Early concepts were that exchangeable H^+ was the source of soil acidity. Titration studies showed that acid clays behaved as weakly ionized acids, which led to the conclusion that acid soils contained exchangeable H^+. Soils were assumed to be 100% base-saturated at pH values of 7 and the difference between the CEC at pH 7 and the sum of basic cations was the amount of exchangeable H^+. Later studies revealed that the weakly ionized acid characteristic of clays was due to exchangeable Al and the hydrolysis of Al^{3+} was the source of soil solution H^+. When saturated with H^+ the clays decomposed, releasing Al, which occupied the exchange sites.

Exchangeable acidity is defined as that which is extracted with a neutral unbuffered salt solution such as KCl. Neutral unbuffered salt solutions must be used to avoid changing the soil pH and altering the

Table 1 The exchangeable and nonexchangeable acidity of acid soils

Soil	pH	Organic matter ($g\,kg^{-1}$)	Exchange Al ($cmol\,kg^{-1}$)	Al saturation (%)	Acidity

Gonzalez-Erico E, Kamprath EJ, Naderman GC, and Soares WV (1979) Effect of depth of lime incorporation on the growth of corn on an Oxisol of Central Brazil. *Soil Science Society of America Journal* 43: 1155–1158.

exchangeable acidity. In mineral soils the exchangeable acidity is Al^{3+}. At pH values of 5 and lower, over half of the active exchange sites are countered by Al^{3+} (Table 1). As previously discussed, exchangeable Al is essentially zero in mineral soils at pH 5.6 and the active cation exchange sites are 100% base-saturated.

Nonexchangeable Acidity

Soils also contain H which is not extractable with neutral unbuffered salt solutions, but is titratable. The nonexchangeable H is associated with carboxyl groups of organic matter, hydroxy Al, and hydrated oxides of Fe and Al. The nonexchangeable acidity of the three Ultisols in Table 1 was primarily due to organic matter. However, with the Oxisol, the nonexchangeable acidity was associated with the hydrated oxides of Fe and Al. Once the exchangeable Al is neutralized the acid buffering capacity of the soil is a function of the nonexchangeable acidity. Neutralization of the nonexchangeable acidity has little effect *per se* on plant growth, but is the source of the pH-dependent CEC. With increasing neutralization of the nonexchangeable acidity, there is an increase in soil pH, CEC, and the retention of the basic cations Ca, Mg, and K.

Acid Soil Constraints to Plant Growth

Hydrogen Toxicity

Poor plant growth in acid soils is usually associated with low soil pH, but the direct effects of H^+ are often confounded with changes in solubility of various elements affecting plant growth. Experiments in hydroponics, therefore, are often used to assess the direct effects of H^+. Roots growing in solutions at pH 4.6 or lower have visual symptoms of injury, namely stunted growth, brownish color, and little lateral root development. Increasing solution Ca concentration alleviates root injury due to H^+ (Table 2). At low pH and Ca concentrations root membranes are damaged, leading to loss of organic substrates and absorbed cations. Under soil conditions with pH below 4.6, root injury due to H^+ can be expected along with reduced plant uptake and possible deficiencies of Ca and Mg.

Table 2 Soybean tap and lateral root length after 12 days of exposure to solutions with different pH and Ca concentrations

Solution		Root length	
pH	Ca ($mmol\,l^{-1}$)	Tap (cm per plant)	Lateral (cm per plant)
4.0	0.2	1.1	0.0
	2.0	3.2	1.0
4.6	0.2	10.2	3.4
	2.0	22.2	36.3
5.5	0.2	27.8	40.1
	2.0	44.6	85.6

Data from Sanzonowicz C, Smyth TJ, and Israel DW (1998) Calcium alleviation of hydrogen and aluminum inhibition of soybean root extension from limed soil into acid subsurface solutions. *Journal of Plant Nutrition* 21: 785–804.

Aluminum Toxicity

Aluminum toxicity is a major cause of poor plant growth in acid soils. Current evidence indicates that Al interferes with various root growth processes: disruption of regulatory signals in root cap cells and interference with cell division in root apices, enzyme activities, DNA replication, and P availability at membranes. The immediate and visible evidence of Al toxicity is a reduction in root length which, in turn, limits plant access to soil water and nutrients. Consequently, plants growing in soils with toxic levels of Al are underdeveloped, sensitive to drought stress, and often present symptoms of multiple nutrient deficiencies.

Concentrations of soil solution Al that reduce crop growth are in the micromolar range. As illustrated in

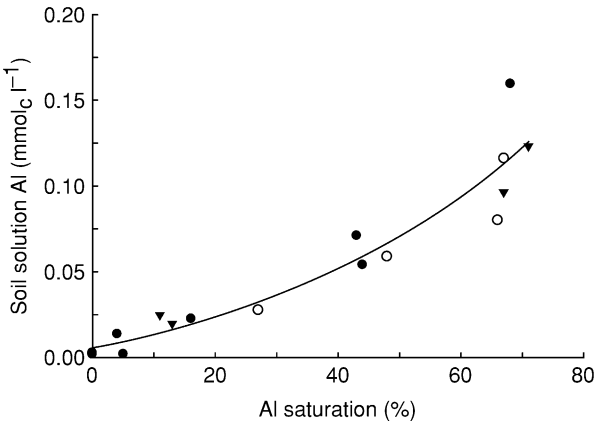

Figure 1 Relations between Al saturation of cation exchange sites and concentration of Al in the soil solution of Oxisols and Ultisols. Filled circles, Haplustox; open circles, Umbraquult; inverted triangles, Paleudult. Figure 2 Effect of Al saturation on relative root length of field-grown corn in Oxisols and Ultisols. Filled circles, Umbraquult; open circles, Paleudult; inverted triangles, Haplustox. Data source: Gonzalez-Erico E, Kamprath EJ, Naderman GC, and Soares WV (1979) Effect of depth of lime incorporation on the growth of corn on an Oxisol of Central Brazil. *Soil Science Society of America Journal* 43: 1155–1158; and Jallah JK (1994) *Assessment of Some Chemical Constraints to Root Growth in Four Acid North Carolina Soils*. PhD thesis. Raleigh, NC: North Carolina State University.

Figure 1, the concentration of Al in soil solutions is related to the percentage of Al saturation of the cation exchange sites, with a marked increase in the Al concentration when the Al saturation exceeds 50%. Most field assessments of crop response to toxic levels of soil solution Al have been based on percentage of Al saturation as a proxy variable, due to its greater ease of measurement. Root length of corn, for example, is markedly reduced at percentage of Al saturation levels corresponding to high concentrations of Al in the soil solution (Figure 2).

Tolerance to Al varies widely among species and even varieties of the same species (Table 3). Yields for most varieties of cotton, mung bean, pearl millet, and wheat are reduced by low levels of percentage of Al saturation, whereas cassava and cowpea tolerate high levels of soil Al. However, considerable differences in Al tolerance/susceptibility have been observed among varieties within a given species. For example, critical percentage of Al saturation levels among field trials with different varieties range from 0 to 40 with corn, 0 to 44 with soybean, and 0 to 60 with upland rice.

Table 3 Threshold values of percentage Al saturation of the cation exchange capacity above which crop yield for various species is normally reduced by Al in mineral soils

Crop	*Critical % Al saturation*
Cassava	75
Corn	30
Cotton	0
Cowpea	60
Mung bean	0
Peanut	40
Pearl millet	0
Phaseolus bean	15
Potato	20
Sorghum	15
Soybean	15
Upland rice	40
Wheat	0

Manganese Toxicity

Acid soils with high contents of Fe and Al oxides often contain large amounts of soluble Mn. Plant growth in such soils is reduced when large quantities of the soluble soil Mn accumulate in their tissues. Although Mn is an essential nutrient, excessive plant uptake is toxic to plants. Liming these soils to pH 5.5 or greater decreases the solubility of soil Mn, which reduces the uptake of excess Mn and increases plant growth. In many instances, improved plant growth upon liming soils with percentage of Al saturation below the critical level is associated with the alleviation of Mn toxicities.

Calcium and Mg Deficiencies

Acid soils with high percentage of Al saturation have very low amounts of Ca and Mg on both the exchange sites and in the soil solution. Soils with very

Kamprath (unpublished data); and McCart GD and Kamprath EJ (1965) Supplying calcium and magnesium for cotton on sandy, low cation exchange soils. *Agronomy Journal* 57: 404–406.

low CEC have a limited capacity to retain Ca and Mg and supply of this nutrient may not be sufficient for normal plant growth. The immediate supply of Ca for continued growth of root tips is dependent on the soil solution concentration, because this nutrient is relatively immobile in plants. Root length of wheat seedlings, for example, was increased by over 50% when 0.1 cmol Ca kg^{-1} was added to an Oxisol which initially contained 0.02 cmol Ca kg^{-1} (Figure 3). Although it is often difficult to separate the extent to which a plant growth response to liming is due to correction of a Ca deficiency versus alleviation of an Al toxicity, the improved root growth of wheat was similar among various sources of Ca. Plant growth responses to additions of Mg are often associated with soil conditions where exchangeable Mg^{2+} and/or the proportion of cation exchange sites occupied by Mg^{2+} is very low.

Response to Liming

A major response of plants to liming is due to the neutralization of H, Al, and Mn, which if present in relatively high concentrations in the soil solution are toxic to plant growth. Toxic concentrations of H generally do not occur in soils except in certain organic soils when pH values are less than 4.5. In acid mineral soils with pH values less than 5.5 liming removes the negative effect of H on absorption of Ca, Mg, and K.

The response of plants to liming is mainly due to the neutralization of exchangeable Al and its replacement on the exchange sites with Ca and/or Mg. Liming of acid mineral soils to pH 5.6 reduces exchangeable Al to essentially zero (Figure 4). This essentially eliminates Al from the soil solution and removes it as a factor limiting plant growth. As previously discussed, the concentration of Al in the soil solution is a function of the Al saturation of the active cation exchange sites. Since the Al saturation of a soil is much easier to determine than soil solution Al, it is an excellent criterion for determining the need to lime a given soil. Since crops and genotypes vary in their tolerance to Al, knowledge about the Al saturation of a given soil provides information whether a particular crop or genotype will require liming. An example of this is the differential Al tolerance of corn as compared to soybean and cotton in a greenhouse study (Figure 5). Corn showed little effect to Al until

the Al saturation was greater than 50%, where there is a marked increase in soil solution Al. Relative grain yields of corn on three soils decreased sharply when Al saturation was greater than 40% (Figure 6), a value similar to that found for dry-matter production in the greenhouse. Organic soils and soils high in organic matter have a lower critical pH than most mineral soils. Maximum plant growth on acid organic soils is generally obtained at pH 5. On these soils the exchangeable Al is held on carboxyl sites and at pH 5 the Al is held quite strongly so there is very little Al in the soil solution. Liming of these soils to pH 5 provides adequate Ca to overcome the H effects on plant growth.

Response to liming can also be obtained on acid soils with low Al saturation but that have high amounts of Mn. Soil with high contents of sesquioxides often contain appreciable amounts of Mn minerals and in these soils Mn toxicity is a problem when pH values drop to 5 and less. Liming to pH 5.6 and above eliminates Mn toxicity on these soils by converting the soluble Mn^{2+} to the relatively insoluble oxides, Mn_2O_2 and MnO_2.

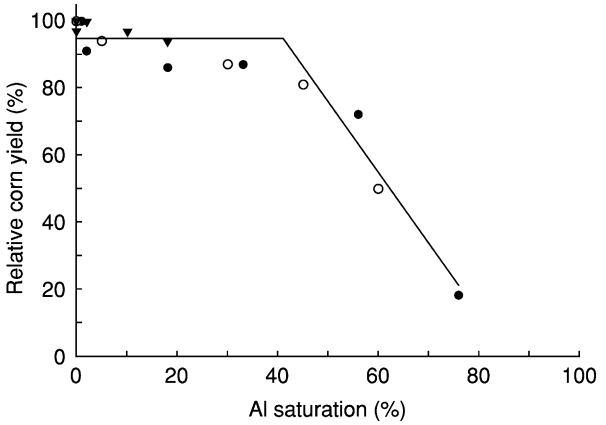

Figure 6 Relative grain yields of corn on three soils (filled circles, Goldsboro; open circles, Wharton; inverted triangles, Morrill) as related to exchangeable Al saturation of the effective cation exchange capacity. Data source: Alley MM (1981) Short-term chemical and crop yield responses to limestone applications. *Agronomy Journal* 73: 687–689; and Fox RH (1979) Soil pH, aluminum saturation and corn grain yield. *Soil Science* 127: 330–334.

Response to liming due to supplying of Ca *per se* is not often the case. In most instances Ca saturations of 20–25% will supply adequate Ca for plant growth except where toxicities to Al, H, or Mn limit plant growth. There is a good relationship between Ca or Ca + Mg saturation and plant growth, because these are the mirror image of Al saturation. On soils with very low CECs a minimum of 1 cmol Ca kg^{-1} soil is needed for optimum growth of most plants. When toxicities are not a factor the percentage of Ca saturation of the CEC is a good indicator of Ca availability. Calcium concentrations of a given plant species are similar when grown on soils with the same Ca saturation even though the soils contain a wide range of exchangeable Ca (Table 4). This is because the Ca concentration of the soil solution is determined by the percentage of Ca saturation rather than the amount of exchangeable Ca. Calcium is transported to the root by mass flow of water and thus the amount arriving at the root surface is a function of the Ca concentration. Magnesium deficiencies on sandy soils are generally associated with pH values of less than 5. The concentration of Al^{3+} and H^+ at pH 5 in mineral soils is sufficient to inhibit Mg uptake by plants. Liming to neutralize Al and H is necessary for optimum uptake of Mg where soil reserves are adequate. On acid sandy soils response to liming is also related to the supply of Mg with the application of dolomitic lime. Availability of soil Mg is related more to the Mg saturation of the CEC rather than the amount of exchangeable Mg. Various studies have shown that Mg saturation needs to be in the range of 5–10% for optimum plant growth.

Soybean and other legumes often show a response to increase in pH beyond that at which Al is neutralized. Raising the pH of mineral soils to 6 has

Table 4 Effect of Ca saturation of the effective cation exchange capacity (ECEC) on Ca availability

		Soil Ca

increased yield because of increased solubility of soil Mo, which is required by bacteria for N_2 fixation. Increasing the OH^- concentration with liming brings about the replacement of MoO_4^{-2} absorbed by the Fe and Al hydrated oxides. Raising the pH to 6.0–6.2 makes sufficient Mo available for optimum N_2 fixation and optimum yields of legumes. Thus the higher critical pH for legumes as compared to nonlegumes on mineral soils is related to the Mo requirement for N_2 fixation and the effect of pH on Mo availability.

Availability of soil P in acid soils has been increased by liming. In acid soils Al at the root surface precipitates P and decreases the amount of P transported to plant tops. Removal of Al from the soil solution by liming prevents this from happening. Neutralization of exchangeable Al also results in more root growth and exploration of a greater soil volume. Phosphorus gets to roots by diffusion and when root growth in a given volume is increased, the uptake of P is increased.

The increased root growth in a given volume of soil when Al is neutralized by liming has a number of general beneficial effects on plant growth. Nutrient and soil water availability are increased. Microbial activity is enhanced; this affects N_2 fixation, decomposition of organic matter and plant residues, making available organically bound nutrients.

Cation Exchange Properties Affecting Liming of Acid Soils

The CEC of a soil is largely determined by the mineral composition of the clay-sized fraction. The source of the negative charge in clay minerals can be either permanent or variable. Permanent charge results from isomorphous substitution among cations with differing valences within the crystalline clay structure, and is a permanent characteristic of the mineral. Smectite, vermiculite, and illite are commonly occurring clay minerals with permanent charge. Variable charge results from the protonation and deprotonation of OH groups on the surfaces of Al and Fe oxides, crystalline or amorphous, and exposed edges of layer-silicate minerals. Kaolinite, hydroxy-interlayered vermiculite, goethite, gibbsite, quartz, and allophane are some of the clay minerals with variable charge. Carboxyl and OH groups in soil organic matter also have a variable-charge behavior, wherein the amount of negative charge increases with soil pH.

Most acid soils have a mixed composition of both permanent- and variable-charge clay minerals. However, the dominant type of clay mineral charge can be estimated through the sum of basic cations and exchangeable acidity (unbuffered salt extraction) relative to the amount of soil clay. Soils dominated by minerals with permanent charge have CEC values $>12\,\text{cmol}\,\text{kg}^{-1}$ of clay, whereas soils dominated by variable-charge clays have CEC values $<12\,\text{cmol}\,\text{kg}^{-1}$ of clay.

When lime is applied to soils with variable-charge clay minerals, part of the potential base reaction is consumed in the neutralization of H^+ released from OH groups. Consequently, the lime required to neutralize a targeted amount of exchangeable acidity is increased.

Lime Requirement Determinations

Soil pH

Soil pH was one of the first methods for determining the need for lime. At pH 7 soils were considered to be 100% base-saturated and had zero base saturation at pH 4. The relationship between soil pH and base saturation was considered to be linear between pH 4 and 7. Measurement of the soil pH provided an estimate of the base saturation. To determine the amount of lime to raise the soil to the desired soil pH requires information about the CEC of the soil which can be estimated based on soil texture and organic matter content. As an example, the amount of lime to bring the pH to 6 (90% base saturation) for a soil which had an initial pH of 5 (50% base saturation) and a CEC of $10\,\text{cmol}\,\text{kg}^{-1}$ soil would be $10\,\text{cmol}\,\text{kg}^{-1}$ soil $\times\, 40\% = 4\,\text{cmol lime}\,\text{kg}^{-1}$ soil, which is equal to $4000\,\text{kg lime}\,\text{ha}^{-1}$. One of the limitations of this approach is in estimating the CEC of the soil. If the estimate of the CEC is off, this will result in recommendations which are either too much or too little of the required amount of lime.

Titration of Soil with a Base

The lime requirement of soils can be determined by titrating acid soils to the desired pH with a base such as KOH or $Ca(OH)_2$. Titration of mineral soils to pH 5.6–5.8 will give the amount of lime required to neutralize exchangeable Al. The amount of lime on an equivalent basis is more than the exchangeable Al because, as the pH increases, nonexchangeable acidity ionizes and reacts with the lime. Titration to pH values above 5.6–5.8 results in the reactions of the base with nonexchangeable acidity which is H associated with hydroxy Al, carboxyl groups of organic matter, and hydrated oxides of Fe and Al.

Reaction of lime with exchangeable and nonexchangeable acidity is shown by the following equations:

1. neutralization of exchangeable acidity:

$$2\text{Al-soil} + 3CaCO_3 + 6H_2O \rightarrow 4\text{Ca-soil} + 2Al(OH)_3 + 3H_2CO_3$$
$$3H_2CO_3 \rightarrow 3H_2O + 3CO_2\uparrow \quad [3]$$

2. neutralization of nonexchangeable acidity:

$$2(\text{R-C-OOH}) + CaCO_3 \rightarrow Ca(\text{R-C-OO})_2 + 2H_2CO_3$$
$$2H_2CO_3 \rightarrow 2H_2O + 2CO_2\uparrow \quad [4]$$

This method is rather time-consuming and does not lend itself to use where large number of samples need to be analyzed.

Buffer pH Method

Many soil-testing laboratories use the soil-buffer pH method to determine the lime requirement. This method is essentially a titration of an acid, the soil, with a base, the buffer solution. The molarity of the buffer solution is known and the amount of base required to neutralize the acidity of the soil can be determined by the change in the pH of the buffer solutions. With these methods a given volume of the buffer solution is added to a given weight or volume of soil and the pH is measured. The decrease in pH of the buffer solution is related to the amount of acidity in the soil.

Four buffer pH methods are being used in the USA to determine lime requirements. The amount of lime needed for each 0.1 decrease of buffer pH to bring the soil to the indicated pH is given in Table 5 for each of the methods. The Woodruff buffer was developed for determining the amount of lime to adjust the pH of Mollisols to a range of 6.5–7.0. The SMP buffer is used for soils with a large amount of three-layer clays and high-organic-matter content, such as Alfisols. The Adams and Evans buffer was developed for soils with low CEC and kaolinitic clay mineralogy. The lime recommendation by this method is to adjust the pH to 6.5. The Mehlich buffer was developed to predict the amount of lime needed to neutralize exchangeable Al. For mineral soils lime rates based on the acidity extracted with the Mehlich buffer raise the pH in the range of 5.8–6.0, which neutralizes the exchangeable Al.

Exchangeable Al

Liming mineral soils on an equivalent basis to the amount of exchangeable Al targets achievement of pH 5.6–5.8 and a soil solution Al^{3+} concentration approaching zero. As previously discussed, lime will neutralize exchangeable Al and also react with protons on variable-charge mineral surfaces. Consequently, the lime equivalence factor to achieve 0% Al saturation of the soil CEC is greater than 1.0 and is usually in the order of 1.5–3.

Yields for many crops are not reduced until soil Al saturation values exceed 40% or even 60% (Table 3 and Figure 5). For these acid-tolerant crops and, especially, in regions where lime materials are expensive, lime requirements can be adjusted to achieve a targeted percentage of Al saturation instead of neutralizing all of the exchangeable Al. An example of this approach is the following:

$$CaCO_3 \text{ equivalent } (\text{t ha}^{-1}) = LF[Al - TAS(Al + Ca + Mg)/100] \quad [5]$$

where LF = the product of 1.5 equivalents of $CaCO_3$/equivalent of exchangeable Al and the conversion to a 20-cm layer for a hectare of soil, Al, Ca, and Mg = exchangeable cations extracted with a neutral unbuffered salt, such as KCl, and TAS = the targeted percentage of Al saturation after liming.

Liming soils to achieve a given percentage of Al saturation requires more information than when liming to neutralize all of the exchangeable Al. In addition to exchangeable Al, analytical data are needed for exchangeable Ca and Mg. Furthermore,

Table 5 Lime requirement as determined with buffer solutions

Method	*Buffer pH*	*Target pH*	*Intended use*	*Lime/0.1 pH decrease in buffer (t $CaCO_3$ ha^{-1})*
SMP	6.8	6.8	High exchangeable Al	0.6
		6.4	Alfisols	0.5
		6.0		0.4
Woodruff	7.0	6.5–7.0	Mollisols	0.5
Adams and Evans	8.0	6.5	Low cation exchange capacity Ultisols	0.1
Mehlich	6.6	6.0	Neutralize exchangeable Al, Ultisols	0.16

CEC, cation exchange capacity.

the percentage of Al saturation tolerated by the intended crop must also be known.

Factors to Consider in Lime Application

Liming Materials

There are a number of different materials which can be used for liming. The most common ones are calcium carbonate (calcitic limestone) and calcium-magnesium carbonate (dolomitic limestone). These are crystalline compounds which must be ground. Marls are soft, unconsolidated calcium carbonates which may contain some clay. Calcium oxide (burnt lime or quick lime) is a white powder and is caustic when it absorbs water. It is difficult to get uniform mixing with the soil because immediately after application absorption of water causes granules to form. Calcium hydroxide (hydrated lime) is a white powder and when wet is caustic. It is also difficult to apply. Basic slag (calcium silicate) is a by-product of the steel industry.

Neutralizing Value

The neutralizing value ($CaCO_3$ equivalent) of liming materials is related to the amount of acid that a unit weight of lime will neutralize. The standard for evaluating materials is pure calcium carbonate which is given a value of 100%. The neutralizing value for pure liming materials is given in Table 6.

The purity of the liming material must also be taken into account when determining the neutralizing value. Most liming materials are not 100% pure. In many instances the purity of the material will have been determined so that the buyer is given this information. Lime recommendations are often based on 100% purity of the material so that the application rate will have to be increased when the purity is less than 100%.

Fineness of Liming Materials

The most commonly used liming materials, calcitic and dolomitic limestone, are crystalline compounds. These materials must be ground to a fineness which will provide a large number of particles per unit volume of soil. The lime particles dissolve when coming into contact with acid soils and will release Ca^{2+} and HCO_3^-: this results in neutralization of H^+ and Al^{3+}. The rate at which the pH of the soil mass is affected depends on how close the individual lime particles are to one another. Since the diffusion of Ca is relatively slow the particles need to be close together so that the zones of neutralization around each particle overlap in a relatively short time.

Calcitic and dolomitic limestones are generally ground so that all of the particles pass a 20-mesh sieve and a certain percentage passes a 100-mesh sieve depending on the regulations of the state or province. Calcitic limestones are often softer than dolomitic limestones and therefore dissolve at a faster rate. The relative efficiency of different particle sizes of these two materials is given in Figure 7. Particles held on a 10-mesh sieve have little value for neutralizing acid soils.

Table 6 Neutralizing value of pure liming materials

Material	*Neutralizing value (%)*
Calcium carbonate, $CaCO_3$	100
Calcium-magnesium carbonate, $CaMg(CO_3)_2$	109
Calcium oxide, CaO	179
Calcium hydroxide, $Ca(OH)_2$	135
Calcium silicate, $CaSiO_3$	86

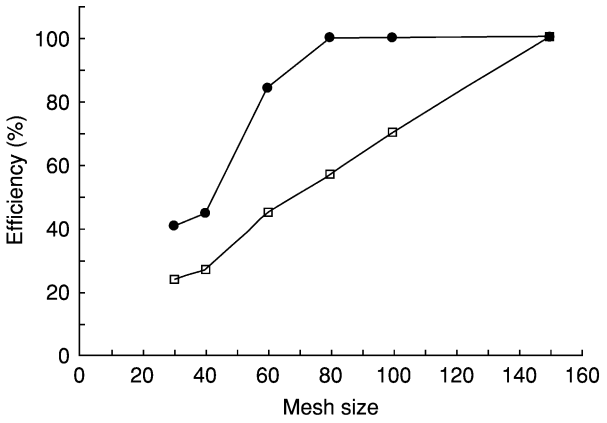

Figure 7 Relative efficiency of various mesh sizes of calcitic (circles) and dolomitic (squares) lime in neutralizing acidity. Data source: unpublished data of E.J. Kamprath.

Incorporation of Lime in the Soil

Since Ca^{+2} and HCO_3^- ions have a slow rate of diffusion, the lime must be well mixed with the soil to neutralize soil acidity throughout the zone which is to be amended. One approach is to apply half of the lime and incorporate it by disking, and then apply the other half and disk to incorporate. However this results in high costs of application and incorporation rather than doing it only once.

Conclusion

Poor plant growth on acid soils is due to toxicities of Al, H, and Mn and deficiencies of Ca, Mg, and Mo. Oxisols, Ultisols, and some Alfisols in their native state have pH values less than 5 and exchangeable Al of the effective CEC greater than 50%. Plant response to liming is due to neutralization of the toxic elements

and the supply of Ca and Mg. The lime requirement for a soil can be based on the amount of lime required to: (1) adjust the pH to a desired value; (2) neutralize exchangeable Al; or (3) neutralize the acidity measured by buffer pH methods. Factors to consider in selecting a lime material are fineness, purity, and the need for Mg.

LIPMAN, JACOB G.

J C F Tedrow, Formerly with Rutgers University, New Brunswick, NJ, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Jacob G. Lipman was one of the most prominent international leaders in soil science. In 1901 he formed the Department of Soil Chemistry and Bacteriology at Rutgers University, the first of its kind in the USA, and probably the world. He was the driving force in internationalizing soil science. He also initiated and edited Soil Science, the first international journal dealing with soil chemistry, soil fertility, soil physics, and soil microbiology.

Lipman (Figure 1) played a major role in the development of agriculture in the USA and beyond during the 1901–1939 period. His main contributions were in the area of soil microbiology and soil fertility, particularly in relation to increased crop production. During later years, he was also involved in worldwide agricultural problems. Not only did he advance science on several fronts but he was also a gifted administrator. He addressed the broader aspects of agriculture, particularly in increasing the world food supply, controlling soil erosion, and improving the general welfare of humanity.

The Early Years

Jacob Goodale Lipman was born in Friedrichstat, Russia, on November 18, 1874. He received his early academic training under private tutors in Moscow and in the classical gymnasium in Orenberg. In 1888, with his parents, he settled at the Baron de Hirsch colony in Woodbine, New Jersey. After graduating from farm school there he entered Rutgers

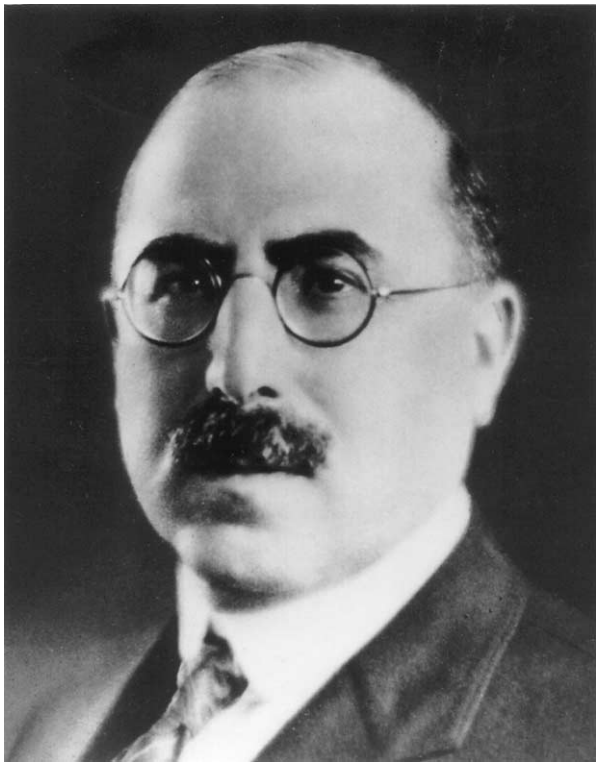

Figure 1 Jacob G. Lipman, 1874–1939.

College (University) in 1894. Next was graduate study at Cornell University where he studied under professors G.A. Caldwell and V.A. Moore. His master of arts degree was completed in 1900 and the doctor of philosophy degree in 1903. As his graduate studies were nearing completion he returned to the New Jersey Agricultural Experiment Station to organize a department of soil chemistry and bacteriology, the first of its kind in the USA. In 1902 he was appointed instructor in agriculture and by 1910 he had attained his (full) professorship. In 1911 he was appointed director of the Agricultural Experiment Station, but also retained his position as chairman of the Department of Soil Chemistry and Bacteriology. Additionally, in 1916 he was appointed as dean of the College of Agriculture, the first time that the office existed.

Lipman the Scientist

Early in his career people were just beginning to gain knowledge of the role of microbes and their applications to soil processes and to agriculture in general. During this time microbes were being recognized as agents responsible for numerous reactions in the soil that led to the liberation of chemical nutrients essential for plant growth.

Immediately after taking office, Lipman outlined a policy of increased service to the state. He saw the need for strengthening and enlarging the staff and adding new departments. This, however, could not be done without increased state appropriations.

During his first address to the Board of Managers after becoming director of the New Jersey Agricultural Experiment Station, Lipman announced the beginning of a policy of increased service to the state. He asserted that there should be a sound basis for development of the land. He also urged the expansion of extension activities. Through his close relationship with leading farmers and prominent businessmen, he convinced the legislature that there was a real need for greater financial support for agriculture. Accordingly, during his tenure, state appropriations were increased 16-fold. Legislators in Trenton looked forward to Lipman's appearance before the Appropriations Committee, not only for the humorous stories he told so well, but also because they thought he was sincere and they liked him. Pointing out that, for many years, the station had been a creative force in developing agriculture in New Jersey and beyond, he asserted that it was time to undertake a comprehensive campaign in the public interest. He proposed studies in farm management, irrigation, soil drainage, fertilization of crops, and product marketing. He also pointed out the need for upgrading the laws governing seed control, fertilizer manufacture, and animal feeds.

Dr. Lipman's own scientific activities began at the turn of the century when the importance of microorganisms in soil processes was beginning to receive increased attention, particularly relating to nitrogen studies. In the history of soil microbiology, the name of Lipman will forever be connected with the study of the cycle of nitrogen in nature, especially the problem of nitrogen fixation by nonsymbiotic bacteria, the liberation of nitrogen as ammonia in the process of decomposition of nitrogenous materials in the soil, and the general relations of nitrogen liberation in soil to the growth of vascular plants.

One of Dr. Lipman's most important scientific contributions dealt with the transformation and fixation of nitrogen by bacteria. In studying some of the organisms concerned in the process he broached two subjects that later developed greatly: the importance of joint action of the soil organisms, and the relation between denitrification and composition of the organic matter concerned, now commonly referred to as the carbon–nitrogen ratio.

During his studies Lipman isolated a newly discovered nonsymbiotic nitrogen-fixing organism, *Azotobacter vinelandii*; he also described several other newly discovered organisms. The genus Azotobacter was recognized as one of the important members of the soil population. Further, Lipman

was one of the first to prove that Azotobacter are capable of fixing large quantities of nitrogen from the atmosphere. Later, he identified two more important species of Azotobacter: *A. beijerinckii* and *A. woodstownii*. Lipman showed that the same soil type under different farming systems had the ability to produce ammonia from various organic compounds. Further, Lipman's work can be considered the forerunner of the Azotobacter method for determining the presence and abundance of available minerals in the soil.

The next signal accomplishment of Dr. Lipman in soil research concerned oxidation of sulfur in the soil. The underlying task was to make rock phosphate more available to plants. Lipman believed that if certain bacteria in the soil were capable of oxidizing the sulfur, the phosphate would be converted into a more soluble form. Together with his assistants, Selman A. Waksman and Jacob S. Joffe, he isolated the bacterium *Thiobacillus thiooxidans* and applied it to the soil. The concept had considerable agricultural appeal and patents were granted covering the process. Subsequent investigations by Lipman's colleagues, however, showed that in New Jersey soils the rate of sulfur oxidation in the uninoculated samples was about the same as that of the inoculated ones.

Dr. Lipman's scientific accomplishments soon achieved worldwide recognition. Students came from many foreign lands to carry out their graduate studies at Rutgers University. In all, students from some 24 foreign countries studied under Lipman and colleagues. Among the future luminaries from the USA and beyond were P.E. Brown, R.T. Dubos, J.S. Joffe, W. Rudolfs, R.L. Starkey, and S.A. Waksman. Further, young investigators who had already completed their doctor of philosophy degrees, as exemplified by Hans Jenny and W.L. Kubiëna, worked in the department for shorter periods.

It was often said that Dr. Lipman kept his associates happy and smiling. He believed in delegating responsibility and in so doing inspired his associates to supreme efforts. But once he delegated an assignment he would hold his staff member responsible. One staff member commented that Lipman could outline in one-half hour more than could be done in 6 months. His colleagues also said of him that, while demanding of students, he was also patient and understanding. He was never known to punish anyone. He felt that everyone should have another chance if they wanted it and he was never known to be angry with any subordinate.

As a writer and speaker Dr. Lipman was at his best. He delivered a series of lectures at other institutions such as University of Illinois, Cornell University, University of Tennessee, University of Nebraska, and Iowa State University. He was also called upon to speak at many agricultural meetings in New Jersey and beyond.

After he became director of the New Jersey Agricultural Experiment Station visitors came to learn from him, not only from nearby but also from all over the world and from all walks of life. Lipman had an encyclopedic mind. His conversations were not limited to agriculture but included general science, economics, and religion. Very few investigators have the skills to master the field of research and also have the ability to convey messages to the ordinary farmer. Lipman, however, bridged the gap admirably. He wrote many reports on the technical phases of soil science and agriculture and contributed articles to various farm journals such as Pennsylvania Farmer, Rural New Yorker, New Jersey Agriculture, and the John Wiley Agricultural Science series. He wrote technical reports for C.E. Marshall's Microbiology and E.O. Jordan and I.S. Falk's book The Newer Knowledge of Bacteriology and Immunology. Lipman was also an advisory editor of the Journal of Agricultural Research, the Internationale Mitteilungen für Bodenkunde, and Annales Agronomiques. Dr. Lipman also edited a series of textbooks in agricultural science. His Bacteria in Relation to Country Life gave him nationwide recognition. This was followed by his Laboratory Guide of Soil Bacteriology, coauthored with his first assistant, P.E. Brown.

Dr. Lipman held membership in a large number of professional societies throughout the USA. The list included the American Health Association, American Association for the Advancement of Science, American Chemical Society, Society for the Promotion of Agricultural Science, American Society of Agronomy, Association of Official Agricultural Chemists, Society of American Bacteriologists, Association of Land Grant Colleges, New Jersey State Sanitary Association, Washington Academy of Science, American Academy of Political and Social Science, National Research Council, American Peat Society, New Jersey Chemical Society, and others. The list of his membership in foreign societies included the International Commission of Agriculture Ecology, Reale Accademia del Georgofili de Firenze, French Academy of Agriculture, Academy of Agriculture of Czechoslovakia, and the Swedish Royal Academy of Agriculture. In 1922 he was awarded a silver medal by the French Academy of Agriculture. Through Lipman's efforts the New Jersey Agricultural Experiment Station received the Bacteria Award at the Panama-Pacific International Exposition of 1915.

In 1923 Rutgers University awarded Dr. Lipman an honorary doctor of science degree and in 1930 he

received an honorary doctor degree from the Catholic University of Santiago, Chile.

Dr. Lipman's research subjects during the 1920s and 1930s included soil microbiological populations, the influence of environmental conditions upon biological changes in the soil, the correlation of soil fertility and microbiological processes, enzymes of microorganisms, anaerobic fermentation of hemicelluloses, and transformation of organic materials.

Dr. Lipman's investigations were carried out during a period of soil microbiology when both scientists and practical microbiologists were seeking applications of science to agriculture. His work was carried out during the time when there was a transition between science developed in the laboratory and application of the results to field conditions. He contributed to both and thus carried the service through one of the most complex periods of development. He not only helped to advance science of the soil, but he also interpreted the application of science to practical agriculture.

At the height of his career Dr. Lipman turned to the broader issues of society. He was one of the pioneers in advancing rural settlement, rural rehabilitation, soil conservation, flood control, afforestation, wildlife sanctuaries, and the general good use of land.

Up until the World War I era there were virtually no important technical journals dealing specifically with soil science published in North America. Americans had to rely mainly on technical papers and books dealing with soil science from Germany and England. The great body of soils information from Russia had not, at that time, penetrated the western world to any extent. In 1916 Lipman founded and edited Soil Science, a journal he personally continued editing for the remainder of his lifetime. In all he edited 46 volumes (two volumes per year). Contributions dealing with soil science came from investigators from all over the globe. Lipman, at an early date, appointed some 35 consulting editors of the journal, over half of whom were from foreign lands. Soil Science was truly an international journal without any society or government affiliation. This venerable journal, published monthly since its inception, has had, over the years, 2000–3000 institutional and private subscribers, with nearly half of them from foreign lands. Lipman's labors with the journal alone served as a vehicle for internationalizing the field of soil science.

At the time when Dr. Lipman became dean of the College of Agriculture and director of the Agricultural Experiment Station, the soils of New Jersey were being surveyed on a scale of 1 in per mile (2.5 cm per 1.6 km). The surveys were being carried out as a joint project with the US Department of Agriculture. By 1927 surveys for the entire state were completed. New Jersey was one of the first states to have such a survey. Soils were also collected and analyzed for their chemical, physical, and mineralogical properties. Also, there were recommendations for cropping systems, land management, soil drainage, and related subjects.

During the latter part of his life Dr. Lipman made a number of trips to Europe, particularly England, the Netherlands, Germany, France, and Italy. Conversing with non-English-speaking colleagues presented few problems because he was fluent in Russian, German, and French. European investigators returned many visits to Lipman. He also made trips to Central and South America. His main purpose was to study various agricultural practices.

Lipman the Administrator

When Lipman became director of the New Jersey Agricultural Experiment Station the physical facilities at the station were rather limited. Office and laboratory space was limited to two buildings on the main campus of the university. There were also a few farm buildings at College Farm on the edge of New Brunswick. Lipman increased the acreage of College Farm from 142 to 800. Over a period of 20 years the entire operation of the Agricultural Experiment Station plus the teaching facilities in agriculture were moved to College Farm where they remain to this day.

During the 1911–1930 period many new, major structures plus ancillary buildings, including animal barns, were constructed at the College of Agriculture. By 1928, with the growth of research and the increase in the number of students, the state legislature approved the construction of an additional building to be devoted primarily to research and the teaching of soil science and in 1931 funds were provided for the new building. But just as the architectural plans were completed, the state, because of the world depression, rescinded all appropriations for capital construction. In 1950, however, the new building was completed and it bears the name Lipman Hall (**Figure 2**).

At the time when Dr. Lipman became director of the New Jersey Agricultural Experiment Station there were only a few departments. In addition to enhancing the physical plant he created departments of seed analysis, plant pathology, agronomy, and farm management. During the later years he also added departments of plant physiology, agricultural biochemistry, agricultural engineering, sewage research, and ornamental horticulture.

Dr. Lipman greatly increased the size and scope of the New Jersey Agricultural Experiment Station but there were times when it was difficult to obtain sufficient funds to carry out his plans, particularly during the World War I era. He was heard to say: "I wake up

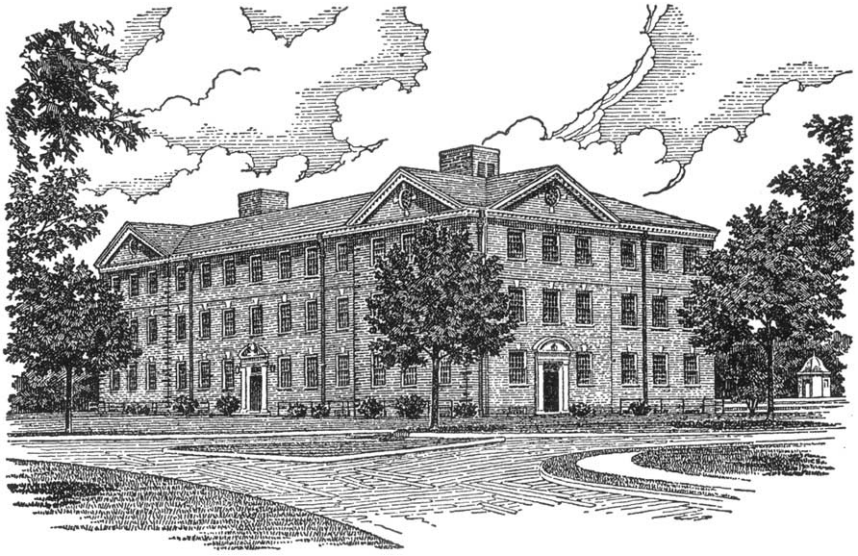

Figure 2 Lipman Hall on the campus of Rutgers University, New Brunswick.

Figure 3 Experimental soil cylinders at the New Jersey Agricultural Experiment Station, Rutgers University, New Brunswick.

in the morning with a vision of a pile of mail waiting for me, requests I cannot fill, complaints I cannot help, and work piled without end. I have an idea I'd rather prefer the trenches."

Dr. Lipman was well aware of the many varieties of soils in New Jersey. Accordingly, he set up management demonstrations on many farms. Branch stations were established for specialized crops such as blueberries and cranberries. Also, a shellfish research station was established, as was a dairy research station.

Experimental work dealing with growing crops on different kinds of soil was initiated by Dr. Lipman's predecessor, Dr. E.B. Voorhees. Initially there were 60 openend, steel cylinders, 4 ft (1.2 m) high with a diameter of 23 1/2 in. (60 cm) installed in a cluster at ground level. Various soils were placed in the cylinders and crops such as tomatoes, corn, and oats were grown (Figure 3). Later, under Lipman's directorship, the number of cylinders was increased to 320 and additional experiments included various soils and fertilizer mixtures. Also, chemical and bacteriological studies were made regarding the pathways of nitrogen and organic matter transformation. In addition to gaining general information on nutrient balance the cylinder experiments demonstrated that enormous

losses of nitrogen may take place in the soil. Also, it was found that soluble nitrogen in liquid manure possesses high value as a source of nitrogen. The cylinder experiments settled many worldwide problems dealing with the availability and fate of many kinds of fertilizers.

Lipman's predecessor at the State Agricultural Extension Service had been operating in New Jersey since about 1890 but the service was greatly expanded under Lipman. Early in his tenure as director there was a major consolidation of the various agricultural organizations in New Jersey. In 1912 extension activities were formally initiated. When the state legislature convened in 1913, New Jersey governor Woodrow Wilson had a bill drafted for an extension system of the governor's own design. Farm demonstrations were to be operated by county agents who would be responsible to a state superintendent appointed by, and responsible to, the governor. Wilson's idea was to have the extension service completely independent of the Agricultural Experiment Station. As soon as the draft bill was made public, Lipman called on the governor and urged that the extension service be incorporated into the college and station. But the governor said, "I want it my way." The bill passed the assembly but the governor was later due for a surprise. Lipman turned to his long-time friend Harry Wheaton, an elderly blacksmith who was chairman of the State Committee on Agriculture and urged him to "sit on the bill." March came and Wilson was inaugurated president. The controversy between Lipman and Woodrow Wilson continued but Lipman had convinced Wheaton to continue to withhold the bill from a final vote. Lipman said to him: "Woodrow Wilson is no longer Governor of New Jersey, now he is only President of the United States." Lipman persisted and, finally, had his own bill passed providing for the extension service to administer activities through Rutgers University.

Dr. Lipman realized the need for international collaboration particularly between investigators from Europe and those from the USA. During the Third International Conference on Soil Science in Prague in 1922 the USA delegated Lipman and C.F. Marbut (Head of the US Soil Survey) to attend. Lipman's mind had developed so keenly and rapidly as to extend well beyond the immediate problems with which soil science was struggling. At the Fourth Conference on Soil Science in Rome in 1924 Lipman again attended the meetings and continued to make very favorable impressions on European colleagues. It was during this meeting that the idea of forming the international society of soil science was finalized. Washington, DC, was selected as the meeting place and Lipman, because of his great organizational talent, was selected as president. Selection of the USA was based on several factors: (1) European investigators were anxious to make observations on US soils in general; (2) there was particular interest in seeing the highly weathered, reddish soils in the south-eastern USA; and (3) investigators wished to make studies and observe the similarity of the dark-colored soils of the prairies and steppes of the central USA to their counterparts in Eurasia.

The First International Society of Soil Science meeting was held during June 1927. President Calvin Coolidge gave the keynote address, which was followed by an address by Lipman. During the meeting Dr. Lipman said:

> Truly in man's upward climb he has accomplished the seemingly impossible. But much as the student of soils may be tempted to ponder on man's past, he must leave this to the philosopher and the poet. It is his task, rather, to inquire into the relations of climates, soils, plants, animals, and man. For all that, soil science must build a foundation large enough and strong enough to support the study of plant food resources, their mobilization, and the interrelations of soils and plants and the characteristics and peculiarities as reflected in the make-up of plants, animals, and man.

Immediately following the First International Soil Science Congress, Lipman was instrumental in arranging a 30-day, 12 000-mile (19 320-km) trip to the west coast of the USA and western Canada. A special train was engaged and it carried over 200 people in 17 railroad cars. The excursion gave delegates the opportunity to make firsthand observations concerning North American soils and make comparisons to European conditions. One individual went so far as to say that the transcontinental excursion was as important to his career as the voyage of the Beagle had been to Charles Darwin.

The End of an Era

In February 1939 Dr. Lipman developed a severe cold and was confined to his home. He was hospitalized several times during the following weeks. Local physicians found his heart completely gone. He died on April 19, 1939. His services to humanity, however, were not forgotten, as exemplified by the following tributes made by various speakers during the dedication of Lipman Hall.

Nobel Laureate Selman A. Waksman said that, with the death of Dr. Lipman, Rutgers completed a period of nearly a century of investigation in the field of soil science, a science which, even if not touched by this group and their coworkers in all its phases, has reached some of the highest pinnacles of its attainment. The investigations of the soil, its origin and

nature, its fertility and its relation to plant growth, its microscopic population, and its microbiological processes are closely interwoven with the other investigations carried out not only in the various institutions in this country but in the world at large. They have served to raise the science of the soil from its beginnings, as a child of geology and as a handmaiden of agronomy to an independent, natural science. We shall provide then for the intensification of production and the support in greater comfort of the growing population of the world. It is the duty of soil sciences to establish more clearly the relation of crops to soils in order that cropping methods may best conserve plant food, solar energy, and human labor. Soil science should teach the farmers how best to modify food quality by soil treatment. It should plan a more far-reaching program of research and education in order that it might serve in a constantly larger way the needs of a human society that from year to year is growing more complex in its organization and more exacting in its demand for such of the products of the land as are essential for maintaining the moral and spiritual values that are the final measure of human activities.

Sir E.J. Russell of England said that there are two ways in which a man may advance science: by his own personal investigations and by organizing investigations of others. And, since nothing succeeds like success, he must ensure success by keeping the whole program well-balanced, favoring none, repressing none. Dr. Lipman followed the above usual sequence and he was successful in all parts he had been called upon to play. His long and faithful service to the New Jersey Agricultural Experiment Station can never be forgotten, nor can his pioneer work in opening up new branches of knowledge.

Further, Rutgers president R.L. Clothier said of Lipman that he saw him as a man endowed with uncompromising intellectual honesty, relentless mental discipline, inspired reasoning, dogged perseverance, and a rare vision of the future of pure and applied research. Clothier also found Lipman to be endowed with the qualities of character and personality that made him a sympathetic friend, a rare raconteur, and a delightful companion.

LOESS

A J Busacca and M R Sweeney, Washington State University, Pullman, WA, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Loess is a terrestrial deposit of eolian (wind-blown) dust composed predominantly of silt-sized particles. Most loess has been altered weakly to strongly by soil-forming processes as it has accumulated and its unique properties create highly fertile agricultural soils that are some of the most productive in the world. Loess covers large land areas, most often downwind of the meltwater streams of large Pleistocene glaciers, although loess is also found downwind of some large and small desert areas. Erosion of loess soils via wind and water can be severe and reduces crop productivity; however, the global redistribution of small amounts of fine dust by wind to areas of highly weathered and leached soils has recently been recognized as adding nutrients that allow these soils to sustain complex ecosystems throughout the world. Buried soil sequences within thick deposits of loess can be used to reconstruct the history of climate and ecological changes during the Pleistocene and Holocene Epochs, covering approximately the last 2.4 Ma of earth history.

Distribution

Loess covers approximately 10% of the earth's land surface (Figure 1) and is generally associated with semiarid to semihumid climate regimes. The thickest deposits are found in China, where approximately 500 000 km^2 is blanketed by loess that is up to 300 m thick. The Great Plains has the largest area of loess in North America. Loess there can be more than 60 m thick. Other loess deposits include the Pampas of Argentina, parts of Europe, the Ukraine, large areas in central Asia, the Palouse and Snake River Plain of the US Pacific Northwest (PNW US), parts of Alaska, and parts of northern Africa. Thinner and less extensive deposits are found worldwide.

Origin of Silt and Eolian Transport of Loess

There are three main processes responsible for the formation of loess: (1) production of silt, (2) wind sufficient to entrain the silt into suspension in the atmosphere, and (3) suitable trap areas where loess can accumulate owing to surface soil moisture or vegetative cover.

Glacial grinding is a dominant producer of fine-grained sediment; however, silt is also produced by fluvial and eolian abrasion, frost-shattering, salt-weathering, chemical-weathering, biological processes, and tectonic processes (i.e., overburden release). Since loess is sometimes found downwind of dune fields, it has been argued that grain-to-grain collision during saltation of sand creates silt particles, but this is only a minor contributor to dust production. Silt, produced by one of the above mechanisms, is commonly transported from its place of origin and redeposited before it is entrained by wind to form loess. Models for different types of loess help to explain its genesis. High-latitude loess is the most extensive and includes periglacial and perimontane loess. Periglacial loess is derived from silts produced by glacial grinding that are transported by water on to outwash or braidplains that are subject to redistribution by wind erosion. Perimontane loess is associated with high rates of erosion in mountainous areas that supply silt for adjacent loess accumulations. More recently recognized, peridesert or 'desert' loess is derived from the eolian reworking of sediments from alluvial fans, dry lake beds, or fluvial channels in deserts. Loess accumulates at the semiarid margins of the desert, where an increase in vegetative cover acts as a trap for the silt. Peridesert loess deposits tend to be thinner, sandier, and less continuous compared to high-latitude loess.

Mineral particles can be entrained by the wind by several processes. Particles can be entrained when a threshold velocity is exceeded, resulting in aerodynamic lift of the particle, or by fluid drag exerted on

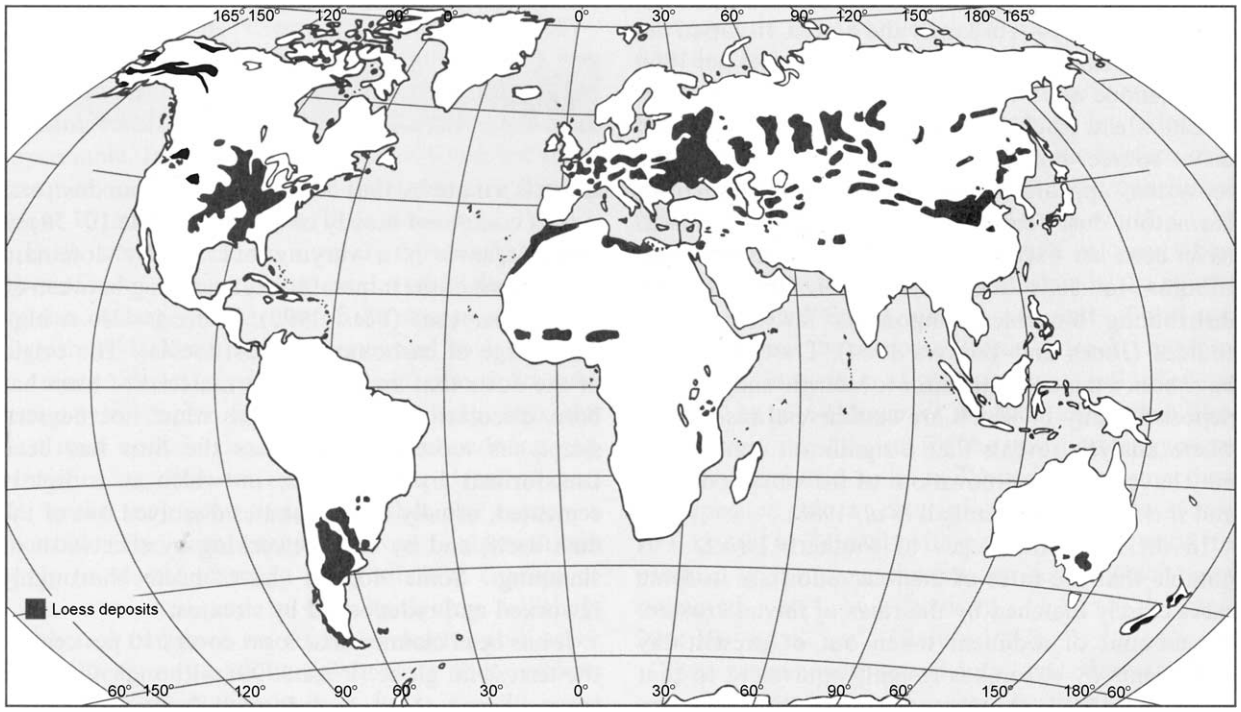

Figure 1 World distribution of major loess deposits. Adapted from AEOLIAN GEOMORPHOLOGY by Livingstone/Warren. © Reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ.

the particle by air. Particles may also be ejected into the air when they are struck by sand-sized grains. Silt- and clay-sized particles have electrostatic binding forces that can cause soil crusting and aggregation and inhibit their entrainment by the wind. (*See* **Erosion:** Wind-Induced.) For this reason, silt and clay are generally entrained as sand-sized aggregates or ejected by grain impacts. Entrainment is hindered by surface crusting, surface armoring (i.e., gravel lag), and surface soil moisture. Disturbance by animals and humans may aid in the deflation of dust.

Once silt and clay are released into the air column, transport is dominantly by suspension. While coarser sediments such as sand are transported close to the bed via creep (rolling) or saltation (jumping), the smaller silt and clay particles are carried vertically higher into the air column by turbulent eddies. Coarse silt and very fine sand are carried in short-term suspension and are deposited within tens of kilometers of the source. Finer silts and clays are carried in long-term suspension for tens to hundreds of kilometers or farther.

Deposition of dust particles out of suspension to form loess occurs when: (1) wind velocity and turbulence decreases; (2) particles are trapped by vegetation, moist soil surfaces, or uneven topography; or (3) particles are washed out of the atmosphere in precipitation events. If dust is deposited on a bare, dry surface, it is likely to be reentrained by the wind, because there is no means to hold it in place.

Sedimentology

Loess is composed predominantly of particles that range in size from 20 to 60 μm. Loess usually has a unimodal grain size distribution, is poorly sorted, and is finely skewed. Loess with more than 20% sand-sized particles can be called 'sandy loess' and that with more than 20% clay 'clayey loess.' Grain size of any loess is a function of the proximity to the dust source and the degree of weathering during soil formation. Loess near its source contains higher percentages of sand and coarse silt. Mean grain size typically decreases downwind, with a concomitant increase in fine silt and clay. This trend is a result of sorting of particles by the wind and decrease in wind velocities downwind. In some loess areas such as the Palouse of the PNW US, downwind sorting and fining are accompanied by increases in density of native vegetation and increased precipitation and surface soil moisture.

The color of loess ranges widely, depending on source mineralogy and weathering; it can be light to dark gray, yellow, pale to dark brown, red, or black. (*See* **Morphology.**) Mineralogy of loess reflects the source from which it is derived. Generally, loess is composed predominantly of quartz grains (50–70%) with feldspars, micas, carbonates, clay minerals, heavy minerals, and volcanic tephra. (*See* **Minerals, Primary.**) Clay minerals may be detrital (inherited from the source rocks) or formed *in situ* by weathering during soil formation. Carbonate minerals are often present in dust and may comprise more than 30% of loess. Inherited carbonate grains may be dissolved and precipitated to form pedogenic calcic horizons in semiarid to arid climates.

On a macroscopic scale, loess generally lacks sedimentary structures such as bedding and thus has a homogeneous appearance. Soil horizons can give exposures of loess a pseudobedded appearance. Frequent wetting and drying may result in formation of prismatic structure in loess. Closer detail of loess sedimentology may reveal fluctuations in the percentage of sand, silt, and clay with depth in the deposit that may reflect changes in wind intensity or in source areas through time. Rarely, laminations of coarse and fine dust have been preserved in loess that are interpreted to represent seasonal fluctuations in wind strength during times of very high dust accumulation rates that outpaced the mixing processes of soil organisms.

Stratigraphy

Loess accumulates in layers or 'strata' and soils commonly form at the top of a loess stratum. The soils become buried with continued deposition of dust, creating 'stratigraphic sequences' of alternating loess and buried soils (paleosols). Loess sequences such as those in China, the US, and in many other areas have been utilized to reconstruct the history of the Quaternary Period. The common occurrence of loess-paleosol sequences has been interpreted to represent episodes of high rates of dust accumulation during which a loess layer is deposited, alternating with episodes of low rates of dust deposition during which soils develop. Micromorphological techniques applied to loess and paleosols (microscope studies of slides of undisturbed materials) have shown that the idea of sequences recording either periods of dust accumulation or soil formation is misleading. In fact, soil-forming processes occur throughout the deposition of dust, and accumulation rates and climate affect the intensity of soil-forming processes (**Figure 2**).

Correlation of loess sequences across regions has been hampered by the lack of reliable dating techniques. Luminescence dating is a relatively new radiometric technique that dates the last exposure of the dust grains to sunlight. It can provide ages up to approximately 100 000 years or older with analytical

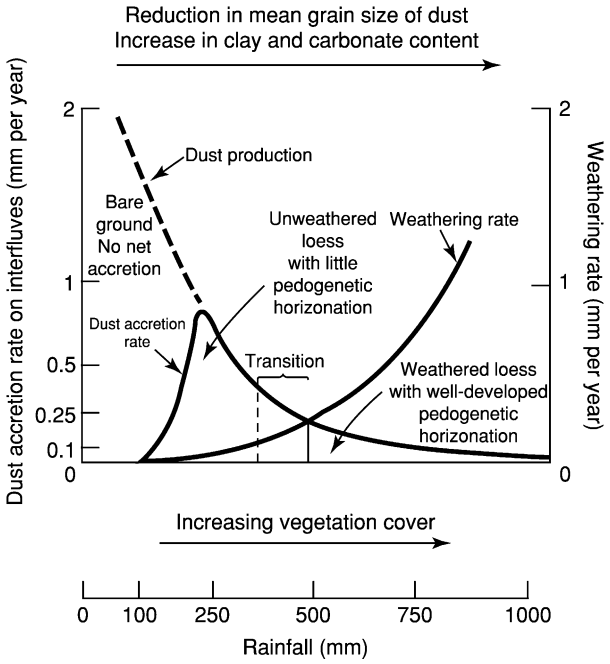

Figure 2 Schematic model showing increase in pedogenesis of loess with an increase in moisture and vegetation and decrease in dust accumulation rate and grain size. Reproduced with permission from Pye K and Tsoar H (1987) The mechanics and geological implications of dust transport and deposition in deserts with particular reference to loess formation and dune sand diagenesis in the northern Negev, Israel. In: Frostick L and Reid I (eds) *Desert Sediments: Ancient and Modern*, pp. 139–156. Special Publication No. 35. Geological Society.

errors as low as 5%. In some cases, prominent paleosols can be used to correlate sequences. Volcanic tephras in loess can be traced over large areas and can have unique chemical and mineralogical fingerprints that aid in correlation.

Chinese loess is as old as 7 million years, but the bulk of the loess there is less than 2.4 million years old. Loess deposition in China has been linked to the uplift of the Tibetan Plateau that may have resulted in climates more favorable to loess formation. Cycles of accumulation of loess followed by soil formation have been attributed in China to variations in the strength of the summer (rain bearing) compared with winter (dust-storm bearing) monsoons, and these have been correlated in turn to Milankovitch cycles (cycles in Earth's orbital parameters) that are thought by some to be the driver of the ice ages. Loess in the Great Plains and Europe show cycles that follow Pleistocene glaciations, with major loess accumulation during the dry and windy glacial periods, followed by soil formation during the more humid and less dusty interglacials.

Early scientists who studied loess were emphatic that loess was purely a glacial phenomenon. Some more recent studies show that there are cases where the opposite has occurred. Study of the Palouse loess indicates that maximum rates of loess deposition occurred during interglacials, while soil formation was dominant during glacials. The majority of the silt is glaciogenic, but it was transported to basins via catastrophic outburst floods triggered by ice dam failures that occurred toward the end of full glacial periods. The flood sediment was reworked by the wind and deposited as loess during interglacials. When full glacial conditions returned to the area, dust-transporting winds appear to have been suppressed by changes in atmospheric circulation, landscapes ceased aggrading, and soil formation ensued.

Geomorphology

Loess is a blanket deposit that accumulates from suspension fallout of dust particles. Regional patterns of thickness are controlled by a number of factors. Loess strata are thickest closest to the source area, as large volumes of the coarser sediment falls from suspension, leaving smaller volumes of finer sediment to be blown farther downwind. An exponential decrease in loess layer thickness with distance along downwind transects has been documented in many places such as the North American Great Plains (Figure 3). Thickness may be increased locally by the presence of trapping mechanisms such as topography or vegetation that separate the saltation load (sand that keeps the dust entrained) from the suspension load. A persistent source of dust-sized particles for eolian entrainment will also result in thick deposits and continuously aggrading land surfaces. The topographic form of loess landscapes can be quite different from place to place. The topography of the Palouse in the PNW US is a classic example. Loess in the drier, western Palouse (mean annual

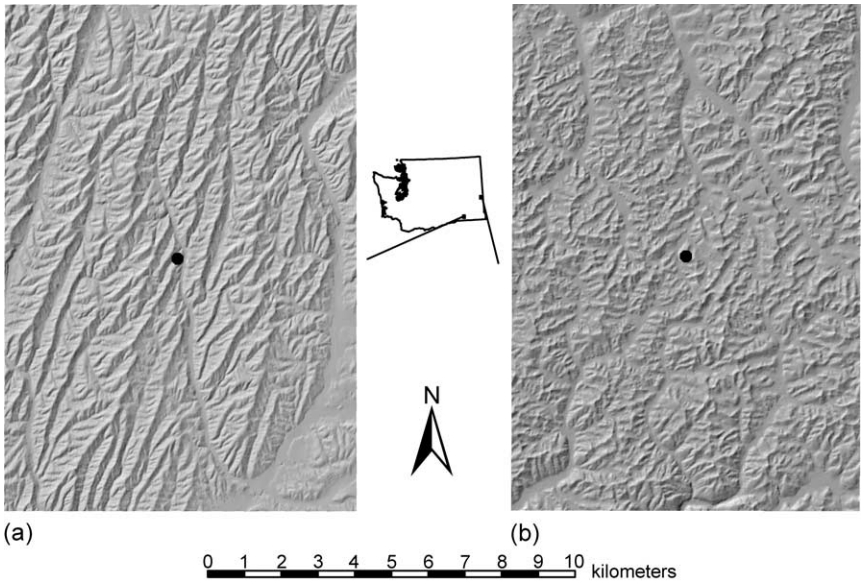

Figure 4 Hillshade models of Palouse topography, in Washington state (silhouette) in figure, based on 30-m digital elevation model resolution. × 2 vertical exaggeration. (a) Distinct, wind-aligned NNE linear ridges, formed during the deposition of sandy loess. Image of Hadley 7.5′ quadrangle; centroid is 118.44° west, 46.19° north; (b) rolling terrain of loess hills shaped predominantly by water erosion in the higher precipitation zone of the Palouse. Image of Garfield 7.5′ quadrangle; centroid is 117.19° west, 47.06° north.

rainfall less than 450 mm) forms a distinctive landscape of NNE-trending linear ridges and valleys (Figure 4a). This linear topography, called 'greda' or 'paha,' has also been observed in the loess of Hungary and the North American Great Plains. Linear ridges commonly form where loess has a more sandy texture. Local topographic highs may influence the deposition of loess in the lee of any preexisting topographic obstacles, resulting in streamlined ridges aligned with the prevailing wind direction. Other workers have argued that loess will accumulate on the windward side of topographic highs owing to deceleration of the wind, but this only may occur in the absence of sand particles. Loess in the wetter eastern Palouse (mean annual rainfall up to 800 mm) forms a dissected terrain of rolling hills with 'cirque-like' amphitheaters and a dendritic drainage network (Figure 4b). There, the combination of greater soil moisture, greater incidence and severity of soil freezing, and existence of buried soils with water-restricting, clayey argillic horizons create a landscape shaped by water erosion on frozen soils and rotational slumps and mass movements.

Loess can also blanket preexisting landforms. In eastern Europe, loess commonly blankets flights of fluvial terraces. Pseudoanticlines are described where loess has accumulated on undulating topography (Figure 5). Where dust accumulates in an area of higher relief, loess thickness can be greater in the valleys due to colluvial or alluvial reworking of loess off the hillslopes.

Figure 5 Thick accumulation of Palouse loess representing approximately 100 ky of deposition. Note the 'pseudoanticline' and the presence of buried soils represented by more resistant, white petrocalcic horizons. Photo by M. Sweeney.

Paleosols in Loess and Studies of Paleoclimate

Loess is considered to be one of the better terrestrial proxies for reconstructing paleoclimate for the Quaternary Period (the last 2.4 million years). This is at least in part because loess deposits aggrade through time, so that the land surface rises as dust accumulates and aggradation results in the preservation of former surface soils, or paleosols.

When soil formation keeps pace with dust deposition, soil horizons such as calcic, cambic, or argillic horizons form upward over time within the

accumulating loess. In situations where loess deposition and soil formation are more or less continuous, buried soils may be indistinct and hard to recognize, because subsoil (B horizon) features are superimposed on topsoil (A horizon) features. 'Welded soils' occur where increments of loess are insufficiently thick to separate episodes of soil development completely, resulting in partial overlap of soil horizons and modification of the properties of buried soils. Only where episodes of dust deposition are episodic and new loess layers are thicker than typical soil profiles are buried soils with distinct A–B–C horizon sequences likely to be preserved.

There are several properties of paleosols that can provide clues to past climates including soil morphology, stable isotopes in pedogenic carbonates and soil organic matter, magnetic susceptibility, preservation of plant opal phytoliths, and plant pollen (Figure 6).

The formation of a soil in loess itself is very informative, as it implies a period of relative landscape stability and decreased dust deposition. Specific soil features can be key indicators of past climates. For example, calcic (Bk), petrocalcic (Bkm), or duripan (Bqm) horizons suggest arid climates, whereas argillic (Bt) horizons may indicate higher precipitation that drove clay illuviation processes, and redoximorphic features suggest changing soil moisture conditions with periodic anaerobism. (*See* **Morphology**.) Platy soil structure may be indicative of freezing conditions. Faunal fabrics formed by burrowing organisms have also provided clues to past ecological conditions. Palouse paleosols often contain horizons rich in cylindrical peds that have been interpreted as burrows formed by cicada nymphs, whereas surface soils at the same sites lack burrows. Recent studies have shown that cicadas reached maximum numbers in association with a periglacial *Artemisia* (sagebrush) shrub steppe. The cicada-burrowed horizons, along with evidence from phytolith assemblages, suggest that these paleosols formed under cold, arid, full-glacial climates. Cicada-burrowed, late-glacial paleosols abruptly grade upward into worm-burrowed horizons of the modern surface soil associated with perennial grass-steppe vegetation and moister, warmer interglacial climates.

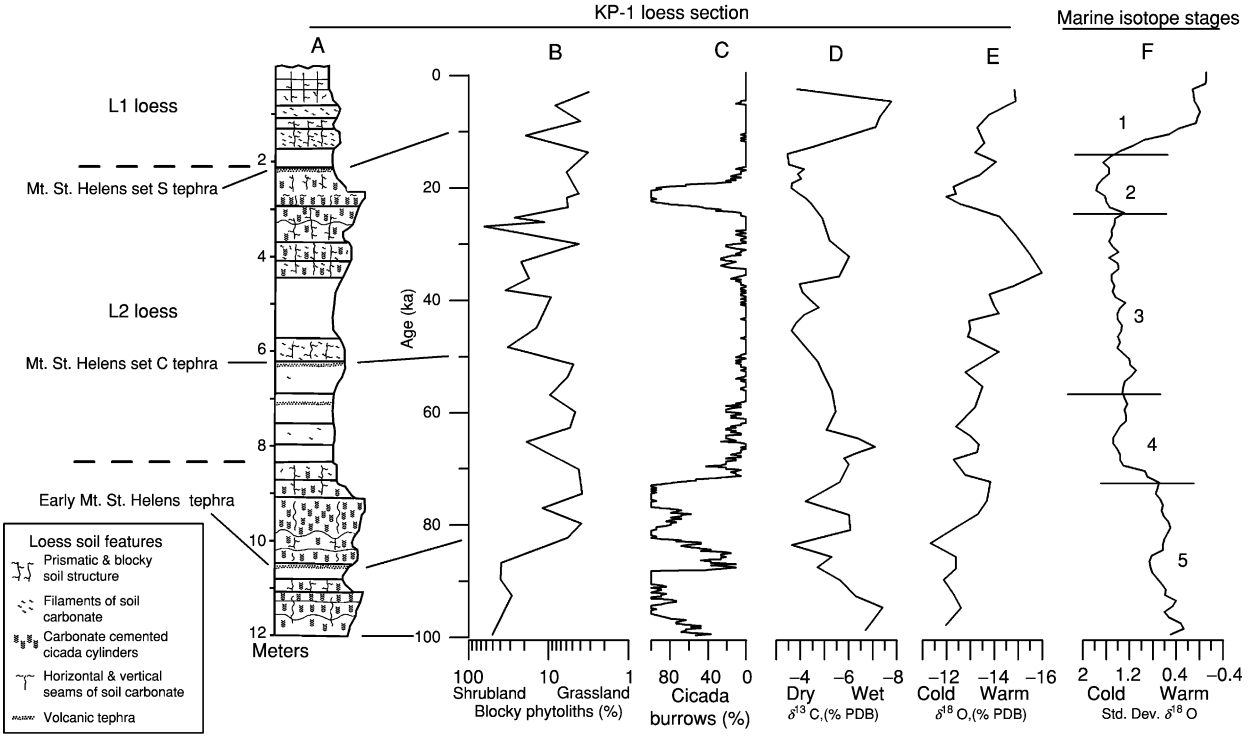

Figure 6 KP-1 loess (Palouse loess, US PNW) stratigraphy and paleoclimate proxies. A, loess stratigraphy and features of buried soils. Age–depth model of loess was derived from luminescence age dating. B, relative percentage of shrub (arid *Artemisia*) versus grass (moist perennial grasses) cover through time based on phytoliths preserved in the loess. D and E, change of carbon and oxygen isotopes (respectively) extracted from pedogenic carbonate. Palouse vegetation is approx. 100% C3 type. Carbon isotope signature is a proxy for paleowetness. Oxygen isotope signature is a proxy for paleotemperature. F, oxygen isotope curve obtained from marine sediments, separated into major isotope stages, with odd numbers representing interglacials and even numbers representing glacials. Cold and arid periglacial conditions in the Palouse indicated by relatively high abundance of shrubland phytoliths, cicada burrows, and positive isotopic signatures. Adapted with permission from Blinnikov M, Busacca A, and Whitlock C (2001) A new 100 000-year phytolith record from the Columbia Basin, Washington, USA. In: Meunier JD and Colin F (eds) *Phytoliths: Applications in Earth Sciences and Human History*, pp. 27–55. Lisse, The Netherlands: AA Balkema. © A.A.Balkema.

Carbon isotopes extracted from soil carbonate have been used as a proxy for temperature and moisture conditions. The isotopic signature can indicate the proportion of plants using the C_3 or C_4 metabolic pathway or, as in the example in **Figure 6**, signal changes in soil respiration rate in a C_3 plant community resulting from changes in precipitation. Oxygen isotopes also retrieved from soil carbonates and soil organic matter may provide information on paleotemperatures. Caution must be advised when interpreting carbon and oxygen isotope data from soil carbonates unless one can assess the possibility of atmospheric, groundwater, or other sources of contamination.

Magnetic susceptibility (MS) has been an important tool in correlating loess-paleosol sequences to deep-sea oxygen isotope records of paleoclimate. During soil formation, magnetic particles can concentrate via dust fall or due to the production of magnetite and maghemite via pedogenic processes, resulting in higher MS signals in paleosols than in unaltered loess. The depth function of MS in long loess-paleosol sequences in China in some cases matches strikingly well with paleoclimate records from deep-sea sediment cores.

Loess is generally too oxidizing for the preservation of plant matter, including pollen, but in some cases pollen analysis has been utilized. Phytoliths composed of opaline silica are formed in plant cells and are preserved in loess paleosols after the plants decay, providing a local, accurate assessment of past plant assemblages. Distinctive shapes can in some cases allow the identification of different genera of grasses, unlike pollen analysis. Phytolith analysis has been demonstrated as an important tool to reconstruct paleoclimate in the Palouse loess (**Figure 6**), New Zealand, and the Great Plains. Local assemblages can be compared with other local or regional proxy records of plant communities.

Surface Soils in Loess

European workers have repeatedly emphasized that loess is more than a sedimentary deposit; that its properties are a result of pedogenic weathering processes that impart porosity, unique structure, tawny color, and that reorganize calcium carbonates.

Large areas of loess soils such as the US Great Plains, Kazakstan, and the Ukraine, are in semiarid climates that supported grass-steppe vegetation prior to agricultural development. As a result, loess soils are dominated by the Mollisol soil order (US Soil Taxonomy System). (*See* **Civilization, Role of Soils**.) Where loess has accumulated in a forest setting or where hardwood or mixed forests succeeded on to loess areas after dust deposition ceased, gray moderately leached Alfisols with a clay-enriched argillic subsoil horizon are common. Soils formed in loess of true desert climates produce Aridisols with pale topsoil horizons and subsoil calcic horizons at shallow depth.

