential.

The tensiometer range is limited to suctions (absolute values of the matric potential) of less than 100 kPa, i.e., 1 bar, 10 m head of water, or ~1 atmosphere. Therefore other means are needed for matric potential measurement under drier conditions.

Heat-dissipation sensors may be applied for a matric potential range from −10 to −1000 kPa. The rate of heat dissipation in a porous medium is dependent on the medium's specific heat capacity, thermal conductivity, and density. The heat capacity and thermal conductivity of a porous matrix are affected by its water content. Heat dissipation sensors contain heating elements in line or point source configurations embedded in a rigid porous matrix with fixed pore space. The measurement is based on application of a heat pulse by applying a constant current through the heating element for specified time period, and analysis of the temperature response measured by a thermocouple placed at a fixed distance from the heating source. With the heat dissipation sensor buried in the soil, changes in soil water matric potential result in a gradient between the soil and the porous ceramic matrix, inducing water flow between the two materials until a new equilibrium is established. The water flow changes the water content of the ceramic matrix which, in turn, changes the thermal conductivity and heat capacity of the sensor, and hence the measured temperature response to the applied heat pulse.

As already mentioned above, for cases where the osmotic potential is negligible, psychrometric measurements can be used to infer the matric potential. A typical range for psychrometers is −800 to −10 000 kPa.

Osmotic Potential

Soil water solutions contain varied quantities and compositions of dissolved salts. The relationships between the salt concentration and ψ_s, and the possibility for estimating ψ_s from the electrical conductivity (EC) of the soil solution, were discussed above. Conventional measurement of soil solution EC involves solution extraction from saturated soil samples and measuring the EC using an electrical conductivity meter (**Figure 4a**).

Electrical conductivity meters rely on Ohm's law:

$$E = I \cdot R \qquad [14]$$

with E the electromotive force (volts), I the current flow (amperes), and R the resistance (ohms). For constant voltage, the current flowing through the solution is inversely proportional to the electrical resistance, or directly proportional to the electrical conductance. The solution EC is thus determined from known voltage and electrode geometry and measurement of the electric current. More recently, a variety of *in situ* methods such as time-domain reflectometry (TDR) have been used to deduce soil bulk EC from electromagnetic signal attenuation, hence enabling simultaneous measurements of water content and soil EC in the same undisturbed soil volume. Concurrent knowledge of θ and EC can be used to infer the soil solution EC, and hence to estimate ψ_s.

WATER RETENTION AND CHARACTERISTIC CURVE

M Tuller, University of Idaho, Moscow, ID, USA

Introduction

A soil-water characteristic (SWC) curve describes the amount of water retained in a soil (expressed as mass or volume water content, θ_m or θ_v) under equilibrium at a given matric potential. An SWC is an important hydraulic property, related to size and connectedness of pore spaces, hence strongly affected by soil texture and structure, and by other constituents, including organic matter. Modeling water distribution and flow in partially saturated soils requires knowledge of the SWC, therefore plays a critical role in water management and in prediction of solute and contaminant transport in the environment. Typically a SWC is highly nonlinear and is relatively difficult to obtain accurately. Because the matric potential extends over several orders of magnitude for the range of water contents commonly encountered in practical applications, the matric potential is often plotted on a logarithmic scale. Figure 1 depicts representative SWC curves for soils of different textures, demonstrating the effects of porosity (saturated water content) and the varied slopes of the relationships resulting from variable pore-size distributions.

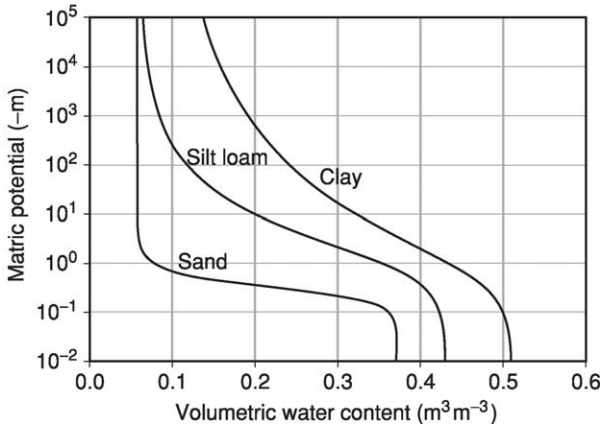

Figure 1 Typical soil-water characteristic curves for soils of different texture.

The Matric Potential

The matric potential is attributed to capillary and adsorptive forces acting between liquid, gaseous, and solid phases. Capillarity results from the surface tension of water and its contact angle with the solid particles. Under partially saturated conditions (i.e., in the presence of the nonwetting air phase), curved liquid–vapor interfaces (menisci) form within the porous soil system. Menisci radii of curvature (R) are a function of capillary pressure (P_c) and are calculated according to the Young–Laplace equation:

$$P_0 - P_c = \Delta P = \frac{2\sigma}{R} \qquad [1]$$

where P_0 is the atmospheric pressure (conventionally referenced as zero), P_c is the pressure of the soil water, and σ is the surface tension of the liquid–vapor interface. If soil pores were behaving as a bundle of capillary tubes, capillarity would be sufficient to describe the relationships between matric potential and soil pore radii. However, in addition to capillarity, the soil also exhibits adsorption, which forms hydration envelopes over the particle surfaces. The presence of water in films is most important in clayey soils with large surface area and is influenced by the electric double layer and the exchangeable cations present. In sandy soils, adsorption is relatively insignificant and the capillary effect predominates. In general, however, matric potential results from the combined effect of capillarity and surface adsorption. The capillary 'wedges' are at a state of internal equilibrium with adsorption 'films,' and the two cannot be considered separately. (*See* **Water Potential; Capillarity.**)

The Bundle of Cylindrical Capillaries Model

Early conceptual models for the SWC and liquid distribution in partially saturated porous media are based on the 'bundle of cylindrical capillaries' (BCC)

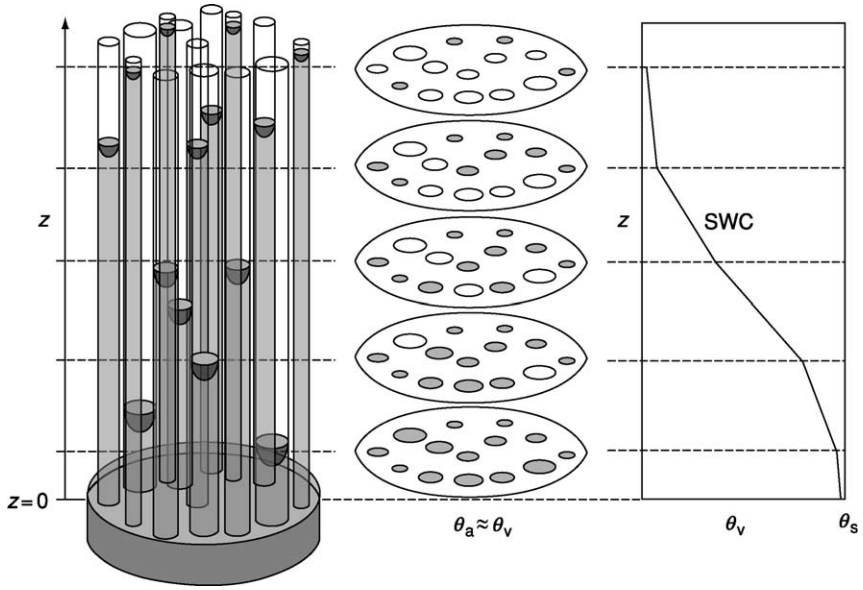

Figure 2 Relationship between the pore space, as represented by the bundle of cylindrical capillaries model, and the soil-water characteristic (SWC). Greater capillary rise occurs in smaller pores, which have smaller radii of meniscus curvature. (Note that z indicates the elevation above free water, θ_a stands for pore volume, θ_v for volumetric water content, and θ_s for volumetric water content at saturation.)

representation of pore-space geometry. The BCC representation postulates that at a given matric potential a portion of interconnected cylindrical pores is completely liquid-filled, whereas larger pores are completely empty (Figure 2). This convenient idealization of soil pore space enables a linkage between the soil pore size distribution and the SWC based on the capillary-rise equation. (*See* **Capillarity**.) However, such representation imposes serious limitations on the practical application of the BCC model to natural porous media as discussed in the following section, including the unrealistic underlying geometry that precludes dual water–air occupancy within the same pores and lack of consideration of adsorbed water films.

Liquid Retention and Pore Shape

Liquid retention in the porous soil matrix is highly dependent on the shape and angularity of individual pores. Inspection of thin sections or soil micrographs (Figure 3) reveals that natural pore spaces do not resemble cylindrical capillaries, as often assumed for an idealized representation. Because natural porous media are formed by aggregation of primary particles and mineral surfaces, the resulting pore space is more realistically described by angular or slit-shaped pore cross-sections than by cylindrical capillaries. In addition to a more realistic representation of natural pore spaces, angular pores offer other advantages over cylindrical tubes in terms of liquid behavior. When angular pores are drained, a fraction of the wetting phase remains in the pore corners (Figure 3c). This aspect of 'dual occupancy' of the invaded portion of the tube, not possible in cylindrical tubes, more realistically represents liquid configurations and mechanisms for maintaining hydraulic continuity in porous media. Liquid-filled corners and crevices play an important role in displacement rates of oil and in other transport processes in partially saturated porous media.

The relationships between liquid retention and pore angularity are known. The water-filled cross-sectional area A_{wt} for all regular and irregular triangles and for regular, higher-order polygons is given by the following expression:

$$A_{wt} = r^2 \cdot F(\gamma) \qquad [2]$$

where r is the radius of curvature of the liquid–vapor interface that is dependent on chemical potential (μ) or capillary pressure (p_c) according to the Young–Laplace equation:

$$\mu = \frac{\sigma}{r\rho} \qquad \text{or} \qquad p_c = \frac{\sigma}{r} \qquad [3]$$

with σ as the surface tension of the liquid, ρ the density of the liquid, and $F(\gamma)$ a shape or angularity factor dependent on angularity of the pore cross-section only. Note that in this discussion we consider

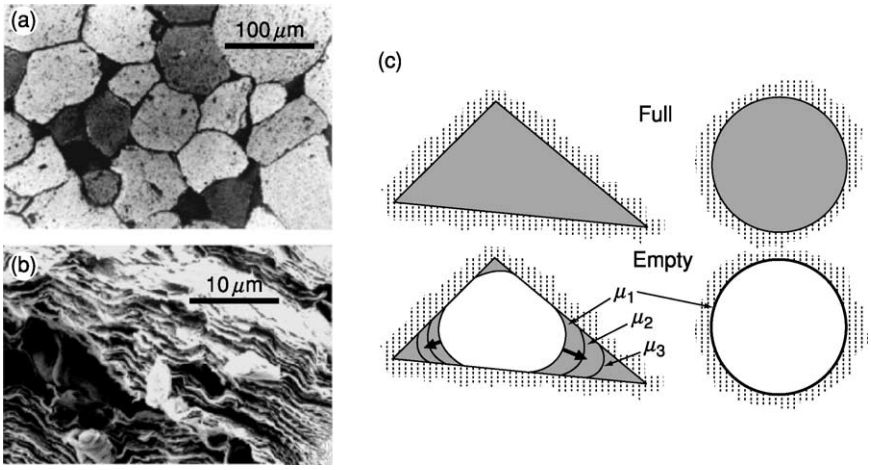

Figure 3 Angular pore space in natural porous media: (a) thin section of Devonian sandstone. AAPG Mem. 28); (b) scanning electron micrograph (SEM) of calcium-saturated montmorillonite; (c) liquid retention in triangular and cylindrical pores. μ, chemical potential.

capillary behavior only, ignoring adsorbed liquid films that cover the flat pore surfaces.

In contrast to the piston-like filling or emptying of circular capillaries, angular pores undergo different filling stages and spontaneous displacement in the transition from dry to wet or vice versa. At relatively dry conditions (low chemical potentials), thin liquid films are adsorbed on all flat surfaces of the angular pore, and liquid accumulates in corners due to capillary forces. A further increase in chemical potential leads to further increase in film thickness and to an increase in the radius of capillary interface curvature in the corners, until the capillary corner menisci contact to form an inscribed circle. At this critical potential, liquid fills up the central pore spontaneously (snap-off). The radius of interface curvature at this critical point is equal to the radius of an inscribed circle in the pore cross-section:

$$r_{\text{imb}} = \frac{2 \cdot A}{P} = \frac{P}{4[F(\gamma) + \pi]} \qquad [4]$$

where r_{imb} is the radius of spontaneous imbibition, A is pore cross-sectional area, and P is the perimeter of the pore cross-section. For drainage, at a certain potential a liquid–vapor meniscus invades the pore and liquid is displaced from its center, leaving liquid in the corners. The radius of curvature at onset of drainage, r_{d}, is expressed in terms of perimeter (P) and the angularity factor $F(\gamma)$:

$$r_{\text{d}} = \frac{P}{2 \cdot [(F(\gamma) + \pi) + \sqrt{\pi \cdot (F(\gamma) + \pi)}]} \qquad [5]$$

An example of the effects of pore shape (and angularity) on imbibition and drainage processes is depicted in Figure 4, showing marked differences between cylindrical and angular pores having equal pore cross-sectional areas. Liquid displacement in cylindrical tubes during drainage is piston-like, leaving no liquid in the cross-section after the drainage threshold. Angular pores, on the other hand, show that liquid is displaced from the central region first (at a radius of curvature given by eqn [5], leaving some liquid in the corners. Subsequent decrease in chemical potential results in commensurate decreasing amounts of liquid in the corners ('lower' chemical potential or capillary pressure indicates more negative values, much like the terminology for the subzero temperature scale). The threshold chemical potential for different pore shapes with the same cross-sectional area increases (becomes less negative) with increasing angularity factor $F(\gamma)$. The same holds for the amount of liquid held in the corners.

The conditions during imbibition are slightly different. Liquid–vapor interfaces in corners of angular pores expand with increasing chemical potential to the point of snap-off (eqn [4]), where the pore completely fills up with liquid. The threshold chemical potential for snap-off increases with angularity $F(\gamma)$, and the amount of liquid held in the corners at a given chemical potential is directly proportional to angularity. Highly angular pore shapes such as triangular pores retain more liquid at the same potential than squares or hexagons (Figure 4). In the extreme case of cylindrical tubes, no liquid is held prior to spontaneous filling by snap-off (the 'empty–full' behavior).

Modeling SWC

Measuring the SWC is laborious and time-consuming. Measured θ–ψ_m pairs are often fragmentary, and usually constitute relatively few measurements over the wetness range of interest. For modeling and analysis purposes, and for characterization and comparison between different soils and scenarios, it is therefore beneficial to represent the SWC in a mathematically continuous form. Several approaches, ranging from empirical parametric expressions to physically based models with parameters derived from measurable medium properties, to pore network or lattice Boltzmann simulations can be employed to represent a continuous SWC.

Empirical SWC Models

Key requirements for all parametric SWC expressions are parsimony (as few parameters as possible), to simplify parameter estimation, and accurate description of SWC behavior at the limits (wet and dry ends) while closely fitting the nonlinear shape of θ–ψ_m measurements.

An effective and commonly used parametric model for relating water content or effective saturation (Θ) to the matric potential was proposed by van Genuchten and is denoted as VG:

$$\Theta = \frac{\theta - \theta_r}{\theta_s - \theta_r} = \left[\frac{1}{1 + (\alpha\,\psi_m)^n}\right]^m \qquad [6]$$

θ_r and θ_s are the residual and saturated water contents, respectively, ψ_m is matric potential, and α, n, and m are parameters directly dependent on the shape of the $\theta(\psi_m)$ curve. A common simplification is to assume that $m = 1 - 1/n$. Thus the parameters required for estimation of the model are θ_r, θ_s, α, and n. θ_s is sometimes known and is easy to measure, leaving only the three unknown parameters θ_r, α, and n to be estimated from the experimental data in many cases. Note that θ_r is sometimes taken as θ at -1.5 MPa, $\theta_{air\ dry}$, or a similar meaningful

value, though it is often advantageous to use it as a fitting parameter.

Another well-established parametric model is denoted by BC (Brooks–Corey):

$$\Theta = \frac{\theta - \theta_r}{\theta_s - \theta_r} = \left(\frac{\psi_b}{\psi_m}\right)^{\lambda} \qquad \psi_m > \psi_b$$
$$\Theta = 1 \qquad \psi_m \leq \psi_b \qquad [7]$$

where ψ_b is a parameter related to the soil matric potential at air entry (b represents 'bubbling pressure'), and λ is related to the soil pore-size distribution. Matric potentials are expressed as positive quantities (i.e., in absolute values) in both VG and BC parametric expressions. Campbell uses the same power law function as BC to express degree of saturation ($S = \theta/\theta_s$) as a function of the air entry potential ψ_b and a factor b that can be related to soil texture:

$$\frac{\theta}{\theta_s} = \left(\frac{\psi_b}{\psi_m}\right)^{\frac{1}{b}} \qquad [8]$$

ψ_b and b are derived as functions of the geometric mean diameter and geometric standard deviation of the particle-size distribution. Equation [8] is often used in relation to the fractal idealization of the soil porous system as discussed below.

Estimation of VG or BC parameters from experimental data requires sufficient data points to characterize the shape of the SWC, and a program to perform nonlinear regression. Many computer spreadsheet software packages provide relatively simple and effective mechanisms to perform nonlinear regression.

Figure 5 depicts fitted parametric VG and BC models to silt loam $\theta(\psi_m)$ data. The resulting best-fit parameters for the VG model are: $\alpha = 0.417\,m^{-1}$; $n = 1.75$; $\theta_s = 0.513\,m^3\,m^{-3}$; and $\theta_r = 0.05\,m^3\,m^{-3}$ (with $r^2 = 0.99$). For the BC model, the best-fit parameters are: $\lambda = 0.54$; $\psi_b = 1.48\,m$; $\theta_s = 0.513\,m^3\,m^{-3}$; and $\theta_r = 0.03\,m^3\,m^{-3}$ (with $r^2 = 0.98$). Note that the most striking difference between the VG and the BC models is the discontinuity at $\psi = \psi_b$ in the BC model.

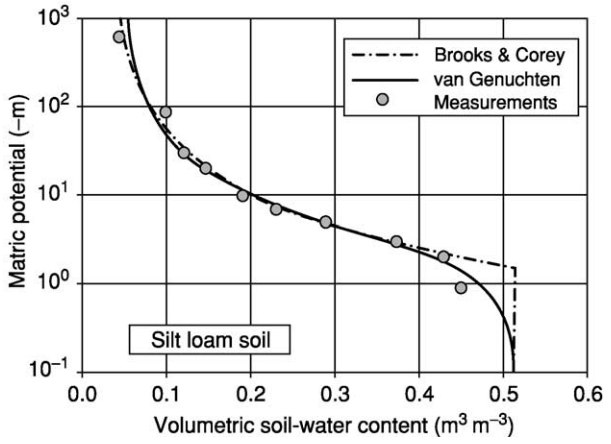

Figure 5 van Genuchten and Brooks and Corey parametric models fitted to measured data for silt loam soil.

Representative measured SWC information based on the VG and BC parametric models is available from a variety of sources. The UNSODA computer database compiled by the US Salinity Laboratory contains an exhaustive collection of soil-water retention and unsaturated hydraulic conductivity information for soils of different textures from around the world. While the authors have attempted to provide some indices concerning quality or reliability of the compiled data, users are advised (as always) to use their own experience and discretion in adapting others' data to their own applications. Regression studies provide a wealth of information on the BC parameter values for many soils. These include estimation of the hydraulic parameters based on other, often more easily available soil properties. These estimates may be sufficiently accurate for some applications and could be used to obtain first-order approximations. Table 1 contains listed values for the VG parameters α and n, and the residual and saturated water contents for various soil textural classes compiled from the UNSODA database. Note that substantial variation in SWC relationships for given soil textural classes is to be expected.

The models introduced so far can be categorized as empirical curve-fitting functions with free model parameters related to the specific shape of the employed

Table 1 Typical van Genuchten model parameters (α, n) including residual (θ_r) and saturated (θ_s) water contents compiled from the UNSODA database

Textural class	*N*	θ_r ($cm^3\,cm^{-3}$)	θ_s ($cm^3\,cm^{-3}$)	α (cm^{-1})	n

mathematical function, rather than to physical properties of the porous medium. Relationships between the SWC and the pore-size distribution have been established, which can be described as a statistical log-normal distribution function. Brutsaert, and more recently Kosugi, established relationships between the SWC and the pore-size distribution, which can be described as a statistical log-normal distribution function. They idealized the soil porous system as a BCC with log-normal distributed radii, and apply the capillary-rise equation to establish a relationship between the matric potential and effective medium saturation. (*See* **Capillarity.**)

The applicability of the latter models is limited to coarse-textured soils and to conditions where capillary forces are the major contributor to the matric potential. They tend to fail in finer-textured soils with high specific surface area (e.g., clay soils) where adsorptive surface forces dominate, especially under drier conditions. (*See* **Water Potential.**)

Fractal Representation of the Soil Pore Space and the SWC

Fractals are hierarchical, often highly complex, spatial, or temporal systems that are generated with iterative algorithms obeying simple scaling rules. Patterns within such systems repeat themselves over a defined range of scales (self-similarity). This enables the reproduction of statistical properties of a particular pattern at other length or time scales. Fractal geometry can be applied to describe quantitatively irregularity and shape of natural objects by estimating their fractal dimension. Several theoretical models have been proposed to derive the SWC from the fractal representations of the soil porous system. There are two general approaches, based on either surface or mass fractals. Surface fractal models assume that water is only present in the form of adsorbed liquid films on pore surfaces, whereas mass fractal models assume that only capillary water obeying the capillary-rise equation is present within the fractal system. As with the BCC approach, fractal models for the SWC are based on derivation of the pore-size distribution from the fractal structure under consideration, neglecting pore connectivity and topology issues. Crawford presented the following relationship between the mass-fractal dimension (D_m) and the degree of saturation (S):

$$S = \left(\frac{\psi_m}{\psi_b}\right)^{(D_m - d_e)} \quad [9]$$

where ψ_m is the matric potential under consideration, ψ_b is the matric potential at the air entry point, and d_e is the embedding dimension. The embedding dimension equals 2 in two-dimensional systems and 3 in three-dimensional space. Note that the mass-fractal dimension D_m is always less than d_e. Due to the identical functional form, eqn [9] is commonly equated with Campbell's version of the B&C SWC function (eqn [8]) to derive Campbell's b-factor from the fractal dimension ($b = -1/(D_m - d_e)$).

Fractal approaches are limited due to the assumption that fractal scaling is valid over an infinite range of matric potentials. In reality natural porous media have lower and upper scaling limits related to their minimum and maximum pore sizes. Perfect proposed a mass-based model for the SWC that accounts for the finite range of the matric potential. Systems that are fractal over a finite range of scales are called prefractal.

Physically Based Models for the SWC

In contrast to the BCC and fractal approaches, angular pore-space models accommodate both capillary and adsorptive phenomena on internal surfaces. The basic unit pore element (**Figure 6**) is comprised of an angular central pore attached to slit-shaped spaces and is defined by the dimensionless slit-width and slit-length scaling parameters α and β, and the central pore length L. Variation of the cell parameters allows accommodation of a wide range of soil textural and structural classes. Sandy soils, for example, may be represented by a relatively large central pore length, and small values for β (i.e., small specific surface area). Fine-textured soils (e.g., clays) on the other

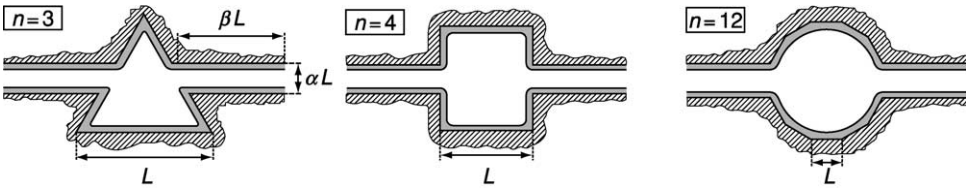

Figure 6 Basic unit elements of the angular pore space model of Tuller *et al.* (Reproduced from Tuller M, Or D, and Dudley LM (1999) Adsorption and capillary condensation in porous media-liquid retention and interfacial configurations in angular pores. *Water Resources Research* 35(7): 1949–1964.)

hand can be represented by relatively small L and large β to account for the high internal surface areas often observed in such soils.

Despite the higher complexity of the angular pore-space model, it has distinct advantages over the more commonly applied BCC approach. First, angular pores more realistically represent natural porous medium pore space and allow dual occupancy of wetting and nonwetting phases (see the section Liquid Retention and Pore Shape, above). The potential of accommodating adsorptive surface forces leads to a more accurate derivation of the SWC for porous media with high specific surface areas as well as under dry conditions.

A modified form of the augmented Young–Laplace equation that considers capillary and adsorptive contributions to the matric potential is employed to calculate liquid–vapor interfaces within a cross-section of the angular pore model. In addition, dynamic liquid displacement mechanisms (see the section Liquid Retention and Pore Shape, above) derive SWC functions for imbibition or drainage at the pore scale. Figure 7 depicts a typical transition of a unit element from dry to wet (imbibition) that includes spontaneous liquid displacement (snap-off) in slits (Figure 7b) and in the central pore (Figure 7d).

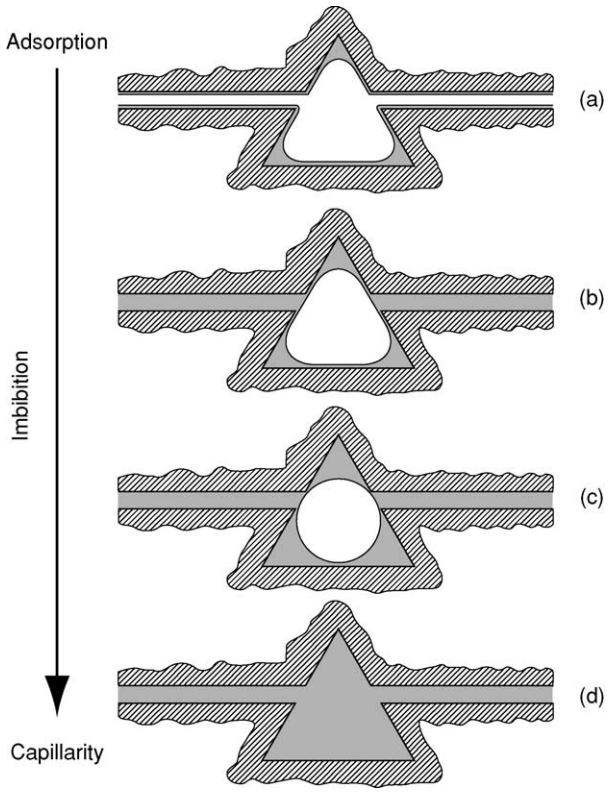

Figure 7 Unit element filling stages during imbibition. (a) Liquid films adsorbed on pore and slit walls and liquid held in corners due to capillary forces at low matric potentials; (b) spontaneous slit fill-up (capillary condensation); (c) pore snap-off; (d) full unit element.

A statistical upscaling scheme using a gamma density function for the central pore length L can be used to represent liquid behavior at the sample scale. The gamma distribution is given preference because it resembles the commonly observed positive skewness of soil pore-size distributions, and at the same time facilitates the derivation of analytical solutions for the SWC.

The upscaling procedure leads to a physically based expression for the SWC, where the degree of saturation (S) defined as a function of matric potential is expressed as the sum of functions corresponding to various pore-filling mechanisms and stages, as depicted in Figure 7. Figure 8a depicts a sample application for the Millville silt loam soil. Because the model calculates the configuration of liquid–vapor interfaces within pores and films, adsorptive and capillary contributions to the SWC can be separated (Figure 8a). Such separation is not possible with any of the empirical or semiempirical approaches presented above. Another important feature of this model is the ability to predict liquid–vapor interfacial area as shown in Figure 8b, comparing model predictions for sand with known surface area of 0.01–0.05 $m^2\,g^{-1}$. The magnitude and changes in liquid vapor interfacial area play an important role in multiphase flow processes, bioremediation of contaminated soils, gas-exchange phenomena, and virus and colloid transport.

Lattice Boltzmann Approach

Lattice Boltzmann models (LBM) are descendants of lattice gas cellular automata, which follow the motions of individual particles and were first presented as a viable means of solving Navier–Stokes equations. In the most simplistic sense, LBMs work with distributions of particles at each lattice point rather than with individual particles. LBMs simulate interactions of hypothetical particles confined to a regular lattice, which greatly enhances solvability of the Boltzmann equation. This has advantages for certain types of simulations in that averaging is not required to obtain smooth velocity fields.

The lattice Boltzmann method has emerged as a powerful tool for simulation of multiphase fluid systems, including water and water vapor. The LBM incorporates complex details of pore shape that characterize realistic porous media, fluid factors, and solid–fluid interactions in a physically sound way, leading to realistic simulation of interfaces between different fluids or between a liquid and its vapor and adsorption of wetting films. Interfaces arise, deform,

and migrate in virtually any pore geometry rather naturally without the need for complex interface tracking algorithms.

An example of LBM application to compute water retention in complex porous media is shown as insets in Figure 9, which are based on two-dimensional (2-D) imagery of a real soil. Vapor and liquid boundaries of equal pressure were applied to the top and bottom of the domain, respectively, in steps corresponding to equal increments of log(−matric

potential). The matric potential is expressed in mass units per time step squared (equivalent to energy per unit volume in a 3-D system). Each potential step was terminated when the relative change in fluid mass in the domain was negligibly small. The simulated liquid behavior and SWC curve show appreciable differences in fluid configurations during wetting and drying that resulted from hysteresis.

Pore Network Models and the SWC

Network models were first developed by Fatt, based on the idea that pore space may be represented as an interconnected network of capillary tubes whose radii represent the dimensions of the pores within a porous medium. For a given matric potential, liquid–vapor interfacial configurations within the network can be determined exactly, based on pore-scale capillary and dynamic displacement considerations. The macroscopic SWC is then determined based on geometric volume averaging of the spatially distributed liquid within the network. A primary advantage of pore network models is explicit consideration of pore connectivity and topology in a simplified and mathematically tractable framework. Some of the limitations involve oversimplification of pore-scale physics (e.g., neglect of adsorptive pore-scale processes), incomplete understanding of interface migration and routing, inadequate technologies for inference of network parameters from real samples, and significant computational burden for detailed 3-D networks even at a core scale (greater than 100 mm).

Hysteresis of the SWC

Water content and the potential energy of soil water are not uniquely related, because the amount of water present at a given matric potential is dependent on the pore-size distribution and the properties of air–water–solid interfaces. An SWC relationship may be obtained by: (1) taking an initially saturated sample and applying suction or pressure to desaturate it (desorption), or (2) gradually wetting an initially dry soil (sorption). These two pathways produce curves that in most cases are not identical; the water content in the 'drying' curve is higher for a given matric potential than that in the 'wetting' branch (Figure 10a). This is called 'hysteresis,' defined as "the phenomenon exhibited by a system in which the reaction of the system to changes is dependent upon its past reactions to change."

The hysteresis in SWC can be related to several phenomena, including: (1) the 'ink bottle' effect, resulting from nonuniformity in shape and sizes of interconnected pores; drainage is governed by the smaller pore radius r, whereas wetting is dependent on the large radius R (Figure 10c); (2) different liquid–solid contact angles for advancing and receding water menisci (Figure 10b); (3) entrapped air in

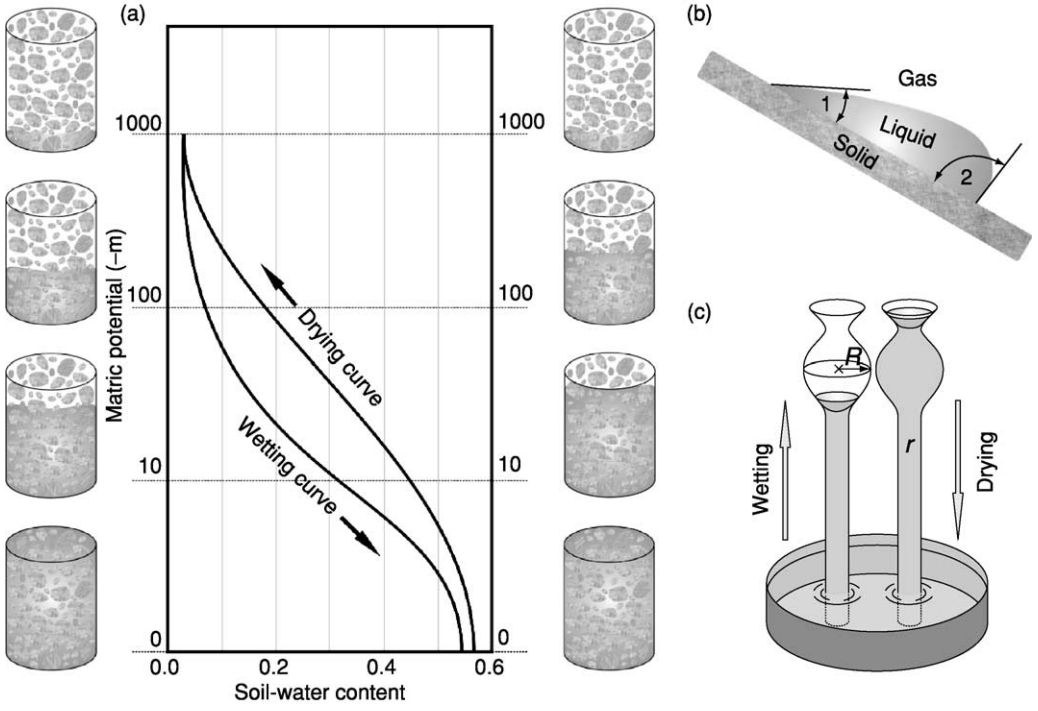

Figure 10 (a) Hysteresis of the soil-water characteristic. (b) The contact angle effect and (c) the ink bottle effect as potential mechanisms for hysteresis.

a newly wetted soil (e.g., pore doublet); and (4) swelling and shrinking of the soil under wetting and drying. The role of individual factors remains unclear and is subject to ongoing research.

Part of the hysteresis phenomena may be attributed to measurement artifacts, for example due to differences between tension- and pressure-induced desaturation. A potentially important aspect of desorption methods under tension is the possibility of liquid displacement (drainage) even in the absence of a continuous gaseous phase due to cavitation initiated by encapsulated gas bubbles or the liquid's own vapor pressure. Surface heterogeneity and impurities in soil and rock water are conducive to lowering the cavitation threshold.

Measurement of SWC Relationships

A variety of methods may be used to obtain requisite θ and ψ_m values to estimate the SWC. Potential experimental problems include: the limited functional range of the tensiometer, which is often used for *in situ* measurements; inaccurate θ measurements in some cases; the difficulty in obtaining undisturbed samples for laboratory determinations; and a slow rate of equilibrium under low matric potential (i.e., dry soils).

In situ methods are preferred in defining SWCs, as is measuring over a wide range of ψ_m and θ values. An effective method to obtain simultaneous measurements of ψ_m and θ_v is by installing time-domain

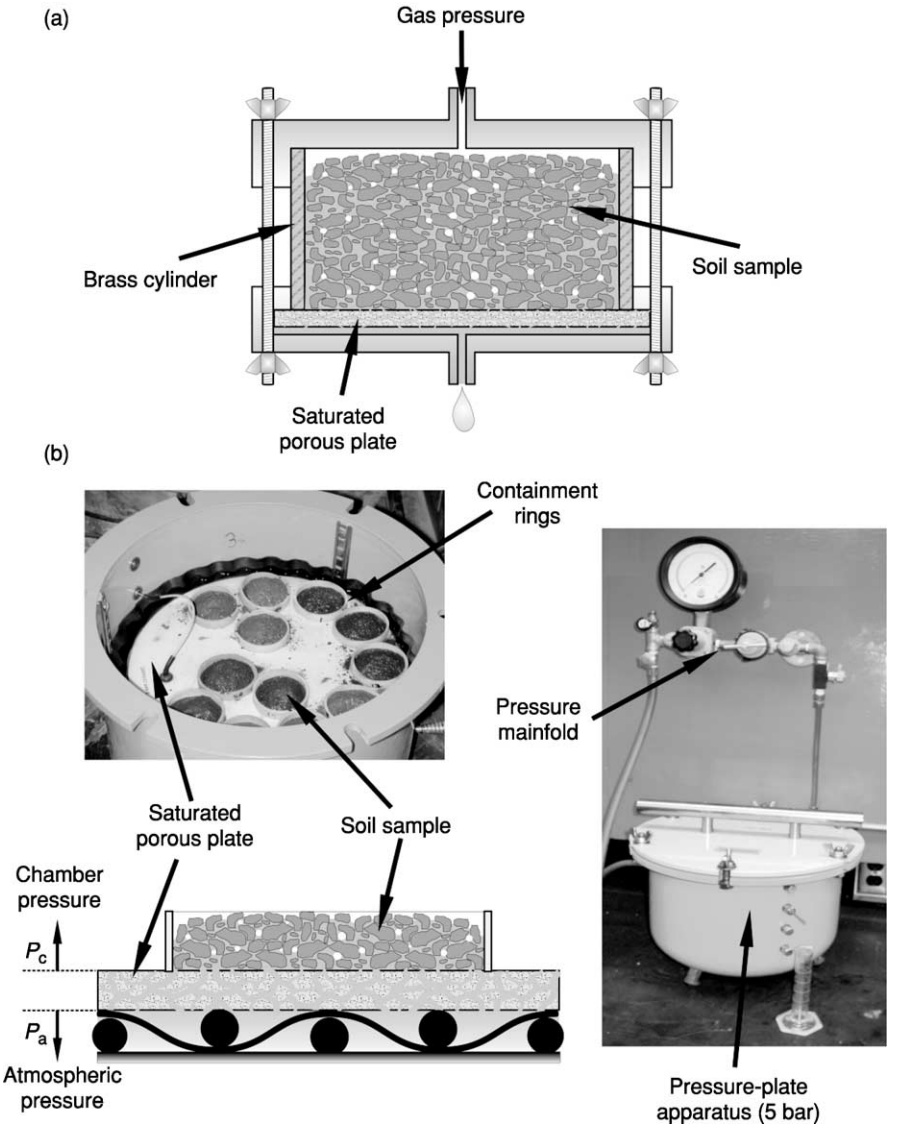

Figure 11 (a) Tempe pressure and flow cell; and (b) pressure-plate apparatus used to desaturate soil samples to specified matric potentials.

reflectometry (TDR) probes in close proximity to transducer tensiometers, with the attributes monitored during variable soil wetness. Large changes in ψ_m and θ_v are expected under highly evaporative conditions near the soil surface, or in the presence of active plant roots.

Pressure-Plate Apparatus and Pressure-Flow Cells

The pressure-plate apparatus comprises a pressure chamber enclosing a water-saturated porous plate, which allows water but not air to flow through its pores (Figure 11b). The porous plate is at atmospheric pressure at the bottom, while the top surface is at the applied pressure of the chamber. Soil samples, usually sieved to less than 2 mm, are placed in retaining rings in contact with the porous plate and allowed to saturate by immersion in water. The porous plate with saturated soil samples is then placed in the chamber and a known N_2 or air gas pressure is applied to force water out of the soil through the plate. Water flows out of the soil until equilibrium between the force exerted by the air pressure and the force by which soil water is being held by the soil (ψ_m) is attained.

Soil water retention at the wet end (less than 1 bar) is strongly influenced by the soil structure and its natural pore-size distribution. Hence, 'undisturbed' intact soil samples (cores) are preferred over repacked samples for this portion of the SWC. The pressure-flow cell (also known as Tempe cell) can hold intact soil samples encased in metal rings (Figure 11a). The operation of the Tempe cell follows that of the pressure plate, except its pressure range is usually limited to 0–1 bar or 0.1 MPa. The porous ceramic material used in pressure plates and flow cells must be completely water-saturated prior to use. Following equilibrium between soil matric potential and the applied air pressure, the soil samples are removed from the apparatus, weighed wet, then oven-dried to determine the mass water content gravimetrically. These may be converted to volume water contents through knowledge of the sample bulk densities. The water content of repacked soils at a given matric potential should not be used to infer θ of intact soils at the same ψ_m, due to modified pore sizes and pore geometry.

Multiple pressure steps may be applied to the same soil samples when using Tempe cells. The cells may be sequentially disconnected from the pressure source, weighed to determine the change in water content from the previous step, then reconnected and the next pressure step applied. Outflow of water from the cells may be collected to calculate or confirm changes in sample water contents.

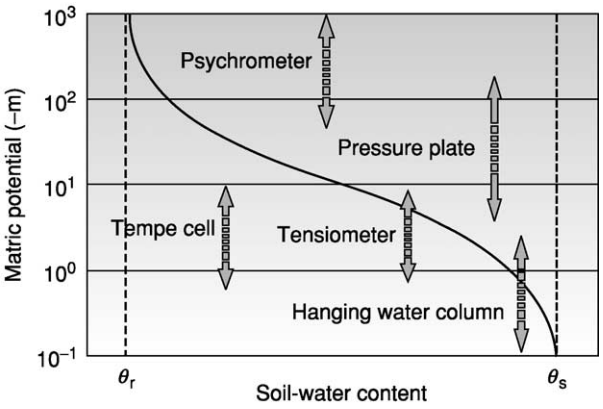

Figure 12 Some common soil-water characteristic measurement methods and their corresponding matric potential ranges.

Paired Sensors for Field SWC Measurement

In spite of the importance of measuring SWCs *in situ*, few suitable methods are available for field or *in situ* application. Paired sensors may be used to measure θ and ψ_m in the same or closely adjacent soil volumes, over a range of soil wetness. Examples include use of neutron moisture-meter access tubes or TDR waveguides, together with tensiometers. Application of paired sensors is often constrained by differences in soil volumes sampled by the respective sensors, different time constants required (e.g., many sensors obtain instantaneous measurements, while many ψ_m methods require equilibrium), and the fact that few matric-potential techniques function over the entire range of interest for wetness. This commonly provides limited overlap in soil water retention measured using different techniques, and measurements obtained using different methods may not be consistent in the ranges of overlap.

Figure 12 presents some common methods to measure or infer soil matric potential, including their respective ranges of application. Many of the available techniques have a limited range of overlap or do not overlap at all, and few of the methods are amenable to field measurements.

Introduction

Our planet is the planet of life primarily because it is blessed with the precise ranges of temperature and pressure that make possible the existence in a liquid state of a singular substance called water. So ubiquitous is water on our globe, covering nearly three-quarters of its surface, that the entire planet really should be called 'Water' rather than 'Earth.' However, as Coleridge's Ancient Mariner complained, most of the water everywhere is unfit to drink. Less than 1% of the water on earth is 'fresh' (i.e., non-saline) water, and that amount is unevenly distributed. Humid regions are endowed with an abundance of it, even with a surfeit, so that often the problem is how to dispose of excess water. Arid and semiarid regions, on the other hand, are afflicted with a chronic shortage.

Life as we know it began in an aquatic medium and water is still the principal constituent of living organisms. It is, literally, the essence of life. As Vladimir Vernadsky wrote a century ago: "Life is animated water." Though we appear to be solid, we are really liquid bodies, similar to gelatin, which also seems solid but is in fact largely water, made consistent by the presence of organic material. The analogous material in our bodies is protoplasm. The water content of a newborn infant is nearly 90% water by mass, and even in adults it is over 65%. Actively growing herbaceous plants typically contain over 90% water. Far from being a bland, inert liquid, water is a highly reactive substance, a solvent and a transporter of numerous substances.

The importance of water was recognized early in history, yet little was known about its real nature. In the Middle Ages, people believed that fresh water emanated magically from the bowels of the earth. They could not imagine that all the water flowing in innumerable springs and mighty rivers (such as the Nile, which appeared to the ancient Egyptians to come out of the driest desert!) could possibly result from so seemingly feeble a source as rain and snow. The first to conjecture this was Leonardo da Vinci, but only in the latter part of the seventeenth century did the English astronomer Edmond Halley and, separately, the Frenchman Claude Perrault prove the principle by calculation and measurement. Water was long thought to be a single element, until early in the eighteenth century, when it was found to consist of hydrogen and oxygen in combination.

Notwithstanding its ubiquity, water remains something of an enigma, possessing unusual and anomalous attributes. Perhaps the first anomaly is that, being a compound of two gases and having relatively low molecular weight, water is a liquid and not a gas at normal temperatures. (Its sister compound, hydrogen sulfide, H_2S, has a boiling-point temperature of $-60.7°C$.) Compared with other common liquids, water has unusually high melting and boiling points, heats of fusion and vaporization, specific heat, dielectric constant, viscosity, and surface tension.

Molecular Structure

One cubic meter of liquid water at 20°C contains about 3.4×10^{28} (34 billion billion billion) molecules, the diameter of which is about 3×10^{-10} meter ($3\times10^{-4}\,\mu$m, or about 3 Angstrom units). The chemical formula of water is H_2O, which signifies that each molecule consists of two atoms of hydrogen and one of oxygen. There are three isotopes of hydrogen (^{1}H, ^{2}H, ^{3}H) and three of oxygen (^{16}O, ^{17}O, ^{18}O), which can form 18 combinations. However, all isotopes but ^{1}H and ^{16}O are quite rare.

The hydrogen atom consists of a positively charged proton and a negatively charged electron. The oxygen atom consists of a nucleus having a positive charge of eight protons, surrounded by eight electrons, of which six are in the outer shell. Since the outer electron shell of hydrogen lacks one electron and that of oxygen lacks two electrons, one atom of oxygen can combine with two atoms of hydrogen in an electron-sharing molecule.

The strong intermolecular forces in liquid water are caused by the electrical polarity of the water molecule, which in turn is a consequence of the arrangement of electrons in its oxygen and hydrogen atoms (Figure 1). The oxygen atom shares a pair of electrons with each of the two hydrogen atoms, through overlap of the 1s orbitals of the hydrogen atoms with two hybridized sp^3 orbitals of the oxygen atom. The H–O–H bond in water is not linear but bent

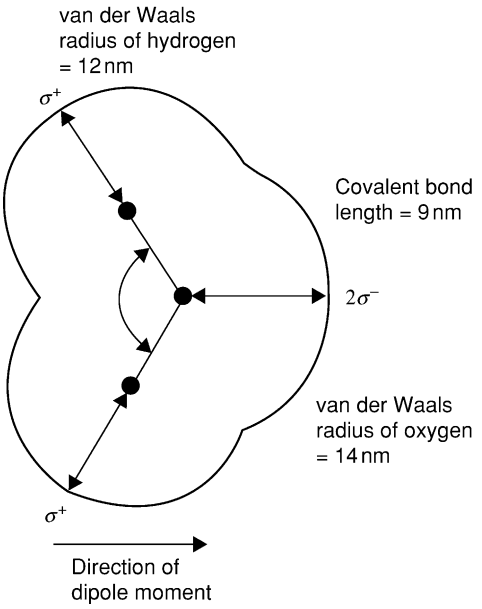

Figure 1 Model of a water molecule. The curved lines represent the borders at which van der Waals attractions are counterbalanced by repulsive forces. Reprinted from *Environmental Soil Physics*, Hillel D (ed.). Copyright (1998), with permission from Elsevier.

at an angle of 104.5°. That angle deviates slightly from a perfectly tetrahedral arrangement of the oxygen atom's four possible sp^3 orbitals, which would have an angle of 109.5°. The mean H-O interatomic distance is 9.65×10^{-5} μm. The arrangement of electrons in the molecule gives it electrical asymmetry. The electronegative oxygen atom tends to attract the single electrons of the hydrogen atoms, leaving the hydrogen nuclei bare. Hence, each of the two hydrogen atoms has a local partial positive charge. The oxygen atom, in turn, has a partial negative charge, located in the zone of the unshared orbitals. Thus, though the water molecule has no net charge, it forms an electrical dipole.

Hydrogen Bonding

Every hydrogen proton, while attached primarily to a particular molecule, is also attracted to the oxygen of the neighboring molecule, with which it forms a secondary link known as a hydrogen bond. Though the intermolecular link resulting from dipole attraction is not as strong as the primary link of the hydrogen to the oxygen of its own molecule, water can be regarded as a polymer of hydrogen-bonded molecules. This structure is most complete in ice crystals, in which each molecule is linked to four neighbors via four hydrogen bonds, thus forming a hexagonal lattice with a rather open structure (Figure 2). When the ice melts, this rigid structure collapses partially, so additional molecules can

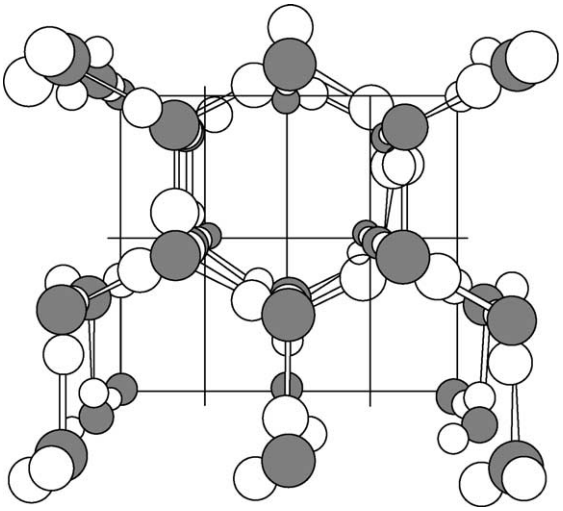

Figure 2 Schematic structure of an ice crystal. The oxygen atoms are shown in gray and the hydrogen atoms in white. The pegs linking adjacent molecules represent hydrogen bonds. Reprinted from *Environmental Soil Physics*, Hillel D (ed.). Copyright (1998), with permission from Elsevier.

enter the intermolecular spaces and each molecule can have more than four near neighbors. For this reason, liquid water can be more dense than ice at the same temperature, and thus lakes and ponds develop a surface ice sheet in winter rather than freeze solid from bottom to top as they would if ice were denser than liquid water.

States of Water

In the vapor or gaseous state, water molecules are largely independent of one another and occur mostly as monomers signified as $(H_2O)_1$. Occasionally, colliding molecules may fuse to form dimers $(H_2O)_2$ or even trimers, $(H_2O)_3$, but such combinations are rare. However, in the solid state a rigidly structured lattice forms with a tetrahedral configuration (Figure 2) that can be schematically depicted as sheets of puckered hexagonal rings (Figure 3). As many as nine alternative ice forms can occur when water freezes, depending on prevailing temperature and pressure conditions. Figure 3 pertains to ice 1, the familiar form, which occurs and is stable at ordinary atmospheric pressure.

The orderly structure of ice does not totally disappear in the liquid state. The polarity and hydrogen bonds continue to bind water molecules together, though the structural forms that develop in the liquid state are much more flexible and transient than in the rigidly structured solid state. Hydrogen bonds in liquid water form an extensive three-dimensional network, the detailed features of which appear to be short-lived. According to the 'flickering cluster' model discovered by Frank and Wen and modified

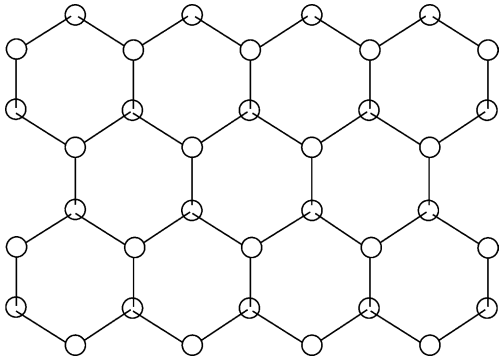

Figure 3 The crystalline structure of ice. Reprinted from *Environmental Soil Physics*, Hillel D (ed.). Copyright (1998), with permission from Elsevier.

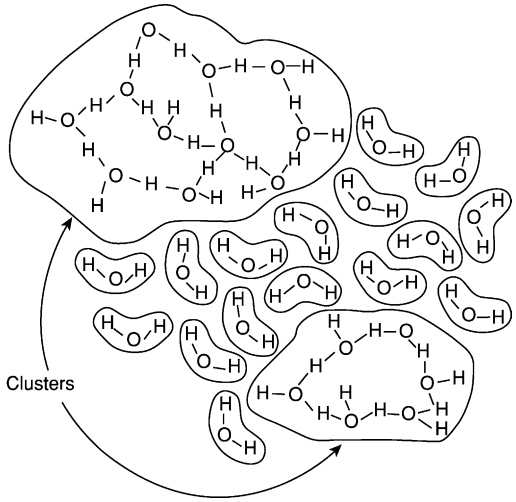

Figure 4 Schematic illustration of 'flickering clusters,' showing polymeric associations and monomeric molecules in liquid water. Reprinted from *Environmental Soil Physics*, Hillel D (ed.). Copyright (1998), with permission from Elsevier.

by Erland, the molecules of liquid water associate and dissociate repeatedly in transitory or flickering polymer groups, designated $(H_2O)_n$, having a quasi-crystalline internal structure. These microcrystals, as it were, form and melt so rapidly on the scale of picoseconds and randomly that, on a macroscopic scale, water appears to behave as a homogeneous liquid (Figure 4).

In transition from solid to liquid, and from liquid to gas, hydrogen bonds must be broken (while in freezing and condensation they are re-established). Hence relatively high temperatures and energies are required to achieve these transitions. To thaw 1 kg of ice, 3.35×10^5 J (80 cal g^{-1}) must be supplied. Conversely, the same energy (the latent heat of fusion) is released in freezing. At the boiling point (100°C at atmospheric pressure), water passes from the liquid to the gaseous state and in so doing it absorbs 2.26×10^6 J kg^{-1} (540 cal g^{-1}). This amount of heat is known as the latent heat of vaporization. Water can be vaporized at temperatures below 100°C, but such vaporization requires greater heat or lower atmospheric pressure. At 30°C, the latent heat is about 2.43×10^6 J kg^{-1} (580 cal g^{-1}). Sublimation is the direct transition from the solid state to vapor, and the heat absorbed by it is equal to the sum of the latent heats of fusion and of vaporization.

Ionization and pH

Because of its small mass and the tightness with which its single electron is bound to the oxygen atom, the nucleus of the hydrogen atom in the water molecule exhibits a finite tendency to dissociate from the oxygen with which it is covalently associated and to 'jump' to the adjacent water molecule, to which it is hydrogen-bonded. Such an event produces two ions: the hydronium ion (H_3O^+) and the hydroxyl ion (OH^-). The reaction described is reversible, and should be written as:

$$2H_2O \rightleftharpoons (H_3O)^+ + OH^-$$

However, by convention it is written simply as:

$$H_2O \rightleftharpoons H^+ + OH^-$$

and one speaks of 'hydrogen ions' rather than of 'hydronium ions.'

Although the self-ionization of water is small, its consequences are extremely important. The ionization is reversible, and it tends to an equilibrium state in which the rate of dissociation into ions equals the rate of ion reassociation to form molecules once again. For such a system in equilibrium (at which the concentration of each of the species H_2O, H^+, and OH^- remains constant), the law of mass action applies; i.e., the ratio of concentrations of the products and the reactants must be constant. Using brackets to denote concentration, we can write this in the following way:

$$K_{equil} = [H^+][OH^-]/[H_2O] \qquad [1]$$

Since the number of water molecules undergoing dissociation at any given time is very small relative to the total number of water molecules present, $[H_2O]$ can be considered constant. Assuming this concentration to be 55.5 mol l^{-1} (the number of grams per liter divided by the gram molecular weight: 1000/18 = 55.5 mol l^{-1}), we can simplify the equilibrium constant expression as follows:

$$55.5 \times K_{equil} = [H^+][OH^-], \text{or } K_w = [H^+][OH^-] \qquad [2]$$

in which K_w is a composite constant called the ion product of water. In fact, the concentrations of H^+ and OH^- ions in pure water at 25°C are 10^{-7} mol l^{-1}, an extremely small value when compared to the overall concentrations of (largely undissociated) water, namely 55.5 mol l^{-1}. Thus, K_w at 25°C is 10^{-14}. If the hydroxyl ion concentration $[OH^-]$ is changed, the hydrogen ion concentration $[H^+]$ changes automatically to maintain the constancy of the product, and vice versa. An excess concentration of hydrogen ions over the concentration of hydroxyl ions imparts to the aqueous medium the property of acidity, whereas a predominance of hydroxyl ions produces the opposite property of alkalinity or basicity. A condition in which the concentrations of H^+ and OH^- are equal is called neutrality.

The ion product of water, K_w, is the basis for the pH scale, a measure of the concentration of H^+ (and of OH^- as well) in any aqueous solution in the range of concentration between 1.0 mol l^{-1} H^+ and 1.0 mol l^{-1} OH^-. The pH is defined as

$$\mathrm{pH} = \log_{10} 1/[H^+] = -\log_{10}[H^+] \qquad [3]$$

As already stated, in a precisely neutral solution at 25°C,

$$[H^+] = [OH^-] = 1.0 \times 10^{-7} \mathrm{mol\,l^{-1}}$$

The pH of such a solution is

$$\mathrm{pH} = \log_{10}[1/(1 \times 10^{-7})] = 7.0$$

The pH value of 7.0 for a neutral solution is thus not arbitrary, but derives from the value of the ion product of water at 25°C. The pH scale is logarithmic, not arithmetic. If two solutions differ in pH by one unit, then one solution has 10 times the hydrogen ion concentration of the other. Thus, a pH of 6 implies a hydrogen ion concentration of 10^{-6} and a hydroxyl ion concentration of 10^{-8}. A pH of 5 indicates $[H^+] = 10^{-5}$ (acidity 10 times that of the above) and $[OH^+] = 10^{-9}$.

Solvent Properties of Water

Water dissolves or disperses many substances because of its polar nature. Hence it has been called the universal solvent. All chemical substances have finite solubilities in water, but these solubilities range widely. Many crystalline salts and other ionic compounds readily dissolve in water but are nearly insoluble in nonpolar liquids such as chloroform or benzene. Since the crystal lattice of salts, such as sodium chloride, is held together by very strong electrostatic attractions between alternating positive and negative ions, considerable energy is required to pull these ions away from one another. However, water dissolves sodium chloride because the strong electrostatic attraction between water dipoles and the Na^+ and Cl^- ions, forming stable hydrated Na^+ and Cl^- ions, exceeds the attraction of these ions to each other. In the case of Na^+, hydration is represented by the process:

$$Na^+ + (n+4)H_2O - Na(H_2O)_4(H_2O)_n^+$$

illustrated in Figure 5. In addition to hydration, there is also the hydrolysis of metal species, a reaction in which the metal ion displaces one of the protons (hydrogen) of water to form basic hydroxides.

Ion solvation is also aided by the tendency of the solvent to oppose the electrostatic attraction between ions of opposite charges. This is characterized by the dielectric constant D, which is defined by the relationship:

$$F = \kappa e_1 e_2 / \mathrm{D} r^2 \qquad [4]$$

Here F is the attractive force between two ions of opposite charge, κ is Coulomb's constant, e_1 and e_2 are charges on the ions, and r is the distance between them. Water has an extremely high dielectric constant, as shown in Table 1. For instance, the attractive force between Na^+ and Cl^- ions at a given distance in water is less than one-third that in ethanol and only

one-40th that in benzene. This fact greatly facilitates hydration of ions and dissolution of the crystal lattices of salts in water.

The effect of a solute on the solvent is manifest in a set of properties, namely, the colligative properties of solutions, which depend on the number of solute particles per unit volume of solvent. Solutes produce such characteristic effects in the solvent as depression of the freezing point and of the vapor pressure, and elevation of the boiling point. They also endow a solution with the property of osmotic pressure. Theoretically, 1 mol of an ideal solute dissolved in 1 kg of water at a pressure of 760 mm of mercury (0.1 MPa, or 1 bar) depresses the freezing point by 1.86°C and elevates the boiling point by 0.543°C. Such a solution also yields an osmotic pressure of 2.24 MPa (22.4 atm) in an appropriate apparatus. However, aqueous solutions usually deviate considerably from ideal behavior, and the deviations are greater the higher the concentrations. The quantitative relationships given above are exact only at infinite dilution.

Osmotic Pressure

Owing to the constant thermal motion of all molecules in a fluid (above a temperature of absolute zero), solute species spread throughout the solution in a spontaneous tendency toward a state of equal concentration throughout. This migration of solutes in response to spatial differences in concentration is called diffusion.

If a physical barrier is interposed between two regions, across the path of diffusion, and if that barrier is permeable to molecules of the solvent but not to those of the solute, the former will diffuse through the barrier in a process called osmosis (from the Greek $\omega\sigma\mu o\sigma$, meaning 'push'). As in the case of unhindered diffusion, this process tends toward a state of uniform concentration even across the barrier. Barriers permeable to one substance in a solution but not to another are called selective or semipermeable membranes. Membranes surrounding cells in living organisms, for example, exhibit selective permeability to water while restricting the diffusion of solutes between the cells' interior and their exterior environment. Water molecules cross the membrane in both directions, but the net flow of water is from the more dilute solution to the more concentrated.

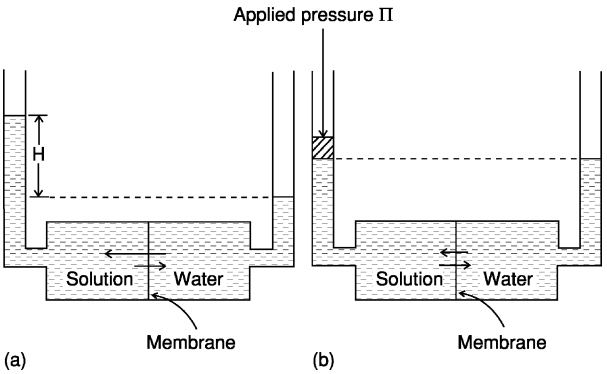

Figure 6 Osmosis and osmotic pressure: (a) in osmosis, the flow of water molecules through the membrane into the solutions is at first greater than the reverse flow from the solution into the water compartment. The hydrostatic pressure due to the column of expanded solution increases the rate of water flow from the solution to the water compartment until, at equilibrium, the opposite flows are equal. (b) The osmotic pressure of the solution is equal to the hydrostatic pressure Π, which must be applied to the solution to equalize the rate of flow to and from the solution and produce a net flow of zero. Reprinted from *Environmental Soil Physics*, Hillel D (ed.). Copyright (1998), with permission from Elsevier.

Figure 6 is a schematic representation of a pure solvent separated from a solution by a semipermeable membrane. Solvent will pass through the membrane and enter the solution compartment, driving the solution level up the left-hand tube until the hydrostatic pressure of the column of dilute solution on the left is sufficient to counter the diffusion pressure of the solvent molecules drawn into the solution through the membrane. The hydrostatic pressure at equilibrium, when solvent molecules are crossing the membranes in both directions at equal rates, is the osmotic pressure of the solution.

In dilute solutions, the osmotic pressure is proportional to the concentration of the solution and to its temperature according to the following equation:

$$\Pi = MRT \qquad [5]$$

Here Π is the osmotic pressure in atmospheres (to be multiplied by 0.101 to obtain megapascal units), M the total molar concentration of the solute (whether molecules or dissociated ions), T the temperature in degrees Kelvin, and R the gas constant (0.08205 liter atm deg^{-1} mole). The osmotic pressure increase with temperature is associated with the corresponding increase of the molecular diffusivity (self-diffusion coefficient) of water, D_w. According to the Einstein–Stokes equation,

$$D_w = kT/6\pi\eta$$

where $k = R/N$, the Boltzmann constant (1.38×10^{-23} JK^{-1}); r is the rotation radius of the molecule ($\sim 1.5 \times 10^{-4}$) and η is the viscosity.

Solubility of Gases

The concentration of dissolved gases in water in equilibrium with a gaseous phase generally increases with pressure and decreases with temperature. According to Henry's law, the mass concentration of a dissolved gas c_m is proportional to the partial pressure of the gas p_i:

$$c_m = s_o p_i / p_o \quad [6]$$

where s_o is the solubility coefficient of the particular gas in water and p_o is the total pressure of the atmosphere. The volume concentration is similarly proportional:

$$c_v = s_v p_i / p_o \quad [7]$$

where s_v is the solubility coefficient expressed in terms of volume ratios (i.e., c_v is the volume of dissolved gas relative to the volume of water). The values of s_c and s_v are determined experimentally. If the gas does not react chemically with the liquid, these properties should remain constant over a range of pressures, especially at low partial pressures of the dissolved gases. Solubility is, however, strongly influenced by temperature. Table 2 gives the s_v values of several atmospheric gases at various temperatures.

The solubilities of various gases (particularly oxygen) in varying conditions strongly influence such vital soil processes as oxidation and reduction, and respiration by roots and microorganisms.

Adsorption of Water on Solid Surfaces

Adsorption is an interfacial phenomenon resulting from the differential forces of attraction or repulsion occurring among molecules or ions of different phases at their exposed surfaces. As a result of cohesive and adhesive forces coming into play, the zones of contact among phases may exhibit a concentration or a density of material different from that inside the phases themselves. As different phases come in contact, various types of adsorption can occur: adsorption of gases on solids, of gases on liquid surfaces, and of liquids on solids.

The interfacial forces of attraction or repulsion may themselves be of different types, including electrostatic or ionic (Coulombic) forces, intermolecular forces such as van der Waals and London forces, and short-range repulsive (Born) forces. The adsorption of water upon solid surfaces is generally of an electrostatic nature. The polar water molecules attach to the charged faces of the solids and to the ions adsorbed on them. This adsorption of water is the mechanism causing the strong retention of water by clay at high suctions.

The interaction of the charges of the solid with the polar water molecules may impart to the adsorbed water a distinct structure in which the water dipoles assume an orientation dictated by the charge sites on the solids. This adsorbed 'phase' may have mechanical properties of strength and viscosity that differ from those of ordinary liquid water at the same temperature. The adsorption of water on clay surfaces is an exothermic process, resulting in the liberation of an amount of heat known as the heat of wetting.

Vapor Pressure

According to the kinetic theory, molecules in a liquid are in constant motion, which is an expression of their thermal energy. These molecules collide frequently, and occasionally one or another at the surface absorbs sufficient momentum to leap out of the liquid and into the atmosphere above it. Such a molecule, by virtue of its kinetic energy, thus changes from the liquid to the gaseous phase. This kinetic energy is then lost in overcoming the potential energy of intermolecular attraction while escaping from the liquid. At the same time, some of the randomly moving molecules in the gaseous phase may strike the surface of the liquid and be absorbed in it.

The relative rates of these two directions of movement depend upon the concentration of vapor in the atmosphere relative to its concentration at a state of equilibrium (i.e., when the movement in both directions is equal). An atmosphere that is at equilibrium with a body of pure water at standard atmospheric pressure is considered to be saturated with water vapor, and the partial pressure of the vapor in such an atmosphere is called the saturation (or equilibrium) vapor pressure. The vapor pressure at equilibrium with any body of water depends on the physical condition of the water (pressure and temperature) and its chemical condition (solutes) but is independent of the absolute or relative quantity of liquid or gas in the system.

The saturation vapor pressure rises with temperature. As the kinetic energy of the molecules in the liquid increases, so does the evaporation rate.

Consequently, a higher concentration of vapor in the atmosphere is required for the rate of return to the liquid to match the rate of escape from it. A liquid arrives at its boiling point when the vapor pressure becomes equal to the atmospheric pressure. If the temperature range is not too wide, the dependence of saturation vapor pressure on temperature is expressible by the equation (Table 3):

$$\ln p_o = a - b/T \qquad [8]$$

where $\ln p_o$ is the logarithm to the base e of the saturation vapor pressure p_o, T is the absolute temperature, and a and b are constants.

As mentioned, the vapor pressure also depends on the hydrostatic pressure of the liquid water. At equilibrium with drops of water (which have a hydrostatic pressure greater than atmospheric), the vapor pressure is greater than in a state of equilibrium with free water (which has a flat interface with the atmosphere). On the other hand, in equilibrium with adsorbed or capillary water under a hydrostatic pressure smaller than atmospheric, the vapor pressure is smaller than in equilibrium with free water. The curvature of drops is considered to be positive, as these drops are convex toward the atmosphere, whereas the curvature of capillary water menisci is considered negative, as they are concave toward the atmosphere.

For water in capillaries, in which the air–water interface is concave, the Kelvin equation applies:

$$-(\mu_1 - \mu_1^o) = RT \ln (p_1^o/p_1) = 2\gamma v_i \cos \alpha / r_c$$

in which $(\mu_1 - \mu_1^o)$ is the change in potential of the water due to the curvature of the air–water interface, γ is the surface tension of water, α is the contact angle, v_1 is the partial molar volume of water, and r_c is the radius of the capillary.

Water present in the soil invariably contains solutes, mainly electrolytic salts, in variable concentrations. Thus, soil water should properly be called the soil solution. The composition and concentration of the soil solution affect soil behavior. While in humid regions the soil solution may have a concentration of but a few parts per million, in arid regions the concentration may become as high as several percent. The ions commonly present are H^+, Ca^{2+}, Mg^{2+}, Na^+, K^+, NH_4^+, OH^-, Cl^-, HCO_3^-, NO_3^-, SO_4^-, and CO_3^-. The vapor pressure of electrolytic solutions is less than that of pure water. The equation is:

$$v_1 \Pi_o = RT \ln (p_1^o/p_1) = \mu_1 - \mu_1^o$$

wherein Π_o is the osmotic pressure of a nonvolatile solute, μ_1^o and p_1^o are the chemical potential and vapor pressure of the liquid in its pure state, and μ_1 and p_1 are the same for the solution. Thus the soil solution has a lower vapor pressure than pure water, even when the soil is saturated. In unsaturated soil the capillary and adsorptive effects further lower the potential and hence also the vapor pressure.

Surface Tension

Surface tension is a phenomenon occurring typically, but not exclusively, at the interface of a liquid and a gas. The liquid behaves as if it were covered by an elastic membrane in a constant state of tension that tends to cause the surface to contract. To be sure, no such membrane exists, yet the analogy is a useful one if not taken too literally. If we draw an arbitrary line of length L on a liquid surface, there will be a force F

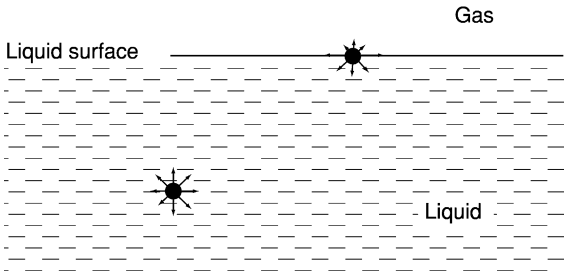

Figure 7 Cohesive forces acting on a molecule inside the liquid and at its surface.

pulling the surface to the right of the line and an equal force pulling the surface leftwards. The ratio F/L is the surface tension and its dimensions are those of force per unit length. The same phenomenon can also be described in terms of energy. Increasing the surface area of a liquid requires work, which remains stored as potential energy in the enlarged surface, just as energy can be stored in a stretched spring. That potential energy can perform work if the enlarged surface is allowed to contract again. Energy per unit area has the same dimensions as force per unit length.

An explanation for occurrence of surface tension is given in Figure 7. A molecule inside the liquid is attracted in all directions equally by the cohesive forces of neighboring molecules, while a molecule at the surface of the liquid is attracted into the relatively dense liquid phase by a net force greater than that attracting it toward the rarified gaseous phase. This unbalanced force draws the surface molecules inward into the liquid and results in the tendency for the surface to contract. This is why drops of a liquid in air as well as bubbles of air in a liquid assume the shape of a sphere, which is a body of minimal surface exposure relative to its volume.

Different liquids exhibit different surface tension values, as in the following list:

Water, 7.27×10^{-2} N m^{-1}(72.7 dyn cm^{-1}) at 20°C;
Ethyl ether, 1.7×10^{-2} N m^{-1} (17 dyn cm^{-1});
Ethyl alcohol, 2.2×10^{-2} N m^{-1}(22 dyn cm^{-1});
Benzene, 2.9×10^{-2} N m^{-1}(29 dyn cm^{-1});
Mercury, 0.43 N m^{-1} (430 dyn cm^{-1}).

Curvature of Water Surfaces and Hydrostatic Pressure

Wherever an interface between fluids (say, between water and air) is not planar but curved, the resolution of forces due to surface tension creates a pressure differential across that interface. For a spherical interface (as in the case of a bubble of air immersed in a body of water), the pressure difference is proportional

BOX 1 A Farewell to Teardrops

For centuries, conventional wisdom held that larger stones fall faster than small ones, that the Earth is flat yet the sun revolves around it, and that the sun and moon are of equal size. We would like to believe that in our time all baseless notions have been replaced by sound science. But have they?

Consider the shape of a raindrop. The conventional standard is a teardrop, rounded at the bottom and tapering to a point at the top. So prevalent is that image that it is printed in textbooks and used as a logo by irrigation companies and even by conferences sponsored by the United Nations. Alas, the vertically elongated, top-pointed raindrop is a physical impossibility.

A drop forming at the tip of a spout assumes that shape only at the very instant of detachment. Because of surface tension, any drop suspended in air 'balls up' spontaneously into a sphere. In a cloud, spherical droplets tend to grow by condensation or coalescence until reaching a critical weight, at which they begin to fall.

Air bypassing a falling drop acquires greater velocity around the curved 'waist' of the drop than near its top or bottom. By Bernoulli's law ($p + \rho v^2/2 = \text{constant}$), the pressure of the air alongside the drop is lowered relative to that of the air above and below the drop. Consequently the drop compresses vertically and comes to resemble an ellipsoid. Such is indeed the shape of small drops (< 2 mm).

In the case of larger drops, the laminar streams of air flowing past the drop may not converge smoothly above the top, but may leave a turbulent wake there. In such a wake, the pressure is lower than it would be in an ideally laminar flow regime. The reduced air pressure at the top causes the drop to bulge a bit there, thus acquiring the appetizing shape of a miniature hamburger bun (described by the appropriately named McDonald as early as 1954).

If a drop were to continue accelerating, it might eventually spread out to form a pancake. But Stokes' law intervenes, decreeing that the drop's acceleration be countered by the increasing viscous resistance of the air. When air resistance equals the gravitational force, acceleration ceases and the drop continues to fall at a constant 'terminal' velocity and with a more or less constant shape. It finally slaps the ground with its flattened face going 'plop'.

Some of us may think it unfair that such an exquisitely sculpted natural body should have no more glorious a fate than to splatter down on some dry bit of earth. But that is where – having at once lost its distinctive shape as it enters the labyrinthine interstices of the soil – our drop might well give life to a thirsty plant, perhaps even to a sunflower. Anyhow, we bid farewell to the sad countenance of the teardrop, a singularly inappropriate symbol for happy rain.

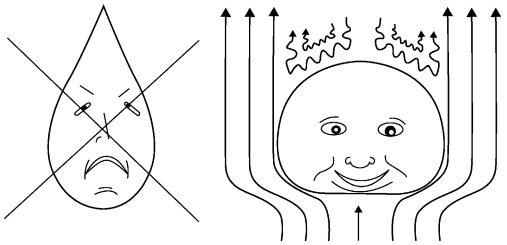

Figure B1 Conventional and real raindrops. Reprinted from *Environmental Soil Physics*, Hillel D (ed.). Copyright (1998), with permission from Elsevier.

to the surface tension and inversely proportional to the curvature:

$$\Delta P = 2\gamma/R \qquad [9]$$

Thus, the smaller the bubble is, the greater is its pressure.

If the bubble is not spherical, then instead of eqn [9] we obtain:

$$\Delta P = \gamma(1/R_1 + 1/R_2) \qquad [10]$$

where R_1 and R_2 are the principal radii of curvature for any given point on the interface. Eqn [10] reduces to [9] whenever $R_1 = R_2$.

Contact Angle of Water on Solid Surfaces

If we place a drop of liquid upon a dry solid surface, the liquid will usually displace the gas that covered the surface of the solid and it will spread over that surface to a certain extent. Where its spreading ceases and the edge of the drop comes to rest, it will form a typical angle with the surface of the solid. This angle, termed contact angle, is illustrated in **Figure 8**.

We now consider what factors determine the magnitude of the angle α. We can expect that angle to be acute if the adhesive affinity between the solid and liquid is strong relative to the cohesive forces inside the liquid itself and to the affinity between the gas and the solid. We can then say that the liquid 'wets' the solid. A contact angle of zero would mean the complete flattening of the drop and the perfect wetting of the solid surface by the liquid. On the other hand, a contact angle of 180° would imply a complete nonwetting or rejection of the liquid by the gas-covered solid. In that case the drop would retain its spherical shape without spreading over the surface at all (assuming no gravity effect). Surfaces on which water exhibits an obtuse contact angle are called water-repellent, or hydrophobic (Greek: 'water-hating').

The contact angle of a given liquid on a given solid is generally characteristic of its interaction under given physical conditions. This angle, however, may be different in the case of a liquid that is advancing over the solid surface than in the case of the same liquid receding over the surface. This phenomenon, where it occurs, is called contact angle hysteresis. The wetting angle of pure water upon clean and smooth mineral surfaces is generally zero, but where the surface is rough or coated with adsorbed surfactants of a hydrophobic nature, the contact angle, and especially the wetting angle, can be considerably greater than zero. This is illustrated in **Figure 9**.

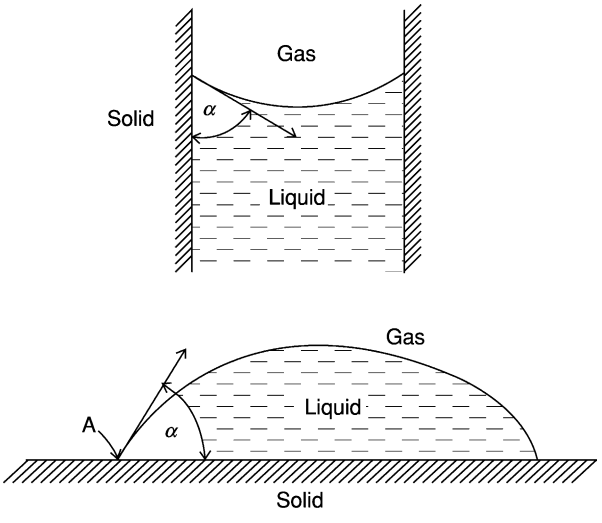

Figure 8 The contact angle of a meniscus in a capillary tube and a drop resting on the surface of a solid. Reprinted from *Environmental Soil Physics*, Hillel D (ed.). Copyright (1998), with permission from Elsevier.

The Phenomenon of Capillarity

A capillary tube dipped in a body of free water will form a meniscus as the result of the contact angle of water with the walls of the tube. The curvature of this meniscus will be greater (i.e., the radius of curvature smaller) the narrower the tube. The occurrence of curvature causes a pressure difference to develop across the liquid–gas interface. A liquid with an acute contact angle (e.g., water on glass) will form a concave meniscus, and therefore the liquid pressure under the meniscus (P_1) will be smaller than the atmospheric pressure (**Figure 10**). Hence, the water inside the tube will be driven up the tube from its initial location (shown as a dashed curve in **Figure 10**) by the greater pressure of the free water (i.e., water at atmospheric pressure, under a horizontal air–water interface) outside the tube at the same level. The

upward movement will stop when the pressure difference between the water inside the tube and the water under the flat surface outside the tube is countered by the hydrostatic pressure exerted by the water column in the capillary tube.

If the capillary tube is cylindrical and if the contact angle of the liquid on the walls of the tube is zero, the meniscus will be a hemisphere (and in a two-dimensional drawing can be represented as a semicircle) with its radius of curvature equal to the radius of the capillary tube. If, on the other hand, the liquid contacts the tube at an angle greater than zero but smaller than 90°, then the diameter of the tube ($2r$) is the length of a cord cutting a section of a circle with an angle of $\pi - 2\alpha$, as shown in Figure 11. Thus,

$$R = r/\cos\alpha \qquad [12]$$

where R is the radius of curvature of the meniscus, r the radius of the capillary, and α the contact angle.

The pressure difference ΔP between the capillary water (under the meniscus) and the atmosphere, therefore, is:

$$\Delta P = (2\gamma \cos\alpha)/r \qquad [13]$$

Recalling that hydrostatic pressure is proportional to the depth d below the free water surface (i.e., $P = \rho g d$, where ρ is liquid density and g is gravitational acceleration) we can infer that hydrostatic tension (negative pressure) in a capillary tube is proportional to the height h above the free water surface. Hence the height of capillary rise is:

$$h_c = (2\gamma \cos\alpha)/g(\rho_1 - \rho_o)r \qquad [14]$$

where ρ_g is the density of the gas (which is generally neglected), ρ_1 the density of the liquid, g the acceleration of gravity, r the capillary radius, α the contact angle, and γ the surface tension between the liquid and the air.

When the liquid surface is concave, the center of curvature lies outside the liquid and the curvature, by convention, is regarded as negative. Thus, for a concave meniscus such as that of water in a clean glass capillary, ΔP is negative with reference to the atmosphere, indicating a capillary pressure deficit, or subpressure, called tension. On the other hand, in a capillary tube that forms a convex meniscus (such as that of mercury in glass, or of water in an only or otherwise water-repellent tube), ΔP is positive and capillary depression, rather than capillary rise, will result.

Density and Compressibility

The open packing of water molecules in ice and liquid water accounts for their relatively low densities. Unlike most substances, water exhibits a point of maximum density (at 4°C), below which the substance expands due to the formation of a hexagonal lattice structure, and above which the expansion is due to the increasing thermal motion of the molecules. The coefficient of thermal expansion of water is rather low, and in the normal temperature range of, say, 4–50°C, the density diminishes only slightly, from 1000 to 988 kg m^{-3}.

The compressibility of water, C_w, can be defined as the relative change in density with change in pressure:

$$C_w = (1/\rho_w)(d\rho_w/dP) \qquad [15]$$

At 20°C and at atmospheric pressure, the compressibility of pure water is about 4.6×10^{-10} m^2 N^{-1}. In

the normal situations encountered on the surface of the Earth, water can usually be considered incompressible. The compression of water cannot be ignored, however, in the case of deep confined aquifers, which may be subject to a pressure of, say, 10 MPa or more.

Dynamic and Kinematic Viscosity

When a fluid is moved in shear (i.e., when adjacent layers of fluid are made to slide over each other), the force required is proportional to the velocity of shear. The proportionality factor is called the viscosity. As such, it is the property of the fluid to resist the rate of shearing and this can be visualized as an internal friction. The coefficient of viscosity η is defined as the force per unit area necessary to maintain a velocity difference of 1 m s^{-1} between two parallel layers of fluid which are 1 m apart. The viscosity equation is:

$$\tau = F_s/A = \eta \, \mathrm{du/dx} \qquad [16]$$

wherein τ is the shearing stress, consisting of a force F_s acting on an area A; η (dimensions: mass/(length $\times$ time)) is the coefficient of dynamic viscosity; and du/dx is the velocity gradient perpendicular to the stressed area A.