Historically it has been observed that loessial soils are very productive compared with soils formed in other parent materials. This is because silty soils provide high porosity and high water-holding capacity, which affords good aeration and high levels of plant-available water, relative ease of root penetration, and a stone-free seedbed. In comparison, sandier soils retain less moisture, and clayey soils retain more total moisture but have less plant-available water than loessial soils. Clayey soils pose additional problems, including limited depth of rooting and excessive wetness. High native fertility of loess soils is most notable in Mollisols, where nitrogen (N) is supplied by the mineralization of humus in the early years of cultivation; however, this must be supplemented by fertilizer N for continued high yields of cereal crops. Soil organic matter in loessial agricultural soils in the PNW US is less than half of native levels because of increased mineralization rates due to annual tillage and because of tillage erosion and water erosion. Loss of organic matter can lead to poor soil structure and increased soil crusting, which in turn can reduce seedling emergence and increase water erosion.

Environmental Concerns

Wind and water erosion have significantly degraded loessial soils worldwide. Erosion results in the loss of topsoil and soil nutrients, which have negative effects on productivity. Eroded soil materials can seriously degrade off-farm surface water, groundwater, and air quality. The North American Great Plains suffered severe wind erosion during the 'dust bowl' drought years of the mid-1930s that resulted in huge economic losses. In the Palouse area of the PNW US, wind erosion of agricultural fields has resulted in a 10-fold increase in atmospheric dust since the late 1800s. As of 2003, wind erosion from agricultural fields is a major producer of particulate matter less than 10 μm in size (PM_{10}), which poses significant heath risks to people of the region. Farmers have attempted to decrease wind erosion on fallow fields by leaving stubble, which increases surface roughness, and by the implementation of annual cropping. (*See* **Windbreaks and Shelterbelts**.) Loessial soils that are most prone to wind erosion are those with less than 1% soil organic matter content and less than 10% clay content.

Water erosion is a serious problem in loessial soils. Soil loss of up to 450 tonnes ha^{-1} per year has been

recorded in autumn-planted winter wheat, where surface protection from rainsplash is minimal over winter. The erosion hazard can be increased by surface crusting and by frozen soils. Surface crusting occurs during rainfall, when raindrop impact detaches particles from soil aggregates and orients platy minerals such as micas. Crusting inhibits infiltration and encourages overland flow of water, which enhances erosion. Frozen soil similarly inhibits or prevents infiltration of rainwater. Snowmelt on frozen loessial soils may cause liquefaction of the thawed surface layer. (*See* **Crusts:** Structural.)

Unweathered loess has high porosity of 40–55% that decreases during pedogenesis due to translocation of particles, precipitation of minerals, and collapse of pores. Dry loess can form vertical walls several meters high, because it has open microfabric, cohesion that may be attributed to cementation of particles by carbonate, clay bridges between silt particles, preferential grain orientation, or attractive forces between small particles. Loading may result in the collapse of open pores, and frequent wetting may wash clay bridges from the silt particles, allowing failure of loess. Subsurface water flow results in piping, and the excavation of these pipes through time may result in collapse. Thick loess in humid regions is typically deeply gullied with high, steep walls. Tensile fractures may be common and can result in failure. Large landslides triggered by seismic activity have been documented in the thick Chinese loess.

Dust Additions to Other Soils

In places where dust accumulation rates are not large enough to result in loess deposits, dust additions still may be of great importance to soil fertility. Dust additions to soils were originally recognized by the presence of minerals such as quartz in places where the bedrock such as basalt contained none. Terra Rossa soils on limestones have been argued to form by very slow dust accretion over eons rather than by residual enrichment of noncarbonate minerals in the limestone. Large dust plumes from Asia and Africa have been well documented to travel in the upper atmosphere around the globe and deposit thousands of kilometers from their source areas. Far-traveled Asian dust is a major contributor to soils in Japan, Korea, and Hawaii and has traveled as far as North America. The same can be said of Saharan dust, which contributes to soils of the Canary Islands and southern Europe. Saharan dust plumes also make their way to South and North America.

Biogeochemical studies of ecosystem development have shown that, in areas of highly weathered soils, productivity is sustained by the deposition of exotic mineral dust, which can supply critically limiting nutrients such as phosphorus and potassium. Rainforest soils of the Amazon in South America include highly weathered Ultisols and Oxisols. These old soils can no longer provide nutrients from weathering of parent material, yet they sustain a diverse ecosystem. It has been shown that African dust is a significant source of nutrients to the Amazon Basin. A similar situation exists for old, weathered tropical soils of Hawaii, which receive an influx of nutrients from Asian dust. Dust has been shown to be a major source of N and P and organic matter in soils of Australia and Israel. Soluble salts in dust may have an impact on soil pH.

On a geologic time scale, additions of calcium carbonate and silica from dust greatly aid the formation of duripans and petrocalcic horizons (cemented horizons of silica and calcium carbonate, respectively). (*See* **Dryland Farming; Productivity; Remote Sensing:** Organic Matter; **Sand Dunes**.)

List of Technical Nomenclature

Alfisol	A soil order in the US system of soil classification; a mineral soil, generally forested, that has a light-colored surface horizon and clay-enriched subsurface horizon that is not highly depleted in plant nutrients
Argillic horizon	A subsurface mineral soil horizon characterized by the illuvial accumulation of clays; a subsurface horizon of clay enrichment by the downward movement of clays
Aridisol	A soil order of the US system of soil classification; a mineral soil that formed in a desertic climate and that has some development of soil horizons, often a calcic or duripan horizon
Biogeochemical	In reference to systems influenced by a combination of biological, chemical, and geological processes
Calcic horizon	A subsurface mineral soil horizon characterized by enrichment in calcium carbonate, often by the downward movement of ions with precipitation of the carbonate in a lower horizon
Cambic horizon	A subsurface mineral soil horizon characterized by the alteration or removal of mineral materials as indicated by mottling or gray colors, or by more intense or redder colors than the parent material from which the soil formed, or by the removal of carbonates

Duripan A subsurface mineral soil horizon cemented by illuvial silica; a type of hardpan

Eolian In reference to entrainment, transport, and deposition of sedimentary particles by the wind

Greda A European term for a linear topographic ridge in a loess-covered landscape

Holocene An epoch of the Quaternary period beginning at the end of the ice ages approximately 10 000 years ago and extending to the present day

Horizon A layer of soil, usually parallel to the land surface, with a distinctive set of physical, chemical, and biological properties and differentiable from horizons above or below it by differences in appearance and properties

Illuviation A soil-forming process involving the movement of soluble or particulate soil materials from one horizon downward into another horizon (cf. argillic horizon, calcic horizon)

Luminescence dating A radiometric age-dating technique that measures the time elapsed since a mineral grain was last exposed to sunlight. Most often applied to age-dating a sample of eolian sediment

Magnetic susceptibility The ratio of induced magnetization to the strength of the magnetic field causing the magnetization

Micromorphology The study of undisturbed soil samples by light microscopy from specially prepared microscope slides, called thin sections

Mollisol A soil order of the US system of soil classification; a mineral soil that has a dark-colored humus-rich surface horizon and one of several kinds of subsurface horizons

Oxisol A soil order of the US system of soil classification; a mineral soil that has an oxic horizon, which is highly weathered, infertile, and is highly enriched in kaolin clays or in iron and aluminum oxide minerals

Paleoclimate Referring to climate conditions of times prior to today

Paleosol A buried soil profile formed in an environment of the past or a surface soil that has undergone weathering during several climatic episodes

Pedogenesis The physical, chemical, and biological processes of soil formation

Petrocalcic horizon A subsurface mineral soil horizon characterized by cementation by calcium carbonate

Phytolith Microscopic structures of opaline silica formed within the tissues of living plant. Phytoliths extracted from soils or sediments are sometimes used like fossil pollen to infer vegetation or climates of the past

Pleistocene An epoch of the Quaternary period that began approximately 2.4 million years ago and ended approximately 12 000 years ago. A time period corresponding to the ice ages

Porosity The ratio of the volume of void or pore space to the total volume of a rock or sediment

Quaternary A period within the Cenozoic era consisting of the Pleisocene and Holocene epochs

Saltation The transport of sand-sized sediment particles in which grains are moved by wind in a series of short leaps or bounces

Stable isotopes One of two or more species of the same nonradiogenic chemical element having the same number of protons but differing in the number of neutrons. The isotopes of an element have slightly different physical and chemical properties owing to their mass differences

Strata Layers of sedimentary rock

Suspension The transport of generally silt-sized and finer sediment particles in air whose velocity or turbulence allows the particle to remain for a time aloft

Tephra Any rock materials ejected from a volcano and transported through the air, including pumice and ash

Ultisol A soil order of the US system of soil classification; a mineral soil that has a clay-enriched subsurface horizon that is highly depleted in plant nutrients

Welded soil Two or more soils of different ages in a depositional sedimentary system that are superimposed on one another and partially overlap

LOWDERMILK, WALTER CLAY

J D Helms, USDA Natural Resources Conservation Service, Washington, DC, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Walter Clay Lowdermilk (Figure 1) often described his profession as "reading the records which farmers, nations, and civilizations have written in the land." While others have belonged to this profession, certainly few had the inclination, ability, and opportunity to indulge in it, as did Lowdermilk. The profession required expertise in many fields of study, but as practiced by Lowdermilk it was not a purely academic exercise. Rather, he sought an ambitious objective – a permanent agriculture for the world. He had begun his career researching the basic processes of erosion and runoff, especially as influenced by humans. Lowdermilk became a member of the early-twentieth-century conservation movement in the USA, a movement with a strong scientific bent. Its scientists held that treatment of natural resources should be in accordance with scientific principles, not propelled by emotionalism or untested theories. A leader in organizing government conservation agencies in the USA and abroad, Lowdermilk put research findings into action. He enunciated plans for agricultural development in *Palestine, Land of Promise*. Later, he worked in Israel to write the plans on to the face of the countryside. As an author he spoke for the conservation

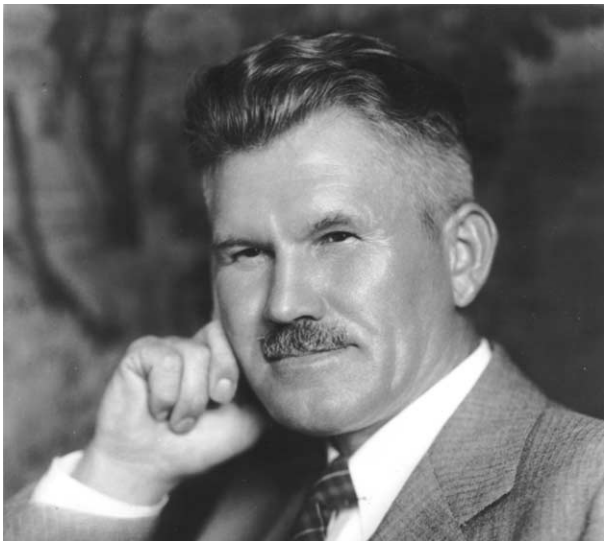

Figure 1 Walter Clay Lowdermilk.

movement, and in his international work served as a humanitarian by furthering conservation and the proper use of land to make and keep it productive.

Lowdermilk, Walter Clay (1 July 1888 to 6 May 1974), soil scientist, geologist, soil conservation leader, and author, was born in Liberty, North Carolina, the son of Henry Clay Lowdermilk, a businessman, lumberman, and rancher, and Helen Vashti Lawrence Lowdermilk. The family moved westward to Missouri, to Oklahoma, and finally to Arizona. Walter Lowdermilk graduated from the Park College Academy in Parkville, Missouri, in 1906 and then attended Park College (1908–10). In 1910 he enrolled at the University of Arizona; after 2 years there he won a Rhodes Scholarship to Oxford University, where he earned a BS degree in forestry (1914); a BA degree in geology (1915); and an MA degree, granted *in absentia* (1922). While at Oxford he had an opportunity to study forestry in Germany. He also served on Herbert Hoover's Commission for Relief in Belgium (1914–15). After the scholarship years, he returned to the USA as a ranger in the Southwest for the Forest Service. During World War I, he returned to Europe as timber acquisitions officer and then measured timber for assessing war-time damages. Returning from World War I, he became the Forest Service's regional research officer in Montana.

A man who enjoyed research work, he had found a position that offered satisfaction. Given his ability, there was opportunity for advancement. But he was not to remain on that career ladder. Soon he would be in China, where, he later recalled, the significance of soil erosion was burned into his consciousness. Through the years in England and afterward, the young forester had corresponded with Miss Inez Marks, a friend from Arizona. On leave from her missionary work with the Methodist Church in China, she agreed to meet him at the Rose Bowl, New Year's Day, 1922. Marriage plans quickly followed. Her entreaties that China desperately needed talented scientists led to his applying for a position with the University of Nanking's school of agriculture and forestry. The couple married in August and departed for China in September 1922. Lowdermilk's charge, for a small salary, was to assist in solving the flooding problems and resulting famines. Exactly how a forester was to help with food production remained a mystery as he attended university classes to learn Mandarin during the first year.

An expedition to the Yellow River solved the mystery. There he stood atop a section of the 650-km-long dike that held the river 12–15 m above the flood plain. This marvel was a result of Chinese labor necessitated by silting of the river's channel – 'aggradation' in the terms of earth scientists. Lowdermilk set out to find the source of the silt. In spring 1924, O.J. Todd, engineer of the International Famine Relief Commission, accompanied Lowdermilk on a 3000-km trip to the watersheds of the Yellow and Wei rivers. Todd's mission was to study the Wei-Peh irrigation project. Few foreigners had visited northwest China, where the pair completed a third of the journey afoot or on mulecart or muleback. In Shensi province, they found a plateau consisting of deep, undulated deposits of loessial soils. Depth, fertility, and erodibility made these fine, wind-deposited soils prime locations for man-induced erosion. In the deforesting activities of the people, Lowdermilk found the reason for the gigantic 200-m-deep gullies. The Chinese shaved the hills clean of all herbaceous shrub and tree growth for firewood. Paradoxes abounded on the trip. Temple forests, reproduced naturally and protected by Buddhist priests, provided evidence of the denuded hills' capability for sustaining vegetation. Bench terraces festooned some slopes. Yet some of the best agricultural land on the level, alluvial plains was used for timber production under irrigation. Surrounding hills were little used for timber.

The pair visited Sianfu, the capital city of China during its Golden Age, where Todd wanted to inspect the irrigation works. The area retained little of its former prosperity, which Lowdermilk conjectured had flowed from a great irrigation project, long since silted up. The forester returned to his post at the University of Nanking with an impression of colossal erosion contrasted with evidences of former grandeur. Already he had decided to expand his study of the sciences involved with natural resources to include the actions of people as well as man's relationship to nature.

Historical research revealed that the Yellow River had changed course eight times since AD 11. Several times the river had been restrained by dikes, only to break free. Once it emerged 600 km from its former outlet. Dikes, therefore, were essential to using the plain for agriculture. But building higher dikes, Lowdermilk concluded, was not a lasting solution unless the aggradation of the river was reduced by checking the supply of silt. Lowdermilk's supposition that erosion caused frequent and severe flooding had been recognized in the USA, but only on the small water courses, not on the lower reaches of major rivers. The China experience – siltation of a major river channel as a cause of flooding and channel relocation – was on a scale unknown in the USA.

Lowdermilk's recommendation for flood control gave some indication of the breadth of his training in sciences, especially geology, and his ability to assimilate the findings into a solution. The Yellow River and its tributaries had excavated a deep channel into

the plateau created by the wind-deposited soils. Recognizing that removal of vegetation allowed runoff to carve gullies in the loessial plain and that gully wash accounted for most of the silt, he proposed attacking erosion by planting trees on the talus slopes at the foot of the gullies. The forested gullies would be guarded and managed by villages as community forests to provide wood. Undissected portions of the loessial plateau could be used for agriculture. Where and when possible, check dams should be used to raise the base level of streams and prevent incision by the gullies farther into the plateau. Treatment of the watershed was directly tied to famine prevention. He concluded that soil and water conservation were urgently necessary to increase the productivity of this region of China.

Lowdermilk was not content to base his recommendations exclusively on empirical evidence. Certainly the scientific forestry school, whence he came, demanded another explanation. Using the runoff and erosion plot method devised by F.L. Duley and M.F. Miller at the University of Missouri, he and his Chinese associates set up plots on 20 temple forests and on denuded areas for comparison. After 3 years of study, he presented the findings. Runoff from denuded areas greatly exceeded that of temple forests or areas reclaimed through reforestation. The main reason for the excess runoff, he believed, was that particles of soil on the denuded areas clogged the pores of the soil surface. Forest litter arrested this action.

Further study convinced Lowdermilk that 40–60% of the uplands in northern China had little cover to retain runoff. So great had been the rapid runoff that it had reduced evaporation and brought on a period of decreased precipitation in the area. With this argument, Lowdermilk projected a hypothesis that he would later apply to other lands. Scholars had long been presented with anomalies of twentieth-century poverty contrasted with evidences of former civilizations which possessed a high degree of culture and prosperity. Some scholars, notably Ellsworth Huntington and Baron Von Richthofen, found the answer in climatic change. In the case of north China, Lowdermilk not only saw soil erosion and flooding as the reason for decline, but also claimed their effects as the reason for a climatic change.

The communist uprising of 24 March 1927 in Nanking ended the Lowdermilks' stay in China. Leaving behind all possessions, they barely escaped. At the University of California, Lowdermilk combined study for a PhD from the School of Forestry (minors in soil science and geology) with research at the California Forest Experiment Station. Here he reentered the fray over the effects of vegetative cover on runoff, erosion, and flooding. On one of his treks in China, Lowdermilk had heard the proverb "Mountains empty – rivers gorged." He judged the application of timber management in that locale to be superior to any system he had observed in Germany. The Chinese and other civilizations had recognized the value of forest cover and acted upon their observations. Scientists in the conservation movement, however, demanded more than proverbs for proof, and the influence of forest cover on soil erosion and streamflow continued to be debated by hydrologists, engineers, and foresters.

In his study of the influence of forest litter on runoff and erosion, he used rain-making machines, soil profiles transferred to tanks, and measuring instruments of his design. In 1929, he presented the confirmation for what he and others had observed. On bared soil the raindrops splashed up muddy. As muddy water percolated into the soil profiles, suspended particles were filtered out at the soil surface. The thin layer thus formed reduced percolation and increased runoff. The water-absorbing capacity of forest litter had little influence on runoff. However, the litter filtered the water and kept the soil profile open to percolation. The experiments confirmed a hypothesis that Lowdermilk had first presented at the Third Pan-Pacific Science Congress in 1926 in Tokyo. He also proposed terms for classifying erosion. 'Accelerated erosion' arose from the 'artificial disturbance of factors which controlled the development of soil profiles.' In the absence of such disturbances, one could view any erosion as the 'geologic norm of erosion.'

As Lowdermilk was completing his dissertation, another research opportunity developed with the Forest Service in California. Partly in response to the prodding of Hugh Hammond Bennett, a US Department of Agriculture (USDA) soil scientist, Congress, in the Agricultural Appropriations Act of 1930, authorized a group of experiment stations to study erosion and runoff. Bennett supervised most of the stations from his post in the Bureau of Chemistry and Soils, but the Forest Service also received funds for stations. Lowdermilk designed the research station and program on a large, isolated watershed in southern California. The San Dimas watershed provided an excellent opportunity to test the effects of watershed management on water yield. Expanding towns and citrus orchardists at the foot of the watershed had to dig increasingly deeper wells to reach underground aquifers. Whether the vegetative mantle should be burned to reduce transpiration or protected from fire for maximum ground water supplies was a matter of controversy. To demonstrate and measure the relationship of percolation to aquifer levels, Lowdermilk

had Civilian Conservation Corps (CCC) enrollees build water-spreading structures, which led to a gravelly basin where the silt settled out and water percolated to the aquifers.

Experiments at San Dimas also contributed to a better understanding of soil genesis processes such as horizonization and the anthropogenic influence on soils in a densely populated region. CCC enrollees sifted and mixed soil, which was then placed in lysimeters. They also kept soil samples in glass containers. Soil scientist Robert C. Graham and colleagues examined the uncontaminated, glass-enclosed samples and compared them with soils in the lysimeters. Lowdermilk had read and cited the major soil scientist treatises of the day by Harry O. Buckman, Jacob S. Joffe, Jacob Lipman, Curtis F. Marbut, G.W. Robinson, and Nathaniel Southgate Shaler; but he did not specialize in topics such as soil genesis, soil mineralogy, or soil chemistry, all topics which were being pursued in the new soil science departments at land-grant universities. Rather his studies addressed the factors that prevented erosion and other soil degradation, and thus preserved the upper soil environment for agriculture.

While working on the San Dimas project, Lowdermilk was recruited to be the vice-director of a temporary New Deal agency in the Department of the Interior, the Soil Erosion Service, in October 1933. The aforementioned Hugh Hammond Bennett had been selected as Director. The news service commenced the campaign for adopting conservation practices on American farms through demonstration projects based in small watersheds. Young soil conservationists worked with farmers to develop conservation plans for the farms. The plans had to achieve both the conservation objectives as well as satisfy the farmers' needs. Enrollees in CCC camps located on the projects and Works Progress Administration workers supplied labor. Later the service expanded operations nationwide by assigning trained conservationists to work with locally organized conservation districts. An act of 27 April 1935 created the Soil Conservation Service (SCS) in the USDA and gave it continuing authorities and duties. Lowdermilk served as associate chief (Dec. 1935 to Mar. 1937), chief of the research division (Mar. 1937 to Nov. 1939), and then head soil conservationist until his retirement.

Lowdermilk contributed to organizing all facets of the new service, but he especially concentrated on the research program. USDA transferred the experiment stations established under the 1930 Agricultural Appropriations Act to SCS in 1935. The stations were already engaged in research on terracing, crop rotations, strip-cropping, tillage methods, and the value of all these to soil conservation. Lowdermilk added runoff and erosion studies. Furthermore, the demonstration projects afforded an opportunity to observe the effects of farmland conservation practices on the entire watershed. Lowdermilk was thus instrumental in the new agency's contributions to understanding small-watershed hydrology.

In 1938 chance again intervened in Lowdermilk's life; and as usual he seized the opportunity. Representative Clarence Cannon suggested that a survey of the Old World could be useful in the United States' efforts toward a permanent agriculture. The trip, August 1938 to November 1939, involved more than 25 000 miles of automobile travel in Europe, the Mediterranean area, and the Middle East. Here he perfected his art of reading the land for evidence of past use and misuse. Before undertaking surveys in each country, Lowdermilk consulted agriculturalists, scientists, and officials. Geologists and archaeologists were especially interested, and valuable to Lowdermilk in explaining the cultural and physical factors involved in land use. In addition to searching for soil conservation and flood prevention measures that might be imported to the USA, Lowdermilk was engaged in what he called 'agricultural archaeology.' Ruins of some preindustrial civilizations indicated a prosperous agriculture, although these areas now had serious resource problems. What events brought about such conditions? What were the lessons for contemporary civilizations?

Lowdermilk's land-read records of past civilizations appeared in numerous articles. Indeed, there were 'Lessons from the Old World to the Americas in land use,' as Lowdermilk titled an article in the annual report of the Smithsonian Institution. He gladly noted the cases of wise land use through centuries, but was usually obliged to find a story of deterioration. The Soil Conservation Service published a summary, *Conquest of the Land Through 7000 Years*, in 1953 and followed it with several reprintings until more than one million copies were distributed. Early on, Lowdermilk had learned the value of written communication and practiced his writing skills. Readers who know Lowdermilk only through this publication have perhaps a truncated view – that of the globe-trotting chronicler of calamities awaiting civilizations that abuse their resources. He realized that a civilization's decline could not be interpreted solely on the basis of soil erosion. However, in writing the pamphlet, he embarked on a didactic mission aimed at all Americans, not just farmers. Soil fertility was a matter of concern for the farmer. Maintaining the medium for fertility – the physical body of soil resources – concerned the

entire nation. Without it, 'liberty of choice and action' was gone.

World War II terminated the trip in Europe but it opened a new opportunity, a return to China. At the behest of the Chinese government, Lowdermilk undertook the dangerous journey to advise the Chinese about increasing their food supply. The Communist triumph in China meant the Lowdermilk's and other advisors' plans for postwar-China would not be acted upon. But the trip afforded Lowdermilk an opportunity to pursue his interest in agricultural archaeology. During the intervening years in the USA, he had continued to study the agricultural archaeology of China. While in China he bought gazetteers, local histories, which Dean R. Wickes, a Chinese-language specialist, then researched for evidences of erosion problems. This research showed that in northern China, an area with a small percentage of level land, the population had increased threefold since the mid eighteenth century. This rapid population increase sent people to the hills for firewood and arable land, without any orderly installation of engineering measures for soil conservation. Unlike areas of central and southern China, they had no elaborate bench terraces to protect farmland. The gazetteers provided accounts of clearing the slopes, removing farmland from the tax rolls as wasteland, and abandoning homes along streams due to frequent flooding.

Lowdermilk retired from the SCS on 30 June 1947, but he continued his international work, which had been fairly continuous since the 1938 trip to the Middle East. He consulted in French North Africa (1948) and in the British colonies in Africa (1949–50). In the USA he contributed to the President's Water Resources Policy Commission. Controlling erosion on the upper reaches of watersheds became a passion for Lowdermilk's generation of conservationists. They favored land cover for increased absorption and engineering works for the controlled disposal of water without erosion. The upstream reservoir on the small watersheds was an integral part of the river development – an assertion that was often contested. Proponents of the control and use of headwaters had stated their case in the publication *Little Waters and Headwaters: Control and Use*. In the late 1940s, conservationists had another opportunity when Morris Cooke, a force behind *Little Waters*, became chairman of the President's Water Resources Policy Commission. Lowdermilk assumed chairmanship of the Committee on Standards for Basic Data. The Cooke and Lowdermilk views held sway in the committee report that emphasized a comprehensive, interdisciplinary approach. The interdependence of land and water called for watershed management, which had been neglected due to "our natural endowment and relatively low population density." Furthermore, the small watershed, the unit of watershed management preferred by the authors, was a cultural unit. The watershed unit had to be small enough so that residents understood its influence on their lives. Then they would devote the time and money needed to bring it to fruition as a community watershed. Lowdermilk's experience in semiarid climates came through in the committee's attitude toward flood control. Where feasible, reservoirs should not be used solely to control floods, but also to store storm waters for later use. Following work with the US Water Resources Policy Commission (1950) and the Supreme Allied Command in Japan (1951), he worked in Israel under the auspices of the Food and Agriculture Organization of the United Nations to organize an SCS.

During the trip to the Middle East in 1938–39, Lowdermilk became inspired by the efforts of urban-born European Jews to reclaim land. Upon returning to the USA, he wrote *Palestine, Land of Promise* (1944), wherein he proposed a Jordan Valley Authority to provide power, water supply, and irrigation water. The book argued, as did his popular pamphlet *Palestine Can Take Millions* (1944), that the land there could support a much larger population. The message contravened the British and American foreign policy of the early 1940s that discouraged Jewish emigration to Palestine. After retirement from the SCS, he worked with the Israelis to implement some of the measures outlined in the book. Drawing upon his Western experience, he advocated diversion of the Jordan River water before it entered the Dead Sea. The water would be utilized for hydroelectric power and irrigation water. Many Israelis favored technical assistance for agricultural development over direct food assistance. That sentiment was concisely conveyed when Minister of Development, Mordecai Bentov, coined the saying, "We don't need powdered milk; we need Lowdermilk." While there, Lowdermilk helped establish at Haifa a school to train conservationists, a school which later bore his name. The Lowdermilk School of Agricultural Engineering emphasized the basic sciences as preparatory to agricultural studies. Students took 2 years of mathematics, chemistry, physics, geology, and biology before moving on to the agricultural sciences. A job-related project in the 5th year was necessary to earn the degree.

Lowdermilk became best known for his work in Israel, probably more so than even for his work in China, at San Dimas, or with the SCS. In a career

that has generally been lauded, recommendations for development in the future state of Israel occasioned the most criticism of his work. A progressive conservationist who came of age in the early twentieth century, he advocated what he saw as positive human intervention to correct past detrimental human actions. In the Middle East he usually discounted climatic causality for land degradation and emphasized the human element. He singled out the nomadic herders as a cause for soil erosion. In place of nomadic herding, he would substitute development of the Jordan River to supply electric power and irrigation water for intensive agriculture and regional economic development. The new state of Israel needed such development to support the immigrants, he argued. In the USA he and Mrs. Lowdermilk spoke for Israeli statehood and were counted as 'Christian Zionists.' Lowdermilk cited an area he knew well, southern California, as an analogy of economic development brought on by the combination of hydroelectric power and irrigation water. While he was careful to say that Arabs would also benefit from economic development, none the less such arguments could be seen as antithetical to Arab interests. During recent decades environmentalism and the study of environmental history have generally looked with some disfavor on the progressive conservationists' merging of conservation with economic development. Some favor indigenous, less-intensive systems such as nomadic grazing as more appropriate.

Lowdermilk received many professional honors. He was a fellow and president of the American Geophysical Union (1941–44) and a fellow of the Society of American Foresters and of the Soil Conservation Society of America. The Lowdermilks had two children, William Francis and Winifred Esther. In retirement the Lowdermilks had a home in the Berkeley hills, California. Walter Lowdermilk died in Palo Alto, California in 1974, having spent his last years at the Veterans Hospital there.

LYSIMETRY

T A Howell, USDA Agricultural Research Service, Bushland, TX, USA

Published by Elsevier Ltd.

Introduction

Lysimeters are standard instruments used in hydrology and water-quality research. In particular, they are used to measure percolation beneath the vegetation root zone and water use through evaporative processes from vegetation. (*See* **Evaporation of Water from Bare Soil; Evapotranspiration**.) They can also measure 'net' additions to the soil from precipitation or irrigation. When used to measure percolation, they become *in situ* water-quality sampling instruments. (*See* **Drainage, Surface and Subsurface; Leaching Processes; Macropores and Macropore Flow, Kinematic Wave Approach; Salination Processes; Salinity:** Management; **Solute Transport; Vadose Zone:** Hydrologic Processes.)

The word 'lysimeter' is derived from the Greek roots 'lysis,' which means dissolution or movement, and 'metron,' which means to measure. The standard definition of a lysimeter is: a device for measuring the percolation of water through soils and for determining the soluble constituents removed in drainage; so clearly the *lysimeter* is a soil physics and hydrologic measurement tool. It defines the water flux at some arbitrary boundary beneath the soil surface so that water balance can be measured or a water sample extracted that represents the naturally percolated chemical constituents. As a water-balance measurement device, lysimeters are used to determine evaporation from the soil–plant system, commonly called evapotranspiration (ET), and/or the latent heat flux in a surface energy balance.

History

Lysimeters are reported to have been used in the Netherlands in the early seventeenth century and in France later in the seventeenth century. Most of these reported studies were focused on measuring crop water use. Lysimetry for determining water use from vegetation has advanced through better knowledge of soil physics of water flow, soil hydraulic and thermal processes, plant root water uptake, and micrometeorologic influences from advection and aerodynamic processes (fetch related).

Lysimeters can be used in a laboratory, greenhouse, environment chamber, or situated in the natural outdoor environment. When used to simulate natural outdoor environments, design details and site selection are critical, together with management, so the vegetation within the lysimeter duplicates the surrounding vegetation. In practical terms, a well-managed lysimeter is indistinguishable from its surroundings. When used in greenhouse, laboratories, or environmental chambers, lysimeters are more 'relative' than 'absolute' measurement devices. The physical and chemical characteristics of the lysimeter soil should duplicate the natural states under study.

Construction materials and drainage methods are critical in lysimetry used to determine soil-water chemical transport or solute fluxes. Care is exercised to select design materials that will not react with or absorb any of the chemicals that are of interest.

There is not a standard for lysimeters that can be followed to construct either a lysimeter for measuring chemical transport or for measuring water evaporation from soils or vegetation. However, one principle has emerged to guide design considerations, which is that the lysimeter must be representative of the conditions desired to be measured. If the lysimeter design, construction, and its operation cannot permit the vegetation or soil condition within the lysimeter to duplicate or accurately represent the environment under study, then reliable measurements of neither the evaporative processes nor the soil-water chemical transport processes can be expected.

Lysimeter Types

Lysimeters are foremost devices, typically tanks or containers, that define a specific boundary to contain soil water and permit measurement of either the soil-water balance or the volume of water percolating vertically and/or its quality. Lysimeters can be broadly defined as percolation lysimeters (sometimes called drainage lysimeters) or weighing lysimeters (Figure 1). Both can serve the purposes of determining the soil-water balance, the vertical percolation flux

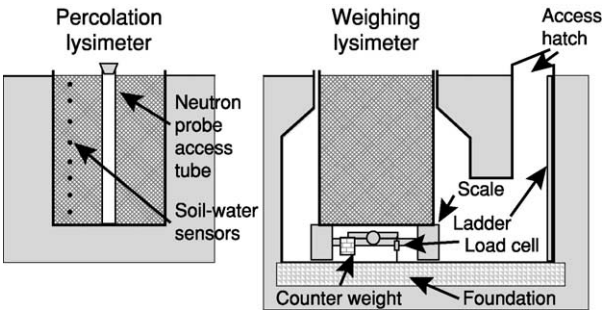

Figure 1 Schematic drawings of a percolation (drainage) lysimeter and a weighing lysimeter (not to scale).

(drainage), and the chemistry of the percolating water.

Percolation lysimeters may be installed to determine simply the vertical soil-water flux (drainage) or the chemical movement within the soil at a defined boundary. Soil-water solution sampling lysimeters can be simple porous devices that can extract soil water under a vacuum or access wells to permit water sampling from beneath a free water surface (i.e., water table). Percolation and weighing lysimeters differ in their measurement methods to determine the vegetation water use and/or soil-water evaporation. Percolation lysimeters must be used with a soil-water profile measurement method (*See* **Neutron Scattering; Tensiometry; Time-Domain Reflectometry**) to estimate 'indirectly' the water use in evaporative processes. Weighing lysimeters permit the mass or volumetric soil-water content change to be determined by weighing the lysimeter and determining its mass change over time. Weighing lysimeters, thus, can determine the 'net' infiltration from rainfall or irrigation and the amount of evaporation between wetting events. If properly designed, weighing lysimeters can coincidently measure the drainage rate as well as the evaporation rate. Percolation-lysimeter accuracy of the evaporative water balance is directly related to the precision of the soil-water measurement and its integration through the vegetation root zone. Weighing-lysimeter precision depends on many factors, the main ones being scale resolution, counterbalancing, and area-to-volume ratio.

Lysimeter Water Balance

The water balance of a lysimeter is given as:

$$\theta_i = \theta_{i-1} + P_{i_i} + I_i - D_i - ET_i \qquad [1]$$

where: θ_i is the lysimeter water volume per unit lysimeter area, in millimeters, at time i; P_i is precipitation, in millimeters; in I_i is irrigation, in millimeters; D_i is drainage from the lysimeter, in millimeters; and ET_i is evaporative loss (evapotranspiration) from the lysimeter, in millimeters, all during the time interval $i-1$ to i. Typically, lysimeters have a rim height of 10–40 mm above the soil surface to prevent runoff and runon. Some lysimeters used in hydrology are equipped with tanks to capture volumetrically runoff above a specified depth of surface storage. If runoff does not occur from the lysimeter, the lysimeter 'freeboard' may increase rainfall or irrigation capture, thereby increasing water available for evaporation or adding to lysimeter percolation volumes. Generally, P and I are measured separately using various methods (i.e., rain gauges, flowmeters, etc.), while D can be measured volumetrically as drainage occurs from the lysimeter.

Although water can move upward, most lysimeters are not equipped to measure or add water to simulate upward water fluxes. Some lysimeters use a static or dynamic water table to mimic field water conditions, and these lysimeters are usually equipped to measure the water additions needed to maintain the water table depth, or raise the water table, or measure the drainage water volume when the water table is lowered. Most percolation lysimeters use manual vacuum pumping or volumetric collection to measure drainage. Some weighing lysimeters that have greater belowground access have used tipping-bucket devices or tanks suspended from load cells from the lysimeter itself to measure drainage rates or volumes.

The main difference between percolation and weighing lysimeters is that weighing lysimeters measure the mass of the lysimeter (in megagrams or kilograms), and this mass change is then converted, taking into account the lysimeter area (meters squared) and the density of water (typically assumed to be $1\,Mg\,m^{-3}$; note: $1\,kg\,m^{-2} = 1\,mm$ assuming a water density of $1\,Mg\,m^{-3}$), to determine θ_i. Assuming no drainage, precipitation, or irrigation during the measurement time period ($ET_i = \theta_i - \theta_{i-1}$), the lysimeter mass measurement precision is a direct ratio of the lysimeter area (i.e., $1\,kg\,m^2$ per millimeter), while the soil volumetric measurement precision is much greater (i.e., $0.001\,m^3\,m^{-3}$ per millimeter). Therefore extremely high soil-water measurement precision is required to determine ET accurately for time periods of a single to a few days. Weighing lysimeters with proper design and electronic measurements can achieve equivalent accuracies for a day without counterbalancing. With counterbalancing of the soil 'dead' mass, excellent ET measurement precision has been obtained for time periods from 15 min to 1 h with typical weighing lysimeters. Weighing lysimeter mass measurement precisions have been noted to decline as wind speeds exceed approximately $3\,m\,s^{-1}$ due to wind load imposed on the lysimeter. Under very windy conditions, longer mass integration intervals may be necessary or numerical smoothing can be used.

Lysimeter Design Considerations

Experimental purpose is the principal consideration in lysimeter design. If the lysimeter facility is intended to represent natural outdoor environmental conditions, then siting becomes a most critical consideration. The site should represent the soil and plant conditions desired. Surrounding conditions, for perhaps up to a kilometer or more, can certainly impact

the use of water by a crop, especially for taller crops. It is important to be aware that in many cases these surrounding areas may not be directly controlled by the investigators using the lysimeters, and features and land use of surrounding land areas can change rapidly, compromising the lysimeter facility. Siting needs to include considerations for adequate surrounding fetch (similar cropped distance usually expressed in the direction of the predominant wind direction), utility access (telephone, electrical power, and sometimes water), and foot-traffic access for maintenance. Fetch needs vary with the research purpose and site conditions, but easily extend from 100 to 200 m. Utility access needs vary if alternate current (AC) power is required or if a telephone modem is used for data transfer. Most current lysimeter data loggers are battery-powered and some use an AC power backup for the batteries. Although analog telephone lines and modems are commonly used for data transfer, cellular telephones are becoming more common, as well as other wireless network technology. All lysimeters require repeated, periodic site visits for maintenance and measurements. Care must be taken to avoid crop damage and 'path' creation that might affect the lysimeter microclimate.

Lysimeter Shape and Area

Percolation and weighing lysimeter shapes are typically circular, square, or rectangular. Cylindrical tanks are inherently stronger per unit wall thickness than square or rectangular tanks, owing to their greater hoop strength. However, circular lysimeters can cause inaccuracies, depending on the vegetation type, especially for row crops with wide row spacing.

Figure 2 shows several typical lysimeter tank surface configurations. An important consideration is the lysimeter surface area. Obviously, larger sizes are desired, but they are constrained by capital resources as well as physical ones. Lysimeter areas in use vary considerably from less than 1 to 30 m^2 or greater. Two principles guide the selection of the appropriate area: (1) soil pedological considerations (size needed to duplicate saturated hydraulic conductivity of natural soil; i.e., macropores and soil cracks); and (2) the unit area of vegetation that might be considered as a minimum representative sample. The soil-pedology factor is particularly important for more structured, heavy vertisols and mollisols that have a high level of shrink–swell and structural cracking. The vegetation-area factor is particularly important in terms of matching the row spacing of crops or the size of the area needed to capture the natural variation in native species. This area is linked to the balance of the evaporative processes for soil water (E) and plant transpiration (T). For closely seeded crops (alfalfa, small grains, grasses, etc.) or selected forestry or native brush species, circular shapes are adequate; but for agronomic crops or horticultural crops (trees, vines, or vegetables) grown in rows, a square or rectangular shape is desirable. Figure 2 shows the 'equivalent' surface area of small, circular lysimeters, which introduces an uncertainty in knowing exactly the 'effective area' of the lysimeter. The square area of the row or multiple rows through the lysimeter (see the dashed lines in Figure 2) represents the sunlight-absorption area of the crop. The E and T components of a circular shape are constrained by the lysimeter surface area. For larger circular lysimeters with many rows, the lysimeter diameter can depart from an even multiple of the row spacing without a large bias on the balance of E and T and not affect the measured ET accuracy. However, for smaller circular lysimeters with a single row or even two rows, it is difficult to avoid biasing the ET accuracy by unbalancing the E and T components of crop water use if the lysimeter diameter is not larger than the row spacing (i.e., for a single row, row spacing is less than lysimeter diameter, which is less than 1.8 × row spacing; for a single row, this is $D_l = \pi^{-1/2} W$, where W is row spacing (in meters) and D_l is lysimeter diameter (in meters)).

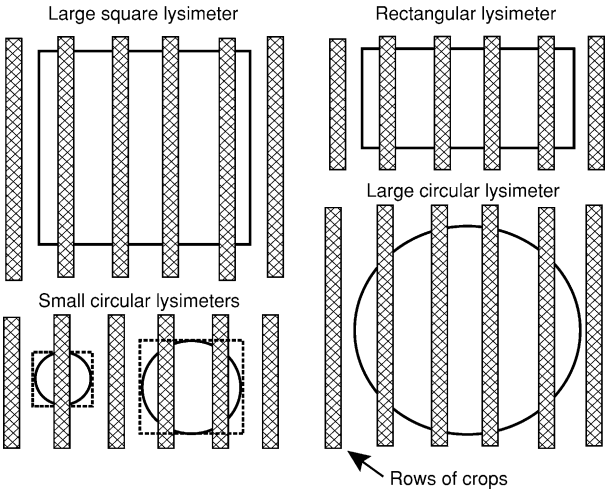

Figure 2 Lysimeter shapes for large and small lysimeters. The dashed lines represent the 'equivalent' area of sunlight interception for the smaller circular lysimeters.

An often unreported factor for interpreting lysimeter water balances has been the lysimeter effective area. For percolation lysimeters and some weighing lysimeters, the area considerations discussed above are important. Most percolation lysimeters have a single wall (Figure 1), so the effective area is assumed to match the inside tank area (i.e., π $(D_l^2/4)$ for a circular lysimeter and L_l^2 or $L_l \times W_l$ for a square or rectangular lysimeter tank, where L_l and W_l are the

lysimeter length and width, respectively, for a square and rectangular design). For a weighing lysimeter, which has two walls (the inner tank and outer tank walls) and an air gap (see Figure 1), the effective area for evaporation is computed for the 'midgap' dimensions. This midgap and wall area might represent approximately 5–10%, or even greater in some cases, of the lysimeter tank inner area. So the measured change in mass is adjusted downward for this area over which the outside and inside vegetation are assumed to be equal. Some hydrologic weighing lysimeters have used precisely beveled upper gap covers to capture the precipitation on the lysimeter correctly.

Lysimeter Depth

The depth of a lysimeter is an important design consideration; greater depths increase construction and installation problems. The basic consideration is to duplicate adequately the field rooting depth for the species being studied. Additionally, lysimeter depth has been shown to affect the lysimeter water-holding capacity and the soil-water flux through the profile. If the lysimeter depth is less than 1.5–2 m, vacuum drainage is required to mimic natural soil-water pressure potentials. If a water table is used to match field conditions and/or to simulate high water tables, care must be exercised in selecting the desired lysimeter depth. Few lysimeter designs have used depths greater than 2.5–2.7 m; but several newer lysimeters (one in China) are 5 m in depth, while some in Arizona in the western USA are 4 m in depth. For weighing lysimeters, greater depth (volume per unit area) necessitates counterbalancing a large fraction of the soil and tank mass to achieve high precision in the ET measurements.

Soil Profile Characteristics

The lysimeter soil profile should match or duplicate the site characteristics so that vegetative growth and water use will be representative of the site and experimental purposes. Both soil monoliths and repacked (reconstructed) soil profiles are used. Under 'well-irrigated' cropping situations, a repacked soil lysimeter column is often adequate. Exact physical, chemical, and/or vegetation characteristics of a soil can only be preserved in many cases by using a soil monolith. Naturally occurring soil spatial heterogeneity (both vertically and horizontally) can affect soil hydraulics, chemical composition, and thermal processes. In many lysimeters, repacked soil profiles have been successfully used for coarsetextured soils and finetextured soils that do not have significant profile stratification. Larger soil monoliths are more difficult to obtain and often require heavy industrial-type equipment (cranes, backhoes, coring equipment, etc.), but the time required to obtain a representative-sized monolith (approximately 5–15 m^3) must not exceed the time or labor needed to repack the same soil volume. Also, an intact soil monolith is ready for research applications almost instantly following collection, while repacked soil columns might take several years to duplicate the natural soil state for research with restricted irrigation (i.e., rain-fed or dryland applications). Figure 3 shows a lysimeter being repacked.

Figure 3 Technician installing soil-water sensors in a repacked lysimeter near Five Points, California. The lysimeter is a 2-m square (4 m^2). (Photo courtesy of USDA–ARS, Water Management Research Laboratory, Parlier, California, USA.)

Soil monolith collection Large soil monoliths are usually collected by coring, encasing, or compositing several smaller monoliths together. In the coring method, an open-ended tank (usually steel) is pushed into the soil using static weights or pulled into the soil using an anchor secured to the earth and various hydraulic or manual jacking methods. The tank's leading edge may be beveled to facilitate soil shearing while reducing internal compression on the monolith. In most cases, coring requires outside excavation as the monolith tank is lowered to reduce outside soil friction and to reduce the shearing forces. Soil monolith tanks that are square or rectangular are supported on the outside of the tank walls, while similar tanks that are repacked can be structurally supported by the floor and internal gussets as well as horizontal wall supports. Circular monolith tanks require simpler hoop-bracing. Figure 4 shows a square soil monolith prior to being pressed into the soil using four anchors to earth piers using a manually operated, hydraulic jacking assembly (shown on top of the lysimeter tank). This hydraulic lowering process allows precise control of installation speed in contrast to adding static 'dead' weights. The hydraulic installation

Figure 4 A monolith soil tank (1.5 m square and 2.3 m in depth) ready for insertion at Bushland, Texas. The hydraulic rams are located on the top corners and offset to permit a backhoe to excavate along the outside of the tank as it is pressed into the soil against the anchors secured into concrete piers. (Photo courtesy of USDA–ARS, Conservation and Production Research Laboratory, Bushland, Texas.)

procedure using rams or jacks avoids any erratic, jerky loading such as those that can occur when static weights are added.

Soil monoliths have been obtained in structured soils by carefully trimming a soil pedestal and gradually pressing a container tank over the soil pedestal while trimming the leading edge or using expandable foam (care has to be used in material selection as some materials react with or leach chemicals into the soil) to seal the soil pedestal against the tank walls. In encasing, a trimmed soil pedestal is carefully fitted with sections that can later be sealed to form the tank. In some encasings, pylon-like sheets are driven into the soil and welded or sealed together after excavating around the soil monolith.

In both coring and encasing methods, the soil monolith is undercut and lifted before a drainage system and tank bottom is installed. Undercutting methods are varied, too, including forcing shear plates under the monolith, boring holes and using 75- to 100-mm pipes, and driving steel rods or structural steel (angle iron, channel iron-type cross sections) to support the monolith during lifting. The boring method works best with more structured subsoils, while plates may be required for coarse sand or gravel subsoils. Monoliths may be desirable in certain situations to preserve natural soil-profile layering that cannot be reconstructed; but they are primarily soil samples with unique heterogeneities inherent in the spatial soil variability at the site. If soil monoliths have to be transported to the lysimeter site, care must be used to minimize the vibrations that inevitably occur during transport which can physically damage the monolith.

Lysimeter tanks The lysimeter tank, whether for a repacked column or for a monolith, should include measures to reduce water flow down the inside walls and even perhaps a division in the tank floor to separate the wall drainage from the inner core drainage. In repacked lysimeter tanks, the inside wall flow can be buffered by the inside horizontal bracing. In monolith tanks, an antiseep collar may be required at a short distance (approximately 200–300 mm) below the soil surface to reduce direct wall flow, particularly for a soil that may shrink away from the inner tank walls. Larger lysimeters require an adequately designed floor-bracing system to avoid tank-floor warping and for scale supports for weighing lysimeters.

Lysimeter drainage systems Lysimeter drainage system designs are quite varied, from those used to maintain static or falling water tables, to those with gravity drainage or manually pumped vacuum drainage, to those with automated vacuum systems. Gravity drainage can be measured volumetrically or by rate (tipping-bucket types). Manual vacuum drainage is often measured volumetrically while pumping. Automated vacuum systems have been used to maintain a constant vacuum on drainage lines, with drain outflows into tanks attached to a weighing lysimeter or suspended with load cells. Drain materials vary widely also. Gravity drains are made from simple, perforated polyvinyl chloride (PVC) pipes or perforated polyethylene (PE) pipes. Vacuum drains are made from ceramic cups, porous blocks, or sintered stainless tubes; and it is important that the 'bubbling pressure' of the soil in contact with the drain media is not exceeded. Some lysimeter drain systems have used outside soil matric potential sensors to match the drainage vacuum and even to add water to the lower soil profile if upward fluxes are detected. The drainage lines are usually embedded in fine sand or diatomaceous earth to apply the vacuum to the soil column uniformly.

Weighing-Lysimeter Scale Systems

Lysimeter scale systems are highly diverse and often uniquely conceived by the lysimeter design team. Scale systems include commercial lever load-cell types, flexure load cells, hydraulic floating-cell types, and hydraulic load-cell types. Mechanical lever-type scales permit a large part of the soil 'dead' (dry) mass and the tank mass to be tared statically to permit a small- to medium-sized electronic load cell to be used to measure the 'live' mass changes (water). Some mechanical scales have movable tare weights to adjust the offset counterbalance mass to maintain

a small electronic measurement range. The greatest advantages in weighing lysimetry are probably widespread availability and low-cost, highly precise analog-to-digital data loggers now commonly used to measure load cells. Typical ET mass accuracy can easily surpass 0.05- to 0.02-mm ranges. Modern data loggers also permit intensive data collection to monitor load-cell drift and other possible electronic problems.

Floating lysimeters were popular before the more expensive electronic–mechanical scales became popular with the improved data-recording precision. Floating lysimeters were designed with lightweight ballast tanks beneath the lysimeter tank, so highly accurate recordings (usually manual liquid depths that were later measured electronically) could be made of the lysimeter displacement to track the lysimeter mass changes. Often the more sensitive of these floating lysimeters were even more accurate than the mechanical scale types, with accuracies as small as 0.025 mm.

Various hydraulic weighing lysimeters have been built with a diverse range of hydraulic reading mechanisms. Some have used simple, homemade hydraulic load cells (often referred to as 'pillows') to measure the lysimeter mass change as the load (pressure) on the hydraulic load cells changes. Hydraulic weighing lysimeters are subject to a greater uncertainty owing to the density changes of the fluid (usually water or a glycol–water solution) and/or a Hg manometer due to temperature changes or flexure changes in the 'pillow' materials. These hydraulic weighing lysimeters achieved accuracies approaching 0.05–0.1 mm.

Lysimeters have been used with only load cells or load-beam scales without counterbalances. Placement of the load cells or scale platform under the lysimeter tank (at approximately 1.5- to 2.5-m depths) greatly reduces temperature influences on the electronic load cells. With highly precise data loggers and larger area-to-mass lysimeters, accuracies within the range 0.1–0.05 mm have been reported. These accuracies are acceptable for good short-term ET research, while greatly reducing the lysimeter scale complexity and construction costs.

Measuring ET or Latent Heat Fluxes with Weighing Lysimeters

The ET rate or mass ET accumulation can be measured easily with precise lysimetry provided no water is added or drained from the lysimeter during the measurement period. If water additions or drainage occur, the water balance can be calculated, but the additions or drainage must be computed separately to determine ET (see eqn [1]). This is a common problem with lysimetry in hydrology. Seldom will either the 'gross' precipitation or irrigation volumes be known in accurate comparison with the measured net soil mass water balance determined via lysimetry. During periods without water additions or drainage, the ET rate is computed as:

$$\mathrm{ET_i} = \{A_\mathrm{l}[(M_\mathrm{i} - M_{\mathrm{i}-1})/A_\mathrm{l}]/A_\mathrm{f}\}/T_\mathrm{i} \qquad [2]$$

where: ET is the evapotranspiration rate, in millimeters per hour (kilograms per square meter per hour), for time interval i; M is lysimeter mass, in kilograms; A_l is the lysimeter inner tank surface area, in square meters; A_f is the lysimeter foliage area (mid wall–air gap area), in square meters; and T is the time in period i in hours. The ratio A_f to A_l^{-1} is the correction factor for the lysimeter effective area. This correction factor assumes the outside and inside vegetation foliage overlap evenly on all of the sides or edges. If there is no overlap, as might occur with a shorter grass, then the correction factor becomes 1.0. Various techniques have been used to obtain reliable short-term ET rates. The lysimeter depletion over a short interval (approximately 30 min to 1 h) might be plotted and a linear line fit to the data so the derivative (ET rate) can be computed for that period. Alternatively a 'numerical' difference can be computed from eqn [2]. If the M terms are 'noisy' (common with high winds), a numerical smoothing technique can be used (equal or weighted averaging running averages).

The latent heat flux is λET, where λ is the latent heat of vaporization in megajoules per kilogram. When the time interval is in seconds, then λET will be in watts per meter squared. **Figure 5** shows the ET rate of irrigated alfalfa on 1998 June 13–14 (day of year (DOY) 164 and 165) at Bushland, Texas, measured with two precision weighing lysimeters. On DOY 164, advection took the form of exceptionally strong winds and a large vapor pressure deficit (VPD), while the second day had calmer winds and a lower VPD, with almost identical net radiation. The increased wind speeds on the 2nd day during the 18.00–19.00 time period was noticeable together with the greater postmidnight, predawn evaporation on that day; while winds and VPD were still greater than those typically experienced in that time period. On DOY 164 peak λET exceeded 1000 $\mathrm{W\,m^{-2}}$ (greater than peak incoming solar irradiance), but, because the crop had a fetch of almost 300 m (NE lysimeter; 100 m fetch for the SE lysimeter) and was 'well watered,' it could maintain the extremely large transpiration fluxes with no discernible 'stomatal control' above typical evaporative conditions (i.e., the next day).

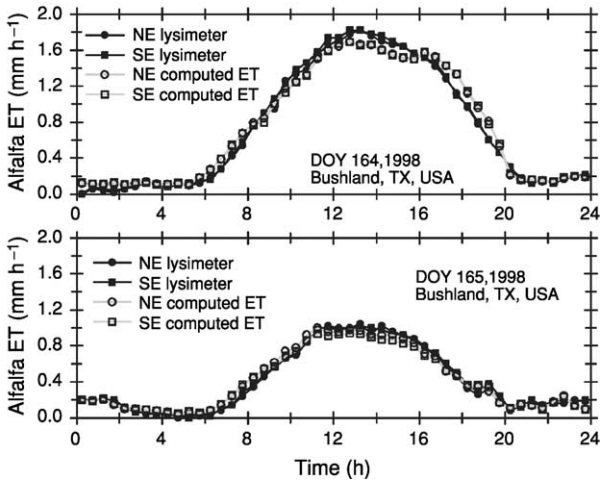

Figure 5 Example alfalfa evapotranspiration (ET) measured with two precision lysimeters at Bushland, Texas, under advective conditions (DOY 164) and on a more typical day (DOY 165) in 1998 contrasted with reference alfalfa ET computed with a Penman–Monteith equation and standardized parameters based on the ASCE/EWRI (American Society of Civil Engineers/ Environmental Water Resources Institute) procedures.

Summary

Lysimeters are hydrologic instruments to measure the percolating water quality and/or to measure the evaporation of water from vegetated surfaces. They can be percolation or weighing types. The water balance is measured in percolation types by soil water balance while the mass change in the weighing types measures the water use (or gain from irrigation or precipitation). The lysimeter design must carefully consider its purpose. Then its size, depth, type, and drainage are key considerations. With well-designed lysimeters that are carefully maintained, high-quality data can be obtained on vegetation water use and percolation water quality.

Introduction

Macronutrients are defined as plant nutrients that typically attain a concentration $>500\,\mathrm{mg\,kg^{-1}}$ in mature plants. They include nitrogen (N), phosphorus (P), potassium (K), calcium (Ca), magnesium (Mg), and sulfur (S). Proper management of these nutrients is essential to ensure that farmers get maximum economic yield while protecting environmental quality. Sensible management of N and P by producers is especially important for environmental protection, because these elements ordinarily limit plant growth in natural terrestrial and aquatic ecosystems. Eutrophication (enrichment) of natural ecosystems with N and P can result in a myriad of undesirable environmental consequences, such as loss of species diversity, fish kills, increased cost of water treatment, impaired navigational and recreational use of waterways, noxious odors, and increased populations of insect pests.

Conservation management of macronutrients implies that these elements will be handled in a manner promoting incorporation into harvestable plant biomass and retardation of movement away from the site of application. To accomplish this goal, management decisions should be based on their cycling patterns, which vary among macronutrients. Two macronutrients (N and S) have gaseous pathways in their cycles that complicate management, while the others have simpler cycles with no atmospheric pathway.

Nitrogen

Nitrogen is the most limiting nutrient in biomass production systems, due to its large requirement by plants and the finite ability of soils to supply available N. Plants take up N as nitrate (NO_3), ammonium (NH_4), or urea ($CO(NH_2)_2$). In moist, warm, well-aerated soils the NO_3 form is dominant. Once inside plants NO_3 is reduced to NH_4 using energy provided by photosynthesis. Plants normally contain between 10 and $50\,\mathrm{g\,N\,kg^{-1}}$ on a dry basis.

Conservation of N in biomass production systems involves preventing losses of N that enters soils through various N-cycle pathways. These pathways include: (1) addition by precipitation; (2) fixation by lightning; (3) biological N fixation, both symbiotic and asymbiotic; (4) addition of organic fertilizers and crop residues; and (5) addition of industrially fixed N as fertilizers. Nitrogen added to soil systems in precipitation is generally in the form of NO_3 and NH_4, and usually amounts to 5–$10\,\mathrm{kg\,N\,ha^{-1}\,year^{-1}}$, with greatest amounts being deposited in regions where acid rain is prevalent. Fixation by lightning occurs when it oxidizes atmospheric dinitrogen (N_2) to $NO + NO_2$, which in turn is converted to NO_3, but this only amounts to 10–20% of the N deposited via precipitation. Amounts of N added in precipitation are not enough to support agricultural biomass production, but may be enough to sustain mature natural ecosystems.

N Fixation

Atmospheric N_2 can be fixed asymbiotically or symbiotically by specialized organisms into organic forms that can subsequently be mineralized into plant available forms. Asymbiotic fixation is performed by free-living organisms such as blue-green algae that fix up to $25\,\mathrm{kg\,N\,ha^{-1}\,year^{-1}}$, and aerobic (e.g., *Azobacter* spp.) and anaerobic (e.g., *Clostridium* spp.) bacteria that fix up to $0.5\,\mathrm{kg\,N\,ha^{-1}\,year^{-1}}$. These organisms do not require a specific host, unlike those which bring about symbiotic N fixation. The latter include rhizobia bacteria spp. in legumes and actinomycete spp. in some trees, that fix atmospheric N_2 in symbiotic association with the higher plants. These microorganisms reside in nodules on plant roots and derive their energy from carbohydrates produced photosynthetically by their higher plant symbiont. Symbiotic fixation's contribution of N to terrestrial biomass production systems can be substantial. For example soybean, cowpea, clover, lupin and alfalfa have been shown to fix up to 75, 85, 130, 160, and

360 kg N ha^{-1} $year^{-1}$, respectively. The alder, a small tree, has been shown to fix up to 170 kg N ha^{-1} $year^{-1}$. Symbiotic N fixation has been recognized as being second in importance among biological processes only to photosynthesis in regard to sustaining life on earth.

Fertilizers and Manures

Atmospheric N_2 is fixed industrially as NH_3 via the Haber-Bosch process, which requires high temperature (1200°C) and pressure (350 atm). Subsequently the NH_3 gas can be converted to various liquid and solid NO_3, NH_4, or $CO(NH_2)_2$ fertilizers.

The major types of organic fertilizers include barnyard manures, liquid manures, processed organic materials, and crop residues returned directly to the soil. Barnyard manures are relatively dry, bulky, solid materials that derive their nutrient value from animal excreta. Liquid manures consist of animal excreta that have been deposited on solid or slatted floors, without bedding material, and then washed into lagoons or storage tanks. Processed organic materials are produced on- or off-farm and include composts, sewage sludge, food-processing wastes, forestry by-products, industrial wastes, and municipal refuse. Crop residues include plant parts (straw, stover, roots, etc.) that remain on the land after crop harvest and green manure or cover crops grown for incorporation into the soil.

Organic fertilizers vary widely in N concentration depending on their origin, and consequently, some materials have greater N fertilizer value than others. Of the barnyard manures, those generated by birds tend to have the greatest N concentration owing to their relatively low water content. Due to low dry matter concentrations, liquid manures typically have low N concentrations. Sewage sludges tend to have relatively high N concentrations. N concentration generally declines when organic wastes are composted, but co-composted dead poultry and chicken manure may have a greater N concentration than barnyard manures. Crop residues (e.g., maize and cotton stover, and wheat and rice straw) usually have low N concentrations in comparison to leguminous green manures (e.g., clover and alfalfa) which, due to their typically greater N concentration, can provide substantial amounts of residual N for succeeding crops.

Typically, for net release of plant available N to occur in the soil, i.e., net mineralization, organic fertilizers should have a carbon (C):N ratio <20. Application of organic materials with C:N >30 will result in immobilization of N by soil microbes. Typically, for immediate release of plant available N, organic fertilizers should have a N concentration >17 g kg^{-1} on a dry-weight basis. The end product of the mineralization of organic forms of N is NH_4, which can be further transformed to NO_3 via the process of nitrification.

Nitrogen-cycle pathways that lead to soil system losses include crop removal, leaching, runoff, NH_3 volatilization, biological denitrification, chemical denitrification, and urea hydrolysis. From a biomass production standpoint, crop removal is the desired outcome, while the others result in economic loss to producers and pollution of the environment.

Leaching results in movement of NO_3 below the rooting zone. Nitrate that escapes the rooting zone can eventually enter groundwater and present a health hazard to humans and livestock. Management to prevent nitrate escape into groundwater includes use of appropriate N application rates; losses of NO_3 via leaching will be minimized if N is not added beyond that needed for maximum yield. Synchronization of N application with crop needs will also decrease risk of NO_3 leaching; plants need little N at planting when the potential for leaching loss can be high. Split or multiple applications in irrigation water allow plants to be fertilized when they need N most, lowering potential for leaching losses. Slow-release N fertilizers may also reduce NO_3 leaching losses, but are expensive, and generally limited to use on high-value crops such as vegetables and turf. Lastly, winter cover crops can help reduce NO_3 leaching by capturing NO_3 that otherwise would be lost below the rooting zone.

Losses of N in runoff are a function of rainfall amount and intensity, infiltration of water into soil, and vegetative cover. Management to prevent losses of N in runoff include maintaining vigorous ground covers on production fields when possible, and maintaining healthy filter strips and riparian areas on borders of production fields year-round. Any management that results in greater water infiltration into the soil will decrease runoff N losses, but may increase losses via leaching and/or denitrification.

Under alkaline conditions the NH_4 ion is unstable and subject to chemical decomposition and subsequent volatilization: NH_4:$NH_{3(solution)} + H$; $NH_{3(solution)}$:$NH_{3(gas)}$. Volatilization losses from surface-applied N can be substantial (>50% of N applied). Ammonia volatilization represents an economic loss to farmers, and atmospheric NH_3 can promote negative environmental impacts such as respiratory problems, acid rain production, soil acidification and ecosystem eutrophication following deposition, and toxicity to plant tissue. Many factors promote NH_3 volatilization as they increase: surface area of the soil solution–atmosphere interface, velocity of air moving across the soil surface, temperature, partial pressure of NH_3 in soil solution, and pH.

Ammonia is also volatilized when surface-applied urea, $CO(NH_2)_2$, comes in contact with the ubiquitous soil enzyme urease. Reduction of NH_3 volatilization is most easily accomplished via techniques such as tillage, injection (liquid manures), irrigation, or timing of application with natural rainfall, which move NH_3/NH_4 to depths where it can be adsorbed by soil colloids.

Biological denitrification is the facultative microbial reduction of NO_3 and nitrite (NO_2) with liberation of N_2 and nitrous oxide (N_2O). Common, widespread species of typically aerobic bacteria use NO_3 and NO_2 as an oxygen source in the absence of O_2. The potential for denitrification losses is high given the appropriate requisites including: anaerobiosis, carbohydrates for energy, $pH > 5.5$, NO_3/NO_2 supply, and warm temperatures. Besides being an economic loss to farmers, release of N_2O into the atmosphere via biological denitrification serves to exacerbate the 'greenhouse effect' by decreasing escape of infrared energy into space. Moreover, N_2O has been implicated in photo-oxidation of stratospheric ozone (O_3), which increases penetration of destructive ultraviolet rays to the earth's surface. Managing for inhibition of biological denitrification involves any processes that: (1) slow nitrification, such as chemical nitrification inhibitors; (2) enhance NO_3 removal such as plant uptake; and (3) promote aeration, such as drainage and evapotranspiration.

Denitrification can also occur chemically under aerobic conditions when NH_4 and NH_4-forming fertilizers are nitrified. This result can be realized through different chemical pathways, but they all involve destruction of the nitrification intermediate NO_2. Thus, from a management standpoint, chemical denitrification is not an important process since NO_2 is ephemeral in soil systems.

Phosphorus

Phosphorus is one of the key essential elements in modern agriculture, and it has many important functions in plants, the premier one being energy storage and transfer. The agronomic literature is replete with examples of grain, fiber and forage yield increases owing to proper maintenance of P fertility in arable soils. Although salutary effects of P in agricultural production are evident, P can also function as a pollutant if it moves from the site of its intended use. The main concern is P transport in surface or subsurface flow from soils to streams, rivers, lakes, and eventually the oceans. Phosphorus transported from agricultural soils can promote eutrophication, and algal growth in surface waters is usually limited by P instead of N availability.

Origins of P in soils include residual soil minerals, or inputs of P from commercial fertilizers and organic fertilizers/wastes. The most common mineral forms of P in soils are: (1) apatite (calcium phosphate), which is found in unweathered and moderately weathered soils; and, (2) iron and aluminum phosphates, which are found in highly weathered soils. The raw material for commercial fertilizer P is apatite mined from various deposits around the world and treated with acid to increase its solubility. Organic P fertilizers/wastes derive from a variety of sources including animal manures, crop residues, and municipal and industrial wastes.

Once a P atom enters the soil environment it is subject to several soil processes that control its fate. In soil solution, P is present as either a monovalent (H_2PO_4) or divalent (HPO_4) anion, the form depending on soil pH. Phosphorus enters the soil solution via either: (1) dissolution of primary minerals; (2) dissolution of secondary minerals; (3) desorption of P from clay and mineral surfaces; and (4), biological conversion of P in organic materials to inorganic forms (mineralization). In most soils, soil solution P ranges between <0.01 and $1\,mg\,l^{-1}$, and a value of $0.2\,mg\,P\,l^{-1}$ is commonly accepted as the solution P concentration desired to support agronomic crops.

Dissolution and erosion are the processes by which P is moved into runoff from agricultural fields. Dissolution of P from a thin zone of surface soil and vegetative material yields dissolved P that is immediately available for uptake by aquatic biota. Erosion via surface runoff transports particulate P in the form of soil and vegetative matter; only that portion of particulate P in equilibrium with dissolved P is available for aquatic biota. Thus, bioavailable P includes dissolved P and a portion of particulate P. Once bio-available P moves from agricultural fields into receiving waters it can contribute to eutrophication.

Although generally considered a less important mechanism than surface runoff, P leaching followed by shallow lateral subsurface flow can contribute dissolved P to surface waters under high water table conditions. This mechanism becomes more important in soils with large accumulations of P that saturate surface soil sorption capacity, leading to downward movement of P.

Escape of soil P to surface waters is affected by a host of soil management practices (e.g., tillage method, cover crops, riparian zones, terracing, etc.). However, the soil P concentration that correlates with P bioavailability is the greatest determinant of the balance between adequate soil P fertility and offsite P escape. In that regard, soil testing is currently the best management tool available to ensure that

crops are provided with adequate soil P. Moreover, soil testing is likely the best management tool available to ensure that soils do not become overloaded with P, which increases the likelihood of their contribution to pollution of downstream water.

Potassium

Potassium is the seventh most common element in the earth's crust, accounting for 2.6% of its mass. It is present in igneous, sedimentary, and metamorphic rocks, and deposits that are mined for fertilizer are evaporites, largely KCl, derived from drying of enclosed bodies of seawater. The quantity of K in soils is dependent on parent material and degree of weathering. Minimally weathered soils in arid regions may contain up to 2.5% K, while weathered soils in the tropics may contain little or no K.

Potassium is taken up by plants in amounts greater than those of N, and depending on species, plant tissue concentrations can range as high as 5%. It does not combine with C in plants to form organic compounds, but exists in a mobile ionic form (K^+). Potassium has many functions in plants, but owing to its high tissue concentration and ionic form, it is not surprising that its primary one is osmoregulation.

Potassium has no atmospheric pathway, and exists in the soil as primary minerals (feldspars and micas), secondary minerals (illite and vermiculite), exchangeable K, and soil solution K. Of the primary minerals, feldspars are more resistant to weathering than micas (biotite and muscovite), and exist mostly in the sand and silt size fractions. Weathered micas exist in the clay size fraction, and eventually release K from interlayer spaces as they hydrate to form secondary minerals. In a reverse process, K can be trapped when the interlayer spaces of secondary minerals collapse upon dehydration, reforming mica. When K^+ leaves the interlayer space of a secondary mineral, it will likely be adsorbed on a cation exchange site of a soil colloid. This exchangeable K maintains an equilibrium with the K^+ in soil solution, together constituting 'available K.'

Loss pathways for K include leaching and erosion/runoff. Leaching of K is increased under conditions that include a high degree of soil colloid saturation with K, sandy subsoils, poor vegetative cover and shallow rooting, and low soil-pH. Soil acidity impacts K leaching through the complementary ion principle: there will be less leaching of K if Ca^{++} rather than hydrogen (H^+) or aluminum (Al^{3+}) is the dominant complementary ion on soil-colloid exchange sites. Thus, management to reduce K leaching from soils includes following soil test recommendations to avoid saturation of soil colloids with K, maintaining vigorous vegetative cover, and liming to maintain soil pH according to soil test recommendations. In regard to K loss via erosion/runoff, management previously described to prevent surface soil losses of P will also prevent K loss.

Calcium

Calcium concentration in the earth's crust is approximately 3.6%, while soils contain only 1.37%. The primary source of soil Ca is from weathered limestone and the weathering of certain primary minerals. This indicates that parent material plays a major role in determining soil Ca concentration. The soil concentration of Ca can vary greatly and is generally related to soil pH. Soils with a pH of 6.0 or greater usually have adequate Ca for plant growth. The majority of plant-available Ca is exchangeable, is much greater than that found in soil solution, and is a divalent cation (Ca^{2+}). An average Ca concentration in soil solution is approximately $0.01\,mol\,l^{-1}$. The approximate range of exchangeable Ca is 20% to 65% of the cation exchange capacity (CEC) for most soils. Soils may have an average CEC of $15\,cmol_c\,kg^{-1}$ and 50% Ca saturation. This results in the exchangeable Ca being about 12 000 times greater than soil solution. Some soils contain mineral Ca in the form of precipitated $CaCO_3$ or $CaSO_4 \cdot 2H_2O$ within the soil profile, which results in Ca concentrations much greater than the exchangeable. In the western USA, these soils are usually found in areas of reduced rainfall.

Soil pH and available Ca are usually directly correlated. For example, as pH increases the base saturation increases, thus the amount of exchangeable Ca, Mg, and K increase. These are considered to be basic cations while Al and H are considered acidic cations. Often, liming soils to raise low soil pH will greatly increase Ca concentration in soils. Limestone is the primary liming material and there are different types of limestone depending on the ratio of Ca to Mg in the limestone. Calcite is $CaCO_3$ with essentially no $MgCO_3$ but as the amount of $MgCO_3$ begins to increase within the limestone, the limestones are referred to as calcitic, dolomitic, and dolomite. Dolomite contains about 50% $CaCO_3$ and 50% $MgCO_3$. Other sources of $CaCO_3$ are marl or chalk, which are soft sources of limestone. Choices of liming material may be determined by the nutrient status of Ca or Mg. Another available Ca source is gypsum ($CaSO_4 \cdot 2H_2O$), often used when soil pH is adequate, but additional Ca is required. Industrial byproducts that have neutralizing properties such as quick lime, burnt lime, basic slag, fly ash and some sludge materials may also contribute Ca.

Calcium has fewer pathways than other macronutrients and thus, the management of adequate soil Ca is simpler. The loss of Ca is generally by plant uptake, since it does not volatilize and leaching is minimal. For example, Ca is not easily leached because it is held to cation exchange sites more strongly than other nutrients, which is demonstrated by the lyotropic series:

$$Al^{3+} > Ca^{2+} > Mg^{2+} > K^{+} = NH_4^{+} > Na^{+}.$$

The strength of retention increases with the charge on the cations, and also depends on their hydrated size with smaller cations being held more tightly. Inputs into the pool of available Ca must be considered for proper management. Very little available Ca is derived from mineralization of soil organic matter. So the input of available Ca is from weathering of Ca minerals or from supplemental applications of Ca sources as those mentioned earlier. Plant uptake of Ca is another pathway and the uptake characteristic is important in the method of supplying adequate Ca.

The major role of Ca in plants is cell-wall integrity and function, and it plays a role in cell division and elongation. Calcium is bound to negatively charged phosphate groups of membrane lipids. This prevents inorganic and organic molecules from leaking out of the cells. When Ca deficiency continues there is a general disintegration of the membrane and cell-wall leaking. In the whole plant, the meristematic tissue shows the deficiency in the growing point and root tips. Most visual Ca deficiency symptoms occur in fruit and storage tissue, because translocation of Ca is by way of xylem tissue. Thus, low soil solution Ca or very low transpiration rate in humid conditions may cause Ca deficiency. Examples of common symptoms include: apples display 'bitter pit' where the surface is pitted with brown spots; tomatoes, peppers, and watermelons have blossom-end rot where there is complete tissue breakdown at the distal end of the fruit; celery has black heart and brussel sprouts have internal browning; and peanuts exhibit 'pops' where the hull is completely formed but the kernel did not develop.

Magnesium

The lithosphere contains about 2.1% Mg and soil generally contains 0.5%. Parent material plays a major role in determining available soil Mg concentration. Soil Mg is derived from the weathering of several minerals, much like Ca. Limestones (dolomitic and dolomite) supply Mg in many soils as well as some primary and secondary minerals. Mg, unlike Ca, is contained in several secondary minerals e.g., montmorillonite, vermiculite, illite, and chlorite. Soils rich in these minerals usually have sufficient available Mg and do not need supplements. Much like Ca, most of the available Mg is exchangeable but usually at a lower concentration. Generally Mg soil solution concentration is about 0.001 mol l^{-1}, which is lower than soil-solution Ca. The lower availability of Mg can be attributed to the lyotrophic series that indicates Mg can be leached more easily than Ca.

As mentioned earlier with Ca, availability of Mg is also often related to soil pH. Soil Mg is normally increased when applying dolomite or dolomitic limestone when correcting soil pH. When adding Mg without adjusting pH other sources are available; such as Epsom salt ($MgSO_4 \cdot 7H_2O$), magnesium ammonium phosphate ($MgNH_4PO_4 \cdot H_2O$), and a more common source Sul-Po-Mag ($K_2SO_4 \cdot 2MgSO_4$). Other organic sources may supply Mg, but mineralization of organic matter does contribute substantially to Mg availability.