The ratio of the dynamic viscosity of a fluid to its density is called the kinematic viscosity, designated ν. It expresses the shearing-rate resistance of a fluid independently of the density. Thus, while the dynamic viscosity of water exceeds that of air by a factor of about 50 (at room temperature), its kinematic viscosity is actually lower.

Fluids of lower viscosity flow more readily and are said to possess greater fluidity (which is the reciprocal of viscosity). As shown in Table 4, the viscosity of water diminishes by over 2% per 1°C rise in temperature, and thus decreases by more than half as the temperature increases from 5 to 35°C. The viscosity is also affected by the type and concentration of solutes present.

WATER-REPELLENT SOILS

J Letey, University of California–Riverside, Riverside, CA, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Dry soil that does not spontaneously imbibe water, but rather has water remain on the surface, is referred to as a water-repellent or hydrophobic soil. Soils which spontaneously imbibe water are considered to be wettable but they can have different degrees of wettability.

The most common observations made on water-repellent soils are: (1) the water resists penetration and 'rolls' off the soil, and (2) very wet soil can be found next to very dry soil even though both receive equal water from rain or irrigation.

Water repellency has been reported in most continents of the world for varying land uses and climatic conditions and has been the topic of two international conferences. The first conference was held at Riverside, California, in 1968, and the second was convened 30 years later at Wageningen, the Netherlands.

The theory and description of soil-water processes described in soil physics textbooks are valid for wettable soils. That theory does not apply to water-repellent soils. Techniques that quantify the degree of soil water repellency are important for characterizing and mitigating such soil conditions.

Characterizing the Degree of Water Repellency

The extent of water repellency of a flat, smooth surface is commonly determined by measuring the water–solid contact angle when a drop of water is placed on the surface. Water will form a 'ball' on a very repellent surface. Soils do not have surfaces that conveniently allow the geometric measurement of a contact angle. Thus, an alternative to geometric measurement is required. Soils have pores and occasionally have been represented as being composed of a bundle of capillary tubes. The capillary tube is a vast oversimplification of the complex geometric arrangements of soil pores. Nevertheless, helpful insights can be achieved by assuming the capillary tube model for soils.

If the tip of a capillary tube is brought in contact with water, the water will be drawn into the tube. The height that the water will rise is given by eqn [1].

$$h = 2\gamma_w \cos\theta / r\rho g \qquad [1]$$

where h is the height of rise, γ_w the water–air surface tension, θ the water–solid contact angle, r the capillary radius, ρ the water density, and g the gravitational constant. According to eqn [1], water will not spontaneously enter the soil if cos θ is zero or a negative number ($\theta \geq 90°$).

A soil is commonly classified as being water-repellent if a drop of water placed on the soil does not spontaneously enter the soil. By this convention, a water-repellent soil is one in which the water–solid contact angle is equal to or greater than 90°. The water-drop penetration time (WDPT) is an index commonly used to specify the degree of water repellency. This procedure involves placing a drop of water on the soil and measuring the time for it to penetrate. Since water only penetrates the soil if $\theta < 90°$, WDPT is the measure of the time required for θ to change from its original value, which was more than 90°, to a value approaching 90°. Therefore, it is a measure of the stability of the repellency when the soil is brought in contact with water, and not necessarily an index of θ. The fact that the degree of repellency is not static but can change with time after contact with water complicates the analysis of temporal effects of water repellency on water flow.

Liquid surface tension that wets the soil material with a 90° contact angle is one index of water repellency. A series of aqueous ethanol solutions producing a range of surface tensions is prepared for this measurement. Drops of these solutions are placed on the soil. The higher-surface-tension solutions set on the surface and the lower-surface-tension solutions will spontaneously penetrate the soil. The 90° surface tension (γ_{nd}) is the surface tension of the solution where there is transition from sitting on the surface to penetration. Sometimes this procedure is followed but the molarity of the aqueous ethanol solution rather than the surface tension is reported as the index, referred to as the molarity of ethanol (MED) test. Others have reported the results of this test in terms of the volumetric ethanol percentage when penetration is initiated. The γ_{nd} has at times been referred to as the critical surface tension.

The solid–air surface tension, γ_s, is a fundamental physical–chemical property of a solid that affects its wetting properties. Therefore, characterizing the magnitude of water repellency by measuring the solid–air surface tension is valuable. Theoretical relationships between various surface tensions and contact angle have been combined to obtain the following two equations:

$$\gamma_s = \gamma_{nd}/4 \quad [2]$$

$$\cos\theta = [(\gamma_{nd}/\gamma_w)^{1/2} - 1] \quad [3]$$

Therefore the measurement of γ_{nd} can be used to calculate the value of γ_s and θ. The values of γ_s and θ determined by measuring γ_{nd} represent initial values before they have had an opportunity to change after contact with water. Both WDPT and γ_{nd} can be measured quickly and easily in either the laboratory or field. Measurement of γ_{nd} provides an index of the initial extent of water repellency, and WDPT provides an index of the stability of repellency after contact with water.

Water-Entry Pressure Head

When $\theta > 90°$, pressure must be applied to force the water into the soil. The water-entry pressure head, h_p, into a capillary tube is:

$$h_p = -2\gamma_w \cos\theta / r\rho g \quad [4]$$

For $\theta < 90°$, h_p is negative and water is drawn spontaneously into the tube. For $\theta > 90°$, h_p is positive and the water head equal to or greater than h_p must exist for water entry. Note that h_p depends on both the water-repellent index (θ) and the pore size (r). Measurement of h_p requires an apparatus that allows the depth of water on a soil column to increase gradually and some means of determining at what point the water penetrates the soil column.

Infiltration Rate

One of the most important effects of soil water repellency on the hydrologic cycle is its effect on infiltration rate. Infiltration will not occur until water has been in contact with the soil surface for a time equal to or greater than the WDPT unless the depth of ponding (h_o) is greater than the water-entry pressure (h_p). Even after conditions allowing water penetration, the infiltration and hydraulic property characteristics of water-repellent soils differ from wettable soils. Wettable soils typically have a high initial infiltration rate which decreases and then becomes relatively constant with increased time of water applied to the surface. In contrast, the infiltration rate into a water-repellent soil is slow during the initial phase of infiltration and increases with time. For soils with a finite WDPT, the degree of repellency changes with time after contact with water, so the increase in infiltration rate with time might be attributed to the changes in the degree of repellency.

In order to isolate and clearly identify the effects of water repellency that are not time-dependent on infiltration behavior, studies have been conducted on soils that have an infinite WDPT (water never penetrates the soil). Because natural soils do not typically have infinite WDPT values, soil materials artificially treated with octadecylamine provide a stable water repellency with an infinite WDPT. Different concentrations of octadecylamine create sands with different degrees of water repellency. Studies have been conducted using such treated sands.

Whereas the infiltration rate into wettable soils is only slightly affected by the depth of ponded water, infiltration into the water-repellent materials is drastically affected by the depth of ponded water (**Figure 1**). The h_p value for this material is 8.4 cm. As expected, no water infiltrates unless h_o is greater than h_p. At low values of h_o, the infiltration rate increases with time. However, for the higher values of h_o, infiltration rate decreases with increasing time, which is typical of wettable soils. Intermediate values of h_o ($h_o/h_p \approx 2.6$) produce a nearly constant infiltration rate as a function of time.

The hydraulic conductivity of the treated sand can be measured by ponding water on the surface of a column and measuring the steady-state water flow through the column. Increasing the depth of water ponding on the surface increases the hydraulic head gradient and therefore should induce an increased water flow. However, the hydraulic conductivity should be unaffected by the depth of water ponding, and this result is typically observed for wettable soils. In contrast, the hydraulic conductivity of the treated sands increases with depth of ponding until a critical depth of ponding is reached, after which the hydraulic conductivity becomes constant (**Figure 2**). The hydraulic conductivity in the water-repellent sand attains a value of the untreated sand when h_o is high enough. The ratio of h_o/h_p that results in maximum K equivalent to the untreated K is approximately 3.1 for each treatment.

Researchers have found that the average water content in the water-repellent sand decreases as the value of h_o decreases. Thus the decreasing K is caused by a decrease in water content, which is consistent with the well-recognized transport phenomenon that hydraulic conductivity is a function of soil water content. The water-entry pressure increases as the pore size decreases (eqn [4]); therefore the increase in water content could be the result of smaller pores being filled with water as h_o increases. Alternatively, finger flow through water-repellent sand could have caused only a portion of the sand to be wet. Whether the decrease in average water content is uniformly distributed in the sand or the result of finger flows

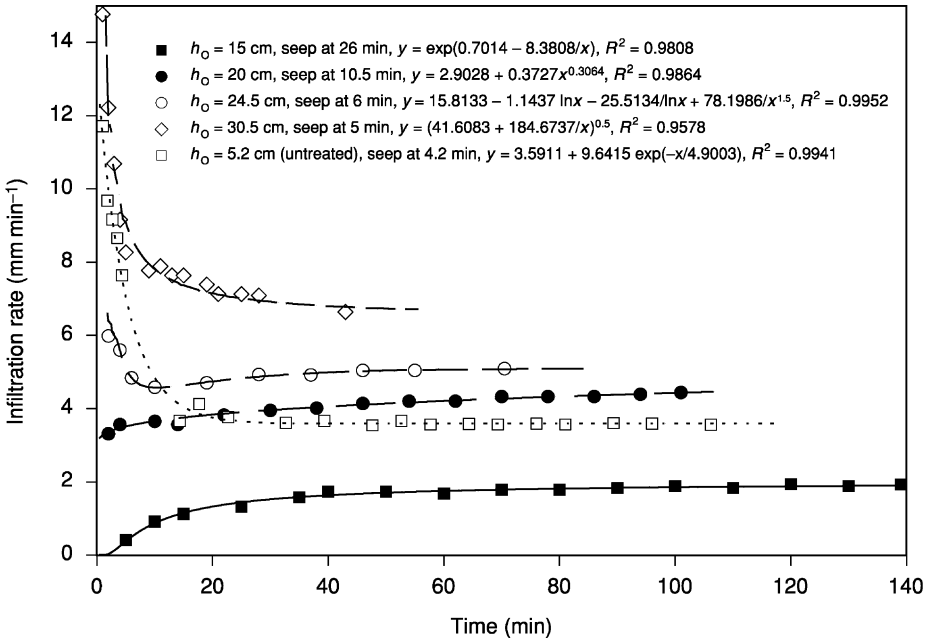

Figure 1 The infiltration rate as a function of time for sand ($h_p = 8.4$ cm) for different values of ponded-water depth (h_o). The equations are for the best-fit curve to the data points. Figure 2 The relationship between hydraulic conductivity and ponded-water depth for sands receiving two treatments to make them water-repellent. The dotted line is the hydraulic conductivity of the untreated sand, which is independent of ponded depth. (Reproduced with permission from Feng GL, Letey J, and Wu L (2001) Water ponding depths affect temporal infiltration rates in a water-repellent sand. *Soil Science Society of America Journal* 65: 315–320.)

where only a fraction of the sand is wet has not been determined conclusively.

The h_o/h_p value at which there is a transition from infiltration rate increasing with time to decreasing with time (Figure 1) is close to the h_o/h_p value that produces a hydraulic conductivity close to that of untreated sand.

The effect on infiltration rate of placing a layer of wettable, untreated sand over the water-repellent sand has been studied. Infiltration rate is rapid into the overlying wettable sand, but stops when reaching the repellent layer until the hydraulic head at the interface exceeds the value of h_p. Thereafter, infiltration into the repellent layer is initiated. The consequence of having the untreated layer is approximately equivalent to increasing the ponded depth. In other words, ponding water 1 cm above a 5-cm layer of wettable sand is equivalent to ponding 6 cm of water on a soil that is water-repellent at the surface.

The hydraulic heads immediately behind the wetting front differ between wettable and water-repellent soils. In a wettable soil, the hydraulic head is negative immediately behind the wetting front and increases as

it moves upward from the wetting front. Conversely, the hydraulic head immediately behind the wetting front is positive in a water-repellent soil and decreases away from the wetting front. These are conditions that contribute to unstable or preferential flow in the soil.

The term 'preferential flow' has been used to describe nonuniform water flow or wetting-front advance through the soil. However, the term 'preferential flow' can have different connotations. Ambiguity arises because of different dimensional scales, ranging from pore size to several centimeters. Indeed, wet and dry zones in a water-repellent field may have dimensions in meters where the term 'preferential flow' might not be appropriate.

Instability of wetting-front advance has been observed in the laboratory on water-repellent soil materials. Instability of a dynamic wetting front is defined as the unconstrained growth of randomly occurring, small perturbations of the wetting front. The effect is to have a wetting-front advance rapidly in random zones, creating a 'finger' wetting pattern.

The depth of ponded water h_o has a profound effect on the extent of finger flow in a water-repellent soil. If the water-repellent layer is at a depth L below the soil surface, the effect of L is comparable to the effect of h_o on finger formation. Water penetrates the wettable surface layer but is constrained by the water-repellent sublayer, which allows pressure to build up in the water to a value comparable to the value that would exist without the wettable layer. One study has found that no water penetrates the water-repellent layer for values of $(h_o + L)/h_p < 1$; unstable flow develops for the values between 1 and 1.5; and a stable wetting front develops for values greater than 1.5.

The basic concepts of flux through a water-repellent layer as affected by the total head may explain the finger formation. Instability of water flow occurs if the flow through the system is less than the saturated hydraulic conductivity. The fact that finger flow and reduced hydraulic conductivity (**Figure 2**) are both associated with low values of h_o is consistent with the theory that instability of water flow occurs when the flow through the system is less than the saturated hydraulic conductivity.

Temporal effects of infiltration rate and preferential flow are influenced by the WDPT value. Infiltration will occur when a WDPT has been reached even without a ponding depth. However, one study has found that the wetting front is unconditionally unstable when h_o is less than h_p, resulting in finger flow. Conversely, the flow has been observed to be stable when h_o is greater than h_p if WDPT is not too large. Finger flow does not occur for a soil that has a WDPT of 1 min. When the WDPT is 10 min, fingers form; however, the fingers broaden and converge after continued flow and an almost uniform wetting front eventually develops.

Uneven wetting patterns, whereby zones of very dry soil can exist next to zones of very wet soils, are commonly observed in the field on water-repellent soils. Location of wet and dry zones usually cannot be determined by visual observations of the landscape. The phenomenon, however, can be triggered by any factor that initiates infiltration. Once infiltration occurs, the infiltration rate increases with time, drawing water away from adjacent zones where infiltration has not been initiated. The 'trigger' may be associated with special distribution of WDPT values, whereby the water starts to infiltrate in those zones with a lower WDPT than an adjacent zone with a higher WDPT. Also the value of h_p is associated not only with differences in repellency, but also with pore-size distribution. Possibly, slight differences in texture or packing that lead to different pore-size distributions could contribute to the variable wetting. Also slight differences in topography that allow slightly more depth of water ponding on one zone than the other could initiate the uneven infiltration.

Wildfires have been found either to create or enhance the severity of water repellency on watersheds. Increases in streamflow, quickflow volumes, and sediment in bedload yields have been observed on fire-induced water-repellent soils. Fire-induced water repellency produces localized runoff and sediment movement on hillsides, but does not appreciably affect the performance of a whole watershed. Because of the effects of cracks, animals burrows, root channels, etc., it is difficult to characterize the effects of water repellency at the watershed scale.

Mitigating Water Repellency

Surfactants can be used to mitigate the effects of soil water repellency. Adding a surfactant to water lowers the surface tension of the water. Reduction of the liquid surface tension also reduces the liquid–solid contact angle, which makes the soil behave as if it were wettable. However, if a soil is wettable, reducing the surface tension of water may actually decrease the infiltration rate. Surfactant molecules are adsorbed by the soil as the solution moves downward. As the surfactant is adsorbed from the solution, surface tension of the solution increases and its ability to wet diminishes. Therefore, surfactants are most effective in treating soil water repellency when it is associated with the surface layer of the soil.

Adsorption of the surfactant molecule converts a water-repellent soil to a wettable soil upon drying.

This phenomenon has been referred to as the 'rewet properties of a surfactant.'

Surfactants have been extensively used to overcome water repellency in turf. Water repellency is a common phenomenon in highly managed golf course soils. Water repellency has been managed through the application of surfactants to areas of turf exhibiting visual symptoms commonly referred to as localized dry spots.

Although there are theoretical relationships between liquid surface tension and soil wetting that should allow the computation of the optimal concentration of surfactant to use for treatment, the adsorption of surfactant by the soil (which alters the liquid surface tension) makes a theoretical basis for describing surfactant treatment virtually impossible. Therefore, developing the most effective surfactant treatment is most commonly done by an empirical approach of applying various treatments and observing the effects.

The application and incorporation of clay into the surface 10-cm layer of a water-repellent sand ameliorates water repellency. The clay, which is hydrophilic, converts the surface layer from a water-repellent to a wettable surface. A wettable layer overlying a water-repellent layer acts as if the depth of water ponding is increased equal to the depth of the wettable layer. Therefore if the water entry pressure is less than 10 cm, providing a 10-cm layer of wettable material by incorporating clay would allow the water to penetrate the underlying water-repellent soil.

One field study has compared soil-wetting patterns on two adjacent plots: one with a water-repellent top layer, and one treated with clay to remove the water repellency in the top 30-cm layer. Dye placed on the soil surface to identify wet and dry zones revealed a mosaic surface wetting of water-repellent soil and a uniform surface wetting of wettable soil. Although water repellency existed in the treated plot below the 30-cm depth, it was uniformly wet. Thus stable flow occurs if the depth to the water-repellent layer is sufficiently deep.

Summary

Naturally occurring water-repellent soils have been reported in many areas of the world. Wildfires either create or enhance the water repellency of watersheds. Processes within the hydrologic cycle such as infiltration and erosion are drastically affected by soil water repellency. Basic water flow principles that have been developed for wettable soils must be modified to be applicable to water-repellent soils. Except under unique conditions where treatment with surfactants is practical, large-scale mitigation of water-repellency is not feasible.

List of Technical Nomenclature

γ_{nd}	Surface tension of solution that wets soil at 90° contact angle
γ_s	Surface tension of solid
γ_w	Surface tension of water
θ	Contact angle (degrees)
h	Height of capillary rise (cm)
h_o	Depth of ponded water (cm)
h_p	Water entry pressure head (cm)
K	Hydraulic conductivity
WDPT	Water-drop penetration time

Introduction

Watershed management may be defined as a set of resource-management practices that are planned and implemented to provide a sufficient source of quality water to sustain human society and natural ecosystems. The practice of watershed management is interdisciplinary, because it recognizes linkages between land and water resources, and because it seeks to balance the needs of society with the capacities of natural resources to meet them. Land-use practices have impacts on hydrologic processes and water quality. Identifying ways to manage these impacts across a mosaic of soils, terrain, and land-use settings is a key challenge in watershed management. Effective watershed management is an iterative process of assessment, planning, and implementation. It begins with an assessment of current land-use practices and their impacts on water resources. Opportunities to improve land management, considering roles of soil, vegetation, and terrain, are then identified and prioritized. Stakeholder groups should be included in planning, to inform citizens about water-resource management issues and provide feedback to ensure recommendations are realistic as well as effective. A range of computerized tools are available to assist with assessing watersheds and alternative management scenarios. Implementation should include a commitment to reassess water-resource management periodically and develop opportunities for further improvement.

An Interdisciplinary Task

Watershed management is aimed at land and water resources, and is applied to an area of land that drains to a defined location along a stream or river. Watershed management aims to care for natural resources in a way that supports human needs for water, food, fiber, energy, and habitation, while supporting other agreed attributes linked to recreation, esthetics, and/or ecologic function. Because of these multidisciplinary concerns, the development of watershed-management strategies can involve complex scientific and public policy issues. Each watershed is unique in physiography, ecology, climate, water quality, land use, and human culture. Therefore any generalized approach to watershed management must be customized to each setting when put into practice. Watershed management requires a long-term commitment that is adaptive to changes in population, climate, culture, and resource-use demands. These issues are unique to each watershed and each nation. Watershed-management experiences from around the globe have dealt with a wide range of issues.

Hydrology and Streamflow Variation

The need to develop a watershed management plan is often identified in response to impacts of floods or drought on society. Long-term monitoring of precipitation, snowpacks, streamflow, and groundwater levels can help society to predict and prepare for these events. Although rainfall (or lack thereof) is not subject to management control, management can reduce the frequency of adverse impacts caused

by extremely wet or dry conditions. Water conservation practices, water storage and control structures, vegetation management, and land-use planning are basic tools that can help manage effects of floods and drought.

Stormflow and Floods

Precipitation may be intercepted by vegetation, or reach the soil surface to infiltrate, pond, or flow over it as runoff. Water at (or near) the soil surface can evaporate, while water below the soil surface may be transpired by plants or may percolate downward. Percolating water can recharge groundwater or move laterally downslope (as interflow) to accumulate at lower parts of the landscape. Some of these low-lying areas have water tables near the surface and can become saturated to the soil surface during a rainfall event. These are called variable-source areas, because they vary in size during an event and become a source of stormflow discharge to streams (Figure 1). Variable-source areas are hydrologically sensitive, meaning that, in many watersheds, management of these areas can help attenuate floods and maintain water quality.

Changes in streamflow that follow precipitation are determined by many attributes that affect water storage on the landscape, the prominence and timing of different pathways of water movement, and the location and extent of variable-source areas. Even in small watersheds, water flow pathways and their timing are difficult to decipher, despite numerous research efforts to deconvolute these pathways using physical, chemical, and isotopic methods. Therefore a hydrograph (Figure 2), a plot showing the response of discharge to precipitation, remains a commonly used basis for watershed characterization. In a small, first-order watershed (the smallest land area generating perennial streamflow), this response will take place more quickly than in large river basins, where a range of soils, terrain, land uses, and travel distances act to desynchronize and lengthen the response.

Flooding occurs when stream discharge exceeds the channel's conveyance capacity and forces water over the stream banks. A flood's magnitude can be characterized by its average frequency of recurrence in years (Figure 2). Engineered hydrologic structures are designed to accommodate a maximum flow defined by a specific recurrence interval. Thereby the probability that the structure will fail can be defined for any given time period. Design criteria may allow a fairly large probability of failure if the cost of failure is small (e.g., culverts beneath low-use forest roads), but will require an infinitesimally small chance of failure if that failure were to be catastrophic (e.g., large dams). The discharge associated with a given recurrence interval must be accurately

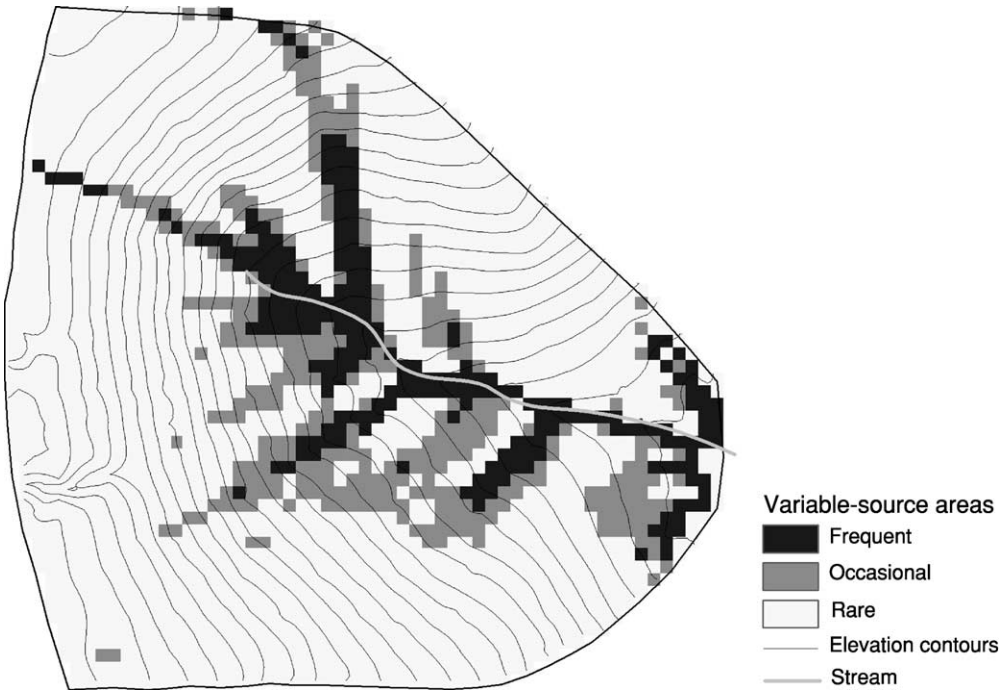

Figure 1 Following precipitation, water is discharged to streams from 'variable-source areas' (or 'partial-contributing areas') that are prone to saturation. The locations of these areas can be estimated based on topographic relationships. This conceptual map indicates the relative frequency of runoff contributions following precipitation.

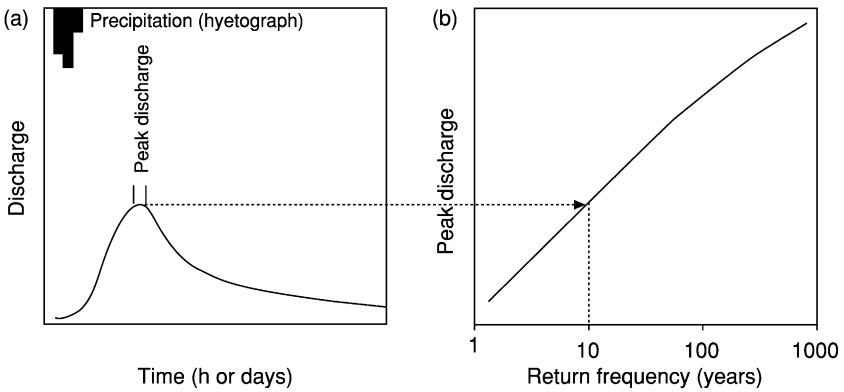

Figure 2 A hydrograph is the response in streamflow to a precipitation event (a). The peak discharge of a hydrograph will have an expected return period; the peak discharge of this event represents a flow that, on average, should only be exceeded once in a 10-year period (b).

known or conservatively estimated. A long-term monitoring record, spanning at least several decades, helps identify the frequency distribution of large flows. Methods of estimation appropriate for small, unmonitored watersheds are also available. These may be based on simple equations (e.g., the synthetic unit-hydrograph method, developed by the US Soil Conservation Service) or sophisticated simulation models.

Snow Hydrology

Seasonal timing of stream discharge is a critical issue, particularly for watersheds with mountainous headwaters where annual snowmelt is an important water source. In many of these watersheds, water yielded by snowmelt is stored in reservoirs for flood mitigation and for later use. Monitoring of annual snowpacks and predictions of water yields are important water management activities in these basins. Snowpacks vary each year, and advance knowledge of water yields helps to plan allocations and warn of potential shortages. Terrain (elevation, slope, and aspect) and wind patterns influence the spatial distribution of snow accumulation and the timing of melt. Vegetation can be managed to moderate these influences.

Drought and Low Streamflow

Prolonged drought can place tremendous pressure on land and water resources, and on society. Dry, hot weather increases demands for water by municipalities and irrigated agriculture when water supply is most limited, causing social conflict. Low streamflow and accompanying warm water temperatures also impact aquatic ecosystems. Drought may contribute to overgrazing and wildfire, which expose soils to erosion once rain returns. Management of groundwater can help protect water supplies and ensure adequate baseflow contribution to streams during drought.

Reservoir water storage, vegetation management, and water conservation measures are among the effective means to reduce impacts of drought. Water harvesting (*See* **Water Harvesting**) is also practiced in some areas. Water conservation can occur through improved methods and scheduling of irrigation, water recycling, and education, and/or regulatory programs to reduce urban water use. Improved irrigation methods may provide the greatest benefit, but return on the investment in conveyance and application systems may take years, in terms of the value of saved water.

Water Quality

Improvements in watershed management may become necessary if water quality becomes impaired. Water quality refers to the capacity of a water body to support certain uses or ecologic functions. It is determined by amounts of dissolved and suspended materials in water, presence or absence of certain microorganisms, and/or physical attributes such as temperature and clarity. Water-quality standards are threshold values (e.g., concentrations, loads) above (or below) which a specific use for water becomes impaired. Water quality can be degraded by natural events or processes, and by pollution resulting from human activities. Common sources of pollution are wastes from municipalities, livestock, and industry, and losses from applications of fertilizer and pesticides to land. Pollution can originate from point sources, where a pollutant enters a water body at a specific location. It can also originate from nonpoint sources where distributed land management activities promote movement of pollutants to ground or surface waters along natural flow pathways. Water quality

management is a process that identifies water uses that are (or may become) impaired, and the contaminants that impair (or threaten to impair) each use. The processes, sources, and pathways that contribute pollutants to a water body need to be understood, and then practices that can sustain water quality according to identified standards must be identified and implemented. This process can raise complex technical and sociopolitical issues. Table 1 lists water quality parameters most commonly of concern, typical sources of pollution for each, possible adverse effects, and some management practices that can control the pollutant. Several types of biologically active trace compounds are included that do not have water-quality standards developed, but that may be of greater concern in the future.

Land-Use Impacts

Soil and vegetation have a major impact on watershed hydrology because they affect partitioning of energy and water near the land surface. While basic soil properties such as texture and depth cannot be influenced through management, soil management can alter the effects of soil disturbance and influence a soil's capacity to support plant growth. Vegetation management can modify canopy interception, evapotranspiration, rooting depths, and seasonal patterns of water use, which affect key hydrologic processes (runoff, infiltration, evapotranspiration, percolation). Soil and vegetation management generally cannot mitigate extreme flood and drought events. However floods with frequent return periods (e.g., less than 10 years) may be mitigated, and low flows associated with annual to perhaps decadal dry periods may be increased. Logically, managing for increased infiltration can achieve both goals, because runoff is reduced, which mitigates flooding, and because groundwater recharge is increased, which contributes baseflow to streams during drought. However, the correspondence of these two benefits is moderated by influences of management on evapotranspiration.

Terrain is an important consideration in soil and vegetation management, and steep lands may require a particular focus, because water is routed from them quickly, contributing to flooding and sedimentation. Risks posed by instability of slopes may be important, especially in populated watersheds with steep terrain where landslides can cause loss of life.

Most watersheds are comprised of agricultural land, forestland, grazing land, urban areas, mine land, riparian zones, wetlands, and lakes in varying proportion and configuration. Each kind of land use poses different challenges and opportunities to improve watershed management. Watershed assessment aims to identify how each land use is influencing hydrology and water quality.

Agricultural Lands

Agricultural lands can contribute to nonpoint pollution, particularly by nutrients, sediment, and agricultural chemicals. It is important to identify erosion control, nutrient, and pest and/or weed management practices to minimize these pollutants effectively. In much of the developed world, crop and livestock production systems have become intensified and spatially aggregated, so that nutrients in animal feed are transferred over longer distances. Treatment, handling, and land application of livestock wastes is a key to effective nutrient management in areas that import feed. Generally, nutrient management aims to apply nutrients at the proper rates and timing to optimize efficiency of crop uptake. Erosion control practices range in scale and include reduced intensity of tillage (including no-tillage), contour farming, vegetative filter strips, and constructed terraces.

Cropping systems can be inefficient in their use of water under rain-fed and irrigated agriculture. Improvement in irrigation efficiencies helps reduce the frequency and severity of water shortages, and can minimize salinization problems in arid regions. Rain-fed agriculture often consists of annual crops that only transpire water during part of the growing season, in contrast to native plant communities. This seasonal restriction on plant water use can increase deep percolation and lead to excess nutrient leaching in humid areas, and salinization in semiarid areas. These problems can be addressed by increasing plant water use with crop rotations that, depending on the setting, may include trees, perennial forages, and/or cover crops.

Forest Lands

Trees have a large capacity to intercept precipitation within their canopy and deep roots that extract soil water from depth. These characteristics diminish the fraction of precipitation that can recharge groundwater and streamflow. Forest harvesting or conversion to other types of vegetation reduces evapotranspiration, which can increase baseflow contributions to streams and allow streamflow responses to small precipitation effects. Historically, observations of severe flooding after extensive forest harvesting brought about early research on the role of vegetation in watershed hydrology, beginning in the early twentieth century. This research quantified relationships between forest cover and streamflow for a number of

Table 1 A summary of common water quality problems associated with land management activities, their impacts, and practices that may address them

Contaminant	*Major causes/sources*	*Adverse impacts*	*Typical solutions*
Physical properties			
Sediment/ turbidity	Erosion, channelization, poor riparian zone management	Fisheries (spawning areas, gill function), aquatic ecosystems, aesthetics, reservoir water storage, water intake and supply systems	Streambank stabilization, erosion control, riparian vegetation management
Temperature	Removal of shading, streambed aggradation, some industry discharges	Fisheries (dissolved oxygen), aquatic ecosystems	Riparian zone management for shading
Inorganic constituents			
Nitrogen	Leaching from soils (NO_3), human and livestock waste (NH_4)	Drinkability (NO_3), toxicity to aquatic animals (NH_4)	Nutrient management, improved waste treatment
Phosphorus	Erosion, accumulation in manured soils	Fisheries, aesthetics, aquatic ecosystems (eutrophication), animal and human health (blue-green algae)	Erosion control, manure management
Dissolved oxygen	High temperature, eutrophication	Fisheries, aquatic ecosystems, aesthetics	Riparian zone management for shading, channel structures to create turbulence, nutrient management
Trace elements	Soil leaching, some pesticides, municipal/industrial wastes	Bioaccumulation, aquatic ecosystems	Increased plant water-use efficiency, industry-specific waste treatment technologies
Salinity	Soil leaching, evaporative discharge of groundwater	Irrigability, drinking, aquatic ecosystems	Management of irrigation water and/ or plant water use in recharge areas, water-table management
Organic materials			
Organic carbon (biological or chemical oxygen demand)	Organic wastes, erosion, eutrophication	Fisheries (reduces dissolved oxygen), aquatic ecosystems, turbidity	Waste treatment, erosion control, nutrient management
Pesticides (herbicides, insecticides, fungicides, nematocides)	Leaching or runoff	Drinkability, potential carcinogenic effects of some compounds and metabolites	Use and losses of nonpersistent compounds, management strategies for reduced pesticide use (e.g., crop selection, rotation, tillage)
Endocrine disruptors	Municipal and industrial wastewaters	Subject of debate, affects metabolic and reproductive function of some organisms	Not clear, but could include waste treatment technologies, alternative formulation of source products that enter the waste stream
Pharmaceuticals	Domestic and livestock wastes	Subject of debate, increased antibiotic resistance in microbial communities hypothesized	Not clear, but could include waste treatment technologies, alternative practices for reduced use in livestock feeding, veterinary, and medical practices
Biological organisms			
Pathogens	Domestic and livestock wastes, riparian grazing, wildlife	Drinkability	Waste treatment, riparian pasture management, improved methods for land application
Algae	Nutrients	Fisheries, aesthetics, dissolved oxygen	Nutrient management, riparian zone management

experimental watersheds. Increases in water yield after harvest may result from greater peak discharges or from greater baseflow contributions to streams, but not necessarily both. Specific factors of harvest disturbance, terrain, and geology determine specific responses in flow regime.

Water yield from forestland can be managed through rotational harvesting that restricts the extent

of harvest during a given period of time (e.g., 20% of the commercial forest under a 25-year rotation may be harvested during a 5-year period). This strategy can desynchronize flows in the watershed and decrease flood frequency. Forest management should consider effects of infrastructure, because forest roads, skid trails, and landings can be major sources of sediment. Harvesting can also increase the risk of mass movement (i.e., rockfalls, landslides) in steep terrain.

Grazing Lands

Rangelands occupy large areas with semiarid to arid climates where extensive crop production is not feasible. Overgrazing and subsequent erosion are prevailing concerns that affect hydrology and water quality. Proper stocking, herd management, and rotational grazing systems comprise effective management strategies, especially if designed to consider the frequency of drought. Managing the distribution of water to livestock is critical, because livestock will not wander far from reliable water sources. In humid areas, pasture management involves more intensive forage production and grazing. Limiting access of cattle to surface waters may address concerns for water quality along small streams.

Mined Land

Mining operations are often small, but the drastic nature of disturbance often requires that effects on water quality and supply be considered. Dewatering of aquifers may occur with subsurface or pit mining, and surface waters may be diverted off-site, or collected in holding ponds. Water quality impacts will vary depending on the method and extent of excavation, the type of rock and/or ore material being mined, the rock and/or ore processing occurring on-site, and reclamation and/or revegetation practices carried out as mining concludes or proceeds to new areas. Acidification, heavy metals, and sediment are common water-quality concerns, depending on the type of mine operation.

Urban Areas

Urban areas also occupy a small part of most basins, but are of predominant concern for the people and the economic activity within a watershed. Daily demands for drinking water, sanitation, and waste treatment are overriding issues due to obvious implications for health and quality of life. Demands for these services increase with development and population. If the growth in demand for water approaches the available supply, or if water quality becomes impaired, then stakeholders will demand improvements in water management. In watersheds with limited water supplies, planning should aim to provide a sustainable match between supply and demand in the longer term, including conservation measures to cope with effects of drought.

Management of storm runoff can be critical in urban areas. Urban development increases the extent of impervious surfaces (rooftops, roads, parking lots), and runoff from these areas must be accepted by a stormwater detention and conveyance system. Construction can cause soil compaction, increasing runoff, and diminishing infiltration and groundwater recharge. Urban development can change flood-frequency characteristics downstream, causing existing floodwater control and conveyance measures to become inadequate. As an example, a 0.1-ha residential lot may have pavement and roofing occupying 40% of that area. If a 10-mm rainfall generates 7 mm of runoff from the impervious surface, then 2.8 m^3 of water will be conveyed down-gradient. Prior to development, a 10-mm rainfall would probably generate little, if any, runoff. Alternative practices being used in some areas include stormwater detention basins with beneficial dry-weather uses (e.g., recreation), small detention basins ('rain gardens') for individual residential lots, 'green' (planted) roofs, and permeable pavements. Urban planning should consider future development and implications for stormwater hydrology.

Riparian Areas and Wetlands

In most watersheds, riparian zones and wetlands also occupy small areas, but they are present in every watershed and their management is frequently a focus of attention. Riparian zones contain variable-source areas that generate storm flow, influence the interaction between groundwaters and surface waters, and form the boundary between aquatic and terrestrial ecosystems. They support biological diversity and wildlife habitat, and provide aesthetic value. Biological processes (e.g., plant growth, microbial activity) are intensified in riparian areas because water and nutrients are usually abundant compared with upslope areas. Management of riparian zones offers the opportunity to improve streamflow regimen (timing) and water quality. Wetlands can detain storm flows and remove nutrients, particularly nitrate via denitrification. Riparian vegetation can take up nutrients and encourage trapping of sediments delivered from upslope areas. It is important to identify objectives for riparian management, locations where those objectives can be met most effectively, and vegetation management systems that can help achieve them. The potential benefits of improved riparian

management, however, can only be fully realized when uplands are also managed to achieve water resource goals.

Approaches, Challenges, and Tools for Watershed Management

The unique attributes of each watershed must be considered in developing and implementing a watershed management plan. While administrative approaches may vary, they usually involve four phases, including problem definition, assessment, selection of alternatives, and implementation and/or evaluation (Table 2). Ideally, watershed management is a continuous process that identifies and develops opportunities to improve environmental quality and resource sustainability.

Watershed planning must balance a number of legitimate, but often competing, resource-use requirements and concerns. Both environmental and social attributes of a watershed must be considered from the outset if planning is to result in successful implementation. Technical experts provide little long-term benefit unless local land managers and community interest groups (stakeholders) perceive their recommendations as balanced and realistic. Therefore stakeholder representation and involvement are necessary from the first stage of planning. An early consensus on resource issues to address and stakeholder groups to include (phase 1) benefits the community and its watershed resources.

Effective watershed planning depends on an objective assessment (inventory) of the current situation (phase 2), best carried out by technical experts from various resource-management and engineering disciplines. Stakeholder involvement can facilitate public education on the causes and impacts of water-resource problems, and can help establish trust between stakeholders and technical experts.

A number of computer tools can help to accomplish a watershed assessment. Use of a geographic information system (GIS) database provides ways to view and evaluate combined map data that include soil survey, land use and ownership, terrain analyses, and remote sensing. While GIS can provide information in compelling graphic formats, its output should be reviewed critically, considering the quality and scale of input data.

Major concerns of watershed management are related to streamflow regime, groundwater availability, and water quality. These all result from a mosaic of interactions among climate, land-use practices,

Table 2 A summary of the watershed management planning process, with a focus on stakeholder involvement

Phase	*Key questions*	*Sources of information*	*Analysis tools*	*Stakeholder role*
1. Problem definition	What are the key problems and who needs to be involved in solving them?	Public, public interest groups, focus group meetings, monitoring data	Statistical analysis of data, public opinion survey results	Source of information; help define formal and informal roles for stakeholders in project
2. Watershed assessment	What information can be gathered to facilitate an assessment of the watershed? Are new assessment/monitoring efforts needed and how can they be accomplished?	Mapped information: population census data, land use, soil survey, remote sensing, surveys of existing conservation systems; intensified and/or synoptic sampling of water resources	Geographic information systems, terrain- and image-analysis techniques, process models	Learning of assessment results, review, and feedback
3. Identify and select management alternatives	What kinds of changes can help solve the problem(s)? Are these changes feasible? Who would need to implement them and what incentives would be needed?	Design criteria and literature on management alternatives and their environmental impacts (e.g., best-management practices)	Process models, decision-support systems, economic analysis	Evaluate feasibility of alternatives; prioritize alternatives; facilitate education of wider community
4. Implement and evaluate	Are incentives effective in encouraging management changes? Are the changes effective in reaching water-resource management goals? What further improvements can be made?	Monitoring data, surveys of new conservation practices, stakeholder feedback	Process modeling, model validation, statistical analysis of monitoring data	Full participants in ongoing project review, help determine if/when new alternatives are required

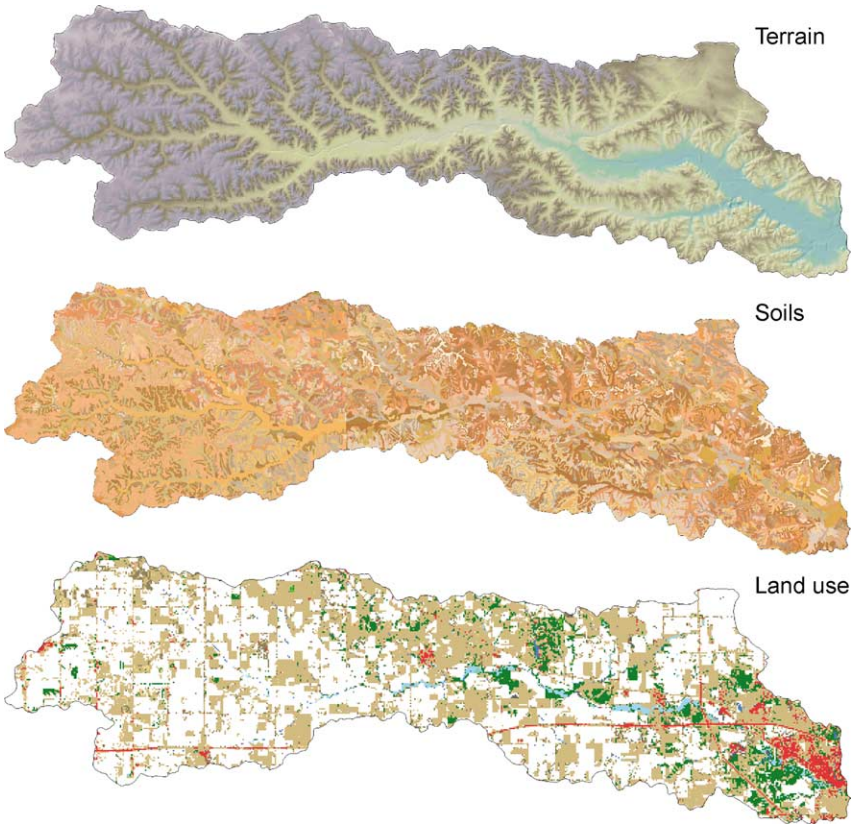

Figure 3 Watershed management and assessment must consider a spatial mosaic of land use, soil, and terrain.

soil, terrain, and geology (Figure 3). Existing hydrologic and water-quality conditions result from these interactions in space and their integration across time. Groundwater quality and stream baseflow are particularly influenced by past land-use practices, because of the slow rate of water movement through most aquifers. A key task for watershed assessment is to segregate this mosaic of spatial and temporal effects, and identify locations and activities that disproportionately influence water resources. Judgment is needed to do this. While there may be obvious areas of focus (e.g., shallow sandy soils, steep slopes, riparian areas), analytic capabilities in this area are not yet fully developed. Many of our working assumptions about effects of land use on hydrology and water quality have been gained through research carried out in small plots, hillslopes, or at small watershed scales. However, analyses conducted at a fine scale may not transfer directly to a large basin. The prominence of biophysical processes affecting hydrology and water quality can vary with the scale of observation. New techniques to analyze hydrologic processes across complex terrain, and analyze relationships between patterns and physical processes, are being developed that may provide new approaches to watershed assessment.

Trends in land use and population must also be considered during watershed assessment. The challenges of watershed management increase with population. The impact can be similar to drought, because pressures on water supplies and on land resources that yield water can increase concurrently. Urban expansion may be accompanied by increased disturbance from overgrazing and deforestation. Trends toward improved management practices should also be documented during an assessment, to help develop information about adoptability and effectiveness of new practices.

Monitoring of flows and water quality can also be important in assessment, because this helps to document water-resource problems. However an adequate set of monitoring data will not always be available, and usually the planning process cannot wait to acquire one. Nevertheless, it is important to continue monitoring, or initiate and/or expand it as soon as possible. Long-term data, gathered using consistent protocols for sampling and analysis, provide the best basis to assess the effects of new practices that are implemented.

Identifying management alternatives (phase 3) aims to propose and select realistic solutions to water-resource problems. Potential solutions include many

land-use practices, vegetation management changes, water-conservation measures, and engineered structures, across all types of land use throughout the watershed. These alternatives are not equal in terms of acceptability, cost, or effectiveness. Decision-support systems and economic analyses can be used to help rank social impacts (e.g., stakeholder acceptance, costs) of each alternative. The rankings also depend on the benefit of each alternative for water resources. Often, these benefits can be estimated using simulation models, which calculate how an alternative might affect biological and physical processes that determine a watershed's hydrology and/or water quality. A wide array of models are available, and the best model to use depends on the specific resource concern(s) and experience of the technical team. It may be possible to use monitoring data to validate model accuracy under current conditions, and this can improve the confidence in using the model to assess the effectiveness of alternatives. The final listing of ranked alternatives is likely to require several iterations of assessing social and environmental impacts.

Once alternatives are ranked, implementation of new practices is encouraged using some set of incentives, and then the management changes are evaluated (phase 4). This takes a sustained commitment. Monitoring data are needed to assess effects of new measures. Changes may not have immediate impact, particularly if they are aimed to improve groundwater conditions. New vegetation management strategies, particularly for forests, may take years to become fully effective. Seasonal trends and extreme events may make it difficult to confirm changes based on interpretation of monitoring data. External factors may also affect success; for example, an understanding of how a changing global climate is affecting water resources may become important. (*See* **Climate Change Impacts**.) These factors reinforce the need for a long-term commitment to watershed management, sustainable development, and periodic review of water-resource management goals and best ways to achieve them.

List of Technical Nomenclature

Baseflow — The portion of stream discharge that originates as groundwater, and that enters the stream channel from the saturated zone via lateral or upward-moving groundwater flow (volume per time)

Drought — A period of time with below-average precipitation that results in significantly diminished stream discharge and water-table elevations

Flood — An event during which a stream's discharge exceeds the capacity of the stream channel to convey water, so that water rises above the stream banks and covers some of the adjoining land surface

Hydrograph — A plot of stream discharge versus time that is often used to show the response of stream discharge to a precipitation event

Infiltration — Vertical entry of water into the soil at the land surface (length per time)

Interception — An amount or fraction of precipitation that wets vegetation and is eventually evaporated from vegetation so that it does not reach the soil surface (length)

Interflow — Water that moves laterally downslope beneath the land surface and at shallow depth above the saturated zone. This flow generally takes place at the scale of an individual hillslope (volume per time)

Perennial stream — A channel that conveys water throughout the year in most years. Usually, perennial flow only occurs where some of the stream discharge originates as baseflow

Physiography — Physical attributes of the terrain, including topography, soils, landform, and surficial geology

Recharge — Water that percolates down through the unsaturated zone and is added to groundwater storage (length)

Runoff — Water that flows across the land surface (volume per time)

Stakeholder — Individuals and/or groups that participate in assessing and solving resource management problems of direct importance to their community or representative constituency

Stream discharge — The quantity of water passing a location on a stream or river (volume per time)

Variable-source area — An area on the landscape that is prone to become saturated to the soil surface in response to precipitation or snowmelt, and that, when saturated, generates runoff that contributes to stream discharge. ('Partial contributing area' is an equivalent term)

Water-quality standard — A threshold value for a constituent concentration or other attribute of water, above or below which a specific use or ecologic attribute of the water becomes impaired

Watershed — A mapped area that contributes runoff or baseflow to a perennial stream or river at a defined location

Water yield This is equivalent to a unit-area stream discharge (volume per area per time)

WATER-USE EFFICIENCY

M B Kirkham, Kansas State University Manhattan, KS, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

For centuries, humans have been concerned with the efficient use of water in the production of crops. The ability to grow crops and manage their needs for water is necessary for civilization. Water-use efficiency is defined as the aboveground biomass production per unit area per unit water evapotranspired. The biomass is usually determined as dry weight rather than as fresh weight. Therefore, water-use efficiency is expressed in equation form as follows:

$$\text{Water-use efficiency (WUE)} = \frac{\text{Dry weight production (DW)}}{\text{Evapotranspiration (ET)}} \quad [1]$$

Water-use efficiency can be expressed on the basis of vegetative growth or reproductive (grain) growth; the basis must be stated. Different units can be used in the numerator and denominator of Eqn [1]. Old units were pounds or tons of dry weight produced per acre-inch of water evapotranspired. We now usually express it as a simple ratio, such as kilogram of dry weight per kilogram of water transpired. Water-use efficiency expressed in the latter dimensionless form is similar to the reciprocal of the old terms 'water requirement' and 'transpiration ratio.' New portable gas analyzers allow us to measure photosynthetic rate and transpiration rate on individual leaves or on parts of individual leaves as small as $6\,cm^2$. So we now can express water-use efficiency on a leaf basis, as follows:

$$\text{Leaf water-use efficiency} = \frac{\text{Photosynthetic rate}}{\text{Transpiration rate}} \quad [2]$$

The unit for photosynthetic rate is micromoles of CO_2 per square meter per second, and the unit for transpiration rate is micromoles of H_2O per square meter per second, so the unit for water-use efficiency on a leaf basis is micromoles of CO_2 per micromole of H_2O.

Water-use efficiency can be based either on evapotranspiration ('ET efficiency') or on crop transpiration ('T efficiency'). The difference is important, because suppression of soil-water evaporation and prevention of weed transpiration can improve ET efficiency. However, it need not improve T efficiency, which is a measure of crop performance. These two water-use efficiencies may also be based on either the

total dry-matter production or the marketable yield, and the basis should always be stated.

In dry regions where the proportion of water returned to the atmosphere by evaporation may be 90% or more, it is necessary to increase water-use efficiency. That is, we want to produce more plant material with smaller amounts of water. Many schemes have been proposed to obtain water for these dry regions: artificial rainmaking, sea-water distillation, and towing icebergs to regions where the melted water can be used for irrigation. However, increasing water-use efficiency may be the best way to provide enough water for crop production in areas where evapotranspiration exceeds rainfall.

History

At the start of the twentieth century, considerable work was in progress measuring water requirement, the inverse of T efficiency. Franklin Hiram King (1848–1911), at the University of Wisconsin (USA), was the first in the USA to research the water required to produce field crops. King was also the author of a classic work entitled *Farmers of Forty Centuries*, which describes his trip to China in the early 1900s. He made careful notes to help him understand how people could farm the same fields for 4000 years without destroying their productivity. King used small lysimeters in a greenhouse and in fields to determine the water requirement of crops. Widtsoe, at the University of Utah (USA), and Kiesselbach, at the University of Nebraska (USA), initiated research in 1902. Widtsoe is also well known for his studies on dry farming. The methods that he described for agricultural production in areas with low rainfall apply equally well today as they did at the beginning of the twentieth century.

Briggs and Shantz, based in Akron, Colorado, compiled much of the early water-requirement data from container experiments that began in 1910. The water-requirement work of Kiesselbach and of Briggs and Shantz was concerned with total dry matter and transpiration on a plant basis rather than on a land-area basis. Briggs, Shantz, and Kiesselbach reviewed the work that had been done up to that time, although they omitted water-culture experiments and those on seedlings. They found that 14 researchers had worked on water-use efficiency prior to 1900. Since that time, there has been an increasing amount of work on water use and water-use efficiency, all done with more elaborate equipment and experiments than those of the last half of the 1800s and early 1900s. However, these early experiments still remain the foundations of our modern understanding of water-use efficiency. One of the best summaries of the water requirement of many different plants is that compiled in 1927 by Shantz and Piemeisel.

Factors that Influence Water-Use Efficiency

Soil Factors

Soil-water content Briggs and Shantz felt that they could make no firm conclusion about the effect of soil-water content on the water requirement. In some experiments, however, the water requirement usually decreased a little when growth was limited by water deficits. The same result was obtained by Kiesselbach, who found that, with a deficient water regime, the dry matter of corn stalks, ears, and leaves were reduced 37%, 28%, and 10%, respectively. The water requirement based on ear weight decreased 4.3%, and the water requirement based on the total dry matter decreased 10%. Later Briggs and Shantz showed that the water requirement of wheat was essentially the same under deficient soil water (dry matter decreased 40%) as when water was adequate. King reached the same conclusion from experiments with corn, oats, and potato. Several decades later, de Wit analyzed experimental data that also showed similar T efficiencies regardless of water shortages.

Measurement of soil-water evaporation independently of plant transpiration is difficult, and models have been developed to separate the two. Evaporation can be measured directly with evaporimeters. Once a canopy covers the ground, most water is lost by transpiration. However, because water is lost by soil-water evaporation, investigators have studied evaporation-retardant chemicals, mulches, and plastic films. Results vary; for example, Letey and Peters have compared water-use efficiency of corn on plots with and without polyethylene film. The covered plots were initially wet and then covered to cut off summer rainfall and evaporation. Control plots received natural rainfall. Water-use efficiency for the covered plots was 345 kg per 100 m^3 of water and for the natural rainfall plots it was 148 kg per 100 m^3. However, in another year of the study, results showed no advantage from the plastic film. Plastic film is expensive and has been used only on high-value horticultural crops. But as water becomes more valuable, antitranspirants, mulches, and plastic films might be economically feasible for field crops, and water-use efficiencies with them need to be determined.

Method of irrigation Israel has dramatically increased its water-use efficiency through the use of new irrigation methods begun approximately in the 1960s (Figure 1). They are high-frequency,

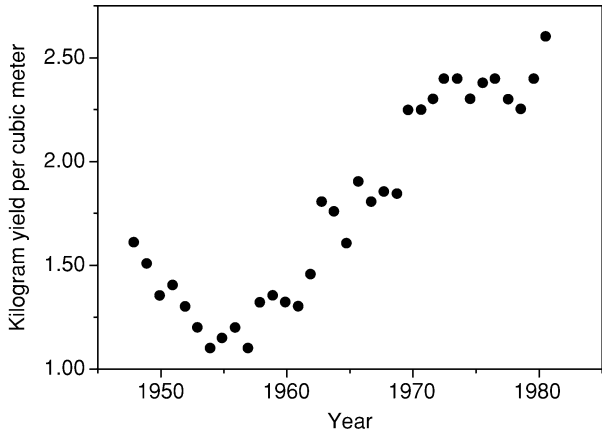

Figure 1 The improvement of crop water-use efficiency in Israel. (From *Rivers of Eden: The Struggle for Water and the Quest for Peace in the Middle East* by Daniel Hillel, © 1994 by Daniel Hillel. Oxford University Press, Inc.)

low-volume techniques of drip (trickle) and microsprayer irrigation. Before the new methods were developed, irrigations (flood or sprinkler) were usually infrequent and large, because it was assumed that soil moisture remained essentially equally available to crops until evaporation and extraction by roots depleted it to the permament wilting point. With the old methods, the topsoil was saturated after an irrigation, a condition that leached nutrients and deprived roots of aeration, followed by a period in which the crops were allowed to dry to a degree that desiccated the roots. Crops often show a pronounced increase in yield when irrigations are provided in sufficient quantity and frequency that water never becomes limiting. The newer irrigation methods became possible with the development of porous tubes for subirrigation and the advent of low-cost tubing that can be fitted with specially designed drip emitters. Drip and microsprayer irrigations can maintain the root zone in a moist yet unsaturated condition, so the roots do not lack water or oxygen. The irrigations are targeted precisely at the base of crop plants, thus wetting only a small fraction of the surface and not the interrow areas, where compaction by traffic, evaporation, and weed proliferation is reduced. Prevention of weed growth further conserves water.

Plant Factors

Species adaptation Because most species are adapted to grow with specific water requirements, plants must be matched with the rainfall. The record of human domestication of plants dates back at least 6000 years, and plant introductions (i.e., nonnative plants introduced into a region from another region) permitted our first great stride forward in efficient water use. In the USA, plant introductions were sponsored by the US Department of Agriculture. Immigrants also brought plants; for example, Turkey winter wheat was introduced into the Great Plains by Russian Mennonites, and winter wheat still is the most important crop in the region.

Plant breeding Briggs and Shantz have shown that plants differ greatly in water requirement. They carried out their research before the photosynthetic pathways had been elucidated. In all plants, photosynthesis involves the 'C_3' process that converts carbon dioxide into molecules with three carbons. In some species, called 'C_4' plants, carbon dioxide is first converted into molecules with four carbons, which are then transported within the leaf to sites (bundle-sheath cells) where carbon dioxide is released, providing a high concentration of carbon dioxide for the C_3 process. The same enzyme that catalyzes the first step in the C_3 process (ribulose 1, 5 bisphosphate carboxylase) can also catalyze an oxidation that leads to photorespiration, which is respiration that occurs in the light. Photorespiration consumes as much as a third of the carbon dioxide that the plant has absorbed in the light. It is slowed by high concentrations of carbon dioxide and, hence, occurs more rapidly in C_3 plants such as wheat than in C_4 plants such as maize. Plants with the C_4 type of photosynthesis have a lower water requirement than plants with the C_3 type of photosynthesis. The reasons for this difference are not fully understood, but it is probably due, in part, to the fact that, under the same environmental conditions, C_4 plants generally have a higher stomatal resistance than C_3 plants. The difference in water use between C_3 and C_4 plants was evident even in the work of Briggs and Shantz (Table 1). Plants which we know today have the C_4 type of photosynthesis (e.g., maize, millet, sorghum) have a lower water requirement than plants with the C_3 type of photosynthesis (e.g., alfalfa, barley, wheat). On average, plants with the C_4 type of photosynthesis have a water requirement of 250–350 g $H_2O\,g^{-1}$ dry weight, and plants with the C_3 type of photosynthesis have a water requirement of 450–950 g $H_2O\,g^{-1}$ dry weight. Alfalfa's water requirement can be greater than this; it has the highest water requirement of any crop species.

A third type of photosynthesis occurs, but the only commercially important plant that has this type of photosynthesis is pineapple. It is called the crassulacean acid metabolism (CAM) photosynthetic pathway. Unlike most plants that have stomata open in light, when carbon dioxide is taken up (and water is lost by transpiration), plants with CAM photosynthesis keep their stomata open in darkness and take

Table 1 Water requirement based on aboveground vegetative dry matter for various crops as determined by Briggs and Shantz before the knowledge of C_3 and C_4 photosynthetic pathways. Photosynthetic pathway of each crop is noted in parentheses

Crop	*Water requirement (g H_2O g^{-1} dry wt)*
Wheat (C_3)	507
Oats (C_3)	614
Barley (C_3)	539
Rye (C_3)	724
Corn (C_4)	369
Sorghum (C_4)	309
Millet (C_4)	275
Peas (C_3)	800
Sweet clover (C_3)	709
Alfalfa (C_3)	1068
Buckwheat (C_3)	578
Rape (C_3)	441
Potatoes (C_3)	448
Sugar beets (C_4)	377
Salsola (saltwort of the Chenopodiaceae family) (C_4)	366
Amaranthus (C_4)	303
Artemisia (C_3)	765

up carbon dioxide at night. The photosynthetic enzymes that CAM plants use are the same ones as found in C_4 plants, but their activity depends upon whether it is light or dark. Because CAM plants keep their stomata open at night and not during the daylight hours when heat and light cause great amounts of water to be lost through the stomata, they have the lowest water requirement of any plants. On average, their water requirement is 50–55 g H_2O g^{-1} dry weight.

Not only do species differ in water requirement, but also cultivated varieties (cultivars) within a species vary. This was noted in 1913 by Briggs and Shantz, who suggested the possibility of developing varieties that are efficient in the use of water.

When water becomes limited during a plant's development, yield differences among species and varieties are due to a plant's water efficiency. Plant characteristics that contribute to such efficiency include maturity (including planting date); leaf area and angle of inclination; leaf rolling; number, distribution, and size of stomata; presence of waxy or corky epidermal cells; the ability to become temporarily dormant; and extensiveness of the root system. Distribution of roots is especially important. Even though roots may be at an optimum depth, the surface roots are often the ones that preferentially extract water after rewatering.

Cultural Factors

Planting patterns Planting patterns have a direct effect on yield, solar-energy capture, and soil-water evaporation and thus an indirect effect on water-use efficiency. Soil-water evaporation is diminished with denser plantings. In humid regions where rainfall exceeds evapotranspiration, plant populations can be increased with a concomitant increase in yield. However, in semiarid regions, when plant populations are increased, the plants most often need to be irrigated. For example, dense planting of sorghum has been advocated as a beneficial method for rain-fed land in Kansas, because it reduces soil-water evaporation, runoff, erosion, and weeds. But the super-thick plantings fail to produce grain if soil moisture is not adequate.

Seed quality A crop-management problem, sometimes overlooked, is seed quality. For most efficient use of water, a grower must start with high-quality seed. Poor seed may mean not only poor germination and weak plants that cannot take advantage of the available water, but also such seed may include weed seeds and thus provide competitors for the water present.

Weeds One of the primary management means of obtaining more efficient water use is the elimination of weeds in crops. Weeds compete with crops for soil nutrients, water, and light. Except in high-rainfall areas, the primary concern is the water factor. The water requirement of many weeds is greater than that of crop plants, because many weeds are C_3-type plants. For example, the average ragweed plant requires three times as much water per pound (0.45 kg) of dry matter produced as a maize plant, a C_4 plant.

Disease and insect pests Few data concerning effects of disease and insect pests on water-use efficiency are available. Rusts decrease transpiration in the early stage of infection, but, on sporulation, they cause epidermal leakage of water vapor and increased water loss in light and dark conditions. The powdery mildews cause a similar decrease in transpiration and then an increase in transpiration. These transpiration trends have been found to decrease the transpiration efficiency. For example, studies show that early rust infection halves the transpiration efficiency of wheat, when based on total dry matter, and, when based on grain yield, it is 25-fold smaller. Infection at later stages of development produces correspondingly smaller decreases. Water-use efficiency data for vascular wilts, root rots, and insect pests are lacking. Breeding for resistant varieties is probably the most economic and longest-lasting method to control

diseases and insects. Efficient crop and water management also includes the wise use of herbicides and insecticides, and their effect on water-use efficiency needs to be determined.

Tillage The surface characteristics of soil can have a profound effect on the water that infiltrates and runs off. Reduced or minimum tillage has been taken up by some farmers in the semiarid Great Plains. While yields are often reduced during the first few years after reduced tillage is initiated (due, for example, to difficulty in controlling diseases and insects), water is conserved. This results in less erosion in wet years and longer survival of crops in droughts, because the mulch that remains on the surface of the soil reduces evaporation. However, water-use efficiency may not be increased. Stubble-mulch tillage in the Great Plains does not necessarily alter rainfall-use efficiency.

Rotations While studies indicate that rotations can improve infiltration and water use, they do not always. For example, a grass–legume crop may have low infiltration rates because of heavy grazing. In Kansas, a deep-rooted alfalfa–fescue mixture was grown on a claypan to increase root penetration of maize, planted the following year. However, the deep-rooted plants removed moisture throughout the soil profile, resulting in low yields of maize. Continuous maize yielded more than maize grown in rotation. Sunflower, with its deep roots and a high water requirement, removes more water from a soil profile than sorghum. Under dry-land conditions, crops planted following sunflower will lack stored moisture. Thus, rotations may not generally improve available water and may result in less available moisture when the preceding crop has a high water requirement.

Fertilization Data have been reviewed from about 20 experiments showing the effect of varying fertility on water requirement and the conclusion is that, with poor soils, the water requirement may be reduced one-half to two-thirds by increasing fertility. In all but five experiments, evaporation from the soil was included in the water use and could bias the water requirement for smaller plants with less transpiration. In experiments where evaporation was prevented, the water requirement did not increase significantly as the fertility and yield decreased, until the dry weight of the plants had decreased approximately 50% because of malnutrition. It appears from these data and others that, unless malnutrition is severe, transpiration efficiency based on total dry matter is not greatly affected by poor fertility. But, when nutrient deficiency reduces yield to about half that on a well-fertilized soil, then transpiration efficiency is reduced markedly.

Climate

The seasonal changes in both transpiration and evapotranspiration efficiencies found with exposures to different radiation, temperature, and humidity regimes show that climate exerts a major influence on water-use efficiencies. Even the early researchers recognized that, with well-watered plants, variation of transpiration with climate causes changes in water-use efficiency as the season progresses, between years and between locations, and that free-water (pan) evaporation or saturation deficit could be used to normalize the transpiration component (Table 2).

The carbon dioxide concentration in the atmosphere is increasing due largely to the increased burning of fossil fuel by industry and automobiles. Since 1958, the carbon dioxide concentration has risen from 316 ppm ($316\,\mu l\,l^{-1}$) to approximately 370 ppm. The concentration increases at a rate of $1.5–2.0\,\mu l\,l^{-1}$ per year. When atmospheric carbon dioxide is relatively low, net photosynthesis is faster in C_4 plants than in C_3 plants, but, at higher levels of carbon dioxide, the change in photorespiration per change in carbon dioxide concentration leads to greater increases in net photosynthesis for C_3 plants than for C_4 plants. Therefore, increasing levels of carbon dioxide should benefit C_3 plants more than C_4 plants. The increasing levels of carbon dioxide do increase the water-use efficiency of C_3 plants. When winter wheat was grown for 3 years with four different levels of carbon dioxide (ambient or $340\,\mu l\,l^{-1}$

and 485, 660, and 825 $\mu l\,l^{-1}$), the water requirement decreased with increasing levels of carbon dioxide (Figure 2). During the 3 years of the study, water required to produce a gram of grain under the highest carbon dioxide concentration (825 $\mu l\,l^{-1}$) and dry conditions (half-field capacity) was less (547 $ml\,g^{-1}$) than that required to produce a gram of grain under well-watered conditions (field capacity) at the ambient carbon dioxide concentration (642 $ml\,g^{-1}$). Under well-watered conditions, the water requirement of the wheat grown with ambient and elevated carbon dioxide was 642 $ml\,g^{-1}$ and 458 $ml\,g^{-1}$, respectively (a reduction of water requirement, based on grain, of 29%).

Even though predictions indicate that C_3 plants will have a higher water-use efficiency with elevated carbon dioxide than C_4 plants, data also show that C_4 plants have increased water-use efficiency. When sorghum, kept under watered conditions, was grown under ambient (330 $\mu l\,l^{-1}$) and elevated (795 $\mu l\,l^{-1}$) levels of carbon dioxide, water requirement for grain production was 1090 $ml\,g^{-1}$ and 776 $ml\,g^{-1}$, respectively (a 29% reduction in water requirement with elevated carbon dioxide).

Measurement of Water-Use Efficiency

Water-use efficiency is usually measured by harvesting plants, determining dry weight of the vegetative portion or grain, and dividing that by the rainfall or irrigation plus rainfall. Weighing lysimeters have allowed more precise measurements of water used. With the development of portable photosynthetic systems, researchers can now measure in the greenhouse or field the water-use efficiency of individual leaves or parts of leaves. Figure 3 shows water-use efficiency determined on different locations of a leaf of puka (*Meryta sinclairii* Seemann), a native tree of New Zealand. The leaves are large and elliptical, up to 0.6 m long and 0.3 m wide. The center of the leaf (to the side of the main vein) and the middle edge have the highest photosynthetic rates and transpiration rates, but the tip of the leaf has the highest water-use efficiency. The base of the leaf has the lowest photosynthetic rate, the lowest transpiration rate,

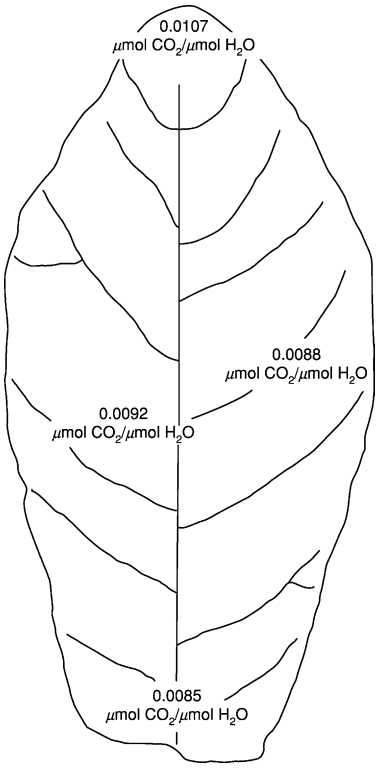

Figure 3 Water-use efficiency at four locations on a leaf of puka, a native New Zealand tree. The locations are tip, edge of middle, base, and center to the side of the main vein. To obtain these values, photosynthetic rates and transpiration rates were measured on puka leaves during a 1-month period in the summer of 1998 in Lincoln, New Zealand. From 14 to 34 values were measured. These values were divided to get the water-use efficiencies shown. The leaf traced for the figure is 25.7 cm long and 12.7 cm wide.

and the lowest water-use efficiency. These results show the power of modern measurement techniques. We can now define with fine spatial resolution the water-use efficiency of parts of individual leaves and try to understand the physiological reasons for the differences.

Another method of determining transpiration efficiency is carbon isotope discrimination. In this method, the discrimination (Δ) of the stable isotope of carbon, ^{13}C, relative to the more abundant ^{12}C, is determined. The discrimination occurs because of the different diffusivities of ^{13}C and ^{12}C across the stomata and the fractionation by the C_3 enzyme, ribulose bisphosphate carboxylase. The method is limited to laboratories that can afford an expensive mass spectrometer with the ability to measure the ratio of ^{13}C to ^{12}C with high precision. However, the method has shown that genetic variation in transpiration efficiency in wheat cultivars does exist, and the variation is approximately twofold. The genetic variation in transpiration efficiency is negatively correlated in C_3 species with the discrimination of ^{13}C relative to ^{12}C, as shown in Figure 4. In C_4 species, Δ does not correlate with transpiration efficiency.

Possibilities of Increasing Water-Use Efficiency

With careful isotopic measurements, C_3 plants that vary slightly in water-use efficiency can be selected. If one cultivar has only a small increase in water-use efficiency compared with another and if grown over many hectares, this small difference could have a significant effect on water conservation.

Genetic engineering for increased water-use efficiency might be a possibility in the far future; for example, incorporating the C_4 photosynthetic pathway into C_3 plants. In the meantime, the increasing carbon dioxide concentration in the atmosphere seems to offer the greatest potential for increasing water-use efficiency. Leaf photosynthetic rates and leaf transpiration rates of a C_3 plant (Kentucky bluegrass) and a C_4 plant (big bluestem) grown in the field under ambient and elevated (twice ambient) levels of carbon dioxide have been measured. The C_3 plant has a photosynthetic rate similar to the C_4 plant under elevated carbon dioxide (Figure 5). The transpiration rate of the C_3 plant under the low and high levels of carbon dioxide is similar. So the leaf water-use

efficiency of the C_3 plant is increased three times due to the doubling of the ambient carbon dioxide–just about the same amount as the photosynthetic rate is increased, if the values are averaged throughout the experiment. Even though increasing carbon dioxide concentrations may have negative consequences (e.g., favoring of weed growth over crop growth), it appears that this does have the positive effect of increasing water-use efficiency.

WEED MANAGEMENT

D D Buhler, Michigan State University, East Lansing, MI, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Soil tillage has been a major element of crop production for centuries. However, tillage has negative side-effects, including increased soil erosion and high labor and fuel requirements. Methods for reducing tillage were proposed as early as the 1920s. For row-crop production, no-tillage methods became much more feasible beginning in the late 1950s and 1960s as herbicides became available to replace tillage for control of unwanted vegetation.

Weed control refers to actions used to eliminate an existing weed population. Weed management is more than control of existing weed problems and places greater emphasis on preventing weed reproduction, reducing weed emergence after crop planting, and minimizing weed competition with the crop. Integrated weed management emphasizes combinations of techniques and knowledge that consider the causes of weed problems rather than react to problems after they occur. The goal of weed management is to optimize crop production and grower profit through the concerted use of preventive tactics, scientific knowledge, management skills, monitoring procedures, and efficient use of control practices.

One of the first steps in effectively managing weeds is understanding weed populations and their responses to tillage systems. As the impacts of tillage systems on weed population dynamics are examined, we must apply basic ecologic principles. Weeds are successful because of their genetic diversity and their ability to adapt to and take advantage of conditions created by crop-production systems. Therefore, modifying tillage practices results in an altered competitive environment in which the morphological and physiological traits that confer success are altered. Understanding weed population shifts leads to the identification of vulnerable stages in weed life cycles that can be exploited in management systems. Understanding population shifts also helps to identify species that are favored as tillage practices are changed, allowing for the development of weed-management systems that target the appropriate weed species.

Impacts of Tillage on Weed Management

General Effects

Crop-production practices exert selection pressure on weed communities and create niches that favor or disfavor various species. Since tillage has been an integral part of many cropping systems for centuries, it has played a major role in shaping the nature of weed communities in most agricultural lands.

Tillage buries crop residue and alters the characteristics of the surface soil, regulating the germination environment of seeds by reducing soil surface cover, altering soil temperature and moisture patterns, changing weed seed distribution in the soil, and disrupting the growth of winter annual, biennial, and perennial species. The term 'safe site' has been used to describe the complex conditions that are required for successful seed germination and seedling establishment. Several studies have pointed out that safe-site conditions vary greatly among plant species. The changes in safe-site characteristics, along with the physical disruption caused by tillage, combine to play a major role in weed-population dynamics in crop-production systems.

Control Options and Efficacy

Tillage systems impact weed-control options available to producers. Certain herbicides may not be used in conservation-tillage systems because of the need for mechanical incorporation into the soil after application. With less tillage and more plant residue on the soil surface, mechanical weed-control operations may become less effective. Rotary hoeing is especially difficult in untilled soil covered with residue of the previous crop. Interrow cultivation can be a component of some conservation-tillage systems and is an integral component of ridge-tillage. Combining interrow cultivation with reduced herbicide use has provided weed control similar to full-rate herbicide treatments in conservation-tillage systems. However, the effects of interrow cultivation on the long-term impacts of no-tillage to soil properties and soil-erosion reduction have not been documented.

Plant residue on the soil surface can alter the behavior of soil-applied herbicides. Depending on percentage surface cover, residue type, and herbicide formulation, up to 60% of the herbicide applied may be intercepted by residue. However, much of this herbicide is often washed off by subsequent

Table 1 Influence of tillage systems on control of selected summer annual weed species with soil-applied herbicides in *Zea mays* and *Glycine max* production systems

	Change relative to moldboard-plow systems[a]

Chenopodium album	+, 0,−	0,−	+, 0
Setaria faberi	−	−	0

[a]+, increased control relative to moldboard plow; 0, no change relative to moldboard plow;−, decreased control relative to moldboard plow.

rainfall and irrigation. The ultimate effect on weed control is determined by the timing of rainfall or irrigation relative to herbicide application, the level of residue cover, and the nature of the weed population.

Setaria faberi (giant foxtail) is more difficult to control with soil-applied herbicides in conservation- versus conventional-tillage systems (Table 1). Conversely, *Abutilon theophrasti* (velvetleaf) control increases as tillage is reduced. The effects of tillage systems on the control of small-seeded dicotyledon weed species vary by species and location. Herbicides applied after weed emergence are influenced less by tillage systems because they are applied directly to the target weeds and do not interact with residue on the soil surface.

The effect of tillage systems on herbicide efficacy is due to the combination of surface-residue interception of herbicides and changes in weed-population dynamics. For example, control of annual grass species is often reduced as tillage is reduced, while control of some annual dicot weeds increases. These variable responses indicate that choices of appropriate control tactics and application timing are critical in conservation-tillage systems. Because of the reliance on herbicides for weed control in most conservation-tillage systems, knowledge of the interactions of weed biology and ecology with herbicide activity is essential to managing weeds in conservation tillage without increasing herbicide use to environmentally and economically unacceptable levels.

Biology and Ecology of Weed Responses to Tillage Systems

Classification of Weed Species

Weeds can be classified in many ways, and understanding weed life cycles is important in predicting population shifts and designing management strategies. Weed species with different life cycles have different requirements for seed germination, seedling establishment, growth, and reproduction. Because tillage greatly alters the environment where weed species survive, altering tillage systems favors certain life cycles over others. In no-tillage systems, there has often been a marked drop in the variety of annual species. Concomitantly, there has been an increase in winter annual, biennial, and perennial weed species.

Weeds of agronomic crops are a unique group of plant species because of their ability to infest and often thrive in intensively disturbed habitats. In addition to classification by life cycle, a classification appropriate to understanding weed-population dynamics under different tillage systems follows:

1. Arable-response weed species that require periodic, regular disturbance of the soil for survival;
2. Inverse-response weed species that require undisturbed soil for survival;
3. Intermediate-response weed species that survive in both disturbed and undisturbed soil.

Combining characteristics of life cycles and tillage response of weed species is useful in predicting weed population shifts. For example, weed populations in reduced-tillage systems where summer annual crops are grown are dominated by arable- and intermediate-response summer annual species, because the soil is disturbed annually and management practices favor summer annual species. In no-tillage systems, weed populations shift toward inverse- and intermediate-response species. Winter annual, biennial, and perennial species are well adapted to no-tillage, because there is little or no tillage to interrupt the life cycle. In addition, summer annual species that do not require burial for establishment are well-adapted to no-tillage systems. However, since soil disturbance is required to plant crop seeds and incorporate fertilizers in annual cropping systems, arable-response species may continue to exist in no-tillage fields. Seed buried by previous tillage may also persist for several years and continue to be a source of arable-response species in no-tillage systems.

Summer Annual Species

Summer annual species are major weed problems in production systems dominated by summer annual crops, because they are well-adapted to the environment created by the production systems (i.e., similar life cycle, high fertility, annual disturbance, production in rows, and herbicide use). Changes that occur in the dynamics of annual weed communities as a function of tillage practices are regulated by species present in the field, biology of the species, and efficacy of weed-management practices.

The most commonly reported change in annual weed populations with decreased tillage is an increase in summer annual grass species, including *S. faberi*, *S. viridis* (green foxtail), *S. glauca* (yellow foxtail), *Panicum dichotomiflorum* (fall panicum), and *Cenchrus incertus* (field sandbur) (Table 2). The magnitude of changes in summer annual grass densities has varied among experiments, but the potential for rapid changes in density and emergence patterns of these weed species clearly exists.

Changes in the population dynamics of summer annual dicotyledon species with changing tillage practices have been less consistent. The most common response among annual dicotyledon species has been reduced density of large-seeded species such as *Ab. theophrasti*, *Xanthium strumarium* (common cocklebur), and *Cassia obtusifolia* (sicklepod) as tillage is reduced (Table 2). The response of small-seeded summer annual dicotyledon weed species to changes in tillage practices has been variable among weed species and experiments. This variable response is typified by *Chenopodium album*. In different studies at different locations, *Ch. album* densities increased, stayed the same, or decreased in response to reduced tillage. Species that germinate under cool soil conditions, such as *Ch. album*, may be prevalent in no-tillage fields prior to crop planting. Early emergence may allow such species to suppress later emerging weeds or result in a significant portion of the population being destroyed by tillage or herbicide prior to crop planting. *Amaranthus retroflexus* (redroot pigweed) is another small-seeded summer annual dicotyledon species that has responded inconsistently to changes in tillage systems. *Am. retroflexus* may be best-suited to systems with moderate tillage, because its seeds are well-adapted to shallow burial.

Table 2 Influence of tillage systems on densities of selected summer annual weed species in *Zea mays* and *Glycine max* production systems

Weed species	*Tillage response*[a]
Abutilon theophrasti	−
Amaranthus retroflexus	+, 0,−
Cassia obtusifolia	−
Cenchrus incertus	+
Chenopodium album	+, 0,−
Echinochloa crus-galli	+
Panicum dichotomiflorum	+
Setaria complex	+
Xanthium strumarium	−

[a]+, increased density with reduced tillage; 0, no change with reduced tillage;−, decreased density with reduced tillage.

Weed Seed Bank and Seedling Biology

It is often difficult to determine whether changes in population dynamics are due to biological properties of the weed species or differences in control efficacy. To address this issue, research has been conducted to separate various aspects of tillage–weed species–weed-control efficacy interactions to elucidate the mechanisms of weed population shifts.

The primary source of arable-response, summer annual weed species is the weed seed bank in the soil, with the largest source of seed being that produced in previous years in the same field. Changes in the weed seed bank occur with time and weed-management programs. Tillage is the primary cause of vertical seed movement in arable soils. Since tillage systems affect weed management, weed seed production, and soil disturbance, changing tillage systems changes the distribution and density of weed seed in agricultural soils.

Moldboard-plow plots have fewer weed seeds in the upper 20 cm of soil than chisel-plow or no-tillage plots after 5 years. Moldboard plowing results in the most uniform distribution of seed over soil depths. In a no-tillage system, more than 60% of all weed seeds are found in the upper 1 cm of soil and few seeds are found at more than 10 cm. The concentration of weed seed in no-tillage decreases logarithmically with increasing depth. In the chisel-plow system, more than 30% of the weed seeds are in the upper 1 cm of soil and seed concentration decreases linearly with depth.

Differences in emergence depths in different field tillage systems reflect differences in weed seed distribution in the soil. Mean seedling emergence depths in no-tillage are the least, followed by chisel-plow and moldboard-plow systems in two soil types (Table 3). At least 40% of the *S. faberi* and *S. viridis* plants emerge from the upper 1 cm of soil in no-tillage compared with approximately 25% in chisel-plow and less than 15% in moldboard-plow plots. Changes in seed depth in the soil and the corresponding differences in emergence depth may contribute to shifts among weed species. In greenhouse research, *Ab. theophrasti* establishment from seed germinating on the soil surface is much less than for seed planted 6 cm deep, and seedlings from surface-placed seed are less vigorous. *S. faberi* seed germinating on the soil surface has an establishment percentage similar to seed planted 1–4 cm deep, but establishment is reduced by 50% when the seeds are planted 6 cm deep.