The pathway for Mg is the same as Ca, except Mg is not held to exchange sites as strongly as Ca and can be subject to some leaching sooner than Ca. Uptake and translocation of Mg is different than Ca. Magnesium is very mobile in the phloem and is translocated from older to younger leaves and translocates to storage tissue. The deficiency symptom occurring first in the older tissue, depending on the type, is an intervenal yellowing or chlorosis, in severe cases becoming necrotic. Magnesium is the central component of chlorophyll and acts as a cofactor in most enzymes activating phosphorylation.

Sulfur

Management of soil S is more complicated than most other nutrients and may be considered similar to that of N. Sulfur content of the lithosphere is about 600 ppm and while there is a large range (30–10 000 ppm) in soil S, the average concentration is estimated at 700 ppm. The four major forms of S in soils are: (1) sulfides, (2) sulfates, (3) organic sulfur, and (4) elemental sulfur. Understanding the S cycle in soil is important for proper management of soil S. Sulfur mineralization is very similar to N mineralization with decay products being in a reduced form (sulfides) then oxidized to a sulfate form. Sulfate is subject to reduction, immobilization, fixation by clays, precipitation, anion exchange, leaching and plant uptake. In maintaining adequate soil S fertility all these processes must be considered. The reduction of sulfates to sulfides requires anaerobic conditions in combination with an available C source. Once reduced it may be lost to the

atmosphere or precipitated and then be subject to oxidation when conditions become aerobic. The oxidation of sulfides or elemental sulfur causes acidification of soils. This may be desirable when attempting to grow acid-loving plants on initially high pH soils. Major inputs into the pool of available soil sulfur are from soil organic matter, fertilizers, and deposition from the atmosphere (wet or dry). Other minor sources are from irrigation water, plant residues or manures, and sulfur-bearing minerals.

In many cases the available sulfur must be supplemented. The common sources of sulfur are gypsum ($CaSO_4 \cdot 2H_2O$; 19% S), elemental S (flowers of sulfur; 95% S), ammonium sulfate ($(NH_4)_2SO_4$; 24% S) and sulfur coated urea (13–16% S). Sulfur-deficient soils requiring these inputs are usually sandy-textured and the deficiency is usually more prominent in early cool spring months. This occurs mainly for two reasons: mineralization is minimal and earlier mineralized S has been taken up or lost due to previously mentioned pathways. Also, root growth is limited due to cool soil temperature. These reasons often explain why crops may grow out of S deficiencies when soil temperature increases, enhancing mineralization and root growth.

Sulfur is taken up mainly as SO_4, is considered nonmobile and is only translocated in the xylem. Thus, deficiencies usually appear in the younger tissue. Deficiency symptoms are often a general chlorosis in younger leaves. Sulfur is a component of many proteins in plants, but when plants become deficient in S there is an accumulation of non-S proteins and an associated decrease in sugars. The decrease in sugar inhibits chlorophyll production, resulting in a general chlorosis.

List of Technical Nomenclature

°C	Celsius
Al	Aluminum
atm	Atmosphere
Ca	Calcium
$CaCO_3$	Calcium carbonate
$CaSO_4 \cdot 2H_2O$	Gypsum
CEC	Cation exchange capacity
$CO(NH_2)_2$	Urea
$cmol_c\,kg^{-1}$	centimole charge per kilogram
$g\,kg^{-1}$	gram per kilogram
H	Hydrogen
HPO_4	Monohydrogen phosphate
H_2PO_4	Dihydrogen phosphate
K	Potassium
KCl	Potassium chloride
$K_2SO4 \cdot 2MgSO_4$	Sul-Po-Mag
$kg\,ha^{-1}\,yr^{-1}$	kilogram per hectare per year
Mg	Magnesium
$MgCO_3$	Magnesium carbonate
$MgNH_4PO_4 \cdot H_2O$	Magnesium ammonium phosphate
$MgSO_4 \cdot 7H_2O$	Epsom salt
$mg\,kg^{-1}$	milligram per kilogram
$mg\,l^{-1}$	milligram per liter
$mol\,l^{-1}$	moles per liter
N	Nitrogen
N_2	Dinitrogen
Na	Sodium
NH_3	Ammonia
NH_4^+	Ammonium
$(NH_4)_2SO_4$	Ammonium sulfate
NO_2	Nitrite
NO_3	Nitrate
N_2O	Nitrous oxide
O_3	Ozone
P	Phosphorus
ppm	part per million
S	Sulfur
SO_4^{2-}	Sulfate

MACROPORES AND MACROPORE FLOW, KINEMATIC WAVE APPROACH

P F Germann, University of Bern, Bern, Switzerland

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Discussion about the significance of structural soil voids carrying water flow dates back at least to the mid nineteenth century when Dupuit applied Darcy's law to two-dimensional flow towards drainage ditches. Many soil scientists at that time were convinced that water flows almost exclusively through wide structural soil pores, which are thought of as any cavity wider than expected from the mere arrangement of soil particles. Structural voids are due to processes like cryo- and bioturbation, stress and strain, shrinking and swelling, and internal transport of particulate and dissolved matter. They are called macropores and permit small water amounts to move quickly through soils.

The dispute intensified and subsided at times depending on the development of various approaches to water flow and transport of solutes and particles in water-saturated and nonsaturated soils. However, the Richards equation has evolved to become the predominant approach to calculating water flow in unsaturated soils since the 1930s, and solute transport has been treated as a convection–dispersion process since the 1960s. Darcy's law, Richards equation and the convection–dispersion approaches to flow and transport in unsaturated soils do not require information on soil structure. Therefore, any new approach to flow and transport in soils that requires structural information or that is designed to explain the effects of soil structure on transport tends to rekindle the controversy and perplexity.

The last three decades have seen intense development in field and laboratory instrumentation, electronic data acquisition and processing, and a generally increased demand for information about environmental processes. Thus, it was recognized that information on soil structure is required to explain better the observed transport of water, solutes, and particles in soils. Knowledge about the operational links between structure and transport processes in soils is still in its infancy despite the demand for suitable scientific and applied approaches. Numerous computer codes simulate the transport processes, although no commonly accepted theoretical framework of rapid flow and transport in structured soils has evolved so far.

Macropores are thought to be structural voids that are responsible for the observed deviations of transport from predictions with the Richards equation and the convection–dispersion approaches. Many empirical measures about the minimum widths and lengths of macropores have been proposed. Because of the nonexistence of alternatives to the Richards equation and the convection–dispersion approaches, there are, at present, few ways of functionally defining the dimensions of macropores with respect to transport processes.

These difficulties result in two consequences for this article: (1) terms like 'macropores' refer to arbitrarily defined soil structural voids. 'Macropore flow' and 'transport' infer processes strongly related to them, but without being properly based on independent and more general flow theory. Therefore, the process-oriented expressions 'preferential flow' and 'preferred' flow paths will be used; (2) because of the many evolving alternate approaches to transport in structured soils, this article cannot assume to be complete and final. Thus, reference to past achievements may illustrate the dynamics of the topic and hint at its evolution.

Early Considerations on Flow and Transport in Soils

Poiseuille, presumably the first researcher rigorously dealing with fluid flow in closed conduits, stated in

1844 that laminar flow through a cylindrical pipe is proportional to the pressure gradient and the fourth power of the pipe's diameter, and inversely proportional to the length of the pipe and the viscosity of the fluid.

Darcy, possibly inspired by the emerging laws of resistance-to-flow – Ohm's law dealing with electric currents, Poiseuille's law dealing with flow of liquids in closed conduits, Laplace's and Fourier's work on heat flow – found in 1856 that flow through a completely water-saturated porous medium is proportional to the medium's cross-sectional area and the gradient of the hydraulic head, and inversely proportional to the length of the macroscopic flow path. The factor of proportionality is called hydraulic conductivity of the water-saturated medium.

In the 1880s agricultural scientists in England reported an early breakthrough concerning drainage flow of water with a chemical composition similar to that of rain water, whereas the composition of drainage flow usually reflected the chemical soil environment. This phenomenon was later dubbed as 'by-pass flow'.

At the beginning of the twentieth century, agricultural plant physiologists discovered that the air-filled soil pores must exceed 5% by volume to guarantee proper aeration of pot-grown sunflowers. At about the same time, Swiss forest scientists, in their quest to justify vast reforestation projects by demonstrating the forests' superiority over many other types of canopies to mitigate peak runoff in steep upland catchments, developed a test that linked infiltration with soil porosity information. A steel cylinder 100 mm high and with a volume of 1 l was completely driven into the soil and covered with a wire mesh. A second cylinder of the same dimensions was tightly set on the first one and filled with water to its rim, and the time for the 100 mm of water to infiltrate completely was recorded. Soil cores were sampled nearby with the same cylinder type. They were completely saturated with water, weighed, drained on a gravel bed for 24 h and weighed again. The weight difference was divided by the density of water and the volume of the core, and its multiplication with 100% resulted in the core's air capacity. More than 50 pairs of infiltration times vs air capacities led to the results shown Figure 1.

The results support the 5%-threshold reported by the plant physiologists. In the 1970s, additional support of the 5%-threshold followed from measurements of oxygen conductivity vs air-filled porosity. The experiments indicate that pores quickly draining to about 5% by volume are hydraulically well-connected.

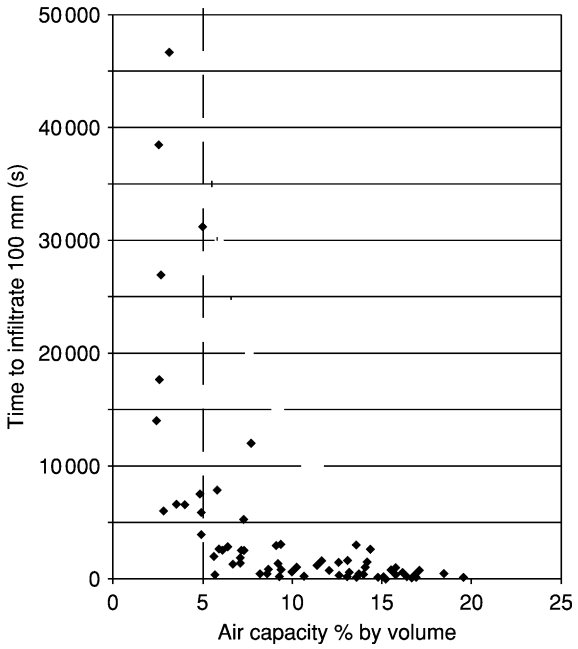

Figure 1 Time to infiltrate 100 mm of water vs air capacity. The empirical threshold at 5% by volume approximately separates the easily-drainable soil samples from those with reduced permeability.

Deviations from Richards Equation and Convection–Dispersion Approaches

Some of the early approaches to flow in unsaturated soils included information on porosity; however, many were not theoretically based and they had to yield to a more rigorous approach. In the late 1920s, Richards included the capillary potential Ψ of the water in unsaturated soils in the hydraulic gradient. He then combined Darcy's law with the volume balance and assumed instantaneous equilibration during transient flow between water content θ and Ψ according to the retention curve. The assumptions led to a quasi-hydrostatic approach to transient flow that expresses the diffusion of water potentials. He called the hydraulic conductivity function $K(\Psi$ or $\theta)$, an expression of proportionality.

Veihmeier's empirical concept of field capacity is close to the one of the 5% threshold of air-filled pore space. It hints at domains not predictable by the Richards equation. However, no theoretical explanation followed, presumably due to the lack of alternative approaches to the Richards equation.

In the 1960s, the concept of hydrodynamic dispersion was introduced to explain the spread of concentrations during solute transport through porous media. Ideally, half of the concentration difference is attained in constant drainage flow when one pore volume of soil water has been replaced. Likewise, at

some depth in the soil the normalized time variation of the solute concentration follows the S-shaped integral of the normal distribution function.

The increasing number of *in-situ* experiments and observations of flow at the scales of soil profiles, the vadose zone to unconfined groundwater tables, hillslopes, and first-order catchments, increasingly demonstrated that small-volume fractions of soil moisture may move rapidly and over long distances, and that the processes were not satisfactorily explained by the Richards equation. The deviating observations are summarized under the term of non-equilibrium conditions with respect to the Richards equation, and macropores of some length are thought to be the cause. In the late 1970s, the hunt started for concepts that supposedly link structure with transport.

Particular interpretations of water retention curves, Ψ vs θ, in terms of the equivalent pore diameters near saturation, were thought to transform nonequilibrium flow conditions to conform to the Richards equation. Also dual-porosity media have been proposed, with one fraction responding rapidly to infiltration and the other fraction showing more gradual responses, allowing for water to flow from one fraction to the other depending on the hydraulic gradient between them. In addition, observed breakthroughs of dye and particle tracers were frequently faster and distorted when compared with the predictions of the convection–dispersion approaches. A broad variety of transport concepts are offered in the literature based on dual-porosity, neural networks, fuzzy logic, and fractal dimensions.

However, the explanation of finger flow is the most subtle case of nonequilibrium flow and does not require structural pores. The hysteresis in the Ψ-θ relationship initiates finger flow that shows in heterogeneous water breakthroughs in soils in the shapes of vertical fingers. Various theoretical approaches to finger flow have been developed, all of which indicate intricate relations between soil and flow parameters.

So far, macropores and macropore flow, preferential flow and preferred flow paths as well as nonequilibrium flow and transport are explicitly or implicitly defined in contrast to 'ordinarily' sized pores and flows at equilibrium with respect to the Richards equation and the convection–dispersion concepts.

Flow paths are frequently visualized *in situ* with dye tracers that are applied to the infiltrating water with subsequent preparation and recording of the stained areas. The staining procedures are applied to sample sizes ranging from typical thin sections covering a few square centimeters to pedons and polypedons. The color patterns provide a visualization of infiltration and indicate the paths taken by the water; however, they do not provide information on the flow dynamics and reveal neither the quantity nor the duration of flow along them. Thus, they are of limited value when developing quantitative approaches to flow and transport in structured soils.

Alternative Approaches to Flow and Transport

General Requirements

Alternative approaches to the Richards equation dealing with transient water flow in unsaturated structured soils have to go back to the basic Navier–Stokes equations to avoid the assumption of equilibrium along the Ψ-θ relationship.

Flow and transport in structured soils and in their artificial physical counterparts are increasingly visualized with computer-aided tomography using X-ray, nuclear magnetic resonance (NMR), or various other radiation techniques. Information on the three-dimensional structure and transport is then used to solve the appropriate Navier–Stokes equations at the pore scale by either applying Boltzman transformations or lattice gas simulations. These process-oriented studies are laborious and require a combination of sophisticated tools and skills. They provide excellent insight into the processes, but up-scaling their results to larger soil volumes is still challenging, mainly because of the pronounced nonlinearity of the processes involved.

According to Newton, a solid body is accelerated when a constant force is acting on it, whereas the same constant force acting on a fluid results in its moving with a constant velocity after a short period of acceleration. Likewise, a solid body gains momentum, whereas a fluid achieves constant momentum when both are exposed to the same constant force. The difference is due to the fluid's viscosity which dissipates linear momentum $\rho \cdot \partial v/\partial f$ perpendicular to the direction of flow towards the solid. However, Richards equation applies to flow in soils as long as momentum completely dissipates within a representative elementary volume, i.e., when the Richards condition is fulfilled.

Preferential flow may expressly consider linear momentum and kinetic energy of transient flow in structured soils. Dissipation of linear momentum during laminar flow results in a shear force in the direction opposite to the flow driving force. Newton's law of shear states that:

$$\tau(f) = -f \cdot g \cdot \rho = \eta \cdot \rho \cdot \frac{\partial v}{\partial f} \qquad [1]$$

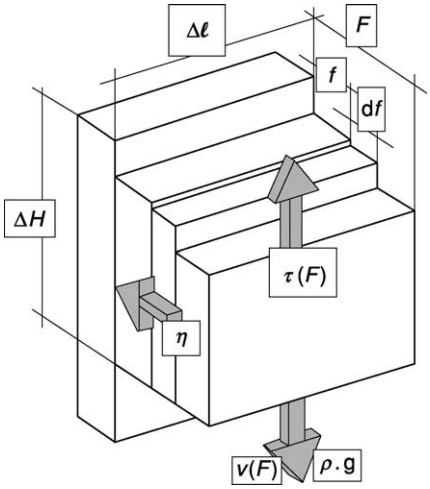

Figure 2 Schematic representation of Newton's law of shear. F(m) Film thickness with its variable f; g (m s^{-2}) acceleration due to gravity; ρ (kg m^{-3}) density of water; $\Delta\ell$ (m) contact length of the water film with the parts at rest; ΔH (m) macroscopic length of coherent water films; η (m^2 s^{-1}) kinematic viscosity dissipating momentum towards the resting part of the soil-water system; $\tau(F)$ (Pa) and $v(F)$ (m s^{-1}) are the shear force and the velocity of the lamina at F.

where $\tau(f)$ (Pa) is the shear force as a function of the film thickness f(m) acting in the opposite direction of gravity (gravity is assumed to be the only flow driving force), g ($=9.81$ m s^{-2}) is acceleration due to gravity pointing vertically downwards, ρ ($=1000$ kg m^{-3}) is the density of water, η (approx. 10^{-6} m^2 s^{-1}) is the kinematic viscosity of water (i.e., the coefficient of momentum dissipation), and $v(f)$ (m s^{-1}) is the velocity of a water lamina at distance f from the parts at rest. Figure 2 illustrates the definitions of the parameters.

Integration of eqn [1] leads to the velocity profile:

$$v(f) = \frac{1}{2\eta} \cdot f^2 \cdot g \qquad [2]$$

Mass and momentum of a layer at f are:

$$dM = \Delta H \cdot \Delta\ell \cdot df \cdot \rho \qquad [3]$$

and:

$$dI(f) = dM \cdot v(f) = \frac{1}{2\eta} \Delta\ell \cdot g \cdot \rho \cdot \Delta H \cdot f^2 \cdot df \,(\text{kg m}^{-1}\,\text{s}^{-1}) \qquad [4]$$

where ΔH is the macroscopic length of well-connected water films. Integration of eqn [4] within $0 \le f \le F$ yields horizontal momentum dissipation due to ρ, g and η from the mobile liquid towards the resting parts, like the solid matrix or stagnant water:

$$I_h(F) = -\frac{1}{6\eta} F^3 \cdot \rho \cdot g \cdot \Delta H \cdot \Delta\ell \,(\text{kg m}^{-1}\,\text{s}^{-1}) \qquad [5]$$

The combination of eqns [1] and [2] yields the vertical momentum of the water film:

$$I_v(F) = \frac{1}{6\eta} F^3 \cdot \rho \cdot g \cdot \Delta H \cdot \Delta\ell \,(\text{kg m}^{-1}\,\text{s}^{-1}) \qquad [6]$$

Steady flow occurs when $I_v = I_h$, acceleration when $I_v > I_h$ and deceleration when $I_v < I_h$.

Mobile volumetric soil moisture is:

$$w = \frac{\Delta H \cdot F \cdot \ell}{\Delta H \cdot A} (\text{m}^3\,\text{m}^{-3}) \qquad [7]$$

where A (m^2) is the cross-sectional area of the soil and $\ell = \Sigma\Delta\ell$(m) is the total contact length of w in A. Integration of eqn [2] under the consideration of eqn [7] leads to the volume flux density of momentum-dominated flow as:

$$q = b \cdot w^a (\text{m s}^{-1}) \qquad [8]$$

where the conductance is:

$$b = \frac{g}{2 \cdot a \cdot \eta} \cdot \frac{A^2}{\ell \cdot \Delta H} (\text{m s}^{-1}) \qquad [9]$$

The dimensionless exponent a is related to the channel geometry. Flow in a cylinder, as in Hagen-Poiseuille's law, results in $a = 2$, whereas flow along a plane or in a planar fissure, also referred to as the cubic law, results in $a = 3$.

Kinematic Wave Theory

The application of eqns [1] to [9] to transient laminar flow leads to the kinematic wave theory as developed by Lighthill and Witham in the early 1950s. It combines Eulerian and Lagrangean concepts of flow where the celerity c (m s^{-1}) describes the velocity of a particular wave property.

The water balance of a kinematic wave is:

$$\frac{\partial q}{\partial t} + c \cdot \frac{\partial q}{\partial z} = 0 \qquad [10]$$

where t and z are time and depth coordinates, the latter is positive vertically down.

The initial and boundary conditions of a rectangular input pulse to the soil surface of duration t_s and volume flux density q_s are:

$$0 \le z \le \infty \quad t \le 0 \quad w(z,t) = 0 \quad q(z,t) = 0 \qquad [11]$$

$$z = 0 \quad t \le 0 \quad \text{and} \quad t \ge t_S \quad w(z,t) = 0 \quad q(z,t) = 0 \qquad [12]$$

$$0 \le t \le t_S \quad w(z,t) = w_S; \quad q(z,t) = q_S = b \,.\, w_S^a \qquad [13]$$

A sharp wetting shock front starts moving vertically down at $t = 0$ with a celerity of:

$$c_W = \frac{q_S}{w_S} = b \cdot w_S^{a-1}\ (\mathrm{m\,s^{-1}}) \qquad [14]$$

The position of the wetting shock front as function of time is:

$$z_W(t) = t \cdot b \cdot w_S^{(a-1)}\ (\mathrm{m}) \qquad [15]$$

and the time lapsed for the wetting front to move to depth z is:

$$t_W(z) = \frac{z}{b \cdot w_S^{(a-1)}} \qquad [16]$$

At $t = t_S$, water input and mobile soil moisture at the soil surface drop to zero. However, the sharp draining shock front at the surface decays to an infinite number of layers (i.e., laminae) in the range of $0 \le w \le w_S$. Each lamina moves with a celerity:

$$c(w) = \frac{\mathrm{d}q}{\mathrm{d}w} = a \cdot b \cdot w^{(a-1)} = \frac{z(w)}{(t - t_S)}\ (\mathrm{m\,s^{-1}}) \qquad [17]$$

corresponding to the position f within the water film. The fastest lamina is the draining shock front whose celerity is:

$$c_D = \frac{\mathrm{d}q_S}{\mathrm{d}w_S} = a \cdot b \cdot w_S^{(a-1)}\ (\mathrm{m\,s^{-1}}) \qquad [18]$$

The depth of the draining front as function of time is:

$$z_D(t) = (t - t_S) \cdot a \cdot b \cdot w_S^{(a-1)}(\mathrm{m}) \qquad [19]$$

and the time lapsed to its arrival at z is:

$$t_D(z) = t_S + \frac{z}{a \cdot b \cdot w_S^{(a-1)}} \qquad [20]$$

The position in depth and time of any mobile water content in the range of $0 \le w \le w_S$ and at time $t \ge t_S$ follows from solving eqn [17] for:

$$w(z,t) = \left[\frac{z}{(t - t_S) \cdot a \cdot b}\right]^{\frac{1}{(a-1)}} \qquad [21]$$

Because $c_D = a \cdot c_w$ the draining front intercepts the wetting front at time:

$$t_I = t_S \frac{a}{(a-1)}\ (\mathrm{s}) \qquad [22]$$

and depth:

$$z_I = t_S \cdot \frac{a}{(a-1)} \cdot b \cdot w_S^{(a-1)}\ (\mathrm{m}) \qquad [23]$$

The total water volume that has infiltrated into the soil and that is contained in the kinematic wave is:

$$V = t_S \cdot q_S = t_S \cdot b \cdot w_S^{a}(\mathrm{m}) \qquad [24]$$

Integration of eqn [21] i.e., $\int_0^{zF(t)} w(z,t)\mathrm{d}_z = V$, yields the position of the wetting shock front for times $t \ge t_I$ and depths $z_F(t) \ge z_I$:

$$z_F(t) = a \cdot b \cdot w_S^{(a-1)} \cdot \left[\frac{t_S}{(a-1)}\right]^{\frac{(a-1)}{a}} \cdot (t - t_S)^{1/a} \qquad [25]$$

Inserting eqn [25] into eqn [21] yields mobile soil moisture at the wetting front at $z_F(t)$:

$$w_F(t) = w_S \cdot \left[\frac{t_S}{(a-1) \cdot (t - t_S)}\right]^{1/a} \qquad [26]$$

and the celerity of the wetting front is:

$$c_F(t) = b \cdot w_S^{(a-1)} \cdot \left[\frac{t_S}{(a-1) \cdot (t - t_S)}\right]^{\frac{(a-1)}{a}} \qquad [27]$$

Equation [21] applies to the ranges of time $t > t_D$ and depth $0 < z < z_D$, z_F. It describes the trailing wave of a kinematic wave. The combination of eqn [19] with eqn [21] yields the decline of mobile soil moisture at a particular depth after the passing of the draining front ($t_S \le t \le t_I$) or the wetting front ($t \ge t_I$):

$$w(z_D,t) = w_S \cdot \left[\frac{(t_D - t_S)}{(t - t_S)}\right]^{\frac{1}{(a-1)}} \quad \text{or}$$
$$w(z_F,t) = w_S \cdot \left[\frac{(t_F - t_S)}{(t - t_S)}\right]^{\frac{1}{(a-1)}} \qquad [28]$$

A complete kinematic wave is shown in **Figure 3**. Application of eqn [8] leads to the volume flux densities, and a combination of eqns [7] and [9] provides the film thickness and the contact length of mobile soil moisture with the resting parts.

Kinetic energy of flow per unit volume of mobile soil water is:

$$E_{kin,w} = \rho \cdot \frac{q^2}{2 \cdot w^2} = \rho \cdot b^2 \cdot w^{2(a-1)}\ (\mathrm{Pa}) \qquad [29]$$

and momentum of flow per unit volume of mobile soil water is:

$$i_w = \rho \cdot \frac{q}{w} = \rho \cdot \mathrm{b} \cdot \mathrm{w}^{(a-1)}(\mathrm{kg\,m^{-2}\,s^{-1}}) \qquad [30]$$

Application of the Kinematic Wave Model

Sprinkling at the soil surface during $0 < t < t_S$ with an intensity of q_S provides for the boundary conditions, eqns [11] to [13]. Because t_I depends only on

t_S, eqn [22], the duration of the latter is selected long enough for the maximum depth of observation to be within $0 < z < z_I$. The kinematic wave approach is applied either to drainage flow at some depth or to soil moisture variations at several depths. Temporal soil moisture variations are typically recorded with time-domain reflectometry (TDR) measurements using horizontally installed waveguides and frequencies of data recording higher than 1/300 Hz. (The system takes repeated water-content readings at each waveguide at intervals of 300 s, i.e., every 5 min.) A time series of drainage flow or soil moisture in the depth range of $0 < z < z_I$ follows three stages:

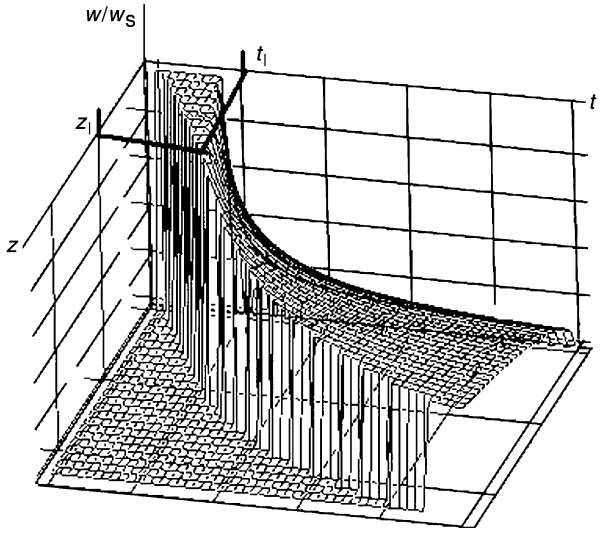

Figure 3 Schematic representation of a kinematic wave normalized with respect to the wave's amplitude w_S.

$$\text{Stage 1: } 0 < 1 < t_W(z) \quad w = 0 \qquad q = 0 \qquad [31]$$

$$\text{Stage 2: } t_w(z) < t < t_D(z) \quad w = w_S \qquad q = q_S \qquad [32]$$

$$\text{Stage 3: } t_D(z) < t < \infty \quad w = w_S \cdot \left(\frac{t_D(z) - t_S}{t - t_S}\right)^{1/(a-1)}$$
$$q = q_S \cdot \left(\frac{t_D(z) - t_S}{t - t_S}\right)^{a/(a-1)} \qquad [33]$$

An example of a model application to data is shown in Figure 4, where the overall soil moisture maximum w_S is replaced by its local amplitude w_{max}.

Soil layers of lower hydraulic conductivity, mainly when they are lacking paths of preferential flow, may backlog water with subsequent distortion of the wave's shape. Water backlogging may also temporarily produce positive pressures, thus requiring adaptation of eqn [1]. In addition, capillary attraction may adsorb parts of the rapidly flowing water at low antecedent degrees of saturation, thus markedly reducing the effects of preferential flow at depths. These more local effects are thought to distort a kinematic wave such that no single set of parameters a and b has so far been found capable of quantifying flow over a considerable depth range. Thus, the kinematic wave model needs calibration to data at the various depths of measurement. However, once calibrated, the model allows for the estimation of flow parameters at particular depths, as their approximate ranges are compiled in Table 1.

Moreover, the local quantification of flow with the kinematic wave model at various depths provides information on the water sorption processes during

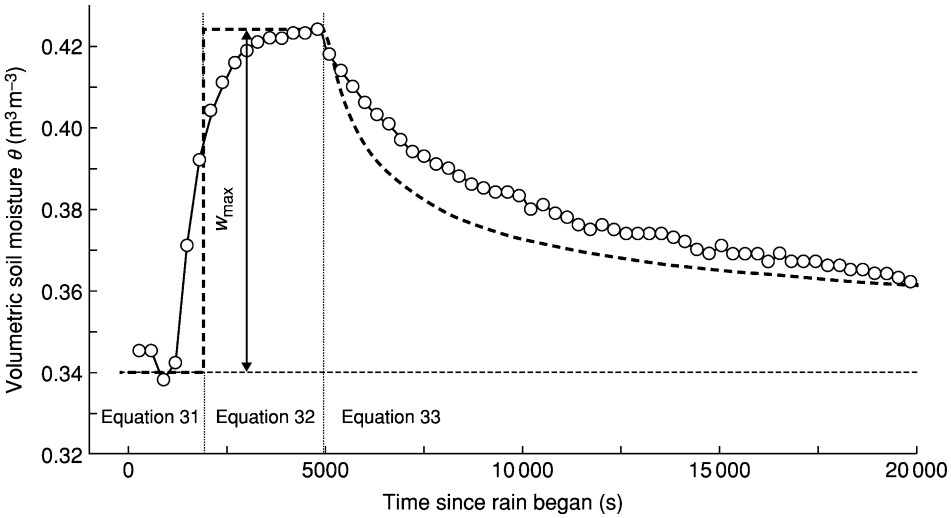

Figure 4 Soil moisture variation at depth 0.35 m due to sprinkling 125 mm during 4500 s (run 1, site Rütti). The local amplitude w_{max} replaces w_S; t_W and t_D are the arrival times of the wetting and draining fronts. The ranges of equation applicability are also shown. (See also Figure 5.) --- model; -o- data.

Table 1 Ranges of flow parameters

Parameter	*Symbol*	*Unit*	*Minimum*	*Typical value*	*Maximum*
Input rate	q_s	$m\,s^{-1}$	3.10^{-5}	8.10^{-6}	2.10^{-6}
Mobile soil moisture	w_S	$m^3\,m^{-3}$	0.003	0.03	0.12
Exponent	a	—	2.0	3.0	6.0
Conductance	b	$m\,s^{-1}$	0.001	0.3	5.0
Contact length of w_S per cross-sectional area	ℓ	$km\,m^{-2}$	0.1	5.0	30
Film thickness	F	μm	2.0	15	50
Momentum per w_S	i_w	$kg\,m^{-2}\,s^{-1}$	0.01	0.5	1.0
Kinetic energy per w_S	$E_{kin,w}$	Pa	10^{-5}	10^{-4}	10^{-3}

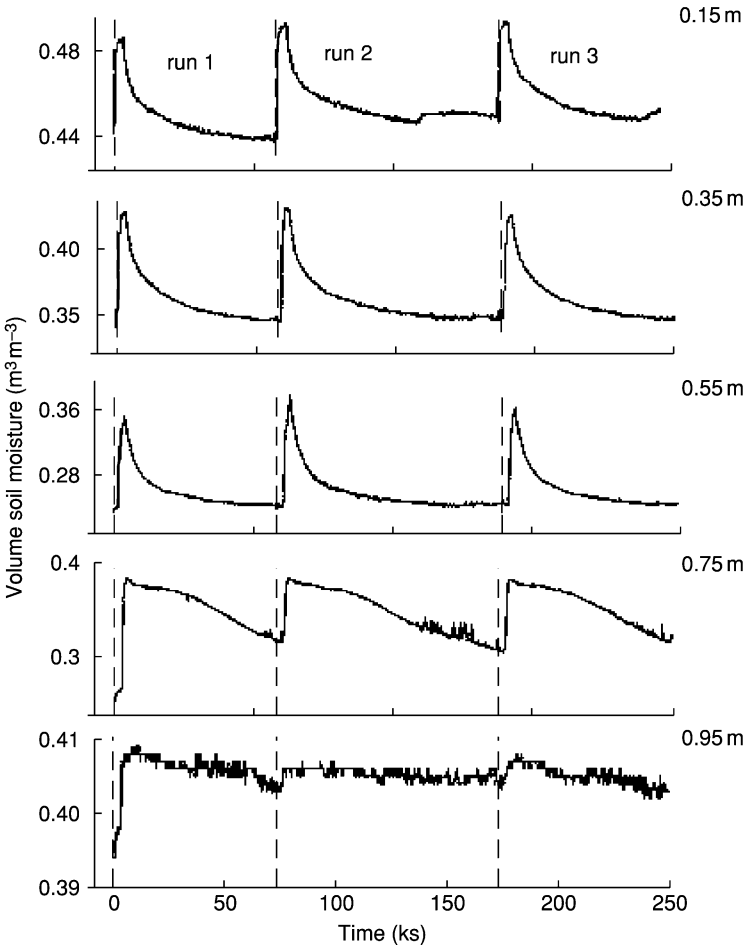

Figure 5 Soil moisture variation at depths 0.15, 0.35, 0.55, 0.75, and 0.95 m due to sprinkling 125 mm three times during 4500 s (site Rütti). The kinematic waves are easily discernible at the upper three depths of measurements. The convex reactions at depth 0.75 m indicate water backlogging above an impermeable layer between this and the 0.95-m depth. Note the different scales on the ordinates.

preferential flow between the two particular depths of soil moisture measurements. Examples of $\theta\,(Z, t)$, variations indicating deviations from the kinematic wave approach are shown in Figure 5.

The contact lengths and film thickness indicate that preferential flow is through a large number of small pores and not exclusively through 'macropores' of not-so-well-defined geometries. The range of the amplitudes includes the empirical threshold of 5% by volume of air capacity and air-filled porosity, as shown in Figure 1. On one hand, the kinetic energy per unit of flowing water is orders of magnitude smaller than the usual range of capillary potential in unsaturated soils, indicating their mutual independence. On the other hand, momentum per unit of flowing soil water is about 100 times greater than

its counterpart of the infiltration rate, indicating channeling of flow in soils. Regarding the fact that capillarity was observed in a pipe of 12 mm inner diameter, preferential flow may concur with Richards-type flow in an approximate pore size range of $6\,\text{mm} > R > 30\,\mu\text{m}$, which represents a relative range of about 1:200. Momentum of infiltration in combination with a minimum degree of antecedent saturation seem to be the two decisive flow parameters that may trigger preferential flow if the geometry of the soil structural voids permit a wave's coherence over a considerable length of flow paths.

Soil hydrologists deal mainly with vertical preferential flow, whereas catchment hydrologists relate preferential flow with lateral subsurface storm flow. The link between the two aspects requires bending of flow from the vertical to the lateral direction at some soil depth. Research on momentum of flow includes the investigation of its scalar and its vector. Early experiments in a layered soil on a hillslope using three-dimensional arrangements of TDR-waveguides indeed revealed bending of preferential flow.

Further Developments of Kinematic Wave Approaches to Preferential Flow

The kinematic wave approach, eqns [1] to [30], explains local soil moisture variations reasonably well. However, no single wave has been found so far that would explain infiltration at the profile scale. Water losses from the preferred flow paths into the soil matrix were assumed to be responsible for the deviations. Therefore, a sink function was introduced in the mid-1980s that rides on the kinematic wave. The water balance of a kinematic wave with a sink-function extension is:

$$\frac{\partial q}{\partial t} + c \cdot \frac{\partial q}{\partial z} = c \cdot w \cdot r \qquad [34]$$

with the sink strength $r\,(\text{s}^{-1})$ defined as:

$$\frac{\partial w}{\partial t} = r \cdot w\,(t) \qquad [35]$$

Due to the sink the wetting front may not penetrate beyond the depth of:

$$z^* = \frac{a \cdot b \cdot w_S^{(a-1)}}{r \cdot (a-1)} \qquad [36]$$

However, no improvement was found when calibrating the extended kinematic wave model, eqns [34] to [36], against data. It seems that water losses from the kinematic wave to the surrounding matrix pores are more complicated than assumed with eqn [35].

An approach based on a traveling diffusive wave was introduced by Di Pietro in 2002. Its water balance is:

$$\frac{\partial q}{\partial t} + c \cdot \frac{\partial q}{\partial z} = u \frac{\partial^2 q}{\partial z^2} \qquad [37]$$

where u $(\text{m}^2\,\text{s}^{-1})$ treats the wave's spreading during flow. The approach based on eqn [37] was successfully calibrated against observed drainage flow from a macroporous soil.

Applications

The concepts of preferential flow may apply to areas outside the hydrology of soils and hillslopes.

The transport of particulate matter through soils is related to the kinetic energy of flow, eqn [29], which results in a drag force acting on suspended particles. Recent investigations demonstrated that breakthrough of latex beads with diameters ranging from 0.5 to 1.75 μm and having electrically neutral surface charges was more strongly related with the kinetic energy of flow than with the variable particle diameters. In contrast, breakthrough of bacteriophages showed very strongly the effects of their variably charged surfaces.

In many areas of the industrialized world, soil compaction is the result of the employment of increasingly more efficient and thus increasingly heavier agricultural machinery. Rotating wheels may not only compact a soil in the vertical direction but knead it back and forth to some depth. The pores allowing preferential flow, rapid drainage, and efficient aeration may be squeezed at times below the plow layer. Soil strength decreases with increasing soil moisture. Thus a vicious cycle starts in that some squeezed preferred flow paths delay drainage and prolong the periods of reduced soil strength. Compaction potential thus increases if the successive soil operation happens under relatively wet soil conditions. Infiltration experiments with subsequent soil moisture recording with TDR-equipment at several soil depths allows an assessment of whether the structural pores are still adequate for drainage and aeration in the 5%-volume fraction range shown in **Figure 1**.

Summary

Poiseuille's early application of momentum dissipation to flow in closed conduits was not considered suitable to deal with flow in porous media. Darcy's law and the Richards equation were developed to deal with such flow. They do not require *a priori* information on soil structure, and the latter is based on the diffusion of potential.

Momentum dissipation approaches were applied to laminar flow in structured and nonsaturated soils with some success, still leaving open many areas for research. The major breakthrough in understanding flow in nonsaturated and structured porous media is expected to come from diffusion wave approaches that seem to lead from strict momentum dissipation and to include diffusive processes. Solute and particle transport in structured and nonsaturated soils will possibly follow similar tracks.

The relative range of pore diameters that are able to carry Richards-type flow as well as preferential flow is about 1:200. Momentum of infiltration is thought to trigger preferential flow when it is exceeding some minimum. The importance of the uppermost soil layer as being able either to transmit or mitigate momentum to deeper layers for the initiation of or prevention of preferential flow is also implicated.

List of Technical Nomenclature

η	Kinematic viscosity of water ($m^2 s^{-1}$)
θ	Volumetric soil moisture ($m^3 m^{-3}$)
ρ	Density of water ($kg m^{-3}$)
τ	Shear force per cross-sectional area (Pa)
ψ	Capillary potential (Pa)
A	Cross-sectional area of soil (m^2)
a	Exponent of kinematic wave (–)
b	Conductance of kinematic wave ($m s^{-1}$)
c	Celerity of kinematic wave ($m s^{-1}$)
c_D	Celerity of the draining front ($m s^{-1}$)
c_F	Celerity of the wetting front after interception ($m s^{-1}$)
c_W	Celerity of the wetting front ($m s^{-1}$)
$E_{kin,w}$	Kinetic energy per unit volume of mobile water (Pa)
F	Thickness of water film (m)
f	Film thickness variable (m)
g	Acceleration due to gravity ($m s^{-2}$)
H	Vertical macroscopic length of connected water films (m)
I	Momentum of water film ($kg m s^{-1}$)
I_h	Horizontal momentum loss of water film ($kg m s^{-1}$)
I_v	Vertical momentum of water film ($kg m s^{-1}$)
i_W	Momentum per unit volume of mobile water ($kg m^{-2} s^{-1}$)
K	Hydraulic conductivity ($m s^{-1}$)
ℓ	Contact length of mobile water (m)
M	Mass of soil water (kg)
q	Volume flux density ($m s^{-1}$)
q_s	Volume flux density of input ($m s^{-1}$)
R	Radius (m)
r	Sink strength ($m s^{-1}$)
t	Time (s)
t_D	Arrival time of the draining front (s)
t_I	Time of front interception (s)
t_S	End of input to the soil surface (s)
t_W	Arrival time of the wetting front (s)
u	Coefficient of wave diffusion ($m^2 s^{-1}$)
V	Water volume of kinematic wave per cross-sectional area (m)
v	Velocity of water film ($m s^{-1}$)
w	Mobile soil moisture ($m^3 m^{-3}$)
w_F	Mobile soil moisture at the front after front interception ($m^3 m^{-3}$)
w_{max}	Local amplitude of the kinematic wave ($m^3 m^{-3}$)
w_S	Mobile soil moisture at the surface during infiltration ($m^3 m^{-3}$)
Z	Specified soil depth (m)
z	Depth vertically down (m)
z^*	Maximum depth of front penetration (m)
z_D	Depth of draining front (m)
z_F	Depth of wetting front after front interception (m)
z_I	Depth of front interception (m)
z_W	Depth of wetting front (m)

Introduction

Animal manures are the solid, semisolid, and liquid by-products generated by animals grown to produce meat, milk, eggs, and other agricultural products for human use and consumption. They are mixtures of animal feces, urine, bedding materials (e.g., straw, sawdust, rice hulls), and other materials associated with animal production, such as waste feed, soil, wash waters, and any chemical or physical amendments used during manure handling and storage. Manures have been used as beneficial soil amendments since the dawn of civilization and were the primary soil amendment used in agriculture until the advent of chemical fertilizers in the 1940s. Today, manures continue to be regarded as valuable agricultural resources, because they are important sources of plant nutrients and are well known to improve soil physical and biological properties through the addition of organic matter. However, the changing nature of animal production in some countries, the move away from small farms that have adequate land bases to recycle manure nutrients through crop production, and the move toward geographically concentrated confined animal feeding operations (CAFOs) have raised concerns about the environmental and human health impacts of modern animal production and manure utilization practices.

Manure Generation, Use, and Properties

Summary of Global Trends in Animal Production

Animal production has increased worldwide in the past 40 years, although it is not distributed evenly over the globe (Figure 1a and Table 1). Long-term trends in animal production are most easily recognized if developed and developing countries are viewed separately, as greater intensification of animal production initially occurred in developed countries. Today, however, many developing countries are rapidly increasing animal production, while in most developed countries the number of animals produced is decreasing or leveling off, as seen for poultry production in Figure 1b. Calories from animal protein cost more to produce than calories from crops. Therefore as a general rule, as poorer countries develop and disposable income increases, the population can more easily afford animal protein, and there is a corresponding increase in animal production. As a result, meat consumption in developing countries is projected to double in the next 20 years, although it will still be below that of developed countries.

Globalization of agriculture has also changed the nature of animal production over the last few decades, increasing the distances that animal feed and animal products travel between sites of production and consumption. For example, poultry and swine produced in the eastern USA may use feed grains grown in the Midwestern US, with the meat

Table 1 Global animal production, by major animal species, for major geographic regions and for developed and developing countries, 2001

	Animal species				
Country	*Cattle (millions)*	*Chickens (millions)*	*Goats (millions)*	*Pigs (millions)*	*Sheep (millions)*
Asia	455	7180	462	551	371
Europe	101	1257	15	164	129
Africa	230	1276	219	18	250
North America	110	1988	1	72	8
South America	309	1765	22	55	75
Developed countries	326	4358	30	282	381
Developing countries	1026	10 501	708	641	675

Data from Food and Agriculture Organization of the United Nations (2003) Available online at: http://apps.fao.org/page/collections?subset-agriculture.

ultimately being consumed in Asia. In many countries these trends have also resulted in marked increases in the geographic intensity of animal production, with more animals being grown in confinement on farms that are located in close proximity to each other and that have the same, or declining amounts of cropland available for manure use. Figure 2 shows the change in the geographic distribution of confined animal production (all species) in the USA from 1982 to 1997.

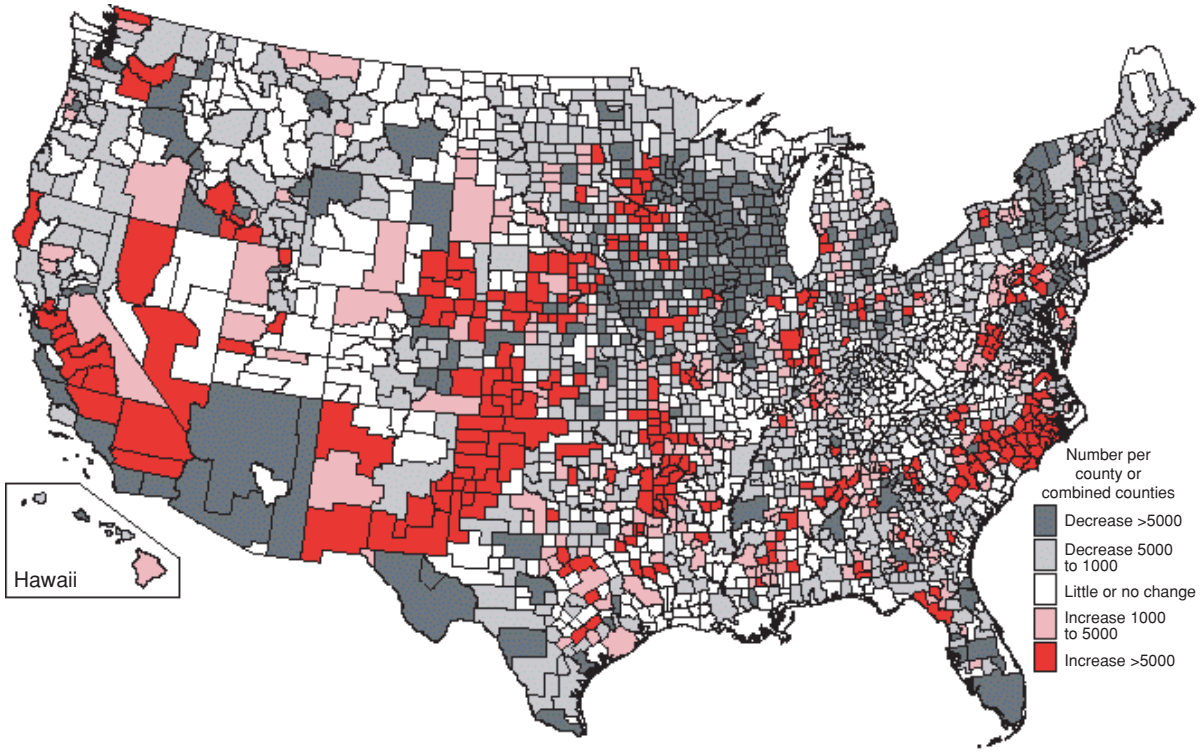

Figure 2 Change in the number of animal units in each county of the USA (1982–97). (Reproduced from Kellogg RL, Lander CH, Moffitt DC, and Gollehon N (eds) (2000) *Manure Nutrients Relative to the Capacity of Cropland and Pastureland to Assimilate Nutrients: Spatial and Temporal Trends for the United States*. Fort Worth, TX: GSA National Forms and Publication Center.)

Trends in Manure Production

The nature of the animal production system directly affects the amount of manure available for use as a soil amendment. For example, unlike the manure from animals grown in confinement (e.g., barns, feedlots), manure is not regularly collected from animals mainly grown on grassland or rangeland. Thus the amount of 'recoverable manure' that is available for land application as a soil amendment can vary widely between and within countries. However, as intensive cattle, swine, and poultry operations are projected to account for an increasing proportion of animal production in both developed and developing countries, collection and spreading of manure will probably become more and more common in the future. Manure production by species also differs widely by country; for example goats are very common in Asia and Africa, while cattle are more predominant in North and South America. In global terms, poultry production has grown the most in the last few decades, followed by pig and goat production, while the number of cattle produced has only increased slightly (Figure 1a). Indeed, in developed countries, poultry meat is seen as the only growth area toward 2010, in terms of per capita consumption. Despite these variations, the amount of manure produced by different animals is reasonably well known, as shown in Tables 2–4, which summarize manure production and characteristics for the major animal species raised today.

In general, the major trend today for animal, and hence manure, production in both developed and developing countries is for increasing intensification and consolidation of producers. This means that in developed countries, even though total manure production is leveling off, it is confined to fewer producers operating at fewer sites, with the result that the amount of manure generated in some regions is increasing markedly. For example, in the USA, the number of livestock operations decreased by 24% between 1982 and 1997, even though total animal production numbers were fairly stable. This concentration of animal production in specific areas in developed countries applies mainly to swine, cattle (beef, dairy, and veal), and poultry (chicken and turkey) production. In developing countries animal production is generally not as intensive but, as these countries develop, their production systems will inevitably become more intensive for the same economic reasons that promoted this trend in developed countries.

Table 2 Liquid-pit manure production and nutrient content for major animal species

Animal	Manure produced (kg year^{-1})	Nutrient concentration (kg 1000 l^{-1})			
		Total N	NH_3-N	P	K
Swine (farrow-finish)	17 007	3.4	1.9	1.3	2.3
Dairy (cow)	24 490	3.7	0.7	0.8	1.9
Dairy (heifer)	11 338	3.8	0.7	0.7	2.8
Beef (cow)	13 605	2.4	0.8	0.8	2.4
Poultry (layer)	59	6.8	4.4	2.7	3.3
Poultry (broiler)	38	7.6	1.6	2.1	2.9

In some cases, the geographic intensification of animal production has led to manure generated within confined areas of production, containing nutrients in excess of local crop requirements, while other areas within the region or country have little or no local supply of manure nutrients for crop production. This is because the economic value of the manure cannot support the costs of its redistribution to areas where it may be needed as a soil amendment. As illustrated for the USA in Figure 3, this has resulted in large 'surpluses' of manure nutrients in some areas where animals are produced and increasing concerns about nonpoint source pollution of air, soil, and water in areas where animal production is concentrated. These concerns arise because farmers who have excess manures, relative to what is needed to produce crops, generally have no economically viable alternatives to land application. Because of this, manure nutrients are often overapplied or applied at inappropriate times of the year, leading to increased nutrient losses to surface water and groundwater by runoff and leaching, and to the atmosphere by volatilization. In some developed countries (e.g., the Netherlands), regulations have been enacted to decrease animal production intensity because of the environmental impacts associated with the disposal of excess manures. Efforts to control manure generation and use are expected to increase in developed countries in the future; however, in developing countries this may not occur until manure and nutrient excesses begin to create similar environmental problems.

Manure Characteristics by Species

The physical properties and nutrient content of animal manures are reasonably well known and tables summarizing manure characteristics have been developed for use by farmers and their advisors (Tables 2–4). Values such as these, however, are only guidelines, as it is recognized that manures can vary widely in composition both between and within species. Therefore, regular testing of manures for properties that influence their agricultural value and potential environmental impacts is often advised. Results from manure testing have consistently shown that differences in manure nutrient content between animal species are apparent (Tables 2–4). For example, both N and P concentrations in manure increase in the order cattle < swine < sheep and goats < poultry. Poultry litter contains two to four times the concentration of manure nutrients as other livestock manures, which leads to particular problems in areas where the poultry industry has intensified, compared with areas of other intensified livestock industries. For example, in the USA, of the 73 counties that

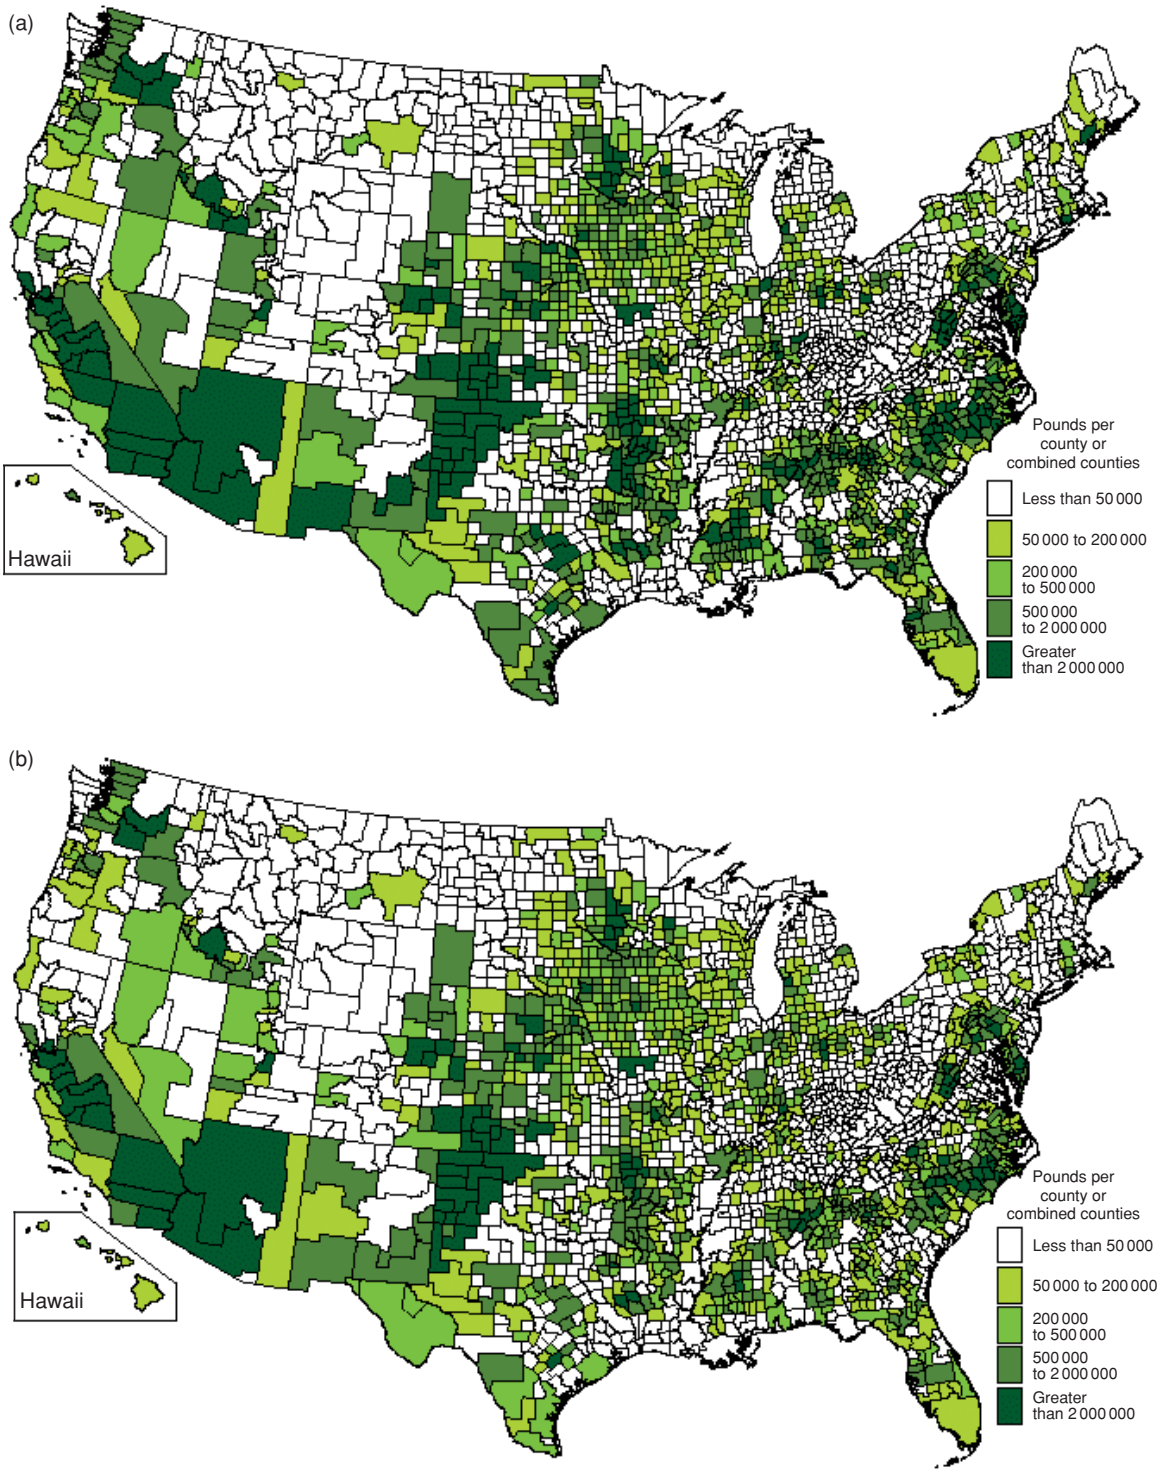

Figure 3 Potential excess of manure (a) nitrogen and (b) phosphorus for each county of the United States in 1997, assuming no export of manure from farms. (Reproduced from Kellogg RL, Lander CH, Moffitt DC, and Gollehon N (eds) (2000) *Manure Nutrients Relative to the Capacity of Cropland and Pastureland to Assimilate Nutrients: Spatial and Temporal Trends for the United States*. Fort Worth, TX: GSA National Forms and Publication Center.)

had insufficient land for the amount of manure N generated, 82% had poultry as the dominant livestock, while of the 160 counties with excess manure P, 64% were dominated by poultry production (Figure 3).

The variability in manure composition is due to a number of factors, including animal species and age, diet, digestibility of feed materials, environmental conditions in animal housing facilities, and the

means by which manures are handled and stored prior to use or disposal. For example, the amount of feed concentrates and other feed additives (e.g., enzymes) in a diet (and thus nutrients in manure) can vary between developed and developing countries; manure storage and drying can reduce nitrogen (N) content through ammonia volatilization; and manure collected from open-housing areas or stored in lagoons can be diluted by rainfall.

Major Uses of Animal Manures

Land application to meet crop N, P, and other nutrient requirements is by far the most widespread and long-standing use of animal manures. However, other uses do exist and are becoming more common, especially in areas where animal production has become so intensive that the amount of nutrients in the manure produced exceeds the nutritional requirements of crops grown on the local land base. Sometimes manure is fed back to animals as a cheap nutrient source (e.g., feeding chicken litter to beef cattle). However human and animal health concerns have been raised about this practice, in the wake of the 'mad cow disease' outbreak in Europe (caused by feeding contaminated animal products back to cattle), and this is not viewed today as a major alternative to land application of manures. Mushroom production in certain areas can use large amounts of manure, especially from horses and poultry. In China, manures are used extensively in fish production. Several other options exist for manure use, and although these uses are only carried out on a relatively small scale today, they represent a growth area, as increasing intensification of agriculture produces excess amounts of manure in localized areas of more countries. Examples of other manure uses are composting to produce high-value soil amendments, methane generation via anaerobic digestion, burning to generate energy, and pelletizing manures to make organic fertilizers.

Best Management Practices (BMPs) for Animal Manures as Soil Amendments

Overview

Years of research have identified the most effective approaches to manage animal manures as agricultural soil amendments and many references provide detailed discussions on this subject. In general, manures have historically been viewed as organic fertilizers and have been applied at rates that would provide adequate nutrients for crops to be grown on the farm, based on realistic yield goals and the results of soil and manure tests that quantify the amount of manure nutrients needed to attain economically optimum yields. In conjunction with this, soil and water conservation practices (e.g., buffer strips, grassed waterways, and cover crops) are usually recommended to prevent off-site movement of manures or manure nutrients. Other benefits of manure use (e.g., increasing soil organic matter content and improving soil physical and biological properties) are recognized but usually do not serve as the basis for determining manure application rates. The most effective BMPs for manure use vary with the type of agriculture being practiced. This can be illustrated by comparing two of the most predominant agricultural settings worldwide: grassland agriculture and arable crop production.

Manure management for grassland agriculture In general, there are two basic systems associated with grassland agriculture: (1) pasturing, and (2) confinement. Animals such as cattle or sheep graze in pastures and deposit manure as they produce it. Thus, manure 'application' is somewhat random and occurs without any form of incorporation into the soil. Where animals are confined indoors for at least part of the year, the manure they generate is collected before being land-applied. For confinement systems, manures are most commonly applied to the surface of pastures without tillage, although in some cases they may be injected into the soil using specialized equipment. With intensification of grassland agriculture, there has been a trend toward animal confinement and manure spreading, and away from solely pasturing animals. It is now estimated that about half of the manure produced in the USA can be collected, with much of the remainder being directly deposited by grazing animals. As more manure is collected, the opportunities to implement BMPs that better utilize the collected manures as soil amendments, or for other end uses, increase.

In general, manures are valuable sources of nutrients for grass and animal production in pasture systems. However, because they are surface-applied, several pathways for the loss of nutrients and other manure constituents (e.g., pathogens, hormones, and antibiotics) exist that are more pronounced than when manures are incorporated into arable soils. These nutrient losses are both economic (loss of plant nutrients) and environmental (deleterious impacts on air and water-quality) problems. For example, substantial gaseous losses of N by volatilization of ammonia occur directly from manures lying on the soil surface. This may increase the need to purchase N fertilizers to compensate for the lost manure N and also contribute to environmental concerns when the volatilized NH_3 is redeposited on to

soils (which may cause soil acidification) or into aquatic ecosystems (where the N may contribute to eutrophication).

As grassland is unlikely to be tilled regularly, there is also a tendency for nutrients to accumulate very near the soil surface as manures slowly decompose. This is particularly true for P, which is strongly adsorbed by soil clays and oxides. When runoff occurs, dissolved and colloidal P either in the manures lying on the surface or contained in the nutrient-rich uppermost layers of the grassland soil can be transported to surface waters, increasing the potential for eutrophication of surface waters.

Managing manures in grassland agriculture thus focuses on the use of BMPs that sustain optimum grass production and also prevent surface and gaseous losses of nutrients and other manure constituents. Examples include the use of soil testing and equipment calibration to prevent overapplication of manures; avoiding poorly timed and badly placed manure applications (e.g., immediately before rainfall events or snowmelts and in close proximity to surface waters or wellheads); use of chemical and physical manure amendments that decrease the solubility or volatility of N and P; and injection of manures below the grassland soil surface, although this is a practice that entails extra technology and costs and is not widely used at present.

Managing manures for arable crop production Unlike manures in grassland agriculture, animal manures used in arable crop production are commonly incorporated into soils by some form of tillage (e.g., plowing, disking, rototilling) or by injection. This is not always the case, however, as many agricultural crops today are produced using reduced or 'no-till' systems, where the soil is not plowed annually or is only tilled to a shallow depth to prepare a seedbed for annual crops. Manures incorporated into soils in arable cropping systems decompose as a function of soil microbial activity, which in turn is dependent upon soil temperature, moisture, aeration, and soil chemical properties (e.g., pH, salinity, nutrient status). As the manures decompose, they release nutrients into the soil solution that can be retained by chemical processes (e.g., ion exchange, adsorption, precipitation) or as part of the soil biota (e.g., incorporation into microbial biomass). Manure decomposition can also affect soil pH, soluble-salts concentration, and soil organic matter content, all of which affect plant growth and the potential for nutrient losses. Much research has been directed toward the development of predictive models that can estimate the rate of manure decomposition in soils and the total amount of nutrients released from different types of manures as a function of soil properties and environmental conditions.

As with grassland agriculture, manures incorporated into arable soils are well known to build soil fertility and improve soil physical properties such as soil structure and tilth and thus are important soil amendments for crop production. Nutrient losses can also occur from arable soils, with the greatest concerns being the erosion of soil particles (and nutrients that are bound to these particles, particularly P) and the leaching of soluble nutrients, especially nitrate-N, through the soil profile to groundwater. Soil erosion concerns are greater with arable crops than grasslands because of the tillage practices associated with manure incorporation and the lack of the permanent plant cover that can filter eroding soil particles from runoff. Gaseous losses of N are much reduced when manures are incorporated into arable soils, because manure ammonium-N is bound to soil colloids and is also not in direct contact with the atmosphere. Similarly, the potential for losses of soluble P is less in arable soils, because manures are not lying on the soil surface and because tillage prevents the development of the highly enriched zones of P accumulation often found in the upper few centimeters of untilled grassland soils.

Manure management for arable crops is similar to that described above for grasslands, with a few key differences. There is a much greater focus on controlling soil erosion and there are greater limitations on the times of year that manure can be applied to annual row crops. In many cases manures must be applied well before planting the crop, which then increases the likelihood for nutrient losses.

Contemporary Approaches to Manure Management

As animal agricultural operations have become increasingly intensive, many problems have emerged that point to the need for improvements in manure-management practices. While these problems are more serious in developed countries, where animal production is most intensified, they are emerging issues in developing countries, where information on how to avoid the environmental problems associated with intensive animal agriculture will be needed in the future.

One of the main problems with traditional approaches to manure management is the fact that, while manures provide most of the nutrients needed by crops, the relative proportions of plant nutrients present in manures are not in balance with the amounts needed by many crops. This can result in under- or overapplication of some nutrients. For

example, manures have usually been viewed as N sources and applied to meet crop N requirements. However, because the N:P ratio in manures is not in balance with the N:P ratio in most crops, applying manures to meet crop N needs, long the recommended practice, has often resulted in the overapplication of P and the buildup of P in soils to values well above those needed for optimum crop yields. Because of this, concerns now exist in many countries about losses of P to surface waters and shallow groundwaters from soils that have received long-term manure applications. Other emerging concerns for manure use as soil amendments include environmental impacts of other manure constituents such as pathogens, hormones, antibiotics, and nonessential trace metals on human health and environmental quality.

In some countries, these concerns have resulted in the development of more-intensive, structured, and even regulatory approaches for manure management, such as the comprehensive nutrient management plans (CNMPs) now recommended by the US Natural Resources Conservation Service for animal feeding operations (AFOs). The six basic components of a CNMP are described below and may apply, in principle, not only to the intensive animal agriculture common in the USA, but to animal production operations worldwide, including the less-intensive systems in many developing countries.

1. Manure and wastewater-handling and storage: This element of the CNMP focuses on the activities at the animal production facility (e.g, barn, feedlot) and any areas where manure is handled and stored prior to land application. The general goals are to minimize the amount of waste produced and to handle, store, treat, and transfer wastes to off-site uses in a manner that minimizes any losses, spills, or direct discharges to the environment. Areas of particular concern include providing adequate manure storage, preventing direct losses of pollutants from the farmstead and manure storage areas to nearby surface waters, minimizing odors and air-quality concerns, and safely disposing of dead animals, spoiled feed, and the like;

2. Land treatment practices: Because land application is the main use of most animal manures, well-designed land-treatment practices are vital components of a CNMP. Factors that must be addressed are: selection of the appropriate rate, method, and timing of application of manures, relative to crop needs; implementation of soil conservation practices that prevent soil erosion and the loss of soluble nutrients from manures and manure-amended soils; and establishment of monitoring programs to assess the effectiveness of the land-treatment practices over time;

3. Nutrient management: This refers to the development of a systematic approach to manage all nutrient sources on the farm, not just manures. Typically this begins with an effort to maintain nutrient balance in the operation, where nutrient inputs in feed, fertilizers, animals, and other sources do not exceed nutrient outputs in crops and animal products, except as needed to build soil fertility to optimum levels for crop growth. Key factors considered in this component of the CNMP include a farm-scale nutrient budget (i.e., is there a nutrient surplus or deficit on the farm?), crop nutrient requirements at realistic yield goals, soil-testing to assess the need for additional nutrients, manure-testing to determine the quantity of manure nutrients available and the need for off-farm nutrients, and the most efficient means to apply all nutrient sources to crops on the farm. Other considerations include how the approach used to manage nutrients might affect air quality, odors, pathogens, and the buildup of soluble salts and heavy metals in soils;

4. Record-keeping: Effective implementation of a CNMP requires good record-keeping. The following information should be recorded, by field, and reviewed to assess current practices and detect trends with time: basic farm characteristics (e.g., amount of land; weather conditions; number and type of animals or animal products produced; type and acreage of crops grown; amount of manure produced, used on the farm or transferred off-site); manure storage, handling, and treatment; soil, manure, and plant tests; crop-management practices (hybrid, planting date, seeding rate, irrigation, yields), and nutrient application practices (source, amount applied, when applied, method applied, equipment calibration);

5. Feed management: Animal-based agricultural operations are increasingly investigating the opportunity to improve nutrient use efficiency by animals, which, in turn, reduces the excretion of nutrients such as N and P. Research has shown that modifying animal diets by reducing the concentration of mineral supplements, or by including enzymes and other feed additives, can result in the same level of animal performance but reduce the amount of N and P excreted. This results in both an economic savings (fewer nutrients are needed for the same level of production) and lower nutrient concentrations in manures, which can be of benefit in areas where nonpoint nutrient pollution of surface and ground waters is of concern;

6. Alternative uses for manures: There is growing interest in developing alternatives to land application for some types of animal manures, particularly in areas where animal production has been geographically intensified and nutrient surpluses exist (see Figure 3). To sustain, or expand, operations in areas

such as these, it is necessary to find alternatives to land application, and this is a central part of an efficient CNMP. This can generate additional income and also help farmers redistribute surplus nutrients to off-site uses. The most common approaches investigated to date have been energy production (methane generation and incineration for electricity), production of value-added products such as composts and pelletized fertilizers, and transportation of manures from areas of nutrient surplus to nutrient deficit, usually mediated by 'manure brokers.'

Summary

The use of animal manures as soil amendments must be done in a comprehensive manner to maximize their agricultural value and minimize their potential impacts on environmental quality and human health. There is no doubt that animal manures are valuable natural resources, particularly in countries where the availability of inorganic fertilizers is limited. When managed properly, manures provide plant nutrients, build soil organic matter, and improve soil physical properties, all of which are vitally important for soil quality and crop production. At the same time, the growing global trend toward intensification of animal production is gradually concentrating manure generation on smaller amounts of land. Transportation costs and the lack of an organized, efficient manure processing and distribution infrastructure are the major limitations to relocation of manures from areas where they are in surplus to areas where they are badly needed. When an adequate land base is not available to recycle manure nutrients in a balanced manner, overapplication of nutrients such as N and P, which can negatively affect air, soil, and water quality, becomes a potential problem. Regional- and/or national-scale planning is required to develop and implement programs that can sustain modern animal production and use animal manures in an environmentally sound manner.

MARBUT, CURTIS FLETCHER

J P Tandarich, Hey and Associates, Inc., Chicago, IL, USA

© 2005, Elsevier Ltd. All Rights Reserved.

The brilliance that characterized the life of Curtis Fletcher Marbut, dedicated to soil science in the service of humanity, ended on August 25, 1935 in what was then Harbin, Manchuria, China. He was the best-known soil scientist–geographer of his day, and his reputation was worldwide. Marbut was a pioneering soil scientist in the classroom, office, field, and laboratory. More than that, he was a disseminator of ideas; an internationalist who did not let politics, ideology or his personal health and welfare stand in the way of scientific advancement and friendship. The biography of Marbut is a remarkable story of a 'self-made' man who came from a progressive Ozarks family in rural southwest Missouri to become one of the foremost agricultural geologists, geographers, and soil scientists in the world during the formative period of modern soil science in the early twentieth century. Modern soil science has its origins in late eighteenth- and early nineteenth-century agricultural chemistry and agricultural geology. The term Bodenkunde, coined in 1837 by German agricultural chemist Carl

Sprengel, meant soil knowledge – a collection of facts. Friedrich Albert Fallou, a German agricultural geologist, attempted to elevate Bodenkunde to a formal science of soil that he called Pedologie. The German scientists never adopted the term, preferring to use Bodenkunde to mean soil science. Russian agricultural geologist Vasilii V. Dokuchaev used the word 'pochvovedenie' for soil science. In the twentieth century, pedology came to mean the study of the genesis, morphology (appearance), nature, classification, and geographic distribution of soil.

This short narrative summarizes the highlights of Marbut's life as a native of the Missouri Ozarks, an academic, a scientist with the US Soil Survey, an explorer and internationalist, and a scientist with a Unitarian philosophy of service to humanity for which he ultimately gave his life.

Missouri Ozarks Native and Academic

Marbut was born during the American Civil War, on July 19, 1963, to Nathan and Jane Browning Marbut, along Little Flat Creek near Verona in Lawrence County, Missouri. After surviving whooping cough in the first weeks of life, he grew up in an atmosphere of love, learning, and a concern for others, largely fostered by his Quaker mother.

His school attendance began in the one-room Marbut family school, and continued at a school in McDowell, Missouri, where he also taught when he was 17. Using his teacher's earnings, he enrolled in the Collegiate Institute of Professor Noah Lee Maiden at Cassville, Missouri (**Figure 1**), an experience that led him ultimately to enroll in the University of Missouri at Columbia (UMC) in 1885. He went on to receive a BS degree from UMC in 1889 and, in 1890, was appointed to the Missouri Geological Survey. In 1891, he married Florence L. Martin of Cassville, Missouri (**Figure 2**) and established residence in Jefferson City, Missouri. They had five children: Louise Marbut Moomaw (**Figure 3**), Thomas Fiske Marbut, William Martin Marbut, Helen Marbut, and Fredrick Browning Marbut. The lifelong correspondence between Louise and her father gives an insight into his life not possible through his published works alone.

The family moved to Cambridge, Massachusetts, in 1893 so that Marbut could enroll as a graduate student in geology at Harvard University. Although his major professor and adviser was the eminent pioneer geographer and geomorphologist William Morris Davis, Marbut revealed in his correspondence to Louise that Nathaniel Southgate Shaler, a pioneer geographer and agricultural geologist, was his academic and professional inspiration to study soils.

Figure 1 Professor Noah Lee Maiden and Curtis Marbut, 1880. Curtis Fletcher Marbut Papers, 1852–1963, Western Historical Manuscript Collection, Columbia.

Just prior to and during Marbut's tenure at Harvard, Shaler had become highly regarded for his publications on soils and natural resources conservation. The most notable of these were *Animal Agency in Soil-Making* (1888), *The Origin and Nature of Soils* (1891), *Nature and Man in America* (1891), *The Interpretation of Nature* (1893), and *The Economic Aspects of Soil Erosion* (1896). Shaler was a compelling lecturer who promoted the education of the whole student: mentally, physically, and spiritually. Marbut received an MA in 1894 under Davis. In 1895, he completed the residence requirements for the PhD and returned with his family to the UMC with a faculty appointment. Although he finished and published his PhD dissertation in 1896 with Davis'

approval, he never returned to Harvard for his oral defense exam and the PhD was never awarded.

Marbut served the UMC Geology Department as instructor (1895–1897), assistant professor (1897–1900), and professor (1900–1910), and was simultaneously appointed assistant geologist in the Missouri Geological Survey until 1904. His PhD dissertation *Physical Features of Missouri* published in 1896 by the Missouri Geological Survey was a pioneering study in physiography and surface hydrology. While at the UMC, Marbut published numerous studies, including: erosional remnants Crowley's Ridge, Cote Sans Dessein, and Grand Tower (1898); coal stratigraphy of areas of northern Missouri (1898); the lowlands of Southeastern Missouri (1902); the geology of Morgan County, Missouri (1908); and the soils of the Ozark region (1910).