Surface topography influences the emergence location of *Ab. theophrasti* seedlings when a field has not been tilled the previous two growing seasons. No *Ab. theophrasti* seedlings emerge from bare soil, and the majority of the *Ab. theophrasti* seedlings emerge

Table 3 Effect of tillage systems on depth of emergence of *Setaria* species under field conditions

	Depth of emergence (cm below soil surface)	
Tillage system	*Range*	*Mean*
Moldboard plow	0–10	3.1
Chisel plow	0–9	2.4
No-tillage	0–10	1.4

Source: Buhler DD (1998) Tillage systems and weed population dynamics and management. In: Hatfield JL, Buhler DD, and Stewart BA (eds) *Integrated Weed and Soil Management*, pp. 223–246. Chelsea, MI: Ann Arbor Press.

from cracks in the soil. Another significant portion of the *Ab. theophrasti* emerge from under surface residue. The presence of surface residue increases soil moisture and reduces soil crusting compared with bare soil, thus providing adequate moisture conditions for germination for a longer period of time. These data suggest that the safe-site concept should be extended below the soil surface to the depth where soil surface conditions influence germination conditions and that soil cracks may be a factor in weed emergence patterns.

The effect of tillage practices on the population dynamics of summer annual weed species is complex and involves several factors. However, seed depth in the soil appears to be the most important factor. Weed species that have the ability to germinate and become established when the seeds are at or near the soil surface have the greatest potential to increase under conservation-tillage systems. These species tend to be small-seeded and are represented by small-seeded, annual dicotyledon and most annual grass species. Deep burial of seed of small-seeded species by moldboard plowing reduces germination and emergence. Conversely, seeds of large-seeded species remain near the soil surface in conservation-tillage systems, inhibiting establishment.

Winter Annual and Biennial Species

Weed species not previously observed in fields planted to summer annual crops have rapidly appeared following elimination of preplant tillage. Species most rapidly and commonly observed are winter annual and biennial species that are characterized by an inverse tillage response. These weed species are unable to complete their life cycles in association with summer annual crops if the soil is disturbed after harvest or prior to crop planting the following spring.

Changes in soil surface characteristics and disturbance patterns in no-tillage systems create an environment where winter annual and biennial species may become established and complete their life cycle. Winter annual species germinate in the late summer and autumn, survive the winter, and flower the following spring. Because of the growth habit and ability to adjust photosynthetic responses to temperature, many winter annual species can grow even during the winter. Established winter annual plants preempt space, suppress summer annual species, and can be very competitive with summer annual crops. Rapid growth early in the spring can also make winter annual species difficult to control with herbicides if allowed to grow until or after the time of crop planting.

When the soil is tilled in the spring, rosettes and seedlings of winter annual and biennial species recruited during the previous growing season are destroyed. However, new seedlings of winter annual and biennial species may emerge under the canopy from seeds in the seed bank or that move in from adjacent areas. If tillage is removed from the system, these seedlings survive and grow during the autumn and winter and are established at the start of the second year. Thus, these species can rapidly infest fields (often during the first year) when tillage is eliminated. The rapid appearance of winter annual species does not appear to result from differences in innate competitive ability relative to summer annual species, but rather from the timing of disturbance, which changes competitive hierarchies.

Conyza canadensis (horseweed) is one of the most common and troublesome winter annual weeds in no-tillage systems in the central and eastern USA and an excellent example of an inverse-tillage response winter annual species. *Co. canadensis* can infest no-tillage fields very rapidly because it is commonly found in field edges and roadsides, produces many wind-disseminated seeds, is tolerant to many commonly used herbicides, and can become established under a wide-range of soil and climatic conditions, making it well-adapted to the no-tillage soil environment. Other winter annual species such as *Bromus tectorum* (downy brome) and *Capsella bursa-pastoris* (shepherd's purse) have also been observed to infest no-tillage fields.

Perennial Species

Perennial weed populations increase as tillage is reduced, because the underground system is not disturbed and most herbicides used to control annual weeds are not fully effective on established perennial plants. A preponderance of the literature indicates that weed flora associated with reduced-tillage systems favor perennial monocotyledon and dicotyledon species. Perennial monocotyledons might be

the greatest threat to the adoption of reduced-tillage systems because of the importance of monocotyledon crops in many regions of the world.

In most studies, more diverse and dense populations of perennial weeds develop in conservation-tillage systems than where moldboard plowing is conducted. Increases in perennial weed populations vary among sites because tillage interacts with weed-management practices, environment, and initial perennial weed populations. Therefore, the general statement that perennial weeds increase as tillage decreases must be made with caution. Management practices such as selective application of glyphosate to tall-growing perennial weeds, the use of crop cultivars resistant to herbicides such as glyphosate, and interrow cultivation help reduce perennial-species densities regardless of tillage system. Conservation-tillage systems have the potential to increase densities and species diversity of perennial weeds, but management practices such as crop rotation, selective application of glyphosate or other herbicides, and interrow cultivation can prevent perennial weed species from increasing to levels that reduce crop yields or increase production costs.

Summary

Although general trends in weed population dynamics in conservation tillage have been observed, it is important to note that location, environment, the type of conservation-tillage system used, producer management skills, and weed-management inputs regulate responses in individual fields. In addition, individual species respond differently among sites or within a site over time. This indicates that weed-management systems and cultural practices interact with tillage to regulate weed populations.

Effective and economical weed management in conservation-tillage systems, especially no-tillage, is a challenge. Due to the changes in biological and management systems, it is important to take a systematic approach to planning and executing weed management in conservation-tillage systems. Assessing the strengths and weaknesses of the available control options relative to expected weed populations is essential when designing weed-management systems.

The intensive tillage traditionally conducted in row-crop production has had a profound effect on weeds and weed management. Effective, economical, and environmentally sound weed management in conservation-tillage systems over the long term will require integration of new information with established principles of weed management. Crop rotation, tillage rotation, judicious use of tillage, herbicide-resistant crop cultivars, and innovative application methods for herbicides will aid weed management in conservation-tillage systems. New technologies are also needed to deal with the altered agroecosystems created by conservation-tillage production systems. New control options such as biological agents and allelopathic cover crops can provide useful new management tools. Many weed species and weed-control tactics behave differently as tillage is reduced or eliminated. These changes must be taken into consideration to develop economically and environmentally sound weed-management systems. It is essential that crop producers and pest managers consider the idiosyncrasies of the biological interactions among weeds, crops, residues, and environment as they develop weed-management plans for conservation-tillage systems.

List of Technical Nomenclature

Abutilon theophrasti Medikus	velvetleaf
Amaranthus retroflexus L.	redroot pigweed
Bromus tectorum L.	downy brome
Capsella bursa-pastoris (L.) Medikus	shepherd's purse
Cassia obtusifolia L.	sicklepod
Cenchrus incertus M.A. Curtis	field sandbur
Chenopodium album L.	common lambsquarters
Conyza canadensis (L.) Cronq.	horseweed
Glycine max (L.) Merr.	soybean
Glyphosate	*N*-(phosphonomethyl)glycine
Panicum dichotomiflorum Michx.	fall panicum
Setaria faberi Herrm.	giant foxtail
Setaria glauca (L.) Beauv.	yellow foxtail
Setaria viridis (L.) Beauv.	green foxtail

Xanthium strumarium L.	common cocklebur
Zea mays L.	corn

WETLANDS, NATURALLY OCCURRING

E K Hartig, New York, NY, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Wetlands are areas that are located where land and water meet, where the habitat is neither aquatic nor fully terrestrial, the soil being for the most part too wet and oxygen-depleted for any but specially adapted plants to survive. Wetlands occur along lakes, creeks, rivers, bays, and deltas; they are found on every continent except Antarctica, in the low-lying peatlands of Indonesia and Siberia as well as in high-altitude montane depressions. Worldwide estimates vary somewhat; e.g., estimated freshwater coverage of 5.3 million km^2, based on soil maps prepared by the Food and Agricultural Organization of the United Nations (FAO); and the commonly used estimate of 8.6 million km^2. Some examples of huge contiguous wetlands are the Pantanal in parts of five countries in South America, the Sudd Marshes of the Sudan along the White Nile River, and the permafrosted peatlands in the northern high latitudes of Canada, Alaska, and Siberia. Examples of very small but highly productive wetlands can be found in the Prairie Pothole region in North Dakota, Minnesota, and parts of Canada. These comprise a vast complex of tens of thousands of individual shallow wetlands that vary in size, some being as small as 0.1 ha.

Historically wetlands have been treated as wastelands to be drained and farmed, or filled and built upon. Traditional attitudes are exemplified by such expressions as 'bogged down,' 'swamped,' 'muddied,' 'mired,' 'murky,' 'morass,' 'malarial,' and 'quagmire.' Great drainage schemes have long dominated approaches to wetlands worldwide. An example of a government works program was the mosquito ditching conducted in the USA during the 1930s by the Work Projects Administration. Most US East Coast marshes bear the scars of these labor-intensive ditching projects. More than 50% of the wetlands in the USA have been drained since colonial times. In the UK more than 90% of present-day agricultural lands were formerly wetlands. Many wetlands remain under threat either from direct human interference or from indirect causes such as sea-level rise inundating coastal areas, or changes in hydrological regimes due to upstream alterations for dams, dikes, or levees. The swamps of southern Sudan are among the largest of the world's wetlands and home to one of the greatest

concentrations of large mammals (such as the buffalo, elephants, hippopotami, gazelles, waterbucks, and zebra). These wetlands are threatened by the planned diversion of the White Nile.

In recent decades, the perception of wetlands has changed, and there is increasing recognition of the many vital functions provided by wetlands. These include providing wildlife habitat, flood and erosion control, aesthetics and recreation, carbon sequestration, and high biological productivity.

Wetland Definitions

Wetland definitions used by scientists and by administrative agencies commonly refer to vegetation types, soils, and/or hydrology. Administrative agencies use variations of the three-parameter approach (vegetation, soils, hydrology). The definition developed by the US Fish and Wildlife Service (USF-WS) and used by the US Army Corps of Engineers (Corps) for delineating wetland boundaries under Corps jurisdiction states:

> Wetlands are areas that are inundated or saturated by surface or groundwater at a frequency and duration sufficient to support, and that under normal circumstances do support, a prevalence of vegetation typically adapted for life in saturated soil conditions. Wetlands generally include swamps, marshes, bogs, and similar areas. (Definition of Waters of the United States; 33CFR328.3(b); 1984)

Wetland Classification

Wetland classifications abound, but usually they are divided according to their relation to water bodies, vegetation types, and substrates. The widely used Cowardin classification takes into account wetlands that can be found in five environments. Of these, Marine, Riverine (along freshwater nontidal rivers and streams), and Lacustrine (along lakes) wetlands are mainly aquatic and have little or no soil development. Estuarine (tidal embayments and tidal portions of rivers) and Palustrine (inland freshwater forested and nonforested) wetlands contain hydric soils.

Estuarine Wetlands

This category includes intertidal salt and brackish low and high marsh zones, nonvegetated tidal flats, brackish waters of coastal rivers and embayments, and mangrove swamps:

1. Estuarine emergent wetlands: These are wetlands dominated by herbaceous grasses and are referred to as salt marsh, low marsh (intertidal marsh), high marsh, and brackish tidal marsh. They are found in protected embayments or behind barrier beaches where the water has slowed. Many, such as the *Spartina alterniflora* intertidal marshes of the northeastern USA, formed within the last 4000–7000 years as the postglacial rise in sea level slowed. Typically there is strong zonation of species in the salt marsh, depending on the frequency and duration of tidal ebb and flow (Figure 1);
2. Estuarine scrub–shrub wetlands: These wetlands contain woody vegetation such as marsh elder or high-tide bush. With exposure to salt spray and infrequent flooding they are adapted to a high-salt environment. This category also includes mangrove swamps.

Palustrine Wetlands

This category includes the majority of freshwater wetlands. It encompasses marshes, bogs, swamps (forested), and ponds. Shallow-water bodies such as

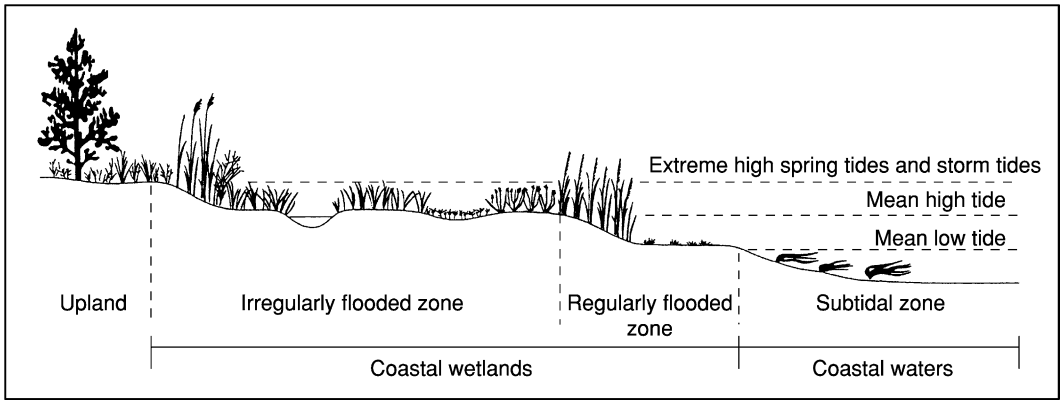

Figure 1 Hydrology of a tidal wetland indicating different zones of flooding. The regularly flooded zone is subject to at least once-daily tidal inundation, while the irregularly flooded zone is inundated less frequently. (Reproduced from Tiner RW and Burke DG (1995) *Wetlands of Maryland*. USFWS, Hadley/Maryland Department of Natural Resources. Annapolis, MD: US Fish and Wildlife Service.)

vernal ponds and playa lakes (less than 2 m deep) are also in this category:

1. Palustrine emergent wetlands: These wetlands are dominated by herbaceous vegetation with many species of grasses, rushes, and sedges. They are referred to as freshwater marshes, wet meadows, and fens. The marshes may be irregularly to permanently flooded. In the US Prairie Pothole region, glacial depressions flood, especially during the spring season following snowmelt (and offer a protein-rich diet to migrating waterfowl). Palustrine emergent wetlands occur in a variety of habitats, including peatlands and freshwater marshes;
2. Palustrine scrub–shrub wetlands: These are characterized by woody vegetation less than 6 m tall. North American bogs with vegetation such as bog laurel, Labrador tea, cranberry, and leatherleaf, and with stunted trees such as black spruce, larch, and balsam fir are examples of scrub–shrub wetlands;
3. Palustrine forested wetlands: These are wetlands with trees greater than 6 m in height. Tree species found in northeastern US wetlands include red maple, pin oak, sweet gum, black spruce, and larch.

Hydric Soils

The definition of a hydric soil is as follows:

> A hydric soil is a soil that is saturated, flooded, or ponded long enough during the growing season to develop anaerobic conditions in the upper part of the soil.

In organic wetland soils, a thick organic layer develops over time where microbial decomposition is severely slowed or remains incomplete under waterlogged conditions. Organic wetland soils develop in depressions or in coastal areas where anaerobic conditions prevail (such as in bogs or intertidal marshes). Included are mucks (saprists), peats (fibrists), and hemists – mucky peat or peaty muck. The accumulated peat or muck layers are 0.6 to more than 9 m in depth. While organic matter is present in all soils, it constitutes greater than 20% (based on dry weight) in organic soils. These soils also have a lower bulk density and higher water-holding capacity than mineral soils.

Mineral wetland soils form either in moving or periodically standing water and can be found in low-lying depressions or slopes (Figure 2). They may

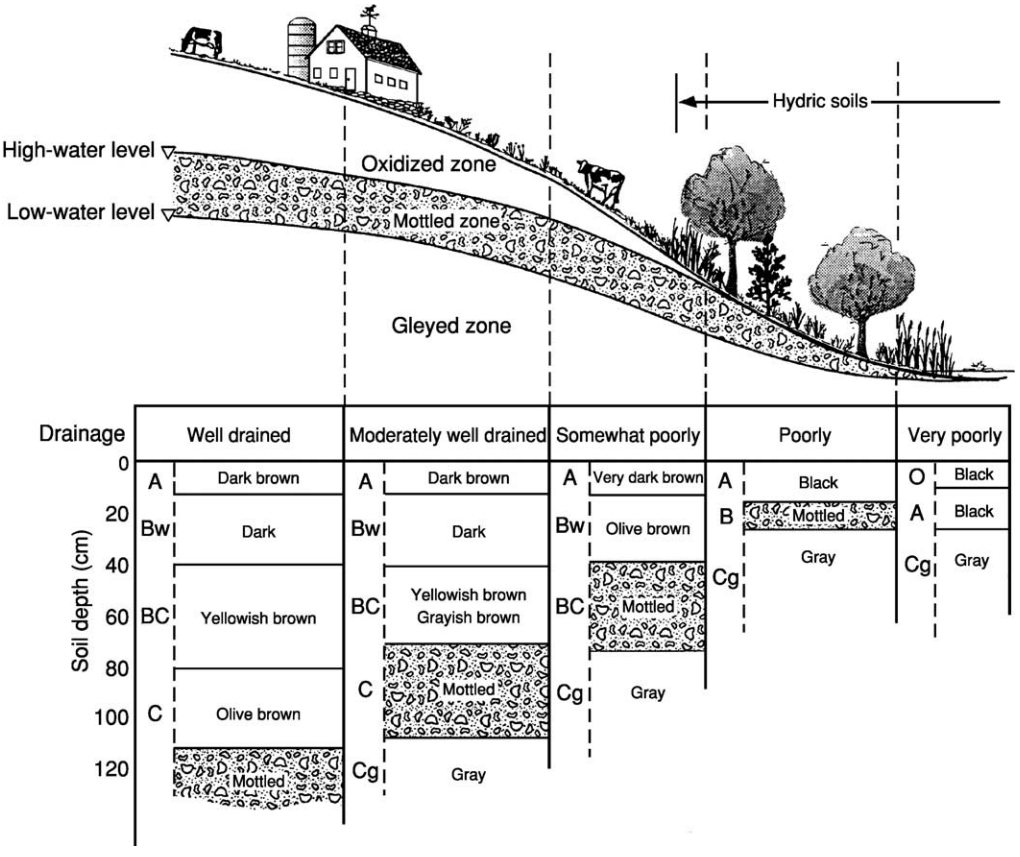

Figure 2 Soil properties are shown along a wetland-to-upland landscape gradient. Note that the seasonal high-water table, indicated by the mottled zone, reaches the surface only at the lower elevations. Reproduced from Tiner RW and Burke DG (1995) *Wetlands of Maryland*. USFWS, Hadley/Maryland Department of Natural Resources. Annapolis, MD: US Fish and Wildlife Service.

receive surface water runoff or groundwater seepage, and there may be the presence of an only slowly permeable soil layer (e.g., a fragipan, clay, or hardpan layer, or confining bedrock) that slows the movement of water. Criteria used to determine whether a soil is hydric are listed in Table 1. Mineral wetland soils have a dry weight consisting of less than 20–35% organic material.

Observable indications (redoximorphic features) of mineral wetland soil include its dominant 'matrix' color chroma that can vary from very dark to washed-out blue-gray or green-gray colors (with often brighter colors found as minor components, as 'mottles'). Mottles are yellow-orange to brown accumulations that form where oxygen-rich zones are encountered, and iron and manganese oxidize and precipitate from solution. These can coat soil peds, walls of voids, or the root channels (rhizospheres), where they can be observed readily. The extent of gleying and mottle abundance, size, and color depends on the prevailing hydrology (e.g., fluctuating water table) and the extent of microbial activity: if it is too cold, then there is little activity and wetland indicators such as gleying and mottling will not be present.

One way to determine whether a soil is hydric is by using a standard Munsell color chart to identify its color strength. Low chromas, generally a 2 or less, indicate hydric conditions. The dark matrix color is the result of prolonged saturation that converts iron from its rust-colored, oxidized (ferric) form to its reduced (ferrous) form (see Iron and Manganese, below). Exceptions occur where hydric color indicators are masked, such as with soils that remain redder, in spite of hydric conditions, having formed from red glacial till material. In these cases other indicators such as iron or manganese concretions and the oxidized rhizospheres can be observed.

Redoximorphic features such as mottling, gleying, and oxidized rhizospheres that develop in hydric soils generally remain visible even after wetlands have been disturbed and thus remain useful in determining former wetland extent.

Table 1 Criteria for hydric soils

Description
1 All Histels except Folistels and all Histosols except Folists
2 Soils in aquic suborders, great groups, or subgroups, Albolls suborder, Historthels great group, Histoturbels great group, Pachic subgroups, or Cumulic subgroups that are: Somewhat poorly drained with a water table equal to 0.0 m from the surface during the growing season or Poorly drained or very poorly drained and have either: Water table equal to 0.0 m during the growing season if textures are coarse sand, sand, or fine sand in all layers within 50 cm, or, for other soils, Water table at less than or equal to 15 cm from the surface during the growing season if permeability is equal to or greater than 15 cm h^{-1} in all layers within 50 cm, or Water table at less than or equal to 30 cm from the surface during the growing season if permeability is less than 15 cm h^{-1} in any layer within 50 cm, or
3 Soils that are frequently ponded for long duration or very long duration during the growing season, or
4 Soils that are frequently flooded for long duration or very long duration during the growing season

Soil Chemistry

At the soil surface, a thin layer of oxidation is crucial in maintaining wetland function. Chemical transformations and nutrient cycling depend on the oxidized ions found in this layer. These oxidized ions are Fe^{3+}, Mn^{4+}, NO_3^-, SO_4^{2-}. Below the oxidized layer, and below the water table where anaerobic conditions dominate, the reduced forms of compounds are found such as Fe^{2+}, Mn^{2+}, NH_4^+, S^{-2}, and CH_4. Table 2 lists the oxidized and reduced forms of these elements.

Nitrogen

As in many ecologic communities, nitrogen is one of the most limiting of nutrients in many wetlands. Much of the nitrogen in soil is derived from dead organic material such as proteins, amino acids, and nucleic acids. These nitrogen-rich compounds decompose into simple compounds by soil-dwelling saprobic bacteria and fungi. These microbes then release the excess nitrogen in the form of ammonium ions (NH_4^+). Figure 3a shows the nitrogen cycle: after ammonium diffuses to the aerobic soil layer, nitrification occurs, converting it to nitrate. The nitrate may

Table 2 Oxidized and reduced forms of several elements in order of their redox potential

Element	*Oxidized form*	*Reduced form*
Nitrogen	NO_3^- Nitrate	N_2O nitrous oxide, N_2 Nitrogen gas, NH_4 Ammonium
Manganese	Mn^{4+} Manganic	Mn^{2+} Manganous
Iron	Fe^{3+} Ferric	Fe^{2+} Ferrous
Sulfur	SO_4^{2-} Sulfate	S^{2+} Sulfide
Carbon	CO_2 Carbon dioxide	CH_4 Methane

then diffuse back into the anaerobic layer where denitrification transforms it into nitrogen gas. Ammonium nitrogen is oxidized to nitrite ions (NO_2^-) through nitrification:

$$2NH_4^+ + 3O_2 \rightarrow 2NO_2^- + 2H_2O + 4H^+ + \text{energy}$$

Nitrite is toxic to higher plants but it does not have a chance to accumulate in the soil owing to the presence of *Nitrobacter*, a genus of bacteria that oxidizes the nitrite to form nitrate ions (NO_3^-), again with a release of energy:

$$2NO_2^- + O_2 \rightarrow 2NO_3^- + \text{energy}$$

Nitrification in wetland soils also takes place within the oxidized rhizospheres of plant roots where sufficient oxygen may facilitate the conversion of NH_4^+ to NO_3^-.

Nitrate can also undergo reduction reactions. Nitrate being more mobile, if not rapidly assimilated by plants or microbes, or lost through groundwater flow, will probably be reduced to ammonium, nitrous oxide (N_2O), or molecular nitrogen (N_2) under anaerobic conditions. Denitrification typically occurs under waterlogged conditions in swamps and marshes. The availability of fresh organic matter together with denitrifying bacteria promotes dentrification:

$$C_6H_{12}O_6 + 4NO_3^- \rightarrow 6CO_2 + 6H_2O + 2N_2$$

In the highly acidic peat soils of northern bogs, nitrifying bacteria are lacking due to the low pH. In such environments carnivorous plant species have evolved that are able to use animal proteins directly as their nitrogen source. The sundew (*Drosera intermedia*) and the Venus flytrap (*Dionaea muscipula*) both attract insects and obtain minerals, including fixed nitrogen from animal prey via sticky hairs that contain digestive enzymes.

Iron and Manganese

Both iron and manganese occur in two oxidation states. Under the conditions that prevail in wetlands, they exist primarily in reduced form. Iron is transformed from ferric (Fe^{3+}) iron compounds to ferrous (Fe^{2+}) iron:

$$Fe_2O_3 + 4e^- + 6H^+ \rightarrow 2Fe^{2+} + 3H_2O$$

Manganese is transformed from manganic to manganous compounds:

$$MnO_2 + 2e^- + 4H^+ \rightarrow Mn^{2+} + 2H_2O$$

Ferrous iron causes gleying of mineral soils, the gray colors observable in highly reduced soils. In the presence of oxygen, when, for example, the water table drops, the reaction can be reversed and insoluble ferric oxides precipitate out. These reactions can be mediated through bacterial activity, forming 'bog iron' ore. Bog iron deposits found in anaerobic groundwater in northern peatlands have been used in iron and steel industries.

Sulfur

Sulfur has several oxidation states and is transformed through microbial activity. Sulfur is usually readily available and so not limiting to organisms. Elevated concentrations of hydrogen sulfide in saltwater wetlands may be toxic to plants and animals. When wetland sediments are disturbed, the smell of rotten eggs is emitted, a smell that is familiar to those working in wetlands. Sulfur-reducing bacteria in anaerobic soils reduce sulfates to sulfides:

$$4H_2 + SO_4^{2-} \rightarrow H_2S + 2H_2O + 2OH^-$$

As shown in Figure 3b, sulfur can be released to the atmosphere as methyl and dimethyl sulfide, organic sulfur compounds, and hydrogen sulfide. Among wetlands, salt marshes have the highest rate of emission of hydrogen sulfide per unit area. The dark color of many wetland peats comes from ferrous sulfide. Sulfur found in peat bogs and coal deposits usually occurs as the mineral pyrite (FeS_2).

A number of sulfur reactions occur in the upper aerobic portion of the wetland soil. *Thiobacillus* obtains energy from the oxidation of hydrogen sulfide to sulfur. Other species further oxidize sulfur to sulfate:

$$2H_2S + O_2 \rightarrow 2S + 2H_2O + \text{energy}$$
$$2S + 3O_2 + 2H_2O \rightarrow 2H_2SO_4 + \text{energy}$$

Purple sulfur bacteria found in salt marshes and mudflats produce organic matter in the presence of light:

$$CO_2 + H_2S + \text{light} \rightarrow CH_2O + S$$

Hydrogen sulfide is used as an electron donor instead of water. This reaction requires anaerobic conditions, ample hydrogen sulfide, and sufficient sunlight near the surface.

Carbon

Major processes for carbon transformations are given in Figure 3c for both aerobic and anaerobic conditions. Through fermentation, sugars are transformed to lactic acid, ethanol, and CO_2. Methane production (methanogenesis) is the result of extremely reduced conditions whereby bacteria (methanogens) reduce CO_2 to CH_4, as in:

$$CO_2 + 8e^- + 8H^+ \rightarrow CH_4 + 2H_2O$$

The resulting methane is often called 'swamp gas' or 'marsh gas.' It is known for being highly combustible especially in peatland environments. Methane production is higher in freshwater than in marine wetlands but has a broad productivity range in each. It is season-dependent, taking place only when warm temperatures prevail. Rice paddies are a major source of methane to the atmosphere. Peatlands are usually a net source of methane; however, under drought conditions, when oxidation occurs below the surface layers, the peat can become a source of CO_2 emissions.

Table 3 US (48 states) wetlands and former wetlands (thousands of hectares) where land use has been determined (nonwetland hydric soils indicate former wetland areas)

1992 land use	*Wetland soils (ha)*	*Nonwetland hydric soils (ha)*	*Total (ha)*
Cropland	4270	22 430	26 699
Pastureland	3232	2611	5843
Rangeland	3142	2426	5568
Forest land	24 732	3829	28 561
Misc.	9753	2501	12 254
Total	45 129	33 797	78 925

Policies, Regulations, and Protection

There are several international treaties that protect wetlands. The first was the Ramsar Convention. The role of wetlands to support migratory waterfowl that cross national boundaries was recognized when the Convention on Wetlands (originally entitled the Convention on Wetlands of International Importance Especially as Waterfowl Habitat) was signed in Ramsar, Iran, in 1971. It is an "intergovernmental treaty which provides the framework for national action and international cooperation for the conservation and wise use of wetlands and their resources." There are 136 signatory nations, and, as of May, 2003, 1283 wetlands sites are listed, comprising 108.7 million hectares. Often the wetlands encompass tracts with multiple uses, including water supply, fisheries, agricultural use, and more. The number of sites and their sizes vary from country to country. The UK has more than 150 sites, whereas the USA has 17 sites. Australia lists sites from 1 ha (Christmas Island Territory) to almost 2 Mha in size in the southern Coongie Lakes. Many countries use the Ramsar Convention as their main instrument for wetland protection.

The USA relies mainly on separate federal, state, and local laws and regulations to limit development in wetlands. In the 1970s the Federal Water Pollution Act was followed by the Clean Water Act of 1977, Section 404, that considered wetlands as waters of the USA covered in part under the Rivers and Harbors Act of 1899. Hence jurisdiction of private property could be given to public agencies as waters are considered a public good. Under Section 404 a permit is needed to conduct dredge-and-fill activities in jurisdictional wetlands even when on private property. The 1985 Food Security Act's 'Swampbuster' provisions denied government farm subsidies to farmers who drained wetlands after December 23, 1985.

In the USA, wetland inventories are conducted every 10 years and their status and trends are compiled. Wetlands comprise approximately 91 million hectares in these 48 contiguous states. Of these, land-use categories of 79 million hectares can be documented through knowledge of soil types (Table 3). Table 3 indicates that about 34 million hectares are no longer wetlands but retain hydric soil characteristics.

Where once the US government actively encouraged drainage, with cost-sharing and expertise, the paradigm has shifted. One of the more successful federal programs, the Wetland Reserve Program (WRP), promotes wetland restoration and offers cost-sharing and expertise to break drainage tiles and return areas to wetlands. Every 5 years Congress sets policies, guidelines, and funding for such agriculture programs. The WRP offers financial incentives and expertise from the USFWS and Natural Resources Conservation Service (NRCS) to take marginal land out of production.

Conserving wetlands is increasingly recognized as beneficial for flood control in a range of rural to urban areas, and as essential habitats for many fish, bird, and other species. In spite of conflicts that occur with pressure from expanding populations, local, state, and national regulations, as well as international agreements, have slowed the drainage of wetland areas.

Soil physics can be defined as the study of the state and movement of energy and mass in the continuum that includes the soil, plants, and surface boundary layer of the atmosphere. Since soil physics is both a theoretical and an experimental science, it includes equations from physics, and knowledge and measurement tools built up through years of laboratory and field experience. Understanding the state and movement of water in soil is an important part of the overall body of soil physics knowledge.

The relationship between water flux and driving force:

$$J_w = -k\nabla\psi$$

called Darcy's law, was already well established for saturated flow of water in porous materials before the beginning of the twentieth century. Darcy recognized that the driving force for flow was a gradient in what we now call the pressure and gravitational potentials. These ideas were extended to unsaturated flow in the early part of the twentieth century by Edgar Buckingham. He recognized that water in unsaturated soil is under negative pressure, i.e., the matric or capillary potential. Buckingham also recognized that gradients in matric potential, as well as in the other potentials, result in water flow. He generalized Darcy's equation by allowing k to vary as a function of the matric potential. While the second laws of both Fick and Fourier (combining the flux equation with the continuity equation to obtain the second-order partial-differential equation) were well known at the beginning of the twentieth century, they had not been extended to water flow. By the end of the twentieth century, the second-order equation for water was well known, with both analytical and numerical solutions available for a wide range of theoretical and practical problems.

Buckingham had no direct way to measure matric potential. He attempted to establish equilibrium in vertical soil columns and then related the water content of the soil in the columns to the height above a free water surface at the bottom of the column. Water content was measured by weighing and oven-drying the soil. By the end of the twentieth century, one could measure soil-water content using neutron scattering, neutron and gamma attenuation, time-domain reflectometry, capacitance, and microwave-drying. Matric potential could be measured using tensiometers, gypsum blocks, heat-dissipation matric probes, thermocouple psychrometers, filter paper, and freezing point. The relationship between water content and water potential is now routinely determined using a pressure plate.

Many of the important soil physics developments of the twentieth century, both in theory and in measurement methods, have direct or indirect ties to the laboratory of Willard Gardner, a professor of physics at Utah State Agricultural College from 1918 to 1948. While Willard Gardner made important contributions to soil physics in his own right, his influence has been amplified many-fold through the disciples he converted and trained. It is an interesting story of science on the frontier, but the story starts much earlier, in the mid nineteenth century.

On July 21, 1847, Orson Pratt and Erastus Snow entered the valley of the Great Salt Lake, the first of the vanguard group of Mormon (Church of Jesus Christ of Latter-Day Saints) pioneers fleeing west to escape religious persecution. Their only hope was to plant crops, even though it was late in the season. However, it was impossible to plow the hard-baked valley soil, so they channeled water from the mountain streams on to the thirsty ground. This was the beginning of modern irrigation in the US Mountain West. Since irrigation was necessary to produce almost all crops in the arid mountain valleys, the practice became widespread. Pratt was a physicist and mathematician who lectured at the University of Deseret (later the University of Utah), but he apparently took little interest in the physics of water flow, preferring astronomy and mathematics instead.

The practical aspects of designing irrigation systems and managing water flow in soil were a part of ordinary life in the frontier towns of the Great Basin, but the scientific study of irrigation in Utah did not begin until 50 years later. It was started by John A. Widtsoe soon after he became Director of the Utah Agricultural Experiment Station in 1900 (Figure 1).

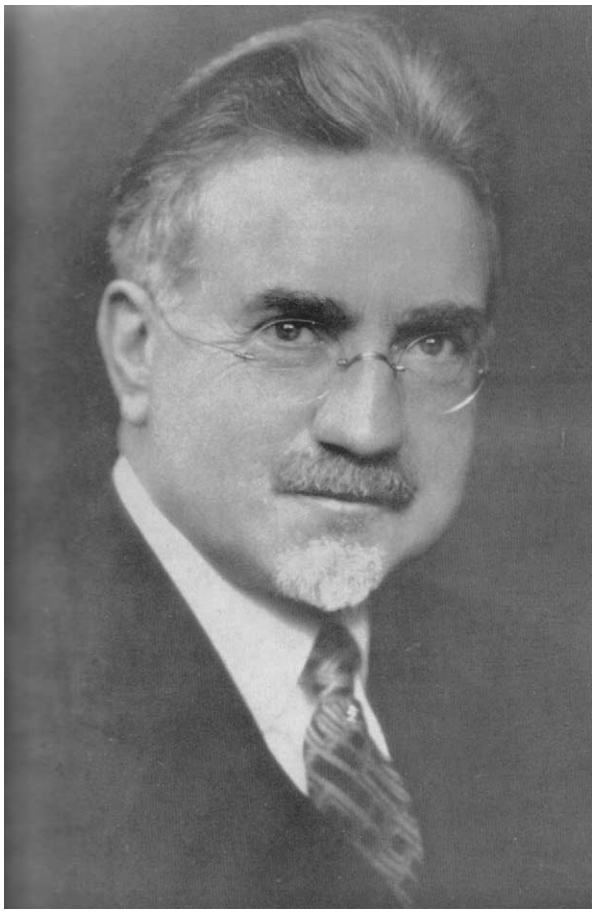

Figure 1 John A. Widtsoe (1872–1953).

Widtsoe was born in Daloe, Norway, in 1872, the oldest son of John Andersen Widtsoe, a schoolmaster, and Anna Karine Gaarden. When John was 6 years old, his father died, leaving his mother, himself, and his 2-month old brother, Osborne. When Widtsoe was 11 years old, he moved with his mother and brother to Utah, and settled in the town of Logan. He worked in Logan for several years to help support the family, but finally graduated from Brigham Young College (a junior college) in 1891. He was then selected as one of six talented Utah students to attend Harvard University, in Cambridge, Massachusetts, where he majored in chemistry with minors in physics and metallurgy, graduating in 1894. On his return to Utah, he joined the faculty of the new Utah State Agricultural College in Logan, where he began studying ways to improve agricultural production. In 1898, he and his new wife, Leah Eudora Dunford, went to Germany for his graduate study. In less than two years, he earned his doctoral degree in chemistry at the University of Goettingen and completed additional studies at Berlin and Zurich.

While still in Europe, Widtsoe was offered the position of Director of the Experiment Station at the Utah State Agricultural College. He served as Director from 1900 to 1905. The following excerpt from

Widtsoe's autobiography indicates the kind of research he and his colleagues undertook:

> By the planting season of 1901, a part of the College farm was supplied with troughs or flumes, by which measured quantities of water could be applied at will to a series of plots planted to various crops. Later, another and more suitable farm was purchased and equipped more extensively for the controlled application of irrigation water to the experimental plots. A vegetation house was also built, housing a large number of tanks, which could be wheeled in and out of the house. These tanks, protected from natural rainfall, filled with various soils, received carefully measured quantities of water. The farm and the vegetation house were undoubtedly the first experimental plant of its kind in the world dedicated to the scientific study of the use of water in irrigation. The results proved that they were very effective tools.
>
> The investigations that followed answered questions concerning the movement of water in irrigated soils; the control of loss of soil moisture by seepage and evaporation; the relation between the water lost by evaporation from soils, and by transpiration from plants; the relation between soil fertility and plant transpiration; the actual quantities of water required in crop production; the yields of crops and their chemical composition under varying quantities and times of application of irrigation water; and many other irrigation problems.

They also studied dryland farming, and the results of both irrigation and dryland research were shared throughout Utah by Dr. Widtsoe and his co-workers through extension activities. Results of the research were published in experimentation bulletins, and in two books: *Dry Farming* (published in 1911) and *Principles of Irrigation Practice* (published in 1914). Reports on the findings of plant–water relations and evapotranspiration research a century later differ little from the reports Widtsoe gave of these few years at the Experiment Station.

Politics were an important part of university life, then as now, and this was certainly true for Dr. Widtsoe. In spite of his amazing accomplishments, he was fired in 1905. He worked briefly at Brigham Young University in Provo, UT, and was then hired back as president of Utah State Agricultural College. This time the politics were in his favor. He served as president from 1907 to 1916, when he was made president of the University of Utah in Salt Lake City, UT. In 1921 he was called to serve as an apostle in the Church of Jesus Christ of Latter-Day Saints (LDS), a position he held until his death in 1953.

Widtsoe's early research on plant–water relations and irrigation practice was, without question, pioneering work, well ahead of its time. It is difficult to trace the influence of that work directly to modern plant–water relations theory. It is not difficult, however, to trace his influence on people who have had a great impact on modern soil physics. For example, in 1920, during the time when he was president of the University of Utah, Dr. Widtsoe joined Willard Gardner in writing a general treatise with the title, *The Movement of Soil Moisture*. A footnote to this article reads:

> The formal development of the mathematical material of this paper was made by the senior author as an outgrowth of the earlier work of the junior author, who has assisted in clarifying this material for publication.

Such participation with, and encouragement of, Utah soil scientists has had enormous impact on the careers of many soil physicists and on soil physics in general.

By the end of the nineteenth century, physics of soil processes had received considerable attention in many places in the USA, in Europe, and in other parts of the world. The names 'soil physics' and 'soil physicist' began to be used to identify subject matter and scientists on the faculties of colleges and universities and in governmental programs. In Utah, this occurred when Willard Gardner become a member of the faculty of the physics department and physicist for the Utah Agricultural Experiment Station in 1918 (**Figure 2**).

Figure 2 Willard Gardner (1883–1964).

Willard Gardner was born in 1883 in the little logging community of Pine Valley, Utah. His parents, Robert Gardner and Cynthia Lovina Berry, encouraged their children to educate themselves. Because they did so, several generations of Gardners have made important scientific contributions throughout the twentieth century. In 1903, Willard completed high school and traveled to Salt Lake City, where he attended business college, learning to type and take shorthand dictation. He became highly proficient at both, typing at faster than 90 words per minute and taking dictation at more than 150 words a minute. He then went to Logan, Utah, where he was employed by the Cache Valley Banking Company as stenographer. He did this work so well that he was often loaned to the local Justice Court to take dictation. In 1910, when the Agricultural Experiment Station at the college offered him a position as a clerk in their campus office, he accepted the position against the advice of his banker employers. This made it possible for him to pursue college classes on the side, and he was able to complete a bachelor's degree in physics. In 1912, he obtained a departmental assistantship in Physics at the University of California–Berkeley, graduating in 1916. His was the eighth PhD degree awarded by the University of California–Berkeley Physics Department.

After graduating, Gardner became principal of the Murdock Academy in Beaver, Utah, where his soil physicist son, Walter, was born in 1917. The following year he taught physics at the Brigham Young Academy in Logan, and in 1918 was invited to join the faculty in physics at Utah State Agricultural College (USAC). He held that position until his retirement in 1949. He became Professor Emeritus and continued to be active in university work until 1954. He died in 1964.

Dr. Gardner retained his stenographic skills and used them to good advantage throughout his career. For him, note-taking was easy, and he always typed his own letters rapidly, using a typewriter with an extra dozen Greek letter keys needed in writing mathematical equations. Not only did this save the college the cost of a secretary, but it was also more economical than to train secretaries to deal with mathematics.

Gardner's PhD thesis was titled *The Photo-Electric Current as a Function of the Angle of Emission and the Thickness of the Emitting Film*. He evidently found the physics of water flow and retention to be an important area to pursue in an agricultural experiment station. O.W. Israelsen, a friend and colleague from graduate school, and professor of irrigation engineering at USAC, encouraged Gardner to undertake irrigation research. Several other faculty members working in soil science had reason to seek his help in dealing with problems involving physics or mathematics.

Widtsoe's early work, Buckingham's 1907 monograph on water in soil, and Dr. Gardner's physics training formed the foundation for the soil physics work carried out by Gardner and his colleagues at USAC. A few of the titles of early papers show that the research direction was set from the beginning. Some are "The movement of moisture in soil by capillarity," "Capillary moisture-holding capacity," and "A capillary transmission constant and methods of determining it experimentally." These papers and others show consistent skill in using physics and mathematics to analyze soil-water flow problems. Research topics included saturated and unsaturated water flow, erosion, drainage, and measurement. The tensiometer, which is still a mainstay of soil physics research, was a product of Gardner's early research efforts, as was the tension or disk infiltrometer. It is no wonder that Dr. Gardner is referred to as the father of modern soil physics.

USAC did not begin offering the PhD degree until after World War II, so Willard Gardner had no official PhD students. In 1950, his son Walter received the first PhD given at USAC, with Wynn Thorne as major professor and his father as research advisor. However, numerous students and colleagues became interested in soil physics as a consequence of studying or working with Willard Gardner. The USAC library and Agricultural Experiment Station records are incomplete, but, from publications and personal files, it is possible to identify most of the students who studied with Gardner. Seventeen MS theses on topics closely related to soil physics are listed in the USAC Graduate School, and 14 published scientific papers with acknowledgements to Willard Gardner are in the library files.

There is little doubt that a number of students who have pursued careers in soil physics developed that interest while attending USAC and working with Gardner. L.A. Richards, one of his earliest students, obtained his masters degree at USAC and then went to Cornell University for his PhD degree. (*See* **Richards, Lorenzo A.**)

Another colleague who was strongly influenced by Gardner was Don Kirkham (*See* **Kirkham, Don**). Kirkham joined the physics faculty at USAC in 1937, having obtained a PhD in physics from Columbia University. Like Gardner, he came with no background in soil physics, but became interested through working with Gardner. After World War II, Kirkham was hired as a soil physicist by Iowa State University and became one of the most influential soil physicists of the twentieth century, both through his own research and through his large number of well-trained PhD students. Kirkham furnishes another tie between the two main characters of this brief history. Before

attending graduate school, Kirkham was a missionary for the LDS Church in Germany. John A. Widtsoe was in charge of the European missions at that time. Widtsoe and the young missionary found themselves together on a train at one point during Kirkham's mission, talking about careers. Widtsoe advised Kirkham to complete his education (i.e., attain the PhD) before he sought employment. Later, as Kirkham was in graduate school, he was offered a good job that would require that he drop out of school. This was tempting, since it was the depth of the depression, and jobs were hard to find. He remembered Widtsoe's advice, however, and completed his studies. Thus an important chapter in the lives of many soil physicists (Kirkham's students), as well as in the history of soil physics itself, would never have been written without the influence of both Widtsoe and Gardner in the life of Don Kirkham. Many similar stories could be told of the influence these men had on students and colleagues.

L.A. Richards, late in his professional career, recorded a revealing story about Willard Gardner's propensity to utilize mathematics in his scientific papers. The story is as follows:

> When I came on the scene as an undergraduate at Utah State College at Logan in 1922, Dr. Willard Gardner was pretty much alone in the subject matter field of soil physics and was making important applications of the Buckingham capillary potentials to the mathematical formulation of water flow in soil. This approach, though basic to progress, limited his current audience to people who understood his papers. I can well remember a conversation that took place between Sir Bernard Keen, then head of the Rothamsted Experimental Station [in the UK], and Dr. Gardner along about 1925. I was in the study room adjoining Dr. Gardner's office and with the door ajar. I, of course, was all ears concerning the conversation that was in progress. At a certain stage Dr. Keen said, 'Dr. Gardner I find your papers hard to read. Why don't you try to express things more simply?' Dr. Gardner was a man of some piety and had a quiet manner of speaking, but he had a prominent lower jaw. I could feel the air crackle in the next room as he paused for reply, which was, 'Sir Bernard, God made physics hard, not Willard Gardner.'

Hard or not, there have been many willing to follow in Willard Gardner's footsteps and learn his approaches to this new science. The result has been a century of solid progress. Like Widtsoe, he carried out pioneering work in many of the areas of modern soil physics. Unlike Widtsoe, he published many papers from which key ideas in modern soil physics can be traced.

Wind Erosion *See* **Erosion:** Wind-Induced

WINDBREAKS AND SHELTERBELTS

E S Takle, Iowa State University, Ames, IA, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Recent interest by agricultural and environmental scientists in finding more sustainable ways of managing landscapes has highlighted the need for a better understanding of plant–atmosphere–soil interactions. Windbreaks and shelterbelts are used to modify meteorologic conditions at the soil surface to meet specific management objectives. Both artificial barriers (fences) and living barriers (trees and shrubs) are used to modify flow near the ground. The terms 'windbreak' and 'shelterbelt' are often used interchangeably. However, a fence is usually considered a windbreak, whereas a living barrier, although also a windbreak, offers shelter not only from wind but also from intense solar radiation, driving rain, and erosive movement of water across the soil surface. The emergence of the fields of agroecosystems and agroforestry has brought further attention to the use of living barriers to modify plant and soil microclimates through changes in micrometeorologic conditions.

Several centuries of practical application, followed recently by a few decades of research, have provided a wide range of reasons for using windbreaks and shelterbelts. The most frequent uses relate to reducing wind speed for purposes such as reducing soil erosion or drifting soil and sand, capturing snow for soil-moisture recharge, or protecting highways, rail lines, farmsteads, and animal confinement areas. Recent research has focused on other benefits such as changing microclimates for crops, preserving soil moisture, improving landscape and biological diversity, and creating recreational opportunities or aesthetically desirable landscapes. Recent advances in numerical modeling of flow fields and microclimate factors around shelterbelts have increased understanding of the complexities of the soil–atmosphere–plant interactions.

Use of Windbreaks and Shelterbelts in Soil Management

The diversity of vegetation offered by shelterbelts in regions of monoculture-managed landscapes promotes biological diversity both above and below the surface. By providing shade, detritus layers, wind speed reduction, soil ventilation, and changes in temperature, humidity, and soil moisture, perennial living barriers offer richer spatial variation in microclimates for plants and belowground ecosystems. In intensively managed agricultural environments, tree shelterbelts provide islands having reduced concentrations of agricultural chemicals and increased biodiversity, with soil and aboveground ecosystems that include earthworms, small mammals, birds, perennial grasses, and woody plants and that deliver a range of beneficial ecosystem services.

Shelterbelts will become increasingly important as the regional impacts of global warming become more clearly identified, both for sequestering carbon and to suppress the negative agricultural impacts relating to reduced soil moisture and increased likelihood of erosion. Simulations of future-scenario climates show higher likelihood of more extreme events (both droughts and floods), and shelterbelts offer protection of crops under such impending changes. Prevention of soil loss due to high wind is a historic benefit of shelters, but they also suppress soil loss due to floods or intense rains on sloped surfaces. Soil erosion decreases soil productivity locally owing to loss of fine soil particles containing organic matter and nutrients and causes off-site damage to structures and unwanted deposition of soil particles. Irreversible damage to soil ecosystems due to extended drought is suppressed by shelters. Perennial living barriers in agricultural fields sequester carbon aboveground by creating biomass and belowground by deep roots, litter production, and providing regions of undisturbed soils that reduce microbial decomposition rates. Shelterbelts restore soil organic matter lost through agricultural practices.

Influence of Shelters on Aerodynamics and Microclimate

Wind Speed Reduction

The main impact of a windbreak or shelterbelt is to reduce mean wind speed near the surface. Acting as a porous barrier to the flow, the shelter creates a small region of wind reduction on the windward side and a low-speed, turbulent wake zone followed by a region of gradual wind speed recovery in the lee, as shown in Figure 1.

Shelterbelts typically reduce wind speed substantially on the leeward side and to a lesser extent on the windward side (Figure 2). The observed wind speed at 2.88 m above the ground reveals the region of wind speed reduction from the undisturbed value of 5.6 m s^{-1} to a sheltered value of 1.5 m s^{-1} in the

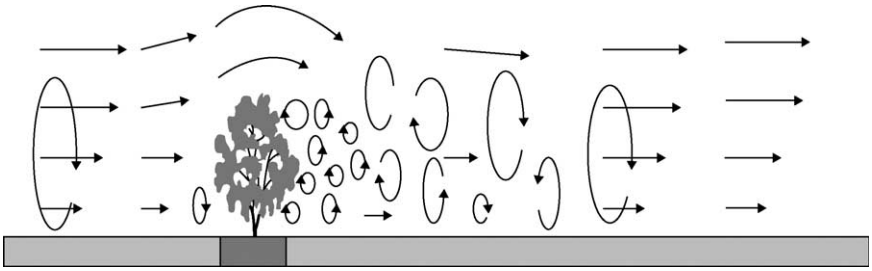

Figure 1 Mean and turbulent flow around a living shelter.

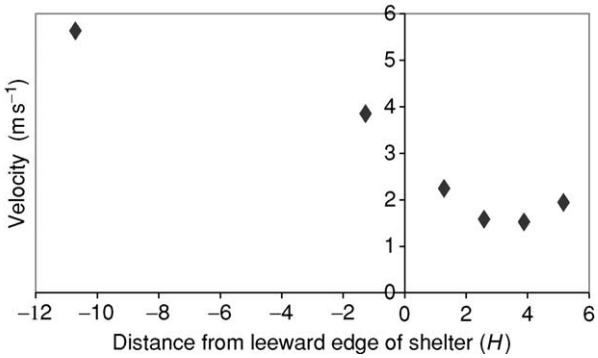

Figure 2 Observed horizontal wind speed at 2.88 m above the ground at various distances upwind and downwind of a two-row shelterbelt with height (H) of 14 m. Undisturbed wind speed at height 2.88 m is 5.6 m s^{-1}. Downwind edge of the shelter is taken as $x = 0$. (Adapted from Zhou XH, University of Nebraska.)

near lee. The barrier shelters strongly in a region approximately 10H leeward (H is height of the shelter), with modest sheltering extending leeward from the shelter approximately 20H.

The length of the sheltered region is reduced for more dense shelters and is larger but with less wind-speed reduction for highly porous shelters. A very dense shelter may even create a recirculation zone behind the shelter. When the wind direction is not perpendicular to the shelter, the sheltered region is reduced in size for successively more oblique angles of attack.

Shelterbelts have been used for many decades to suppress negative effects on soils due to high winds, namely to stop or slow drifting soil and sand. Suppression of drifting snow, on the other hand, makes important contributions to growing-season soil moisture in dry regions. Shelterbelts have been used widely to protect crops whose foliage or fruit are prone to damage from abrasion due to wind-blown material.

Turbulence Fields

The atmosphere contains turbulent eddies that connect the upper part of the atmospheric boundary layer to the surface (e.g., left-most eddy in Figure 1). These large eddies regulate surface exchange of heat, moisture, and trace gases between the atmosphere and the soil. Shelterbelts break up the large and efficient eddies that ventilate the surface into smaller eddies (e.g., see small eddies just downwind of the shelter in Figure 1) that are less efficient, thereby suppressing the transport of heat, moisture, and trace gases away from the surface. These small eddies have short lifetimes and dissipate within a few H of the shelter. Reduced turbulent fluxes of heat and moisture lead to higher near-surface air temperatures and soil temperatures within approximately 8H of the shelter compared with unsheltered regions during both day and at night.

Further downwind, where the large eddies reattach to the surface and where mean wind speed is reestablished, enhanced ventilation leads to slightly lower temperatures than in unsheltered areas. At night under low wind speeds and laminar flow (very small eddies) the shelter may increase the eddy size and transport heat downward. But if winds are already near calm, the barrier may reduce both mean and turbulent flow and allow the sheltered region to be cooler than unsheltered areas.

Pressure Fields

A shelterbelt, as a barrier to the flow, increases the static pressure upwind and reduces pressure in the lee of the shelter, as revealed by measurements shown in Figure 3. Since it is not a direct microclimate factor affecting crops and soil, pressure is often overlooked as one of the key influences of a shelter. However, fluctuations in the stationary pressure field created by the shelter can have substantial influence on movement of trace gases in soil or mulch layers.

Surface Fluxes of Heat and Moisture

The breakdown of large, efficient eddies in the lee of the shelter reduces vertical transport of both heat and moisture away from the near-surface air, which increases humidity near the surface and reduces surface evaporation or evapotranspiration. Lower evaporation allows more incoming radiant energy to be

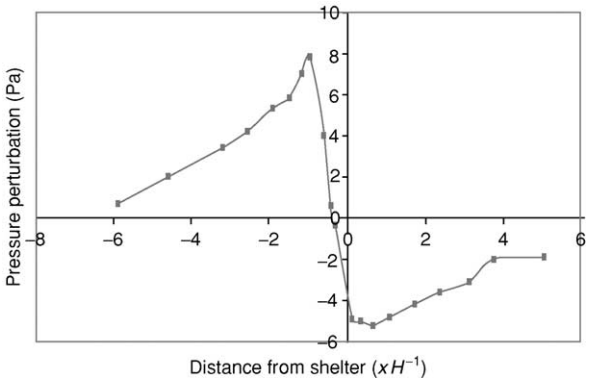

Figure 3 Perturbation of static pressure at ground level at various distances upwind and downwind of a two-row shelterbelt with height (H) of 14 m. Undisturbed wind speed at height 2.88 m was observed to be 5.6 m s^{-1}. Downwind edge of the shelter is taken as $x = 0$. (Data provided by Zhou XH, University of Nebraska.)

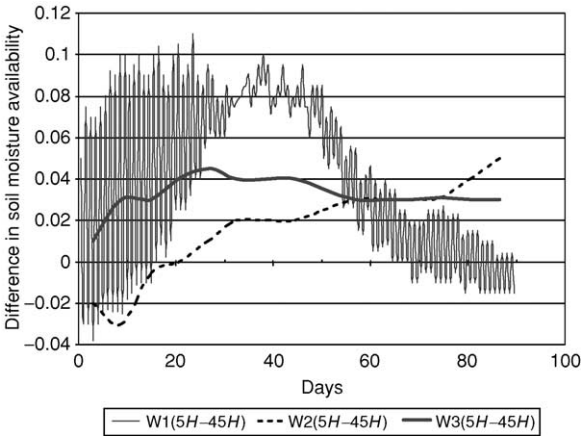

Figure 4 Differences in simulated soil moisture availability (dimensionless) between a sheltered region (5H downwind) and unsheltered region (45H downwind) at depths of 2.0 cm (W1), 1.0 m (W2), and 2.0 m (W3). The surface is assumed to be bare soil. (Adapted from Wang H, Shen J, and Takle ES (1997) Influences of agroforestry ecosystem on evapotranspiration and soil moisture. *Proceedings, 13th Conference on Hydrology*. Boston, MA: American Meteorological Society.)

partitioned to sensible heat, which thereby raises the surface temperature of the sheltered area. Energy loss by longwave radiation, which is proportional to the fourth power of temperature, keeps the surface temperature from getting too far above the temperature of the overlying atmosphere.

These modifications to the surface, and hence the near subsurface, of the soil lead to increased soil temperature and soil moisture compared with unsheltered regions, which in turn cause many soil chemical and biological processes to proceed at different rates in sheltered areas compared with open fields.

Living barriers consisting of woody plants also create a layer of litter or detritus mulch in the near vicinity to the stem or trunk. This layer does more than simply reduce extreme temperatures at the soil surface and preserve soil moisture; it also provides an additional zone for chemical and biological processes, such as methanogenesis. Being highly porous, such layers are subject to enhanced ventilation by mechanisms described below.

Soil Moisture

Most agricultural regions have deficient soil moisture at some point in the growing season. Observations suggest that shelterbelts raise both the daytime temperature and humidity in the sheltered region under most conditions, but exceptions do occur, in some cases due to soil-moisture conditions. Changes in soil moisture occur much slower than changes in air properties, so heat and humidity supplied due to the presence of soil moisture can modify micrometeorologic conditions in ways that may sometimes be counterintuitive.

Soil-moisture preservation in the lee of a shelter after a rain event that saturated the soil at all levels is shown in Figure 4. In this simulation, the soil surface was covered by a transpiring crop and was protected by a medium-density shelterbelt of height H. The time series of this plot gave the differences in soil moisture availability between sheltered and unsheltered locations at three depths for 90 days after a simulated precipitation event.

During the first 15 days after the onset of saturated conditions, daytime soil moisture at a depth of 2 cm (W1 in Figure 4) is higher in the sheltered region during the day (positive difference), but is lower at night (negative difference), presumably due to higher near-surface nighttime temperatures in the sheltered region. After 15 days, soil in the sheltered region has higher moisture both day and night. The relative benefit of shelter to soil-moisture preservation increases with time to a maximum near 40 days after the saturating rain event. At this time the soil-moisture availability near the shelter is approximately 25% higher than in unsheltered regions. Beyond this time the sheltered region loses moisture faster than unsheltered regions out to approximately 80 days, by which time the soil-moisture availability is everywhere uniform at approximately 0.14.

Deeper in the soil (1.0 m, plotted as W2, and 2.0 m, plotted as W3 in Figure 4), soil moisture is preserved in the sheltered region throughout the period except for the accelerated loss in the first 15 days from the 1-m layer due to higher temperatures. The region 4–8H downwind from the shelter is the region of highest protection, although evapotranspiration is

reduced by 10% or more compared with unsheltered areas out to approximately 13*H*.

Meteorologic Mechanisms that Move Gases in Soil

Most descriptions of gas movement in soils refer to the process as diffusional; however, ambient meteorologic conditions frequently create processes that move gases much more effectively than pure molecular diffusion. Numerous external (to the soil) factors are responsible for the movement of gases in soils. Most notably, pressure changes in the atmosphere are transmitted through airways within the soil and force movement of gases by nondiffusive means.

Static air pressure at a point (in either the atmosphere or soil above the saturated zone) is the horizontally averaged accumulated weight per unit area of atmospheric (gaseous) mass and the mass of any solid or liquid suspended by the atmosphere (birds, airplanes, liquid or solid H_2O, particulate matter, etc.) above that point. And changes in static pressure are caused by changes in the accumulated mass above the point. A point in the soil (we exclude soil locations not having a gaseous connection to the free atmosphere) may therefore experience pressure changes due to changes in the mass accumulation in the atmosphere above the point or due to phase changes of liquids or solids to vapors in the soil or on its surface. The region below the surface has zero mean flow in the absence of pressure gradients and volume expansion resulting from liquid-to-gas phase change. Any nonzero flow below the possible thin, turbulent layer in the soil is related to a pressure change or phase change, i.e., some change in the overlying mass accumulation.

Several mechanisms can lead to movement of gases within the soil and to effluxes from the soil. Many of these are related to changes in atmospheric pressure on various time scales or to liquid-to-gas phase changes. Because shelterbelts and windbreaks create spatial and temporal variations in surface pressure and temperature, they indirectly and importantly contribute to gas movement in the below-surface environment. Figure 5 provides a stylized view of pathways linking atmospheric gases with soil gases to assist in visualizing various mechanisms for gas movement.

Type 1: Large-Scale Pressure Changes

Changes in the static pressure of the atmosphere (and hence soil) due to movement of large-scale weather systems represent lowest-frequency pressure changes that might lead to externally driven transport of gases

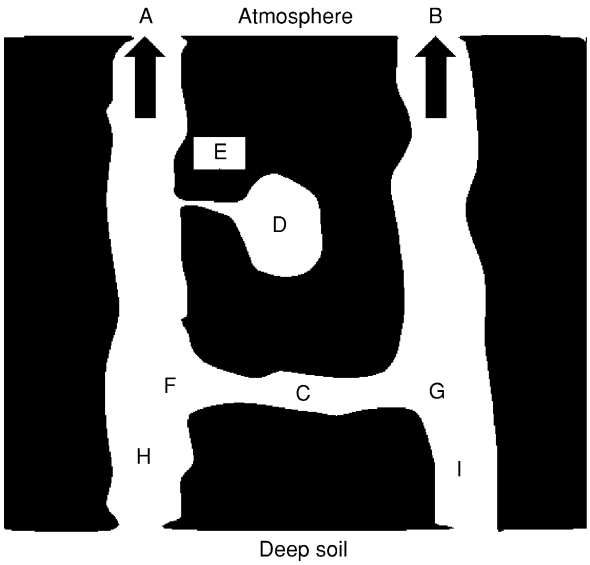

Figure 5 Stylized view of soil reservoirs and pathways for movement of trace gases.

in soils near the surface. Barometric pressure changes with periods of hours to days due to mesoscale and synoptic-scale weather systems cause changes in static pressure on the order of ±2% of total pressure over large areas, leading to uniform flow in or out at the surface.

Type 2: Traveling Atmospheric Pressure Waves

Traveling atmospheric pressure waves (of frequency assumed to be high enough to exclude the previous type of flow) transported over a flat, featureless surface can generate pressure fluctuations. For instance, observations of pressure, temperature, and wind fluctuations at several levels within tree canopies have revealed 'coherent structures' consisting of episodic bursts that penetrate and flood the canopy with overlying air. Pressure changes of this type at the soil surface cause oscillatory flow at A and B in Figure 5, with possibly different amplitudes and phases depending on the relative spatial separation as compared to the wavelengths of turbulent eddies. Point C experiences transient flow depending on conditions at A and B, and flow through E is oscillatory with zero mean. This type of flow offers a mechanism for drawing air with trace gases (water vapor, methane, nitrous oxide, carbon dioxide, oxygen) of high concentration out of D and replacing it with air of low trace-gas concentration.

Other atmospheric disturbances leading to traveling pressure waves include passage of a sea-breeze front, mountain lee waves, and outflow boundaries from thunderstorms and mesoscale convective complexes.

Type 3: Static Horizontal Pressure Gradient in Soil (Standing Wave)

Flow can be generated if points A and B, for illustrative purposes, are on opposite sides of an obstacle (e.g., tree, fence, rock outcropping, topographic feature) that creates a static horizontal pressure difference, as shown in Figure 3, due to a uniform (nonturbulent) wind blowing from left to right. Point A experiences high pressure and B low pressure that moves gas at a uniform rate from A to B through channel C owing to a pressure difference between F and G. As in type 2, passage E experiences only weak or zero flow. This process leads to horizontal as well as vertical motion in soils.

Type 4: Fluctuations on the Standing Wave

Wind that is not uniform in speed but has frequency ω (also assumed to be high enough to exclude the first type of flow but probably is lower than turbulence frequencies) may encounter an obstacle between A and B, thereby giving a fluctuating pressure of:

$$p = p_o e^{\omega t - k \cdot r} \quad [1]$$

at A, where k is the horizontal wave number and r is the horizontal distance vector. At B the pressure will be out of phase by π and possibly have different magnitude. Note that this forcing arises from changes in the static pressure due to dynamic interaction of the wind with the obstacle and is different from flow related to turbulence in the free atmosphere (see Type 5: Turbulence). This fourth kind of pressure change causes flow through C to be unidirectional and oscillatory, and flow through E to be oscillatory with zero mean. The venting of trace gases from cavity D, as described in type 2 flow, more effectively contributes to surface fluxes under this regime due to the unidirectional flow between A and C. If the obstacle is not between A and B, the pressure fluctuation is not out of phase, but the pressure gradient across C still leads to unidirectional flow.

Type 5: Turbulence

A turbulent atmosphere has stochastic fluctuations of pressure as well as wind speed, and larger turbulent pressure fluctuations generally accompany higher wind speeds. Despite the fact that the magnitude of these pressure fluctuations increases exponentially with mean wind speed, the resulting pumping action at the soil surface may displace an air parcel only a few micrometers at the surface. However, these pressure fluctuations may penetrate with minor loss of amplitude to the depth of pore D in Figure 5, and contribute to a substantial venting of the isolated pore. The resulting pumping action can move trace gases out of D at a much higher rate than is possible by molecular diffusion. Although this mechanism itself does not contribute strongly to surface effluxes, it may lead to higher availability of trapped gases for movement by other mechanisms.

Type 6: Venturi Effects

Differences in sizes of the soil channels through which air is ventilated lead to different flow speeds and therefore different rates of vaporization and gas transfer from solid or liquid surfaces lining the channel. Hollow stems of plants also have Venturi-like constrictions that cause irregular flow speeds.

Type 7: Rainfall

Rainwater ventilates soil gases by displacing air from pores and also enriches the soil air with dissolved O_2. Differential penetration of rainwater into the soil can lead to heterogeneous flushing of soil air. As rainwater percolates downward in the soil, the upper liquid surface also moves downward, drawing atmospheric air into the soil.

Type 8: Phase Change of Liquid to Vapor

When a liquid changes phase to a vapor, the accompanying volume expansion creates gaseous flow. For instance, evaporation of 1 cm of liquid water from a horizontally homogeneous soil and resulting expansion by a factor of 1000 leads to a net vertical discharge of 10 m ($10\,m^3\,m^{-2}$) of water vapor from the soil. This vertical efflux of water vapor carries other trace gases also. Horizontal differences in soil temperature lead to different evaporation rates and therefore different rates of soil-gas venting.

Spatial and temporal variability in soil pressures and temperatures created by shelterbelts, windbreaks, and isolated trees indirectly influence soil-gas movement, particularly by mechanisms 3, 4, 5, and 6 listed above. The presence of windbreaks or shelterbelts can therefore be expected to influence movements and distributions of trace gases in soil in complex ways.

Aesthetic and Recreational Value

Shelterbelts add diversity to agricultural landscapes, which, in turn promotes other biological diversity both above and below the surface and helps maintain delivery of a range of ecosystem services. Shelterbelts prevent loss of soil productivity owing to soil erosion. Finally, the addition of shelterbelts to the landscape, with their attendant diversity, enhances the aesthetic

and recreational value of rural environments, thereby promoting a sense of connectedness to the land that may be compromised in an increasingly urbanized society.

List of Technical Nomenclature

Angle of attack	Angle between the wind direction and a line perpendicular to a linear shelterbelt
Anthropogenic	Of human origin
Eddy	A transient circulation in a fluid that interacts with the mean flow to redistribute momentum, energy, and mass
Mesoscale convective complexes	Massive and long-lived storms that are relatively circular in shape, persist for 36 or more hours and produce large amounts of rain and possibly severe weather

WOMEN IN SOIL SCIENCE (USA)

M J Levin, USDA Natural Resources Conservation Service, Washington, DC, USA

Published by Elsevier Ltd.

Introduction

Women have been involved in soil science and soil survey since interest in this most basic of natural resources emerged. Women employed by the early US Soil Survey were largely restricted to office activities, but soon they ventured into fieldwork. Albeit brief, the first appointment of a woman to a field party came about in 1901, only 2 years after the soil survey began in earnest. It would be another 45 years, however, before the Soil Conservation Service (SCS) would appoint a woman as a field soil scientist.

The delay in women joining the ranks of field scientists has significance for telling the story of women's place in the soil survey. Soil science is first and foremost a field-based science. Soil mapping begins by studying the landscape and building a conceptual model of how the topography, geology, plants, climate, water, and animals interact to determine soil characteristics. Mapping then continues in the field where the soil scientists validate their determinations of soil types by digging, describing, and sampling the soils and vegetation. Benchmark samples are analyzed in the laboratory to validate conceptual models. Finally, the information is consolidated on to aerial photo maps, associated computer databases, and manuscripts for publication. Until women gained an equal place as scientists in the field, they remained in supporting roles in the soil survey.

The Pioneers (1895–1965)

Women's roles in the earliest years of the soil survey appear to have been limited to clerical work, copy-editing of manuscripts, and cartographic drafting of maps, although women with appropriate academic

training soon began to work in the laboratories. Janette Steuart and Sorena Haygood, who maintained the laboratory and field records for the US Department of Agriculture's (USDA) Division of Agricultural Soils, were among the first women to work for the soil survey. According to Macy H. Lapham's account, Steuart was hired January 4, 1895, making her the first woman appointed to the Division of Soils, then part of the US Weather Bureau, located in the USDA. Both Steuart and Haygood were career employees; Steuart retired in the late 1920s with nearly 30 years of service and Haygood retired some time later.

The soil survey remained resistant to women in field parties. Julia R. Pearce, one of the earliest female pioneers in soil survey, joined the soil survey as a member of the field party at Hanford, California, in June 1901, but never had the opportunity to join her party in the field. Pearce had been one of only two 1901 graduates in agriculture from the University of California at Berkeley (UCB). In his commencement address, Secretary of Agriculture 'Tama Jim' Wilson lamented the small size of the graduating class and emphasized that the Department of Agriculture needed candidates trained for technical positions. After the speech, Pearce sought Wilson out and told him 'she was ready and willing to come to the relief of the Departments.' Pearce found herself almost immediately appointed as an assistant to Macy Lapham's all-male field party at Hanford.

While Secretary Wilson was sympathetic to the idea of women in the workplace, Lapham was uncomfortable with having women in the field with an all-male crew. On the day that Pearce arrived in Hanford, it was said that Lapham sent a telegram that stated, 'Miss Pearce is here, what in hell shall I do with her?' In the end, he put her to work copying maps. In 1903, she was transferred to the Bureau of Soils in Washington as an assistant in soil survey and later transferred to the Bureau of Plant Industry as a laboratory assistant.

From Lapham's memoirs, it appears fieldwork was out of the question for women before the 1940s. Women found places in the field in unofficial capacities, however. Mary Baldwin, the wife of soil inspector Mark Baldwin (employed by the Soil Survey 1912–1944), mapped with her husband in northern Wisconsin and the Boundary Waters of Minnesota during the early 1920s. They worked during the summer months, camping and using a small boat to go from island to island. Mary would drop Mark off on one side of the island, he would map, and she would wait for him with the boat on the other side of the island. While she waited, she might search for survey markers or make observations on her own of the general area. Mary recalled that there were times when she wished that she could have tried mapping on her own. As it was, she accompanied her husband everywhere during his remote mapping experiences, transcribing or taking field notes for him and assisting with the sampling.

Mary Baldwin might still have had difficulty finding employment with the USDA, even if she had the background and training to map soils. At the time, married couples were discouraged from working for the same federal agency, and the USDA already employed Mary's husband. A clause in a 1932 appropriations law even stated that married persons with a federally employed spouse would be dismissed first in the case of government reductions in force and the preference should be given to others for new appointments. Although this legislation was repealed in 1937, it limited married women's employment by the federal government at that time and perhaps set a precedent for the future.

During the decades of the 1930s, 1940s, and 1950s, women contributed to the soil survey through editing, writing erosion history, and conducting laboratory work. Lillian H. Weiland – the first female employee of the newly established Soil Erosion Service and secretary to Hugh Hammond Bennett – put together a 'Bibliography on Soil Conservation Compiled in the Office of the Chief of SCS' in 1935. The bibliography consolidated ideas for soil erosion control technology for the new agency. In 1937, Lois Olson and Dr Arthur Hall spoke on studies in erosion history as part of a series of research seminars for SCS staff. Some of today's thinking on interpretations of the soil survey and field practices to control erosion can be attributed to this series of lectures. Olson, a geographer by training, headed the SCS's Erosion History Section.

Charlotte Whitford (Coulton), a graduate of Ohio State University with a master's degree in botany, joined the SCS as a secretary with a field soils staff in Zanesville, Ohio, in the mid-1930s. J. Gordon Steele, an old classmate, soon recruited Whitford to work as an assistant soil technologist in Washington, DC, on a series of reports on soil erosion. She later worked as an editor on soil surveys and eventually became head of the SCS publication staff. She retired in the 1980s with almost 50 years of service.

Dorothy Nickerson, a soil color technologist for the USDA from the late 1920s through the 1940s, was instrumental in developing the soil color standards for soil survey. Nickerson had been an assistant manager of the Munsell Color Company before joining the USDA in 1927. She made extensive colorimetric tests in the laboratory and worked with soil scientists in the field to match soils to the Munsell colors and to create a new set of color names, first introduced in preliminary form in 1941. She then

worked with Thomas D. Rice, Kenneth Kelly, and Albert H. Munsell to adapt the Munsell color chart system for describing soil color in the laboratory and the field. The US Soil Survey adopted the Munsell color charts and new color names in 1949.

The first woman soil scientist officially assigned in the field for the SCS was Mary C. Baltz (Tyler). Mary Baltz graduated from Cornell University and joined the soil survey as a 'junior soil surveyor' in 1946. Labor shortages during World War II provided the opportunity for her to work in a job that, up to that time, appeared to be reserved for men. By 1951, Mary was responsible for mapping in Madison and Oneida Counties in New York, and later she was assigned the task of map measurement for the entire state. In contrast with today's electronic techniques, the work was done by cutting out the soil map delineations on copies of the field sheets. Areas with the same label were weighed together and a factor converted the weight to acres. She hired a team of women to do this conversion job in the winter months.

Erwin Rice, a retired soil scientist in New York, mapped under Mary Baltz's direction. He remembered Mary as a confident, petite woman who enjoyed mapping in the field, was comfortable with the all-male crews, and had a good sense of humor. He called her a 'splitter,' a soil scientist who tends to separate out concepts for new soils as opposed to lumping them together under general categories of old soil names. Mary Baltz worked for the SCS until about 1965.

Ester Perry was a major figure in the California soil survey effort. Her 1939 PhD in soil science from UCB was the first received by a woman in the USA. For her doctoral research, 'Profile Studies of the More Extensive Primary Soils Derived from Granitic Rocks in California,' she may have been one of the first students to use X-ray diffraction to look at clay mineralogy structure in soils. She studied under Charles Shaw at Berkeley, and Kelly, Doer, and Brown were mentors and coworkers with her in Riverside, California, where she worked at the Subtropical Horticulture Research Center during her graduate studies. From 1928 to 1939 she worked as an associate soil technologist for the California Agricultural Experiment Station.

From 1939 until she retired in 1965, Perry essentially ran the USDA soil survey laboratory in Room 33 in the basement of Hilgard Hall at UCB. She moved up through the ranks during that time, from 'junior soil technologist' (1939–1954) to 'associate specialist soils' (1954–1960) to 'specialist' (1960–1965). In a 1952 presentation to the Western Soil Science Society in Corvallis, Oregon, Perry praised the benefits of close collaboration between a soils laboratory and a field soil scientist for quick turnaround of information in support of mapping. After the establishment of the Beltsville Agricultural Research Center in 1952, the Berkeley Soils Laboratory was slowly phased out.

In soil science, or more specifically, in pedology (the study of soil genesis), as with all the earth sciences, there were very few women working in the field before the 1970s. Gary Sposito, who was a student in Ester Perry's laboratory for a year, recalls that she was well aware of being a pioneer in her profession. As one of 'Ester's boys' (as students who worked part-time in her laboratory were known), he thought she effectively mentored many young men and women into a soil science career. Dr Perry maintained an all-business approach in the laboratory, but also remembered to bring birthday cakes for her students and provided a bed in the laboratory for those who might work through the night on important projects. Despite her accomplishments, Ester Perry was never promoted to associate professor or put on the tenure track. This was not unusual, however, since many women and men worked as researchers or technicians for their entire careers at the agricultural experiment station without receiving academic status. She also was not acknowledged in USDA records as an official soil survey collaborator.

Foundations: Building on the Pioneers (1959–1975)

During the 1950s and 1960s few women ventured directly into the field of soil science. Some arrived through other disciplines, such as geology, microbiology, or one of the plant sciences. They found through their graduate studies that soil science was a key element in their research and then continued on to further studies in soil science. Some were mentored and encouraged by major professors (as Ester Perry had been by Shaw and Kelly) to pursue soil science and stick with it. As scientists and teachers, the women soil scientists who started in the 1950s and 1960s spent a good deal of their careers as mentors themselves, and many placed a high value on that aspect of their work.

Ester Perry, who bridged the gap from the pioneer era to this period of building foundations, was, herself, one such mentor, not only through her work with students in the Berkeley Soils Laboratory, but also particularly in her effort to bring equal access to soil survey field training to women in the mid-1950s. In that decade, a summer field course – Soils 105 field trip – was a requirement for a soil science major from UCB and the University of California at Davis (UCD). The course was offered each summer, and since the 1930s had convinced many a prospective soil science student that soil survey could be a lifelong interest and career path. In 1953, Eva Esterman, a soil science honors student, was the

first woman to request to take the course. The UCB Soils Department offered Eva an option to graduate without participating in the field course, but she wanted to take the trip just like all of the other students. For 6 weeks in the field, the university arranged for Eva to have separate sleeping facilities and comfort stops. Dr Earl Story's wife served as chaperone, accompanying the students in a separate car and with some discomfort. The academic dean at the time, Dr Frank Haridine, considered the experiment a complete disaster and swore publicly that no women would ever again take the field course.

The event triggered Ester Perry to step in and offer a Soils 105F course ('F' for female), which she planned and made available from 1956 to 1959. The trip was soil survey-oriented but because Ester had different professional contacts, the course had a somewhat different approach. Three women took the course in 1959, the last year the specialized course was offered. In 1965, the 'Soils 105' course officially became co-ed and included two women students. Perry accompanied the group as a chaperone. Seven years later, the class was almost 50% women, and there was no women's chaperone.

In addition to mentoring students of soil science, many women professors and researchers made substantial contributions to our understanding of soils and soil science during the 1960s and 1970s. In the USA, Cornelia Cameron, Jane Forsyth, Jaya Iyer, Eva Esterman, Nellie Stark, and Elizabeth Klepper have been among the most prominent, although there are no doubt many others. Scientific publications usually list the first names of researchers only by their initials, which makes identifying the authors by gender difficult at best; the individuals included here were identified by their students and colleagues.

Dr Cornelia C. Cameron completed her PhD in geology (with an emphasis in geomorphology) at the University of Iowa in 1940. After 11 years teaching earth sciences, Dr Cameron joined the US Geological Survey (USGS) in 1951 and spent the next 43 years in the field. Her field career began in military geology, with terrain analysis of military sites in over 30 countries on five continents, many of them dangerous militarized zones at the time. Dr Cameron's colleagues remember her as quite a character in the field.

In part, Dr Cameron's reputation for eccentricity had to do with her mother. One of the USA's first female PhDs in botany, Dr Cameron's mother had a strong interest in her daughter's work and accompanied Cornelia on field expeditions until she was 103 years old. The younger Dr Cameron joked that when her mother got so old that her eyesight had deteriorated, she put a cow bell on her so she could find her if she wandered off. In a story about daughter and mother's adventurous military terrain investigations in the Caribbean area in early 1961 before the Bay of Pigs invasion, Dr Cameron recounted that "Mother and I were a perfect pair. We told everyone that we were Canadian tourists. One time, as I was doing traverses along the slopes of one of the islands, Mother stayed in the car. I was upslope from her when I saw a truck full of guerrillas pull up. Mother simply charmed them and they drove off."

Dr Cameron was an internationally recognized authority on peat soils and their use as a soil additive and source of energy, and on the impact of peat removal on swamp and bog environments; she wrote prolifically – 110 publications – on the subject. Both the USGS and the Department of the Interior recognized her accomplishments in research and public service. Dr Cameron received the USGS's Meritorious Service Award in 1977 and its Distinguished Service Award in 1986, and received the Department of the Interior's Public Service Recognition Award in 1990.

Dr Jane L. Forsyth, a professor of geology at Bowling Green State University in Ohio, has contributed much to our understanding of the age relationship of soils and till to northern Ohio glacial geology. Among her peers she has been affectionately dubbed the 'Queen of the Pleistocenes,' according to her colleague Peter Birkeland, retired from the faculty at University of Colorado, Boulder. Dr Forsyth earned her PhD from Ohio State University in 1956 and taught at University of Cincinnati, Miami University, UCB, and Ohio State University, before joining the faculty at Bowling Green State University in 1965.

Dr Jaya Iyer, professor of soil science at the University of Wisconsin, Madison, has focused her research on relating soil properties and tree growth. Dr Iyer earned her PhD in botany from the University of Bombay, India, in 1959. The external referee for her PhD research, soil scientist Dr Sergei Wilde of the University of Wisconsin and a member of the Wisconsin Forestry Hall of Fame, encouraged her to take an interest in soils, and she completed a second PhD in Soil Science at the University of Wisconsin, Madison in 1969. Dr Iyer has had a highly successful career as a national expert in soils for tree nurseries, specializing in urban, Christmas tree, and forestry production.

Dr Eva Esterman, who received her PhD in soil science from UCB in 1958, nearly 20 years after Ester Perry, was only the second woman to earn a soil science PhD from Berkeley. She went on to become a professor at San Francisco State University in 1960, where she taught botany and later added soil science to the curriculum. She focused her soils research on soil microbiology and biochemistry before she retired in 1982 and began raising sheep.