In 1904, Marbut and Agriculture College Dean Henry J. Waters collaborated on a large-scale plaster physiographic map of Missouri that won a gold medal at the 1904 Louisiana Purchase Exposition in St Louis. In addition, Marbut and Waters coauthored the first attempt at a general soil map of Missouri that, together with two geological maps and a chapter on geology and physiography by Marbut, were published in the Exposition's volume, *The State of Missouri*. The following year, due to the influence of Waters and Cyril G. Hopkins of the University of Illinois, the University of Missouri Board of Curators organized the Missouri state soil survey and named Marbut as director. For the next 5 years, Marbut oversaw and contributed to the preparation and publication of individual county soil surveys. Thus began a lifelong interdisciplinary collaboration between Marbut and UMC faculty members Merritt Finley (known as M.F.) Miller of the Agronomy Department (**Figure 4**) and Homer L. Schantz of the Botany Department (**Figure 5**).

When, in 1909, USDA Bureau of Soils Chief Milton Whitney came to the University as keynote speaker at the annual Farmer's Week activities, he lured Marbut into the federal service as Special Agent in the national soil survey. Marbut's first task was to make a reconnaissance soil survey of the Ozark region of

Figure 5 Homer L. Schantz and Curtis Marbut taking soil samples in South Dakota, 1925. Western Historical Manuscript Collection, Columbia.

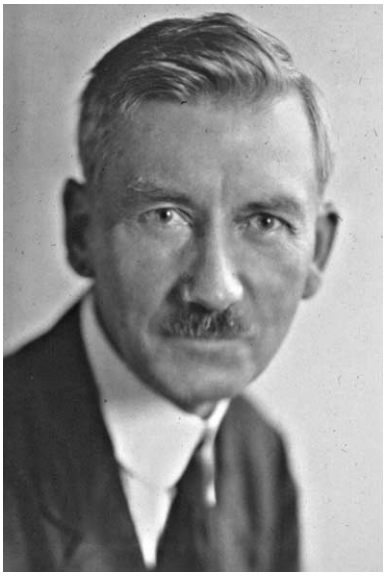

Figure 6 Curtis Marbut, *c.* 1920. Western Historical Manuscript Collection, Columbia.

Arkansas and Missouri. However, Marbut's wife Florence died from pneumonia that same year, leaving him in care of the family. When he was promoted to Scientist in the Soil Survey in 1910, he took a 2-year leave of absence from UMC for him and the family to take up residence in Washington, DC.

Scientist in Soil Survey

Marbut began his federal professional career by publishing the results of his Ozark soil survey in 1911, and leading the preparation of a monumental tome on US soils published in 1913. Marbut was dissatisfied with the latter work because the soil concepts and descriptions used in the soil survey program were unsystematically applied throughout the country. Nevertheless, he was appointed Scientist-in-Charge of the Soil Survey in 1913, but he and the family returned to the UMC. Suddenly, he decided to return to Washington and left the family at home in Columbia with a housekeeper and Louise to begin the most significant part of his professional life.

Upon his return to Washington, Marbut revisited the soil survey concept–description problem. He wrote to Louise about the situation that, "For four years I continued to grope in darkness without a ray of light." Then in 1914, Marbut discovered one of the two copies of *Die Typen der Bodenbildung* by Konstantin D. Glinka, a student of pioneer Russian soil scientist Vasilii V. Dokuchaev. The books were obtained by the USDA Departmental Library just prior to the outbreak of World War I. After his first reading of Glinka, Marbut wrote, "it comes to me suddenly – the soil profile." He translated the work in 3 years, and then unsuccessfully tried to publish it 1920 in during the height of the 'Red Scare' of anti-Bolshevik sentiment. Another obstacle was Whitney's disdain for foreign ideas and work. As with the departure of his predecessor Charles Nelson Coffey, Marbut feared a similar fate awaited him from Whitney who "had a reputation for getting rid of those who did not agree with him." When confronted by Whitney, Marbut told him that he would "follow his policies, but would think for myself." Marbut encountered anti-Bolshevik sentiment in the Bureau of Soils, writing: "I was called a Russian worshipper by my own men."

Marbut evaded this ethnocentric attitude, as he said, by having "to work in secret." By 1920, he had prepared a limited number of carbon copies of the Glinka translation for circulation to a few selected colleagues (Figure 6). In 1921, at the American Soil Survey Workers Association (ASSA) meeting in East Lansing, Michigan, he introduced the Russian concepts of classification and soil profile without identifying their origin. The ASSA, founded in 1920, was an organization started by scientists in soil survey for the promotion and publication of their ideas. Roy W. Simonson, however, has stated that the ASSA was formed "to counteract the growing influence of C.F. Marbut." Nevertheless, the ASSA was influential in disseminating ideas and it joined with the Soils Section of the American Society of Agronomy to create the Soil Science Society of America (SSSA) in 1936.

He worked with ASSA colleagues and soil survey parties to apply these 'new ideas' in the USA. Marbut's own notes in his personal papers clearly indicate his dedication to convince US soil scientists of the

efficacy of using the Russian profile concept as a basis for soil descriptions. To this end, he personally visited as many soil survey field parties as possible and participated in their yearly field reviews to exercise his influence and powers of persuasion – a practice that he continued his entire career.

During this time, Marbut's reputation grew in disciplines outside soil science, such as Pleistocene geology. An example of this is his interaction with University of Illinois faculty member and Illinois state geologist Morris M. Leighton. In the 1920s, Leighton was working to develop the weathering profile concept, originally conceived by Iowa state geologist George F. Kay. He stated that both Glinka's book and Marbut influenced him during the latter's visits to the University of Illinois between January and July 1923. Leighton credited Marbut for further insights obtained on the soil profile and its homologous application in geology as the weathering profile.

By the 1924 ASSA meeting, Jethro Otto Veatch of Michigan State University knew of the Russian origin of the ABC soil profile when he publicly referred to it as 'the Glinka scheme.' The foreign source of this soil concept was known among the soil scientists and seemed to be less of a problem.

Marbut's 1927 presentations at the First International Congress of Soil Science (see below; Figure 7) and his 1928 lectures in the Graduate School of the USDA represented further opportunities to promote the Russian ideas. The lectures, some of which were published in 1951, contained numerous references to the Russian work and influenced many soil scientists, particularly his own staff members, such as Mark Baldwin, Charles Kellogg, and James Thorp (Figure 8). The results of his lifelong work on the description and classification of the soils of the USA were published in the 1935 *Atlas of Agriculture* that included a monumental soil map.

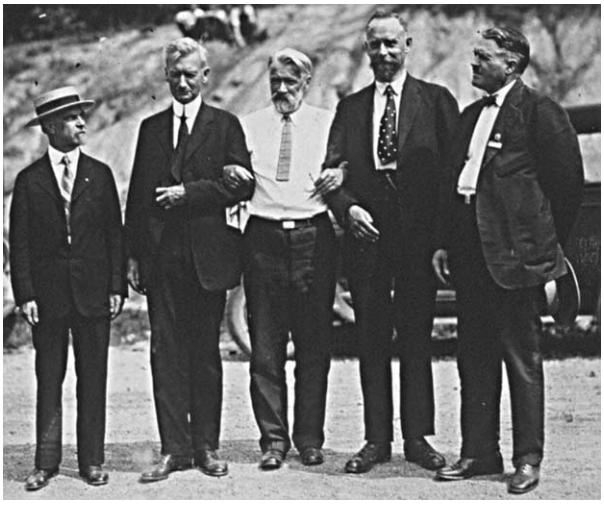

Figure 7 Oswald Schreiner, Curtis Marbut, Konstantin D. Glinka, D.J. Hissink, and Arthur G. McCall, 1927. Western Historical Manuscript Collection, Columbia.

Internationalist–Explorer

From 1920 until 1935, Marbut assumed the role of an internationalist in the field of soils. His extensive travels and explorations during this period carried him to many parts of the world and gained for him the well-earned reputation as an international authority on soil geography – as much at home in the study of the soils of Europe, Africa, and South America as those of his homeland (Figures 9 and 10).

Marbut acquired his first-hand knowledge of soils and landscapes of the world through his exhausting schedule of trips and expeditions. His first trip to Europe was on a sabbatical from UMC in 1899–1900 with colleague Isidor Loeb, during which they studied the Alps, the Hungarian plain, the Mediterranean region, the British Isles, and Scandinavia. In

Figure 9 During the Amazon expedition, 1923. Western Historical Manuscript Collection, Columbia.

1918, Marbut and Schantz, who had gone from the UMC to the USDA Bureau of Plant Industry, studied the vegetation and soils of Africa for the American Commission to Negotiate Peace. In April 1919, Marbut and Bureau of Soils colleague Hugh Hammond Bennett went to Latin America to soil survey a disputed boundary between Guatemala and Honduras, sponsored by the American Geographical Society (AGS). He traveled to Prague, Czechoslovakia, in 1922 for the International Agrogeology Conference and subsequent field trip. From July 1923 to January 1924, he mapped the interior Amazon basin as a representative of the Brazilian-American Rubber Commission. Immediately afterward, until July, he studied the soils of Argentina under sponsorship of the AGS. Later that year, he traveled to Rome for the meeting of agro-geologists at which he assisted in the formation of the International Society of Soil Science (ISSS). At this meeting, Jacob G. Lipman of Rutgers University and he began preparations for holding the First International Congress of Soil Science in Washington, DC in 1927.

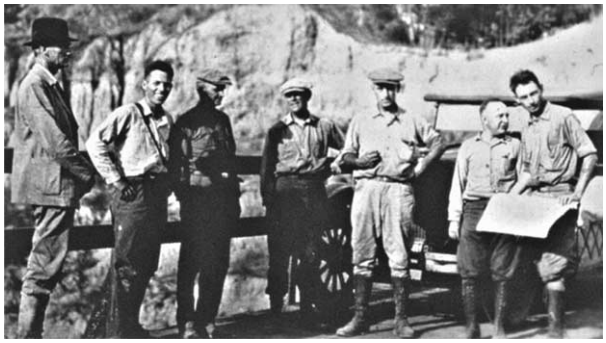

Figure 10 Curtis Marbut (far left) visiting soil survey party in North Dakota in early 1920s. Western Historical Manuscript Collection, Columbia.

Though Marbut made two presentations on soil classification during the Commission V session of the 10-day First International Congress that lasted from 13–22 June, 1927, his legacy of the meeting was the organization of the post-meeting Transcontinental Excursion (Figures 11 and 12). The Excursion was a 12 000-mile railroad train trip of 30 days (commencing on June 22) through 23 states in the

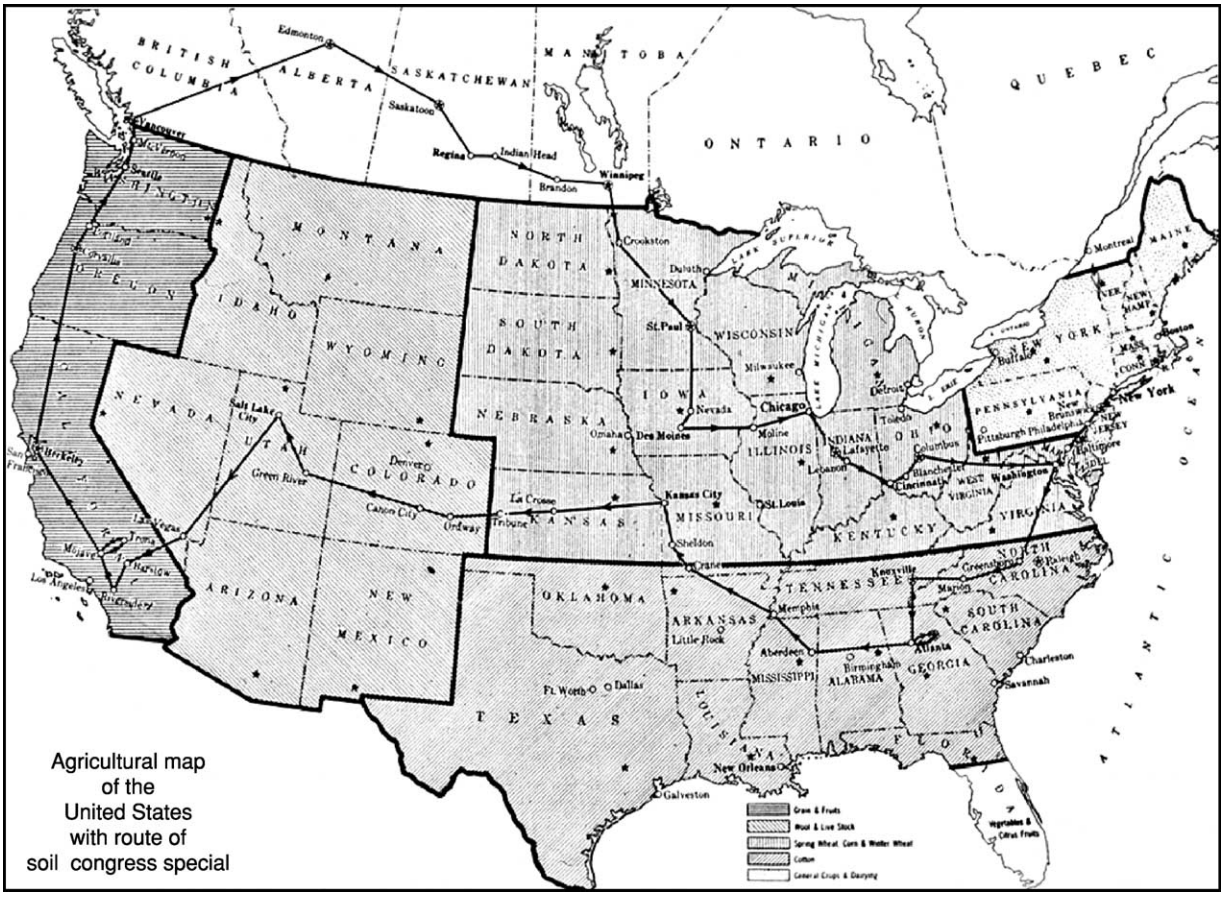

Figure 11 Route of the Transcontinental Excursion train 'The Soil Congress Special' through the USA and Canada, 1927. Archives of John P. Tandarich.

USA and four Canadian provinces to examine soils and landscapes at 34 stops. The Excursion advanced the sharing of ideas among soil scientists from around the world through the constant opportunities for interaction on the train, at the individual stops and through the daily Excursion newspaper, the *Boden Bull*.

In early 1928, Marbut visited Bennett's soil survey party in Cuba. In May 1929, he went to Danzig (modern Gdansk) for ISSS Commission V meetings and then to Soviet Russia in mid-1930 for the Second International Congress of Soil Science. The Excursion following the Second Congress meetings gave Marbut a view of the soils of western Russia from Moscow south to the region between the Black and Caspian Seas. He also visited Germany, particularly the Black Forest region, immediately afterward. James Thorp reported that Marbut visited his soil survey party in Puerto Rico early in 1932. This was immediately after attending the Fourth International Congress of Sugar Cane Technologists (Figures 13 and 14).

In 1933, Marbut accepted an assignment to advise the National Geological Survey of China in their organizing of a soil survey. To this end, Marbut sent James Thorp, his colleague from the Washington, DC soil survey office, to China in 1933 to train students in soil survey methods. By early 1935, enough progress in the soil survey of China had been made that it was necessary for Marbut to travel to China to render opinions on the descriptions and classification of the soils. In consultation with Thorp, Marbut decided to travel to China following his attendance at the Third International Congress of Soil Science in Oxford, UK (Figure 15).

In August 1935, Marbut traveled to England as a delegate to the Third Congress. Immediately after the

Figure 14 Participants in Second International Congress of Soil Science at Leningrad, 1930. Marbut is second from left in front. Western Historical Manuscript Collection, Columbia.

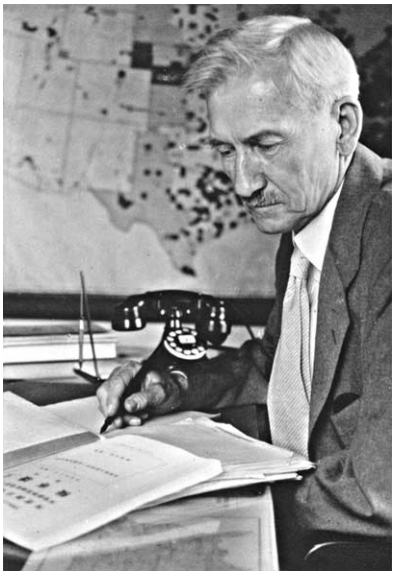

Figure 15 Curtis Marbut preparing for trip to China, 1935. Western Historical Manuscript Collection, Columbia.

meetings, he traveled through Europe and then, by the Trans-Siberian Railroad, through southern Russia. During the Siberian leg of the trip, Marbut was stricken with double pneumonia. He was taken from the train in Harbin, Manchuria (now Haerpin in Heilungkiang province) to the German-Russian hospital there. When summoned to Marbut's bedside, Thorp recalled Marbut telling him, as he neared death at age 72, "You've got to get me out of here; I have ten more years of work to do." Unfortunately, he died early the next morning. According to Thorp, the American Consulate held a beautiful memorial service at which a Russian refugee chorus sang. His ashes were sent back to southwestern Missouri.

In Service to Humanity

Marbut made his own independent place in the emerging discipline of soil science, but his concerns became more than the scientific facts of soils and their classification. His subjects at professional meetings and in his publications became more international in scope. His presidential address to the Association of American Geographers in December 1924 dealt with the Malthusian theory. He also examined Soviet soils and the capacity for that country's wheat production potentially to rival that of the USA.

The AGS, in awarding him the Cullum Medal in 1932, its highest distinction, described his achievements in the following words: "For geographical works on the study of soils – the foothold of all things." He also received awards from Berlin and Czechoslovakia, and honorary doctorates from UMC in 1916, and Rutgers in 1930. About this and other honors he received, Marbut was grateful but, as he indicated in his correspondence to Louise, they were but a means to an end. He wrote Louise that all his recognition and achievements were important only as they could be used to strengthen his position and influence to bring to the countries of the world knowledge of their soil resources and, thereby, self-sufficiency in agricultural production so that food would not be a reason to wage war. He wrote that he believed it was his duty and responsibility as a Unitarian scientist to do all one man could do to ensure that the countries of the world could feed themselves without having to rely on other countries for food. Marbut shared his unspoken goal of knowledge in the service of humanity, a point-of-view advocated by Unitarians such as Shaler and Davis, in his correspondence with Louise. However, she never mentioned his philosophy in the biographical sketch she wrote for the SSSA memorial volume; it remains only within the letters that she transcribed and incorporated into the manuscript biography of her father.

Epilog

Curtis Fletcher Marbut is mentioned along with Russian Vasilli V. Dokuchaev and American Eugene W. Hilgard when speaking of the 'founders' of modern soil science. He was a pivotal person – well-known as a teacher and promulgator of ideas. Marbut had to battle provincialism to achieve acceptance of the Russian ideas in the USA that he believed necessary to the advancement of the science. He was the world authority on soils in the 1920s and 1930s. Marbut became a scientist in demand worldwide for his knowledge, a circumstance that prompted US President Franklin D. Roosevelt to grant Marbut three yearly extensions beyond the mandatory retirement age of 70. As Thorp said in his eulogy: "[W]ho of us can fail to aspire to a long life such as his, with its earlier hardships, struggles and disappointment and its ultimate triumph; and who can but wish to follow our chosen work until we are old ... His life was full and rich and he passed on his flaming torch to younger hands while he was still running a strong race." Marbut was installed in the US National Agricultural Hall of Fame in 1989.

MEDITERRANEAN SOILS

J Torrent, Universidad de Córdoba, Córdoba, Spain

© 2005, Elsevier Ltd. All Rights Reserved.

The term 'Mediterranean' is applied to a specific climate and kind of vegetation that is typical of areas surrounding the Mediterranean Sea but also found in five other world regions, namely California, central Chile, Southwest and South Australia, and the Cape region of South Africa. Although there is no consensus on the precise delineation of the Mediterranean region, the total area with a true Mediterranean climate is probably some $2\times10^6\,km^2$, the Mediterranean region *sensu stricto* occupying approximately $1.2\times10^6\,km^2$. Because soil-forming factors vary widely among Mediterranean areas, the resulting soils share neither morphology nor genesis. Despite their high diversity, the body of properties of soils in the Mediterranean areas makes them significantly different from soils in subtropical and other temperate climatic regions. This justifies separate consideration of the genesis and properties of 'Mediterranean soils,' a term that is used here with no intended specific genetic meaning and encompasses all soils in areas with a Mediterranean climate.

Soil-Forming Factors

Climate

In Köppen's classification scheme, the Mediterranean climate is designated as a warm, temperate, rainy climate with dry summers (*Cs*), the wettest winter month receiving at least three times as much rain as the driest summer month. Areas with a Mediterranean climate lie mostly around the Mediterranean sea and at latitudes of 30–45° on the west coast of some continents and thus form transitional zones between

the influence of the westerlies of higher latitudes and subtropical high-pressure cells. The winter weather is dictated by the fronts of the westerlies, whereas the dry summer reflects the dominance of the midtropospheric anticyclone.

The Mediterranean climate encompasses an interesting variety of subclimates, as illustrated by the temperature and rainfall data from selected stations listed in Table 1. The mean annual precipitation ranges from 300 to more than 1500 mm, with one or two maxima in the rainy season. Summer drought lasts from less than 2 to approximately 5 months. The mean annual temperature ranges from about 11°C (e.g., in regions of Anatolia and central Spain) to approximately 19°C (e.g., in coastal areas of Cyprus), and absolute maxima above 45°C and minima below −20°C have been recorded at some stations. The difference between the mean temperatures of the warmest and coldest month is less than 8°C in some coastal areas affected by cold ocean currents (e.g., San Francisco Bay, California) but exceeds 20°C in inland areas with little oceanic influence. The difference at stations by the Mediterranean Sea is typically 13–16°C. From the standpoint of pedoclimate, the contrast in moisture content between winter and summer was used as the basis for defining the *xeric* moisture regime, an important diagnostic criterion in the soil taxonomy classification system. Under this regime, the soil zone affecting plant growth is dry for more than 45 days in summer and moist for more than 45 days in winter.

The influence of the Mediterranean climate on soil development can be gleaned by considering two simple parameters, namely: the degree of leaching (L) and the actual evapotranspiration (AET). The annual value of L is calculated as the sum of the excess precipitation (P) over potential evapotranspiration (PET) for those periods in which $P > PET$ less the soil water-holding capacity (WHC). The annual value of AET is equivalent to $P - L$. Table 2 shows the water balance for a station with a warm continental Mediterranean climate (Córdoba, Spain) and includes the mean monthly and annual values of P, PET, AET, and L. Winter leaching (37 mm) is low, consistent with other Mediterranean stations with mean annual P below 600–700 mm, if mean monthly P data are used in the calculations. As can be seen from Table 2, the summer drought leaves the soil with little water to meet plant needs and enable mineral weathering and biological activity. The intensity of these processes peaks in autumn and late spring when soil is moist and temperatures are mild. In summary, the relative lack of coincidence between high soil temperatures and high moisture contents precludes strong weathering and continuous biological activity.

Variability in annual rainfall is high in the Mediterranean region. For instance, the annual rainfall in Córdoba for the 1901–2000 period ranged from less than 250 mm to more than 1250 mm, i.e., by more than five times. The annual leaching for the same period ranged from 0 to more than 650 mm (at WHC 125 mm), with a moderately bimodal distribution (Figure 1). Because of the high variability in rainfall, L takes relatively large values in some years. Mean climatic data thus lead to gross underestimation of the leaching potential of the Mediterranean

Table 1 Climatic data from selected stations in the Mediterranean region

climate, which is generally significant if the mean annual *P* exceeds 500 mm.

Vegetation

Most Mediterranean areas were once covered with a sclerophyllous forest, which adapts itself readily to both summer drought and light winter frost. The exact nature of this forest in the areas bordering the Mediterranean Sea is difficult to ascertain, but the native vegetation probably included coniferous and broad-leaved evergreen trees. Among the latter, holm oak (*Quercus ilex* and *Q. rotundifolia*), cork oak (*Q. suber*), and Kermes oak (*Q. coccifera*) are widespread. Typically sclerophyllous species include wild olive (*Olea europaea*), carob (*Ceratonia siliqua*), and lentisk (*Pistacia lentiscus*). Isolated specimens of stone pine (*Pinus pinea*) and masses of Aleppo pine (*P. halepensis*) are also commonplace. Degradation of the original forest has often resulted in the establishment of scrub communities that are given local names (*garriga* in Catalonia, *maquis* in France, *macchia* in Italy, etc.) and include cistus (*Cistus* spp.), heathers (*Erica* spp.), gorse (*Ulex* spp.), broom (*Genista* spp.), and thyme (*Thymus* spp.). Some scrub communities probably constitute the original vegetation in areas where either low precipitation or pervious rocks and wind exposure gave rise to habitats that were too dry for the sclerophyllous forest to survive.

In North America, the sclerophyllous forests of western California are rich in species of *Quercus* and *Cupressus* similar to those of the Mediterranean basin (e.g., *Q. agrifolia* resembles *Q. ilex*). In areas with mean annual rainfall below 500 mm, a formation similar to the maquis, namely the *chaparral*, reaches 3 m in height and encompasses bush oaks in addition to species of *Ceanothus* and *Arctostaphylos*. In South America, the Chilean sclerophyllous forest exhibits a completely different floristic composition but is remarkably similar in appearance to analogous formations; *Quillaja saponaria*, *Rhus caustica*, and *Peumus boldus* are especially commonplace. Uncultivated land in the Cape region is now occupied by sclerophyllous scrub called *fynbos*, which varies between 1 and 4 m in height and exhibits a bluish-green hue; the only tree is *Leucodendron argenteum*, which is accompanied by scrub species pertaining to the Proteaceae, Brassicaceae, and Rosaceae families. Finally, in the Southwest and South Australia Mediterranean areas, the vegetation typically consists of *Eucalyptus* species with coriaceous leaves. The *jarrah* forest with *E. marginata* is typical of areas with a mean annual rainfall of 600–1200 mm; on the other hand, the drier (500–600 mm) *wandoo* zone has a less dense forest of *E. redunca*.

Sclerophyllous vegetation seems to be efficient in cycling of bases; however, relatively little information is available on the biogeochemical cycles for the

different areas. Transformation of fresh organic matter usually results in a mull humus that grades into a moder humus in the subhumid borders of the Mediterranean region, particularly when soils develop on coarse-grained, acidic parent materials.

Lithology and Relief

A number of Mediterranean areas are mountainous and exhibit a complex lithology that derives from the strong tectonic activity typical of zones involved in crustal plate collision (Mediterranean Sea, California, central Chile). Sedimentary rocks predominate, but plutonic, volcanic, and metamorphic rocks are well represented in most areas. In the Mediterranean region proper, limestones and dolomites constitute a fairly high proportion of the mountains. Frequent erosion and deposition episodes since the Upper Tertiary have led to the formation of large surfaces covered by fine-grained sediments at the foot of the mountains.

The abundance of steep slopes has contributed to make water erosion the principal process in slope development, which was particularly active in Quaternary periods with scarce or uneven rainfall and soils without a continuous vegetation cover. In periods of more-even rainfall, slope development under a continuous vegetation cover was probably more markedly influenced by soil creep and subsurface water erosion, similarly to slopes in humid temperate regions. The strong influence of water erosion is apparent in the slope profiles of many lithologically uniform areas, which, as predicted by geomorphic models, consist of a long, concave element at the foot, a straight middle segment, and a short, convex summit.

Structural reliefs with parallel-retreating slopes are commonplace in areas of sedimentary rocks (particularly in the drier regions). These slopes commonly merge into pediments. Depositional pediment surfaces, which are more common in Mediterranean areas than in humid temperate regions, generally have slopes of less than 1–2% and occasionally extend over tens of square kilometers. Some such surfaces are very old and covered by strongly weathered soils. Not rarely, opposite pediment surfaces form V-shaped, wide valleys dissected to a greater or less extent by a central stream and its tributaries.

Alluvial plains and their contiguous terraces dominate landscapes over stretches of tens of kilometers in the middle and lower parts of major river valleys, where they support irrigated agriculture. River terrace systems provide excellent soil chronosequences for the study of the major soil-forming processes as the systems formed over long periods during the Quaternary. For instance, the oldest river terraces reach heights of more than 200 m above the present river channel in the river Guadalquivir valley (southern Spain).

Time

Because the Mediterranean region underwent no glaciation, its landscape exhibits geomorphic surfaces of widely different age. Some surfaces (e.g., the *raña* surfaces in several parts of Spain) date back to the Pliocene. Lower Pleistocene surfaces are not uncommon, and are well represented by different pediments and river terraces. An intricate mosaic of soil formation times is therefore the rule rather than the exception in most areas. Unfortunately, absolute dating is impossible in most cases, so many pedologists rely on geomorphic data to establish relative soil age and its relationship with soil development.

Soil-Forming Processes

Mass Additions and Losses

The strong influence of water erosion results in marked catenary differentiation in mountainous and hilly areas. Thin, occasionally skeletal soils in the upper part of the slope give way to increasingly thick soils as the footslope is approached. Increasing thickness is usually associated with increasing textural fineness and with changes in the mineralogical assemblage of the clay fraction.

Some Mediterranean areas lie at the fringe of deserts (e.g., the Sahara and Negev deserts). This has resulted in more or less frequent episodes of eolian dust addition. Direct measurement of the dust carried by 'mud rains' and detailed mass balances in soils close to the Mediterranean have yielded or supported figures of a few grams per square meter and per year. Dust accretions, gradually assimilated by the soil during the Quaternary, may account for up to 50% of the mass of some soils. Unfortunately, balance calculations are difficult because the receiving soils and the dust contain similar minerals.

Leaching and Redistribution of Calcite and Silica

Weak-to-moderate winter leaching enables weathering of silicates and significant translocation of basic cations. Thus, mature soils that developed on base-poor parent materials exhibit acid pH values in the surface horizons, with pH and base saturation generally increasing with depth. If the parent material contains calcite, dolomite, or Ca-rich weatherable minerals and winter leaching is scarce to moderate, Ca precipitates as secondary calcium carbonate (in the form of calcite) in some soil horizons. Calcic horizons with carbonate nodules of different forms and sizes occur in soils in areas with $P < 700$–800 mm

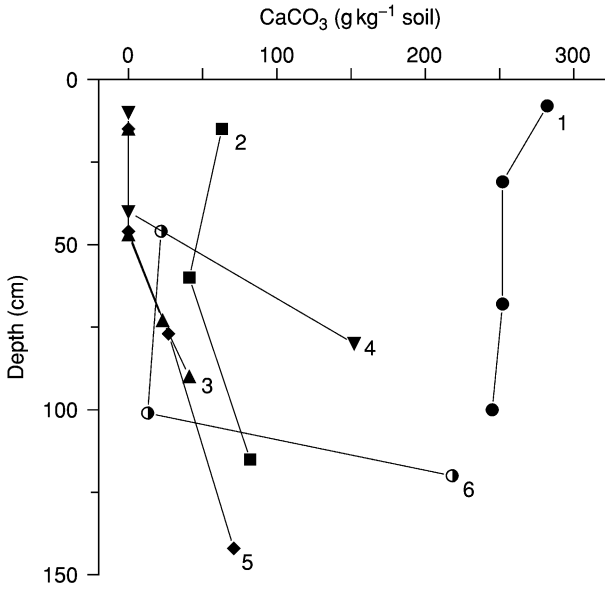

Figure 2 Depth distribution of $CaCO_3$ in soils of a river terrace sequence (Henares River, central Spain). Numbers denote relative soil age (1, recent alluvium; 6, highest terrace). Data from Daz MC (1986) *Estudio de los Procesos de Rubefacción de los Suelos de las Terrazas de la Cuenca del Ro Henares y del Ro Jarama*. PhD thesis, Universidad Politécnica de Madrid, Spain.

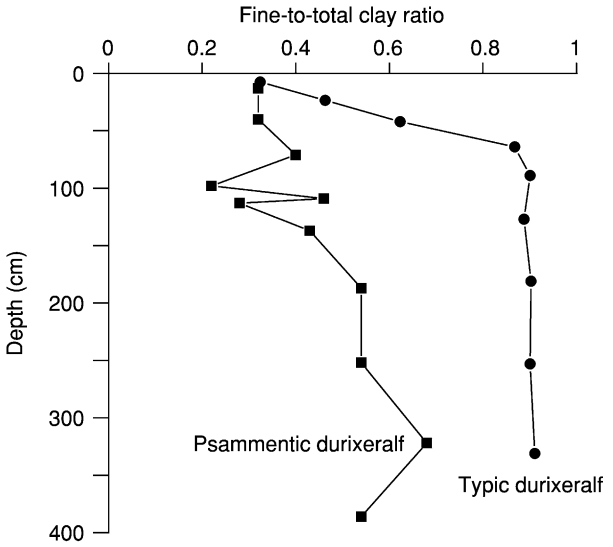

Figure 3 The increase with depth in the fine-to-total clay ratio in two deep soils of southern California is taken as evidence for clay translocation. Data from: Torrent J, Nettleton WD, and Borst G (1980a) Clay illuviation and lamellae formation in a Psammentic Haploxeralf of Southern California. *Soil Science Society of America Journal* 44: 363–369; and Torrent J, Nettleton WD, and Borst G (1980b) Genesis of a Typic Durixeralf of southern California. *Soil Science Society of America Journal* 44: 575–582.

and are replaced by indurated calcrete (petrocalcic) horizons where $P < 400$–500 mm. Long stretches of the dry Mediterranean areas (e.g., La Mancha region in central Spain) are covered by soils with calcrete. The depth at which carbonate accumulates is a function of not only the climate and parent material, but also relief and, particularly, time (Figure 2).

The weathering of silicates releases Si into solution; dissolved silica is translocated and can precipitate as silica (opal) in the form of nodules or crusts (duripans). This process is generally restricted to the drier areas, provided the parent material contains highly weatherable silicates or volcanic glass. Therefore, silica and mixed silica–carbonate are less abundant than carbonate accumulations in Mediterranean soils.

Clay Translocation

Clay translocation (illuviation) has been, and continues to be, a major process in the genesis of Mediterranean soils, particularly in the more humid areas and periods. Because of the strong flocculating effect of Ca ions, decalcification is required for clay particles to disperse and be carried by percolating water; however, translocation of clay has occasionally been observed in calcareous soils. Summer drought seems to favor clay translocation, probably because, when the soil dries, cracks develop and clay on the freshly exposed surfaces is easily dispersed and transported by the water percolating after the first autumn rains. Clay translocation is generally a slow process, but soils with horizons rich in illuviated clay (argillic horizons) have formed within only 2000–3000 years on the alluvium of some rivers of Spain. Summer drought generally contributes to disruption of the clay cutans resulting from clay translocation. Thus, evidence for clay translocation is provided by the presence of undisturbed cutans in deep soil horizons, or by the increase in the fine-to-total clay ratio with increasing depth (Figure 3), since the fine clay particles are assumed to be more mobile than the coarse ones.

Rubefaction

Rubefaction (i.e., reddening due to pedogenic hematite formation) is quite common in the Mediterranean region. It follows decalcification because the high pH of calcareous soils hinders weathering and Fe release from primary minerals. Appropriate environmental conditions for the formation of hematite from ferrihydrite (the initial product of the weathering of Fe minerals) include a high temperature, water activity of less than 1, low organic matter content, near-neutral pH, and high concentrations of Ca^{2+} and Mg^{2+}. In the absence of one or more of these conditions, only goethite (a yellow Fe oxide) is formed.

The vivid red hue of some Mediterranean soils has attracted the attention of pedologists, geologists, naturalists, and travelers. Terms such as the Italian 'Terra Rossa' or 'red Mediterranean soils' have been incorporated into some classification schemes and used (and abused) by pedologists to denote different red-colored Mediterranean soils. Indeed, pedogenic hematite possesses a high pigmenting power, so a concentration of more than than 10 g kg^{-1} soil often results in reddish brown or redder hues. Interestingly, redness ratings derived from the Munsell color notation and the soil hematite content are correlated (Figure 4).

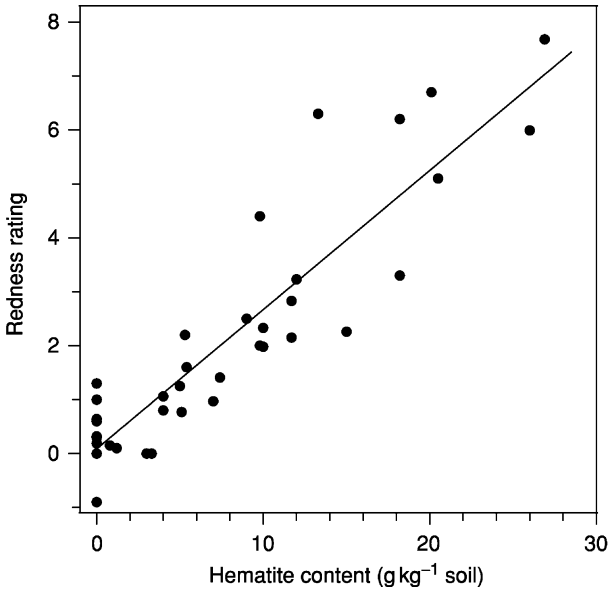

Figure 4 Relationship between a redness rating derived from the Munsell color notation and the hematite content in a group of Mediterranean soils. Data from: Peña F and Torrent J (1984) Relationships between phosphate sorption and iron oxides in Alfisols from a river terrace sequence of Mediterranean Spain. *Geoderma* 33: 283–296; Torrent J and Cabedo A (1986) Sources of iron oxides in reddish brown soil profiles from calcarenites in southern Spain. *Geoderma* 37: 57–66.

Soil chronosequences indicate that rubefaction and clay illuviation develop at similar rates once the upper soil horizons have been decalcified. These three processes play a crucial role in soil development on stable geomorphic surfaces. This is shown in Figure 5, which depicts an idealized development sequence on calcareous alluvium under an 'average' Mediterranean climate. Soils comparable with members of this sequence are seen on widely different parent materials that range from hard igneous rocks to unconsolidated sediments. Two related development sequences must be considered here. One has soils with no carbonate accumulation, so it must be assigned to base-poor rocks. In the other, the old soils exhibit a seasonally perched water table that develops as a result of pore clogging by illuviated clay. In this case, reductomorphic features appear and the red hue is lost due to reductive hematite dissolution.

Development of Vertic Features

The xeric regime favors development of the vertic features typical of Vertisols and other clayey soils that usually experience several major shrink/swell cycles each year. Vertic features seem to develop over short pedogenic times in clayey sediments as recent alluvium or Tertiary marls. Also, vertic features are enhanced by smectite formation in the soils

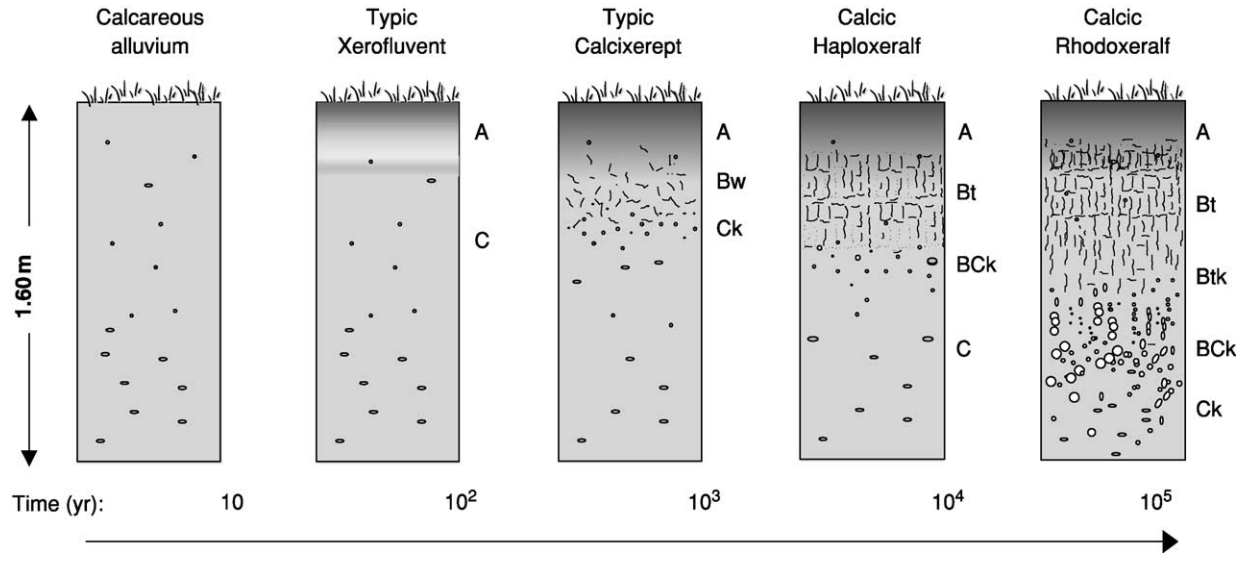

Figure 5 Idealized soil development sequence from a calcareous loamy alluvium in a typical Mediterranean environment.

of footslopes and closed basins as a result of lateral illuviation of silica and bases. For this reason, Vertisols occupy the lowest topographic positions of some Mediterranean soilscapes, even though the parent material may not be clayey.

Major Soil Types

Many pedologists would subscribe to the idea that the Mediterranean climate dictates the predominance of some specific soil-forming processes and thus justifies the term 'Mediterranean soils.' However, pedodiversity is probably higher in the Mediterranean region than in any other climatic zone. How can these two conflicting views be reconciled? Probably by remembering that: (1) the Mediterranean climate encompasses a rich variety of subclimates and (2) the effect of the Mediterranean climatic and biotic environments is modulated by the high lithological and geomorphic diversity resulting from the complex tectonic and climatic history of Mediterranean regions.

Various classification schemes have been used – some only at a national level – to encompass the Mediterranean pedodiversity. Some of the older schemes incorporated geographical and color terms (e.g., 'Black Andalusian Earths') with somewhat diffuse definitions. Most pedologists have by now adopted the UN Food and Agriculture Organization (FAO) legend (or the more recent International Society of Soil Science (ISSS)–International Soil Reference and Information Center (ISRIC)–FAO *World Reference Base for Soil Resources*) and the Soil Taxonomy System developed by the Soil Survey Staff of the United States Department of Agriculture (USDA). The latter is used here for a cursory description of the main soil types.

Eleven of the 12 orders in the soil taxonomy are represented in the Mediterranean region: Alfisols, Entisols, Inceptisols, Mollisols, and Vertisols are commonplace to abundant; Aridisols and Ultisols can be locally important; Andisols, Histosols, and Spodosols are rare; and Oxisols, as those found in some areas of California, are considered to be relict soils.

Alfisols are widespread and correspond to most of the development stages of the chronosequence in Figure 5 (and similar chronosequences). Alfisols are generally found on stable geomorphic surfaces over a wide variety of parent materials and are represented by the Aqualf and Xeralf suborders. The former are locally significant in depressions, closed basins, and plateaus, and they tend to exhibit a perched rather than a permanent water table. Among the Xeralfs, Durixeralfs (with duripan) are generally restricted to volcanic areas, and Fragixeralfs (with fragipan) and Plinthoxeralfs (with plinthite) are relatively rare. Rhodoxeralfs, which exhibit vivid red colors, are commonplace – but not so much so as the Haplo- and Palexeralfs – and cover a variety of well-drained parent materials (calcarenites, hard limestones, arkoses, sandstones, colluvia of acid rocks, basalts, etc.). Terra Rossa *sensu stricto* (i.e., a red, clayey soil on pure, hard limestone) generally belongs to the Rhodoxeralf group. Reddish-brown Xeralfs not meeting the stringent color requirements for Rhodoxeralfs are also commonplace and generally classed as Haploxeralfs. Palexeralfs ('old' Xeralfs) generally occupy old geomorphic surfaces such as high river or marine terraces and ancient pediments. Some possess a petrocalcic horizon; others tend to support a perched water table. In any case, Haploxeralfs, which are regarded by many as the ragbag of Xeralfs, constitute the most widespread great group.

Entisols, which exhibit minimal pedogenic alteration, are particularly abundant in the mountainous or hilly areas, where water erosion and other mass-wasting processes keep the soil permanently thin. These soils are usually classed as Xerorthents. Less abundant, but agriculturally important, are Xerofluvents, which occupy alluvial plains and some colluvial areas. Psamments (sandy Entisols) are confined to alluvia, coastal dunes, and sandy continental deposits, as are Aquents (wet Entisols) to some depressions, deltas, and alluvial flats. Not uncommonly, the soils of these two suborders underlie highly ecologically significant rather than agriculturally valuable areas.

Inceptisols in Mediterranean areas often represent steps in evolutionary sequences ranging from raw soils (Entisols) to Alfisols or Vertisols, but they are truly mature soils in other cases. Most are Xerepts, but Aquepts are also present. Xerepts include soils with calcic or petrocalcic horizons (Calcixerepts) and acidic soils (Dystroxerepts). They occur in all types of landscape and climatic area, and include agricultural and forest soils. Aquepts are restricted to alluvial and coastal plains, and closed basins; also, like Aquents, some are environmentally significant and can be turned into good agricultural soils after drainage.

The presence of a dark, well-structured (mollic) epipedon (a requirement for the Mollisol order) was probably common at some time under the typical sclerophyllous vegetation. Man's activities (deforestation, ploughing, grazing, etc.) have resulted in substantial losses of organic matter and deterioration of the good structural properties of the epipedon. Assessing the extent of such changes, however, is a difficult task. At present, less than 10% of the Mediterranean region is covered by Mollisols (mostly Xerolls), which tend to be concentrated in mountainous areas, man-made grasslands, and other uncultivated areas.

Table 3 Soil types most commonly found in Mediterranean areas

Order[a]	*Suborder*[a]	*Group*[a]	*WRB*[b]	*Probable extent (%)*
Entisols	Orthents	Xerorthents	Leptosols, Regosols	20–25
	Fluvents	Xerofluvents	Fluvisols	1–3
	Psamments	Quartzipsamments	Arenosols	<1

		Haploxerolls	Phaeozems	2–4
Ultisols	Xerults	Haploxerults	Acrisols	1–2
		Palexerults	Acrisols	<1
Aridisols	Salids		Solonchaks	<1

[a]According to Soil Survey Staff (1999) *Soil Taxonomy*, 2nd edn. Agricultural Handbook 436. Washington, DC: USDA.
[b]ISSS–ISRIC–FAO (1998) *World Reference Base for Soil Resources*. Leuven, Belgium: Acco Press.

Vertisols form readily where the parent material is clayey or the local conditions favor the formation of smectite. Mediterranean Vertisols (Xererts) occupy relatively large areas on Tertiary marls and Quaternary clays (e.g., in the river Guadalquivir valley in Spain and some plains of western Morocco, where smectite is largely inherited from the parent material ('lithogenic' Vertisols)). In closed basins, footslopes, and some poorly drained areas, where smectite is neoformed ('topogenic' Vertisols), Xererts alternate with Aquerts and gradually merge into Alfisols at some higher topographic locations. Among Xererts, Calcixererts are probably more abundant than Haplo- and Durixererts, because the low hydraulic conductivity hinders decalcification in Vertisols.

Ultisols exhibit low base saturation in the subsoil, so they cannot be expected to form under the leaching regime imposed by the average Mediterranean climate. However, they do occur in areas where at least two of the following conditions are met, namely: (1) high (more than 200–300 mm) winter leaching; (2) base-poor parent materials (e.g., slates or quartzites); and (3) a stable geomorphic surface. These three conditions are fulfilled, for instance, by Xerults and Aquults in Pliocene *raña* formations, which occupy more than 10 000 km^2 in Spain.

The only Aridisols present in the Mediterranean regions are Salids. Although not abundant, these saline soils fairly frequently host ecologically unique areas in deltas, enclosed depressions, and coastal plains.

Finally, only the coincidence of unusual local conditions favors the occurrence of Spodosols, Andisols, and Histosols. For instance, Spodosols in western Portugal form on coastal dunes under a pine forest in a subhumid Mediterranean environment.

Table 3 shows the probable extent for the most common soils in the Mediterranean region. These figures can only be tentative, given the relative scarcity of detailed soil maps for some Mediterranean countries.

Physical, Chemical, and Mineralogical Properties

Many lands bordering the Mediterranean have been deforested and cultivated for centuries and even millennia. Man-induced water erosion and organic matter depletion have affected extensive areas, which have been worn down to unacceptable limits. Soil degradation in other Mediterranean areas has been less marked, but current risks derived from agriculture, forestry, industrial activities, or modern urban needs run high in most areas. Soil properties must be envisaged in any case from the standpoint of their significance and evolution in different man-influenced scenarios, which change – sometimes dramatically – with time.

Physical Properties

Generally, the quality of Mediterranean soils is more strongly influenced by physical than by chemical properties. Moreover, some physical properties cannot be significantly modified (e.g., texture) or changed without much effort (e.g., structural stability).

Mediterranean soils tend to be more clayey than soils from cool temperate areas. Textural contrasts such as those exhibited by Alfisols are common and generally result in water-holding capacity increasing with increase in depth, which favors growth of rainfed crops. Stoniness is widespread and generally reduces crop production; however, surface stoniness helps reduce surface evaporation, protects soil against splash erosion, and delays runoff.

The low structural stability of many cultivated soils has been attributed to their low content in organic matter. Various studies, however, have revealed other factors (Fe oxides, Ca saturation, clay type) to be equally important with a view to creating structure. Soil crusting affects many soils rich in silt and fine sand, where it hinders emergence of small seedlings and triggers runoff. Hardsetting A horizons, which combine structural instability and high strength when the soil is dry, have been reported in the Xeralfs of Southwest Australia and some countries bordering the Mediterranean.

Low water availability in summer limits the yield potential of Mediterranean soils, even though they possess, on average, a water-holding capacity exceeding that of soils in humid temperate regions. Soil crusting and low infiltrability may offset the latter advantage, however.

Mineralogical Properties

The lack of coincidence of high temperatures and high moisture contents prevents intensive weathering in the Mediterranean environment. Therefore, highly weathered soils occur only on old, stable geomorphic surfaces in subhumid regions. Generally, because of the low-to-moderate degree of weathering, much of the soil silicate clays is inherited from the parent material or produced by transformation of primary micas rather than neoformed from solution. Illite constitutes approximately 50% of the clay fraction on average, as it abounds in sedimentary rocks and is produced by transformation of muscovite.

The overall sequence of abundance of clay minerals is illite > smectite, illite–smectite > kaolinite > chlorite, vermiculite, hydroxy-interlayered vermiculite >> halloysite, palygorskite, pyrophyllite, talc. The composition of the soil solution in many soils falls near the lines bounding the kaolinite and smectite stability fields. There is indeed evidence that kaolinite in the more leached soil environments and smectite in solute-rich environments are neoformed in substantial amounts. Neoformation of illite has been documented in K-rich solutions, such as those in microcracks of potassium feldspar grains. The presence of different microenvironments, leaching gradients in the soil profile, and lateral eluviation combine to create differences in clay mineralogy with depth and along a catena. Figure 6 depicts an idealized spatial distribution of the minerals present in the clay fraction in a typical catena.

Iron oxides are the most abundant among nonsilicate clay minerals; they typically account for 5–10%

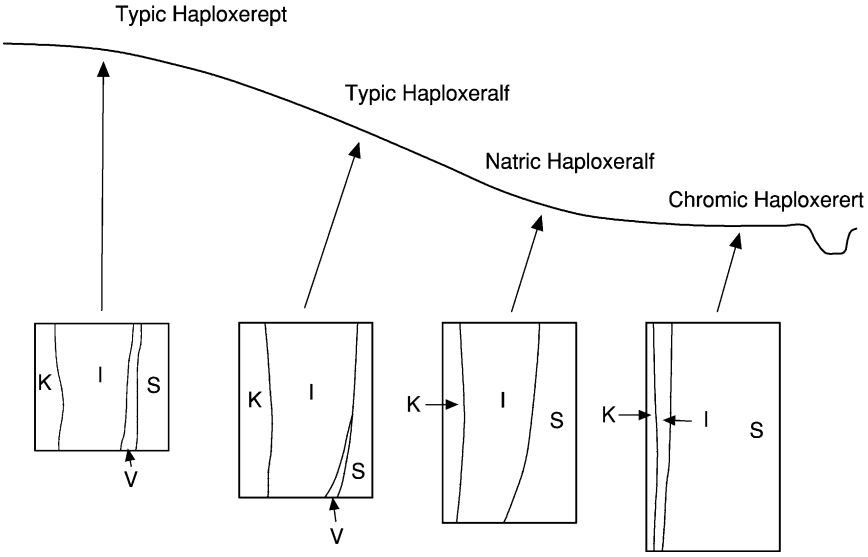

Figure 6 Relative abundances of silicate clays in the clay fraction of soils of a hypothetical catena on a granodiorite saprolite in a typical Mediterranean environment. K, kaolinite; I, illite; V, vermicullite; S, smectite.

of the clay fraction. The Mediterranean pedoenvironment favors crystallization of ferrihydrite to goethite and hematite, so that the ratio of poorly crystalline to crystalline Fe oxides is generally low. Aluminum oxides are rare, gibbsite being present in some excessively drained soils formed on coarse-grained, acidic plutonic rocks.

Among the abundant carbonates, calcite and magnesium calcite are either inherited or secondary, whereas dolomite is always inherited. Calcite crystals can be dispersed in the soil matrix or aggregated in nodules, tubules, or crusts. Crystals range in size from clay to fine sand, but the fine silt fraction is generally the most abundant.

Chemical Properties

The pH of Mediterranean soils generally lies within the slightly acidic to moderately alkaline range and, because of the occasionally steep vertical leaching gradient, can increase substantially with depth. Thus, the idealized mature soils of Figure 5 typically have a pH of approx. 6 on the surface and approx. 8 in the horizons where carbonate accumulates. However, ploughing and accretion of dust from nearby or distant sources often result in recalcification of surface horizons. Consequently, the highly acidic soils formed on old geomorphic surfaces on acidic rocks lie usually far from areas with calcareous soils and rocks.

The characteristic mineral assemblages of Mediterranean soils endow them with interesting quantitative adsorption features. Thus, the cation exchange capacity of the clay fraction generally ranges from 40 to 60 $cmol_c\,kg^{-1}$ as a result of the prevalence of 2:1 clay minerals. Specific ion adsorption by hydroxylated mineral surfaces largely arises from Fe oxides and, to a lesser extent, from the edges of clay minerals and aluminum oxides. Calcite surfaces also play a prominent role in adsorption and heterogeneous precipitation processes. Quantitative relationships between adsorption capacity and simple mineralogical or chemical properties can be established for most of the inorganic adsorbates of interest (e.g., phosphate).

Generally, the adsorptive properties of Mediterranean soils depend strongly on depth as a result of steep gradients in pH, particle size distribution, and mineralogical composition. Consequently, the appropriate 'filters' for the different nutrients and pollutants lie at different depths – and make morphological and mineralogical characterization of the soil profile necessary.

From the standpoint of chemical fertility, Mediterranean soils compare favorably with soils in other geographic areas. After N, P is the most limiting nutrient in native soils; fortunately, most soils are acceptably responsive to fertilization with P. Most are well supplied with K, because of the high illite content, and contain adequate levels of Ca and Mg. However, Fe, Cu, Mn, Zn, and B deficiencies frequently arise in some horticultural crops cultivated on calcareous soils.

Salinization, occasionally accompanied by specific ion toxicity problems, has made its way in both old and recently irrigated areas. Even though the principles for good management of irrigation have been known for decades, salinization continues to be a major issue; the scarcity of good irrigation water in most areas, and the use of water-saving irrigation systems, contribute to the problem.

METAL OXIDES

Introduction

The oxide minerals typically present in soils comprise oxides, hydroxides, oxyhydroxides, and hydrated oxides of Si, Fe, Mn, Al, and Ti. With the exception of the Si oxide quartz and some Ti oxides, which are predominantly inherited from primary (rock) minerals, most oxides form in soil. The metal cations Fe^{2+}, Mn^{2+}, Ti^{4+}, Al^{3+}, and Si^{4+} are released from silicates by weathering. The divalent cations Mn and Fe oxidize and hydrolyze, and precipitate almost exclusively as oxide minerals. Al^{3+} and Si^{4+} have a strong tendency to form secondary aluminosilicate clay minerals; the formation of Al and Si oxides requires special conditions. All oxides have a very low solubility at common soil pH and are therefore enriched during pedogenesis. Highly weathered soils, which have lost a substantial part of their alkalis, alkaline earths, and Si, may contain as much as 50% wt metal oxides.

Oxides of Fe, Mn, and Al may exhibit a high surface area, with reactive surface sites which strongly bind oxyanions and metal cations, thereby impacting the availability and mobility of plant nutrients and toxic metals. Some Mn oxides have a strong oxidizing power and may degrade organic pesticides, decrease or increase the toxicity of heavy metals, and contribute to the formation of soil organic matter. In contrast, sand-sized crystals of the Si oxide quartz are chemically very inert.

The basic structural unit of Fe, Mn, Al, and Ti oxides are cationic metal centers bound to six oxygens. If one drastically reduces the size of the oxygens in relation to the metal cations, this arrangement can be visualized as an octahedron (Figure 1). The octahedra may be linked to each other in three ways, sharing oxygen corners (1 O), sharing edges (2 O), or faces (3 O). Many oxide minerals such as goethite contain only the first two types of connections, while the Fe oxide hematite contains all three. Silicon is bound to four oxygens, forming a tetrahedron. These tetrahedra are connected via corners only. We will use this polyhedral approach in the text and in figures to introduce the mineral species and highlight their major differences and similarities. For each oxide group, we will give an overview including general formation pathways and influence on soil properties. This overview is followed by a description of the minerals, their occurrence in soil, and specific conditions of their formation.

Fe Oxides

Iron is released by weathering of Fe(II)-containing silicates (biotite, pyroxene, amphibole, olivine). After oxidation to Fe^{3+} and hydrolysis, most Fe precipitates as Fe(III) oxides. (Only a small remaining amount of Fe^{2+} becomes a structural part of pedogenic phyllosilicates.) Under oxic conditions, Fe oxides are very insoluble, hence are enriched during pedogenesis. They readily dissolve, however, under reducing soil conditions:

$$2Fe_2O_3 + CH_2O + 8H^+ \Rightarrow 4Fe^{2+} + CO_2 + 5H_2O \qquad [1]$$

This reaction is driven by microorganisms, which metabolize biomass (in eqn [1] represented by CH_2O), and transfer freed electrons to Fe^{3+}, thereby

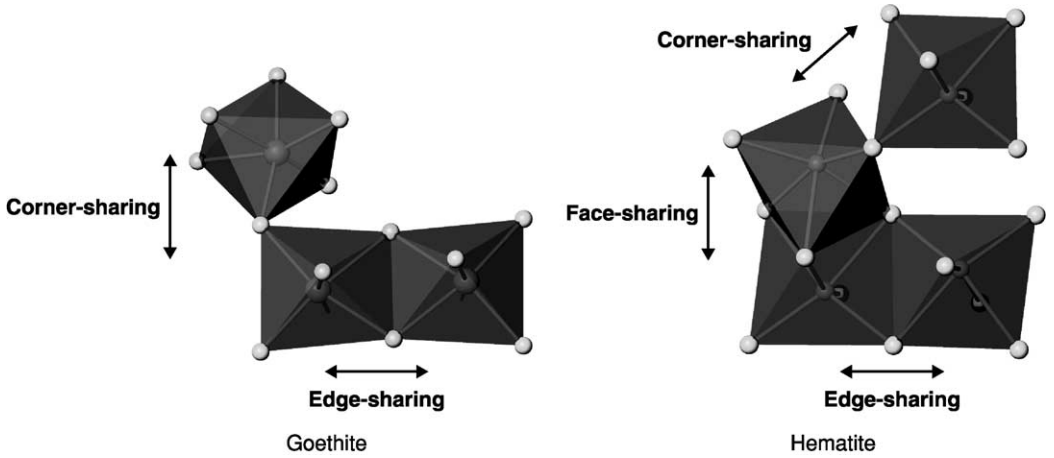

Figure 1 Linkage of metal octahedra by corners, edges, and faces, involving one, two, and three oxygen ligands, respectively. Shown are small structural subunits of the two Fe oxides goethite and hematite.

reducing it to Fe^{2+}. Dissolution of Fe oxides is therefore linked to microbial activity. Depending on parent material, degree of weathering, and soil redox conditions, the amount of Fe oxides in soils varies between less than 1 and more than 500 g kg^{-1}. The Fe oxides are commonly the strongest pigments in soil, and small quantities may impart vivid colors of red, orange, yellow, brown, and even blue-green (Table 1). Depending on pedogenesis, they occur either evenly distributed in the soil matrix, or locally enriched as skins, patches, and concretions. Soil horizons indurated by Fe oxides form ferricretes or laterites.

Soil Fe oxides commonly exist as very small crystals (2–50 nm), responsible for a large surface area (50–450 $m^2\,g^{-1}$). Due to the their circumneutral point of zero charge (PZC), they contribute to the anion exchange properties of soils. In addition, their surfaces have a strong affinity for oxyanions and many metal cations. Finally, other metal cations with an ionic diameter similar to Fe^{3+} (e.g., Al^{3+}, Ni^{2+}, Ti^{4+}, Mn^{4+}, Co^{3+}, Cr^{3+}, Cu^{2+}, Zn^{2+}, V^{3+}) may partially replace Fe in the crystal structure of Fe oxides. Due to these properties, Fe oxides play a significant role in the environmental cycling of plant nutrients such as N and P, of transition metals relevant for metabolic reactions (e.g., Mn, Zn, Co), and of toxic elements such as As and U. The 10 Fe oxide minerals observed in soils or sediments at the Earth's surface and some of their diagnostic criteria are listed in Table 1. Crystal structures are shown in Figure 2. Schematic formation and transformation pathways of the eight most common Fe oxides are shown in Figure 3.

Goethite (α-FeOOH)

Due to its high stability, goethite is the most ubiquitous Fe oxide mineral in soils. In the absence of hematite, its yellowish color is responsible for the yellowish-brown hue of many soils (7.4 YR–3.5 Y). Goethite formation is favored by slow hydrolysis of Fe^{3+} hydroxy cations at low temperature. The even distribution of goethite in a soil horizon indicates therefore that this soil has formed under aerated, temperate, humid conditions. The crystal structure

Table 1 Iron oxide minerals

Mineral name and formula	*Structural type*	*Median color*	*Range of hue*	*Typical crystal shape*	*Occurrence*	*Figure*
Goethite[a] α-FeOOH	Diaspore	Strong yellowish-brown	7.3 YR–1.5 Y	Needles, laths	Ubiquitous in soils of all climates	2a
Lepidocrocite[a] γ-FeOOH	Boehmite	Moderate orange	4.9 YR–7.9 YR	Laths	Seasonally anaerobic, noncalcareous soils in cool-temperate climate	2c
Akaganeite β-FeOOHCl	Hollandite	Strong brown	1.2 YR–6.8 YR	Spindle-shaped rods	Hot springs, volcanic deposits	2f
Feroxyhyte δ'-FeOOH		Brownish orange	2.8 YR–9.2 YR	Spheres		2e
Schwertmannite $Fe_8O_8(OH)_6SO_4$	Hollandite	Dark orange yellow	6.2 YR–0.3 Y	Hedgehog aggregates	Acid-sulfate springs and mine drainages	2f
Ferrihydrite[a] $Fe_5HO_8 \cdot 4H_2O$		Strong brown	3.7 YR–5.4 YR	Plates, needles	Frequent in seasonally wet and/or organic-matter rich soils in cool-temperate climate	–
Hematite[a] α-Fe_2O_3	Corundum	Moderate reddish brown	3.5 R–4.1 YR	Hexagonal plates	Frequent in soils of tropical, subtropical, and Mediterranean climate	2b
Magnetite[a] $Fe^{II}Fe^{III}_2O_4$	Inverse spinel	Dark yellowish brown	6 YR–9.5 YR	Laths, cubes	Inherited from magnetite-containing bedrock, microbial origin possible	2d
Maghemite[a] γ-Fe_2O_3	Defect spinel	Black		Octahedra	Common in highly weathered, tropical and subtropical soils	2d
Green rust $Fe^{II}Fe^{III}(OH)_4Cl$	Hydrotalcite (pyroaurite)	Bluish-green		Plates	Permanently wet subsoils	2g

[a]Minerals commonly occurring in soil.

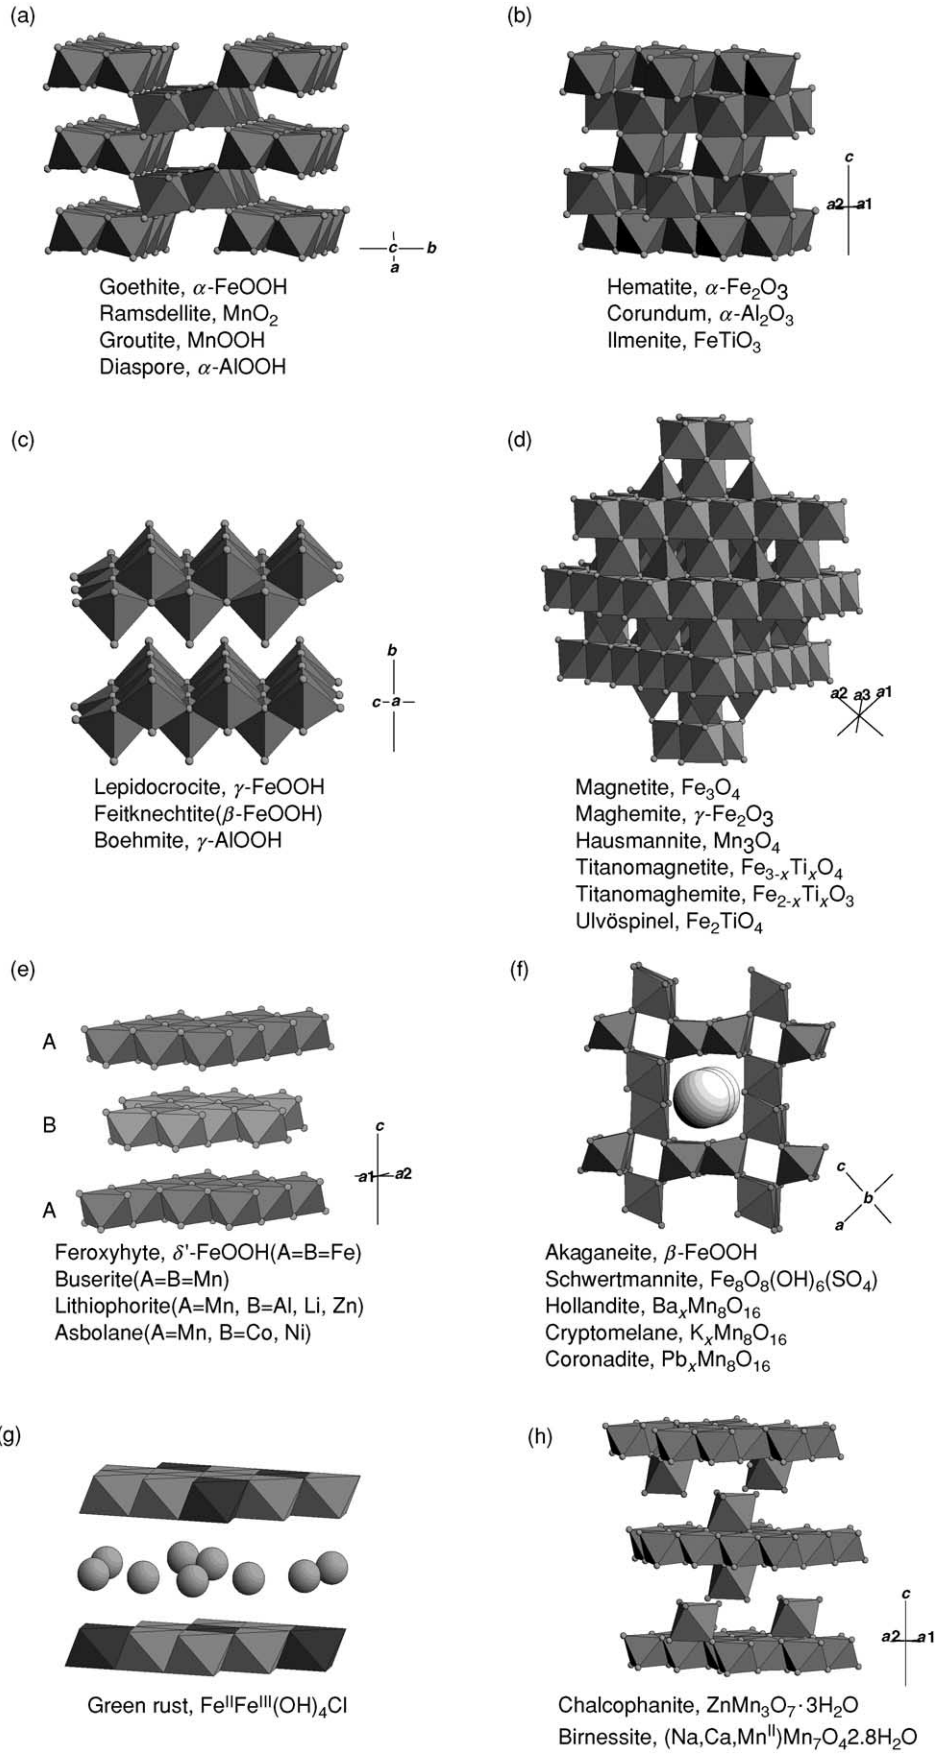

Figure 2 Crystal structures of common oxide minerals.

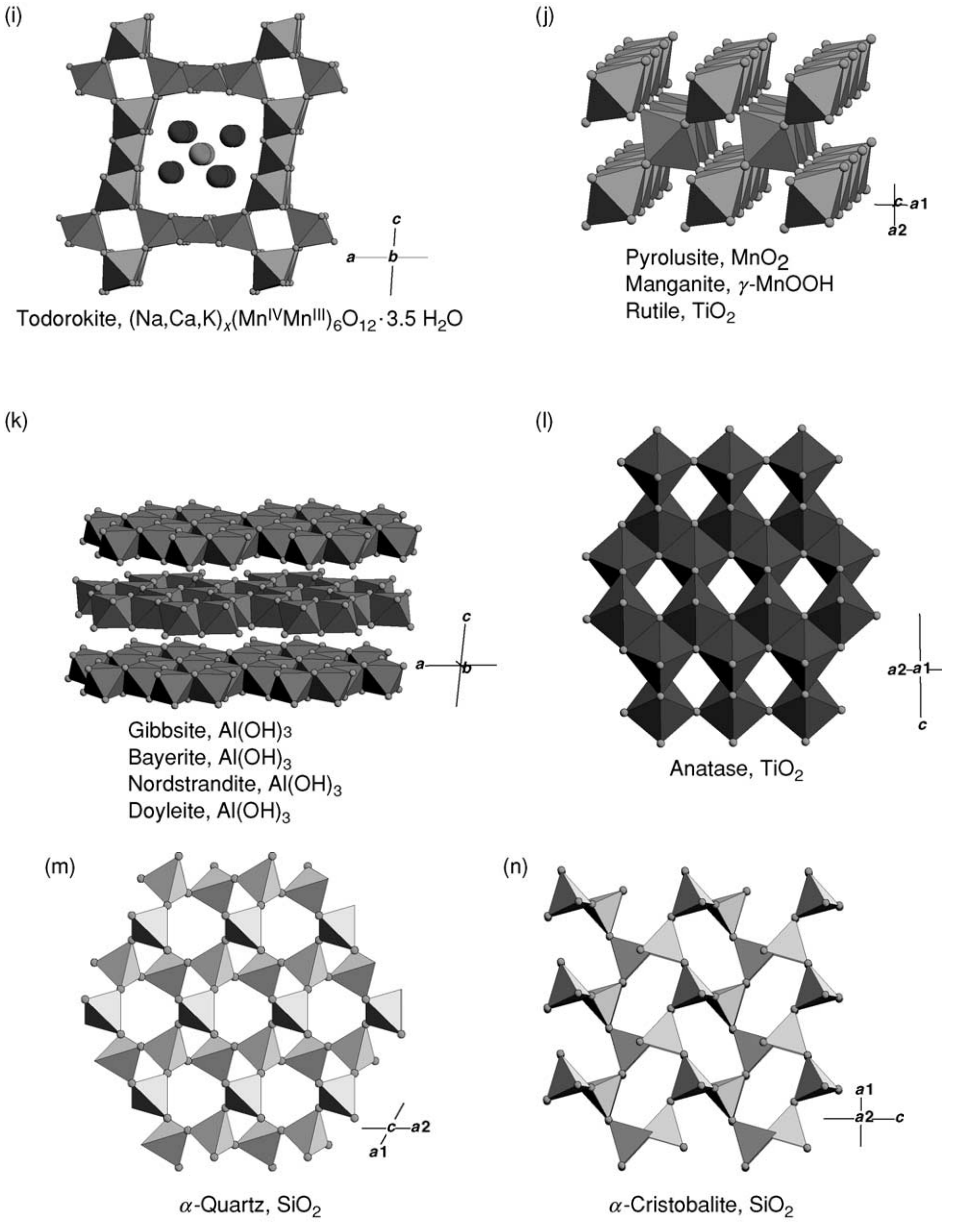

Figure 2 (*Continued*)

of goethite consists of double chains of edge-shared octahedra that are joined to other double chains by sharing corners and by hydrogen bonds (Figure 2a).

Hematite (α-Fe_2O_3)

Soils forming at subtropical or tropical climates often have reddish or even purplish hues (8.0 R–1.4 Y), derived from blood-red hematite. Hematite usually coexists with goethite, but, due to its greater tinting strength, masks the yellowish color of goethite even at low concentrations. Hematite forms by dehydroxylation of ferrihydrite (see below) via a solid-state mechanism which is not yet fully understood. In comparison with goethite, the formation of hematite is favored by neutral pH, increasing soil temperature, and decreasing water activity. The crystal structure of hematite consists of sheets of edge-sharing octahedra. The sheets are connected by edge- and face-sharing octahedra (Figure 2b). The unique face-sharing arrangement and the resulting proximity of neighboring Fe centers is responsible for the red color of this mineral.

Ferrihydrite ($Fe_5HO_8\cdot 4H_2O$)

This poorly crystalline, hydrous oxide commonly occurs in cooler soils with changing redox conditions. Its formation is favored by rapid oxidation and hydrolysis of Fe^{3+} from solution. The transformation

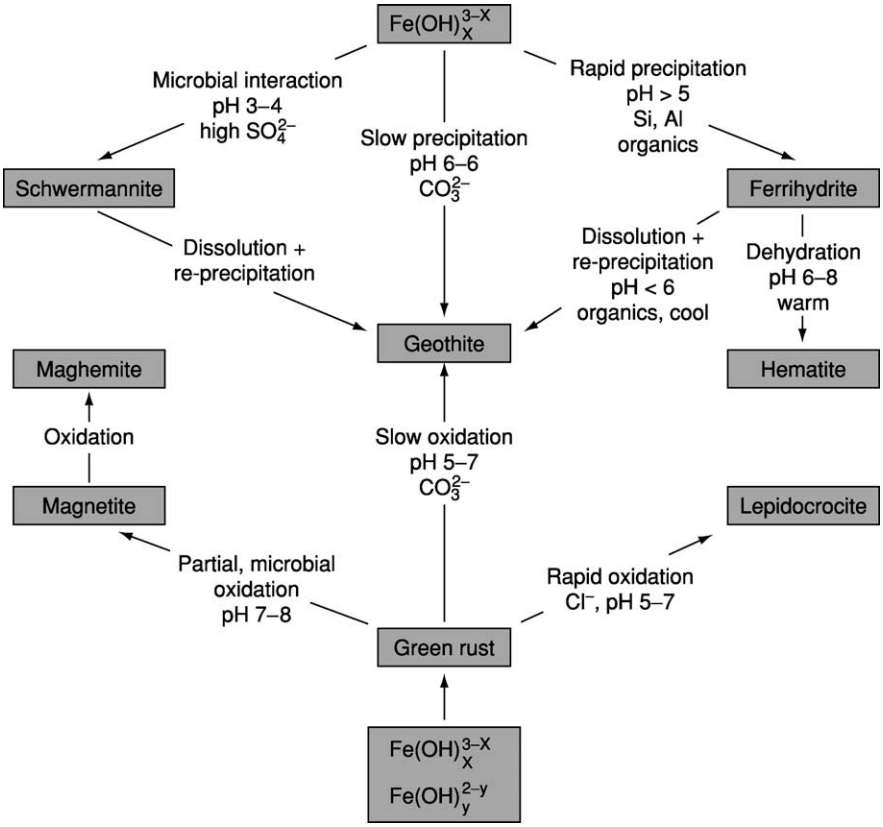

Figure 3 Schematic formation and transformation pathways of common Fe oxides in soils. The precipitation of Fe oxide minerals proceeds either from ferric hydrolysis species (top) or from mixed ferric-ferrous hydrolysis species (bottom). Figure modified after Bigham JM, Fitzpatrick RM, and Schulze DG (2002) Iron oxides. In: Dixon JB and Schulze DG (eds) Soil Mineralogy with Environmental Application, pp. 323–366. Madison, WI: Soils Science Society of America and Cornell RM and Schwertmann U (2003) The Iron Oxides: Structure, Properties, Reactions, Occurence and Uses, 2nd edn. Weinheim, Germany: VCH Verlagsgesellschaft.

into thermodynamically more stable goethite may be hindered by adsorption of silicate, phosphate, and organic anions, making ferrihydrite a common constituent of younger soils in association with goethite. The brownish-orange color of ferrihydrite often marks gradients between anoxic and oxic soil regions, e.g., at the transition between water-saturated and aerated soil horizons, and along root channels or other macropores. Ferrihydrite is also responsible for the brownish-orange color in podzol B horizons. The structure is still being investigated, but can be visualized as a defective hematite structure containing both edge- and face-sharing octahedra.

Lepidocrocite (γ-FeOOH)

This vividly orange, less abundant mineral occurs in seasonally anaerobic, clay-rich, carbonate-free soils in cool climates in association with the more stable goethite. Lepidocrocite forms through relatively slow oxidation of Fe^{2+} at low concentrations of carbonate. Its crystal structure contains double chains of octahedra which are joined by shared edges, resulting in corrugated sheets of octahedra. These corrugated sheets are stacked one on top of the other and are held together by hydrogen bonds (Figure 2c).

Magnetite (Fe_3O_4) and Maghemite (γ-Fe_2O_3)

Blackish magnetite is usually inherited from the parent material, but may also form in soil through biotic processes. The brownish-red maghemite is common in soils of tropical and subtropical climate, but occurs occasionally also in temperate soils that have been exposed to forest or heath fires. Maghemite forms either through oxidation of magnetite, or by heating (300–425°C) of other Fe oxides in the presence of organic compounds. Both magnetite and maghemite have the same inverse spinel structure, with octahedral and mixed tetrahedral/octahedral layers stacked along the direction [111] (Figure 2d). In magnetite, which contains both Fe^{2+} and Fe^{3+} ions, Fe^{3+} occupies both tetrahedral and octahedral sites, while the larger Fe^{2+} ion occupies octahedral sites only.

Rare Fe Oxide Minerals

Several minerals have rarely or never been observed in soils. They may form in extreme natural environments (akaganeite, schwertmannite), in polluted surface waters (schwertmannite, feroxyhite), or transform rapidly into more stable phases (green rust). Feroxyhyte, δ'-FeOOH, has been observed in rusty

precipitates of rapidly flowing, Fe^{2+}-containing water, which was quickly oxidized. It consists of sheets of edge-sharing octahedra (Figure 2e). Akaganeite (β-FeOOHCl) has been found in environments with high chloride concentrations (0.1 mol l^{-1}), low pH (3–4), and high temperature (60°C), e.g., in hot springs and volcanic deposits. Akaganeite consists of 2×2 channels (referring to the width of the channels in octahedral units) built by edge-sharing double chains (Figure 2f). These tunnels 0.5 nm in cross section contain Cl^- ions that stabilize the structure. Schwertmannite, $Fe_8O_8(OH)_6SO_4$, is isostructural with akaganeite, but SO_4^{2-} occupies the tunnels (Figure 2f). Schwertmannite has been found in strongly acid sulfate waters associated with mining activities (acid mine drainage) or pyritic rock outcrops. Green rust, $[Fe^{II}_{1-x}Fe^{III}_x(OH)_2]^{x+} \cdot (x/n)A^{n-} \cdot mH_2O$ (where A represents anions such as Cl^-, NO_3^-), has been observed rarely in reducing, weakly acid to weakly alkaline subsoils. Its greenish-blue color changes rapidly to yellowish brown on exposure to the air, indicative of its instability against oxidation. Green rust consists of sheets of edge-sharing octahedra, which are occupied by both Fe^{2+} and Fe^{3+}. The resulting positive layer charge is balanced by hydrated anions in the interlayer space (Figure 2g). Due to its anion exchange capacity, redox reactivity and high surface area, even small amounts of green rust may play an important role in aquifers and the vadose zone. Since the mineral forms as a metastable corrosion product of metallic iron at anaerobic conditions, green rust is also relevant for barriers of scrap iron engineered to clean up groundwater.

Mn Oxides

Mn is released by weathering of Mn(II)-containing silicates (biotite, pyroxene, amphibole). After oxidation of the soluble Mn^{2+} to Mn^{3+} and Mn^{4+}, brownish-black Mn oxides of low solubility precipitate, which redissolve only under reducing soil conditions. The reaction equation assuming a Mn(IV) oxide can be written in analogy to the dissolution of Fe oxides

$$2MnO_2 + CH_2O + 4H^+ \Rightarrow 2Mn^{2+} + CO_2 + 3H_2O$$

As for the Fe oxides, the dissolution depends on microbial activity. While oxidation of Mn^{2+} is catalyzed by mineral surfaces, microbial oxidation seems to be the more dominant process in soil environments. Therefore, both formation and dissolution of Mn oxides are intimately linked to microbial activity.

Mn oxides may occur evenly distributed in the soil matrix like the stable Fe oxides goethite and hematite. Due to their low concentration (about 1/50 of the concentration of Fe oxides) and their low crystallinity, however, they are extremely difficult to identify. Therefore, most soil Mn oxides have been identified in local enrichments, such as black coatings of peds, dendrites, or nodules, which form along redox gradients. The blackish colors of Mn oxides are often separated from the brownish-orange color of Fe oxides (ferrihydrite) by extending further toward the higher redox potential, indicative of a higher mobility of Mn^{2+} as compared to Fe^{2+}.

Mn oxides are able to accumulate a wide range of other elements such as Li, Ba, As, Pb, and almost all first-row transition metals. These elements are either part of the crystal structure or they are tightly sorbed to the large surface area of Mn oxides. Mn oxides have an oxidizing potential stronger than that of O_2. Therefore, they are able to oxidize inorganic ions such as Co^{2+}, Cr^{3+}, and As^{3+}, thereby either increasing (e.g., Cr^{6+}) or decreasing (e.g., Co^{3+}, As^{5+}) their mobility and toxicity. They are also able to oxidize organic molecules, thereby enhancing the degradation of anthropogenic compounds like pesticides. Furthermore, Mn oxides catalyze condensation reactions such as the Maillard reaction. Hence, Mn oxides may play an important role in the abiotic formation of humic substances.

In spite of their importance for the geochemistry of metals and carbon, knowledge of their mineralogy and formation in soils is still relatively poor. This is due to their low crystallinity and low concentration, but also due to their complex mineral chemistry. Since microspectroscopic methods became available recently which are suited to study Mn oxides in soils, this may change within the next years.

Based on the arrangement and linkage of their metal octahedra, the Mn oxides have been categorized into three major groups: (1) phyllomanganates or layer structures, (2) tectomanganates or tunnel structures, and (3) chain structures. The most common Mn oxide minerals are listed in Table 2, and their crystal structures are shown in Figure 2.

Phyllomanganates (Layer Structures)

Phyllomanganates are commonly observed after microbially catalyzed oxidation of Mn^{2+} and they are ubiquitous in soils.

Birnessite forms in a wide variety of soils. It consists of sheets of edge-sharing MnO_6 octahedra with vacancies. The resulting negative layer charge is compensated by cations such as Na^+, K^+, Ca^{2+}, Mg^{2+}, and Mn^{2+}, which may cover the vacancies. The interlayer region contains water, resulting in a d-spacing of 7 Å (Figure 2h). Three other minerals, vernadite, chalcophanite, and buserite, are structurally very similar to birnessite. Vernadite is frequently observed as an initially amorphous oxidation product of microorganisms and has been found in soils and in

Table 2 Manganese oxide minerals

Mineral name (synthetic equivalent)	*Formula*	*Structural type*	*Figure*
Birnessite[a]	(Na, Ca, Mn^{2+})$Mn_7O_4 \cdot 2.8\ H_2O$	Layer structure	2h

Hausmannite	Mn_3O_4	Inverse spinel	2d

[a]Minerals commonly occurring in soil.

freshwater lakes. Its structure may be similar or identical to turbostratic H^+-birnessite. Chalcophanite has been observed in Zn-contaminated soils. In comparison with birnessite, it has a higher number of vacancies that are covered by Zn in octahedral or tetrahedral coordination (Figure 2h). Buserite forms in hydrothermal environments. In comparison with the former phyllosilicates, it has a larger d-spacing of 10 Å, probably due to a larger amount of interlayer water. By dehydration, buserite transforms into birnessite.

Lithiophorite has been frequently identified in soils. Its layer structure consists of sheets of edge-sharing MnO_6 octahedra which alternate with sheets of (Al, Li)$(OH)_6$ octahedra (Figure 2e). The cation sites in the Mn-O octahedral sheet are occupied with Mn^{4+} and Mn^{3+}. The net negative layer charge is counterbalanced by the positive charge of the (Al, Li)-OH octahedral sheets. Li is frequently replaced by Ni, Cu, and Zn, while Co substitutes for Mn within the octahedral Mn sheets. Asbolane forms in soils with high Co and Ni concentrations. Its structure is very similar to that of lithiophorite, with alternating sheets of Mn^{4+}-O octahedra and Co-Ni-OH octahedra (Figure 2e). The Co-Ni sheet may be discontinuous (island-like).

Tectomanganates (Tunnel Structures)

Tectomanganates are formed from double or triple chains of MnO_6 octahedra, which form tunnels (or channels). These tunnels are occupied by large foreign cations and water molecules.

Todorokite is the most frequently observed soil tectomanganate. It consists of triple chains of edge-sharing MnO_6 octahedra linked to form large 3×3 tunnels. These tunnels contain Na, Ca, K, Ba, Sr, and water molecules (Figure 2i). The occurrence of variable tunnel widths (3×2, 3×3, 3×4, and 3×5) observed in high-resolution transmission electron microscopy (HRTEM) images suggests that todorokite represents a family rather than a single mineral.

Hollandite, cryptomelane, and coronadite, sometimes grouped as α-MnO_2, have rarely been observed in soils. They consist of double chains of edge-sharing MnO_6 octahedra linked to form 2×2 tunnels (Figure 2f). The tunnels contain water molecules along with cations, which are primarily Ba^{2+} in hollandite, K^+ in cryptomelane, and Pb^{2+} in coronadite. Natural samples usually contain a variety of cations in the tunnels. The large cations are located at specific tunnel sites, and their presence is necessary to prevent the structure from collapsing. The charges of the tunnel cations are balanced by the substitution of Mn^{4+} by Mn^{3+} in the tunnel walls.

Chain Structures

Mn oxides of this group have been synthesized in the laboratory at ambient temperature and pressure, and at moderately alkaline pH. However, they have rarely been observed in soil. Pyrolusite (MnO_2) and manganite (γ-MnOOH) consist of single chains of edge-sharing MnO_6 octahedra which form 1×1 pseudotunnels (Figure 2j). Ramsdellite (MnO_2) and groutite (α-MnOOH) are isostructural with goethite (Figure 2a); feitknechtite (β-MnOOH) has a structure similar to lepidocrocite (Figure 2c). Hausmannite (Mn_3O_4) has a disordered-spinel structure analogous to magnetite (Figure 2d).

Al Oxides

In contrast to Fe and Mn, most Al released by the weathering of Al-containing silicates is taken up by

secondary, pedogenic phyllosilicates. As long as the Si concentration in soil solution is more than 0.5 mg l^{-1}, the formation of phyllosilicates out-competes the formation of Al oxides. Furthermore, the complexation of Al^{3+} by organic matter prevents Al oxide precipitation. Therefore, Al oxides are commonly observed only in organic matter-poor soils of tropical and subtropical climate, where intense weathering causes secondary phyllosilicates to dissolve and Si is lost by leaching. The (colorless) Al oxides are either evenly distributed within the soil matrix or enriched in concretions (pisolites). Horizons cemented by Al oxides are called alcretes.

Al oxides may have a high surface area (up to 600 $m^2 g^{-1}$), a high PZC (pH 8–10), and a pH-dependent surface charge. Similar to Fe and Mn oxides, they tightly sorb heavy metals (Cu, Pb, Zn, Ni, Co, Cd) and anions (phosphate, silicate, molybdate, sulfate, catechol) by forming inner-sphere sorption complexes. The adsorption is related to the reactive surface area (singly coordinated OH^- groups at crystallite edges) rather than the total surface area. Aluminum oxides, in addition to Fe oxides, are responsible for the aggregation of Oxisols and Ultisols, but the mechanism of aggregation is unclear. Aluminum oxides have a low solubility at slightly acidic and neutral pH, but at low pH soluble species form that are toxic to plants and animals. These soluble species impact food production on naturally acidic soils and contribute to forest decline in areas influenced by acid rain.

Of six different Al oxide minerals, predominantly gibbsite and, less commonly, boehmite, nordstrandite, and bayerite form under soil conditions (Table 3). Diaspore and corundum are occasionally found in bauxite deposits, but are rare in soils. Aluminum also forms highly reactive, poorly crystalline precipitates and colloids.

Gibbsite

Of the four $Al(OH)_3$ polymorphs (Table 3), only gibbsite (γ-$Al(OH)_3$) is common in soil. It consists of sheets of edge-sharing octahedra stacked along the *c*-axis (Figure 2k). Only two-thirds of the available octahedral sites are filled with Al^{3+} ions analogous to the dioctahedral sheets of phyllosilicate clay minerals. In soil, gibbsite forms thick, platy crystals. In saprolites, feldspars (plagioclase) may transform directly into gibbsite, while maintaining the original shape of the feldspar crystals (pseudomorphs).

Gibbsite is found in Oxisols on old, stable upland landscapes in association with Fe oxides (goethite, hematite) and the aluminosilicate kaolinite. Intense weathering and leaching under humid tropical and subtropical climate over long periods of time (millions of years) have depleted these soils with respect to alkali metals, earth alkali metals, and Si, thereby enhancing the formation of gibbsite. Gibbsite contents of Oxisols may be as high as 600 g kg^{-1}, but some Oxisols do not contain gibbsite at all. In Ultisols and Inceptisols of tropic to temperate climates, gibbsite is derived from the underlying saprolite, which has formed by weathering of igneous and metamorphic rocks. The gibbsite content generally decreases from the saprolite to the soil surface. Finally, gibbsite has been observed in Andisols, where it formed from rapidly weathering volcanic ash. Although these soils are often very young (hundreds of years) and Si-rich, sufficient Si was leached locally to explain the formation of gibbsite.

Gibbsite formation is conditioned by the intensity of leaching which, in turn, is affected by rainfall, temperature, parent rock, topography, ground-water table, vegetation, and time. Environments with warm temperatures, high rainfall, and free drainage favor desilication and leaching of ions, as well as mineralization of organic matter. Anions such as sulfate, carbonate, phosphate, and silicate, as well as organic ligands such as citric, malic, tannic, aspartic, and fulvic acid, which have a strong affinity for Al^{3+}, may interfere with the crystallization of $Al(OH)_3$. This explains why there is no or only small amounts of gibbsite in the A horizon of acidic soils high in organic matter and exchangeable Al, while it is found in greater quantities in deeper horizons. However, gibbsite may also decrease with soil depth. A possible explanation is an inverse gradient of $Si(OH)_4^o$ (silica) activity: rain water infiltrating at the soil surface is not yet in equilibrium with silicates and therefore has a lower silica activity as compared to the soil water at a greater depth, which had more time to equilibrate. The heterogeneous distribution of gibbsite in a landscape may be similarly explained by the silica activity of percolating waters.

Table 3 Aluminum oxide minerals

Mineral	*Formula*	*Figure*

[a]Minerals commonly occurring in soil.

Rare Al Oxide Minerals

The difference between gibbsite and its other polymorphs, bayerite, nordstrandite, and doyleite,

consists of a slightly different arrangement of hydroxyl groups. While gibbsite formation is favored by slow hydrolysis of Al and by a pH <6, nordstrandite and bayerite form at neutral to alkaline pH under fast hydrolysis. Correspondingly, their rare occurrences are related to limestone materials. Boehmite (γ-AlOOH), which is isostructural with lepidocrocite (Figure 2c), has been identified in lateritic materials and in bauxites. It may form from gibbsite by diagenesis or hydrothermal alteration. The oxyhydroxide diaspore (α-AlOOH) is isostructural with goethite (Figure 2a). It has been identified as a surface-weathering product formed by the desilication of kaolinitic clay. The rarely found oxide corundum (α-Al_2O_3), which is isostructural with hematite (Figure 2b), may be derived from corundum-containing parent rock or form by heating of the soil by bush fires.

Al Hydrolysis and Poorly Crystalline Al Hydroxides

Al^{3+} cations released from Al-bearing minerals are initially coordinated with six water molecules, forming the hexaquo complex $Al(H_2O)_6^{3+}$. This hexaquo complex hydrolyses in several steps, the first and most important one in soil solution being:

$$[Al(H_2O)_6]^{3+} + H_2O \Leftrightarrow [Al(OH)(H_2O)_5]^{2+} + H_3O^+$$

$$pK_s = 5.0$$

At higher Al^{3+} or OH^- concentrations, the mononuclear complexes start to polymerize to form polynuclear species. The smallest unit identified so far is $AlO_4Al_{12}(OH)_{24}(H_2O)_{12}^{7+}$. This so-called Al_{13} or Keggin polymer consists of a highly symmetrical, tetrahedrally coordinated Al center enclosed in a cage-like structure of 12 octahedrally coordinated Al centers. Further polymerization of this colloidal species leads to the precipitation of a poorly crystalline solid phase.

Si Oxides

The Si oxides differ from the oxides of Fe, Mn, and Al in several aspects. The most prevalent Si oxide, quartz (SiO_2), is a primary mineral in many rocks, contributing approx. 120 g kg^{-1} to the average composition of the Earth's upper mantle. In soils, dissolved Si associates with Al to form aluminosilicate clay minerals. However, secondary Si oxides precipitates may also form in soil, sometimes to such an extent that they cement the soil matrix to form duricrusts and silcretes. Primary quartz crystals are very pure, hard, and recalcitrant, and occur in soil as large particles (sand). Their small surface area, their small amount of reactive bonds at the surface, and the lack of isomorphic substitution make them chemically very inert. Quartz has the lowest ion exchange capacity of all soil minerals. The solubility of Si oxides is low at usual soil pH (2–8), but strongly increases at pH >8. The main soluble species, $Si(OH)_4^o$ (monosilicic acid), is taken up by higher plants, especially grasses, to increase the mechanical strength and the resistance against fungal pathogens and herbivores, and is later recycled back into the soil as biogenic opal. Radiolarians, diatoms, silica sponges, and cyanobacteria are known to accumulate large amounts of Si oxides in fresh and marine waters, and microorganisms may exert a similar function in soils, competing with the inorganic formation of aluminosilicate clay minerals.

The Si oxides are tectosilicates. The repeating unit is a SiO_4 tetrahedron in which each O is linked to Si atoms of adjacent tetrahedra, forming a 3D framework structure. This contrasts with the Fe, Al, Mn, and Ti oxides, in which the basic unit is a cation in octahedral coordination. In the following sections, only α-quartz, α-cristobalite, and opal, which commonly occur in soil, will be described (Table 4).

Table 4 Silicon oxide minerals

Mineral	*Formula*	*Structural type*	*Occurrence*	*Figure*

Opal-A[a]	$SiO_2 \cdot x H_2O$	Nearly amorphous	Biogenic ubiquitous; inorganic in strongly weathered soils, duripans, silcretes	–

[a]Minerals commonly occurring in soil.

Quartz and Cristobalite

α-Quartz consists of paired helical chains of corner sharing SiO_4 tetrahedra that spiral along the *c*-axis. The intertwined chains produce open, hexagonal channels (Figure 2m). In cristobalite, the tunnels are larger (Figure 2n), and the density is smaller ($2.32\,g\,cm^{-3}$) than quartz ($2.65\,g\,cm^{-3}$).

Quartz is ubiquitous in soil environments, while cristobalite is restricted to soils developed from volcanic materials. The quartz in soils is mainly a primary mineral, inherited from the parent material. In soil solution, quartz may form from soluble $Si(OH)_4^o$ by polymerization, precipitation of amorphous, hydrous SiO_2, which slowly transforms into crystalline quartz. Direct precipitation from solution seems to be unlikely. Quartz is generally concentrated in the sand and silt fractions of soils, with a lower frequency in the coarse-clay fraction (0.2–2 μm). Quartz may comprise more than 90% of the inorganic fraction of Quartzipsamments. By contrast, highly weathered and leached Oxisols have only very low amounts of quartz left. The solubility of quartz ranges from 1 to $4\,mg\,l^{-1}$ Si depending on particle size.

Opal

Opal is classified into three structural groups, opal-C (well-ordered α-cristobalite), opal-CT (disordered α-cristobalite, α-tridymite) and opal-A (highly disordered, nearly amorphous). Opal contains 40–90 $g\,kg^{-1}$ water, and the specific gravity ranges from 1.5 to $2.3\,kg\,dm^{-3}$.

Opal-C and α-cristobalite occur in Andepts and other soils derived from volcanic material. Opal-CT has been identified in soils derived from bentonites, siliceous shales, and indurated silicates. Opal-CT is also a primary constituent of many cherts, porcelanites, fossil wood, silcretes, and some duripans. Opal-A may form by both organic and inorganic processes in pedogenic environments. Biogenic opal-A originates from Si accumulated by plants and aquatic organisms, and thus occurs under a wide range of environmental conditions. Biogenic opal is a nearly ubiquitous constituent of soils. Opal phytoliths are mostly derived from grasses, while sponge spicules, diatoms, and radiolaria, which form in aquatic environments, may reach soils via weathering of sediment bedrocks. Amounts of opal phytoliths in soils commonly range from less than 1 to $30\,g\,kg^{-1}$, usually occurring in the 5- to 50-μm size fraction, and decreasing with soil depth. Inorganic opal-A forms from supersaturated soil solution. It occurs as nodules and as the primary cement of indurated soil horizons (duripans) and silcretes.

At ambient temperature and neutral pH, the solubility of amorphous Si is approximately 50–60 mg $Si\,l^{-1}$, and therefore much higher than that of quartz. The presence of organic molecules greatly enhances the dissolution rates of Si oxides. Coatings of chemisorbed Al and Fe, however, reduce the dissolution rates. Oxides of Fe and Al, by acting as a sink for soluble Si, greatly increase the dissolution rates of amorphous Si oxides and of reactive, uncoated quartz surfaces. Dissolution (weathering) of Si oxides, which starts below approximately 3 mg $Si\,l^{-1}$, is induced by the reduction of Si levels in soil solution by leaching and plant uptake.

Ti Oxides

Titanium oxides are common in many igneous and metamorphic rocks and sediments. Due to their resistance against weathering, they are often inherited to soils. However, Ti oxides also form in soil after weathering of less-resistant, Ti-bearing minerals (biotite, amphibole). Titanium oxide minerals are relatively heavy (density more than $2.9\,g\,cm^{-3}$). Their concentration in soils is usually low; because of their small surface area, they do not contribute significantly to soil reactivity. Only in tropical soils, where they become increasingly enriched during pedogenesis, has some influence on phosphate and arsenate retention been observed. Old sand dunes may contain enough Ti oxides to be mined as a commercial source for TiO_2, which is used to produce white paint. Due to their recalcitrant nature, Ti oxides can be used as reference minerals to study weathering and soil genesis.

Titanium occurs primarily in octahedral coordination, and like the Fe and Mn oxides, the structures of the various Ti oxide minerals can be described in terms of the different arrangement of the Ti-containing octahedra. The principal Ti minerals are listed in Table 5. Rutile (TiO_2) is isostructural with pyrolusite and manganite, consisting of single chains of edge-sharing TiO_6 octahedra (Figure 2j). Rutile is a common residual mineral occurring in the sand and silt fractions of a variety of soils.

Table 5 Titanium oxide minerals

Mineral	*Formula*	*Figure*
Rutile[a]	TiO_2	2j
Anatase[a]	TiO_2	2l
Ilmenite[a]	$Fe^{2+}\,TiO_3$	2b
Pseudorutile[a]	$Fe_2O_3 \cdot nTiO_2 \cdot mH_2O$ ($n = 3$–5, $m = 1$–2)	–
Ulvöspinel	Fe_2TiO_4	2d
Titanomagnetite	$Fe_{3-x}\,Ti_xO_4$	2d
Titanomaghemite	$Fe_{2-x}\,Ti_xO_3$	2d

[a]Minerals commonly occurring in soil.

Anatase consists of edge- and corner-sharing octahedra that outline a three-dimensional framework, rather than distinct chains (Figure 2l). The platy crystals found in soils are believed to be a weathering product of titanite ($CaTiSiO_5$) and Ti-bearing silicates. Anatase is easily synthesized at room temperature. Ilmenite ($FeTiO_3$) is almost isostructural with hematite, with one-half of the octahedral centers occupied by Fe^{2+}, the other half by Ti^{4+} (Figure 2b). By oxidation of structural Fe^{2+} to Fe^{3+}, ilmenite weathers to pseudorutile ($Fe_2O_3 \cdot n\,TiO_2 \cdot mH_2O$; $3 < n < 5$ and $1 < m < 2$), a structurally disordered and poorly characterized mineral. Pseudorutile has been widely identified in soils, primarily as the weathering product of ilmenite. Ilmenite itself is relatively unstable in soils, because it easily weathers to pseudorutile and mixtures of rutile, anatase, and Fe oxides.

Titanomagnetites ($Fe_{3-x}\,Ti_xO_4$) are solid solutions of magnetite with ulvöspinel (Fe_2TiO_4), with Ti^{4+} occupying only octahedral sites of the magnetite structure (Figure 2d). Their formation is probably related to that of magnetite. Titanomaghemites ($Fe_{2-x}\,Ti_xO_3$) form by weathering of titanomagnetites. Their composition is between those of magnetite, maghemite and ulvöspinel. Many aspects of the Ti oxides, such as whether the minerals are relict or pedogenic, and the conditions responsible for their weathering and formation in soils, are still unresolved.

Introduction

Fungi and bacteria from all major taxonomic groups have been found in metal-rich habitats such as mineral ores, acidic soils, or polluted environments. The survival of these microorganisms may depend on a number of biochemical, structural, and physiological properties that modify metal bioavailability and toxicity, which are constitutive to a species and/or have been selected by adaptation.

All microorganisms have essential metabolic and structural requirements for specific metals in metabolism, including K, Na, Mg, Ca, Mn, Fe, Cu, Zn, Co, and Ni, while some metals, e.g., Rb, Cs, Al, Cd, Ag, Au, Hg, and Pb, and metalloids, e.g., As and Te, have no apparent essential function. Intense competition for some metals, coupled with low bioavailability, has driven the evolution of tightly regulated mechanisms for metal acquisition. These include highly specialized, metal-specific membrane transport systems and metal chelates to scavenge metals effectively from the environment. All metals and metalloids, regardless of their metabolic function, are, however, toxic in excess and can inhibit growth, affect sporulation and adhesion, induce morphological changes, and affect biochemical activities. This potential toxicity has led cells to develop diverse mechanisms of defense. Both genetically coded mechanisms of resistance and nonspecific mechanisms such as oxidation or reduction of the metals to

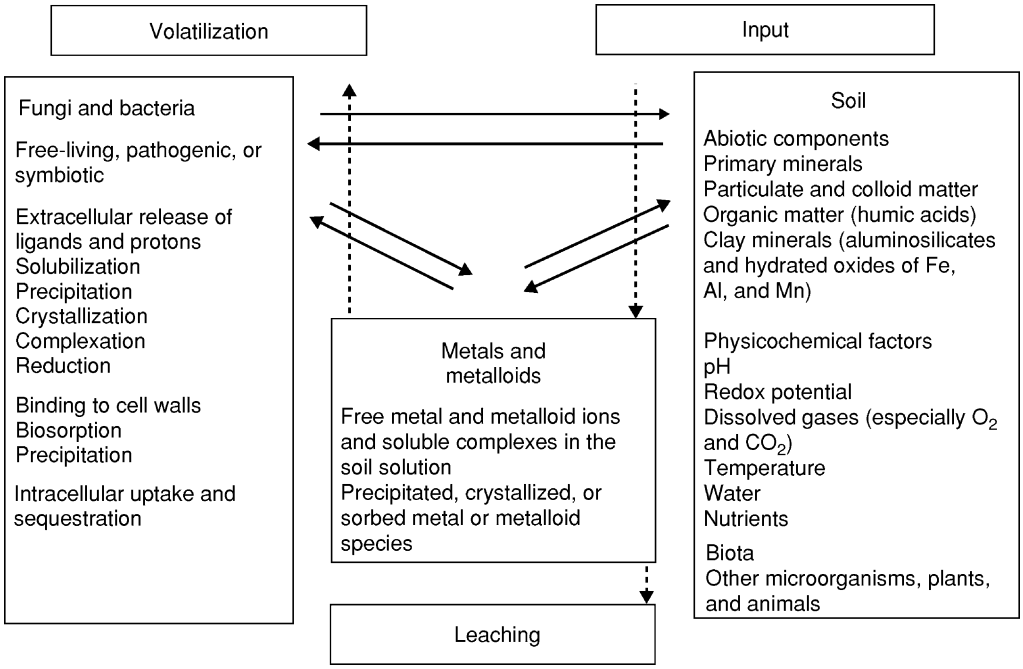

Figure 1 Fungal interactions with metals and metalloids in the soil environment. Metal(loid) species lost from the soil environment are indicated by broken arrows. Interactions mediated by microorganisms are indicated by solid arrows.

produce less toxic chemical species, or sorption and precipitation on cell surfaces, protect cells from toxic metals.

The chemical form, or species, of metals is also affected by microbial processes other than those related to nutrition and toxicity. Metal speciation is important because different metal species can have widely differing chemical and biological properties, including mobility in the environment and toxicity. Excreted cellular metabolites transform metal compounds by nonspecific reactions such as dissolution by protons and organic acids. Some bacteria use metals as electron donors and acceptors during respiration, a process that is a major pathway for the cycling of metals in soils and sediments. Such microbial transformations both mobilize and precipitate metals, leading to alteration and modification of soils and sediments. Many of these processes also have potential for the bioremediation of metal-contaminated sites.

Microbially Induced Metal Transformations

Interactions between microorganisms with metals and soil components take many forms; unravelling their complexity is integral to understanding metal speciation in the soil. The relative role of fungi and bacteria depends on associative biota (other microorganisms, plants, and animals) as well as on abiotic factors such as physicochemical components of the environmental matrix, e.g., pH, water, inorganic and organic ions, molecules, compounds, colloids, and particulates (Figure 1).

The ability of microorganisms to affect metal speciation in the soil environment stems from two opposing phenomena: mobilization and immobilization, which influence the distribution of metal species between soluble and insoluble phases. The solubilization of metals can be achieved by various mechanisms: protonation, chelation, and chemical transformation. Metal immobilization can occur by precipitation or crystallization of insoluble organic or inorganic compounds, or by sorption, uptake, and intracellular sequestration. In addition, redox reactions can mobilize or immobilize metals, depending on the metal species.

Mobilization

Fungi and bacteria can facilitate the transformation of metals into soluble forms via the dissolution of metal compounds, including oxides, phosphates, sulfides, and more complex mineral ores, or by desorption from exchange sites on clay minerals or organic matter. Metal leaching by Fe- and S-oxidizing bacteria is discussed further on. A number of other mechanisms by which microbes can leach metal ions have been proposed.

Acidification

Competition between protons and the metal (in a metal–anion complex) leads to protonation of the

anion under conditions of increased acidity, and results in the release of free metal cations. Fungi and bacteria can acidify their environment in a number of ways; for example, proton efflux via plasma membrane H^+-ATPases, maintenance of charge balance, or as a result of respiratory carbon dioxide accumulation.

Complexation by Ligands

Microorganisms produce a number of extracellular metabolites that can complex metals in solution, including polysaccharides, pigments, organic acids, and siderophores. Organic acids are important in energy production as intermediates in the tricarboxylic (TCA) cycle and in cellular pH homeostasis. They can correct internal perturbations in charge balance and pH resulting from nutrient uptake by their ability to produce and consume protons via the formation and removal of carboxylic groups, and by efflux from the cell.

Citric and oxalic acids are the most commonly reported organic acids in soils and are released into the soil by fungal hyphae, lichens (a symbiotic relationship between fungi and a photosynthetic cyanobacterium or alga), bacteria, and plant rootlets (mycorrhizae). Organic acids are believed to have an essential role in nutrient acquisition as a result of their acidification and metal-binding properties. For example, phosphate is released from common soil compounds such as $CaHPO_4$, $Ca_3(PO_4)_2$, $FePO_4.4H_2O$, and $AlPO_4$, either by direct exchange of chemically binding species, or ligands, between phosphate and the organic anion or by binding of the metal to the anion. Metal complexation depends on metal-to-anion availability, the stability of the particular metal–ligand complex, and pH. Anion concentration (which will depend on the pK_a of the acid) is important, because fully protonated organic acids chelate metals poorly. The affinity depends on the stability constant of the organic acid–metal complex. For example, the efficiency of organic acids to solubilize phosphate from soils often follows the order: citrate > oxalate > malate > acetate. The bioavailability of a solubilized metal–ligand complex will depend ultimately on its long-term fate in the environment, including sorption on to components of the soil matrix or potential utilization by biota. For example, metal citrates can be highly resistant to microbial degradation, which can result in effective leaching of metals from soil. In contrast, metal oxalates crystallize.

Many soil bacteria, fungi, and lichens are particularly efficient at solubilizing metal phosphates and other metal-bearing compounds, which has been attributed to their ability to produce protons and organic ligands. This can be tested by simple laboratory experiments: if insoluble metal compounds are incorporated into solid growth medium, clear zones may appear around microbial colonies if they are capable of mineral dissolution.

In addition, organic acid production by microbes is an important agent of mineral deterioration, playing a role in both biogenic chemical weathering and soil formation. Fungi can also physically weather minerals by etching and fracturing mineral grains during hyphal growth.

Siderophores

Siderophores are the largest class of known compounds that can bind and transport, or shuttle, Fe. They are highly specific Fe(III) ligands (formation constants often greater than 10^{30}). These low-molecular-weight coordination molecules are excreted by a wide variety of fungi and bacteria to aid Fe assimilation. Although the mechanism could be used to acquire other metals, Fe is the only known essential element for which these specific organic shuttles operate. This is most likely because Fe is needed in larger amounts by cells than other poorly soluble metals, and, given the low solubility-product constant of ferric hydroxide (less than 10^{-38}), the concentration of free Fe^{3+} is too low to support microbial growth at pH values where most life exists.

In a typical soil, many different species, including plants, compete for Fe via siderophores. Organisms have most likely evolved mechanisms to ensure that Fe demand is met through the production of species-specific siderophores, or attachment to solid mineral Fe (e.g., Fe oxides) to shorten the pathway between the Fe substrate and the site of uptake.

Biomethylation

Methylation of Hg, As, Se, Sn, Te, and Pb is mediated by a range of microorganisms, including clostridia, methanogens, and sulfate-reducing bacteria under anaerobic conditions, and principally fungi under aerobic conditions, such as *Penicillium, Cephalosporium*, and *Alternaria* spp. as well as a variety of bacteria, including pseudomonads. Methyl groups are enzymatically transferred to the metal, and a given species may transform a number of different metal (loid)s. Methylated metal compounds formed by these processes differ in their solubility, volatility, and toxicity. Volatile methylated species, e.g., $(CH_3)_2Se$ and $(CH_3)_2Se_2$, are often lost from the soil.

Redox Reactions

Microorganisms mobilize metals, metalloids, and organometallic compounds by reduction and oxidation processes, exemplified by pathways for metal

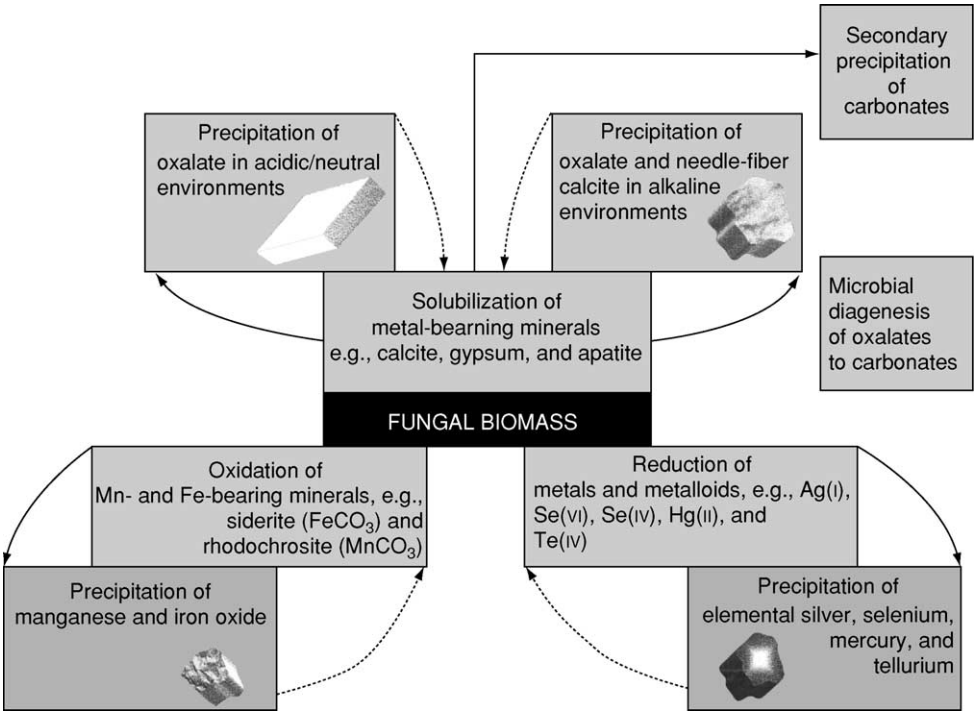

Figure 2 Metal precipitation by microorganisms. Solid arrows represent precipitation by fungi and bacteria. Broken arrows represent precipitation and association with microbial biomass (living or dead).

cycling by fungi (Figure 2). For example, oxidation of metal-complexing dimethylsulfide, dimethylsulfoxide, or thiosulfate increases metal availability if metal sulfates are formed, and the solubilities of Fe and Mn increase upon reduction of Fe(III) to Fe(II) and Mn(IV) to Mn(II). While many microorganisms reduce small amounts of Fe during metabolism, most Fe reduction is carried out by specialized anaerobic bacteria such as *Shewanella* spp. and *Geobacter* spp. that use Fe for respiration, and there is evidence that reduction of Fe(III) was one of the first forms of microbial respiration. In this process, oxidized forms of metals are used as the final electron acceptor in place of the oxygen consumed during aerobic respiration. The dissimilatory metal-reducing bacteria respire and thereby reduce oxidized metal species at or near the outer cell wall. The membrane-bound electron transport system provides energy to cells by cycling electrons through an electrochemical cascade of metalloenzymes, expelling e^- and H^+ from the cell. Energy is generated by the flux of H^+ into the cell through specific membrane-bound channels (Figure 3). Dissimilatory metal-reducing bacteria can use a variety of metal(loid)s with an appropriate redox couple, including Fe(III), Mn(IV), Se(IV), Cr(VI), and U(VI). While Fe and Mn increase their solubility upon reduction, the solubility of other metals such as U(VI) to U(IV) and Cr(VI) to Cr(III) decreases, resulting in

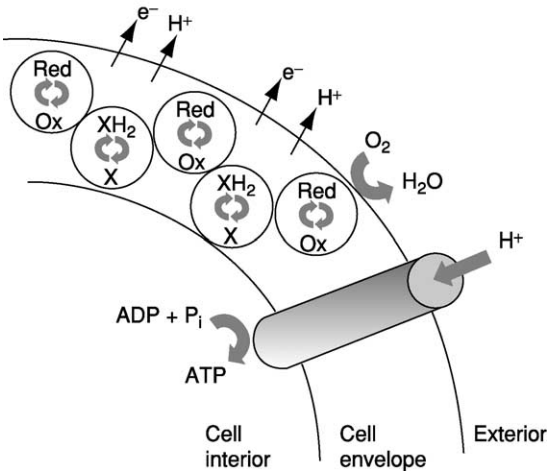

Figure 3 Simplified bacterial electron transport chain, showing linked carriers in the cell wall that cycle electrons down an electrochemical gradient to the final electron acceptor (in this case O_2). Energy is generated by the flux of protons through specific channels across the membrane. Red, reduction; Ox, oxidation; P_i, inorganic phosphorus; ADP, adenosine diphosphate; ATP, adenosine triphosphate.

immobilization (see Precipitation of Metals and Minerals, below). Reduction of Hg(II) to Hg(0) by bacteria and fungi results in diffusion of elemental Hg out of cells, and conferment of Hg resistance on organisms that possess this property since Hg(0) is considerably less toxic than Hg(II).

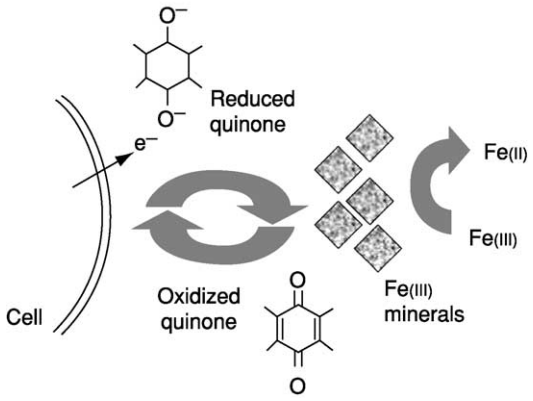

Figure 4 Proposed mechanism for electron transfer from metal-reducing cells to oxidized Fe minerals via chemical reduction of a quinone shuttle. The shuttle regenerates when Fe(III) is reduced to Fe(II).

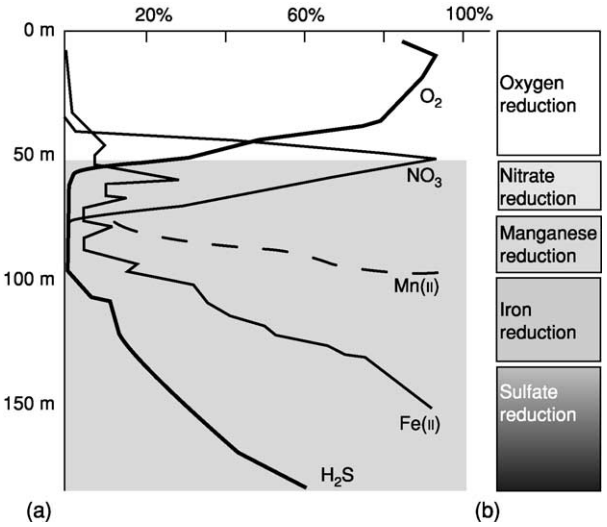

Figure 5 Reductive processes in the environment: (a) representative electron acceptor profiles (percentage of maximum) with water depth in meters. Data are from the Black Sea; (b) major processes occurring in the redox zone with depth. (Reproduced with permission from Nealson KH and Saffarini D (1994) Iron and manganese in anaerobic respiration: environmental significance, physiology and regulation. *Annual Review of Microbiology* 48: 311–43. © Annual Reviews, Inc.)

Dissimilatory metal reduction requires that bacteria access relatively large amounts of insoluble metals. Bacteria can use redox-active organic compounds to shuttle electrons between cells and the metal being respired under anaerobic conditions. Many quinoid compounds, common components of humic substances, can function as electron shuttles. These compounds move electrons from the cell membrane to the target metal, such as iron contained in ferric oxides. The shuttle molecule regenerates when the metal is reduced and the cycle continues (Figure 4). While the use of electron shuttle mechanisms appears to be widespread among bacteria, the impact and ecologic significance of the process in natural subsurface environments are not fully understood.

In the absence of processes that mix water columns, sediments, and soils, redox potentials tend to decrease with depth, reflecting a change in the dominant electron acceptors from O_2 to NO_3^-, Mn, Fe, and (finally) S. The interplay between microbial and abiotic metal reduction forms characteristic element profiles (Figure 5). *Shewanella*, *Geobacter*, and *Desulfovibrio* spp. have been intensively studied for their metal-reducing capability. Molecular studies reveal that many as yet uncultured species exist in the subsurface which can also contribute, and improved culturing methods are likely to show novel dissimilatory metal reducers amongst these organisms. The poorly crystalline iron fraction is generally considered to be the 'reactive' fraction for these bacteria; however, iron in some clay minerals and crystalline Fe oxides could be available for reduction.

Immobilization

There are a number of processes whereby microbial biomass can immobilize metals in the soil environment. Although immobilization reduces the external free metal activity, it may also shift the equilibrium to release more metal into the soil solution.

Biosorption

The strong interaction of metals with cell surfaces stems from cell wall characteristics, including component pigments and polysaccharides. Bacterial cells depend on the diffusion of nutrients for survival, and their small size, shape, and characteristic membrane structures have evolved to maximize their interaction with nutrient solutes. There is remarkable similarity in the general format of bacterial wall structure, which falls into two broad classes based on reaction with Gram's stain, which utilizes crystal violet. Gram-positive walls consist of a thick matrix of peptidoglycan and secondary polymers, which provides structural support and gives the cell its shape and form (Figure 6). The phosphate and carboxyl groups within the wall fabric and exposed at the surface confer pH-dependent negative charge to the cell in the types of environments where microbes generally exist. The point of zero charge (PZC), or pH where positive charge equals negative charge, is approximately pH 2–3 for bacterial cell walls. This charge provides the basis for metal sorption. At pH values above the PZC, the net charge on the cell wall is negative, which facilitates sorption of positively charged metal species. Gram-negative cells are also negatively charged, although structurally more

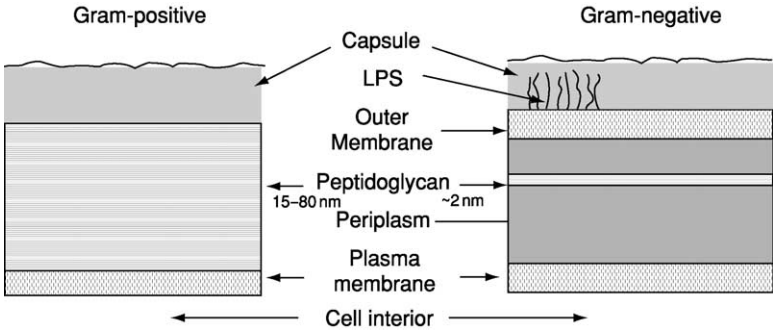

Figure 6 Cross-section view showing the cell wall structures characteristic for Gram-positive (left) and Gram-negative (right) bacteria. LPS, lipopolysaccharide.

complex. In this case, a thin layer of peptidoglycan floats in a gel-like periplasm, sandwiched between the plasma membrane and the outer membrane (Figure 6). The outer membrane has characteristic surface lipopolysaccharides (LPS) containing ionizable phosphoryl, carboxyl, hydroxyl, and amine groups; the phosphoryl groups are the most reactive to metals. In addition to these basic structures, surface capsules, sheaths, and S-layers provide additional sites for metal interaction and the heterogeneous nucleation of minerals.

Fungal cell walls are predominantly composed of polysaccharides (80–90%) with glycoproteins and some lipids. The polysaccharide component includes microcrystalline fibrils of β-linked polysaccharides (chitin, chitosan, and β-glucans) that are responsible for wall strength and rigidity. As for bacteria, the chemical properties of the functional groups associated with fungal walls, including carboxyl, amine, hydroxyl, phosphoryl, and sulfhydryl groups, provide the basis for the attraction of metals to cell walls. In addition, pigments such as melanin contribute to rigidity and have significant metal-binding properties, preventing metal entry into melanized structures.

Precipitation of Metals and Minerals

Partitioning in the cellular environment Metals are found in all parts of bacterial and fungal cells: in the cytoplasm, the cell wall, or sorbed to the cell surface. At sufficient concentrations, metal precipitates begin to develop or nucleate on or within cells, or in the immediate extracellular environment (demonstrated for a bacterial cell in Figure 7). In addition to immobilizing metals, this also reduces the external free metal activity and may shift the equilibrium to release more soluble metal to the soil. Precipitation and crystallization restrict metal leaching and bioavailability, and can potentially release nutrients such as sulfate and phosphate.

The formation of extracellular and sorbed precipitates depends on the chemical composition of the

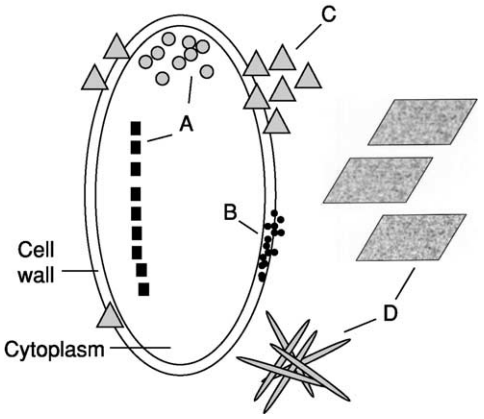

Figure 7 Possible locations of metal precipitates and minerals associated with a bacterial cell: A, biogenic precipitates within the cell cytoplasm; B, metal precipitates formed by nucleation in the cell wall, e.g., periplasmic; C, mineral nanocrystals formed independently of cell activities and subsequently sorbed to the cell wall; D, minerals formed outside cells due to the influence of cellular activities.

extracellular environment and is often mediated by cellular processes. The precipitates can be copious and may completely enmesh the cells, effectively mineralizing them (Figure 8). Environmental anions, such as OH^-, SO_4^{2-}, PO_4^{3-}, and CO_3^{2-}, provide counterions for mineral hydroxides, sulfate and sulfides, phosphates, carbonates, and oxalates. It is possible that cellular metabolism and excretion of such anions also contributes to these minerals. Metal oxide and hydroxide minerals formed by abiotic reactions also attach to cells, and it can be difficult to distinguish these phenomena (Figure 9). This is, however, another important mechanism by which cells can concentrate metals.

Inside cells, metals can be built into cellular constituents. Excess or toxic metals may be effluxed, form intracellular precipitates, bind to metal-complexing molecules, and, in eukaryotes, partition into vacuoles. The formation of internal precipitates often results from a change in metal oxidation state, which does not require an active cell; for example, gold is

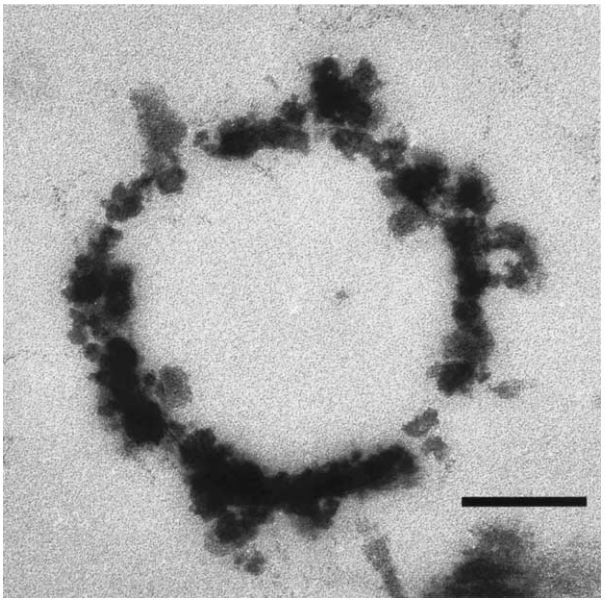

Figure 8 Transmission electron micrograph of a thin-section sample taken from a Yellowstone hot spring, showing an unknown bacterial cell embedded in metal-rich precipitates. Scale bar 150 nm.

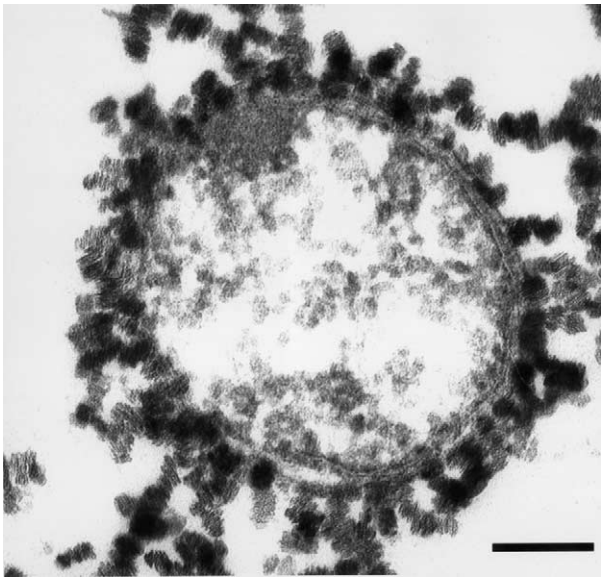

Figure 9 Transmission electron micrograph of a thin section showing abiotically precipitated goethite nanocrystals sorbed to the cell wall of *Shewanella putrefaciens*. Scale bar 150 nm.

highly toxic to cells, yet intracellular precipitates of elemental gold form in bacteria after cells are killed. The formation of oriented chains of magnetite (Fe_3O_4) crystals by magnetotactic bacteria, found in sediments and hydric soils, is a unique example of directed, intracellular mineral precipitation. In this case, the formation of mineral precipitates is a mechanism that enables the bacteria to orient in the Earth's magnetic field.

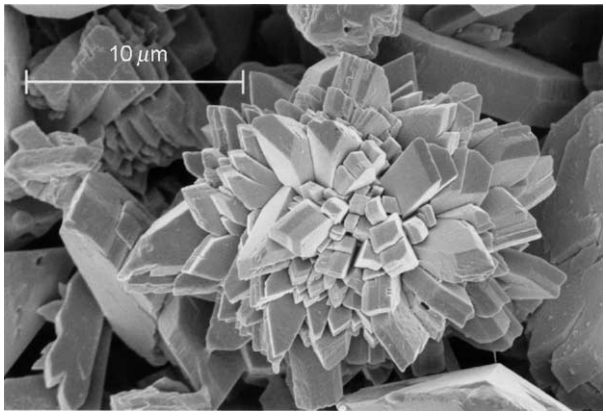

Figure 10 Calcium oxalate precipitated by *Aspergillus niger*. Scale bar 10 μm.

Oxalates Calcium oxalate is the most common form of oxalate associated with soils and leaf litter, occurring as dihydrate (weddellite) or the more stable monohydrate (whewellite). Calcium oxalate crystals are commonly associated with free-living, pathogenic, and plant-symbiotic fungi and are formed by the reprecipitation of solubilized calcium as the oxalate. Fungal-derived calcium oxalate can exhibit a variety of crystalline forms (tetragonal, bipyramidal, plate-like, rhombohedral, or needles), which often associate with the outer surfaces of hyphae (Figure 10). The formation of calcium oxalate by fungi has an important influence on biological and geochemical processes in soils, acting as a reservoir for calcium in the ecosystem, and also influencing phosphate availability.

Fungi can also produce other metal oxalates with a variety of different metals and metal-bearing minerals, e.g., Cd, Co, Cu, Mn, Sr, and Zn. The formation of metal oxalates may provide a mechanism whereby fungi can tolerate environments containing potentially high concentrations of toxic metals. A similar mechanism occurs in lichens growing on copper sulfide-bearing rocks, where precipitation of copper oxalate occurs within the thallus.

Carbonates In many arid and semiarid regions, calcareous soils and near-surface limestones (calcretes) are often secondarily cemented with calcite ($CaCO_3$). This phenomenon has been partly attributed to physicochemical processes; however, the abundance of calcified fungal filaments in weathered profiles of chalky limestone and Quaternary calcretes indicates fungal activity. Calcite precipitation on fungal hyphae has also been observed with the ectomycorrhizal fungus *Pisolithus tinctorius* in calcareous soil.

Calcite has been proposed to form indirectly through fungal excretion of oxalic acid and precipitation of calcium oxalate, which results in dissolution

of the internal pore walls of the limestone matrix. This enriches the matrix solution in free carbonate ions. During passage of the solution through the pore walls, calcium carbonate recrystallizes as a result of a decrease in CO_2, hardening the limestone. Calcite crystals act as sites of further secondary calcite precipitation when the hyphae decompose. Through these processes, fungal activity is important in lithification (hardening), alteration, and diagenesis of subsurface limestone formations.

Mineralized carbonate precipitates are also found in association with bacterial biofilms. One striking example of microbial carbonate precipitation is the towering microbialites at Lake Van (Turkey), formed by thick biofilms of cyanobacteria (*Pleurocapsa* spp.) that colonize crusts of inorganic calcite precipitated in the alkaline soda lake water. Groundwater forced up and through the carbonate matrix raises the towers of aragonite and calcite to heights up to 40 m.

Redox Reactions

Bacterial and fungal oxidation The range of bacterial species with the capability to oxidize Fe and Mn spans sedimentary and soil environments. For bacteria to use Fe(II) specifically for growth, however, they must recover the energy produced in the oxidative process. Demonstration of a respiration-linked, energy-yielding reaction is particularly difficult for iron due to its rapid chemical oxidation at neutral pH and atmospheric O_2. It has been more readily shown for bacteria that grow at low pH and/or low O_2, conditions that drastically slow chemical oxidation of Fe(II). Bacterial Fe oxidation is probably ubiquitous in environments with sufficient Fe^{2+} and conditions to support the growth of bacteria that can make a living by oxidative respiration of reduced metal species. Specific environments include drainage waters and tailing piles in mined areas, pyritic and hydric soils (bogs and sediments), drain pipes and irrigation ditches, and plant rhizosphere zones.

Iron-oxidizers found in acidic soil environments are acidophilic chemolithotrophs, organisms that use inorganic sources of chemical energy, such as *Thiobacillus ferrooxidans*, which is significant for its role in generating acid mine drainage. Facultative chemolithotrophic microaerophiles such as *Leptothrix ochracea*, *Sphaerotilus natans*, and *Gallionella ferruginea* are common in mildly acidic to neutral environments, and accumulate abundant Fe hydroxide precipitates on their filament or stalk structures that can age to more crystalline minerals.

After Fe, Mn is the second most abundant transition metal in the Earth's crust and is actively cycled in the same environments as Fe. Mn oxidation is carried out by many of the organisms that are implicated in Fe oxidation, including *Bacillus*, *Pseudomonas*, and *Leptothrix* spp. In contrast to Fe^{2+}, substantial chemical oxidation of Mn^{2+} does not occur below pH 8, and solutions containing Mn^{2+} can be stable for weeks. This fact has allowed bacterial Mn oxidation to be identified more readily than its Fe counterpart.

It is not yet clear why cells carry out metal oxidation if not for gaining energy. Oxidation may help the cell rid itself of toxic intracellular concentrations of the metal, or the precipitates that coat the bacterial surface subsequent to oxidation may protect the cells from attack by other microbes. Protection from UV radiation would have been especially crucial during the early evolution of life on Earth.

Fungi also oxidize metals in their environment. Desert varnish is an oxidized metal layer (patina) a few millimeters thick found on rocks and in soils of arid and semiarid regions, and is believed to be of fungal and bacterial origin. *Lichenothelia* (a fungus) can oxidize manganese and iron from metal-bearing minerals such as siderite ($FeCO_3$) and rhodochrosite ($MnCO_3$), and metals from rainfall or windblown dust.

Dissimilatory metal-reduction by bacteria When dissimilatory metal-reducing bacteria utilize relatively soluble metals such as Cr(VI) and U(VI) as electron acceptors, less-soluble Cr(III) and U(IV) species may result. Once reduced, soluble metals sorb to the cells or partition to the bulk extracellular solution, where new minerals can form from the metals and suitable counterions. Postreduction partitioning of metals depends on the element. For example, U(IV) accumulates as fine precipitates in the periplasm of Gram-negative metal reducers (**Figure 11**). Fe^{2+} and Mn^{2+}, generated by dissimilatory reduction, can form copious extracellular precipitates and nodules. The fate of the reduced metal depends on the environment, and it is feasible that a metal such as Fe, along with any associated redox-active metals, could be cycled hundreds of times between reducing and oxidizing zones before being incorporated into refractory minerals (**Figure 12**).

Fungi and other microorganisms also precipitate reduced forms of metal species, e.g.: Ag(I) to Ag(0); selenate (Se(VI)) and selenite (Se(IV)) to Se(0); and tellurite (Te(IV)) to Te(0), by a variety of mechanisms.

Biotechnological Applications of Microbial Metal Transformations

Ore Leaching

Metals in ores that are not worth recovering by smelting can sometimes be effectively leached by

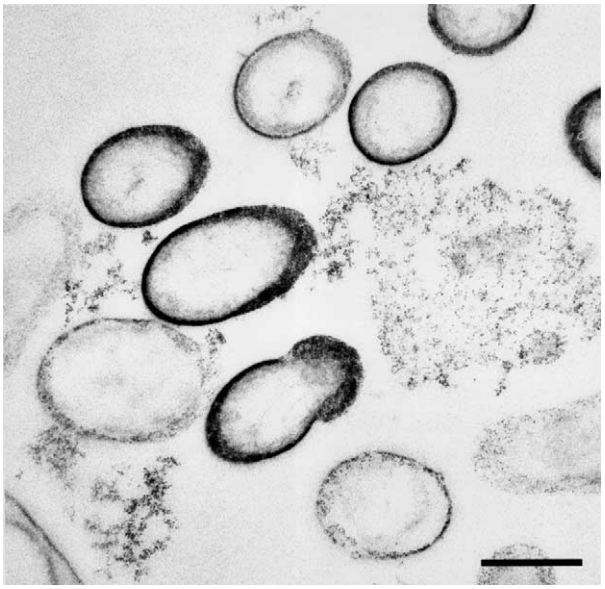

Figure 11 Transmission electron micrograph of a thin section showing uranium precipitates formed in the periplasmic space of *Geobacter metallireducens* cells during dissimilatory reduction of U(VI). No metal stains were used, so that the contrast in the image is from the uranium precipitates only. Scale bar 150 nm.

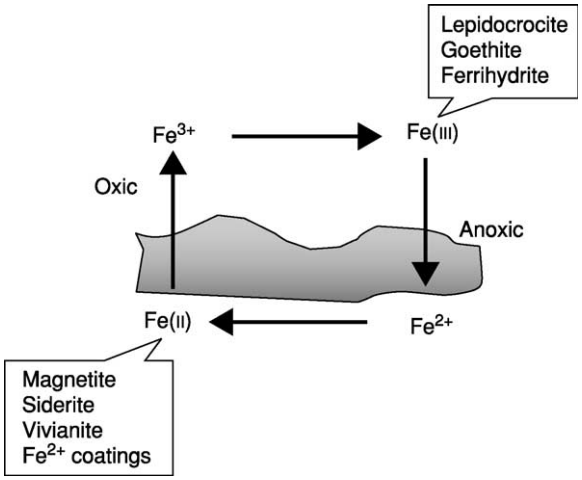

Figure 12 Cycling of Fe between soluble and insoluble mineral, oxidized and reduced forms mediated by microorganisms in soils and sediments. Although by quantity Fe is the major element to undergo redox transformations, other metals can be cycled by the same processes and associate with the precipitating minerals.

bacteria and fungi. Important species of bacteria in such processes are Fe and S oxidizers such as *Thiobacillus ferrooxidans*, *T. thiooxidans*, and *Leptospirillum ferrooxidans*. Their activities solubilize Fe and S contained in metal sulfides, with the concomitant release of associated metals such as Cu and Zn. Large amounts of Fe^{2+} and sulfuric acid are generated in the process. It has been accepted most commonly that bacteria catalyze the oxidation of Fe^{2+} to regenerate Fe^{3+}, but do not directly attack the mineral:

$$14Fe^{2+} + 3.5O_2 + 14H^+ \rightarrow 14Fe^{3+} + 7H_2O \quad \text{bacteria} \quad [1]$$

$$FeS_2 + 8H_2O + 14Fe^{3+} \rightarrow 15Fe^{2+} + 2SO_4^{2-} + 16H^+ \quad \text{abiotic} \quad [2]$$

where eqn [1] gives the reaction for bacteria, and eqn [2] is the abiotic reaction. There is, however, increasing evidence that *T. ferrooxidans* may directly enhance dissolution of metal sulfides via an enzymatic mechanism. Approximately 90 mol Fe^{2+} is oxidized to assimilate 1 mol C, which explains the tremendous amount of acidity – 'acid mine drainage' – that is generated. Industry can take advantage of the acidic leachate by recirculating it through the ore body to dissolve and harvest more metal. Here, the acidic leachate is recirculated through the ore body to solubilize more metal, and the soluble metals are then separated by sedimentation, solvents, or electrodialysis. When uncontrolled, such as at poorly managed or abandoned mining sites, the same process can have disastrous environmental consequences.

Extracellular ligands produced by fungi, including *Aspergillus* and *Penicillium* spp., have also been used to leach metals such as Zn, Cu, Ni, and Co from a variety of solid materials, including low-grade mineral ore, solid waste, and electronic scrap materials.

Bioremediation

Toxic metals in natural, industrial, and agricultural soils may be a risk to biota at all trophic levels if they exist at potentially toxic levels and are, or become, bioavailable. Some of the processes outlined above have potential for application to treat contaminated land. Solubilization processes provide a route for removal of metals from soil matrices, whereas immobilization processes enable metals to be transformed to insoluble chemically inert forms. Although some processes could be used *in situ* (e.g., leaching using S-oxidizing bacteria), many are probably most suitable for *ex situ* use in bioreactors, where the mobilized or immobilized metal can be separated from soil components. Living or dead fungal and bacterial biomass and metabolites have been used to remove metals and metalloids from solution by biosorption or chelation.

Recently there has been renewed interest in the ability of some mycorrhizal fungal symbionts to improve plant metal tolerance and increase metal translocation to the aboveground parts of plants. Such associations could be used to enhance the

phytoextraction capabilities of plants grown for removing toxic metals from soil by accumulation in their shoots. Amelioration of metal phytotoxicity by mycorrhizal fungi has been widely demonstrated, particularly when inoculated with mycorrhizae isolated from metalliferous or acid soils.

The increased attention to microbial activities in anaerobic, subsurface environments in the past few years has opened up new possibilities for the bioremediation of metal contaminants. Metal(loid)s that form insoluble precipitates when reduced may be of particular interest for *in situ* treatment, such as Se(0), Cr(III), Tc(IV), and U(IV). Natural processes in subsurface soil may immobilize contaminants otherwise predicted to leach. Thorough knowledge and monitoring of the system are essential for such treatment schemes, because reoxidation can result in mobilization.

Summary

Dissolution, precipitation, oxidation, and reduction processes are vital to metal cycling in aerobic and anaerobic surface and subsurface environments. As active agents in cycling, bacteria and fungi are fundamental biotic components of natural biogeochemical cycles for metals and metalloids. Some important processes catalyzed by microorganisms also have important applications in environmental biotechnology in the areas of ore leaching and bioremediation.

Environmental Factors

Introduction

The activity of all living organisms in soils is affected by environmental factors. These environmental factors are commonly divided into abiotic and biotic factors: the primary abiotic factors include nutrients, water, oxygen, temperature, pH, and light; the primary biotic factors include organism–organism interactions of mutualism, commensalism, amensalism, competition, predation, and parasitism. In addition to these primary factors, other factors (e.g., ionizing radiation in a uranium-rich soil) exist in a few specialized soil habitats, but these rare factors are not considered here.

Before one can predict how an environmental factor will affect the activity of microbes in a particular soil, there are a number of points to consider with respect to the soil, the soil organisms, and the environmental factors. With respect to the soil, it is important to consider how soil differs from other environments. A typical mineral soil is 50% solid material and 50% pore space, and has a bulk density (the weight of the soil divided by the total volume of the soil) ranging from 1.00 to 1.80 $g\,cm^{-3}$. Because of its density, soil can offer a much broader spectrum of varying environmental factors than other environments. For example, bacteria incapable of tolerating oxygen can exist only micrometers apart from bacteria incapable of existing without oxygen. The creation of these microsites allows soil to contain an exceptional diversity of microorganisms over a small space, and gives soil a complexity unlike all other habitats.

Further, all these organisms live in the soil pores. Under normal circumstances, chemical and physical forces limit movement of most soil organisms in these pores. In terms of chemical forces and bacteria, these organisms are negatively charged at typical soil pH values (5–8) and are held in place by negatively charged clay and organic matter through ion exchange, coordination bonding, hydrogen bonding, and van der Waals forces. In terms of physical forces, soil pores, particularly micropores (less than 30 μm), offer only a tortuous path to movement. Only when soils are saturated, or when plant roots or larger soil organisms actively or passively transport smaller soil organisms, do smaller soil organisms overcome these physical and chemical forces to move great distances (centimeters or more). Therefore, when environmental factors become adverse, most soil organisms are stuck in place and cannot escape to better conditions elsewhere.

With respect to soil organisms, many soil organisms are unidentified. Although the percentage of identification is comparatively good for soil algae and many soil protozoa, nematodes, and other soil fauna, only 0.1–10% of all soil bacteria and archaea, and 5% of all fungi are speciated. Molecular techniques, especially nucleic acid analyses, will increase these percentages, but at present, generalizations about how environmental factors affect microbial activity must be interpreted with caution when the identity of so many species is unknown.

With respect to environmental factors, these factors range from essential to unimportant. Like Goldilocks, soil organisms prefer essential factors to be "just right." For an organism to be outside the boundary of an essential environmental factor means diminished microbial activity, and, if sufficiently far outside the boundary, death (Figure 1). Understanding how environmental factors affect microbial activity is more difficult than it appears, because environmental factors are often dependent on each other.

Abiotic Factors

Nutrients

Nutrients are substances that soil organisms must obtain from the environment to survive and grow. Soils vary in their ability to contain and to hold these nutrients. On a chemical basis, the ability of a soil to hold nutrients is based on its anion exchange capacity and cation exchange capacity, and it is the

type and amount of clay and organic matter in soil that determine this.

Some nutrients provide energy, whereas others provide cell constituents. In terms of energy, all soil organisms are either chemotrophs, which derive all their energy from organic and inorganic sources (sometimes also called organotrophs and lithotrophs, respectively), or phototrophs, which convert light energy into chemical energy. Because carbon is the most common element in all soil organisms, chemotrophs and phototrophs are typically further divided into autotrophs, which convert inorganic carbon (i.e., CO_2 or carbonates) into organic compounds, or heterotrophs, most of which are saprophytes and feed on nonliving plants and animals or on humic substances in soil. Table 1 shows examples of this classification.

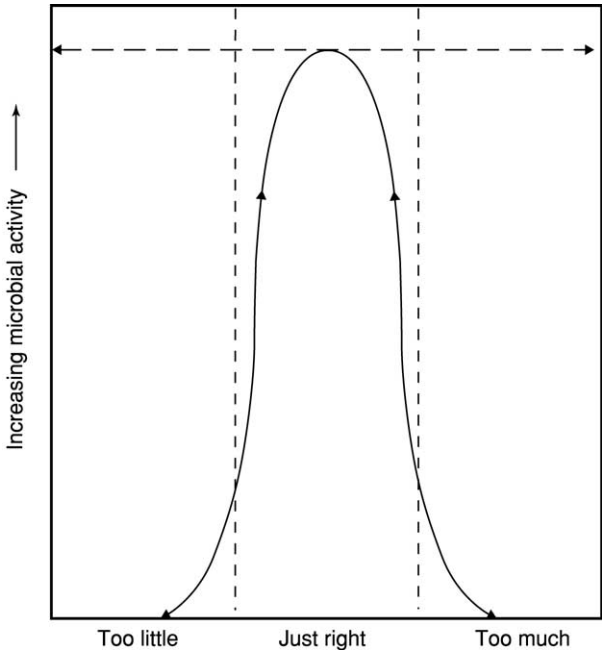

Figure 1 Idealized response of a soil organism to a critical soil environmental factor (solid line). The response of the organism does not have to be bell-shaped, and can be asymptotic to the left or to the right (horizontal dashed line).

In terms of cell constituents, nutrients are divided into macronutrients, substances required in large quantities by organisms, and micronutrients, substances required in small quantities (nanograms per gram of dry weight). Besides carbon, the major macronutrients for soil organisms are nitrogen, phosphorus, and sulfur, and, to a lesser extent, calcium, magnesium, potassium, and sodium. The major micronutrients are cobalt, copper, iron, manganese, molybdenum, and zinc. Macronutrients comprise the vast majority of the structural components such as carbohydrates, proteins, lipids, and nucleic acids, while micronutrients are typically found in growth factors and enzymes.

There are only three natural conditions during which soil organisms see nutrients in abundance. The first is governed by the natural life cycle of plants. As annual plants die and perennial deciduous plants shed their leaves, the accumulated nutrients are released into the soil.

The second condition is the relatively steady exudation of organic compounds from plant roots. Because some soil organisms can promote plant growth through the production of plant growth hormones and other mechanisms, plants have evolved to exude a complex mixture of organic compounds through their roots, primarily organic acids, amino acids, and carbohydrates. The rhizosphere, or zone of soil under the influence of the plant, has sufficient nutrients such that the colony-forming units of bacteria and fungi per gram of rhizosphere soil are typically 10- to 100-fold higher than bulk soil, and the numbers of soil animals that prey on these microbes are doubled or tripled. With such high numbers, it is unsurprising that microbial activity is often intense.

The third condition is when something disrupts the first two conditions. Natural disruptions include conditions such as fire and the episodic drying and rewetting of soil. Fire, by consuming aboveground biomass, minimizes the rhizosphere effect by reducing the energy supply to the soil organisms. Episodic drying causes soil organisms to die, unless these organisms have developed a mechanism to avoid desiccation (e.g., they form a resistant structure such as a spore or cyst). When soil is rewetted, the survivors

Table 1 Classification of all soil organisms based on their source of energy ('photo-,' light; 'chemo-,' organic or inorganic sources) and carbon ('auto-,' CO_2 or carbonates; 'hetero-,' organic C sources)

Energy source	*Carbon source*	*Classification*[a]	*Example(s)*
Light	Inorganic carbon	Photoautotroph	Algae, cyanobacteria
	Organic carbon	Photoheterotroph	Photosynthetic bacteria
Organic or inorganic sources	Inorganic carbon	Chemoautotroph	Nitrifying and sulfur-oxidizing bacteria
	Organic carbon	Chemoheterotroph	Fungi, most bacteria, and soil fauna

[a]The suffix '-troph' means to nourish.

dine on the deceased. Human disruptions include conditions such as clear-cutting and tillage. Clear-cutting has the same effect as fire, while tillage disrupts the soil structure, releasing occluded organic matter and causing a temporary glut of nutrients to the soil community.