Dr Nellie Stark, tenured professor and forest soil ecologist at the University of Montana, Missoula, from 1970 to 1992, gave us the theory of the 'biological life of a soil,' which describes how soils and plants interact during development and decline phases of soil genesis. The theory explains the variation in nutrient uptake by plants based on the stage of soil genesis. Indirect nutrient cycling, which involves uptake of ions by the roots from the soil, predominates when a soil is young; direct nutrient cycling, which involves uptake of ions by the roots directly from the litter, by-passing the soil, occurs as the soil becomes older and depleted by weathering.

Stark earned a PhD in botany (ecology) from Duke University in 1962, with a minor in soils based on credits she collected at Oregon State University in 1961. Dr Stark's research with the Desert Research Institute, Reno, Nevada, focused on soils and nutrient cycling of litter in the tropical ecosystems of Brazil and Peru. The soil chemistry laboratory for forestry that Dr Stark operated at the University of Montana was well-known and received and processed samples from all over the world.

Finally Dr Elizabeth L. Klepper, a research leader and plant physiologist at the Columbia Plateau Conservation Research Center, Pendleton, Oregon, concentrates her research on root growth and functioning under field conditions and plant–soil water relations. Dr Klepper holds degrees from Vanderbilt University and Duke University. She has been recognized for her accomplishments by all three professional agronomic research societies of the USA: the American Society of Agronomy (ASA), the Crop Society of America (CSA), and the Soil Science Society of America (SSSA). She was the first woman ever to receive the Fellow award from the SSSA (American Society of Agronomy).

These are but a few of the women who dedicated their lives and research to soil science and soil survey during this period. It is inspiring to consider their achievements. Over the course of about 50 years, women in soil science and soil survey moved out from under their restriction to clerical support to become influential researchers and field investigators. Both Dr Stark's theory of the biological life of a soil and Dr Cameron's important and risky fieldwork would have been virtually unimaginable when the soil survey began in 1899.

In the Classroom, in the Field, and in the Laboratory (1970–1990)

Despite great strides in the field of soil science, women were still not actively recruited into the USDA's Soil Survey Division in the 1960s. For example, in a 1962 recruitment speech to the Agronomic Education Division of the American Society of Agronomy in Ithaca, New York, Assistant Soil Survey Administrator Charles Kellogg expressed his agencies' concern about recruiting good candidates, "especially of well-trained, broadly educated young men who can develop rapidly." His comments were not surprising perhaps, since the professional workforce of the country at that time was still predominantly male.

The transition during the 1960s was profound, however. By the 1970s, career counseling documents were beginning to discuss ways to channel girls into nontraditional careers, and encouraging young women to enter nontraditional occupations continued as a theme into the 1980s. Corresponding changes occurred in the classrooms; as more and more young women began to enter previously male science and employment territories, materials and approaches to education changed to meet the needs of this more diverse student population.

In the soil survey, as well as in some of the other earth sciences professions, a woman still needed to be persistent in the 1970s to obtain a field appointment. In the SCS of the 1970s, there were fewer than 15 women in the federal employment series soil scientist (470 series) at anyone time nationally, despite an acceleration in soil survey mapping and a general increase in field crews.

Most of these women soil scientists thought they were the only female soil scientist in the agency. In addition, there were no formal professional organizations for women field soil scientists; the Association of Women Soil Scientists (AWSS), organized by a group of women soil scientists in the US Forest Service, was not formed until the early 1980s. But slowly more career opportunities began to emerge for women. Title VII of the Civil Rights Act of 1964 and the Civil Service Reform Act of 1978 helped increase opportunity by prohibiting sex discrimination in employment and requiring diversity in the workforce, and the Women in Science and Technology Equal Opportunity Act of 1980 opened up more opportunities for women to receive support in university settings.

In the 1970S and early 1980s, the SCS soil survey staff in California included five women field soil scientists (Arlene Tugel, Nancy Severy, Chris Bartlett, Lisa Holkolt, and Maxine Levin), a crowd compared to other states. Many states had only one woman working as a soil scientist in the field – Carole Jett in Nevada; Carol Wettstein in Florida; Sue Southard in Utah; Margaret Rice in Mississippi; Caryl Radatz in Minnesota; Mary Collins in Iowa; and Debbie Brasfield in Tennessee, for example. Some states had two or more women in the field, and there may have

been more. Records of employees for those years are spotty and have not been saved comprehensively. But, in any event, women still comprised a small percentage of the total field soil scientist staff. Nevertheless, their contribution to soil survey was sizable, with millions of acres mapped, at times with some physical hardship.

Many of the women who worked in field parties during the 1970s went on to achieve greater responsibilities and position. By the late 1980s, the SCS had appointed the first woman state soil scientist, followed by others in the early 1990s, and women grew more prominent as soil survey party leaders. Carol Wettstein became the first woman state soil scientist, serving in Maryland from 1988 to 1989 and as state soil scientist in Colorado from 1990 to 1995. Carole Jett served as state soil scientist in California in 1991, and Carol Franks was state soil scientist in Arizona in 1994. In 2000, Maxine Levin was appointed national program manager of the Soil Survey Division. In the 1980s, there were at least three published soil surveys for which women were the party leaders or the principal field investigators: Sacramento County, California (Arlene Tugel); City of Baltimore, Maryland (Maxine Levin); and Indian River County, Florida (Carol Wettstein).

We can anticipate seeing more women listed in soil surveys of the 1990s, as the number of women party leaders increased significantly during the decade. An all-female crew of soil scientists led by Deborah Prevost mapped the Hualapai-Havasupai Indian Reservation, Arizona, in the late 1980s and early 1990s. This soil survey was published in 1999 – exactly 100 years after the establishment of the USDA Soil Survey.

Women have also contributed to soil surveys in many other ways that are not reflected in publications. Soil correlators and data management specialists make significant contributions to soil survey data and manuscripts, and a number of women have held these positions: Sue Southard (California), Renee Gross (Nebraska), Carmen Santiago (Puerto Rico), Panola Rivers (Pennsylvania), Kathy Swain (New Hampshire), Laurie Kiniry (Texas), Diane Shields (Delaware), Susan Davis (Maryland), Marjorie Faber (Connecticut), Tammy Cheever (Nebraska), and Deborah Anderson (North Carolina). In the last few years, women soil scientists have been instrumental in the effort to digitize the soils information that is used in the publications, including Vivian Owen (Texas), Jennifer Brookover (Sweet) (Texas), Darlene Monds (Massachusetts), Barbara Alexander (Connecticut), Caroline Alves (Vermont), Lindsay Hodgman (Maine), Caryl Radatz (Missouri), Adrian Smith (Nebraska), Amanda Moore (Oregon), Sharon Schneider (Oregon), Marcella Callahan (Arkansas), Brandi Baird (Oregon), and Jackie Pashnik (Rhode Island).

In the National Cooperative Soil Survey there are also a number of women field soil scientists who work mostly with soil survey interpretations and education, including Sue Southard (California – volcanic soils and vertisols), Lenore M. Vasilas (Maryland – hydric soils), Sheryl Kunickis (Washington, DC – landscape analysis), Susan Ploetz (Minnesota – resource inventory), Susan Casby-Horton (Texas – soil geomorphology), Christine Clarke (Maryland – geographic information systems), Jeannine Freyman (Virginia), Karen Kotlar (New York), Lisa Krall (Connecticut), Gay Lynn Kinter (Michigan), Donna Hinz (Nebraska), Patricia Wright-Koll (Minnesota), Jeanette Bradley (Arkansas), and Deborah Prevost (Nevada). Like agricultural extension specialists, these soil scientists act as a bridge between university research, soil survey mapping, and the public, interpreting soil surveys for practical use by both agencies and individuals, including providing on-site field investigations.

Women in the SCS, now the Natural Resources Conservation Service (NRCS), have made significant contributions to soil science in the National Soil Survey Laboratory (NSSL) and the National Soil Survey Center (NSSC), and as researchers in the Soil Quality and Watershed Sciences Institutes. Carolyn G. Olson has been a lead research scientist at the NSSC, located in Lincoln, Nebraska, since 1989. Dr Olson's research focuses on soil geomorphology, quaternary geology, and clay mineralogy. Olson received the honor of being made a Fellow of the Soil Science Society of America in 1996. Other women soil scientists at NSSL and NSSC include Rebecca Burt (soil chemical properties), Joyce Scheyer (urban soil properties), Susan Samson-Liebig (soil quality), Deborah Harms (soil physical properties), Sharon Waltman (national soil survey databases and GIS interpretations), and Carol Franks (soil biology). In the Institutes, Arlene Tugel (New Mexico), Betty McQuaid (North Carolina), and Cathy Seybold (Oregon) have been working with soil quality and watershed health indicators.

Other federal agencies, such as the USGS, also provide opportunities for women in soil science research. Jennifer W. Harden, with USGS in Menlo Park, California, built on her PhD research using soil chronosequencing to develop the Harden Index, which used soil horizons and carbon-dating to measure time in the alluvium sequencing. Since then, she has worked on the effect of climate on soil, particularly as it relates to groundwater recharge and wetland assessment. She has been a front-runner in research on global change issues of soil carbon, carbon dioxide emissions, and soil carbon sequestration. Marith Reheis, with the USGS in Denver, has

also done significant research in using soil properties as a paleoclimatic record for chronosequence mapping in Rocky Mountain glacial outwash. Originally a geologist by training, she received her PhD in soil science under Pete Birkeland at the University of Colorado, Boulder, in 1984.

At NASA's Goddard Space Flight Center, Elissa Levine has been working with soils in forested ecosystems since 1987. She models soil physics and soil chemistry to assess watershed leaching, soil carbon ecosystem effects, and the effects of acid precipitation on soils and groundwater. She was recently appointed lead scientist for the NASA Global Change Master Directory. She was also selected as a Fellow of the Brandwein Institute for Science Education, an award based on her work as the principal scientist in the GLOBE program's soil investigations for teaching soil science worldwide to K-12 students.

Since the 1970s, women scientists with the US Forest Service have been involved with the National Cooperative Soil Survey ecological unit inventories, as well as with technical soil interpretations in the specialties of forest soil productivity, soil erodibility, fire ecology, and forest ecosystem health. Some of the prominent women involved in this effort include Gretta Boley (Washington, DC), Clare Johnson (Six Rivers National Forest, California), Carol Smith (SCS-USDA and Tahoe National Forest, California), Barbara Leuelling (Superior National Forest, Minnesota), Connie Carpenter (White Mountain National Forest) and Mary Beth Adams (Northeast Forest Experiment Station, West Virginia).

In 2000, three women held positions as pedology (soil genesis) professors in US universities: Janice L. Boettinger, Utah State University, Logan; Christine Evans, University of New Hampshire, Durham; and Mary Collins, University of Florida, Gainesville. Dr Boettinger is working on an extensive review of worldwide zeolite mineral occurrences in soils and the use of zeolite and clinoptilolite for waste disposal systems of animal production operations. She is also working on characterizing selected soil resources of Utah, which includes research on saline, wet soils and irrigation-induced hydric soil characteristics. Dr Evans is focusing her research in the field of describing anthropogenic (human-influenced) soils and developing terminology to describe soil properties derived from human activity.

Dr Collins' research at the University of Florida focuses on the genesis, morphology, and classification of soils; identifying and delineating hydric soils; using ground-penetrating radar to study subsurface properties; and pedoarcheology. She is best known for her dedication to soil survey fieldwork and reaching out to other countries to spread soils technology. As part of the People to People Program, she first opened the door to doing ground-penetrating radar soil investigations in China and Portugal. Dr Collins was made a Fellow of the American Society of Agronomy in 1996 and a Fellow of the Soil Science Society of America in 1997.

A number of women who have been made Fellows of the Soil Science Society of America have provided outstanding contributions to soil science. Mary Beth Kirkham, made a Fellow in 1987, is a professor at the Kansas State University Evapotranspiration Laboratory. Her work has focused on heavy-metal uptake by plants and soil–plant–water relations for over 20 years. Mary K. Firestone, who became a Fellow in 1995 and also received the Emil Truog Soil Science Award, is a professor of soil microbiology at UCB. Her research focuses on the microbial population-basis of carbon and nitrogen processing in ecosystems. Jean L. Steiner, made a Fellow in 1996, is director of the USDA Agricultural Research Service (ARS) Southern Piedmont Conservation Research Laboratory in Watkinsville, Georgia. Her research is on humid region water balance studies in complex topographies. Finally, Diane E. Stott, a 1997 American Society of Agronomy Fellow, is a soil microbiologist with ARS in West Lafayette, Indiana. Her work has focused on the effects of organic matter dynamics on soil structure and erodibility and modeling the effects of plant residue decay on erodibility.

The women described above are only a sample of the many women who have contributed research, mapping, applications, and education to the field of soil science in the last 25 years. Others, to name only a few more, include Nancy Cavallaro (University of Puerto Rico – soil chemistry and tropical soil fertility), Laurie Drinkwater (Rodale Institute, Pennsylvania – sustainable agriculture), Kate Scow (University of California, Davis – soil microbiology), Laurie Osher (University of Maine, Bangor – soil science), Samantha Langley (University of Southern Maine, Gorham – soil science education), Kate Showers (Boston University – soil conservation), Jeri Berc (NRCS-USDA – soil conservation), and Katherine Newkirk (Woodshole Marine Biological Laboratory – global warming).

1990 and Ahead

Clearly, women have made significant and numerous contributions to the field of soil science and soil survey through research, mapping, applications, and education. As the numbers of women have increased in the classroom, laboratory, and field, changes have also taken place within the soil science discipline. The women who are graduating in soil science in the 1990s are confident and intellectually engaged and

are quickly gaining recognition for their work. As an example, Eva M. Muller of Spokane, Washington, a soil survey project leader with only 7 years of experience, was awarded the National Cooperative Soil Survey Soil Scientist of the Year Award in 2001. Lenore M. Vasilas, who finished her MS in soils in 1997, remarked about any remaining stereotypes in her work, "Oh we don't think about it... We just go ahead and do it!"

There is a world of difference between Julia Pearce's experience in the early 1900s and Lenore Vasilas's reality in 1998. In the educational realm, between 1987 and 1996, soil science, along with education, communication, and social science, experienced the largest percentage growth of female participation. While overall enrollment of students (BS, MS, and PhD) in the soil sciences held relatively steady between 1987 and 1996, fluctuating between 1200 and 1500 students, enrollment of women in the soil sciences rose from 16.2% in 1987 to 32% in 1996. In 1996 there were 228 female BS graduates in soil science, almost double that of 10 years before. PhD and MS candidates in the soil sciences in 1996 were also about one-third female, once again double from 10 years before.

Progress in employment numbers in the SCS/NRCS appears a little less dramatic. In 1985, the SCS employed 85 women soil scientists at the federal level; in May 1998, there were 94 women soil scientists in various level positions. The progress is significant, however, given the overall reduction in the total number of soil scientists in the agency. Currently, about half of the NRCS's new soil scientists are women. We can anticipate a twenty-first century that witnesses a continuing trend of more women working in the field in soil survey and private consulting firms and as teachers and researchers in the field of soil science in university and laboratory settings across the USA and the world.

Introduction

Soil is commonly described as the mantle or the skin covering the land mass of planet Earth. In some places, bare rock is exposed and the skin is absent or may be just a few centimeters thick. In other locations, the mantle is several meters thick with distinct layers that reveal the formation or depositional history of the mantle. For most people, soil is the natural medium for the growth of nonaquatic plants and has a thickness that is determined by the rooting depth of plants. It is composed of solids (mineral and organic), liquids, and gases. Soil scientists differentiate between the initial material (if it was a sediment) and the soil derived through soil-forming processes. The upper

limit of the soil is the contact between soil and air or shallow water (less than 2.5 m deep). The soil on a landscape is a continuum, and across the landscape it grades into nonsoil materials such as rock, ice, or deep water.

The study of soil is 'pedology' and the scientists who study it are referred to as pedologists or soil scientists. The soil that is studied is the zone that extends to the nonsoil material (if the latter occurs at less than 200 cm) or to approximately 200 cm if the nonsoil material occurs deeper, as this is the zone where much of the biological or pedological processes operate. This is a convention, though; for some studies, depths of 20 m or more are considered. The different climates that prevail in the world and their interactions with the rocks or sediments produce a range of soils that vary in their physical, chemical, biological, and mineralogical properties. The kind of soil is also determined by the geomorphology of the land, the amount and rate of water moving in and on it, and the kind of disturbances it has been subject to, including human influence.

It is important to understand and know the different kinds of soils and how they form, as this helps in sustainable land management. Soil classifications, created to help organize knowledge about soils, have been structured to enable this. An important difference between classification of soils and classification of plants and animals is that, unlike the latter, soil is not discrete but a continuum, and as a consequence the boundaries between named soils are artificial. Depending on the objectives for which the classification was created, the class definitions and the architecture of the classification system may vary. Many countries have national soil classification systems but one that is widely used and employed is Soil Taxonomy. Soil surveys enable the depiction of soils across a landscape and soil maps are made to show the patterns of soils that exist and provide information on the management properties of the soils. Specialized maps with technical soil classifications are produced for specific objectives. The soil maps are produced at different scales: detailed maps (1:10 000 or larger scale) to show soils on farms, and general maps (1:100 000 or smaller scale) to depict soils over large areas such as countries, continents, or the world. Soil classification has the additional function of linking the information of these different maps.

Soil Classification

To appreciate the variety of soils that occur on this planet, it is necessary to understand the classification system used to demonstrate this. Two classification systems are widely used: the Food and Agriculture Organization of the United Nations (FAO) initiated the World Reference Base for soil classification; while Soil Taxonomy is a system developed in the USA with the collaboration of international soil scientists. Soil Taxonomy has six categories, as listed in Table 1. Each category serves specific functions determined by its information content. The soil series is the lowest category and is defined with the maximum amount of information. Information is generalized in the definition of each higher category. Consequently, each category can only be used for specific purposes. When employed to designate map units, the scale of the maps limits the category that is represented, as shown in Table 1. The highest category, the order, has only 12 classes. There are 64 classes in the suborder, 300 classes in the great 10 470 group, and 2400 classes in the subgroup. In the USA soil families and 21 000 soil series are recognized. No global estimates for the number of classes in these two categories exist.

Soils are grouped into 12 orders in Soil Taxonomy. Figure 1 shows the global distribution of the soil orders and Figure 2 shows representative examples. Soil-forming processes (Table 1) and the attributes they provide for the soil are used to define the soil. This is expressed in another manner in Table 2. As soils are composed of mineral or organic materials or mixtures, when these primary components dominate the system, the resulting properties define the soil: short-range minerals in Andisols, smectitic clays in Vertisols, organic matter in Histosols, and low-activity clays in Oxisols. In the second group of soils, processes listed in Table 1 result in horizons of accumulation or depletion. The next group of soils (Inceptisols and Gelisols) also results from soil-forming processes but the manifestations are slight or mainly physical. Finally, Entisols are the soils where the original material is least altered or not modified by soil-forming processes. As climate or hydrology controls many of the processes, each of these major kinds of soils has a specific place on the landscape. However, each soil may have properties transitional to other soils, and such secondary features are used to define the intergrades or the lower categories. Each order of soils also has specific subordinate properties that are employed to define the lower categories.

Unlike other soil classification systems, Soil Taxonomy incorporates soil climate by using the soil moisture regime (SMR) and the soil temperature regime (STR) to define lower categories. Soils with an aridic SMR (deserts) occupy approximately 36% of the total land area, making such land only available for agriculture if there is a source of irrigation. The soils with a xeric SMR (Mediterranean) occur in areas with winter rains and, like those with an ustic

Table 1 Defining characteristics of the categories in soil taxonomy

Category	*Definition*	*Functions*	*Potential uses*
Order	Soils having properties (marks) or conditions, resulting from major soil-forming processes that are sufficiently stable pedologically and that help to delineate broad zonal groups of soils	Depict zones where similar soil conditions have occurred for general understanding of global patterns of soil resources Establish global geographic areas within which more specific factors and processes result in the diversity of soils	General global, continental, or regional assessment Global climate-change studies AMS $<$1:10 000 000 MSD $>$40 000
Suborder	Soils within an order having additional properties or conditions that are major controls or reflect such controls on the current set of soil-forming processes and delineate broad ecosystem regions	Demarcate broad areas where dominant soil-moisture conditions generally result from global atmospheric conditions Delineate contiguous areas with similar natural resource endowments Ecosystems with distinct vegetation affinities usually determined by limiting factors of soil moisture or conditions	Demarcate areas in regions or large countries for assessment and implementation of economic development Analysis of international production and trade patterns Priority setting for multipurpose uses of land resources AMS 1:1 000 000–1:10 000 000 MSD 4000–40 000
Great group	Soils within a suborder having additional properties that constitute subordinate or additional controls or reflect such controls on the current set of soil-forming processes, including landscape-forming processes	To demarcate contiguous areas with similar production systems or performance potentials	Development of strategic plans for regional development Basis for coordinating national resource assessment and monitoring programs Infrastructure development to assure equity in development AMS 1:250 000–1:1 000 000 MSD 250–4000
Subgroup	Soils within a great group having additional properties resulting from a blending or overlapping of sets of processes in space or time that cause one kind of soil to develop from, or toward, another kind of soil: Intergrades show the linkage to the great group, suborder, or order level; Extragrades have sets of processes or conditions that have not been recognized as criteria for any class at a higher level, including nonsoil features The soil is considered as the 'typic' member of the class if the set of properties does not define intergrades or extragrades	To demarcate production land units with similar land use and management requirements	Targeting research and development for specific land use or cropping systems Implementing conservation practices and ecosystem-based assistance Community development projects and monitoring sustainability Basis for diversification of agriculture and uses of land resources Basis for implementing environmental management programs and modeling ecosystem performance AMS 1:100 000–1:250 000 MSD 40–250
Family	Soils within a subgroup having additional properties that characterize the parent material and ambient conditions The most important properties are particle size, mineralogy, and soil temperature regime	To demarcate resource-management domains characterized by similar management technology and production capabilities	Basic units for extension and/or technology transfer Modeling cropping systems' performance Addressing socioeconomic concerns AMS 1:25 000–1:100 000 MSD 2.5–40
Series	Soils within a family having additional properties that reflect relatively narrow ranges of soil-forming factors and processes, determined by small variations in local physiographic conditions, that transform parent material into soil	To delineate land units for site-specific management of farms	Implementing soil-specific farming Designing farm-level conservation practices AMS $>$1:25 000 MSD $<$2.5

AMS, appropriate map scale; MSD, minimum size delineation: smallest area that can be delineated on a map with a legible identification, in hectares.

Oxisols	Mollisols		
Vertisols	Spodosols		
	Aridisols		

[a]Only a small accumulation of organic matter.

SMR (semiarid), have moisture stress for prolonged periods during the year. These two groups of soils occupy approximately 21.5% of the land and form the semiarid zones, where a second crop requires supplemental irrigation. The soils with an aquic SMR represent the wetlands, which generally are ecologically fragile systems. Thus only approximately 33% of the total land is relatively free from moisture stress, although low temperatures may also stress part of this. The very cold pergelic soils, which occupy approximately 11% of the land, are generally under sparse forest vegetation or are free of vegetation. The cryic and frigid (boreal) soils are generally under forest but are cultivated in some areas with an annual grain crop of short duration. The temperate climates are reflected by soils with mesic, thermic, isomesic, and isothermic STRs, and in general if the SMR is conducive, they are the soils with the highest agricultural potential. The humid tropical soils are represented by the combination of an isohyperthermic STR and udic or perudic SMRs. They occupy approximately 9% of the land surface and have not only some of the poorest soils, but also a heavy incidence of pests and diseases. Each combination of SMR and STR represents a unique pedoenvironment that also contains a myriad of soils.

The distribution of the different kinds of soils is presented in Table 3. The Aridisols are the largest order of soils, occupying approximately 23% of the land. The Histosols, Andisols, and Vertisols individually occupy less than 3% of the area. These are soils formed on special materials or under special conditions and so occupy specific geographic areas. The Gelisols are confined to the very cold regions of the world. Due to intense weathering and leaching by the tropical environment, most of the Oxisols and Ultisols are located in the tropical zones. The unique soil-formation conditions of the tropics are also reflected in the distribution of the Alfisols and Mollisols, which are more extensive in the temperate regions. Inceptisols and Entisols are present under a range of climatic environments. Estimates of the distribution of the suborders of soils are also given in Table 3.

Global Distribution

Gelisols

In areas where the mean annual soil temperature is less than 0°C, the soils are frozen for long periods of the year and thaw out during the short warmer spells. The freezing and thawing processes promote physical changes in the soil. If there is sufficient water and the warm period is long enough, vegetation is established and organic matter accumulates on the soil. Organic-rich soils or peat develop. Due to low temperatures, these Arctic soils have unique features such as ice-lenses, or a layer of ice may underlie the soil. In situations where free water is limited, permafrost layers are present. Depth to the permafrost layer is determined by several factors, including the protective organic-rich layers on the soil surface. In arid areas, the soil particles are held together by dry permafrost. A thin film of frozen water forms a binding film around the particles. The three suborders in Gelisols are:

1. Histels: characterized by a histic epipedon with ice lenses; may be underlain by ice or permafrost, or rock;
2. Turbels: characterized by disrupted horizons or ice wedges penetrating upward into horizons;
3. Orthels: characterized by permafrost layers at depth; but the surface horizons do not show disruptions or distortions due to freezing and thawing. Frequent in the transition to warmer soils.

Histosols

Most soil classifications, including Soil Taxonomy, separate mineral soils from organic soils. Histosols are soils that consist of dominantly organic soil materials. Histosols comprise only a small portion of the world's land area (1.2%), but are widely distributed irrespective of climate. They develop where the rates of organic matter accumulation exceed decomposition and removal. Most of these soils have formed

under saturated conditions where the soil is saturated or nearly saturated with water most of the year. These soils are referred to as bogs, moors, peat, or mucks.

To be farmed, most Histosols must be drained. Management of the water table depth is critical to their use. When drained, Histosols oxidize and subside, and require further drainage. The rate of subsidence can be several centimeters per year and is affected most by depth of drainage. Experience has shown that Histosols in cool temperate areas have the lowest levels of subsidence under tillage. Climate is the main limitation for crops grown on Histosols. Many are used for vegetable crops. Fire and wind-erosion hazards increase after Histosols have been drained.

Histosols are and have been mined as a source of fuel and as a source of organic matter for soil amendment. Because of their extreme instability, Histosols present special problems when roads or other structures are built on them. They are removed if possible during road construction, and buildings constructed on them are normally placed on pilings driven into the mineral soil below them.

Vegetation found on Histosols ranges from grasses, sedges, and rushes to shrubs and trees, all of which are usually water-loving or water-tolerant. Most recently Histosols have been recognized for their importance worldwide as wetland wildlife habitats. Those associated with open bodies of water are especially important habitats. Histosols are recognized as equally important filters of pollutants such as phosphates, nitrates, and other agricultural and industrial contaminants that migrate in water.

The suborders of Histosols are separated by the degree of decomposition of the organic matter, and climate:

1. Folists consist of leaves, twigs, and branches resting on rocks, stones, or coarse fragments in which the interstices are partly filled with organic materials. They are not saturated with water for more than a few days per year if rock is present at shallow depths; they occupy a small area (0.14 million km^2), mainly in the northern latitudes;
2. Fibrists consist largely of plant remains so slightly decomposed that rubbing does not destroy them and their botanical origin can be determined easily. They occupy large areas (1.1 million km^2) in the northern latitudes;
3. Hemists consist of organic materials that are so decomposed that the botanic origin of as much as two-thirds of the materials cannot be readily discerned or the fibers can be largely destroyed by rubbing between the fingers. They occupy small areas in the northern latitudes and may also be found in the tropics;
4. Saprists consist of almost completely decomposed plant remains and their botanic origin cannot be determined. Only small areas of these soils are found in the cool and cold regions of the world; most of them are confined to the tropics.

Andisols

Soils formed on volcanic ash and cinders and having andic properties are distributed along the circum-Pacific belts and occur sporadically elsewhere (1.8% of the land mass). The mineralogical composition is a function of the age of the deposit and the climatic conditions it has been exposed to. The Andisols have mineralogical composition ranging from volcanic glass, short-range-order minerals such as allophane and immogolite, and variable amounts of halloysite. This mineralogical association gives unique properties to such soils, including a high phosphate-fixing capacity, low cation retention, and a high water-holding capacity. Many of these soils are found on volcanic slopes or are developed through the weathering of plateau basalts. These soils support a high human population density owing to their general ease of cultivation and also because of the cool environment of the volcanic mountains, which is generally free of pests and diseases.

The success of human habitation on Andisols is largely due to the soil and climatic environment. Though phosphorus availability is a problem, there is usually a sufficient supply to meet most needs. For intensive cultivation, fertilizers are needed. The soils are friable and well drained so tillage is not a problem. As the soils have been used for generations, conservation practices have been installed in most situations.

Seven suborders are recognized in the Andisols. These are:

1. Aquands: these soils are wet and experience extensive water saturation for prolonged periods during the year. Aquands are local and do not occupy enough land to be shown on small-scale maps;
2. Cryands: these soils have a cryic or pergelic STR. Cryands are found in small areas of Canada, the Kamchatka peninsula of Russia, and high elevations in the tropics;
3. Torrands: these soils have an aridic SMR. Torrands have been reported in the volcanic areas of Mexico and Syria; many have not been studied in detail and so classification is still in doubt;
4. Xerands: these soils have a xeric SMR. Xerands occur sporadically in the Mediterranean areas of

the Near East, and not much information on them exists;

5. Vitrands: these soils are recent ash or cinder deposits where some weathering and soil formation has taken place. Vitrands are normally very recent deposits such as those around Mount St. Helens in the USA or around Mount Pinatubo in the Philippines. Mostly they occur on steep upper slopes, and no reliable estimates on them are available;

6. Ustands: these soils have an ustic SMR. Ustands are widespread on the leeward side of tropical volcanoes and are generally used intensively for agriculture;

7. Udands: these soils have an udic SMR. Udands are most widely used for agriculture and generally support the highest population density. Large areas of South-East Asia, Central Africa, Mount Cameroon in West Africa, and the Andean range in South America, as well as many of the volcanic islands of the Pacific, including Japan, are the main locations of Udands.

Spodosols

A black, reddish-brown to dark-brown subsoil (spodic) horizon is the primary identifying characteristic of a Spodosol. It is often overlain by a gray to light-gray eluvial horizon. These distinctive and contrasting colors make Spodosols easily identifiable, although there are always exceptions. The simple explanation for this horizon sequence holds that, under cool, humid, or perhumid climates, organic acids from a litter layer leach amorphous mixtures of organic matter and aluminum with or without iron from the eluvial horizon and deposit them in the illuvial spodic horizon. Most Spodosols have formed under such conditions and thus are common in the northern latitudes where most of these soils are to be found. However, Spodosols vary widely depending on climate and other soil-forming factors. In some, the gray (albic horizon) may be absent; in others, it may be more than 2 m thick over a spodic horizon; furthermore, in some the spodic horizon may be cemented and is then called 'ortstein.'

Most Spodosols have few silicate clays. The particle-size class is mostly sandy, sandy-skeletal, coarse-loamy, loamy-skeletal, or coarse-silty. In hot, humid intertropical areas and other warm humid areas, they have for the most part formed in quartz-rich sands that have a fluctuating water table. Spodosols may form rather quickly (several hundred to several thousand years), again depending on climate and other soil-formation factors.

Many Spodosols are forested. They are generally used for forestry, cultivated crops, and pasture. Spodosols are naturally infertile, but with fertilization, commonly additions of large quantities of lime, nitrogen, and phosphorus, they are quite productive. They tie up considerable amounts of phosphorus, at times returning only approximately 0.45 kg of phosphorus for every 2.7 kg applied. In some Spodosols there may be a deficiency in heavy metals such as selenium or cobalt in forage used for ruminants. There are four suborders of Spodosols:

1. Aquods have an aquic SMR or the climate is extremely humid. They have a spodic horizon, with very high organic matter content, and are generally found in depressions or where the soils have an impermeable subsoil;

2. Humods have a spodic horizon enriched with organic matter. They are well drained and are generally found in cool climates, including high elevations in tropical mountains. On sandy coastal plains of the tropical littoral, such soils frequently occur with Histosols, the latter in depressions;

3. Cryods have a cryic STR;

4. Orthods have a spodic horizon enriched with both iron and organic matter. These are the most extensive Spodosols (2.7 million km^2) and are dominant in cool temperate areas of the northern latitudes.

Oxisols

Oxisols are reddish, yellowish, or grayish soils. They are most common on the gently undulating surfaces of geologically old surfaces in tropical and subtropical regions where they occupy approximately 11.8 million km^2. Oxisol profiles are distinctive because of the lack of obvious horizons. Their surface horizons are usually somewhat darker in color than the subsoil, but the transition to subsoil features is gradual.

Oxisols consist mainly of quartz, kaolinite, oxides, and organic matter. Both the structure and 'feel' of Oxisols are deceptive. Upon first examination they appear structureless and feel like a loamy particle-size class. While some may be loamy or even coarser, many are extremely clayey, but that clay is aggregated in a strong grade of fine and very fine granular structure. To obtain a true feel of the fine texture, a wet sample must be worked for several minutes in the hand to break down the sandy-textured, granular structure. The strong granular structure apparently causes most Oxisols to have a much more rapid permeability than would be predicted by the particle-size distribution class. Although compaction and reduction in permeability can be caused by cultivation, they are extremely resistant to compaction and so free drainage can take place soon after rain without puddling.

Oxisols are present in every soil-moisture regime from aridic to perudic and aquic. Natural vegetation ranges from tropical rainforests to savannas. Although many Oxisols are extremely infertile, there are some that have small but adequate supplies of nutrients and are immediately productive when cultivated. The reserves of plant nutrients even in the most fertile Oxisols are not great, and to sustain yields, fertilizers and lime are needed after only a few years of cultivation. In most of the Oxisols, fertilizers are needed for the first crop unless enough fertility for one or two crops is available from the ash derived from the burning of natural vegetation. Phosphorus is generally the most restrictive plant nutrient, mainly because of the tendency for the sesquioxide-rich clays to fix large amounts of fertilizer phosphorus. However, once this capacity to fix phosphorus is satisfied by initial applications, phosphorus fixation is no longer a problem.

Road-building and other engineering practices are relatively easy on most Oxisols because of the physical stability of the material. Soil organic carbon is generally much higher than indicated by the color, but, unlike most other soils, much of the carbon is inert and does not contribute to the nutrient-holding capacity or to the physical properties.

The most extensive areas of Oxisols are on the interior plateaus of South America, the lower portion of the Amazon basin, significant portions of the Central African basin, and important areas in Asia, northern Australia, and several tropical islands of the Pacific.

The suborders of the Oxisols are based on the soil moisture regimes:

1. Aquox have an aquic SMR and so are the very wet Oxisols. They occur in depressions associated with the better-drained upland Oxisols;
2. Torrox have an aridic SMR. Such soils are reported in the literature but no contiguous areas have been mapped;
3. Ustox have an ustic SMR. They are the second most extensive kind of Oxisols and occupy large areas in the Brazilian Shield;
4. Perox have a perudic SMR. They represent the most typical Oxisols of the very wet zones of Amazon, Central Zaire, and South-East Asia;
5. Udox have an udic SMR. They are the most extensive of the Oxisols, with large areas in the Amazon area, Central Africa, Borneo, and some of the Pacific Islands.

Vertisols

Vertisols are clayey soils, which have deep, wide cracks on some occasions during the year and slickensides within 100 cm of the soil surface. They shrink when dry and swell when moistened. Vertisols make up a relatively homogenous order of soils because of the amount and kind of clay that is common to them.

In many countries where Vertisols are common, they are known by their local names. For example, Gilgai soils (Australia), Adobe (Philippines), Sha Chiang (China), Black Cotton Soils (India), Smolnitza (Bulgaria), Tirs (Morocco), Makande (Malawi), Vleigrond (South Africa), and Sonsosuite (Nicaragua).

Vertisols generally have gentle slopes, although a few slope strongly. They develop commonly in large pedons and polypedons. The natural vegetation is a function of the soil climate. Most Vertisols are well suited for mechanized farming if there is plenty of rainfall or irrigation water and if suitable management practices are followed. Large areas of Vertisols in the world, however, are not farmed, because their cultivation would require too much energy, especially where traditional, low-input methods are used. This is one of the basic limitations of using Vertisols. Irrigation also presents special problems due to their low saturated hydraulic conductivity. Bypass flow in open cracks is the common situation. Because of their low permeability, irrigation of these soils may result in waterlogging and a buildup of salinity unless adequate artificial drainage is provided. A drainage system designed for Alfisols or Ultisols may be totally inadequate for Vertisols.

Six suborders of Vertisols are recognized based on the SMR or STR:

1. Aquerts: wet Vertisols with an aquic SMR, important locally;
2. Cryerts: cold Vertisols with a cryic or pergelic STR; little information is available;
3. Torrerts: Vertisols with an aridic SMR, present in areas where the SMR is transitional between aridic and ustic, although in most years it is aridic. Large areas are found in Sudan, the Near East, and Central Asia;
4. Xererts: Vertisols with a xeric SMR; the typical reddish-brown Vertisols of the Mediterranean areas, found in Jordan, Turkey, and Tunisia;
5. Usterts: Vertisols with an ustic SMR, geographically the most widespread, occupying approximately 1.8 million km^2; the dominant Vertisols in Africa, India, and Australia;
6. Uderts: Vertisols with an udic SMR, large areas being found in Bengal, some of the Caribbean Islands, Eastern Europe, and Argentina.

Aridisols

Aridisols, as their name implies, are soils that do not have water available to mesophytic plants for long

periods. During most of the time when the soil is warm enough for plants to grow, soil water is held at potentials less than permanent wilting point or if it is salty, or both. There is no period of 90 consecutive days when moisture is continuously available for plant growth.

The concept of Aridisols is based on the low availability of soil moisture for sustained plant performance. In areas bordering deserts, the absolute precipitation may be high but due to runoff or a very low storage capacity of the soil, or both, the actual soil-moisture regime is aridic. In these areas, tree vegetation may exist. Deep-rooted acacias are frequently the dominant vegetation but, if the trees are removed, the soil cannot support general farm crops. In general there is a 70% probability (7 of 10 years) that there will be a crop failure.

Many Aridisols, due to an extreme imbalance between evapotranspiration and precipitation, are similar to incipient evaporites. The dominant process is one of accumulation and concentration of salts. The high salt concentration is an adverse attribute in these soils and is the second most important constraint to the use of the soil. Many soluble salts may be eliminated or changed in concentration through irrigation. In Aridisols, however, the availability of good-quality irrigation water is a fundamental problem; secondly, together with irrigation, a mechanism for evacuation of salts must be provided or a rapid buildup of salinity and/or alkalinity will occur. Thirdly, irrigation and drainage systems must be well maintained to prevent the soils from reverting to their original state.

The classification of Aridisols includes these constraints or performance-restrictive qualities, at a high categoric level. Some Aridisols are also situated on geologic evaporites. It is often difficult to enter these substratum conditions into a classification system, but care must be taken to evaluate these deep-seated salt accumulations, particularly in irrigation projects. Some Aridisols also present inherited features, which may be attributed to earlier wetter or drier paleoclimatic conditions. These attributes, and specifically an argillic horizon, are also considered, as they are important in the use and management of soils.

The suborders reflect the results of dominant soil-forming processes. Unlike many other soils, the redistribution of soluble materials and their accumulation in some layers in the soil is a dominant process in Aridisols. The products of this process not only give special attributes that distinguish the soils, but also present constraints to the use of the soil. Four of the six suborders are defined on the composition and accumulation of the soluble fraction. Weathering and clay translocation also take place in Aridisols, although the expression of the products is not as vivid. The fourth and sixth suborders reflect these processes. The six suborders are:

1. Salids: characterized by accumulation of salts more soluble than gypsum; the typical soils of the playas or desert depressions, or closed basins;
2. Durids: characterized by accumulations of silica, but infrequently found; associated with soils formed from volcanic materials. They have been reported in the western USA but not in other parts of the world;
3. Gypsids: characterized by an accumulation of gypsum; extensive in the Near East, especially in Syria, Iraq, Saudi Arabia, and Iran. They have a total area of approximately 1.1 million km^2;
4. Argids: characterized by an accumulation of clay by translocation, the Argids are present in areas adjoining soils with an ustic SMR. They have not been mapped in large areas of North Africa or the Near East and are currently reported only in the USA. Correct classification of Argids is a problem;
5. Calcids: characterized by an accumulation of carbonates, the soils have a calcic, petrocalcic, or a hypercalcic horizon. There are extensive areas of these soils in the major deserts of the world, the total area exceeding 10.2 million km^2;
6. Cambids: characterized by a transformation of material, these soils are the most extensive of the Aridisols and occupy approximately 13.3 million km^2.
7. A special suborder, cryids, is provided for those aridisols with low soil temperature.

Ultisols

Ultisols are similar to Alfisols in having a subhorizon of clay accumulation but have few bases, especially at depth. Most Ultisols are acid, although some may have a high pH in the surface horizons owing to aerosolic additions of carbonate dust. The ideal Ultisol has a subsurface horizon of clay enrichment due to clay translocation from the surface horizons. However, in areas bordering the deserts, wind-blown sand may bury a former Oxisol, such as in western Zambia and Zimbabwe or in Mali and Niger. These soils have highly weathered subsoil with very low clay activity but, owing to the wind-blown material on the surface, show an increase in clay content with depth. There is little evidence of clay translocation in these soils. Similar situations prevail in the soils of old geomorphic surfaces where the subsoil is heavier-textured and with low clay activity but with little evidence of clay translocation. If the surface horizons have more than 40% clay, for practical purposes, these soils that change in texture with depth are considered as Ultisols. If there is less than 40% clay, they are classified as Oxisols.