Bioavailability, or the degree to which nutrients are accessible to soil microorganisms or extracellular enzymes, depends not only on chemical characteristics of the nutrients (e.g., whether they are polar or nonpolar) and their physical place (e.g., whether they are in inaccessible nanopores or not), but also on abiotic factors. For example, in the case of leaf fall in northern temperate regions, microbial activity reaches a peak in autumn, diminishes in winter with its cooler temperatures, and then resurges again in spring when favorable abiotic factors recur. Activity in summer is low because water is often limited.

Not surprisingly, soil organisms have developed an array of different mechanisms to deal with this periodic, episodic, or steady flow of nutrients. Some soil organisms opt for rapid growth only when nutrients are plentiful. By placing all their efforts into reproduction, these organisms attempt to occupy a niche as quickly as possible and then die to low numbers awaiting the next flush of nutrients. Organisms like this are termed 'r-selected' or 'zymogenous' strategists, and this strategy is characteristic of many bacterial species and soil fauna. Some organisms, by virtue of being left with 'crumbs from the table,' opt for a slower growth rate and tend to metabolize more complex nutrients. Organisms like this are termed 'K-selected' or 'autochthonous' strategists, and this strategy is characteristic of many fungal and actinomycete species. Finally, other organisms lie on the continuum between these two strategies.

For autotrophs, there is no problem of limited carbon, because CO_2 and bicarbonate are usually present in excess of demand. For heterotrophs, microbial activity is dependent on the quality and quantity of available carbon. Readily available natural organic compounds such as simple sugars are degraded quickly and microbial activity is high. For natural organic compounds that are recalcitrant or resistant to degradation (e.g., lignin), microbial activity is low. Toxic compounds such as antibiotics also have the capacity to diminish microbial activity. There is one special case for xenobiotics, anthropogenic compounds that have no biological parallel in the environment. These nonnatural compounds typically have either halogen substituents (e.g., Cl) or are branched polymers (e.g., polypropylene). Soil organisms, by virtue of their enzymatic virtuosity, degrade most xenobiotics as they would natural compounds. Sometimes, however, an organism accidentally metabolizes a xenobiotic in the process of metabolizing a second compound. This process, called cometabolism or fortuitous metabolism, is beneficial to humans in terms of biodegradation of xenobiotics in soils, but is detrimental or at best neutral to the activity of the organism, because the process does not yield any energy or carbon. For example, a bacterium cometabolizing polychlorinated biphenyls (PCBs) yields chlorinated aliphatic and aromatic acids, both dead-end products that the bacterium cannot assimilate.

Water

All soil organisms – without exception – require water for microbial activity. The major force governing water in soil is the total water potential, which is composed primarily of gravitational, matric, and osmotic potentials, and is measured in units of pressure, pascals (Pa). Gravitational potential is the force of gravity pulling water toward the Earth's center, matric potential is the adsorption of water to surfaces of soil particles and capillary forces, and osmotic potential is the attraction of solute ions for water molecules. Soil organisms have their own water potentials, composed primarily of osmotic and turgor potentials. Before considering these potentials, it is important to consider the relationship among these potentials, soil oxygen, soil texture (the mixture of sand, silt, and clay in soil), and soil porosity. The relationships among temperature, pH, light, and total water potential are considered in later sections.

The major mechanism by which oxygen moves into soil is diffusion. The diffusion coefficient of oxygen in air is $0.189\,cm^2\,s^{-1}$, but the diffusion of oxygen in water is $0.000\,025\,cm^2\,s^{-1}$. Thus, oxygen diffuses 10 000-fold slower in water than in air. How much water a soil holds is dependent on soil texture and soil porosity. Sandy soils have less pore space (35–50%) than clayey soils (40–60%), but the pore space in sandy soils is mostly macropores (30–100 μm), whereas the pore space in clayey soils is mostly micropores (less than 30 μm). For this reason, sandy soils drain quickly and hold less water than clayey soils, which drain more slowly and hold more water.

The theoretical limits for microbial activity in soil are between 0 and -81 MPa. At 0 MPa, soil is completely saturated; at -81 MPa, DNA is denatured. Besides the effect of each water potential on microbial activity, it is also important to consider oxygen, movement, and nutrients. When the soil is saturated, diffusion of oxygen into the soil is slowed, and if the oxygen consumption rate exceeds the diffusion rate, the soil, regardless of its texture and porosity, becomes anaerobic. Heterotrophs incapable of anaerobic respiration (e.g., most fungi) fare poorly. Heterotrophs capable of anaerobic respiration (e.g.,

many bacteria) fare better but show diminished activity because the amount of energy produced under anaerobic conditions is less than under aerobic conditions. Phototrophs on the soil surface (e.g., eukaryotic algae and cyanobacteria) fare well and even prefer saturated conditions. Movement by aquatic soil organisms is maximal because the water film thickness around soil particles is maximal. Texture plays a role because soil organisms move more easily in sandy soils than in clayey soils (again, because sandy soils have more macropores). Concentrations of water-soluble nutrients are low. Water stress for almost all soil organisms is minimal.

Once water drains from the macropores, the water potential becomes negative (approximately −0.01 MPa for sandy soils and −0.03 MPa for other soils), and oxygen diffusion increases. Sandy soils, which contain more macropores than clayey soils, are more oxygenated than clayey soils. Except for movement by aerial (i.e., living in air-filled spaces) soil animals such as microarthropods (mites and collembolans), movement by aquatic soil organisms such as nematodes, protozoa, oomycete zoospores, and bacteria becomes more difficult as the water-film thickness dwindles to only a few micrometers. However, the combination of aerobic conditions, concentrated nutrients, and good water relations means microbial activity is near maximal.

As the total soil water potential decreases from −0.01 to −0.1 MPa, oxygen diffusion improves, but water films become discontinuous, and consequently nutrient availability and movement by aquatic organisms decrease. Because matric potential is related to capillary forces and these forces are directly related to the soil pore diameter, clayey soils, by virtue of their more numerous micropores, contain more water than sandy soils and dry more slowly. This drying rate is important, because the faster the rate of drying, the greater the mortality of the organism. Because microbial activity depends on each soil organism maintaining proper turgor pressure for cell functioning, soil matric and osmotic potentials increase in their importance. Except in saline soils, matric potentials are more important than osmotic potentials.

By −1.5 MPa, water is gone from the micropores and only water bound to soil solids is available for microbial activity. The soils are relatively oxygenated; movement stops. Diffusion of nutrients is so retarded that starvation conditions are created. Furthermore, because all soil organisms contain semipermeable membranes that allow water to enter and exit in near equilibrium with the environment, osmotic potential becomes critical as soil ions become more and more concentrated. To avoid plasmolysis (contraction of the cytoplasm from the cell wall), most soil organisms divert their energy to accumulating stress solutes (e.g., K^+) and compatible solutes (e.g., glycerol; so named because they must be compatible with cell functioning) to counter this negative potential. By −4.0 MPa, most biological processes (e.g., nitrification) stop and only variously named osmophiles, halophiles, or xerophiles show appreciable microbial activity. Unless an organism can form a resistant structure (e.g., spores in bacteria and fungi, akinetes in the cyanobacteria, cysts in the protozoa), most organisms desiccate and die.

Oxygen

As already noted, oxygen in soil depends on soil water, soil texture, and soil porosity. Both soil depth and temperature can be added to this mix: generally, oxygen decreases and CO_2 increases with increasing depth, and gas solubility, particularly in water, decreases with increasing temperature. Most soil organisms are obligate aerobes and use oxygen exclusively as a terminal electron acceptor. Because aerobic respiration produces more energy per mole of substrate than anaerobic metabolism, obligate aerobes recover more energy for biomass production than anaerobic organisms. For this reason, population densities of obligate aerobes are higher than those of anaerobes. Without a source of oxygen, aerobic respiration ceases and no energy is produced. In contrast, obligate anaerobes cannot survive the presence of oxygen because aerobic respiration temporarily yields hydrogen peroxide (H_2O_2) and superoxide (O_2^-), toxic products to which obligate anaerobes lack the enzymes (catalase and superoxide dismutase, respectively) to break down. As a result, obligate anaerobes live strictly by fermentation. Some obligate aerobes that prefer oxygen as the terminal electron acceptor can respire anaerobically by substituting nitrate (NO_3^-), sulfate (SO_4^{-2}), or carbonate (CO_3^{-2}) for oxygen. This anaerobic respiration is restricted to bacteria and for this reason these bacteria dominate in anaerobic soils. Many bacteria and some fungi are facultative anaerobes, which grow in the presence or absence of oxygen. When oxygen is available, the organisms grow aerobically; when oxygen is unavailable, the organisms grow by either fermentation or anaerobic respiration. Finally, aerotolerant anaerobes lack an electron transport system and function solely by fermentation.

Redox (reduction–oxidation) potential, the tendency of a compound to accept or donate electrons, can also give some insight to oxygen tensions in soil and which organisms are likely to be active in a particular soil environment. From a standpoint of processes, soils with a positive redox potential (0–400 mV) are 'oxidizing' habitats and are

conducive to aerobic processes, whereas soils with a negative redox potential (0 to −400 mV) are 'reducing' habitats and conducive to anaerobic processes such as methane production. However, it would be a misstatement that highly aerobic soils contain few or no anaerobes. The ability of soils to contain water-filled micropores restricts oxygen diffusion and guarantees that anaerobic microsites exist. Thus, it is common to find obligate anaerobes in the upper soil horizons. Also, some anaerobic processes, such as denitrification, can occur in soils with a positive redox potential when molecular oxygen is absent but other terminal electron acceptors are present.

Temperature

For soil organisms, it is important to consider not only the temperature at which microbial activity is optimal, but also the minimum and maximum temperature that the organism can tolerate. Soil organisms are divided into psychrophiles, mesophiles, and thermophiles. Psychrophiles do not grow above 20°C, have minima of 0°C or lower, and optima around 16°C. Mesophiles have minima of above 0°C, maxima below 50°C, and optima between 15 and 40°C. Finally, thermophiles have minima at or above 20°C, maxima at or above 50°C, and optima between 40 and 50°C.

There is an important relationship between temperature, water potential, and microbial activity. Both water potential and temperature must be within critical range for microbial activity to occur. Assuming water potential is within this range, at one extreme, reduced temperatures slow cellular processes. At the other extreme, excessive temperatures denature proteins and alter cell membrane permeability. At either extreme, soil organisms typically alter the fatty acyl composition of their membrane lipids and produce either cold-shock or heat-shock proteins to withstand these stresses. Between these extremes is another relationship, often referred to as the 'Q_{10} rule for biological systems,' where Q_{10}, the temperature quotient, equals 2. This rule states that, within a limited range, microbial activity doubles for each 10°C increase in temperature. For example, mesophilic organisms at 30°C will have twice the activity as the same organisms at 20°C. Again, this rule is a range, and there are examples, such as petroleum mineralization in Alaska, where Q_{10} values much greater than 2 have been measured.

Because most soil temperatures correspond well with the temperature optima of mesophiles, it is not surprising that most soil organisms are mesophiles. However, some specialized habitats (e.g., volcanic soils) do favor thermophilic actinomycetes and fungi.

pH

As the negative log of the hydrogen ion concentration, pH is intimately connected to water in the soil and the soil organisms. With regard to soil, wherever rainfall is abundant, water leaches bases from the soil and the soils are predominantly acid; wherever rainfall is scant, there is not enough water to leach the bases from the soil and the soils are predominantly alkaline. Because soils have a pH-dependent charge originating from organic matter and the broken edges of clays, this charge decreases as the soil becomes more acid, reducing not only the cation exchange capacity of the soil, but also the ability of the soil to retain nutrients. Reducing the pH does not necessarily reduce the entire cation exchange capacity in soil; some charge may be associated with isomorphous substitution in clay minerals and this charge is pH-independent. With regard to soil organisms, when soils are saturated, the hydrogen ion concentration is diluted; when soils are dry, the hydrogen ion concentration is concentrated and this concentration affects the ability of soil organisms to control anions and cations and offset high osmotic potential.

Although some bacteria and soil fauna tolerate low pH (acidophiles; able to grow at pH 3 or lower) or high pH (alkaliphiles; able to grow at pH 9 or higher), most bacteria and soil fauna are neutrophiles and prefer a near-neutral pH range of 6–7. The same is true of soil algae, which again are found in acid and highly alkaline environments, but prefer pH ranges of nearly neutral to slightly alkaline. Many bacteria and algae prefer this pH range because soil nutrients are most available. Furthermore, a neutral pH avoids heavy metal toxicity, because almost all these metals (a density of greater than 5 $Mg\,m^{-3}$) are only active in acid soils (pH <5). In contrast, fungi are acid-tolerant (pH 4–7) and tend to be abundant in acid soils, where there is less competition from bacteria.

Light

For phototrophs such as cyanobacteria and algae, light is an essential factor because it is required as a source of energy. Soil affects light because soil constituents absorb or reflect it (the albedo effect), and soil disturbances (e.g., tillage) affect how far light penetrates into the soil. For these reasons, the photic zone in soil is variable. Nevertheless, phototrophs decrease with increasing soil depth and decreasing light intensity. Except for a few phototrophs that are facultatively capable of heterotrophy, phototrophs deep in the soil are likely to be metabolically inactive.

For chemotrophs, light is important for a different reason. Although visible light may be important for certain phototrophic responses (e.g., spore formation

in fungi), ultraviolet-B (UV-B) light (290–320 nm) is a source of nonionizing radiation. This irradiation splits water molecules into free radicals that damage DNA. This irradiation links light to water potential: the higher the water content, the more free radicals produced, and the higher the DNA damage. Although ozone screens out most UV-B light, ozone depletion in the atmosphere offsets this. Therefore, it is likely that this abiotic factor will increase its deleterious effect on microbial activity in the photic zone, and only soil organisms that produce UV-absorbing pigments or develop rapid mechanisms of DNA repair will be relatively unaffected.

Biotic Factors

Soil organisms can also interact with other organisms, and, with the exception of neutralism (no interaction), these interactions affect their microbial activity. These biotic interactions can also include plants and larger soil fauna, and at their most complex, populations of organisms or consortia. These interactions are mutualism, symbiosis, commensalism, competition, amensalism, predation, and parasitism (Table 2).

Symbiosis or Mutualism

In symbiosis or mutualism, both organisms benefit. This association can be specific or general and, in some cases, so highly specialized that one or both organisms are obligate symbionts and cannot live without the other. Relationships where there is mutual benefit but no obligation on the part of either organism are often termed 'synergistic.' Because of its importance to agriculture, the best-known symbiosis is the presence of nitrogen-fixing bacteria in plants. In return for the bacteria fixing atmospheric nitrogen, the plant supplies the bacteria with nutrients. An agricultural example is the symbiosis between *Bradyrhizobium japonicum* and the legume soybean (*Glycine max*); a forestry example is the symbiosis between the actinomycete *Frankia* and a range of angiosperms such as alder (*Alnus* sp.). A similar situation is observed with several genera of soil fungi, the mycorrhizae, which colonize plant roots, thereby enhancing uptake of water and mineral nutrients by the plant, principally phosphorus. Again, the plant supplies the mycorrhizae with nutrients. Symbiosis or mutualism is much more frequent than commonly realized. For example, 95% of all plants are mycorrhizal. These kinds of mutually cooperative ventures – not competitive ones – are the norm in nature.

Table 2 All possible positive interactions (+), no effect (0), and negative interactions (−) between two organisms. The effect of these interactions on microbial activity corresponds with the symbol

Organism No. 1	*Organism No. 2*		
	+	*0*	−
+	Mutualism, symbiosis	Commensalism	Predation, parasitism
0	Commensalism	Neutralism	Amensalism
−	Predation, parasitism	Amensalism	Competition

Commensalism and Amensalism

In commensalism, one organism benefits while the other is unaffected. For example, one organism can provide an essential growth factor, such as a vitamin, for another organism. This type of cross-feeding is common in soil organisms. The opposite of commensalism is amensalism, where one organism is harmed while the other is unaffected. A good example of this interaction is when one organism produces an antibiotic against another organism. Such an interaction is often the basis of biological control. For example, some isolates of the bacterium *Pseudomonas fluorescens* can suppress the fungal pathogen *Gaeumannomyces graminis*, responsible for 'take-all' in wheat (*Triticum aestivum*).

Competition

In competition, both organisms vie for the same resource. This resource can be for any one of the abiotic factors as well as space. In the case of nutrients, the three factors that govern competitive success are growth rate, substrate affinity, and efficiency. If nutrients are unlimited, then microbial activity is governed by the maximal growth rate. This maximal growth rate is rarely the case in soil; the norm for most organisms in soil is starvation. Under these circumstances, substrate affinity and efficiency govern the ability to compete. In the case of substrate affinity, assuming an organism can metabolize a substrate, an organism that recognizes a substrate at a low concentration outcompetes an organism that only recognizes a substrate at a high concentration. In the case of efficiency, an organism that is more efficient in its carbon and energy use outcompetes a less efficient organism.

Predation and Parasitism

Finally, in predation and parasitism, one organism feeds on another. The most common example of predation in soil is protozoa and nematodes preying on bacteria and fungi, particularly in the rhizosphere,

where numbers of bacteria and fungi are high. In Figure 2, two types of soil protozoa, a ciliate (*Colpoda* sp.) and a flagellate (*Bodo* sp.), as well as a bacteriovorous nematode, are preying on bacteria attached to the clay particles and organic matter, while, above, a mycophagous mite is preparing to eat some mycorrhizal hyphae. Predator responses follow classic predator–prey curves: increases and decreases in numbers of predators lag behind increases and decreases in numbers of prey, respectively. Numbers may not be a good reflection of microbial activity, however. The C:N ratio of soil fauna is approximately 20:1, whereas the C:N ratio ranges from 4 to 5:1 for bacteria and up to 15:1 for fungi. When protozoa prey on bacteria and fungi, nitrogen is in excess and is excreted into the environment. This nitrogen is then available to promote microbial activity.

The most common example of parasitism in soil is viruses. Even though viruses are nonliving (because they have no intrinsic metabolism or ability to replicate), they parasitize numerous soil bacteria, fungi, and soil fauna. This parasitism is normally a negative interaction, but viruses can sometimes interact positively because they are capable of transduction (adding a new gene or modifying an existing gene in the host DNA). If this addition or modification makes the host more competitive, then the change benefits microbial activity.

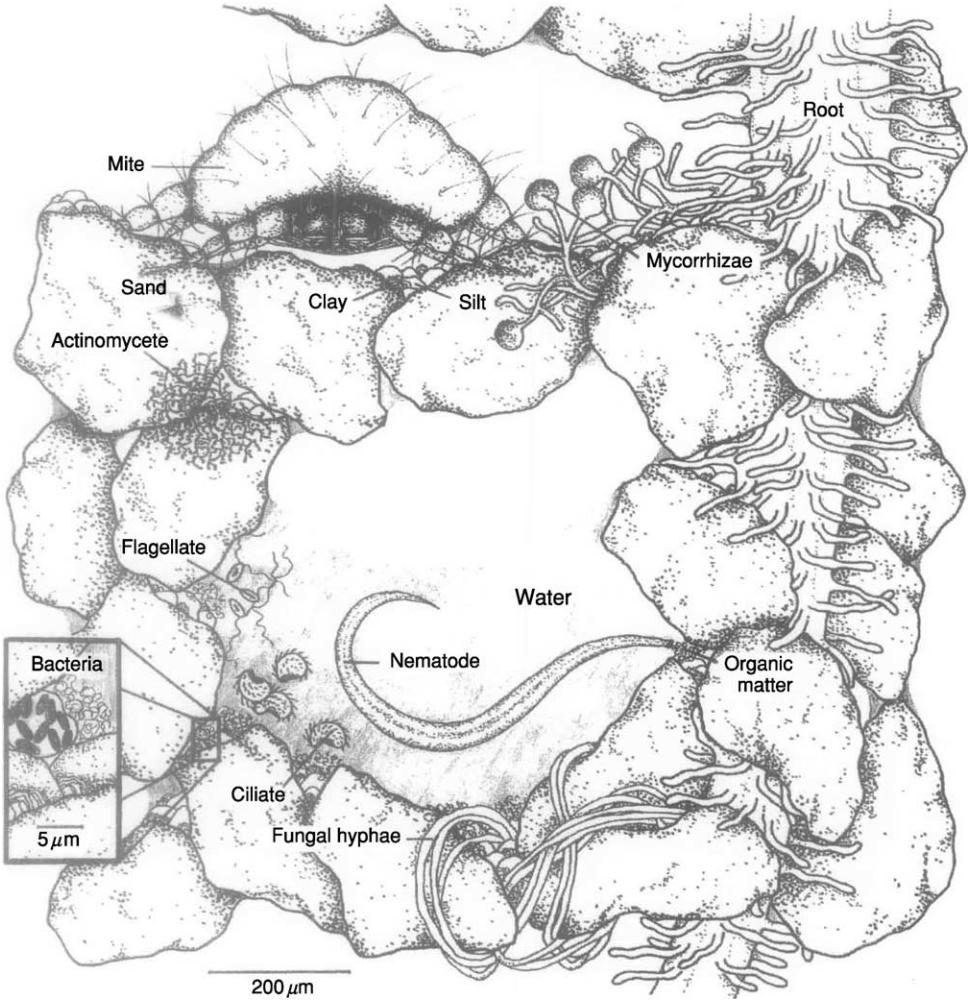

Figure 2 A sample of well-aggregated soil, slightly greater than 1 mm^2, showing a variety of biotic and abiotic factors. As gravitational water flows out of the two largest pores, water potential and oxygen vary from top to bottom, while a small root creates a rhizosphere effect, a gradient of nutrients from high (right) to low (left). Root transpiration affects the water potential depending on whether it is day (more) or night (less). The root alters the soil pH by releasing H^+, HCO_3^-, and organic compounds, depending on the type of nitrogen in the soil (NO_3^- increases, NH_4^+ decreases), symbiotic relationships (here, mycorrhizae), and microbial activity. Temperature also affects the rate of microbial activity. Biotic factors, and interactions of biotic and abiotic factors are noted in the text. In all, a wide variety of microsites are being created, many only micrometers apart. (The mite has been turned head-on to fit.) (An original drawing by Kim Luoma.)

Integrating Abiotic and Biotic Factors

In addition to interactions between and among soil abiotic factors, and interactions between soil organisms, there are also interactions between the abiotic and biotic factors. In one direction, soil abiotic factors affect biotic interactions. For example, nutrient availability, water potential, and oxygen profoundly affect microbial interactions. In Figure 2, the aerial soil mite would not be preparing to eat the mycorrhizae unless the limited soil nutrients (e.g., phosphorus) had promoted the symbiotic relationship between the plant and the fungus, and the gravitational water had drained from the pore, permitting sufficient oxygen diffusion for the mite to breathe. In the other direction, biotic interactions affect soil abiotic factors, both physically and chemically. In Figure 2, actinomycetous and fungal hyphae, and bacteria in a extracellular polysaccharide 'plug' are binding the soil particles, thus promoting soil aggregation, one of the most important physical effects of microorganisms on soil. This aggregation affects soil porosity, which, in turn, affects soil water and oxygen relations. As an example of a chemical effect, the nematode and protozoa eat the bacteria and excrete excess ammonia, which chemoautotrophic bacteria convert to nitrite, which, in turn, is converted commensalistically by nitrite-oxidizing bacteria to nitrate. These acidifying reactions lower the soil pH.

The interactions between and among abiotic and biotic factors are the equivalent of an intricate and elegant dance with many partners. Our understanding of this dance, particularly among microbial communities, is still rudimentary. The major barriers to understanding this dance are our poor understanding of the identity of most soil archaea, bacteria, fungi, and undoubtedly many of the soil fauna, and the nature of the soil matrix to provide a multitude of microsites, each with their properties, over distances that may be only a few micrometers apart. This is what gives soil a spatial and temporal dynamicism and heterogeneity unlike all other habitats.

Community Analysis

Introduction

The ecological diversity of soil microbial communities is a measure of microbial community richness and abundance. Richness is an indication of the number of different species present, whereas abundance is the number or biomass of each species present. Microbial communities can also be analyzed for their functional role in soil. There is not a single method available that can provide complete information on a microbial community; the method chosen is dependent on the question being posed. In the past, soil scientists relied mainly on cultivation and measuring substrate transformation to assess and monitor microbial communities. Now a common view in soil microbiology is that cultivation-dependent methods represent only a small fraction of the microbial community present in soil. Beginning in the 1980s, Vigdis Torsvik and her advisor, Professor Jostein Goksøyr, began testing the use of deoxyribonucleic acid (DNA) reassociation kinetics to demonstrate the true extent

of soil microbial richness. They have concluded that 1 g of soil has an estimated 4000–10 000 different bacterial genomes present, of which less than 1% can be readily cultivated. This work has prompted largely the move from isolation and phenotypic characterization of microbial communities to direct analysis using genetic and biochemical tests to survey a more representative group. Using a variety of molecular techniques, investigators are studying soil microbial communities from a wide range of habitats and geographic locations. Their results generally demonstrate that soil environments are far more diverse, even under harsh environmental conditions, than was expected and that previously undescribed groups are important components of the soil community. Analytical approaches adopted are crucially dependent on the questions being addressed and availability of equipment and resources.

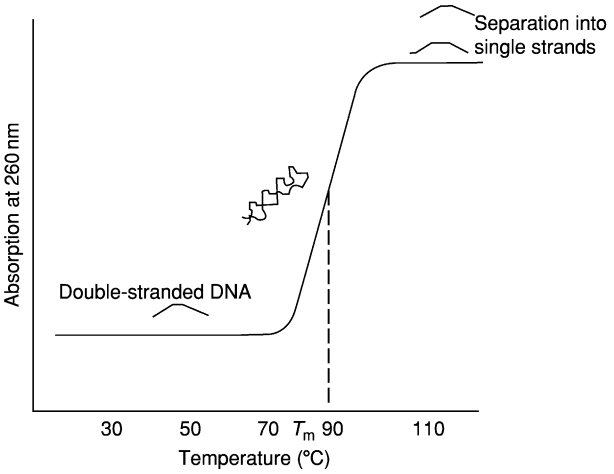

Figure 1 Melting curve of DNA showing the melting temperature, T_m, when half the DNA is denatured.

Background

Nucleic Acids

Nucleic acids are polymers of nucleotides joined by covalent (phosphodiester) bonds formed between their sugar and phosphate groups. There are two types of nucleic acids that differ chemically because of their sugar component, deoxyribose in DNA and ribose in ribonucleic acid (RNA). Physically the two differ because DNA is composed of two strands that form a helix and RNA is single-stranded. Attached to the sugar and phosphate groups are nucleotide bases of which there is a total possibility of five: cytosine (C), thymine (T, in DNA only), uracil (U, in RNA only), adenine (A), and guanine (G). The two strands comprising DNA are joined by hydrogen bonds between complementary nucleotide bases, where G always bonds with C (by three hydrogen bonds) and A with T (by two hydrogen bonds). The relative content of G + C compared with A + T in the genome of an organism can be used to differentiate taxonomic groups. The different order or sequence of nucleotide bases codes the information to determine appearances and functions in every organism. Nucleotide sequences that code for proteins are called genes. After nucleotide sequences are obtained, one can compare them with sequences in a databank (e.g., GenBank, EMBL) to determine whether any similar sequences have been found. This can provide information about potential function and phylogeny of a gene.

Denaturation and Renaturation

Denaturation of DNA occurs when the weak hydrogen bonds between the double strands are disrupted and the molecule becomes single-stranded. Thus the rate of denaturation is dependent on the proportion of G + C versus A + T bases. This process can be reversed in a process called renaturation or annealing. In the laboratory, DNA can be denatured by applying heat, increasing pH, or by adding denaturing chemicals (e.g., urea, detergents). In addition to these factors, viscosity and ionic strength can be adjusted to influence rates of denaturation and renaturation. As the DNA strands become denatured, different measurable properties of the molecule changes over time. Often DNA is quantified spectrophotometrically by measuring its ultraviolet (UV) light absorption at 260 nm. This approach can be used to track the melting characteristics of DNA, because in the single-stranded form it absorbs more light than when it is double-stranded. The data when graphed reveal the melting curve of the DNA (Figure 1). The melting temperature, T_m, is the transition temperature at which half the strand is denatured, as reflected in the halfway point in the change in absorbance at 260 nm. This temperature is important when carrying out experiments such as hybridization and polymerase chain reaction (PCR), where denaturation and/or renaturation of DNA strands is required.

Soil Nucleic Acid Extraction

Nucleic acids can be extracted directly from soil to analyze the microbial community. Alternatively cells can first be separated from the soil then the nucleic acids extracted. The latter approach decreases contamination by soil components but may also be biased toward cells that are separated more easily from soil. Most researchers isolate DNA from soil because it is more stable than RNA; however, protocols have been developed for soil RNA isolation. All

methods for nucleic acid extraction and purification follow the same principles. Cell lysis is the first step, followed by separation of the nucleic acids from the other cellular components, and finally concentrating the nucleic acids into a working volume. There are many papers that outline these methods, and commercial kits are marketed by a number of companies. An important factor when extracting nucleic acids from soil is to ensure the approach achieves equivalent lysis of all cell types so that the analysis is representative of the community. This is the main source of bias in direct-analysis methods of soil-extracted nucleic acids. Many laboratories have chosen to use mechanical methods such as bead-beating to ensure cell lysis. Lysis efficiency can be determined by microscopic examination of the sample before and after the extraction procedure. The other factor that must be considered is soil composition, because nucleic acids are charged and will bind to components, particularly clay. After the nucleic acids are extracted, a number of methods can be considered that examine nucleic acids directly or indirectly after amplification by PCR.

Ribosomal RNA

Ribosomes are comprised of proteins and ribosomal RNA (rRNA) and are found in all organisms, because they are the sites for protein synthesis. Presently, the genes coding for rRNA are used most extensively to obtain phylogenetic information. These genes were chosen because: they are present in all organisms; rRNA function is conserved; rRNA sequences have regions with high and low evolutionary conservation, making them phylogenetically informative; and, in actively growing cells, ribosomes can occur in high copy numbers (more than 10 000). The ribosome is composed of two subunits, referred to as small and large rRNA, differentiated by their sedimentation coefficient, *S*. In prokaryotes the small subunit contains 16*S* rRNA and the 70*S* large subunit contains both 23*S* and 5*S* rRNA. In eukaryotes the small subunit is slightly larger and contains 18*S* rRNA and the 80*S* large subunit contains 28*S*, 5.8*S*, and 5*S* rRNA. The 16*S* rRNA gene has been used the most in prokaryotic soil-community analysis. Many laboratories are determining 16*S* rRNA sequences from environmental sources and adding them to databanks, increasing the utility of using these genes for community analysis. In eukaryotic organisms the sequences between the rRNA genes, i.e., the intergenic region, are often included in analyses, because the gene sequence itself is often too conserved to differentiate species. The rRNA or rDNA can be isolated directly from soil and examined directly or after amplification using PCR. Many of the soil-community analytical techniques discussed herein are based on analysis of these genes or gene regions. It is important to note that the number of rRNA gene copies in an organism is variable, therefore one must not assume that determining the number of rDNA copies is equivalent to counting the number of cells in a community.

Direct Community Analysis

G + C Content

The G + C method is a coarse scale method, because different populations with similar G + C content will group together. It is used to determine compositional differences between microbial communities in different soils or after the soils have been perturbed, for example by the addition of a pesticide. A dye that preferentially binds to A + T or G + C nucleotides is added to DNA extracted from a soil community. Presently, the most commonly used dye is bisbenzimidazole (Hoechst 33258), which binds to A + T-rich regions. The buoyant density of the DNA decreases as more dye is bound to AT regions. Populations with different A + T content are then separated by cesium chloride density gradient centrifugation. Populations with similar G + C content will layer at the same gradient concentration. These layers can be collected in fractions and quantified by spectrophotometry to estimate G + C group sizes. Each of these fractions can be differentiated again by density gradient centrifugation at a finer scale, or some of the methods described below can be used to obtain more information about community composition. This method is not recommended if large quantities of DNA (more than 50 μg) and an ultracentrifuge are not available. The number of samples examined can be limited by the capacity of sample handling in the laboratory and amount of soil available for DNA extraction.

DNA Reassociation

A method to determine species richness in a soil community is reassociation of DNA strands after they have been completely denatured. It is based on the assumption that the rate of reassociation is dependent on the number of different genomes in a sample. Strand reassociation takes longer when the genetic heterogeneity of a community is greater. This method can be very time-consuming, because soils of high heterogeneity can take weeks to reassociate. The heterogeneity of the sample is proportional to the $Cot_{1/2}$ value, where Co is the initial molar concentration of DNA and $t_{1/2}$ is half the time required for complete strand reassociation. The number of different species can then be estimated by comparing the sample $Cot_{1/2}$ value to that of a reference strain with a known genome size. This method requires large quantities

(25 μg) of highly purified DNA, sheared to equivalent lengths. Due to the length of time required for reassociation, it is mandatory to have a UV spectrophotometer equipped with a thermally controlled sample cell dedicated to the analysis.

Nucleic Acid Hybridization

Nucleic acid hybridization methods can be used in soil community analysis to assess the composition, physical distribution, abundance, and/or relatedness of nucleotide sequences to DNA or RNA extracted from soil samples or left intact in cells (discussed in the next section). Nucleic acid hybridization methods rely on the ability of complementary single-stranded nucleotide sequences to anneal to form nucleic acid duplexes (discussed in the section Denaturation and Renaturation). This is commonly accomplished by hybridization (or annealing) of a previously characterized nucleic acid sequence (probe) to its counterpart (target) within a mixture of DNA or RNA (Figure 2). Probes are labeled with a radioisotope or fluorescent marker for detection. The target is

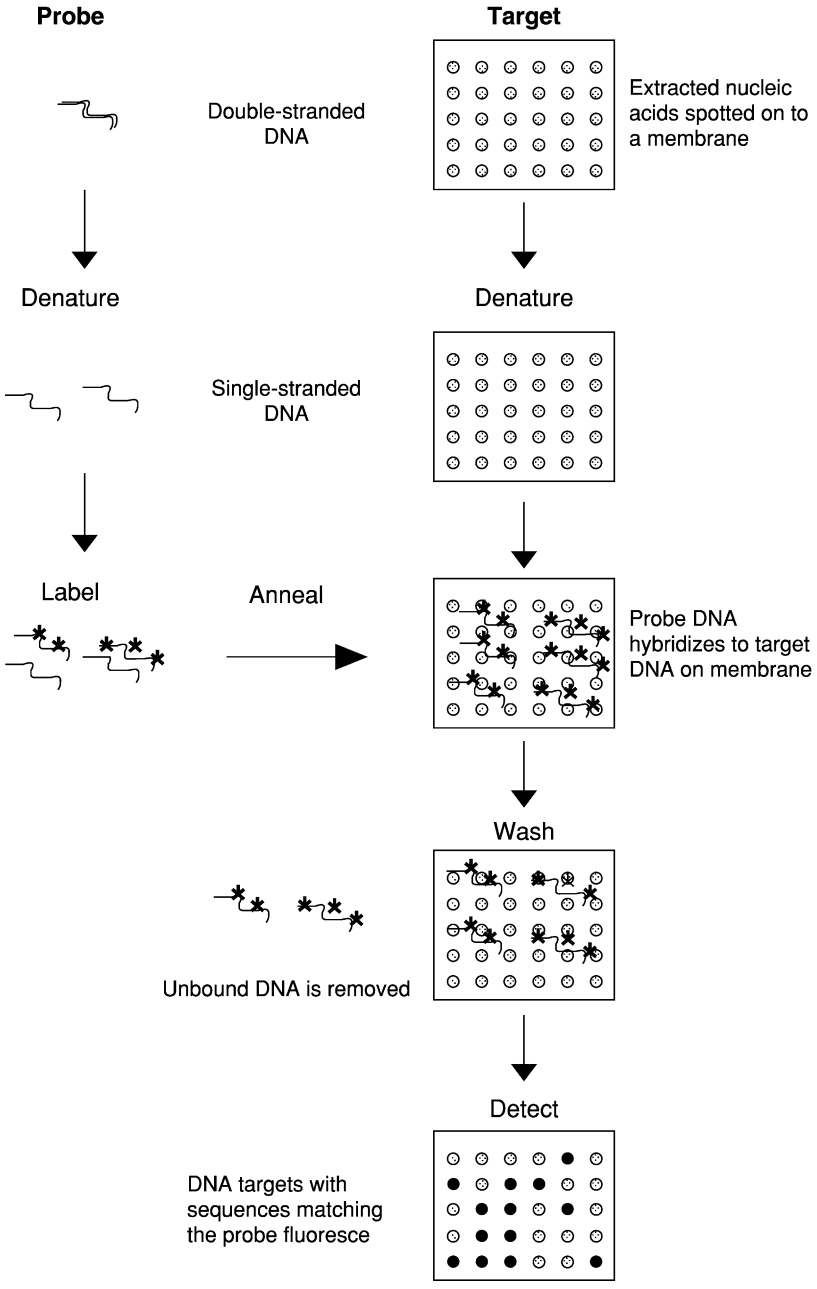

Figure 2 Hybridization and detection of a fluorescently labeled probe to target DNA that has been attached to a nylon membrane.

immobilized on to a solid support such as a nylon membrane or glass slide to facilitate hybrid detection. For these assessments, the nucleic acid sequences need not match exactly, because a limited number of base-pair mismatches can be tolerated if hybridization conditions (temperature, salt concentrations) are properly manipulated. Quantification of the active community members can be accomplished by using rRNA as a target instead of DNA, because the rRNA numbers increase with cell activity. Microarray technology is now making it possible simultaneously to hybridize to thousands of targets on a relatively small surface area. If adequate quantities of target nucleic acids are not readily obtained by extraction, potential targets can first also be amplified by PCR.

To obtain a relatively coarse measure of community composition, 16*S* rRNA gene probes are often used. Probe sequences have been determined that can differentiate community members at phylogenetic levels, ranging from broad (all organisms, kingdom, classes) to narrow (species or strain; examples given in Table 1). The broad probes can provide numbers of different groups present in a community. It is also possible to use all these sequences as targets for microarray analysis. However, due to the large number of microbial species still not described from soil, it is presently not possible to use this method to determine species richness. The species- and strain-specific probes are also useful to track the fate of a specific microorganism within a soil community. This approach has been used extensively to detect the presence of specific functions or functional groups such as ammonia-oxidizing bacteria in a soil community. If microarrays are not being used, then this method does not require specialized equipment other than those found in standard molecular biology laboratories.

Microscopic Examination and Fluorescent *In Situ* Hybridization

To examine microorganisms in the context of their soil environment, analysis can be made microscopically. An *in situ* hybridization-based procedure is employed in which fluorescently labeled probes diffuse into the cell, hybridize to the target rRNA, and can then be observed microscopically. Microscopic observations of bacterial cells are typically made using phase-contrast, epifluorescent, or confocal laser microscopes. Cells are usually killed then stained to detect all organisms or specifically to detect certain groups. General stains such as acridine orange, Hoechst 33258, and ethidium bromide bind to nucleic acids and thus can be used to detect all organisms. Specific groups are detected using the rRNA as the target, because this target has a high copy number in active cells and it is single-stranded to allow hybridization to take place. Sequences have been determined that are specific to different phylogenetic levels, ranging from all organisms to specific species. The availability of different-colored fluorescent markers makes it possible simultaneously to observe cells hybridized to different probes. In addition to determining the spatial distribution of cells in a community, this approach is beneficial because it is cultivation-independent and does not suffer from the biases of PCR. However, as in all methods, there are other shortfalls that must be considered when deciding the appropriateness of its use. Some of the limitations are: background fluorescence from the soil; interference by soil components; low cellular ribosome content making it difficult to see labeled cells; poor penetration of probe into the cell; and differential penetration of probe into different cell types.

Table 1 Examples of oligonucleotide probes targeting Bacteria at different phylogenetic levels

Fatty Acid Analysis

Although many researchers are using nucleic acid-based analyses, phospholipid fatty acids (PLFA) have also been used extensively as a cultivation-independent method for soil-community analysis. With the exception of Archaea, phospholipids are found in cell membranes of all living organisms and are rapidly degraded upon their death. Thus this analysis can provide a measure of viable community biomass, structure, and at a crude level, composition. Unlike most of the other methods discussed that are genotypic, this is a phenotypic approach. There are many different PLFA that can be identified by gas chromatography after their conversion to fatty acid methyl esters (FAME). The PLFA profile of a microorganism is phylogenetically informative. The mixture of different PLFA profiles extracted from a soil can be used as a fingerprint of the community structure. Changes in community structure can be monitored by following changes in their PLFA fingerprint profiles. There are 'signature' PLFA profiles found in certain groups, which allow the identification of the presence and quantity of PLFA in a community. For example, there are fatty acids specific to fungi, Gram-positive bacteria, Gram-negative bacteria, and plants, which can then be used to calculate diversity of the community at a coarse level. However, there are overlapping fatty acids between microorganisms in a community, therefore this method cannot be used to identify or track specific species. Also, due to the ubiquity of lipids, it is essential that great care is taken during sample handling and processing in the laboratory. The method requires an evaporator to dry samples for storage, a spectrophotometer for biomass measures, and a gas chromatograph for FAME analysis.

Indirect Community Analysis

Polymerase Chain Reaction

PCR is extremely useful in soil-community analysis, because an organism does not need to be cultivated for the procedure to be used. It mechanizes the steps in nucleic acid replication in the laboratory, thus allowing the amplification of a specific nucleotide sequence by approximately 10^6-fold. DNA replication is semiconservative. Each strand of DNA serves as a template, and the newly replicated daughter strand is complementary to the parent strand because of basepair specificity. The nucleotides are added to the growing strand by an enzyme called DNA polymerase. Polymerization begins at a primer site and always occurs by joining the carbon 5 (5′) of one sugar to carbon 3 (3′) of the adjacent sugar (5′ to 3′ direction). Primers are short lengths of nucleotides, oligonucleotides, ranging from 8 to 24 basepairs in length for PCR depending on the desired specificity, which increases with primer length. PCR amplifies a region in the genome that is delimited by the oligonucleotide primers chosen for the initiation of DNA replication (Figure 3). The sequence of steps in the replication of genetic material is controlled by changes to the temperature of the solutions. The temperature of the solution is first raised (usually 94–95°C) to denature the two strands of DNA. Then it is lowered to allow primers to anneal to the template DNA (typical range is 50–65°C). It is then raised to a temperature optimal for activity of the thermal tolerant polymerase (e.g., Taq polymerase is best from 75 to 80°C) to synthesize new strands of DNA. The cycling of temperatures is repeated many times, resulting in amplification of discrete regions of DNA. This technology is used for nucleotide sequencing, synthesis of probes for hybridization experiments, detection of mutations, production of site-specific mutations, and synthesis of genes. As with all techniques, PCR-based methods also have limitations. The primers chosen for PCR can bias the populations amplified. The specificity of the primers is dependent on the sequence information available, thus different results can occur when different primer sets are used. Other limitations to the technique include: overestimates of diversity due to the formation of heteroduplexes, chimeric molecules, or sequence heterogeneities; and underestimation of diversity due to unequal amplification, the resolving power of the gel, or sequences comigrating in the gel. Nevertheless, this approach is very effective if the limitations of the primers are understood and PCR conditions are optimized to minimize errors in the PCR process. All the methods require access to a thermal cycler for PCR and gel electrophoresis units.

Community Richness

The identity of species and a crude measure of richness in a soil community can be determined by nucleotide sequence determination of rRNA genes. The method is independent of cultivation by using PCR directly to amplify rRNA genes from soil DNA extracts. The PCR products are cloned, unique clones identified by restriction fragment length polymorphism (RFLP), and then the nucleotide sequences determined. RFLP is sometimes referred to as amplified ribosomal DNA restriction analysis (ARDRA). The number of unique clones obtained can give an estimation of species richness in systems that are not too complex. The method is labor-intensive therefore an

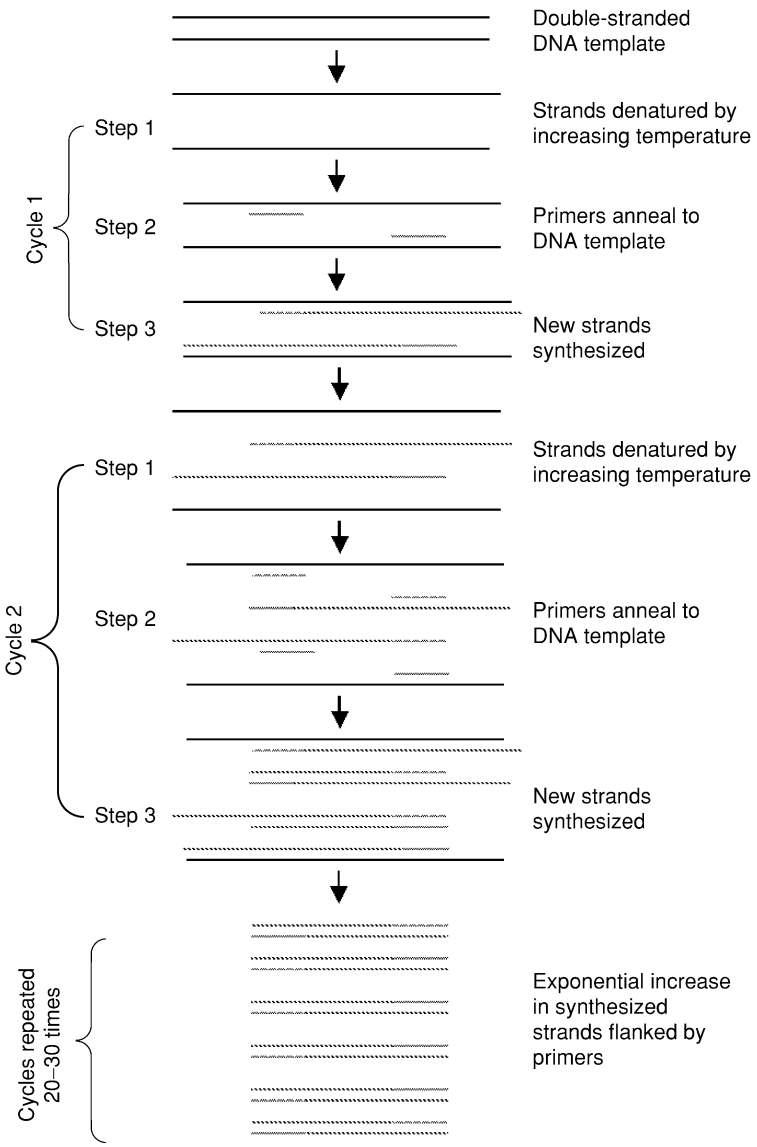

Figure 3 Steps in the polymerase chain reaction.

absolute number of species present in most soils is too time-consuming to obtain; for example, a variety of soils have been examined in which over 100 clones were screened and each clone was unique. However, the use of this approach has added new sequences to the rRNA database, revealed the presence of previously undescribed groups important in soil functions, and been used to determine unique oligonucleotide sequences to track specific strains in the community. For community analysis this method is best used in conjunction with other methods that can reduce the complexity of the sample. This method requires access to nucleotide-sequencing equipment or funds to send samples to a facility. Both are becoming more available to researchers.

PCR-Based Community Structure Analysis

To study differences in soil microbial community structure, researchers are using genetic profiles or fingerprints based on differences in rDNA sequences. The rRNA gene from the community mixture is first amplified by PCR. The primers chosen for PCR can be used to determine the level of discrimination between groups in the community. For example, primers can be used to amplify all Bacteria, or only the Actinomycetes. The products are then distinguished using gel electrophoresis, a means of separating nucleic acids by applying an electric current. The negative charge of the nucleic acids at neutral pHs allows the molecule to travel contained within a solid

matrix, agarose or polyacrylamide gels, through an electric field. The nucleic acids typically separate according to their size, but denaturants can be added that will separate the molecules by their melting nature. The fractionated nucleic acids can be viewed after staining with a dye, e.g., ethidium bromide or SYBR green, and visualized by UV illumination. There are two electrophoresis methods that are being used to distinguish between PCR products of different populations present in a community. One approach, terminal restriction fragment length polymorphism (TRFLP), separates products by size and the other approach, by sequence composition, denaturing gradient gel electrophoresis (DGGE), or thermal gradient gel electrophoresis (TGGE).

Terminal restriction fragment length polymorphism TRFLP analysis is based on size differences of the terminal fragment of the rRNA gene after restriction enzyme digestion. In this method one or both of the primers used for PCR are labeled with a fluorescent molecule or a radioisotope. If both primers are labeled, then different fluorescence colours are used to distinguish the two ends. The PCR products are digested using a frequently cutting enzyme, e.g., *Rsa*I, *Hha*I. The more enzymes that are used to digest the fragments the finer a distinction can be made between numbers of different populations present. However, as the number of enzymes are increased, the time for analysis and interpretation increases. The products are separated in a polyacrylamide gel that can distinguish 1-bp differences in fragment length. The fluorescent fragments can then be visualized and counted. To facilitate the handling of a large number of samples and accuracy of fragment length distinction, automated nucleotide sequencing apparatuses are being used for analysis. Each fragment length represents a group that may consist of one or more populations. The band intensity can be used to quantify the number of PCR products represented by each fragment length, but this does not equate to the numbers of cells, because rDNA copy numbers vary between species. As more rRNA sequence information is accumulated, populations can potentially be identified based on their terminal fragment lengths.

Gradient gel electrophoresis This method uses electrophoresis in a denaturing gradient gel to distinguish PCR products of the same size by differences in their nucleotide sequence composition. There are two techniques that are based on the same principles, but one uses chemical denaturants, DGGE, while the other uses temperature, TGGE. The hydrogen bonds holding the two DNA strands are disrupted under denaturing conditions; the extent of disruption is dependent on the denaturant concentration and nucleotide sequence of the fragment. The extent of strand separation will affect the electrophoretic mobility of the DNA molecules. The different distances that the PCR products migrate can produce a distinct fingerprint profile. The band intensity can be used to quantify the number of PCR products. However, as stated earlier, potential PCR biases and variable rDNA copies should be considered when interpreting the data. In this method it is possible to identify populations represented by each band by nucleotide sequence determination of excised bands or by hybridization with specific probes.

Genetic fingerprinting methods are a useful first step in community analysis because multiple samples can be simultaneously and quickly analyzed to get an indication of richness, then subsequent analytical methods can be chosen if needed. They are an effective technique to discriminate between communities and monitoring dynamics of communities after environmental perturbation. Many soil communities (e.g., agricultural soils) have numerous populations in relatively equivalent proportions, thus resulting in a smear of bands that makes it difficult to differentiate communities (**Figure 4**, lanes 7 and 8). They can be differentiated if dominant bands are seen because of strong selective conditions, e.g., polyaromatic hydrocarbons (PAH), that give certain populations a competitive advantage or the overall richness has been decreased (**Figure 4**, lanes 1–6). Then the number of dominant bands in profiles with low complexity can be counted roughly to estimate richness. Care must be taken, because one band may represent one or more populations. Changes in the microbial community structure can be monitored by the appearance and disappearance of bands in the profiles over time. The presence and absence of bands can be used in quantitative analysis to estimate the similarity between two communities. However, care should be taken when interpreting these data because of the biases of PCR discussed earlier.

Data Analysis

The various methods described here need statistically valid analysis of the data produced. Similarity indices, such as Dice or Jaccard, are currently being used to quantify the relationship between two profiles. These data can be represented by cluster analysis, e.g., unweighted pair group method with arithmetic means (UPGMA), which provides a graphic illustration of the relationship between communities. Principal components analysis (PCA) is often used on large datasets. This method reduces the number of variables, determines whether there is a structure to the relationship between these variables, and can identify

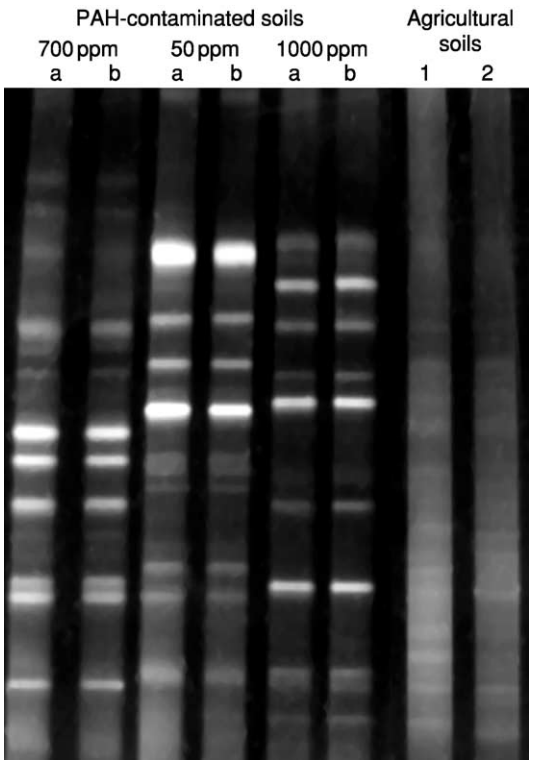

Figure 4 Soil community fingerprint profile of 16*S* rRNA gene V3 region amplified by polymerase chain reaction (PCR) and separated by denaturing gradient gel electrophoresis. Comparison of community profiles from soils contaminated with different concentrations of polyaromatic hydrocarbons (PAHs) to two different agricultural soils (labeled 1 and 2). Lanes a and b are replicate PCR reactions amplified from the same soil DNA extract. Primers used for PCR are bacterial primers BA338F (5′ AC TCC TAC GGG AGG CAG CAG 3′), with a GC clamp attached to the 5′ end (5′ CGC CCG CCG CGC GCG GCG GGC GGG GCG GGG GCA CGG GGG G 3′), and BA518R (5′ ATTACCGCGGCTGCTGG 3′).

main factors contributing to the variation. These techniques just begin to address specific research questions quantitatively, and now research groups are in the process of using these data to construct predictive statistical models of soil microbial communities. It is important that the proper experimental design and appropriate statistical analysis are employed to answer the research question being addressed.

Introduction

Kinetics (Greek κινηματική, forcing to move) is a branch of natural science that deals with the rates and mechanisms of any process – physical, chemical or biological. Kinetic studies in soil microbiology cover all the quantitative and dynamic aspects of microbial life in the soil: growth and multiplication, mutation, survival and death of soil microorganisms, microbial interactions with the soil environment, other microbes, plants, and animals. Often studies of microbiological kinetics are part of interdisciplinary environmental research on soil processes on which microorganisms play a unique or essential role: organic matter decomposition, biogeochemical cycles of methane, S, N, Fe, P. Kinetics provides a theoretical framework for a better understanding of soil function and for the optimal design of environmental biotechnologies. These technologies are based on the release of beneficial microbes into the environment or activation of the indigenous microbial community and

may benefit research into soil bioremediation, sustainable agricultural systems, and an integrated plant defense system. Recently the kinetics of microbial processes has increasingly focused on the construction of various 'soil modules' in large-scale ecosystem and biosphere models aimed at quantitative prediction (e.g., global climatic changes) and optimal resource management.

Contrary to simple monitoring of soil dynamics (time-series record of the soil state), kinetic studies require an understanding of the mechanisms underlying processes of interest. For example, a complex process such as plant litter decomposition must be viewed as the interplay of several simpler reactions: the conversion of individual litter components, growth of particular degraders, and specific enzymatic transformations. Ideally, mechanistic studies infer the coupling of experimental measurements with simulation mathematical models. These models formalize postulated mechanisms, so that the comparison of observations and the model's predictions allows incorrect hypotheses to be discarded.

Microbial kinetics is tightly linked to growth stoichiometry (Greek στοιχείο, element), which is the quantitative relationship between substrates and the products of microbial growth. In practical terms, stoichiometry mainly addresses problems of a static nature, like 'how much?' and 'in what proportion?' while kinetics considers the dynamics and deals with questions like 'how fast?' and 'by which mechanism?'

The Main State Variables and Growth Parameters

There are two types of kinetic models, deterministic and stochastic. The former describe clear, determined, and regular processes. The latter models deal with random processes. The main variables used in deterministic models are the same as in chemical kinetics – concentrations of cell mass, substrates, and products – while stochastic models consider instead probabilities, frequency distributions, and variance. For example, a deterministic model can describe the process of N_2-fixation as a function of energy and nutrient supply to the rhizosphere, while a stochastic model considers the probability of rhizobia to infect legume roots for a given frequency distribution of bacteria across the soil space. Any real soil process has both deterministic and stochastic components, so ideally the kinetic model should be a 'hybrid' and contain a deterministic core with a stochastic interface, generating probability distributions and confidence corridors rather than single values or curves.

The major state variables of kinetic models describing microbial processes in the soil are summarized in Table 1 and described in detail below.

Amount of Soil Microorganisms

Amount of soil microorganisms can be expressed as biomass (x) or cell numbers (N) of unicellular organisms (bacteria, yeasts, protozoa, fungal spores) per unit soil mass, volume, or surface area. The filamentous organisms (fungi, actinomycetes) are characterized by length (L) of mycelium and number of hyphal tips, n, initiated by hyphal branching. Note that n is equivalent to N, as soon as branching is equivalent to cell division.

The relationship between x and N or L is not straightforward because the mass of individual cells and hypha varies among different organisms and even for the same species depending on growth conditions. Generally, a plentiful supply of nutrients fosters the formation of bigger cells or wider filaments while starvation causes the formation of smaller cells and thinner filaments. To estimate soil biomass from direct microscopic counting, one should generate several arrays of data: the number $\boldsymbol{N} = \{N_1, N_2, \ldots N_n\}$ of cells with specifying biovolume $\boldsymbol{V} = \{V_1, V_2, \ldots V_n\}$, where N_i is the number of cells in the ith volume class V_i and n is the number of such classes, the volumes being calculated from lengths and widths of all detected cell shapes (spherical, ellipsoid, rod-shaped, irregular). For filamentous microorganisms one should have arrays of hyphal length

Table 1 The major dynamic variables used in deterministic kinetic models

Variable	*Symbol*	*Dimension (examples)*
Density/concentration of cell biomass	X	μg cell mass (g soil^{-1}) or g cell mass m^{-2} or μg cell mass (cm^3 soil)$^{-1}$
Cell number[a]	N	10^6 cell (g soil)$^{-1}$ or 10^6 cell (ml soil solution)$^{-1}$
Single-cell mass	m	g dry weight per single cell
Mycelium length[b]	L	m (g soil)$^{-1}$
Tips number	n	10^6 (g soil)$^{-1}$
Concentration of limiting substrate	s	mg (g soil)$^{-1}$, g m^{-2} or g l^{-1} of soil solution
Concentration of product (CO_2, CH_4)	p	mg (g soil)$^{-1}$, g m^{-2} or g l^{-1} of soil solution

[a]For unicellular organisms (bacteria, yeasts).
[b]For filamentous organisms (fungi, actinomycetes).

$\boldsymbol{L} = \{L_1, L_2, \ldots L_m\}$ and corresponding hyphal diameters $\boldsymbol{D} = \{D_1, D_2, \ldots D_m\}$. The total soil biomass, x, can be calculated as a sum

$$x = \boldsymbol{V} \times \boldsymbol{N} \times (1 - \Theta) + 1/4\pi \boldsymbol{D}^2 \times \boldsymbol{L} \times (1 - \Theta) \quad [1]$$

where Θ is the water content in wet cell mass (usually taken from lab data).

Advanced microscopic (ultraviolet, electron, and atomic force microscopy) and computer-aided image-analysis techniques make cell counting and sizing less tedious. Additionally, fluorescence *in situ* hybridization (FISH) allows targeting of specific taxonomic or functional groups based on the use of RNA-oligonucleotide probes. The total soil biomass, x, can be quantified by extracting from soil samples and quantifying one of the following integral and unique cell constituents: (1) DNA; (2) adenosine triphosphate (ATP); (3) microbial phospholipids; (4) microbial cell wall components (chitin for fungi and muramic acid for bacteria); or (5) the sum of labile/extractable C released after soil fumigation with CCl_3.

Selection of x or $N(L)$ depends on the specific research question. Biomass, x, has the obvious advantage in studies of carbon and nutrient cycling, while cell number, N, is preferred in population studies when, say, mutation or plasmid transfer is crucial for an understanding of the studied soil processes.

Substrate Concentration

Substrate concentration in the soil, s, stands for the amount of some essential soil constituents used by soil microbes for growth and maintenance. There are two groups of such constituents: (1) catabolic substrates, which are sources of energy; and (2) anabolic or conserved substrates, which are sources of biogenic elements forming cellular material. Examples of catabolic substrates are H_2 for lithotrophic hydrogen bacteria, NH_4^+ and NO_2^- for nitrifying bacteria, sulfur for sulfur-oxidizing bacteria, and oxidizable or fermentable organic substances for heterotrophic species. Their consumption is accompanied by oxidation and dissipation of chemical substances into waste products which are no longer reusable as an energy source (H_2O, NO_3^-, SO_4^{2-}, CO_2, etc.). (Fermentation products like acetate, ethanol, butyrate, H_2 etc. seem to be an exception as they do contain reusable oxidation potential, but it is not available under anaerobic conditions supervising fermentation.) After uptake, anabolic substrates are incorporated into *de novo* synthesized cell components, being conserved in biomass; thus, sometimes anabolic substrates are referred to as conserved substrates. In contrast to catabolic substrates, the conserved substrates can be reabsorbed after excretion or cell lysis. They include nearly all noncarbon sources of biogenic elements (N, P, K, Mg, Fe, and trace elements), CO_2 for autotrophs, as well as amino acids and growth factors.

Two variables, cell mass x and substrate concentration s, are linked via stoichiometric parameter growth yield:

$$Y = -\frac{dx}{ds} \approx -\frac{\Delta x}{\Delta s} \quad [2]$$

where Δx is the increase in microbial biomass consequent on utilization of the amount Δs of substrate. Dividing both parts of eqn [2] by $x\delta t$, gives the relationship between growth rate and substrate production:

$$Y = -\frac{\delta x}{\delta s} = -\frac{\delta x}{x\delta \mathrm{t}} : \frac{\delta s}{x\delta \mathrm{t}} = -\mu/q \quad [2a]$$

where μ is specific growth rate and q is specific rate of substrate consumption.

The reason for Y variation is different for catabolic and anabolic substrates. In the case of energy sources, some fraction of the total substrate flux is diverted from growth *per se* to meet so-called maintenance functions, such as resynthesis of self-degrading cell proteins, nucleic acids and other macromolecules, osmotic work to keep the concentration gradient between cell interior and environment, and cell motility. The energy balance is described by the following equation:

$$\begin{array}{lcll} \text{Total energy source consumed} & & \text{Consumption for growth} & \text{Consumption for maintenance} \\ q & = & \mu/Y^{\max} & + \quad m \end{array} \quad [3]$$

where m is the maintenance coefficient or the specific rate of catabolic substrate consumption by nongrowing cells (i.e., $m = q$ when $\mu = 0$). (With some rare exceptions (fungal exospores and bacterial cysts), the microbial cells are not stable at $\mu = 0$ and either grow ($\mu > 0$) or decay ($\mu < 0$). Therefore the maintenance coefficient is found by linear extrapolation of a series of $q(\mu)$-measurements to the point where μ is zero.) Under chronic starvation the maintenance coefficient, m, becomes progressively smaller in contrast to higher values associated with intensive growth; as a result, when $\mu \to 0$, the growth yield Y approaches a low, nonzero value $Y^{\min}$ (**Figure 1**).

There is also wasteful oxidation of substrate under at least three specific circumstances: (1) when growth is nutrient-limited and energy-sufficient; (2) when starving cells are brought to rich nutrient medium (famine-to-feast transition); and (3) when cells are exposed to uncoupling inhibitors. In all these cases,

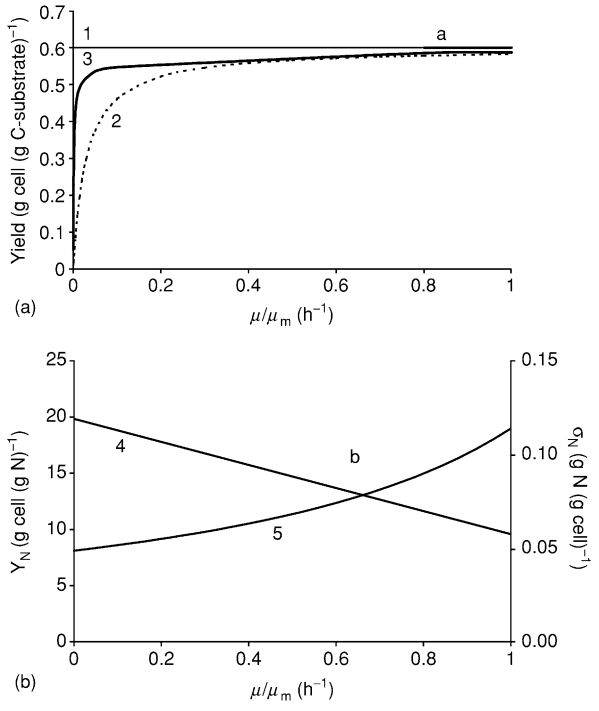

Figure 1 Variation of the cell mass yield on catabolic (a) and anabolic (b) substrates related to specific growth rate of soil microorganisms. Curves calculated assuming no maintenance (1), constant maintenance coefficient (2), and adaptive decrease in maintenance in slowly growing cells (3), Curve 4 is cell yield per g N, and curve 5 is cell quota, g N/g cell. Curves 3–5 were calculated using SCM.

the cell's catabolic machinery produces more energy that can be used for ATP generation. Such wasteful catabolism should be differentiated from maintenance *per se*.

Cell yield on anabolic substrates varies mainly as a result of alterations in biomass chemical composition as expressed by the parameter σ_s, the intracellular content of deficient element or cell quota. The variation in N content in bacteria from 5 to 15% gives the σ_s diapason 0.05–0.15 g N (g cell mass)$^{-1}$. For most known cases, the quota σ_s increases in parallel to growth acceleration, because the higher growth rate requires higher intracellular content of proteins and RNA (containing N, P, S) as well as K^+, Mg^{2+}, and vitamins participating in all primary metabolic reactions. The yield and cell quota are inversely related to each other, e.g., low N-content ($\sigma_N = 0.05\,g\,N\,g^{-1}$) corresponds to high cell yield ($Y_N = 1/\sigma_N = 20$ g cell per g of N utilized), high N-content in rapidly growing cells can be attained only with low cell yield ($Y_N = 1/0.15 = 6.67$ g cell per g N) (Figure 1).

Products

There may be intermediate and end metabolic products accompanying microbial growth. The typical intermediates are organic acids forming in glycolysis/Etner–Doudoroff pathways or various fermentations:

1. glucose → 2 pyruvate$^-$ + 2H
2. glucose → gluconic acid → pyruvate
3. pyruvate → acetate

The only end product of aerobic decomposition is CO_2, whereas products formed under anaerobic conditions include organic acids, alcohols and ketones, CO_2, CH_4, and various reduced inorganic compounds (S^{2-}, Fe^{2+}). The CO_2 evolution rate is probably the most popular parameter to characterize soil biological activity due to the wide availability of gas analyzers (gas chromatography, infrared, and mass spectrometry). In particular cases of aerobic decomposition, the measured CO_2 evolution is a significant fraction of the C budget, as described by the following equation:

$$\begin{array}{cccccccc} \text{Total carbon consumed} & & \text{C incorporated into cell} & & \text{C oxidized to } CO_2 \text{ to provide energy} & & \text{C in extracellular products} \\ \Delta C - s & = & \Delta C - x & + & \Delta C - CO_2 & + & \Delta C - p \end{array} \quad [4]$$

Dividing by time increment δ/t gives:

$$\begin{array}{cccccccc} \text{Uptake of C-substrate} & & \text{Microbial growth} & & \text{Respiration} & & \text{Products formation} \\ \dfrac{\delta s}{\delta t} & = & \dfrac{\delta x}{\delta t} & + & \dfrac{\delta [CO_2]}{\delta t} & + & \dfrac{\delta p}{\delta t} \end{array} \quad [4a]$$

Thus, the microbial consumption of C-substrate is the sum of growth, respiration, and product formation. Based on such C-balance, we can reconstruct the missed variables. For example, cell mass x in a laboratory soil incubation study can be calculated as the difference between the amount of initially added substrate and current s, p, and CO_2 values. (The priming effect of added organic matter on decomposition of soil humus must be evaluated independently – it is usually small enough. The priming is fully excluded when using labeled amendment.) However, it would be incorrect to identify the CO_2 evolution rate alone with total soil decomposition, as some degraded C can be (and really is) incorporated into soil organisms or their extracellular products.

The Models of Microbial Growth

Exponential Growth

Under favorable growth conditions (temporary excess of nutrient substrates, absence of inhibition), the bacterial growth rate should be proportional to

the instant cell mass, x, the quotient μ remaining constant:

$$\frac{\delta x}{\delta t} = \mu x \qquad [5]$$

The integration of eqn [5] at initial condition $x = x_0$ at time $t = 0$, gives the exponential equation:

$$x = x_0 e^{\mu t} \quad \text{or} \quad \ln x = \ln x_0 + \mu t \qquad [5a]$$

The rate of CO_2 or CH_4 production (gas production rate: GPR) is proportional to the growth rate of the respective group of soil microorganisms:

$$\underset{\frac{\delta p}{\delta t}}{\text{GPR}} = \underset{\frac{1}{Y}}{\text{Yield factor}} \times \underset{\frac{\delta x}{\delta t}}{\text{Cell growth}} = \frac{\mu x}{Y} = \frac{\mu x_0}{Y} e^{\mu t} = A e^{\mu t} \qquad [6]$$

where p is gaseous product concentration, expressed for simplicity in the same units as biomass, say mg C per g soil. Integration of eqn [3] under initial condition $p = 0$ at $t = 0$ gives:

$$p = \frac{x_0}{Y}(e^{\mu t} - 1) = B \times (e^{\mu t} - 1) \qquad [6a]$$

Comparing eqns [5a] and [6a], we see that x and p dynamics are not identical, although both imply exponential cell growth; the $p(t)$ curve deviates from the exponential law, especially at small t. In particular the '$\ln x - t$' plot is linear, but '$\ln p - t$' is not. As t increases, the difference becomes smaller and smaller.

In contrast to the exponential growth equation described above, the logistic equation sets an upper limit for microbial growth by empirically assuming that the specific growth rate μ is dependent on microbial concentration:

$$\frac{\delta x}{\delta t} = \mu(x)x = \mu x\left(1 - \frac{x}{x_m}\right) \qquad [7]$$

where x_m is the upper limit of cell mass. In ecological and demographic literature, x_m is called the carrying capacity of ecosystem, K. This equation produces the S-shaped growth curve frequently observed in nature. However, this equation is no more than empiric, and parameters μ and x_m are not 'fundamental,' i.e., they cannot be measured and tabulated for particular soils or ecosystems or predicted before actual observation.

Monod Model

This model, developed by the famous French scientist in 1941, is still very popular due to its elegant simplicity. There are two basic premises: (1) the specific growth rate, μ, is dependent on the concentration of one nutrient component which happens to be the most deficient, the so-called limiting substrate: and (2) biomass formation is linked to substrate uptake by mass-conservation conditions (eqn [2a]). Therefore, according to these premises:

$$\frac{\delta x}{\delta t} = \mu(s)x = \mu_m \frac{s}{K_s + s}x$$
$$\frac{\delta s}{\delta t} = -\frac{1}{Y}\frac{\delta x}{\delta t} \qquad [8]$$

Eqn [8] contains three parameters: yield Y, maximal specific growth rate μ_m, and saturation constant K_s (substrate concentration at which $\mu = 0.5\ \mu_m$), which can be thought of as the 'ID' for particular organisms and used to predict their growth dynamics.

Remarkably, this model was used to develop a chemostat theory before actual experiments with continuous culture had been undertaken, one of the very rare events in the history of mathematical biology! The model predicted a number of counterintuitive features of the chemostat, e.g., that specific growth rate μ can be set up by an experimentalist by changing the medium flow at any values between 0 and μ_m (previously, exponential growth was believed to occur only at $\mu = \mu_m$) and that μ-values do not depend on the feed-substrate concentration and are governed solely by the residual substrate concentration in the culture.

However, the Monod model fails to explain a number of essential growth phenomena observed experimentally, namely: lag-phase, death of starving cells, product formation and any kind of adaptive changes in microbial population, such as induction-repression of enzymes, yield variation, and changes in the cell RNA content. These gaps were filled in by so-called structured models.

Structured Models

Structured models explicitly describe variations in cell composition. They usually include mass balance equations not only for external substrate(s) but also several intracellular components, C_1, C_2, ... C_n. For each variable C_i a differential equation is written which takes into account all sources, r_+, and sinks, r_-, as well as its dilution due to cell mass expansion (growth):

$$\frac{\delta C_i}{\delta t} = r_+(s, C_1 \ldots C_n) - r_-(s, C_1 \ldots C_n) - \mu C_i \qquad [9]$$

The earliest structured models accounted for no more than 3–5 cell constituents, e.g., total cell proteins, RNA and DNA, reserved polysaccharides, and ATP-pool. Modern models contain up to hundreds

and even thousands of internal variables taken directly from available genomic/metabolic databases. Currently the challenge is to create a virtual cell (so-called cell *in silico*) that is complex enough to function as a real cell. However the predictive capability of these intricate models is rather modest: they are still a 'caricature parody' of the real cell, but too complex to be efficiently studied mathematically (stability analysis, parameters identification) or to improve our understanding of the biosystem. The best choice of a mathematical model lies, apparently, midway between the unstructured and highly structured models outlined here. One of the known examples is the synthetic chemostat model (SCM).

Synthetic Chemostat Model

According to the SCM, microbial growth occurs by converting exosubstrate, S, into a number of cell macromolecules, X', via a pool of intermediates, L, part of which are respired to CO_2 (Figure 2).

Macromolecular cell components are susceptible to degradation (turnover), and intermediates L can leak out. The array X', the cell composition, is not fixed and varies in response to the changing environment. The heart of the SCM is the solution of the problem: how to characterize these variations without going too deeply into details?

For this purpose, all the macromolecular cell constituents are divided into two groups: Primary cell constituents necessary for intensive growth (P-components), and components needed for cell survival under any kinds of growth restriction (U-components). The content of P-components (ribosomes and all enzymes of the primary metabolic pathways) increases in parallel with growth acceleration. The contribution of U-components under good growth conditions decreases (to comply with conservation conditions $P + U = \text{constant}$), and attains the maximum under chronic environmental stress to improve cell resistance. Typical U-components are enzymes of secondary metabolism, protective pigments, reserved substances, and transport systems of high affinity. An interdependent variation of individual P- and U-components is approximated by linear function of some master variable r:

$$\mathrm{P}+\mathrm{U}=\begin{vmatrix}P_1\\P_2\\\cdots\\P_n\end{vmatrix}+\begin{vmatrix}U_1\\U_2\\\cdots\\U_m\end{vmatrix}=\begin{vmatrix}P_1^{\min}\\P_2^{\min}\\\cdots\\P_n^{\min}\end{vmatrix}+\begin{vmatrix}U_1^{\min}\\U_2^{\min}\\\cdots\\U_m^{\min}\end{vmatrix}+r\begin{vmatrix}P_1^{\max}-P_1^{\min}\\P_2^{\max}-P_2^{\min}\\\cdots\\P_n^{\max}-P_n^{\min}\end{vmatrix}+(1-r)\begin{vmatrix}U_1^{\max}-U_1^{\min}\\U_2^{\max}-U_2^{\min}\\\cdots\\U_m^{\max}-U_m^{\min}\end{vmatrix} \quad [10]$$

where $P^{\max}$, $U^{\max}$, and $P^{\min}$, $U^{\min}$ are respectively upper and lower boundaries for P and U adaptive variations, and r is the scalar function, not array! The r-value depends directly on environmental factors, e.g., on the limiting substrate concentration and is included in all kinetic expressions (q_s, m, μ) to simulate the combined effects of current environmental factors and the cellular physiological state, as determined by past growth conditions.

The predictive and explanatory capabilities of SCM are higher than that of more complex structured models. It usually gives good agreement with most available experimental steady-state and transient growth data, such as batch culture from lag- to decline phase or continuous culture after abrupt changes in dilution rate, pH, or temperature. For ecological applications, SCM realistically describes and predicts not only growth *per se* but also many other dynamic phenomena: survival dynamics under starvation, formation of dwarf cells under growth restriction, the adaptive adjustment in cell maintenance requirements, variation of growth potential and affinity to substrate, and utilization of substrate mixture. Below we will use SCM to explain microbial growth kinetics both in culture and in the soil.

Growth Kinetics *In Situ* and *Ex Situ*

Soil as a microbial habitat is a system of relatively independent microsites, each of which can be drastically dissimilar in the amount and nature of growth substrates, aeration level, texture, and moisture. However, there are several general features which

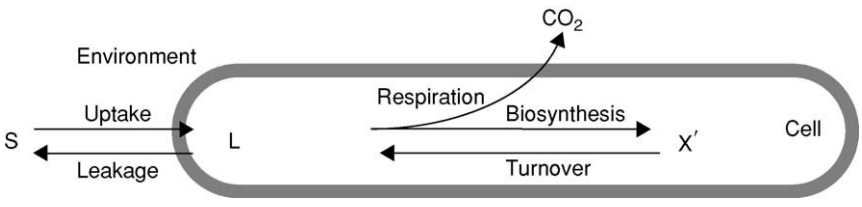

Figure 2 Flow diagram of major cell processes used to stimulate microbial growth by basic SCM.

Table 2 Matrix of growth patterns *in situ* and *ex situ*

	Substrate input			
	Continuous (1)		*Single-term (2)*	
Spatial organization	*Cell removed (α)*	*Cell retained (β)*	*Cell removed (α)*	*Cell retained (β)*
Homogeneous (a)	1aα	1aβ	2aα	2aβ
Heterogeneous (b)	1bα	1bβ	Forbidden combination	Forbidden combination

are most essential for determining the population dynamics of microorganisms occupying a respective microsite:

1. Substrate input may be continuous (1) or discontinuous (2).
2. Growing cells can be retained within a microhabitat (α) or eliminated (β). Examples of elimination include: cell washout, predation (consumption of microbial cells by protozoa, nematodes, microarthropods) or lysis by parasites, active migration due to taxis (motile bacteria) and tropism (vectorized apical growth of hyphal organisms).
3. Habitats vary in spatial organization, being (a) homogeneous and (b) heterogeneously organized. In the first type of system, there is an even or at least random distribution of cells, substrate, and metabolic products in space, whereas in the second type of habitat there are gradients in x, s, and p. The homogenization in soil occurs due to tillage and fossorial animals. Homogeneous microenvironments are also formed when the growth substrates are mobile: gases and volatiles.

These three independent characteristics of ecotopic conditions produce eight possible combinations (Table 2): two of them are logically forbidden because any kind of spatial heterogeneity implies continuous rather than momentary single-term delivery of substrate from some parts of habitat across the *s* concentration gradient. Figure 3 depicts several characteristic microbial habitats occurring in the soil. The most spacious and poorest/oligotrophic habitat is called the dispersion zone (1aβ); the subsoil and patches of bare topsoil are devoid of plant roots or fresh litter. Numerous microbial populations inhabiting these habitats grow very slowly on volatile or readily soluble compounds, which continuously diffuse from other soil loci where monomeric concentration is high due to intensive decomposition (plant litter) or excretory activity of plants (rhizosphere). The lack of elimination (no motility in the majority of soil bacteria and no predation due to low prey density) combined with slow but uninterrupted continuous growth eventually results in a significant buildup of a half-dormant cell mass.

The highest and most continuous microbial activity is localized in the soil litter layer, rhizosphere, and digestive tract of soil animals (habitats of the types 1aβ–1bβ). The C-substrates for microbial populations are the monomeric labile compounds (sugars and organic acids) derived from plants either as root exudation in the rhizosphere or released by extracellular hydrolytic enzymes from the lignocellulose and other polymeric material in plant litter. The litter layer on the soil surface is formed from deposition of aboveground plant remnants, while belowground plant senescence (root litter and root sloughing) provide microbial C-substrates in the rhizosphere. Root exudation is closely related to plant photosynthesis and changes diurnally, whereas hydrolytic release is monotonous. Spatially, all these habitats are rather heterogeneous; however, the random distribution of microloci combined with macroscopic sampling size allows us to use homogeneous kinetic models. Clear vertical gradients are formed in the litter layer from uncolonized fresh plant debris on the top to highly decomposed sublayer at the interface with mineral soil. At the microscale, the spatial heterogeneity of microbial colonies (mainly fungi) is manifested in its differentiation into growing extension zone and the nongrowing reproductive compartments (Figure 4). Within the rhizosphere, there are also several spatial gradients of different scales: (1) the vertical gradient of the root phytomass, which reflects the spatial pattern of belowground allocation of photosynthate; (2) the horizontal gradient between distant trees or tussocks; and (3) the micro-scale gradient around root hair with maximal concentration of microbial cells and substrates on the root surface (rhizoplane) and exponential decline outwards. (Some researchers found a statistically significant decline in cell density of rhizosphere bacteria on the plant surface, probably due to excretion of antibiotic compounds by plants.)

Soil millipedes, isopods, some earthworms and other primary decomposers inhabit the litter layer and feed on plant debris. The ingested lignocellulose material is mechanically disrupted by the mandible,

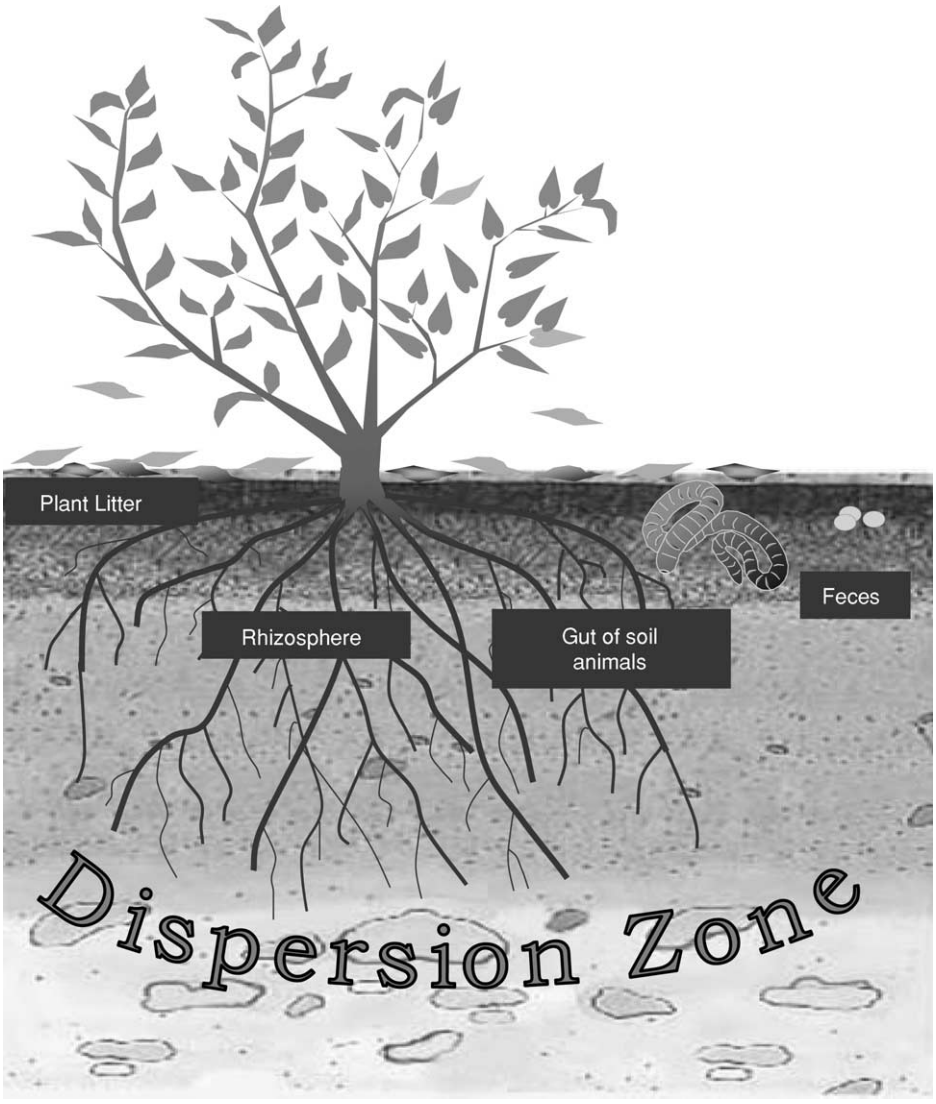

Figure 3 The principal microbial habitats in the soil (see text for explanation).

moistened with saliva, and then passed to the mid- and hindgut. The digestive tracts of various soil invertebrates harbor not only specific symbionts, but also the normal free-living microorganisms occurring in soil or plant litter, e.g., *Pseudomonas*, *Flavobacterium*, *Vibrio*, *Enterobacter*, and *Streptomyces*. The acceleration of their growth in the hindgut is due to favorable conditions: neutral pH, optimal moisture, elevated concentrations of nutrient and growth factors (amino acids, peptides, vitamins), as well as the continuous input of fresh substrate and concomitant removal of digestion products (glucose) to prevent the negative feedback (so-called catabolic repression) on cellulase synthesis. Due to peristaltic motion the content of the gut is mixed and homogeneous. Secondary decomposers (i.e., the earthworms *Allolobophora chlorotica*) feed on amorphous humus containing bacteria and fungal mycelia; they eliminate some microbial species and greatly stimulate growth of others.

Discontinuous, explosive microbial growth occurs within hot spots initiated by sudden increases in the availability of organic substrates/nutrients in the soil (2aα–2aβ), such as feces and carcasses of animals, rain washing of organic matter from plant foliage, dry–rewet or freeze–thaw cycles, manure application, and soil fumigation. Growth is usually accompanied by elimination in the form of grazing, myco- and bacteriolytic activity, as well as the active migration of microbial cells.

The dynamics of microbial growth in any type of habitat is described by the mass balance equations:

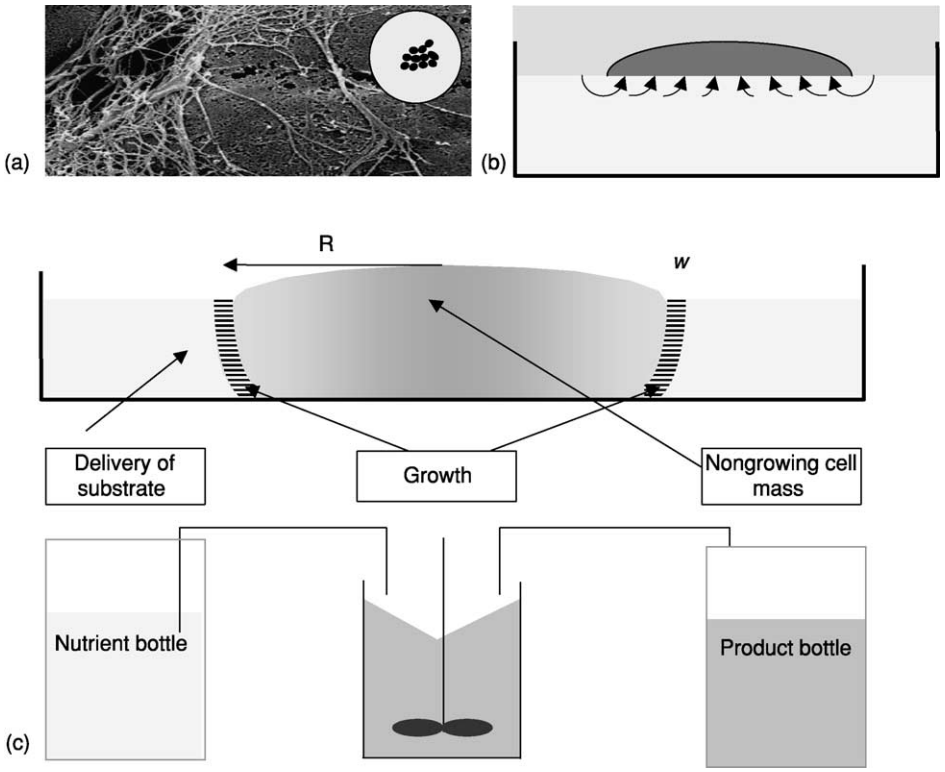

Figure 4 The colony growth: (a) in the soil; (b) bacterial growth on agar plate; (c) fungal growth in nutrient agar. Note that bacteria grow only on the agar surface and the colony expansion is controlled by diffusion of substrates from outside the colony. The fungi and actinomycetes are able to penetrate into the depth of the agar layer, so their mycelium expansion is not dependent on nutrient diffusion within agar layer. The fungal colony follows a chemostat-type growth pattern, being: (1) continuous; (2) steady-state; and (3) limited by substrate availability. The role of the fermentation vessel of the conventional chemostat is played by the peripheral zone of the colony; the product bottle is analogous to the central part of the colony, while the pump is substituted by the chemotropic movement of hyphae tips along the substrate concentration gradient.

$$\begin{array}{lcccccccc} \text{Net change} & & \text{Substrate input} & & \text{Substrate loss} & & \text{Uptake for growth} & & \text{Uptake for maintenance} \\ \dfrac{\delta s}{\delta t} & = & F(t) & - & G(s) & - & \dfrac{\mu(s)x}{Y} & - & mx \\ \text{Net change} & & \text{Immigration} & & \text{Elimination} & & \text{Growth} & & \\ \dfrac{\delta x}{\delta t} & = & V(t) & - & H(x) & + & \mu(s)x & & \end{array} \quad [11]$$

To specify kinetic expressions, we can rely on kinetic models developed for the laboratory cultivation system which is closest to the respective soil habitat (Table 3). For instance, growth of soil bacteria in the intestine of earthworms is remarkably similar to a tubular (plug-flow) reactor, the rhizosphere community is related to a chemostat or phased-batch culture with injection of the growth-limiting substrate once per day (simulation of photosynthesis-dependent root exudation), the slow microbial growth in dispersion zone is adequately simulated by dialysis culture, and growth of fungi degrading plant litter contains kinetic patterns similar to colonies developing on agar.

Growth models based on SCM for various homogeneous cultivation systems are shown in Figure 5, and colonial growth is illustrated in Figure 4. One of the best criteria of adequacy of the selected cultivation system is specific growth rate, μ, of the studied microbial population. If the values of μ for *ex situ* and *in situ* populations coincide, then the cultivation technique may be regarded as appropriate.

Diversity of Growth Characteristics: Life Strategy Concept

In soils, there are always multiple microbial populations performing the same function. They have different growth parameters and regulators, but they require and compete for the same nutrient substrates. Their coexistence, which contradicts the well-known principle of competitive exclusion, can be explained by at least two factors:

1. spatial segregation of soil microsites, which leads to a lack of direct interactions between potentially competing species in the soil

Table 3 Examples of typical soil habitats and their counterparts in laboratory cultivation systems

		Soil habitats		
Kinetic type	*Lab cultivation system*	*Locus*	*Substrate flux*	*Elimination factor*
1aα	Chemostat, turbidostat, pH-auxostat	Rhizosphere	Rhizodeposition: exudation and sloughing	Root extension, predation by protozoa and nematodes
1aβ	Fed batch culture, dialysis culture	Dispersion zone	Diffusion of gases, volatile and soluble organic matter	No or very weak
1bα	Plug-flow, colonies on plate	Digestion tract of invertebrates	Predigested plant litter	Excretion
1bα	Colonies, solid-phase fermentation	Plant litter	Litter fall, root sloughing	Predation by microarthropods, apical hyphal extension
1bβ	Column packed with microbe attached, biofilms	Vertical network of the soil water channels	Trickling solutions	Cell motility
2aα	Phased culture	Temporary hot spots of microbial activity	Excrements and corpses soil animals, manure	Predation/grazing and exposure to harmful factors
2aβ	Simple batch	Hot spots without intensive microbial grazing	Washout of labile organic matter with rainwater	No or weak predation[a]

[a]Low probability of intense predation if no buildup of microbial biomass (prey population density) occurs.

2. perpetual environmental changes which cause variation in the direction/intensity of natural selection, so the fittest competitor today can be different from the day before, none of them being excluded completely

Studying microbial communities from a kinetic perspective can describe quantitatively why the pressure of natural selection can differ. One can distinguish the following three types of natural selection which correspond to three types of life strategy:

1. *K*-selection for high competitive power ('lions'); operates in climax ecosystems
2. *r*-selection for reactivity and ability to recover after perturbations ('jackal'); operates on the pioneer stages of succession
3. *L*-selection for resistance to stress-factors ('camel'); operates under adverse environmental conditions (**Figure 6**)

Figure 7 summarizes results of kinetic studies of the typical microbial *r*-, *K*-, and *L*-strategists. The *Enterobacteria*, *Pseudomonas*, Baker and Fodder yeast are mainly *r*-selected organisms. Their dynamic behavior is erroneously considered to be typical for all microbes: rapid and balanced growth, short lag-periods, and smooth transitory processes. They dominate in those soil habitats that are frequently 'rejuvenated' to the pioneer succession stage: hot spots of substrate amendment, animal guts and feces, rhizosphere with diurnal fluctuations in exudation rates and perpetual changes in 'address' of exudation loci due to apical extension of root hair. Plating is a good simulation of such hot spots; that is why *r*-selected species are easily isolated from soil.

K-selected bacterial species are much less amenable to isolation and cultivation. Probably most unculturable microbial species belong to this type of life strategy. When cultivated under artificial laboratory conditions, they are fastidious and unpredictable (a 'lion' in captivity). The best option for their cultivation is continuous culture with cell retention: fed-batch, dialysis culture, or batch culture with C-substrate delivered via gas phase (volatile C-substrates, such as ethanol or volatile fatty acid). Under these cultivation conditions the *K*-selected species display high yield and almost 100% viability, even at extremely slow cell division (generation time up to months). In other cultivation systems, their growth patterns are characterized by: (1) biphasic growth on the single substrate in batch culture (false diaxia); (2) long survival under starvation; and (3) oscillations and bistability (two or more steady states at one dilution rate) in chemostat. To simulate mathematically the described abnormal behavior of *Arthrobacter* and other oligotrophic species, the SCM was elaborated to include intermediates with autoinhibition functions (e.g., peroxides as respiratory by-products) and the possibility of direct incorporation of deficient C-substrate to a pool of reserved compounds (**Figure 7**). The main feature of growth control in oligotrophic species is the relative autonomy/independence of several metabolic domains: transport, respiration, and biosynthesis.

Many *L*-selected microorganisms (bacilli, actinomycetes, some fungi) share the following common

Cultivation method	*Design*	*Equations of mass balance*	*Growth dynamics*
Chemostat		$\frac{\delta s}{\delta t} = D(s_0 - s) - q_s x$ $\frac{\delta x}{\delta t} = \mu x - Dx$ $\frac{\delta r}{\delta t} = \mu\left(\frac{s}{K_r + s} - r\right)$ [12] $q_s = rQ\frac{s}{K_s + s}$; $D = F/V$ $\mu = Y[q_s - mr]$	Batch		Dilution rate $D = 0$ and $s = s_0$ at $t = 0$; the rest is according to eqn [12]	Phased culture		D = constant $s_0 > 0$ at $t = i\Delta t$, where $i = 0, 1 \ldots n$, and $s_0 = 0$ at other t; the rest is according to eqn [1]	Continuous dialysis		$\frac{\delta s}{\delta t} = \frac{F}{V_m}(s_0 - s_m) - q_S x$ $\frac{\delta x}{\delta t} = \mu x$ [13] The rest is according to eqn [12]	Fed-batch culture (FBC)		$D = F/(V_0 + Ft)$ The rest is according to eqn [12]	Continuous plug-flow		$\frac{\partial s}{\partial t} + f\frac{\partial s}{\partial z} = D\frac{\partial^2 s}{\partial z^2} - q_s x$ $\frac{\partial x}{\partial t} + f\frac{\partial x}{\partial z} = D\frac{\partial^2 x}{\partial z^2} - \mu(s)x$ The rest is according to eqn [12]	
Figure 5 The major cultivation systems relevant to the purposes of microbial ecology. *s*, *x*, and *r*, limiting substrate concentration, biomass, and variable of physiological state; q_s, specific rate of substrate uptake; *mr*, maintenance requirement; *m*, specific growth rate; *V*, reactor volume; *z*, distance along tubing reactor in the plug-flow system.

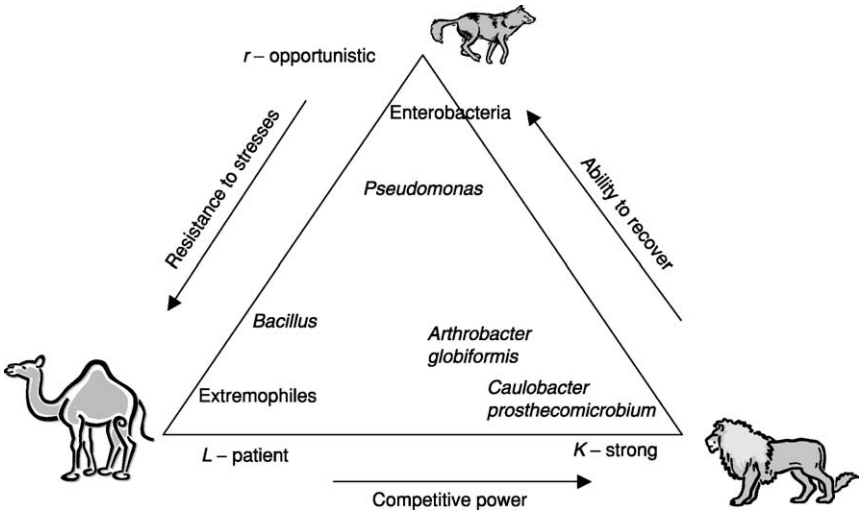

Figure 6 The concept of life strategies. All soil microorganisms are located along three axes characterizing the survival triad: the ability to compete for resources (*K*-axis), recover after stresses (*r*-axis), and resist unfavorable environment (*L*-axis). One can distinguish the following three types of natural selection which correspond to three types of life strategy:

1. *K*-selection operates in climax ecosystems under stable and predictable conditions with no or rare perturbations and stresses. The products of *K*-selection are highly competitive species with 'lion' type of life strategy. The bacterial 'lions' are oligotrophic species that have evolved powerful transporters to absorb the nutrients from diluted solutions (K_s in the range 10^{-6}–10^{-9} mol l^{-1}).
2. *r*-selection operates on the pioneer stages of succession initiated by some perturbation of a climax ecosystem (fire, nutrients flash, cataclysmic elimination of competitors) that has resulted in a temporary relief from competition for nutrient resources. *r*-selected species survive in ephemeral habitats due to mobility and high reproduction rates (opportunistic or 'jackal' type of strategy).
3. *L*-selection operates under adverse environmental conditions caused by abiotic stresses (high/low salt concentration, temperature, pH, water content) or biotic negative interactions (antagonism, starvation caused by depletion of substrate by more successful competitors). The products of *L*-selection are the patient species resistant to a particular stress factor ('camel' type of strategy).

features: endospore formation, production of antibiotics, and synthesis of hydrolytic enzymes. All these features help them to survive even if they lose in direct combat with competitors for deficient nutrients. Kinetic studies allow us to understand why they are weak competitors. The most striking feature was observed in *Bacillus* dialysis culture: the bacteria stopped growing after 2–3 weeks when the residual glucose level dropped below the threshold value of 20–50 $\mu g/l^{-1}$. In rich environments, even with an intermittent supply of nutrients (feast-to-famine transitions simulated in batch culture), these bacteria perform well. They rapidly deplete the available substrates, which triggers sporulation and transition to a dormant state, preserving the bacteria from extinction. However, the chronic starvation typical of most oligotrophic environments is the 'trap' for bacilli; they are provoked to sporulate but are not able to finish it in a normal way. The slow feed via the dialysis membrane provides glucose levels too high to allow termination of normal sporulation and too low for growth due to the uncoupling action of metabolite H and acceleration of turnover rate (Figure 7).

Decomposition Kinetics

Decomposition of organic matter is the most essential soil process. There are several ways to quantify kinetics of decomposition.

Decomposition as Self-Decay

The simplest way is to use a first-order kinetic equation:

$$\frac{\delta s}{\delta t} = -ks \qquad [14]$$

where k is a constant dependent on environmental factors. To account for the heterogeneity of detritus, the same equation is written for n (usually $n = 2$ or 3) arbitrarily selected organic matter fractions and then summed as follows:

$$\frac{\delta s}{\delta t} = -(k_1 s_1 + \ldots + k_n s_n) = -\sum_{i=1}^{n} k_i s_i \qquad [14a]$$

Literally, eqn [14a] stands for spontaneous (without involvement of soil organisms or enzymes)

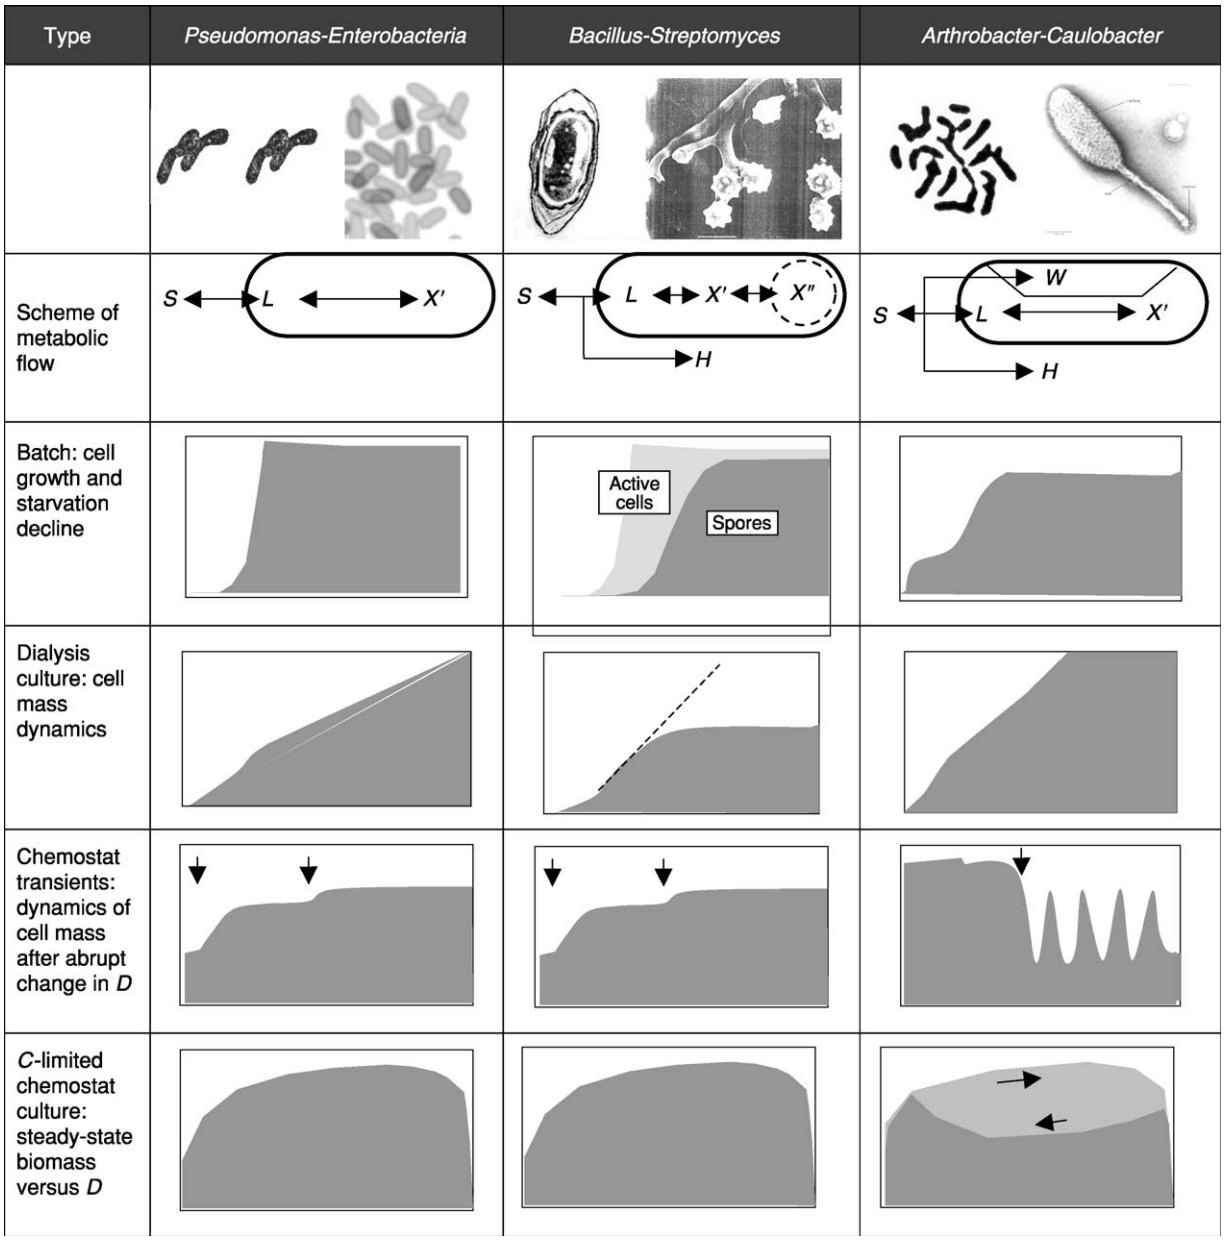

Figure 7 Diversity of growth patterns displayed by soil bacteria in various life strategies in several contrasting types of laboratory cultivation (1) and dialysis (2) cultures as well as chemostat during transient (3) and under steady-state conditions (4). Upper row shows typical morphology of selected microbial groups; next row demonstrates cell growth chart and the main state variables of the respective modification of SCM used for simulation (X″ is prospore compartment, H is autoinhibitor, and W is poly-b-oxybutyrate – reserved compounds): for S, L, and X′. see **Figure 2**. Arrows indicate the time of switching from one dilution rate, D, to another in chemostat culture (3) or derection of sequential D-changes (4, from low D to high or reverse) in chemostat culture displaying multistability.

decomposition of organic matter as well as independent and parallel decay of different individual compounds; no transformation reactions are assumed. All the listed assumptions are unfair; but eqn [14a] is the most popular in modeling of the soil decomposition due to its simplicity.

To account for the transformations accompanying decomposition of organic matter in the soil, e.g., the synthesis of microbial cells and exometabolites from original plant litter, condensation reactions, and formation of organomineral complexes, eqn [14] is modified as follows:

$$\frac{\partial f(z,t)}{\partial t} + \frac{\partial V(z,t)}{\partial z} = -U(z,t)f(z,t) \qquad [15]$$

Here $f(z,t)$ is the distribution of detritus components with respect to their susceptibility to microbial

degradation, z, where z ranges between 0 and the maximum value z_m; $V(z,t)$ is the amount of detritus converted into more or less available compounds; and $U(z,t)$ is the degradation rate.

Decomposition of Simple Individual Compounds Added to Soil

More realistic models explicitly account for the soil organisms responsible for biodegradation. Fortunately, such a task does not require a mandatory microbiological analysis, because microbial growth can be evaluated indirectly, from the decomposition dynamic patterns. Such an approach is especially useful in soil incubation studies, when decomposition of added individual organic compounds (pollutants, ameliorators, model compounds) is recorded as residual concentration of chemicals and/or as the CO_2 formation rate. As shown in Figure 8, nonmicrobial degradation should follow zero- or first-order kinetics with a monotonous decline of soil respiration. If enzymes or nongrowing cells are involved, then decomposition follows the Michaelis–Menten equation with its mixed order. The growth of degraders is manifested as a temporary increase in the degradation rate. Overall, more biomass (x_0) before amendment and a faster growth (higher μ) leads to a steeper response and shorter lag-phase. The approximation of substrate-induced soil respiration dynamics with SCM allows us to find the exact value of x_0 and r_0, characterizing the physiological state of studied microorganisms *in situ*.

As another example, decomposition of glucose in bare soil kept for a long time without plants or fresh litter always shows a characteristic wavy dynamic pattern (Figure 8, line 5): rapid glucose uptake the first 1–3 h, followed by deceleration and then acceleration of glucose uptake until all the added compound is consumed. In this case, the respiration dynamics remains monotonic. A remarkably similar pattern was found in a batch culture of *Arthrobacter globiformis* and other *K*-selected oligotrophic species; the first phase of intensive uptake is attributed to filling of storage cell compartment, while the second one is due to normal exponential growth.

Decomposition of Cellulose

Significantly more complicated is the decomposition kinetics of polymeric plant material, e.g., cellulose. In contrast to monomeric substrates, plant polymers are degraded by extracellular enzymes, and the depolymerization products are shared by the whole community. In addition, senescent plant tissues are poor in biogenic elements (N, P, Mg, Fe), while production of extracellular enzymes requires extra amounts of N, Mg, Ca, and P (direct incorporation into protein molecules and support of ribosomal machinery). The deficiency of biogenic elements coupled with C-sufficiency provides a higher risk of metabolic imbalance: catabolic repression of enzyme synthesis, accumulation of inhibitory products, and 'substrate-accelerated death.' In the sphagnum bog, these obstacles are expressed in the highest degree. In addition to metabolic imbalance, these systems are partially anoxic and decomposition rates are so low that peat accumulates. A microbial decomposition under extremely unfavorable conditions is made possible only by the 'cooperative efforts' of the entire community.

The minimal structure of the cellulolytic community consists of three microbial groups: (1) *L*-selected hydrolytic populations producing extracellular cellulases; (2) *r*-selected copiotrophic organisms capable of explosive growth and some way to cope with deficiency of mineral nutrients (e.g., N_2 fixation); and (3) the *K*-selected oligotrophic populations capable of scavenging monomeric products diffusing from decomposition hot spots. In addition, free cellulases immobilized on soil particles provide some background level of depolymerization activity.

The chain of events after cellulose is added to soil is as follows:

1. induction of microbial cellulase synthesis, splitting polymers into mono- and oligosaccharides which are accumulated within the hot spot of microbial activity
2. sugar uptake and ephemeral microbial growth until one of the nutrients, for example N, becomes depleted
3. N-starvation stops hydrolytic activity by driving these organisms into a dormant stage (most hydrolytic microbes form spores), or possibly switching to N_2 fixation
4. growth of this group is stopped when the available C-source is depleted and double N and C starvation occurs, then the third group of *K*-selected oligotrophs continue to function as a sink for depolymerization products (generated by free enzymes).

The oligotrophic bacteria are not affected by N-starvation due to location outside the decomposition hot spot. This verbal description is translated into a mathematical model which gives fair agreement with observations (Figure 9). Fertilization of soil with NPK considerably stimulates cellulose decomposition; however, the highest activity is achieved if soils are air-dried and rewetted before incubation (compare the left and right parts of Figure 9). The

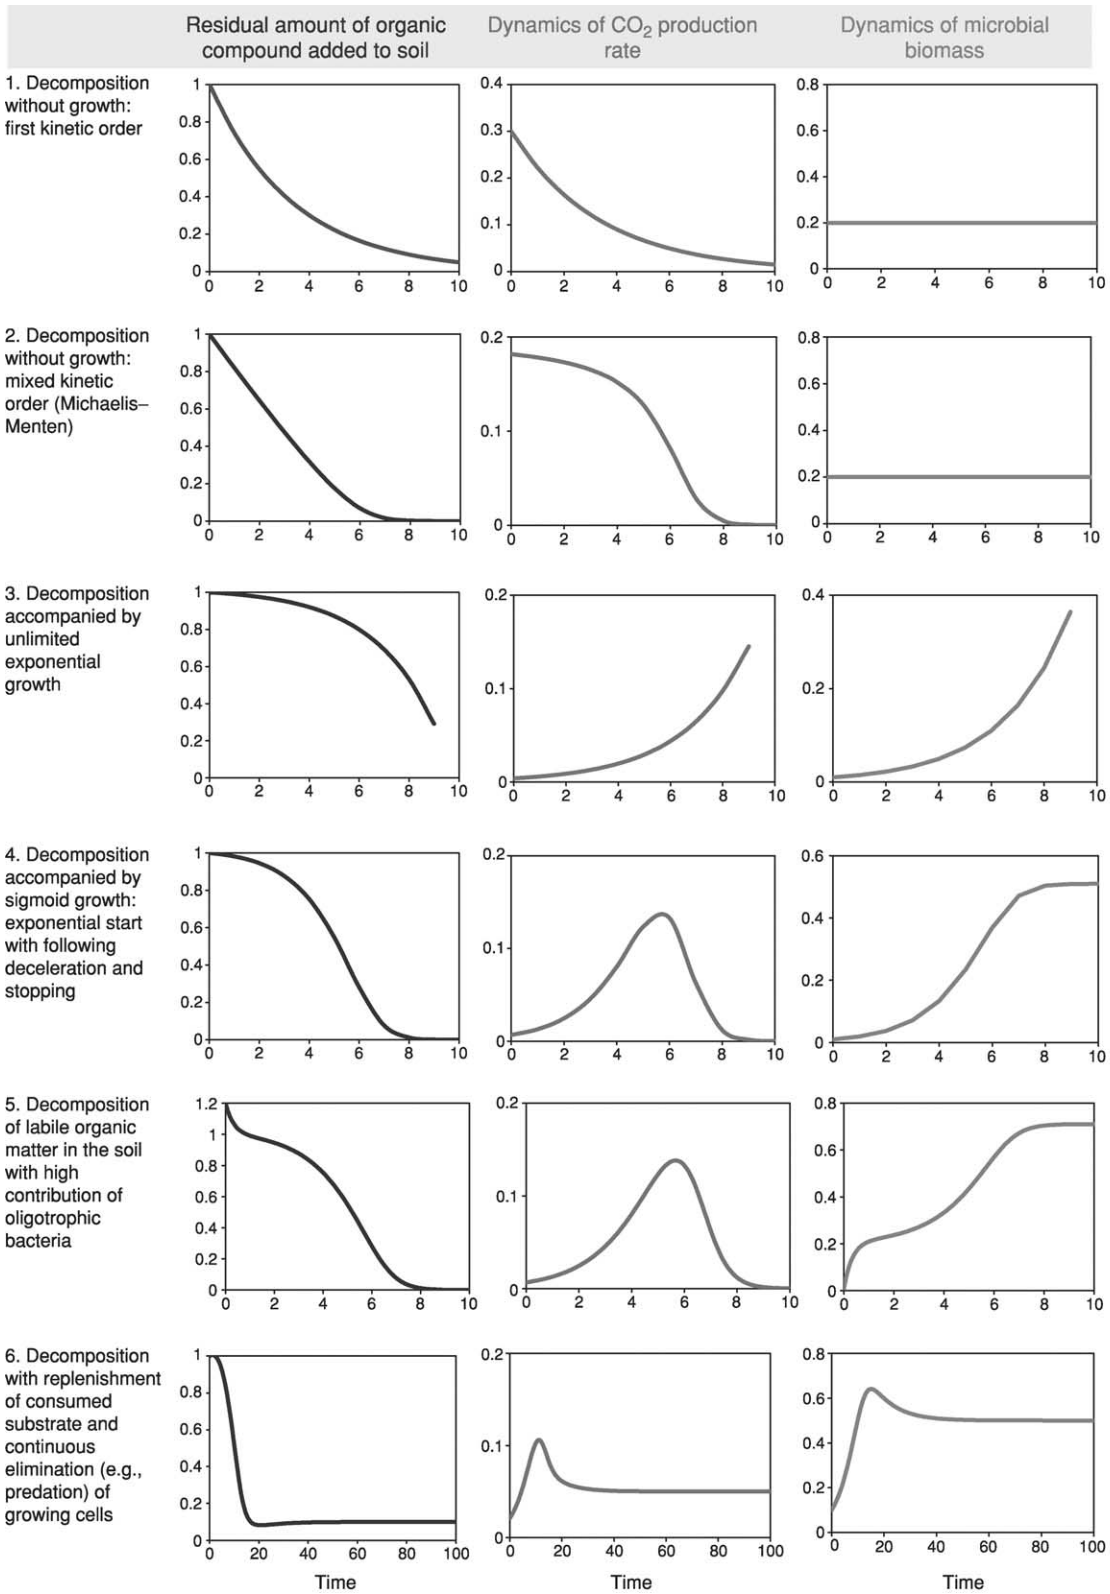

Figure 8 Biodegradation dynamics recorded in soil incubated with added organic substrates. In typical soil incubation studies degradation of labile organics (glucose, amino acids, degradable pesticides, etc.) is followed by recording of residual amount of added compound (first column), CO_2 evolution rate (second column) and microbial biomass (third column). The shape of dynamic curves is a sensitive indicator of the biodegradation mechanisms as indicated by six shown examples.

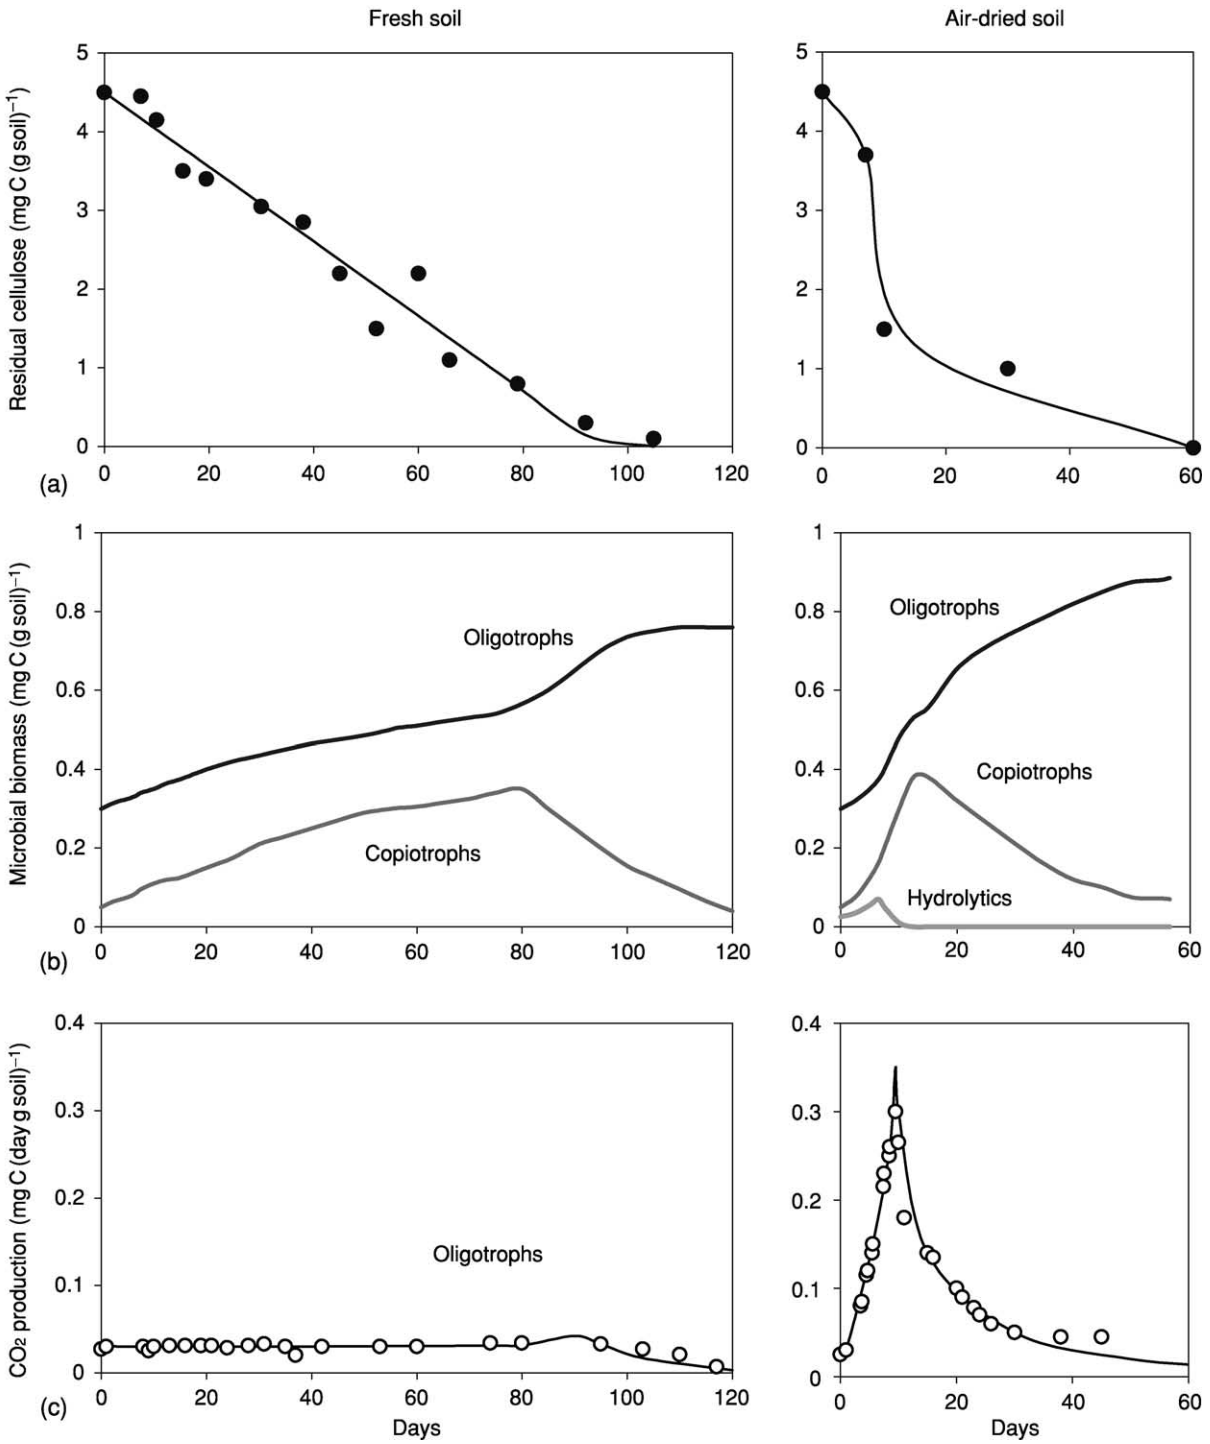

Figure 9 Cellulose decomposition in the soil as related to population dynamics of cellulolytic microbial community. Left: fresh forest soil; right: the same soil after air-drying and rehydration 5 days before cellulose amendment. (a) Residual cellulose; (b) simulated dynamics of: (1) hydrolytics producing extracellular cellulases; (2) copiotrophic N_2-fixing organisms; and (3) the oligotrophic populations capable of scavenging monomeric products diffusing from decomposition hot spots; (c) respiration dynamics. drying–rehydration causes partial damage to microbial cells (similar to fumigation) and release of cell constituents into soil solution. In addition, this treatment removes inhibitors and signaling metabolites, which arrest the biosynthetic activity of hydrolytic microorganisms. It is interesting that healthy soils have restricted hydrolytic activity (slow zero-order decomposition due to action of 'free' soil enzymes). An excessive activation of soil hydrolases takes place more often in pathological cases, e.g., in arable soil after continuous use of NPK and development of soil toxicity.

Decomposition of Plant Litter

The final step from cellulose to lignocellulose and entire plant litter adds the following complications: (1) in lignocellulose the polysaccharide component is further preserved from microbial enzyme by lignin; (2) the heterogeneity of plant litter as a substrate is essentially higher due to the presence of the complex mixture of heteropolysaccharides, waxes, and monomeric phenolic compounds (often considered as inhibitors of decomposition process); and (3) a more complex soil community. However, degradation of cellulose and lignin is carried out jointly, the carbohydrate component being used as available C-source and to generate peroxides driving the oxidative destruction of lignin. Although lignin slows the decay rate, lignocellulose is decomposed as a whole, and there is no significant enrichment of lignin in the old residual substrate. Therefore the kinetic mechanisms of decomposition revealed for cellulose alone are also applicable for lignocellulose.

Introduction

Micronutrients in soils and their plant availability are critical to plant nutrition. The supply of nutrients to plants is included in the discipline of soil fertility. Micronutrients are elements found in plants at concentrations less than $100\,mg\,kg^{-1}$ and are generally found at low concentrations in soils, with the notable exception of Fe. Four are present as cations (Zn, Cu, Mn, and Fe), one is an uncharged molecule (B), and one is an anion (Mo) in soil solution and in plants. Several other elements have been shown to be essential to plant nutrition, such as Ni and Cl, but they are not controlled through soil amendments, and deficiencies have only been found in research settings. Not only are the element concentrations important to soil fertility, but more so are the soil properties and processes that influence availability to plants.

Zinc

Zn is taken up by plants in the divalent form, which is the form most often found in soil solution at normal soil pH values. Concentrations in the soil solution that are usually adequate for plant growth are $0.05–0.25\,mol\,l^{-1}$, but will become toxic

at concentrations greater than 3–6 mol l^{-1}. Soil-solution concentrations of Zn^{2+} are usually low at 0.01–1.0 mol l^{-1} in calcareous soils, but higher in acid soils. There is still uncertainty about whether Zn uptake by plants is an active or passive process. The main interaction with other micronutrient ions is with Cu^{2+}, which can inhibit Zn uptake as well as compete for transport sites within the plant. Zinc interacts with the macronutrient P, in that high P availability can cause Zn deficiency. It is still not known for certain whether the P–Zn interaction takes place mostly in the soil or the plant. Divalent cations such as Mg^{2+} and Ca^{2+} can also interfere with Zn uptake by competition. Zinc deficiencies increase when the soil is waterlogged as for rice-growing. These deficiencies could come from the precipitation of Zn or by increases in Zn–organic complexes.

Zinc is found at higher concentrations in basic rocks than in acidic or sedimentary rocks such as limestone and occurs naturally as sulfides, carbonates, and silicates. The mean concentration in the Earth's crust is 80 mg kg^{-1}. As for most elements, Zn is found at higher concentrations in the topsoil than the subsoil, because plant roots bring Zn to the surface. Of all the soil properties affecting Zn availability to plants, pH is certainly the most important. There are several causes for the increase in availability with decreasing pH: first, the adsorption of Zn by colloids increases with increasing pH; second, Zn can precipitate at high pH values as in calcareous soils. The availability is very low at pH > 7.0; finally, diffusion to the plant root is decreased by increasing pH. Zinc usually does not become toxic unless the pH is low (less than 4.0) or the plants are susceptible, as in the case of peanuts. Soil organic matter also has a profound effect on Zn availability. The two forms of organic matter, solid and soluble, have opposing effects on Zn, as they do for most metals. Soluble organic matter–Zn complexes in solution assist in bringing Zn to plant roots, thus enhancing availability. Solid organic matter provides negative adsorption sites, as well as specific adsorption sites that bind Zn and decrease plant availability. As a result, Zn availability is low in organic soils; however, the action of soil microbes in breaking down solid soil organic matter releases Zn and increases plant uptake. Soil secondary clay minerals as well as Fe and Al oxides also have high bonding energies for Zn and high adsorption capacity. These can bind Zn and hinder plant uptake. Zinc is not susceptible to oxidation and reduction in soils, so redox status per se does not affect availability. In soils that undergo oxidation–reduction cycles, the freshly precipitated amorphous (or microcrystalline) Fe oxides are in abundance, and these have approximately 10 times more adsorptive capacity than aged, crystalline Fe oxides.

Copper

Cu is adsorbed by plants as the divalent ion Cu^{2+}. Of the micronutrients considered here, it is most strongly bound with organic chelating materials (Cu > Zn > Mn > Fe) and thus is strongly associated both with solid soil organic matter and with soluble organics in soil solution. Up to 98% of Cu found in soil solution is bound by low-weight organic compounds. For adequate growth and development, plants need at least 0.02 mmol l^{-1} in solution. Since the free Cu^{2+} ion is the form taken up by plants, Cu bound by organics is not readily available. Soil moisture has little effect on uptake except that flooding decreases both water-soluble Cu and Cu available to plants.

More Cu is found in soils developed from basic rocks and shales than from sands, sandstones, and acid igneous rocks; basalts are higher in Cu, while granites are low in Cu. Cu deficiencies are prevalent in organic soils such as peats and mucks, and the mean total Cu found in soils is 70 mg kg^{-1}. Cu is strongly associated with oxides of Fe and Al according to adsorption and fractionation studies. As with most metals, it is more strongly adsorbed by soil colloids at higher pH values, but plant availability is not as sensitive to pH as for some other metals because of Cu–organic complexing. Soil-solution Cu concentration in terms of chemical activity is a linear function of soil pH (Figure 1). Plants can develop Cu toxicity symptoms when grown in acid soils of pH less than 6.5. High organic matter content can lead to Cu deficiencies due to the formation of insoluble organic complexes. On the other hand, in calcareous soils, where high pH could decrease Cu availability, soluble organic complexes can help to keep availability above deficient levels. The soluble organics are evidently able to shift the equilibrium from the solid organic complexes to the soluble, so that even at higher pH values the soluble organics can enhance Cu concentrations in solution. Also, over time, the Cu associated with solid organic matter is released through microbial breakdown of the organic matter. Cu does not change oxidation values readily in soils, so the decrease in availability in flooded soils could come from the chemical reduction of crystalline Fe and Mn oxides to amorphous forms, which provide surfaces for Cu adsorption.

Manganese

Mn and Fe are considerably different in their soil chemical reactions from Zn and Cu, because they

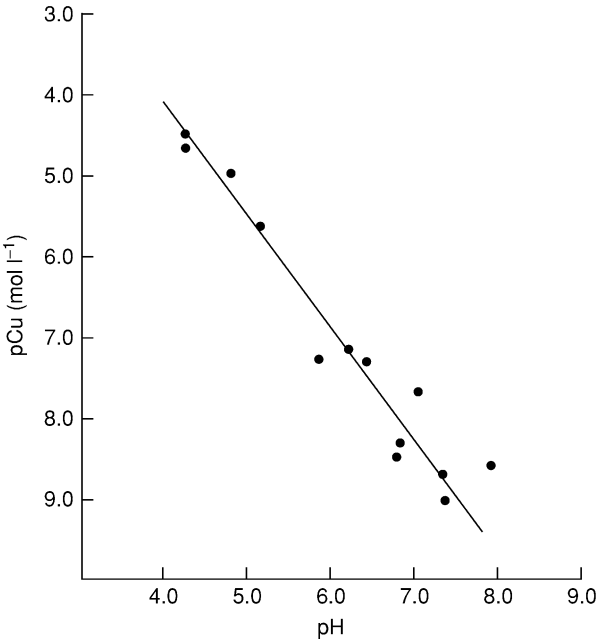

Figure 1 Activity of Cu^{2+} versus soil-suspension pH. pCu, negative $\log_{10}$ of Cu concentration in solution. (Adapted from McBride MB and Blasiak JJ (1979) Zinc and copper solubility as a function of pH in an acid soil. *Soil Science Society of America Journal* 43: 866–870, with permission.)

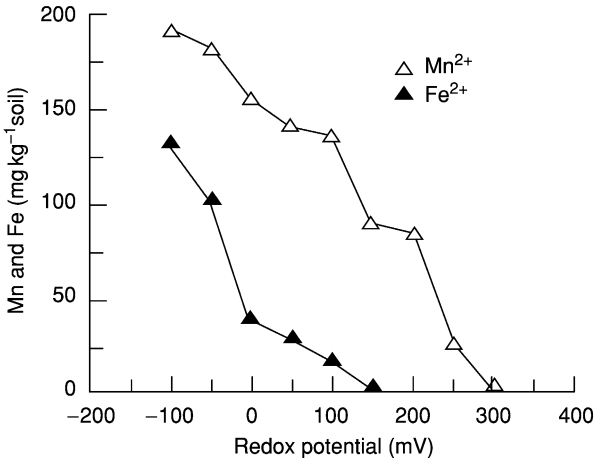

Figure 2 Soluble Mn^{2+} and Fe^{2+} in soil suspensions versus redox potential during an oxidized-to-reduced cycle. (Adapted from Patrick WH Jr and Jugsujinda A (1992) Sequential reduction and oxidation of inorganic nitrogen, manganese, and iron in flooded soil. *Soil Science Society of America Journal* 56: 1071–1073, with permission.)

are easily oxidized and reduced in soils. Mn is taken up by plants as Mn^{2+}, although most of the Mn in soils is in the Mn^{4+} oxidation state. Mn concentrations in soil solution can vary from less than 0.1 mmol l^{-1} in well-aerated soils to as high as 400 mmol l^{-1} in submerged soils. Plants need a range of 0.01 to approximately 50 mmol l^{-1}. Chelation of Mn occurs in soils as for the other metals, but the uptake of chelated Mn by plants is poorly understood. High soil-moisture content tends to reduce the oxidized Mn^{4+} form to the reduced Mn^{2+} form, making it more available. Thus, deficiency is not a problem on wet soils, and toxicity may result, especially for susceptible plants.

Mn is the 11th most common element in the Earth's crust and averages 0.09% or 900 mg kg^{-1}. The oxides or sulfides are often associated with Fe. Mn can be found in soil minerals such as MnO_2, MnOOH, and Mn_3O_4. Mn is low in soils that are derived from crystalline shales and acid igneous rocks, but is higher in soils derived from basalt, limestone, and shales, especially limestones. Deficiencies occur in organic, calcareous, and poorly drained acid sandy soils. Usually the higher the clay content of a soil, the greater will be the Mn content. For example, the soils of the US southeastern piedmont have significant amounts of clay and some are derived from limestone. These soils are so high in Mn that toxicities can result. However, on the southeastern lower coastal plain, the sandy soils are alternately wet and dry and can cause Mn deficiencies. Manganese availability is tied closely to the oxidation–reduction status of soils. Soils that are waterlogged are reduced and release Mn^{2+} from the oxidized forms. The more negative the redox potential, the higher the Mn concentration in soil solution (Figure 2).

Besides oxidation–reduction, the other major influence on Mn availability is soil pH. At pH values greater than 6 and under high-oxidation conditions, Mn is mostly in the insoluble Mn^{4+} form. At lower pH and/or under wet conditions, the Mn is in the soluble Mn^{2+} form and is readily available to plants. At pH values less than 5, oxidation–reduction is not as important as pH in determining Mn availability, but at pH values of 6–8, oxidation–reduction becomes very important. Plant roots themselves exude protons and chelating agents which can assist in mobilizing Mn. Solid soil organic matter can complex Mn with stability increasing at increasing pH.

Iron

Approximately 5.1% of soil on the average is Fe, but availability can be low in well-aerated soils. Soil Fe is derived from ferromagnesium silicates, which includes a great number of rock types. Mineral forms are oxides, hydroxides, and silicates, as well as amorphous oxides. These minerals take on forms such as goethite and hematite depending on the hydration status and crystalline form. The Fe released by weathering is redistributed into secondary

minerals. The solubility of soil Fe depends very much on pH. Iron is solubilized from solid Fe oxides and hydroxides by the following reaction with protons:

$$\text{Soil Fe} + 3H^+ = Fe^{3+} + 3H_2O \qquad [1]$$

In solution, Fe hydrolyzes to Fe^{3+}, $Fe(OH)_2^+$, and $Fe(OH)_4^-$, which is again dependent on the pH. As for Mn the oxidation–reduction status of the soil also affects Fe solubility. Figure 2 shows that, as for Mn, the more positive the redox potential, the less the Fe concentration in soil solution. The divalent form is more soluble than the trivalent form and is the form that plants absorb. But in well-aerated soils at pH values of approximately 6–8, the Fe is in the Fe^{3+} state and is relatively insoluble, with concentrations around 10^{-8}–10^{-3} mol l^{-1}. Submergence of soils can cause chemical reduction of Fe^{3+} to Fe^{2+}, resulting in Fe toxicity. However, damp soils can cause a decrease in the Fe absorption capacity of plant roots and affect bicarbonate in calcareous soils, decreasing uptake. Fe is strongly complexed by soil organic matter, and the soluble organic matter can increase the soil-solution Fe concentrations to 10^{-5}–10^{-3}. This soluble organic matter comes from solid organic matter degradation and from release of siderophores (nonprotein complexes) by plant roots and soil bacteria and fungi. Plants need Fe concentrations of the order of 10^{-4}–10^{-2}, so plants must have mechanisms to increase soil Fe availability. Plants have two strategies to increase Fe availability. What has been named strategy I is release of reductants to reduce Fe^{3+} to Fe^{2+}, and strategy II is release of Fe-binding organic ligands and protons to help solubilize soil Fe. Strategy II is used by grasses and strategy I by dicotyledons and nongraminaceous monocotyledons.

Boron

B and Mo are found in combination with oxygen in nature. A common mineral for B is borax, with the formula $Na_2B_4O_7 \cdot 10H_2O$. B is present in soil solution and in plants as boric acid ($B(OH)_3$), a compound that is considered an acid because it hydrolyzes according to the following reaction, producing hydronium ions:

$$B(OH)_3 + 2H_2O = B(OH)_4^- + H_3O^+ \qquad [2]$$

This ionic form is a very weak acid, which accepts OH^- ions; at usual soil and plant pH values, the acid is undissociated. The mechanism of uptake is not well understood. B has a narrow range of sufficiency to toxicity for plants. Plants need 0.01 mmol l^{-1} in soil solution, but 0.03 mmol l^{-1} is toxic to B-sensitive plants, which include citruses and peaches. Drought conditions in soil increase B deficiency in many crops, which was first noticed in sugar beet; B deficiency restricts root growth, having more severe effects than any of the other micronutrients. Drought also restricts the mineralization and availability of organically bound B.

One mineral that is known for its B content is tourmaline; however, it is so insoluble that it cannot be considered a B source for plants. Boron is found as a substitute for Si in other minerals, and the rate of weathering of these minerals is slow. Soils derived from granite and other igneous rocks are usually low in B content, whereas those derived from sedimentary rocks of marine origin are usually higher in B content. The mean concentration of B in the crust is 50 mg kg^{-1}. B is water-soluble and is easily leached from soils, so sandy, porous soils can often be B-deficient. Sandy soils have more B available to the plant at a given hot water-extractable level than finer-textured soils, because the B is bound more strongly by the clays and oxides in the finer-textured soils (Figure 3). B is sometimes toxic in arid and semiarid soils; the B content in irrigation water can cause B buildup in semiarid soils, leading to toxicity. As for most other micronutrients, high soil pH (6–9) causes low B availability. Higher pH levels mean higher adsorption on soil clays and oxides, thus liming can have a large effect on B availability. At lower pH values, the uncharged boric acid is not readily adsorbed and is held by ligand exchange; at higher pH values, the $B(OH)_4^-$ ion forms and is strongly adsorbed by electrostatic anion exchange. At low pH, soil B can become toxic to plants. Most B in the soil is contained in the organic matter and becomes more available as the conditions for microbial degradation become favorable, such as warmer temperatures, higher moisture, and better aeration. In organic soils such as peats and mucks, the availability can become too high as the B in the organic matter is

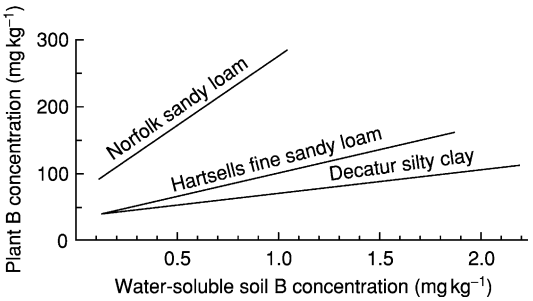

Figure 3 Plant boron (B) concentration versus water-soluble soil B concentration for three soils of different textures. (Adapted from Wear JJ and Patterson RM (1962) Effect of soil pH and texture on the availability of water-soluble boron in the soil. *Soil Science Society of America Proceedings* 26: 344–346, with permission.)

mineralized from the microbial biomass. B does not undergo oxidation–reduction reactions in soils.

Molybdenum

Mo concentrations are the lowest in soils of any of the micronutrients, being only 2.3 mg kg^{-1} on average in the crust. Soil Mo is derived more from shale and granite rocks, which are higher in content than sandstones or limestones. Soils that are very high in organic matter content, are alkaline, or are poorly drained are generally higher in Mo availability than other soils. Mo is different in its response to soil pH from the other micronutrients. As soil pH increases, the Mo plant availability also increases (Figure 4). Mo is adsorbed by Fe and Al oxides as the molybdate ion, MoO_4^{2-} at pH > 4.2, and this adsorption decreases at higher pH values. Thus, liming soils increases the uptake of Mo. Mo toxicity is rare in agricultural crops, but has been observed in controlled experiments and on peats and mucks that are poorly drained. Mo availability is higher in soils as the organic matter content or the Fe and Al oxide content decreases. Since Mo is so strongly associated with Fe and Al oxides through adsorption and precipitation, Mo availability is negatively correlated with the contents of Fe and Al oxides, whereas total Mo content may be positively correlated with Fe and Al oxide content. Oxidation and reduction processes do not affect Mo, so any oxidation–reduction effects on availability are indirect. Mo is needed by plants for nitrate reduction and symbiotic N-fixation by legumes. Deficiencies are usually on acid soils and are usually in legumes. Increases in soil moisture increase Mo availability due to decreased soil adsorption of MoO_4^{2-} under the higher soil pH conditions resulting from waterlogging. The reducing conditions caused by waterlogging reduce Fe^{3+} to Fe^{2+}, and Mo is less associated with the reduced form of Fe so therefore more available. Also, under wet conditions, Mo moves to the plant root more by mass flow than it does under drier conditions.

Micronutrient Soil Tests

This discussion will be limited to soil chemical testing, which is the major diagnostic tool used for both macronutrients and micronutrients, designed to predict micronutrient availability to the crop. If the soil is found to be nutrient-deficient, the test should give an indication of the severity of the deficiency and possible yield losses. Field calibration studies are carried out to estimate the amounts of micronutrient fertilizers to be added in response to a certain soil-test result. In interpreting soil-test data, a 'critical level' is used below which are expected yield responses to micronutrient fertilizers. One approach is the Cate–Nelson procedure, where a scatter diagram is formed from soil-test results on the *x*-axis and yields on the *y*-axis. Crossed lines are drawn such that a minimum number of points are in the upper left and lower right quadrants (Figure 5). The value found on the *x*-axis

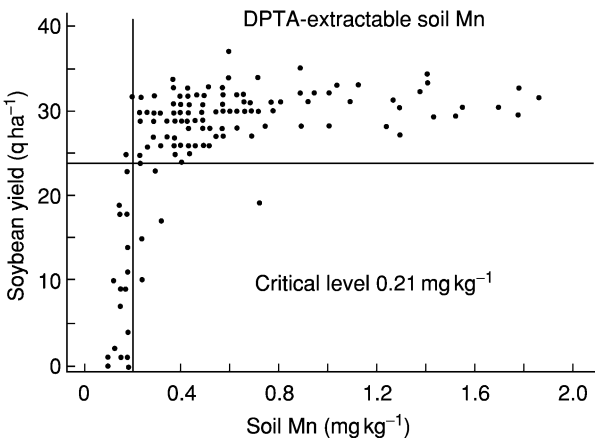

Figure 5 Cate–Nelson plot for soybean yield versus diethylenetriaminepentaacetic acid (DTPA)-extractable soil Mn. (Adapted from Shuman LM, Boswell FC, Ohki K, Parker MB, and Wilson DO (1982) Critical soil manganese deficiency levels for four extractants for soybeans grown in a sandy soil. *Soil Science Society of America Journal* 44: 1021–1025, with permission.)

is the critical level below which fertilizer is applied to keep yields at maximum. Another approach is correlation analysis. Since some micronutrients are very sensitive to pH, an approach often used is to have different critical levels for various pH levels. At times other soil properties are combined with soil-test results, but pH is usually the only value used.

Micronutrient soil tests should be able to extract, from the soil samples of the micronutrients in question in proportion to those taken up by plants; in other words, the samples should contain micronutrients in the same forms as those available to the plants. Soil is usually sampled in the root zone at approximately 0 to 15–20 cm. Soil tests should be accurate, repeatable, rapid, and correlated well with crop response from severe deficiency to sufficiency. Ideally a test will show differences in availability due to changes in soil properties such as pH or oxidation–reduction conditions. Soil tests are usually designed to remove the soluble and exchangeable forms, but in some instances they dissolve mineral forms that contain precipitated or occluded forms, as for Mo. These chemical extractants are usually fairly simple reagents such as water, dilute acids or bases, and salt solutions, and more recently include chelating agents such as diethylenetriaminepentaacetic acid (DTPA) or ethylenediaminetetraacetic acid (EDTA). Dilute acids commonly in use are 0.1 mol l^{-1} HCl, and an acid mixture of 0.025 mol l^{-1} H_2SO_4 and 0.05 mol l^{-1} HCl (Mehlich 1). These acids are used on acid soils to dissociate, displace, or dissolve the cations from soil clays, oxides, or organic matter. The chelating agent DTPA is found in Mehlich 3, DTPA, and AB-DTPA; and EDTA is in the acid ammonium acetate–EDTA extractant. All these tests extract multielements. Chelates promote extraction from surfaces of clays, oxides, and organic matter. See Table 1 for commonly used micronutrient soil tests, with the deficiency critical ranges for each.

Zn is usually extracted using a multielement extractant, e.g., Mehlich 1 and 3, AB-DTPA, and 0.1 mol l^{-1} HCl. Some of these are used in conjunction with soil pH tests. Cu deficiencies are rare, but Cu is routinely tested using the same extractants as for Zn. Since Cu binds readily with organics, the better extractants are those with chelating agents. For Mn, dilute acids and chelating agents are both used, such as in Mehlich 1 and 3, 0.1 mol l^{-1} HCl, 0.03 mol l^{-1} H_3PO_4, and DTPA tests. Soil pH is often used with these extractants, using a 'sliding scale' for critical levels based on soil pH. Some chelating reagents such as DTPA and AB-DTPA were designed for use with Fe. The dilute acids mentioned are also used for Fe extraction as a soil test. Hot water was found to be a good soil test extractant for B in 1939 and it is still in use today. Mo is associated with oxides and is extracted by acid ammonium oxalate, which also extracts Fe and Al oxides. Soil pH is a big factor in Mo deficiency, so is often used in conjunction with the soil test.

Table 1 Major soil diagnostic tests and critical ranges for deficiency

Micronutrient	*Soil-test method*	*Critical range*
Zinc	AB-DTPA	0.5–1.0 mg kg^{-1}
	DTPA	0.2–2.0 mg kg^{-1}
	Mehlich 1	0.5–3.0 mg kg^{-1}
	Mehlich 3	1.0–2.0 mg kg^{-1}
	0.1 mol l^{-1} HCl	1.0–5.0 mg kg^{-1}
Copper	AB-DTPA	0.5–2.5 mg kg^{-1}
	DTPA	0.1–2.5 mg kg^{-1}
	Mehlich 1	0.1–10 mg kg^{-1}
	Mehlich 3	0.3–15 mg kg^{-1}
	0.1 mol l^{-1} HCl	0.1–2.0 mg kg^{-1}
Manganese	AB-DTPA	0.5–5.0 mg kg^{-1}
	DTPA	1.0–5.0 mg kg^{-1}
	Mehlich 1	5.0 mg kg^{-1} at pH 6 10 mg kg^{-1} at pH 7
	Mehlich 3	4.0 mg kg^{-1} at pH 6 8.0 mg kg^{-1} at pH 7
	0.1 mol l^{-1} HCl	1.0–4.0 mg kg^{-1}
Iron	AB-DTPA	4.0–5.0 mg kg^{-1}
	DTPA	2.5–5.0 mg kg^{-1}
Boron	Hot water	0.1–2.0 mg kg^{-1}
	Mehlich 3	0.7–3.0 mg kg^{-1}
Molybdenum	Ammonium oxalate–pH 3.3	0.1–0.3 mg kg^{-1}

Micronutrient Fertilizers

Micronutrient fertilizers include four major types: inorganic salts, synthetic chelates, natural organic complexes, and frits. Certainly the most commonly used are the inorganic sources, since they are the least expensive (Table 2). These include oxides, carbonates, and metallic salts such as the sulfates, chlorides, and nitrates. Manganese oxide and zinc oxide are used to some extent, but are relatively insoluble and become available over a long period of time. The sulfates of Zn, Cu, Mn, and Fe are the most common fertilizers in use, being quite soluble and immediately available to the crop. For B, borax is the fertilizer of choice, and for Mo it is sodium molybdate.

The synthetic chelates include *N*-hydroxylethylenediaminetriacetic acid (HEDTA) and EDTA, with EDTA salts being the most commonly used (Table 3). The rates of chelate application are about two to five times less than inorganic sources, but the cost is 5–100 times greater. The chelates are usually

Table 2 Inorganic fertilizer sources for micronutrient fertilizers

Micronutrient source	*Solubility in water*	*Element concentration (%)*
Zinc		
$ZnSO_4 \cdot H_2O$	Soluble	36

sold as liquid preparations so are sprayed either on the soil or directly on the crop. Elements applied as chelates are Zn and Fe. Manganese chelate can be sprayed on a growing crop, but, when applied to the soil, the Mn is quickly replaced by Fe and the Mn is ineffective. The high concentrations of Fe in the soil solution cause Fe to replace the Mn on the organic chelate molecule.

Natural organic sources most often in use are the lignosulfonate complexes made from a by-product of the wood-pulping process in paper mills. These complexes are cheaper than synthetic chelates, but are also not as effective because they are readily decomposed in the soil. Inorganic salts are reacted with these organic by-products to form complexes. The elements applied with natural chelates are Zn and Fe.

The last major fertilizer type is frits. These are glass beads with micronutrients occluded in them by melting sand with the inorganic salts added. Like the oxides, these slowly release the micronutrients and are used for maintenance. They are most often applied in sandy soils with a high water table, where leaching of soluble salts is likely to move elements below the root zone before they can be taken up by the plant.

Finally, another source is industrial waste products that contain micronutrients, such as wastes from the steel industry. Even farm manures can be micronutrient sources; for example, pig manure is high in Cu and poultry manure high in Zn.

List of Technical Nomenclature

AB-DTPA A soil-testing method using a solution of $1.0\,mol\,l^{-1}$ ammonium bicarbonate (NH_4HCO_3) and the DTPA soil test solution buffered at a pH of 7.6

DTPA Diethylenetriaminepentaacetic acid

DTPA	A soil-testing method using a solution of $0.005\,mol\,l^{-1}$ DTPA and $0.01\,mol\,l^{-1}$ $CaCl_2$ buffered at a pH of 7.3 by $0.1\,mol\,l^{-1}$ triethanolamine (TEA)
EDDHA	Ethylenediaminedi(*o*-hydroxyphenylacetic) acid
EDTA	Ethylenediaminetetraacetic acid
HEDTA	*N*-Hydroxyethyl-ethylenediaminetriacetic acid
Mehlich 1	A soil-testing method using a solution of $0.0125\,mol\,l^{-1}\,H_2SO_4 + 0.05\,mol\,l^{-1}$ HCl
Mehlich 3	A soil-testing method using a solution of $0.2\,mol\,l^{-1}\,CH_3COOH + 0.25\,mol\,l^{-1}$ $NH_4F + 0.013\,mol\,l^{-1}\,HNO_3 +$ $0.001\,mol\,l^{-1}$ EDTA $+ 0.25\,mol\,l^{-1}$ NH_4NO_3
NTA	Nitrilotriacetic acid
pCu	Negative $\log_{10}$ of the Cu concentration in solution in moles per liter
pH	Negative $\log_{10}$ of the H^+ concentration in solution in moles per liter

Introduction

Minerals, organic components, and microorganisms are three major solid components of the soil. They profoundly affect the physical, chemical, and biological properties, and processes of terrestrial ecosystems. They should not be considered as separate entities but rather as a united system constantly in close association and interactions with each other in soil environments.