The subsurface horizon of clay accumulation is an important feature in the semiarid environments. In general, the loamy soils have low water-holding capacity and so any horizon with more clay enhances the water-holding capacity. Moisture management is a most important feature of the semiarid Ultisols and even in some Ultisols in the humid areas. The additional acid nature of the soils exaggerates the moisture stress in them. Deep liming is essential to enable a proliferation of roots so that a larger volume of soil is exploited for moisture and roots.

The suborders of the Ultisols are based on the SMRs except for the Humults, which are characterized by an accumulation of organic matter:

1. Aquults are wet Ultisols, with an aquic SMR;
2. Humults have accumulations of organic matter and usually occur in areas with an udic SMR and cool temperatures;
3. Udults have an udic SMR;
4. Ustults have an ustic SMR;
5. Xerults have a xeric SMR.

Mollisols

Generally in Soil Taxonomy, it is the presence or absence of subsurface horizons and their characteristics that are used to separate the orders. In Mollisols, however, it is the presence of a thick, dark, humus-rich surface horizon (mollic epipedon) that is the key to placement. In the development of Soil Taxonomy, this surface horizon is the only common characteristic that can be found to tie together the grassland soils of North America, Europe, Asia, and South America. It is an important separation, because these soils are most easily cultivated, generally without irrigation. Thus most Mollisols have had grass vegetation at some time, and melanization – the process of darkening of the soil by organic matter additions – is probably the most important process in the formation of a Mollisol. It is the addition, decomposition, and accumulation of relatively large amounts of organic matter in the soil profile, with the presence of calcium, that forms the central concept of Mollisols. Mollisols have a variety of subsurface horizons and/or diagnostic characteristics, or horizons may be entirely absent.

To a large extent, Mollisols are the breadbasket of the world – the prairies in the USA, the steppes of Russia, and the pampas of Argentina. Most Mollisols are cultivated; in fact there are only limited areas in the world where they have not been cultivated. Mollisols may initially be farmed with no additions of fertilizers. However, to sustain the high yields of corn, soybeans, sorghum, and small grains of today, fertilizers must be used. Soil temperature and moisture are principally used to separate all but two (Albolls and Rendolls) of the seven suborders of Mollisols:

1. Albolls have a bleached subsurface horizon called the albic horizon and are usually wet;
2. Aquolls are wet Mollisols and may have a histic epipedon;
3. Rendolls are shallow and stony soils formed on limestone and have an udic SMR;
4. Xerolls have a xeric SMR;
5. Cryolls have a frigid, cryic, or pergelic STR;
6. Ustolls have an ustic or an aridic SMR;
7. Udolls have an udic SMR.

Alfisols

Most Alfisols were or are forested, with moderate to high base saturation; most formed under deciduous forest. Typically they have a light-colored surface layer over a horizon of silicate clay accumulation (argillic). The cooler Alfisols tend to form a belt between the grassland Mollisols and the Spodosols of the more humid climates. Where temperatures are warmer, they form a belt between the Aridisols and the older Ultisols and Oxisols. Along with Mollisols, Alfisols account for a major portion of soils that are used to grow crops in the world. They are found generally in climates favorable to crop production; in warm moist climates, they are used to grow many crops. They generally contain adequate plant nutrients, but like Mollisols they must be fertilized to obtain high yields. Crop production may become more difficult when these soils are eroded down to the argillic horizon. The higher clay content of the argillic horizon may impede root, water, and air movement.

All five suborders of Alfisols are defined by the SMR:

1. Aqualfs are wet Alfisols;
2. Cryalfs have a cryic STR, or, if the SMR is not xeric, have a frigid STR;
3. Ustalfs have an ustic SMR;
4. Xeralfs have a xeric SMR;
5. Udalfs have an udic SMR.

Inceptisols

The Latin word ‘inceptum’ means beginning and the central concept of Inceptisols is that of soils in the early stages of soil formation. The initial stage of soil formation is exemplified by several attributes, which are the result of the presence or absence of certain processes.

Soil formation on rocks consists of weathering of the rock which is essentially a geochemical process

accompanied by soil-forming processes acting on the weathered products. In cool, humid climates, the soil-forming process may be the accumulation of organic matter to give rise to a mollic or umbric epipedon. In warmer climates, cambic horizon formation takes place; this is expressed by clay formation or release of iron to form a 'color B' horizon. On steep slopes, even if moisture and temperature conditions are conducive to form an argillic horizon, the slow soil loss through erosion retards any of the other horizons from being expressed. Such soils may have just an ochric epipedon and a weak cambic horizon.

Inceptisols are more prevalent on sediments, and a major morphological change is the removal of the original stratification, which takes place through bio- and pedoturbation. Structure and color development are common marks of cambic horizons. If a permanent or a fluctuating water table is present, oxidation–reduction processes leave their marks and are frequently sufficient evidence for a cambic horizon. In extremely wet environments (perudic soil moisture regime) and even on steep slopes, or in soils with a fluctuating water table, weathering of primary minerals may release sufficient iron, which percolates through the soil and accumulates in a subsurface layer to form a thin iron pan or placic horizon. The placic horizon is sufficient evidence to consider the soils Inceptisols.

Some coastal sediments contain pyrite which, when exposed to oxidizing conditions, oxidizes to jarosite, releasing sulfuric acid. The presence of the straw-yellow jarosite aggregates and extreme acidic conditions of the soil is sufficient to place the soil in the order of Inceptisols.

The Inceptisols consequently comprise a wide array of soils, which range not only in properties but also in behavior. The lower categories in the Inceptisols attempt to cluster more homogeneous soils.

Five suborders of Inceptisols are recognized:

1. Aquepts are wet Inceptisols;
2. Plaggepts have a man-made surface horizon thicker than 50 cm called the plaggen epipedon (these soils are not extensive enough to be shown on the map);
3. Ustepts have an ustic SMR;
4. Xerepts have a xeric SMR;
5. Udepts have an udic SMR.

Entisols

The Entisols show little or no evidence of soil formation. They are most extensive on recent alluvial plains and valleys or on steep slopes where erosion is rapid. The rate of soil formation is reduced for several reasons. Generally time has not elapsed since deposition of the material for soil-forming processes to act. In some of these soils, peraquic conditions prevail where the soil is saturated with water during the whole year. The soil is permanently reduced, preventing cambic horizon formation. On steep slopes, rapid erosion results in shallow soils where weathered parent materials rest on hard rock. Rates of soil loss are much greater than soil formation and so cambic horizons do not form. Entisols may also occur on older deposits where, for example, the material is formed from quartzitic sands. There are no primary minerals in the deposit to weather and form clay or liberate iron. In fluvial deposits, Entisols show marked stratification. This is frequently evidence for recent deposits.

Five suborders are recognized in the Entisols:

1. Aquents are wet Entisols;
2. Arents have been subject to deep plowing;
3. Psamments are sandy Entisols;
4. Fluvents are recent alluvial soils showing stratification;
5. Orthents are shallow soils on steep slopes.

In many countries Entisols, on flat alluvial plains or riverine terraces, are widely used for annual crops. Terrain conditions are frequently suitable for low-input agriculture. The major civilizations of the world developed on Entisols and Inceptisols of the larger river terraces owing to good farming conditions and easy navigation.

Summary

A wide diversity of soils exists and each has its own potential and limitations. The performance-related attributes result from the properties and the prevailing environmental conditions. There are large land areas where it is too cold, or too dry, or the soils are on steep slopes and the potential for human use is limited. For most agricultural uses, only about 9% of the global land surface is relatively constraint-free. Understanding the soil and its relation to the rest of the environment is important for its sustainable use. Detailed soil surveys provide such information, but most countries of the world lack access to it. Less information is available on the state of soil resources. Assessment and monitoring of land conditions are essential to the judicious use of soil.

Introduction

Many soil chemical reactions occur at the interface between solid particles and the aqueous phase. Fundamental to the reactivity of this interface is the surface charge on soil particles, which affects a range of chemical phenomena including adsorption of charged solutes, the nature and extent of the electrical double layer on soil particles, kinetics of colloid aggregation, and mineral dissolution rates. Cation and anion exchange capacities, which influence the retention of plant-available nutrients, are directly affected by the nature of soil surface charge and its response to changes in solution of chemical parameters such as pH, ionic strength, and ion composition.

Charge properties have traditionally been used to characterize soils as 'permanent' or 'variable' charge media. These characterizations reflect the relative predominance of one or more soil solid-phase constituents. Whereas the surface chemistry of permanent charge soils is governed by isomorphically substituted mineral particles (i.e., 2:1 layer-type clays such as smectite and vermiculite), variable-charge soils are dominated by amphoteric hydroxylated surfaces (i.e., metal oxides, hydroxides or oxyhydroxides, and organic matter). As a result of the ubiquity of hydroxylated solids in soil environments, all soils comprise some portion of their total surface charge that is conditional upon aqueous chemical conditions.

The law of surface-charge balance states that, irrespective of the source of particle surface charge, it must be balanced by net accumulation of ions in the surrounding diffuse swarm. The balance of surface charge and relationships among components may be used to constrain the application of molecular models to the particle–water interface and to verify internal consistency of adsorption measurements. Particularly useful in this respect are points of zero charge, which define the physicochemical conditions wherein one or several components of surface charge sum to zero.

Components of Surface Charge

Electric charge develops on soil particle surfaces as a result of: (1) structural disorder or isomorphic substitutions among ions of differing valence within soil minerals, and (2) reactions of surface functional groups with ionic species in aqueous solution. These mechanisms of charge development are incorporated into four 'components of surface charge' that together contribute to the *total particle surface-charge density*, σ_P. Surface-charge density is conventionally expressed in coulombs per square meter, consistent with the International System of Units (SI). For complex solids, including soils, charge is likely to be distributed unequally among the many phases present, owing to differences in structural charge, surface site density, and specific surface area. Furthermore, measurement of total surface area alone is nontrivial and method-dependent. For these reasons, soil charge is often measured on a mass basis and expressed as moles of charge per kilogram. Values presented in each of these sets of units differ by the factor F/a_s, where F is the Faraday constant and a_s is specific surface area.

The *net structural surface-charge density*, σ_0, is created by isomorphic substitutions in soil minerals. These substitutions occur in both primary and secondary minerals, but they produce significant surface charge only in the 2:1 layer-type aluminosilicates (e.g., Figure 1). The *net proton surface-charge density*, σ_H, results from the difference between the moles of protons and the moles of hydroxide ions complexed by surface functional groups (Figure 2). The *net inner-sphere complex surface-charge density*, σ_{IS}, results from the net total charge of ions, other than H^+ and OH^-, which are bound into inner-sphere surface coordination. Inner-sphere complexation involves the formation of one or more direct bonds between the adsorbate molecule and adsorbent surface functional group, with no water molecules

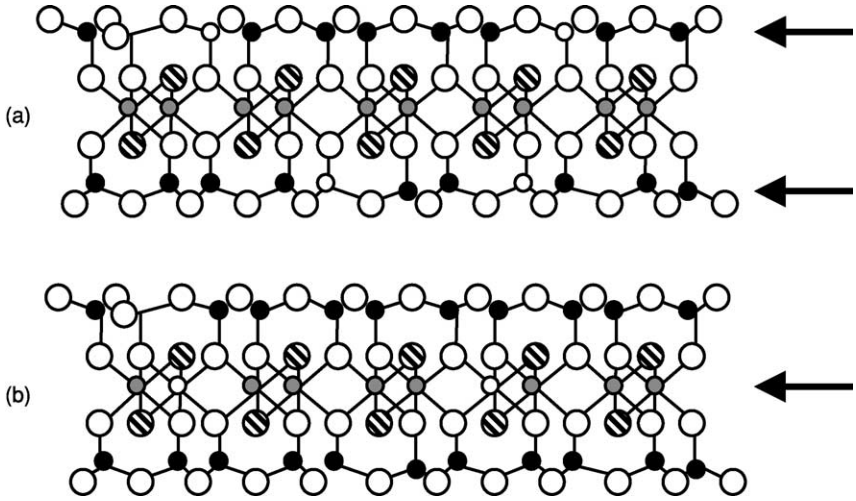

Figure 1 Isomorphic substitution of ions of differing valence gives rise to structural charge density (σ_0) that is independent of solution chemistry. Model structures of vermiculite (a) and smectite (b) show that substitutions (small white spheres) can give rise to charge in the (a) tetrahedral (Al^{3+} for Si^{4+} substitution) or (b) octahedral (e.g., Mg^{2+} for Al^{3+} substitution) sheets of 2:1 layer-type silicates. The location of substitution, particularly in regard to proximity to the surface, affects site reactivity. Large white spheres, O; black spheres, Si; gray spheres, Al; hatched spheres, OH.

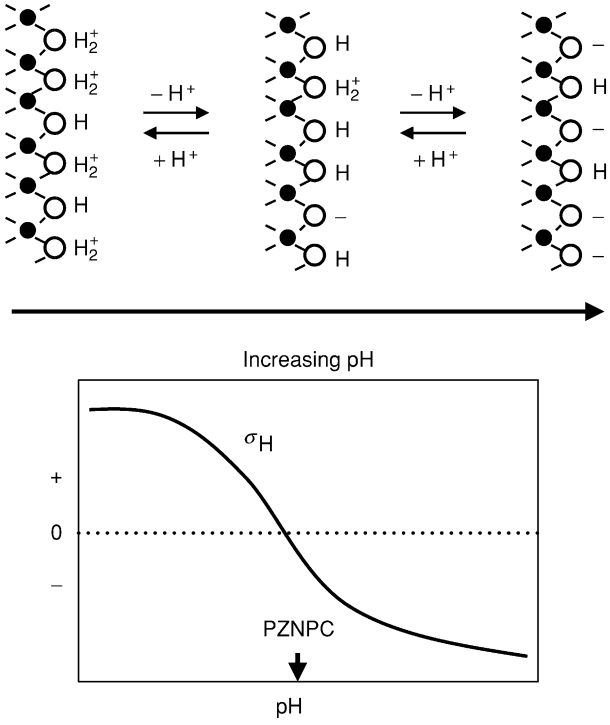

Figure 2 Development of proton surface-charge density (σ_H) derives from the net adsorption of protons on particle surfaces and reflects the Brönsted acid–base chemistry of surface functional groups. PZNPC, point of zero net proton charge.

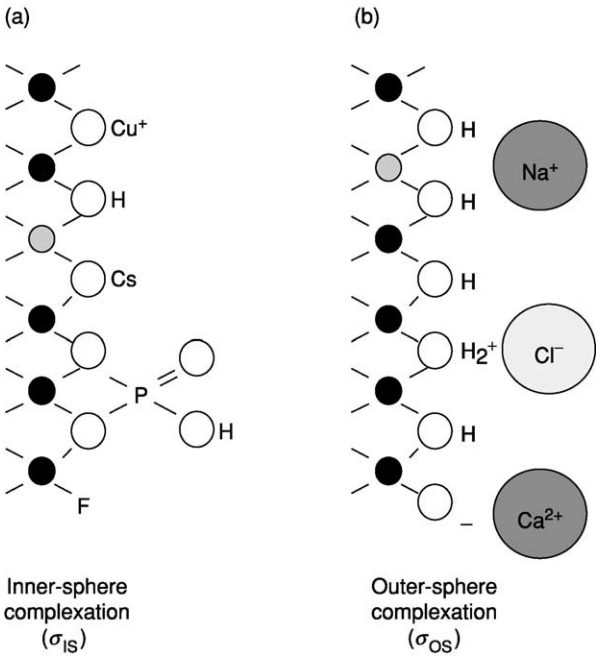

Figure 3 Surface coordination of ions in stable complexes results in the development of (a) inner-sphere complex surface-charge density (σ_{IS}) and (b) outer-sphere complex surface charge density (σ_{OS}), both of which contribute to total particle surface charge. Isomorphic substitutions, are shown schematically as gray spheres.

interposed (Figure 3a). The *net outer-sphere complex surface-charge density*, σ_{OS}, results from the net total charge of ions, other than H^+ and OH^-, which are bound into outer-sphere surface coordination. Outer-sphere complexes involve hydration water interposed between the adsorbate and the adsorbent surface (Figure 3b). The net total particle surface charge is the sum of these four components:

$$\sigma_P = \sigma_0 + \sigma_H + \sigma_{IS} + \sigma_{OS} \quad [1]$$

The right side of eqn [1] indicates contributions to particle surface charge from both permanent (σ_0) and conditional (σ_H, σ_{IS}, σ_{OS}) components; the value of σ_0 is dependent only upon the composition and structure of the solid phase, while the values of the remaining components depend upon the nature of both the solid and the solution phases. The last two terms on the right side of eqn [1] together define adsorbed ions that are immobilized in surface complexes, also known as the 'Stern-layer charge', σ_S.

Surface Charge Balance

Aqueous particle suspensions are electrically neutral. Therefore, if σ_P is nonzero, it must be balanced by a diffuse swarm of ion charge equal in magnitude but opposite in sign to σ_P. These ions differ from those bound into the Stern layer because their much greater mobility relative to the adsorbent surface is analogous to diffusive motions of free ions in aqueous solution. The net charge of such ions defines the *diffuse layer surface-charge density*, σ_d. The charge balance equation for soil particles may then be written:

$$\sigma_P = -\sigma_d \qquad [2]$$

and substituting the left side of eqn [1] into eqn [2] gives:

$$\sigma_0 + \sigma_H + \sigma_{IS} + \sigma_{OS} + \sigma_d = 0 \qquad [3]$$

The terms σ_{IS}, σ_{OS}, and σ_d correspond to different molecular mechanisms of ion adsorption that are difficult to distinguish on the basis of quantitative macroscopic measurements. These three terms in eqn [3] together give the *adsorbed ion charge density*, Δq, which is the net charge of ions, other than H^+ and OH^-, adsorbed at the soil–water interface (**Figure 4**):

$$\Delta q = \sigma_{IS} + \sigma_{OS} + \sigma_d = q_+ - q_- \qquad [4]$$

The value of Δq in eqn [4] can be determined by measuring the difference between *surface excess* of cation charge (q_+ corresponding to all cations other than H^+) and *surface excess* of anion charge (q_- corresponding to all anions other than OH^-). The charge balance may then be rewritten as:

$$\sigma_0 + \sigma_H + \Delta_q = 0 \qquad [5]$$

Points of Zero Charge

Points of zero charge are defined most commonly as pH values for which one or more of the surface-charge components is equal to zero at a given temperature, pressure, and aqueous solution composition. The

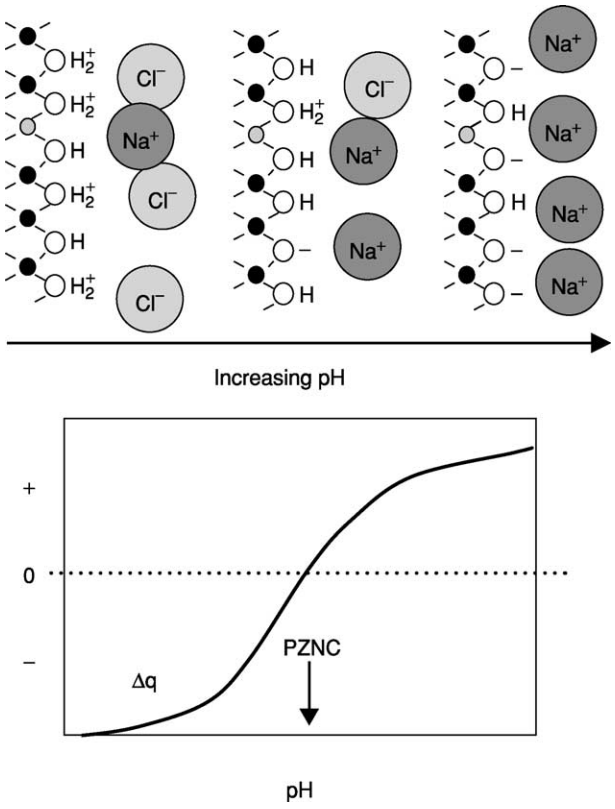

Figure 4 The net charge deriving from adsorption of ions (other than H^+ and OH^-) in surface complexes ($\sigma_{IS} + \sigma_{OS}$) plus the diffuse ion swarm (σ_d) constitute the net adsorbed ion charge density (Δq). PZNC, point of zero net charge.

emphasis on pH derives from the wide and dynamic range of proton concentrations in soil solutions, and the fact that complexation of H^+ and OH^- at soil particle surfaces strongly affects the adsorption of other cations and anions (e.g., see **Figure 4** and eqn [5]). Although pH will be used to illustrate points of zero charge here, it is important to note that one can also define them in terms of aqueous concentrations of other surface complexing ions, such as $H_2PO_4^-$ or Pb^{2+} (**Figure 3a**), which can affect the value of σ_P directly. Three principal points of zero charge are named conventionally as: (1) the point of zero charge (PZC), (2) the point of zero net proton charge (PZNPC), and (3) the point of zero net charge (PZNC).

Point of Zero Charge

The PZC ($\sigma_P = 0$) is defined as the pH value at which the net total particle surface charge, σ_P, is equal to zero. According to eqn [2], σ_d also vanishes at the PZC, so that all adsorbed ions (other than H^+ and OH^-) must be bound into surface complexes. Traditionally, the PZC has been assessed by measuring

the pH value at which soil particles exhibit zero electrophoretic mobility (i.e., the isoelectric point or IEP), assuming that a negligible portion of the diffuse ion swarm is advected during the electrophoresis measurement. However, this assumption has never been verified. Furthermore, model calculations suggest that surface charge heterogeneity or patchiness can also result in a nonzero electrophoretic mobility for a particle whose overall charge is equal to zero. This raises additional questions regarding the validity of equating PZC and IEP values. Values of PZC for soil minerals derived dominantly from electrophoresis measurements are presented in Table 1.

According to the DLVO (Derjuagin–Landau–Verwey–Overbeek) theory, a suspension of colloidal particles should undergo rapid flocculation when net charge in the diffuse ion swarm (σ_d) is reduced to zero. Therefore, the PZC may also be determined by measuring the pH where a colloidal suspension of particles undergoes rapid coagulation (flocculation). However, the influence of surface-charge heterogeneity probably affects collision efficiency as well. New

Table 1 Points of zero charge for selected soil mineral constituents

Solid	*Chemical formula*	*PZNPC*	*PZNC*	*PZC*
Albite	$NaAlSi_3O_8$	3.9	–	–

methods, involving the use of scanning force microscopy, appear promising in regard to elucidating patchwise heterogeneity of surface charge and providing direct force measurements of the PZC (e.g., as used to obtain the value of PZC for quartz in Table 1).

Point of Zero Net Proton Charge

The pH value at which the proton surface-charge density, σ_H, is zero defines the PZNPC. Proton surface-charge density is given by:

$$\sigma_H = q_H - q_{OH} \quad [6]$$

where q_H and q_{OH} are the surface excess (e.g., in moles of charge per kilogram) of H^+ and OH^-, respectively. Therefore, at the PZNPC the moles of surface-adsorbed H^+ and OH^- are balanced. Proton and hydroxide adsorption reactions can be represented by the mass action expressions:

$$SOH(s) + H^+(aq) = SOH_2^+(s) \quad [7a]$$

$$SOH(s) + OH^-(aq) = SO^-(s) + H_2O(l) \quad [7b]$$

where SOH is a neutral surface hydroxyl group on a soil particle, and *s*, *aq*, and *l* represent the solid, aqueous, and liquid phases, respectively. If proton adsorption–desorption is assumed to occur dominantly at hydroxylated sites (e.g., as in the case of pure metal oxides), then the PZNPC defines the condition where the density or concentration of protonated sites is equal to that of proton-dissociated sites [i.e., $(SOH_2^+) = (SO^-)$]. Thus, both protonated and proton-dissociated sites can coexist at the PZNPC.

In 'indifferent' electrolyte solutions (i.e., those comprising monovalent cations and anions that do not form stable complexes at particle surfaces), proton adsorption behavior, as depicted in Figure 2, is a function of the Brönsted acidity of surface functional groups. Soil particles exhibit a wide range in surface acidity, as indicated by the PZNPC values shown in Table 1. Low PZNPC values are typical of more strongly acidic soil constituents such as silica, quartz, Mn oxides, and natural organic matter, whereas higher values are observed for (hydr)oxides of Fe and Al. Table 1 shows PZNPC values of soil minerals suspended in indifferent electrolyte solutions. However, the presence of cations (anions) that form inner- or outer-sphere surface complexes (Figure 3a) will tend to decrease (increase) the PZNPC because of adsorptive competition with H^+ (OH^-).

Proton- and hydroxide-promoted dissolution of soil minerals is found to increase at pH values both below and above the PZNPC. Correlations are observed between dissolution rate constants and the absolute magnitude of σ_H, suggesting that metal–oxygen bonds at the particle surface are weakened as reactions in eqns [7a] and [7b] proceed to the right.

Point of Zero Net Charge

The first two terms in eqn [5] are often combined to provide a measure of *intrinsic surface-charge density*, σ_{in}, which derives from the crystal and surface structure of the adsorbent:

$$\sigma_{in} = \sigma_0 + \sigma_H \quad [8]$$

The PZNC is the pH value at which σ_{in} is equal to zero. The intrinsic surface charge is balanced by the adsorption of ions. Since σ_{in} results from both proton adsorption–desorption reactions (pH-dependent) and isomorphic substitutions, it comprises conditional and permanent components (Figure 4). Since $\sigma_{in} = -\Delta q$, the PZNC may be determined: (1) by measuring the pH where surface excess values of cation and anion charge are equal (i.e., $\Delta q = 0$), or (2) by measuring the pH where $\sigma_0 = -\sigma_H$.

Charge balance dictates that, as σ_H decreases with increasing pH (affected by mass action as indicated in eqn [7]), ion adsorption–desorption reactions must balance the change in intrinsic charge density. The dependence of σ_H on pH is shown schematically in Figure 2, and corresponding effects on Δq are illustrated in Figure 4. For a soil adsorbent that is devoid of structural charge (i.e., $\sigma_0 \approx 0$), such as a highly weathered Oxisol that contains a negligible quantity of 2:1 layer-type silicates, $\Delta q = -\sigma_H$, and the PZNPC equals the PZNC (Figure 5, top). This is also the case for pure oxides and hydroxides that are free of structural defects. The presence of negative structural charge ($\sigma_0 < 0$), as occurs because of isomorphic substitutions in many temperate-zone soils, results in PZNC being less than PZNPC, and the value of Δq (or σ_H) at the PZNPC (PZNC) is equal to $-\sigma_0$ (Figure 5, middle). Whereas positive structural charge ($\sigma_0 > 0$) is rare in soils, it is detectable from PZNPC being less than PZNC, and its magnitude is given by the value of Δq (or σ_H) at the PZNPC (PZNC) (Figure 5, bottom).

In addition to the effects of σ_0, the nature of variable-charge behavior, such as that depicted in Figure 5, is highly dependent on the Brönsted acidity of the soil particles. For example, the magnitude and pH range of greatest local slope (i.e., $\delta\sigma_H/\delta$pH or $\delta\Delta q/\delta$pH) is dependent on the identity and quantity of surface sites undergoing proton adsorption–desorption reactions. Whereas oxides and hydroxides of Fe and Al are weakly acidic, with PZNPC values near neutrality, more strongly acidic groups such as those residing on natural organic matter functional

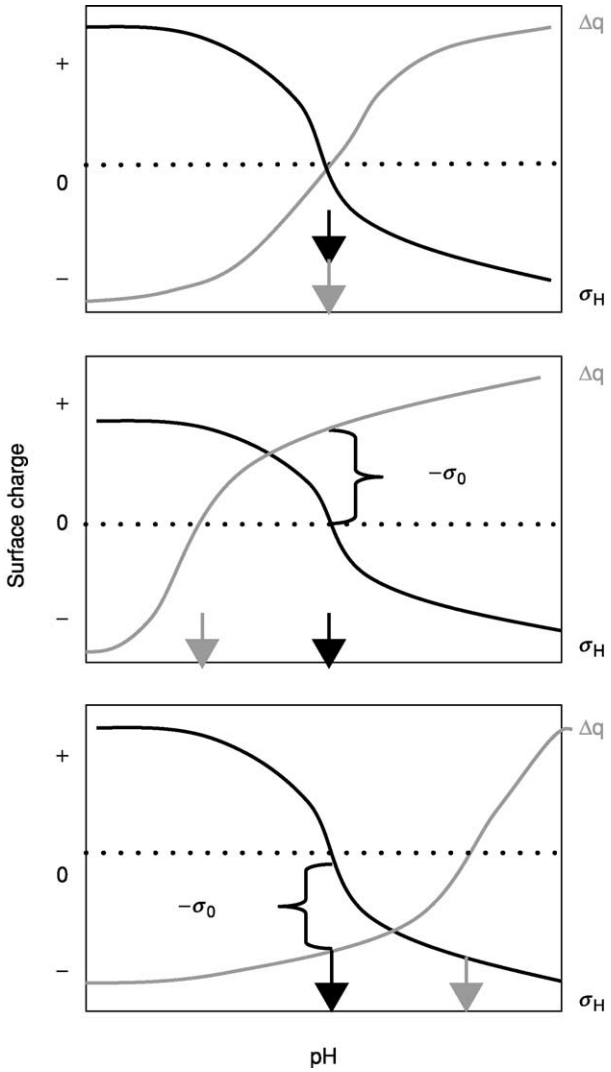

Figure 5 The inverse relation between σ_H and Δq is depicted schematically for (a) $\sigma_0 = 0$ (PZNC = PZNPC), (b) $\sigma_0 < 0$ (PZNC < PZNPC), and (c) $\sigma_0 > 0$ (PZNC > PZNPC). The PZNC is indicated by gray arrows and the PZNPC is indicated by black arrows. PZNC, point of zero net charge; PZNPC, point of zero net proton charge.

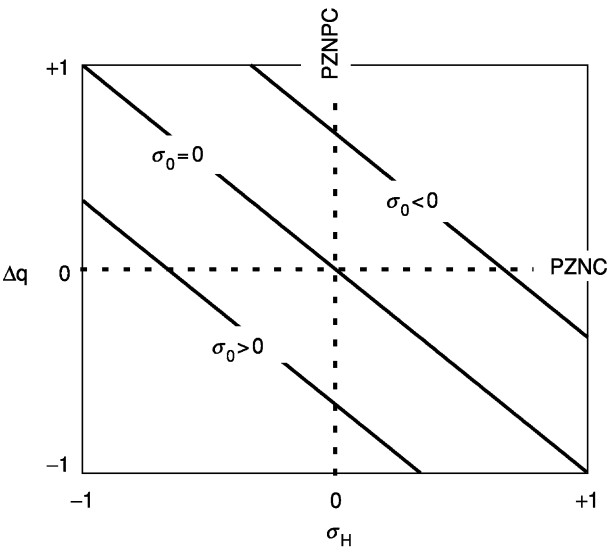

Figure 6 Surface-charge balance dictates that a plot of Δq versus σ_H must be linear, with a slope equal to -1 and x and y intercepts equal to $-\sigma_0$. PZNPC, point of zero net proton charge; PZNC, point of zero net charge.

groups (e.g., carboxylic acids), silica or quartz surfaces, and Mn oxide surfaces all tend to decrease PZNPC values for whole soils.

The surface-charge balance of eqn [5] is summarized in Figure 6; a plot of Δq versus σ_H should be linear with a slope equal to -1, and x and y intercepts equal to $-\sigma_0$. The x and y scales in Figure 6 are arbitrary and actual values depend on surface chemistry of the adsorbent and the units selected for plotting surface-charge data (e.g., moles of charge per kilogram or coulombs per square meter). Whereas curves such as those depicted in Figure 5 (with pH as independent variable) are strongly affected by ionic strength and electrolyte composition for a given adsorbent, the relation depicted in Figure 6 must be reproducible for a given soil, irrespective of changes in solution chemistry.

List of Technical Nomenclature

Adsorbate	Matter accumulating at the interface between adsorbent and the aqueous phase
Adsorbed ion charge density (Δq)	The net charge density created by adsorption of ions, other than H^+ and OH^-, into inner-sphere complexes, outer-sphere complexes, and the diffuse ion swarm
Adsorbent	The solid surface on which matter accumulates
Adsorption	The net accumulation of matter at the adsorbent surface
Diffuse layer surface-charge density (σ_d)	The net surface charge density created by adsorbed ions in the diffuse layer
Inner-sphere complex surface-charge density (σ_{IS})	The net charge density created by ions adsorbed via direct coordination to surface functional groups (i.e., with no water molecules interposed between adsorbate and surface)
Intrinsic surface-charge density (σ_{in})	The sum of structural and proton surface charge densities

Outer-sphere complex surface-charge density (σ_{OS})	The net charge density created by adsorption of hydrated ions that form stable complexes with adsorbent surface functional groups
Point of zero charge	The pH value at which particle surface charge is equal to zero
Point of zero net charge	The pH value at which adsorbed ion charge density is equal to zero
Point of zero net proton charge	The pH value at which proton surface charge density is equal to zero
Proton surface-charge density (σ_H)	Surface-charge density created by the formation of adsorption complexes involving proton or hydroxide ions as adsorbate; the difference between surface excess of protons and hydroxide ions ($\sigma_H = q_H - q_{OH}$)
Structural surface-charge density (σ_0)	Surface-charge density created by isomorphic substitutions among ions of differing valence in the crystal structure of an adsorbent

ZONE TILLAGE

J L Hatfield and A T Jeffries, National Soil Tilth Laboratory, Ames, IA, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Tillage is the act of disturbing the soil through some type of mechanical means. It has been practiced since the development of crude instruments such as a pointed stick to create a hole into which a seed was dropped. The largest advance in the progress of tillage implements has been the invention of the moldboard plow, which inverts the soil and allows rapid cultivation. Since that invention, there have been continual advances in the development of tillage equipment for the purposes of: creating a seed bed that is favorable for rapid germination; removing weeds; destroying crusts that impede the emergence of seedlings, or prevent water or gases from moving into or out of the soil; or removing compacted layers from the upper soil profile. There is a large array of tillage tools available to producers that reshape the soil into a more compliant medium for producing plants.

Tillage can be considered as a time-and-space operation within a given field. The time component is introduced because different tillage implements are used throughout a production sequence to achieve different goals in manipulating the soil profile. The space component is introduced because different tillage implements affect the soil in a variety of ways across a field. An example of this is that the preplant tillage operation often disturbs the entire soil surface, while cultivation only disturbs the area between the rows of plants. An entire production sequence can be considered as a series of tillage operations that changes the soil surface in different ways.

Zone tillage is a unique subset of tillage operations in which only a portion of the soil surface is disturbed. In a very broad sense, zone tillage can be considered to represent cropping in which strips of the field are planted to different crops and managed differently or a strip is left in a fallow area to conserve precipitation for the subsequent crop. In the Great Plains of the USA and the Prairie provinces of Canada, the practice of strip farming with cultivated and fallow strips could be considered as a large-scale form of zone tillage. In this case, the zone is created by the temporal distribution of tillage operations in which strips of the field are cultivated one year and the next year the fallow strip is cultivated.

Zone tillage is more often referred to as tilling only a narrow zone of the seedbed and is practiced on row crops more than on small-grain or forage crops. Zone tillage can take on many different forms, uses an array of equipment, and is often the primary tillage operation following crop harvest. Zone-tillage units provide the following attributes in soil disturbance: (1) arrangement of shanks or rippers is placed in combination with coulters and disks to till only a select portion of the soil in a regular pattern; (2) crop

residue is removed or incorporated in the tilled area, leaving the soil surface with little residue in this zone; and (3) fertilizers may or may not be incorporated into the tilled area. These operations occur either to till over the row of the previous crop or between the rows. The depth of tilling depends upon the desired effect either to remove a compaction layer beneath the soil surface or to place fertilizer into the soil. In either case, the disturbed area serves as the planting zone for the subsequent crop.

Zone tillage is shown in Figure 1, in which the disturbed area is relatively small compared with the undisturbed area and the volume of the tilled area is distributed more vertically than horizontally. Zone tillage is often referred to as vertical rather than horizontal tillage, since the goal is to till more deeply into the soil profile than to till extensively over the soil surface. There are advantages to this type of system: the primary reasons are protection of the soil surface from erosion due to water or wind coupled with placement of fertilizer into an area in which the plant roots can easily extend.

In zone-tilled systems, crops tend to proliferate their roots into the disturbed area first and then through the side walls of the tilled area. One can image that the root system in Figure 1 is confined to the tilled area, and early in the growing season this area supplies the nutrients and water required for proper plant growth. Root systems in zone-tilled systems have more of their root mass concentrated in the tilled area. They also increase their rooting depth earlier in the growing season, which leads to greater support for the plant and less lodging or breakage in high-wind conditions. Altering the root system also has an effect on the water and nutrient uptake patterns. Water and nutrients are removed from deeper in the soil profile, because more roots are concentrated there, as depicted in Figure 2. Nutrient placement in zone tillage becomes a critical management factor in crop production.

Changes in soil with zone tillage are isolated to the tilled area. Bulk density of the soil is reduced in this area because of the tillage practice and the incorporation of crop residue. In comparison, the area that is not tilled may have an increased bulk density and a surface crust that forms if heavy wheel-traffic is used when the soil is wet. The increased bulk density between the crop rows may reduce both water infiltration and exchange of gases, with a shift to greater exchange rates in the tilled area. In contrast, if zone tillage is practiced in fields that have a slope and the tilled areas are positioned parallel with the slope, then the tilled zone can act as a conduit for water, and erosion rates can be increased in this zone because of the loose nature of the soil surface.

The effects of zone tillage on soil properties have not been extensively documented. Observations suggest that the positive benefits of zone tillage on crops are the increased rooting depth and consequently more-rapid exploration of the soil volume by the plant roots. Increased resistance to lodging and plant breakage occurs because of the greater rooting depth and concentration of root mass below the stem. Higher water and nutrient uptake from the lower portion of the soil profile leads to better crop performance in periods of drought. The soil changes

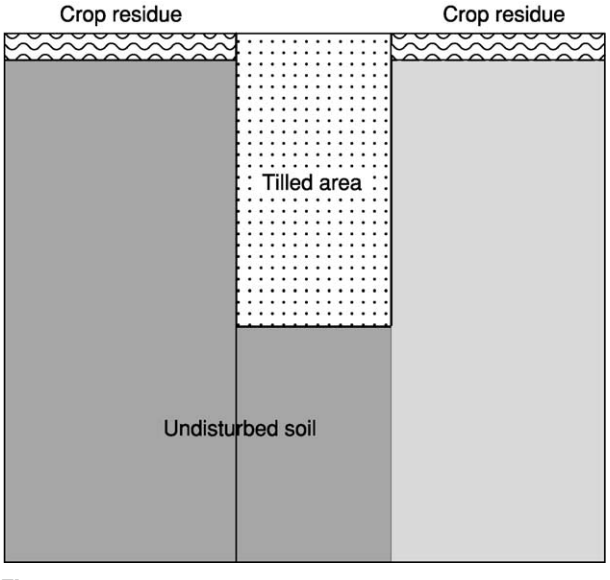

Figure 1 Zone-tilled soil in the central Corn Belt region of the USA.

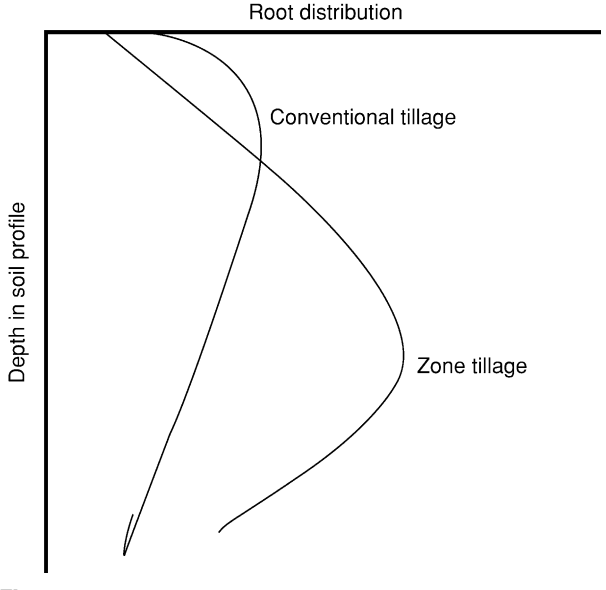

Figure 2 Root distribution patterns as a result of broad conventional tillage compared with zone tillage.

that occur in zone tillage are a decrease in the bulk density in the upper portion of the soil profile and removal of compaction layers from the soil, because the tillage operations are deeper than typical tillage systems. The zone-tillage system creates a more favorable seed zone for planting, and, e.g., in the US Midwest, plants emerge more quickly in zone-tillage systems because of better seed–soil contact, less crusting, and slightly warmer temperatures in the seed zone. Crop emergence is more uniform and early-season plant vigor appears to be enhanced through a combination of soil microclimate and seed-zone conditions.

Zone tillage is a practice that is beginning to be adopted in areas that need protection from soil erosion. Also it is being used where reduced tillage results in maintenance of crop residue on the soil surface. The types of implements include those employed exclusively after harvest in the autumn to incorporate nutrients (P and K) in the seed zone. These implements prepare an area into which the next crop is planted directly the following spring. There are single-operation planters that give a shallow form of zone tillage and only disturb a small portion of the soil surface into which the seed is placed, and nutrients are banded alongside the seed furrow. Emergence of tillage systems that are directed toward soil management and creation of a seed zone that increases crop production efficiency and reduces environmental problems, e.g, erosion or nutrient loss, will continue.