Interactions of these three solid components mediated by soil solution and atmosphere govern mineral weathering transformation, the formation of organo–mineral complexes, microbial and enzymatic activities, soil structural stability and dynamics of aggregate turnover, biogeochemical cycling of C, N, P, and S, and transformation and dynamics of organic pollutants and metals. Therefore, interactions of these components have enormous impacts on terrestrial processes critical to environmental quality and ecosystem health.

Mechanisms of Binding of Organic Matter by Soil Mineral Colloids

Nature of Mineral Colloid Surfaces

The surface properties of soils are dependent on the weathering processes of the parent materials that are initiated by geological, hydrological, and biological agents. Therefore, soil formation processes have a tremendous impact on the formation and modification of surface properties of soils. The surface of 2:1 expansible layer silicates is negatively charged. The ditrigonal cavities of the surface can thus adsorb positively charged ions and polymers to form hydroxy-interlayered minerals in soil and related environments

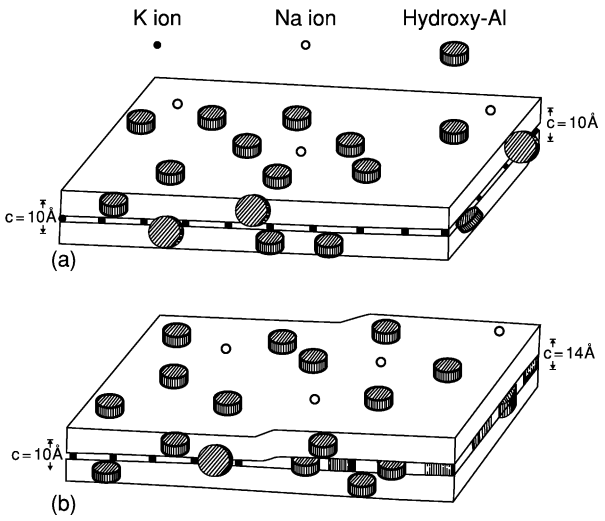

Figure 1 Structural models depicting the hydroxy-Al coatings on external surfaces (a) edge and planar surfaces of micas; and (b) of mica-vermiculite and on interlamellar surfaces of K-depleted layers of mica-vermiculite. Reproduced with permission from Huang PM (1980) Adsorption processes in soil. In: Hutzinger O (ed.) *The Handbook of Environmental Chemistry*, vol. 2/part A. *Reactions and Processes*, pp. 47–59. Berlin: Springer-Verlag.

(Figure 1). These hydroxy-interlayered minerals occur in soils throughout the world and are present in soils of several orders of soil taxonomy systems. In addition, positively charged hydroxy polymers can be adsorbed on the edges and external surfaces of phyllosilicates (Figure 1).

The complexity of surface properties of soil mineral colloids is further manifested by the formation of iron oxyhydroxide or calcium carbonate coatings on the external surfaces of layer silicates, the growth of two-dimensional solid solutions of trace metal oxides on the periphery of Mn oxide nodules, and the coating of calcium carbonate on Mn oxides. Similar effects can occur on the surfaces of other minerals in soils. The surfaces of soil mineral colloids can also complex with organic matter through the formation of inner-sphere and/or outer-sphere complexes. The surface complexation reactions may result in the formation of thick envelopes of colloidal organics on metal oxides and aluminosilicates. Therefore, the surface chemistry of soil minerals is mainly that of the functional groups exposed on the coatings rather than that of the groups in the underlying matrix. The surface chemistry of soil mineral colloids has a very significant effect on the transformation and dynamics of organic matter in soils.

Binding of Organic Matter

Organic molecules interact with the surfaces of mineral colloids by a variety of mechanisms, as summarized below. The reaction mechanisms mainly depend on the intrinsic nature and properties of the organic species, the kind of exchangeable cation on the surface of the mineral, the water content of the system, and the properties of mineral colloids.

Ion exchange Organic cations such as protonated amines and quarternary ammonium cations will enter into exchange reactions with metal cations on the surfaces of mineral colloids. Organic cations are often preferred over metal cations because of size considerations.

Protonation Some organic molecules may become cationic after adsorption at the surfaces of mineral colloids by protonation. The relative basicity of the organic species and the Brønsted acidity of the mineral surface determine whether or not protonation happens. The degree of protonation of the organic molecule is determined by its intrinsic basicity and the ability of the surfaces of the mineral colloids to donate protons. The nature of exchangeable cation, the water content, and the nature of mineral colloids play an important role in influencing the degree of protonation of organic molecules.

Coordination and ion dipole Coordination or ion–dipole interaction is another kind of mineral colloid–organic interaction. Where exchangeable cations are of the transition metal type, unfilled d orbitals will allow the formation of coordinate covalent bonds wherein an electron donor such as N or O on functional groups of organic molecules is available as a ligand. Where exchangeable cations are not able to form classical coordination complexes, they will interact with polar molecules through ion–dipole interaction processes.

Hydrogen bonding Hydrogen bonding is another type of interaction which is possible between organic molecules and mineral surfaces. Where a polar organic molecule cannot displace a water molecule solvating an exchangeable metal cation, it settles for a secondary role by H bonding with the directly coordinated water. This type of arrangement is referred to as 'water bridge,' where water acts as the linking entity between an exchangeable metal cation and a polar organic molecule.

Hydrophobic bonding on clay–organic complexes Natural clay–organic complexes may have adsorption properties quite different from pure clays. Many organic molecules, including aromatics and particularly the halogenated types such as chlorinated and brominated phenyls and biphenyls, are adsorbed a little, if at all, on clay surfaces. The surfaces of clays

can be made hydrophobic after reaction with organic molecules which have some hydrophobic properties. When this happens, the surfaces of clay–organic complexes become hydrophobic and in turn organophilic. Therefore, hydrophobic portions of the organic adsorbate can react with the hydrophobic organic portions of clay–organic complexes.

Anion adsorption Although pure clay minerals are negatively charged, hydroxy-interlayered clay minerals have positively charged sites (Figure 1). Organic anions can interact with polyvalent cations such as Al and Fe on the surface coatings of clay minerals.

Adsorption on external mineral surfaces The extent of adsorption of organic matter on external mineral surfaces depends on the physical and chemical characteristics of the surface, the pH of the system, and its water contents. Complexation reactions of humic acid (HA) and fulvic acid (FA) with structural cations of edges of mineral colloids are important binding mechanisms. Hydrogen bonding, which apparently involves H and O of COOH and OH groups of HA and FA and O and H of external planar surfaces and edges, is also of considerable importance.

Adsorption in clay interlayers Interlayer adsorption of FA by expansible silicates is pH-dependent, being greatest at low pH, and no longer occurring at pH 5.0 (Figure 2). An inflection occurs in the adsorption–pH curve near the pH corresponding to the pK of FA. Since the degree of dissociation of the FA is very low at low pH, undissociated FA can penetrate the clay interlayer and displace water coordinated to the cation in the interlayer. Therefore, interlayer adsorption of FA is greatest at low pH. One of the well-defined precursors for the formation of humic substances, hydroquinone, can be transformed in aqueous solution even at near-neutral pH (6.5) to humic macromolecules and adsorbed in the interlayers of nontronite (Fe(III)-bearing smectite) saturated with Ca (Figure 3); this is the most common and most abundant exchangeable cation in soils and sediments. The decrease in the organic carbon contents of the complex on heating between 150 and 500°C is accompanied by a decrease in basal *d* values. Most of the interlayer humic macromolecules are highly resistant to alkali extraction and are, thus, humin-type materials. Therefore, the formation of humic substance interlayers in 2:1 expansible-layer silicates, through polymerization of phenol monomers and associated reactions in soils and sediments, deserves close attention.

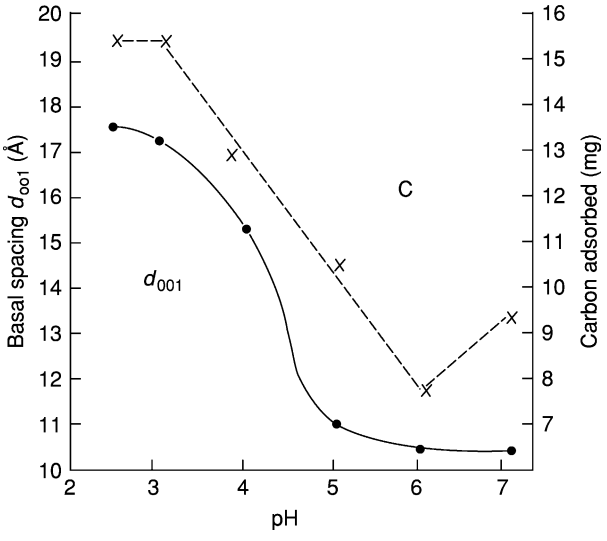

Figure 2 Effect of pH on basal spacing (d_{001}) and adsorption of fulvic acid. Reproduced with permission from Schnitzer M and Kodama H (1966) Montmorillonite: effect of pH on its adsorption of a soil humic compound. *Science* 153: 70–71.

Influence of Organic Matter on the Formation and Surface Chemistry of Metal Oxides

Metal oxides play a significant role in influencing soil behavior. They may exist as crystalline minerals, short-range ordered minerals, or noncrystalline precipitates which form surface coatings on clay minerals and humic substances. Organic components exert an important influence on the formation and surface properties of metal oxides.

Aluminum Oxides

The influence of a particular organic acid is generally related to the stability constant of the complex that the acid forms with Al (Table 1). Therefore, *p*-hydroxybenzoic acid, which forms the least stable complex with Al, does not inhibit the crystallization of Al hydroxides, whereas aspartic, tannic, malic, and citric acids increasingly retard crystallization. Besides the stability constant of the complex, the concentration of the organic acid is important. At certain low concentrations, the presence of some organic acids actually promotes the crystallization of particular $Al(OH)_3$ polymorphs by catalysis, but above a critical concentration, it disrupts crystallization through complexation with Al.

Humic substances also influence the transformation of Al by hampering the formation of more crystalline phases and promoting the formation of microcrystalline boehmite. FA and HA resemble aliphatic acids such as citric and malic acids, in that they contain COOH and aliphatic OH groups. They also resemble quercetin and tannic acid, because they contain phenolic

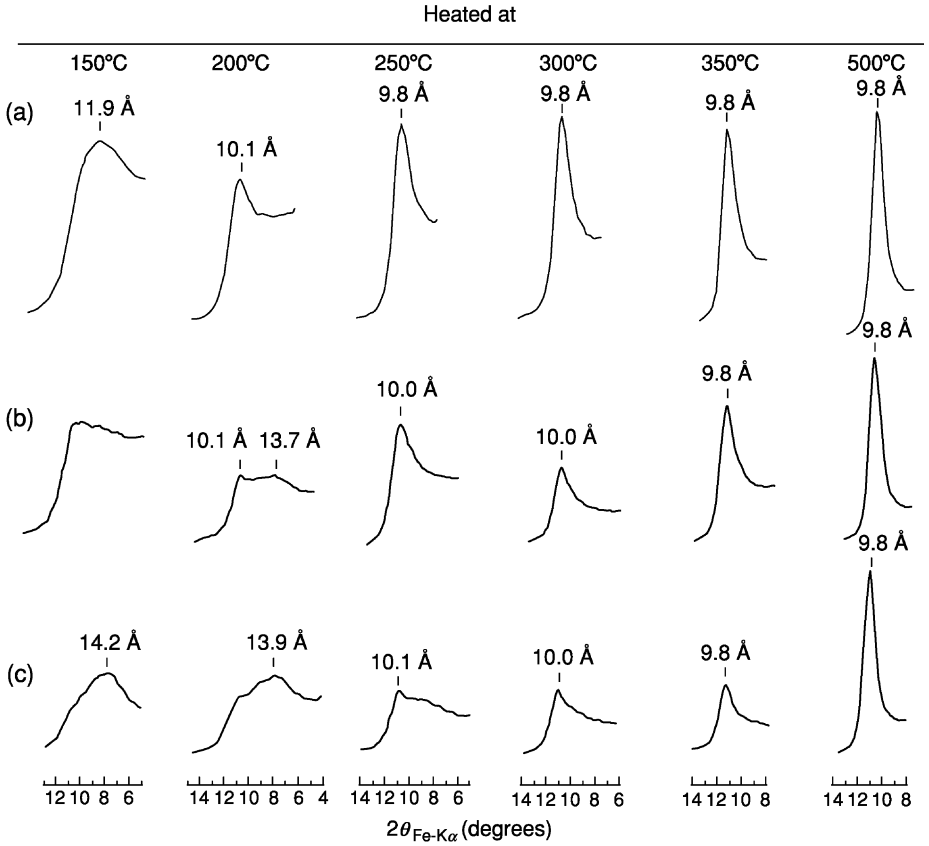

Figure 3 X-ray diffractograms of Ca-nontronite, influenced by deposition of humic macromolecules in the interlayers through polymerization of hydroquinone and the associated reactions. Diffractograms were recorded on a Philips X-ray diffractometer using Fe-Kα radiation with an Mn filter. hydroxyl and ketonic C=O groups. Through these functional groups, FA and HA form stable complexes and inhibit the crystallization of Al hydroxides.

Organic components have an enormous impact on the surface properties of Al transformation products. For example, the presence of organic acids during aging of Al hydroxide gel for 40 days increases the specific surface of the products up to 30-fold over that of the control and higher organic acid concentrations result in higher specific surface. The surface charge characteristics of the products also dramatically change. The intermediate transformation products of Al, which include soluble mononuclear and polynuclear Al species and colloidal short-range ordered Al hydroxides, are the most reactive Al species in influencing physical, chemical, and biological processes of soil and related environments.

Iron Oxides

Soil organic matter plays a vital role in the formation of pedogenic Fe oxides (Figure 4). In soil environments where the amount of organic matter is low, for example in subsoils, the Fe supplied will form goethite and hematite depending on environmental factors. As organic matter content increases, more of the Fe will be complexed with organics, leading to decreases of Fe activity. The activity of Fe(III) ions

is so low that only the solubility product of goethite (10^{-41} to 10^{-42}), but not the solubility product of ferrihydrite (10^{-37} to 10^{-39}) is exceeded. Consequently, goethite but not ferrihydrite may form. Therefore, no hematite will form in an environment where the organic matter is high, since ferrihydrite is deemed to be a necessary precursor for hematite. This trend is generally observed in soils in temperate and cool regions as well as in wet depressions and surface soils of subtropical and tropical regions. At a higher content of organic matter, the rate of Fe supply is high; ferrihydrite will form and may survive for pedogenic times. If the content of organic matter is even higher, such as in O horizons or in peaty environments, all of the Fe may be in the form of Fe–organic complexes.

In an aqueous weathering environment, Fe oxides generally form via solution transformation. The oxidation products of Fe(II) solutions are thus important because it is in this valence state that Fe is commonly mobilized during weathering under the *E*h-pH region of natural soil environments. The kinetics of Fe(II) oxidation and the nature of Fe oxides are greatly influenced by a series of organic ligands. The rate constant of Fe(II) oxidation at the same ligand/Fe molar ratio generally decreases with the increase in the stability constant of the Fe(II)–ligand complex. The rate constant of Fe(II) oxidation also decreases with the increase in the perturbing ligand/Fe(II) molar ratio due to the increasing formation of the Fe(II)–ligand complex. The retardation of Fe(II) oxidation inhibits the nucleation of goethite and promotes the crystal growth of lepidocrocite. A further increase in the amount of the perturbing ligand distorts the structural order, resulting in the increasing inhibition of crystal growth of lepidocrocite and the formation of noncrystalline Fe oxides.

Surface properties of Fe oxides have a profound impact on microaggregate formation, water flux, nutrient and pollutant flux, and the ability of soils to promote plant growth, to maintain reasonable soil biotic habitat, and to respond to management, and resist degradation. The specific surface, charge characteristics, mean surface roughness, fractal dimension, and microporosity of Fe oxides depend on the nature and concentration of organic substances in the solution in which the Fe oxides are formed.

Role of Soil Minerals in Abiotic Catalysis of the Formation of Humic Substances

Polyphenol Pathway

Soil minerals play an important role in catalyzing the abiotic polymerization of phenolic compounds and the polycondensation of phenolic compounds and amino acids and the subsequent formation of humic substances. Layer silicates have the ability to catalyze the abiotic formation of humic substances. The promoting effect of 2:1 layer silicates is higher than 1:1 layer silicates. This is attributed to the higher specific surface and higher lattice imperfection of the former than the latter. The edges of kaolinite are virtually the only catalytic sites for the formation of phenol-derived humic substances. The edges of nontronite have a very important role as catalytic sites in the formation of hydroquinone-derived humic macromolecules. The Fe(III) in the octahedral sheet of nontronite also serves as a Lewis acid site to catalyze the oxidative polymerization of hydroquinone.

Aluminum, Fe, and Mn oxides, hydroxides, and oxyhydroxides also catalyze the oxidative polymerization of phenolic compounds. Among these minerals, Mn oxides are the most powerful catalysts in the transformation of phenolic compounds. Manganese oxides (birnessite, cryptomelane, and pyrolusite), which are common in soils, act as Lewis acids that accept electrons from phenolic compounds, leading to their formation of semiquinone and their oxidative polymerization and formation of humic substances. The catalytic power of metal oxides in affecting the C turnover and humic substances formation via abiotic processes in soil and related environments merits attention.

Poorly crystalline aluminosilicates are common in soils. Allophane has the ability to catalyze the polymerization of polyphenols. Proto-imogolite sol, which is present in soil solution, also plays a role in the abiotic formation of humic substances.

Primary minerals differ in their ability to catalyze the abiotic polymerization of hydroquinone. The sequence of the catalytic power of primary minerals is tephroite > actinolite > hornblende > fayalite > augite > biotite > muscovite ≃ albite ≃ orthoclase ≃ microcline ≃ quartz.

Maillard Reaction

The Maillard reaction is considered to be a major pathway in humification because of significant similarities between humic substances and melanoidins formed through this pathway, involving sugar–amino acid condensation. Birnessite (δ-MnO_2) significantly increases the extent of humification of the glucose–glycine system over the pH range of 6–8 (Figure 5). The chemical shifts of FA formed in the Maillard reaction system resemble those of natural humic substances. Further, light intensity of 168 μE $s^{-1}m^{-2}$ exerts an increase in the browning of the glucose–glycine–birnessite system compared with the same system kept in the dark. Equally important is that, even in complete darkness, birnessite catalyzes the Maillard reaction between glucose and glycine. Therefore, birnessite catalysis can occur in soil and sediment environments at any depth, but the presence of sunlight should accelerate the reaction.

Interactions of Soil Mineral Colloids with Microorganisms and Enzymes

Surface Interactions of Soil Minerals with Microorganisms

Soil is a habitat for myriads of microorganisms. The microbial biomass constitutes only a very small proportion (3%) of the total organic carbon in soil, but it is the most active and dynamic fraction of the living organic pool. Among the inorganic components of soil, mineral colloids are the most reactive because of their large specific surface and reactive charge characteristics. Being enriched in ions, water, and organic matter relative to the bulk soil, the surface of mineral colloids serves as a preferred habitat for soil microorganisms. Complex formation between mineral colloids and microorganisms can and does occur.

The surfaces of bacterial cells and crystalline clay minerals are both negatively charged. However, bacteria have a propensity for producing extracellular polysaccharides (EPS) which bind simultaneously

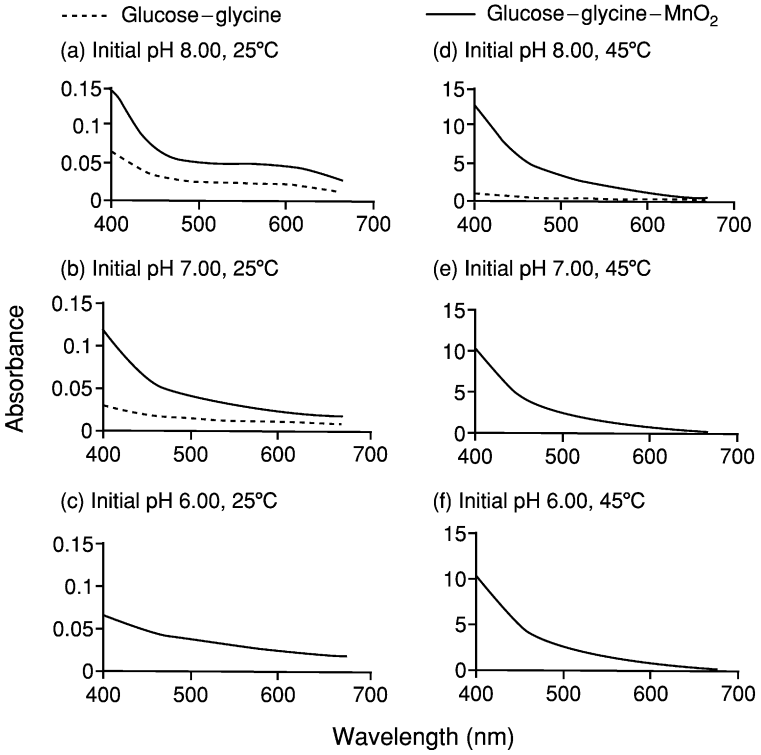

Figure 5 Absorbance versus wavelength plots in the Maillard reaction between glucose and glycine as influenced by birnessite catalysis. (a), (b), and (c): 30-day reaction period. (d), (e) and (f): 15-day reaction period. Reproduced with permission from Jokic A, Frenkel AI, Vairavamurthy MA, and Huang PM (2001) Birnessite catalysis of the Maillard reaction: its significance in natural humification. *Geophysical Research Letter* 28: 3899–3902.

to cell and clay surfaces through 'cation bridging,' involving polyvalent cations (Figure 6). Further, mineral colloids in soils are generally coated with hydroxy Al (or Fe) polymers (Figure 1). These coated minerals thus behave as a positively charged species or display amphoteric characteristics. Therefore, mineral colloids can strongly interact with negatively charged microbial cells in soil environments. This type of bonding, which is much stronger than cation bridging, is also expected to occur with Al and Fe oxides over the pH range of soils. The attachment of microorganisms to short-range minerals and the crystal edges of layer silicates through electrostatic interactions would also be predicted to occur when the soil pH falls below 6 because all of these surfaces would then be largely positively charged.

In the majority of cases, minerals in topsoils are partially covered with organic materials, especially humic substances (HS), which are microbially resistant and the most prevalent. The most common mode of mineral colloid–organic material–microorganism interactions may be represented by the following scheme:

$$[\text{Mineral colloid} - \text{HS}]^{-} \ldots . \text{M}^{n+} \ldots .^{-} [\text{EPS} - \text{B}]$$

In humic-rich calcareous Mollisols, Ca would be the predominant bridging cation. In Andisols, Oxisols, Ultisols, and the B horizon of spodosols, HS largely occur as complexes with Al and Fe, or their respective poorly crystalline oxides. In soils with little organic matter and in subsoils, mineral colloid–microorganism interactions are largely influenced by the mineralogical composition and pH of the system.

Mineral colloids can directly or indirectly influence the activity of microorganisms in their immediate vicinity. The effect of mineral colloids may be positive, negative, or sometimes so small as to escape detection. Mineral colloids have a stimulating effect on the activity of adhering bacteria by keeping the pH of microhabitats within the optimum physiological

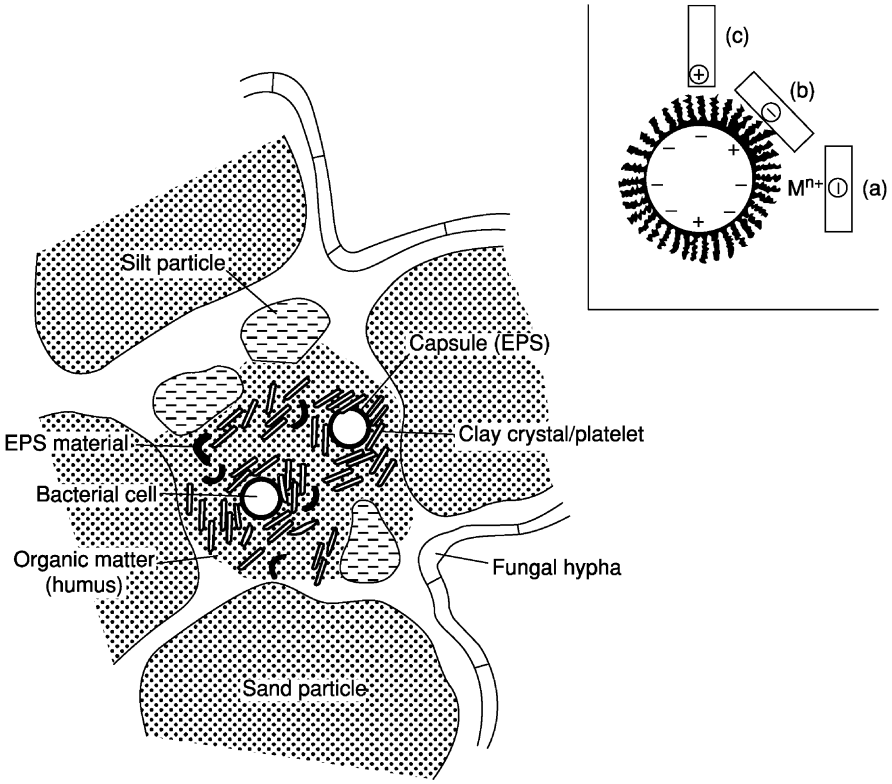

Figure 6 Diagram illustrating the interaction of bacteria and fungi with mineral particles in a soil aggregate. Bacterial cells with a coat of extracellular polysaccharides (EPS) are enveloped by clay particles. The pore space where clays and bacteria interact, bounded by silt- and sand-size particles, is relatively enriched in organic matter, including EPS residues. Fungal hyphae are attached to the outside surface of an aggregate. Inset: an enlarged view of a bacterial cell with its complement of EPS. At normal soil pH conditions, the cell has a net negative surface charge. Most clay particles adhere to the cell surface by bridging through polyvalent cations, represented by M^{n+} (a), although some may be attached directly by electrostatic interactions, either in a face-to-face (b), or edge-to-face (c) association. Reproduced with permission from Theng BKG and Orchard VA (1995) Interactions of clays with microorganisms and bacterial survival in soil: a physicochemical perspectives. In: Huang PM, Berthelin J, Bollag J-M, McGill WB, and Page AL (eds) *Environmental Impact of Soil Component Interactions*, vol. II. *Metals, Other Inorganics and Microbial Activities*, pp. 123–143. Boca Raton, FL: CRC/Lewis.

range for growth. Mineral colloids can also stimulate microbial activity by sorbing metabolites that would otherwise have an adverse effect on microbial growth. Further, the surfaces of mineral colloids can adsorb other toxic substances to microorganisms such as antibiotics and pesticides.

By forming an envelope around bacterial cells, mineral colloids may provide protection from extreme fluctuations in physicochemical environments, and thus enhance bacterial survival. The protective effect of mineral colloids, especially montmorillonite, is manifested in the ability of soil microorganisms to withstand exposure to hypertonic osmotic pressure, desiccation, and ultraviolet radiation. Mineral colloids can also act as a cementing agent of soil particles. Therefore, the addition of clay to soils, especially those of light texture, would modify the spatial arrangement of particles and especially the pore size distribution within soil aggregates. Such a modification of aggregate structure often benefits the bacterial population by increasing the proportion of pores of a certain size range ($<6\ \mu$m) from which bacteria could freely enter to colonize pores. However, bacterial predators – notably protozoa – are effectively barred from entering such pores due to steric hindrance.

The content and type of mineral colloids are influential in determining the balance between different microbial populations in soil. A well-known example is the failure of some fungi to thrive and spread in certain soils. This is largely attributed to the presence of montmorillonite in the 'suppressive' soils. Montmorillonite can serve as a proton sink and is thus able to promote the growth of acid-sensitive bacteria in these soils. This gives bacteria a selective advantage over fungi in competing for available nutrients, and fungal growth and proliferation are, thus, effectively suppressed.

Formation of Mineral Colloid– and Humic–Enzyme Complexes

Enzymes are rapidly sorbed at mineral colloids and humic substances in soil environments. Mineral colloids have a high affinity for enzymes, although this is not always synonymous with the retention of their enzymatic activity. Enzymes associated with soil humic substances retain their catalytic activity for long periods.

The mechanisms whereby enzymes are retained by mineral colloids have usually been assumed to include cation exchange reactions but not all observations have supported this view. Therefore, besides cation exchange reactions, adsorption of enzymes by mineral colloids may proceed through ionic, covalent, hydrophobic, and hydrogen bonding, and van der Waals forces. Although individual van der Waals forces are regarded as weak, retention may be cumulative if the enzyme is in close contact with the adsorbing surface. Recent studies show that enzymes such as tyrosinase have a very high affinity to the surfaces of hydrous manganese oxide birnessite. Analysis by atomic force microscopy (AFM) clearly shows the unfolding in an ellipsoidal shape of the tyrosinase protein after adsorption and immobilization on the mineral surfaces, especially the frayed edges of the phyllomanganate layer. AFM pictures along with X-ray diffraction and infrared absorption data of the tyrosinase protein complex show the coating of the mineral surfaces by the protein molecules as well as the changes in protein conformation.

Enzymes adsorbed or immobilized on mineral colloids operate in a structurally restricted system. The behavior of such enzymes toward their respective substrate is, thus, different from that occurring in a homogeneous, aqueous solution. When enzymes are adsorbed on mineral colloids, changes in the tertiary structure of the enzymes and their active sites decrease the activity or eliminate it altogether. However, there are notable exceptions to the 'adsorption-decline in activity' rule. Various supports show different enzyme immobilization capabilities (Table 2). There is considerable variation in the retained activities of the enzymes immobilized. The residual specific activities of laccase and peroxidase immobilized on all supports are high. Further, laccase immobilized on montmorillonite shows specific activity higher than that of the free enzymes. This is attributed to steric modification of the immobilized enzymes.

Many mechanisms have been proposed to account for the stability of enzymes which are complexed with soil humic substances. These include ion exchange, H-bonding, entrapment within three-dimensional micelles, lipophilic reactions, and covalent bonding during organic matter genesis. Functional groups of enzymes implicated in covalent bonding to humic polymers include terminal and basic amino, carboxyl, sulfhydryl, phenolic, and imidazole groups. All these may be involved in the stabilization process provided they do not form part of the active sites of the enzymes and not crucial to the retention of its tertiary structure. Enzyme–humic complexes can also be attached to mineral colloids and in some instances this further enhances enzyme stability.

Soil Mineral Weathering Transformations as Influenced by Microbial Activity

Mineral Weathering

Mineral weathering reactions can be enhanced by microbial activity by a factor as high as 10^6.

Table 2 Immobilization of a laccase (from *Trametes versicolor*) and a peroxidase (from horseradish) on different supports

		Enzymatic activity		
Enzyme and support	*Protein adsorbed*[a] *(mg/%)*	*Units adsorbed*[b]	*Specific activity*[c]	*Residual specific activity*[d] *(%)*
Laccase

Microorganisms can dissolve minerals by direct and indirect action under aerobic and anaerobic conditions. The modes of attack of minerals by microorganisms include: (1) direct enzymatic oxidation or reduction of a reduced or oxidized mineral components; (2) indirect attack with a metabolically produced redox agent or inorganic and organic acids; (3) indirect attack by metabolically produced alkali, usually in the form of ammonia; (4) indirect attack with a metabolically produced ligand that forms a highly soluble product with a mineral component; and (5) indirect attack by biopolymers. The mode of microbial attack of a mineral may involve a combination of some of these mechanisms.

Uptake and concentration of elements by absorption and/or adsorption were observed with bacteria and fungi for P, Ca, Fe, and K. Fungi can adsorb K from solution, shift K equilibrium, and transfer micas to vermiculites. Such process can also occur for major and trace elements. When oxidized metal compounds such as Fe(III), Mn(IV), and As(V) act as electron acceptors, anaerobic respiration becomes an example of direct dissolving action under anaerobic conditions. Oxidation of sulfur entities of metal sulfides to obtain energy is an example of direct dissolving action under aerobic conditions. Volatilization of metals and metalloids or biomethylated metal and metalloid compounds from the soil into the atmosphere can be a mechanism of detoxification for toxic elements such as Hg, As, and Se.

Fine-Grained Mineral Formation

The physical and chemical characteristics of bacteria, such as their large surface area-to-volume ratio, serve to increase the metal-binding capacity of their charged surfaces, leading to precipitation and formation of mineral phases on their cell walls or surface polymers. The mechanisms by which bacteria initiate the formation of minerals in bulk solution vary widely between species. There may be a combination of biochemical and surface-mediated reactions during the process. Bacteria surface layers may passively adsorb and indirectly serve as a nucleation template. Bacteria can also more directly initiate mineral precipitation by producing reactive compounds, such as enzymes, metallothioneins, and siderophores, which bind metals and metalloids and catalyze their transformations. In addition, bacteria can instigate the spontaneous precipitation of metals and metalloids by altering the chemistry of their microenvironments.

An example of microbially mediated fine-grained mineral development is the formation of Mn oxides. Microbial oxidation of Mn(II) is a major process that can produce Mn oxide coatings on soil particles 10^5 times faster than abiotic oxidation. Manganese oxides are highly reactive minerals and can restrict the mobility of metals in soil and related environments. Biogenic Mn oxides have significantly larger specific surface and higher Pb adsorption capacity than abiotically precipitated Mn oxides. Bioformation of minerals thus merits attention in the remediation of metal contamination in the environment.

Impacts of Mineral–Organic Matter–Microbe Interactions on Soils in the Environment

Soil Structural Stability

The processes by which soil organic matter strengthens the bonds between soil mineral particles

are complicated. Root exudation and microbial action produce organic compounds with a range of composition and molecular weights. These compounds interact with the mineral particles which also vary in size, shape, crystallinity, and electric charge. Interactions between soil mineral particles, organic substances, and microorganisms can occur at many different size scales, since the materials have a large size range in soils (Figure 7). The mechanisms for stabilization of soil structure vary with aggregate size.

The adsorption of organic molecules such as microbially derived polysaccharides and other unaltered

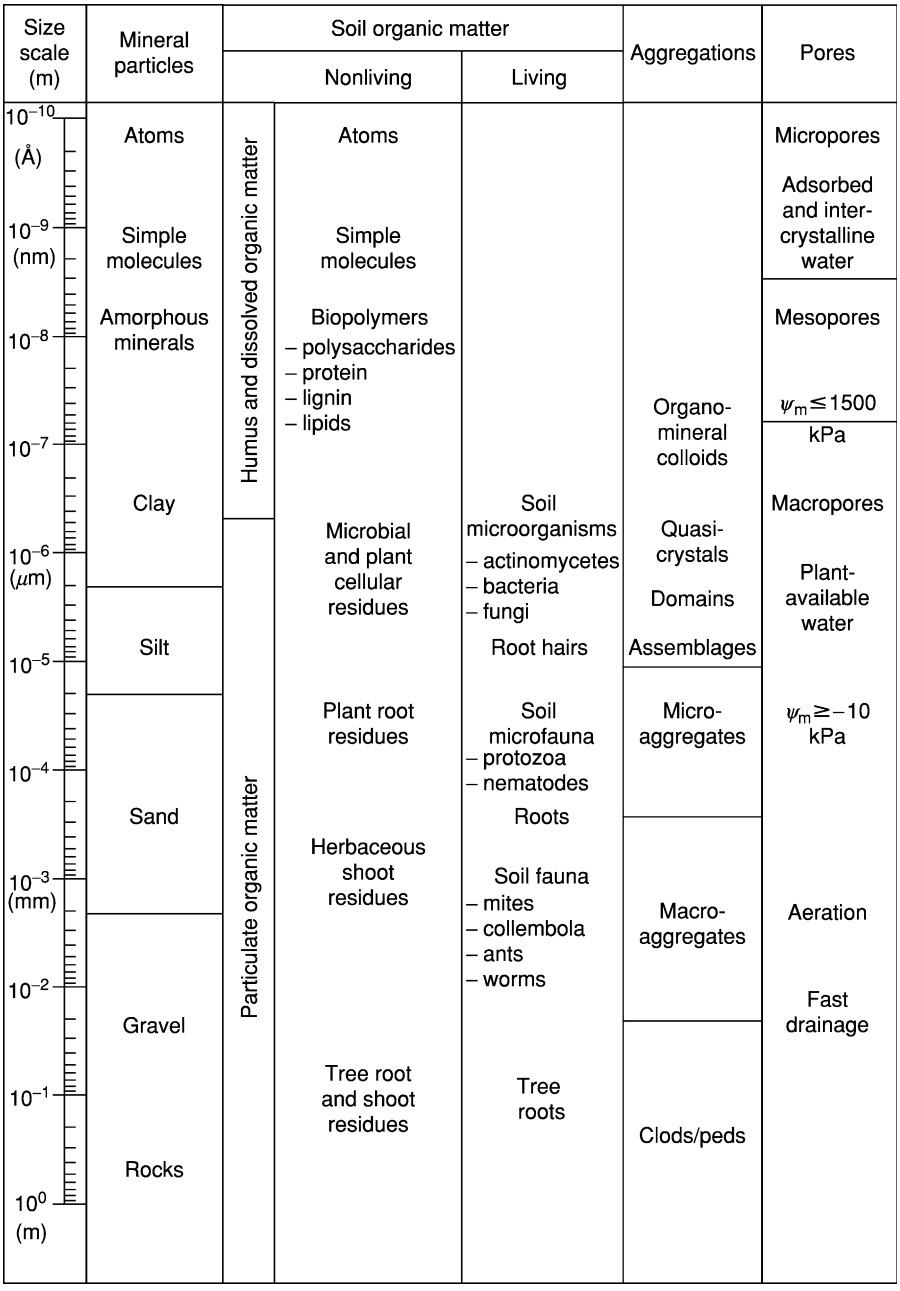

Figure 7 Size scales associated with soil mineral particles, organic components, pores, and aggregations of mineral and organic components. The definitions of pore size have used those developed by International Union of Pure and Applied Chemistry (IUPAC) (micropores <2 nm, mesopores 2–50 nm and macropores >50 nm). Alternatively the pore sizes corresponding to the lower ($\psi_m = -1500$ kPa) and upper ($\psi_m = -100$ kPa) limits of water availability to plants may be used to define the boundaries between the different classes of pore size. ψ_m is soil water metric potential. Reproduced with permission from Baldock JA (2002) Interactions of organic materials and microorganisms with minerals in the stabilization of structure. In: Huang PM, Bollag J-M, and Senesi N (eds) *Interactions Between Soil Particles and Microorganisms. Impact on the Terrestrial Ecosystem*, pp. 85–131. IUPAC Series on Analytical and Physical Chemistry of Environmental Systems. Chichester, UK: John Wiley.

and altered biomolecules on mineral surfaces can enhance the stability of individual clay microstructures. Adsorption is also important in the binding-together of clay microstructures and silt particles into small microaggregates with 2–50 μm diameters and densities $>20\,\mathrm{Mg\,m^{-3}}$. The high stability of these small microaggregates is demonstrated by their resistance to ultrasonification.

Mechanisms of stabilization of soil structure can operate over larger distances to bind microaggregates together to form macroaggregates (Figure 7). In view of the distances involved, the stabilization of macroaggregates is related to the presence of nonliving particulate organic matter (POM) capable of spanning distances $>100\,\mu$m or the existence of a network of fungal hyphae and plant roots that physically enmeshes microaggregates. The death of roots and hyphae growing within and through microaggregates results in the formation of biochemical binding agents capable of stabilizing the structure of macroaggregates.

Biochemical Cycling of C, N, P, and S in Soil

Chemically stabilized organic C in soils is slowly degraded to inorganic forms on time scales from centuries to millennia. Soil minerals are known to play a stabilizing role in soil organic matter. The interaction of Al and Fe with organic matter is of primary importance in the determination of the content of organic matter in tropical and temperate soils. The Al and Fe that complex and stabilize humus against microbial decomposition are released from soil minerals during soil formation and present as polymeric hydroxy cations. Their supply rates apparently control the content of soil organic matter to a great extent, as indicated by the relationship between pyrophosphate-extractable C and pyrophosphate-extractable Al and Fe.

The data from the radiocarbon analyses to explore interactions between soil mineralogy and soil organic C in volcanic soil environments show that the abundance of noncrystalline minerals accounts for >40% of the variation in organic C content across all the mineral horizons, substrate age, and soil orders (excluding the O and A horizons dominated by fast-cycling plant litter). Noncrystalline minerals also strongly influence turnover of organic matter.

Generally, more than 95% of the N and S and between 20 and 90% of the P in surface soils are present in soil organic matter. The close relationship between the organic forms of C, N, P, and S is well-established. The turnover of organic C is closely associated with the dynamics of N, P, and S in soils. The release of the stored organic nutrients depends on the mean residence time of soil organic matter associated with the mineral phase. The mean residence time of soil organic matter varies widely with the type of organomineral associations and the spatial location within the aggregate structure of soil (Table 3). Pools I and II are generally related to plant fragments, divided into easily available cell constituents and lignocelluloses at various degrees of degradation, respectively. Pool III consists of soil biomass and readily available organic matter within aggregates. On average, pools I–III account for about 20–30% of the total C in soil organic matter. These pools must be renewed continuously by fresh plant residues to maintain a relatively constant nutrient level and release by mineralization. The balance between decay and renewal processes, which is sensitive to management, controls the availability of N, P, and S. Pool IV is physically protected soil organic matter and is also affected by cultivation, because physical disturbance such as ploughing destroys macroaggregates and large microaggregates. Pool V is chemically stabilized soil organic matter which has the longest mean residence time. This pool represents 50–70% of the total C in soil organic matter and is seldom affected by management practices. Noncrystalline minerals have the ability to stabilize soil organic matter and thus reduce the turnover of C, N, P, and S.

Transformations of Organic Pollutants

Organic pollutants can be degraded through biotic and abiotic catalysis. Enzymes are biotic catalysts and mineral colloids are abiotic catalysts. It is frequently difficult to determine whether an organic pollutant is transformed abiotically or biotically. In many cases, significant abiotic and biotic catalytic reactions take place simultaneously.

The degradation of organic pollutants by extracellular enzymes is well-documented. Malathion, for instance, is hydrolyzed to a monocarboxylic acid (via loss of an ethyl group) by a carboxyl esterase isolated from soil. Enzymes commonly occurring in soil, such as esterases, amidases, phosphatases, and proteases, catalyze the hydrolysis of the respective chemical bonds in xenobiotic molecules.

Most organic chemicals, including xenobiotics, exhibit a strong affinity to humic substances. However, transformation of xenobiotics in terrestrial systems is greatly influenced by mineral components of soil. Mineral colloids, which are abundant in soil and have large specific surface and relatively high-charge density, contribute to the overall xenobiotic transformation at least as much as does the organic matter.

Soil organic matter and especially humic substances exert catalytic or inhibiting effects on abiotic hydrolysis of organic pollutants. Humic and fulvic acids have the ability to enhance the acid hydrolysis

Table 3 Comparison of estimated mean residence times of soil organic matter (SOM) in soil physical fractions

	Mean residence time (years)			
Pool	*Jenkinson and Rayner (1977)*[a]	*Parton et al. (1987)*[b]	*Buyanovsky et al. (1994)*[c]	Carter (1996)[d]

of phenoxy acetic acids and esters and chloro-s-triazines and to retard the alkaline hydrolysis of the *n*-octyl ester of 2,4-D. The mechanisms proposed to explain the catalytic effects of humic and fulvic acids on dechlorohydroxylation of the chloro-s-triazines, simazine, atrazine, and propazine, consist of the interaction through H-bonding between the surface carboxyl groups of humic and fulvic acids and the heterocyclic nitrogen atoms of the triazine ring.

Soil minerals play an important role in catalyzing the abiotic transformation of organic compounds. Their ability to catalyze the transformation substantially varies with their structural configuration and surface chemistry and the structure and functionality of the organic matter involved. Manganese oxides are most powerful soil minerals in catalyzing abiotic oxidation of phenolic compounds. Organic compounds such as 2,4-D and ethyl ether can be degraded by the catalysis of birnessite (δ-MnO_2). These organic compounds can be adsorbed on birnessite and rapidly oxidized, both producing CO_2 as a major product (**Figure 8**), but by somewhat different mechanisms. Therefore, the solid degradation of organochlorine herbicides can occur by catalysis of birnessite, which is common in the environment.

Mineral surfaces may also detoxify adsorbed organic pollutants by catalysis through their ability to behave as Brønsted acids and donate protons or to act as Lewis acids and accept electron pairs. Brønsted acidity derives essentially from the dissociation of water molecules coordinated to surface-bound cations. Therefore, this acidity is strongly influenced by the hydration status and polarizing power of surface-bound and structural cations on mineral colloids. Certain organic pollutants such as organophosphate and s-triazine pesticides can be degraded by catalysis of mineral colloids through their surface acidity. This type of reaction deserves attention in a wide range of other organic compounds in soil environments. Besides the Brønsted acidity, the Lewis acidity of metals such as Al and Fe exposed at the edges of minerals is important in mineral-catalyzed hydrolysis reactions, at least for those that are hydroxyl ion-catalyzed. The ability of a metal ion to catalyze the hydrolysis varies with its ability to complex with reactant molecules and shift electron density and conformation in ways favorable to the reaction.

The degradation of organic pollutants may be considerably reduced when they are retained by soil mineral and humic colloids. The major reason for reduced biodegradation rates is the diminished bioavailability of chemicals involved in binding processes. The availability of sorbed xenobiotics to microorganisms varies with the chemical properties of the pollutant, the

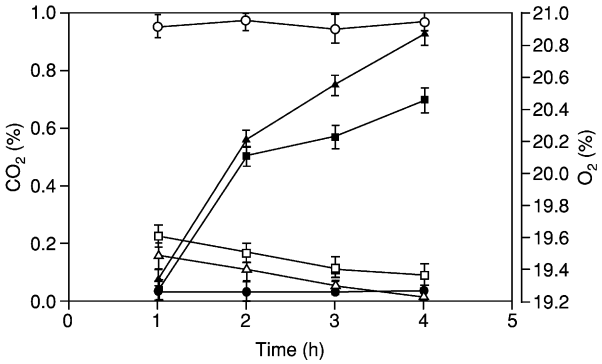

Figure 8 Gas chromatographic measurements of CO_2 and oxygen in the headspace of reaction vials and 2,4-D at 1, 2, 3, and 4 h, respectively. A. Physicochemical and Engineering Aspects* 107: 131–140.

nature of the sorbent, the mechanism of sorption, and the properties of the organisms. The impact of structural configuration and surface properties of soil mineral and organic components on the activity of microorganisms and their ability to degrade organic pollutants with different structure and functionality merit increasing attention for years to come.

Transformations of Metals

The transformation of metals in the environment is influenced by soil mineral–organic matter–microbe interactions. The impacts of these interactions on metal transformation are especially important in the soil rhizosphere because of root exudation. This leads to colonization by different populations of bacteria, fungi, protozoa, and nematodes. Plant–microbe interactions result in intense biological processes in the rhizosphere. These interactions, in turn, affect physicochemical reactions in the rhizosphere. Physicochemical properties that can be different in the rhizosphere include acidity, concentration of complexing biomolecules, redox potential, ionic strength, moisture, and nutrient status. The total rhizosphere environment is governed by an interacting trinity of the soil, the plant, and the organisms associated with the root. Therefore, reactions in the soil rhizosphere, which is the bottleneck of metal contamination of the terrestrial food chain, can only be satisfactorily integrated based on physical, chemical, and biological interactive processes.

A series of complexation reactions in soils affect metal transformation in the rhizosphere. Complexation reactions of metals with organic ligands are significant in determining the chemical behavior, availability, and toxicity of metals in the rhizosphere. The plant and prolific microbial activity results in increased amounts of organic ligands at the soil–root interface. Therefore, a larger fraction of the metal contaminant is in a complexed and usually soluble form in the rhizosphere soil than in the bulk soil.

The transformation of metals is significantly influenced by adsorption–desorption reactions in soil environments. These reactions are affected by biochemical and biological processes, especially in the rhizosphere. There is increasing evidence that organic ligands modify the adsorption–desorption reactions of metals in soils. For most of the trace metals, direct precipitation from solution through homogeneous nucleation appears to be less likely than adsorption–desorption by virtue of the low concentrations of these metals in soil solutions in well-aerated dryland soils. In aerobic soils, although precipitation of trace metals through homogeneous nucleation is not likely, heterogeneous nucleation may play a significant role in metal transformation because of the presence of mineral, organic, and microbial surfaces that catalyze the nucleation set of crystallization. The energy barrier to nucleation is reduced or removed by surfaces. The catalytic processes reduce the extent of supersaturation necessary for precipitation to occur.

Besides physicochemical reactions, metals have easy access to microbial surfaces through diffusion. All microorganisms contain biopolymers, such as proteins, nucleic acids, and polysaccharides, which provide sites where metal ions can bind. These binding sites include negatively charged groups such as carboxylate, thiolate, phosphate, and groups such as amines which coordinate to the metal center through lone pairs of electrons. Because of the ability of these biopolymers to bind metals, large concentrations of metals are frequently associated, not only with living microbial biomass, but also with dead cells. Many metals bind with various degrees of tenacity to the largely anionic outer-surface layers of microbial cells. Some metals are bound by cell walls to a greater extent than by clay minerals (Table 4), indicating that bacterial cell walls and membranes may act as foci for accumulation of metals in soils. Surface metal concentrations frequently exceed the stoichiometry expected per reactive chemical sites within cell walls. The sorption of metals can be so great that precipitates can be formed and distinct metallic minerals are eventually formed by biomineralization (the

Introduction

Primary minerals are formed at elevated temperatures and inherited from igneous and metamorphic rocks, sometimes through a sedimentary cycle. In most soils, the sand and silt fractions consist largely of primary minerals. In the clay fraction of weakly weathered soils, primary minerals are present but are minor constituents of the clay fraction of most agricultural soils.

The most abundant primary minerals in soils are quartz and feldspars, just as they are the dominant rock-forming minerals in the Earth's crust. Quartz consists of a continuous framework of silica tetrahedra and is the main form of free silica occurring in soils. Feldspars are anhydrous, three-dimensional aluminosilicates containing varying amounts of Na, K, and Ca, and occasionally of other large cations such as Ba. Feldspars are found in virtually all sediments and soils in quantities that vary with the nature of the parent material and the stage of weathering. Weathering of feldspars is an important Earth-surface geochemical process. Feldspars are stores of the macronutrients K and Ca; they play a substantial role in overall K dynamics of soils.

Micas are 2:1 phyllosilicates with tightly held, nonhydrated, interlayer cations balancing a high layer charge. They are largely of primary origin, occur extensively, and serve as precursors for expansible 2:1 phyllosilicates, vermiculites, and smectites in soil environments. Micas are often present in soils as components of particles that have been only partially transformed to expansible 2:1 minerals through interstratification with the other minerals or the formation of mica cores surrounded by expanded zones. Micas are important reserves of soil K for growing plants. The K-supplying power of a soil depends to a considerable extent on the nature and amount of micas present and their dynamics of K release.

Olivines, pyroxenes, and amphiboles are important accessory primary minerals that occur in small but significant amounts. Olivines are olive-green nesosilicates in which Mg and Fe^{2+} are octahedrally coordinated by O atoms. Pyroxenes and amphiboles, which are inosilicates, are ferromagnesian minerals with single- and double-chain structures, respectively, of linked silica tetrahedra. The variety of isomorphous substitution possible in olivines, pyroxenes, and amphiboles and their relative ease of weathering make them excellent source minerals for Ca, Mg, and trace elements in soils. Furthermore, the ability of nesosilicates and inosilicates to catalyze the abiotic formation of humic substances in soils merits attention.

Quartz

Silica occurs in nature as seven distinct polymorphs: quartz, cristobalite, tridymite, coesite, stishovite, lechatelerite (silica glass), and opal. Disordered cristobalite commonly occurs in soils; tridymite is rare in soils and usually associated with siliceous volcanic rocks; and coesite, stishovite, and lechatelerite are rare polymorphic forms. Opal is a hydrated, amorphous silica and is not uncommon, but, of these minerals, quartz is the most abundant in soil environments.

Quartz is one of the last minerals to crystallize from magma. Therefore, it is formed under conditions closer to present Earth-surface conditions than minerals crystallized earlier. This contributes to its high stability. Compared with other silica polymorphs, dense packing of the crystal structure and high activation energy required to alter the Si-O-Si bond are major factors contributing to the high stability of quartz. Quartz is present in essentially all soils and often constitutes the major portion of all sand and silt fractions. It is a major component of the coarse clay fraction of many soils.

The silica tetrahedron of quartz is almost symmetrical and has an Si-O distance of 0.161nm. The Si-O bond is approximately equally ionic and covalent in nature. The structure of quartz can be visualized as a spiral network of silica tetrahedra about the *z*-axis (**Figure 1**). Each tetrahedron is repeated in the network by a rotation of 120° and a translation of one-third about the *z*-axis. The tetrahedra are linked to form a hexagonal structure in quartz.

The solubility of silica minerals decreases as a function of increasing packing density of the silica tetrahedra and long-range crystal order. Solubility of quartz at ambient temperatures and neutral pH is commonly 3–7 mg Si l^{-1}, which is much lower than that of amorphous silica (50–60 mg Si l^{-1}). Freshly ground quartz commonly shows abnormally high solubility levels (37 mg Si l^{-1}). This has been attributed to the formation of a disrupted surface layer, which is believed

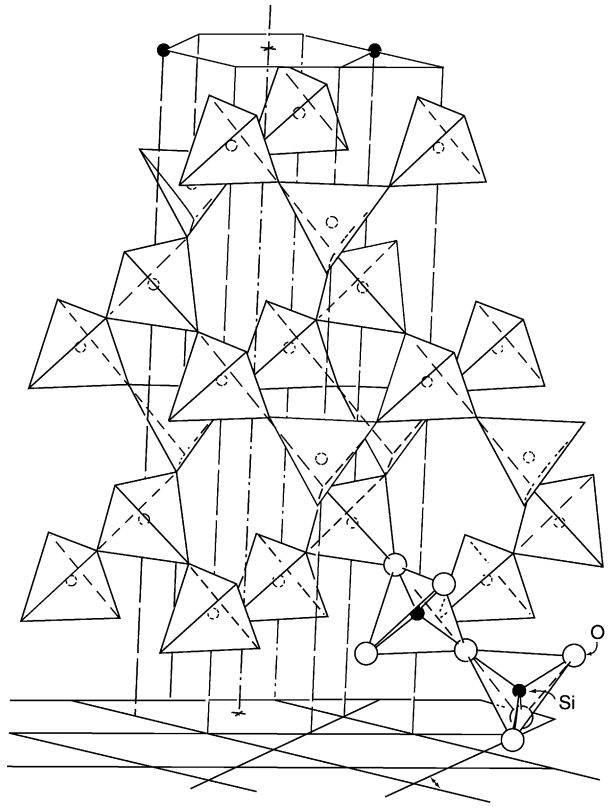

Figure 1 The structure of low quartz, SiO_2, shown as SiO_4 tetrahedra with a small silicon atom at the center of a group of four oxygens in tetrahedral coordination. Each tetrahedron shares a corner (oxygen) with an adjoining tetrahedron. For simplicity most of the tetrahedrons are shown without the circles representing oxygen. The screw axis symmetry (threefold) of the *c*-axis is shown by the dashed line, repeating each tetrahedron with a rotation of 120° and a translation of *c*/3. Two units of structure along *c* are shown. (Reproduced with permission from Berry LG and Mason B (1959) *Mineralogy*. San Francisco, CA: WH Freeman.)

to be amorphous or microcrystalline. Further, the solubility of quartz is a function of temperature, pH, and particle size. It increases with increasing temperature and is essentially constant between the pH values of 2 and 8.5, but increases rapidly above 9, due to the ionization of monosilicic acid:

$$Si(OH)_4 + OH^- = Si(OH)_3O^- + H_2O$$

The dissolution rate of quartz increases with the decrease in particle size. This is mainly attributed to an increase in specific surface of quartz as particle size decreases.

The presence of organic molecules such as amino acids greatly enhances the dissolution of silica, including quartz. The high rate of quartz dissolution in soils is attributable to leachates rich in organic molecules which react with quartz to form Si–organic molecular complexes in soil solution. The dissolution of quartz is greatest in the root zone, where production of biomolecules increases the dissolution of quartz by complexing with monosilicic acid.

Sesquioxides are a significant component of most soils and play a role in determining the concentration of dissolved silica in soils. They are responsible for much of the capacity of soils to sorb soluble silica, with the maximum adsorption occurring between pH values of 8 and 10. They act as a sink of dissolved silica and greatly increase the dissolution rate of silica. Therefore, finely divided quartz may not be stable at these pH values in the presence of excess sesquioxides.

Oxygen-isotope composition of minerals is a useful tool for determining the genesis and history of soil parent materials. The oxygen-isotope composition of quartz is dependent on the temperature of formation; delta values ($\delta^{18}O$) decrease as the temperature of formation increases. Delta values ($\delta^{18}O$) are defined as follows:

$$\delta^{18}O = \left[\frac{^{18}O/^{16}O \text{ sample}}{^{18}O/^{16}O \text{ SMOW}} - 1\right] \times 1000$$

where SMOW stands for standard mean ocean water. Quartz in igneous rocks has delta values in the order of 8–13‰; whereas quartz from metamorphic rocks has somewhat higher delta values, with a wider range that results from varying degrees of metamorphism. Oxygen-isotope ratios of quartz in shales range from 15 to 24‰; the ratios of quartz in sandstones range from 10 to 16‰. Silica minerals formed at ambient temperatures (chert, diatom, plant opal) have considerably higher delta values. The intermediate values for sedimentary deposits are attributed to the mixed origins of the sediments. Delta values of quartz from soils range from 9 to 30‰, which are generally similar to those of sedimentary rocks. Quartz is exceedingly resistant to oxygen-isotope exchange; therefore, the isotopic composition of quartz in soils, dusts, and sediments has been used as an indicator of provenance. The main use of isotopic composition of quartz in pedologic studies has been for identification of eolian additions to soils.

Feldspars

Feldspars make up an average of $595\,g\,kg^{-1}$ of igneous rock, $300\,g\,kg^{-1}$ of shale, and $115\,g\,kg^{-1}$ of sandstone. Many metamorphic rocks also contain large amounts of feldspars. Therefore, feldspars are present in virtually all sediments and soils in quantities that vary with the nature of parent material of soils and their degree of weathering. They play a substantial

role in overall dynamics of macronutrients, K and Ca, in soils.

The structure of feldspars is a three-dimensional framework of linked SiO_4 and AlO_4 tetrahedra, with sufficient opening in the framework to accommodate K, Na, Ca, or Ba to maintain electroneutrality. In the building up of the framework, four-membered rings of tetrahedra are the basic units. Chains of four-membered rings of tetrahedra are parallel to the *a*-axis and cross-linked to adjacent parallel chains by shared O atoms (Figure 2). One zigzag chain is formed by superimposing four-membered rings of tetrahedra that share some of their vertices to form new, four-membered rings. The remaining vertices form cross-links between chains. The repeat periodicity along the chain is 0.84 nm in the ideal case. The range of the *a* axis of different feldspars approximately varies from 0.81 to 0.86 nm. These four-membered rings are linked together to form a honeycomb-type arrangement.

Feldspars represent limited solid solution between the three end members (K-feldspar, albite, and anorthite) with pure K, Na, and Ca, respectively. Alkali feldspars are the K- and Na-rich members of the group with a small amount of Ca. Plagioclases are members of this group of minerals, rich in Ca and/or Na, but with small amounts of K.

Alkali feldspars have a range of chemical composition and the end members may be written as $KAlSi_3O_8$ and $NaAlSi_3O_8$. The K-feldspar polymorphs, sanidine, orthoclase, microcline, and adularia have identical chemical compositions. Sanidine is a monoclinic alkali feldspar with small optic axial angle (2V) and commonly occurs in volcanic rocks. Orthoclase is a monoclinic alkali feldspar that has the larger optical axial angle and looks homogeneous; it does not show cross-hatched twinning. Microcline is triclinic, has the larger optic axial angle (2V), and exhibits the typical cross-hatched twinning (Figure 3a). The alkali feldspars, which can be either monoclinic or triclinic but have a special crystal habit and occur in low-temperature hydrothermal veins, are referred to as 'adularia.' Anorthoclase is a triclinic, Na-rich feldspar that shows a very fine cross-hatched twinning.

Plagioclase feldspars have a chemical composition between pure albite and pure anorthite. The classification of the plagioclase series is based on the mole fractions of the albite (A_b) and anorthite (A_n) components (Table 1).

The high-temperature series of mixed crystals is quite continuous between the end-member orthoclase

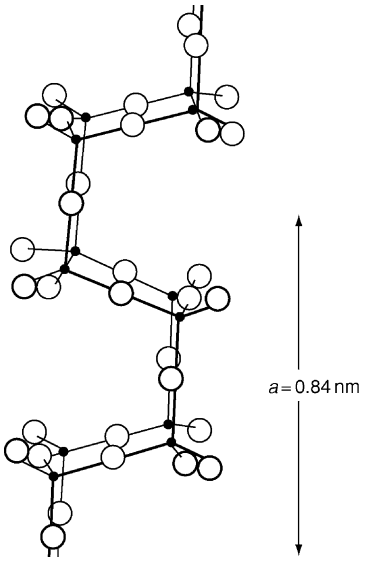

Figure 2 The essential structural feature of all feldspars projected on the (001) plane. The small black circles are Si and Al, the large circles, O. Table 1 The classification of plagioclase feldspars

Plagioclase feldspars	*Mole fractions of albite (Ab) and anorthite (An)*
Albite	Ab_{100}–$Ab_{90}An_{10}$
Oligoclase	$Ab_{90}An_{10}$–$Ab_{70}An_{30}$
Andesine	$Ab_{70}An_{30}$–$Ab_{50}An_{50}$
Labradorite	$Ab_{50}An_{50}$–$Ab_{30}An_{70}$
Bytownite	$Ab_{30}An_{70}$–$Ab_{10}An_{90}$
Anorthite	$Ab_{10}An_{90}$–Ab_{100}

and albite and also between albite and anorthite. However, under low-temperature conditions, these phases undergo structural changes and tend to unmix. The unmixing results in the formation of a lamellar aggregate whose composition is similar to that of the end members. The lamellar aggregate, which is composed of a large amount of alkali feldspar and a subordinate amount of albite, is referred to as 'perthite.' Except for authigenic K-feldspar, which is formed through reconstitution and precipitation, most alkali feldspars usually contain varying amounts of Na in their structure and are thus more or less perthitic. The morphology of soil perthitic crystals that appear to contain a second phase, most likely albite, in a host crystal of K-feldspar is shown in Figure 3b.

Feldspars are present in nearly all soils, but their quantities vary with the intensity and capacity factors of weathering reactions. They are completely absent or present only in small quantities in strongly weathered soils, though the parent material contains considerable quantities of those minerals. However, some feldspars may be present in humid tropical soils that contain relatively fresh rock materials due to erosional and depositional processes. Feldspars are commonly present in the silt and sand fractions of young to moderately developed soils representing various soil parent materials and soil-forming conditions. Alkali feldspars are even present in the clay fraction of moderately weathered soils.

Persistence of feldspars in soils is related to the nature of the minerals, climate, topography, degree of leaching, complexation, redox potential, and certain solution ionic activities. According to the Goldich stability series, the increasing order of stability of feldspars is: anorthite < bytownite < labradorite < andesine < oligoclase < albite < K-feldspars. This order is related to the decrease in Al and Ca contents. Within the K-feldspar group, microcline is more stable than orthoclase. This is attributed to the difference in the volume occupied by the O atoms in the minerals. Compared with the monoclinic symmetry of orthoclase, the smaller volume is occupied by the O atoms of microcline by virtue of its triclinic symmetry.

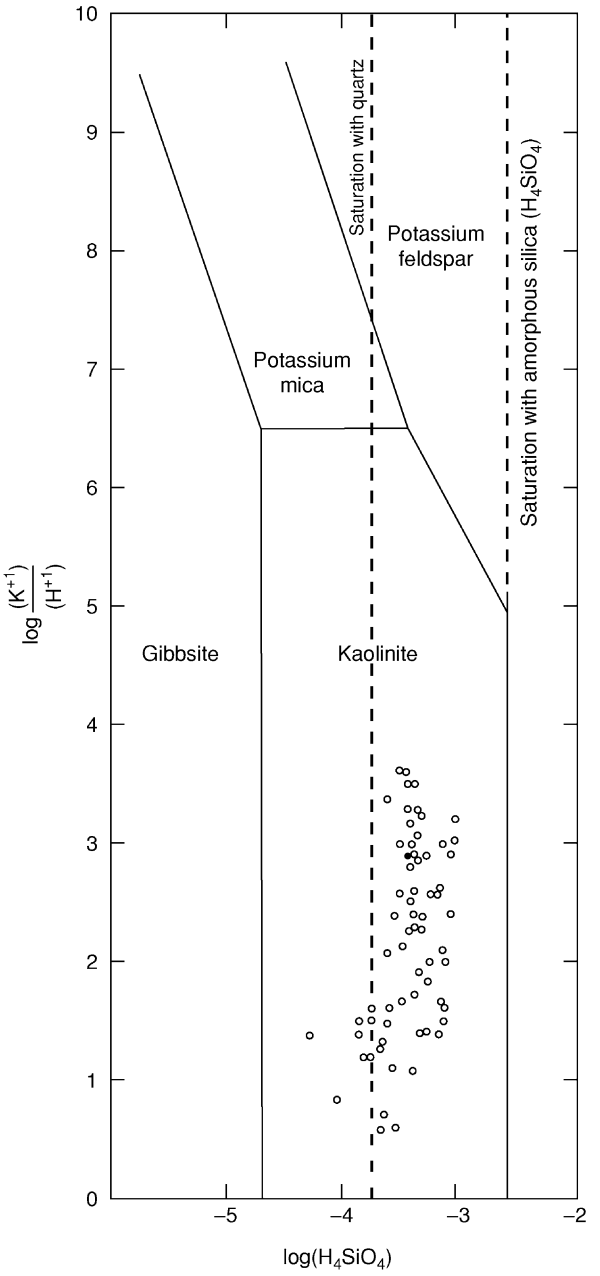

Figure 4 Stability relations of some phases in the system K_2O-Al_2O_3-SiO_2-H_2O at 25°C and 0.1 MPa pressure as functions of $(K^+)/(H^+)$ and (H_4SiO_4). US Geological Survey Water Supply Paper, 1535-I.)

Since establishment of the empirical stability series of Goldich, relative stabilities of feldspars at 25°C and 0.1 MPa have been thermodynamically shown in stability diagrams. The stability diagrams of K-feldspar and albite are shown in Figures 4 and 5, respectively. These stability diagrams are plotted as a function of the activity of H_4SiO_4 and the ratio of the

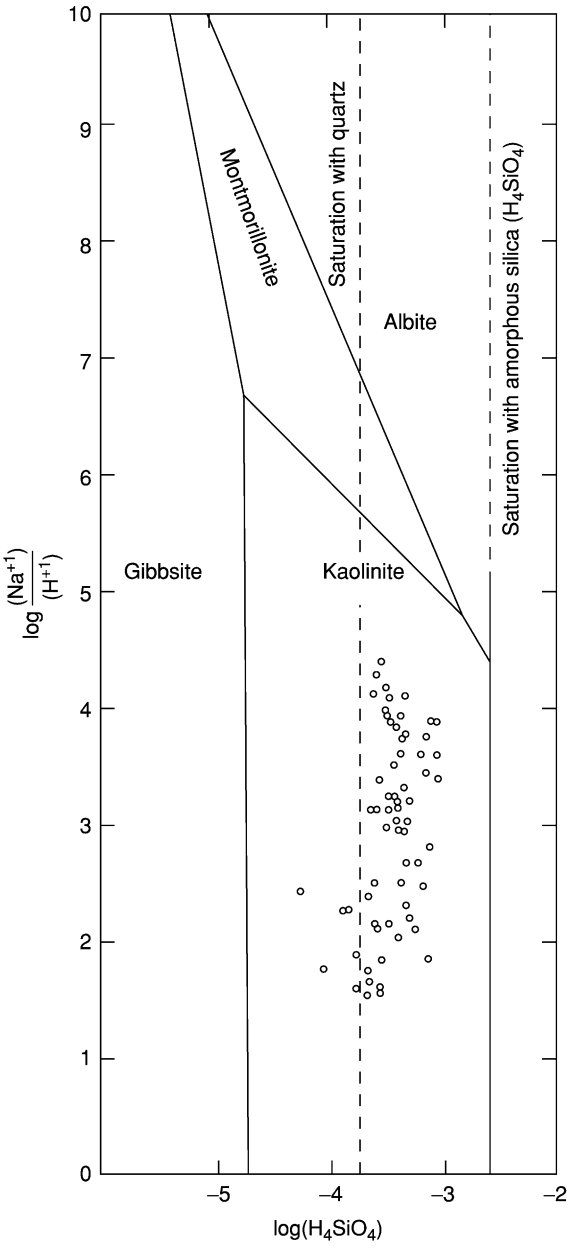

Figure 5 Stability relations of some phases in the system Na_2O-Al_2O_3-SiO_2-H_2O at 25°C and 0.1 MPa pressure as functions of $(Na^+)/(H^+)$ and (H_4SiO_4). activity of each alkali ion to that of H ion. The diagrams show that mica and kaolinite are intermediate phases in the weathering of K-feldspar and that montmorillonite and kaolinite are intermediate phases in the weathering of albite. The ionic compositions of groundwater fall within the stability fields of kaolinite. This indicates that kaolinite is the stable mineral phase and mica and montmorillonite are unstable phases in groundwaters and eventually will be transformed to kaolinite. This is in agreement with the fact that groundwaters tend to transform rock minerals to kaolinite.

Feldspars are stores of the macronutrients K and Ca. Ligands of complexing organic acids may play a significant role in the release of these cations from the feldspar structure. Organic acids such as acetic, aspartic, salicylic, and citric acids have the ability to enhance the dissolution of feldspars. Their effect on dissolution increases in the order: acetic < aspartic < salicylic < citric. Citric acid is more effective than the other acids in releasing Ca, particularly from Ca-rich plagioclases, apparently because of the formation of Ca–organic complexes. In the case of the weathering of orthoclase by oxalic acid, the ridges on the cleavage surface (Figure 6) are evidently preferentially attacked by the acid and thus modified. The surfaces of orthoclase weathered by oxalic acid look much like those of naturally weathered K-feldspars. The sequence of K release from K-bearing minerals by oxalic and citric acids is biotite > microcline ≅ orthoclase > muscovite (Table 2). This differs from the sequence that occurs through cation exchange reaction

Table 2 K released from K-bearing minerals by various solutions at the end of a 10-day reaction period

Mineral	Organic acid[a]		
	Oxalic ($g\,kg^{-1}$ structural K)	Citric ($g\,kg^{-1}$ structural K)	NaTPB[b] ($g\,kg^{-1}$ structural K)
Biotite	44	11	1000
Muscovite	1.1	0.9	83
Microcline	2.3	1.4	1.6
Orthoclase	2.2	1.2	1.3

using sodium tetraphenyl boron (NaTPB). The reaction of feldspars with complexing organic acids and its relation to nutrient release from soils merit attention.

Micas

Micas are 2:1 phyllosilicates with tightly held, nonhydrated, interlayer cations balancing a high layer charge. Primary attention is given to those micas with K^+ as the interlayer cation, because they are the abundant and important micas in most soils. Micas are abundant in many rocks, e.g., shales, slates, phyllites, schists, gneisses, and granites and in sediments derived from these and other rocks. The micas in soils are mainly inherited by soils from soil parent materials. Micas serve as precursors for expansible 2:1 phyllosilicates, i.e., vermiculites and smectites, to which micas may be transformed by replacement of the interlayer cations (usually K^+) by hydrated cations. Through K release, micas in soils are an important mineral source for plant growth.

The 2:1 layer of micas is composed of an octahedral sheet between two sheets of tetrahedra, as depicted in Figure 7. Micas can be classified as dioctahedral or trioctahedral, depending on the types and locations of cations in the octahedral sheets (Table 3). In trioctahedral micas such as biotite, all three octahedral positions are filled, whereas in dioctahedral micas such as muscovite, only two out of three octahedral cations are filled. Isomorphic substitution in the mica structure creates negative charge, which results in a strong coulombic attraction for charge-compensating interlayer cations such as K, which is not exchanged in the standard cation exchange-capacity determination. The negative layer charge of micas arises by some combination of three mechanisms: (1) substitution of R^{3+} (primarily Al or Fe) for Si^{4+} in tetrahedral positions, (2) substitution of R^{2+} for R^{3+} in octahedral positions, and (3) vacancies in octahedral positions. The resultant layer charge may originate entirely within the tetrahedral sheet, or may originate entirely within the octahedral sheet in some species, or may come partly from both sheets. The layer charge of micas is expressed on a formula unit basis (Table 3).

Muscovite is the most abundant dioctahedral primary mica. In muscovite, excess negative layer charge results from the substitution of Al for Si in one out of each of four Si^{4+} in the tetrahedral sheet positions. Biotite is the most common trioctahedral mica. Approximately three-quarters of the cation locations in the tetrahedral sheets of biotite are filled with tetravalent Si and about one-quarter is filled with trivalent Al. The excess negative charge generated by substitution of Al for Si results in the negative charge that is localized in the basal O atoms of the tetrahedral sheets where Al substitution occurs. In soils and sedimentary rocks, mica in the clay fraction is usually identified as illite. Illitic minerals have been called 'hydrous mica,' 'clay mica,' and 'sericite.' Illite is commonly found to be dioctahedral, but its chemical composition and layer charge differ from that of muscovite (Table 3). Glauconite structure has many similarities to that of illite, with relatively little minor substitution of Al for Si in the tetrahedral sheet. Compared with illite, the octahedral sheet of glauconite contains considerably more Fe.

After feldspars and quartz, micas are the third most extensive group of minerals in granitic and sialic

Table 3 General chemical formulas and layer charge for some dioctahedral and trioctahedral micas

Mineral	Layer charge (mol per formula unit)	Cations			Anions
		Tetrahedral sheet composition	Octahedral sheet composition	Interlayer cation	
Dioctahedral					
Paragonite	1	Si_3Al	Al_2	Na	$O_{10}(OH)_2$
Muscovite	1	Si_3Al	Al_2	K	$O_{10}(OH)_2$
Phengite	1	$Si_{3.5}Al_{0.5}$	$Al_{1.5}[MgFe^{(II)}]_{0.5}$	K	$O_{10}(OH)_2$
Illite	0.75	$Si_{3.5}Al_{0.5}$	$Al_{1.75}[MgFe^{(II)}]_{0.25}$	$K_{0.75}$	$O_{10}(OH)_2$
Glauconite	0.8	$Si_{3.67}Al_{0.33}$	$[AlFe^{(III)}]_{1.33}[MgFe^{(II)}]_{0.67}$	K	$O_{10}(OH)_2$
Margarite	2	Si_2Al_2	Al_2	Ca	$O_{10}(OH)_2$
Trioctahedral					
Phlogopite	1	Si_3Al	Mg_3	K	$O_{10}(OH)_2$
Biotite	1	Si_3Al	$Mg_{0.6–1.8}Fe^{(II)}{}_{1.2–2.4}$	K	$O_{10}(OH)_2$
Annite	1	Si_3Al	$Fe^{(II)}{}_3$	K	$O_{10}(OH)_2$
Lepidolite	1	Si_3Al	$[Li,Al]_3$	K	$O_{10}(OH,F)_2$
Clintonite	2	$SiAl_3$	Mg_2Al	Ca	$O_{10}(OH)_2$

(acid) rocks in general but less extensive in most mafic rocks. On land areas of the world, the sialic rocks are more extensive than mafic rocks. Muscovite and biotite are the most extensive micas in igneous and metamorphic rocks. Phlogopite occurs as a product of metamorphism of magnesian limestones or dolomitic limestones and also in serpentine rocks. Micas are generally more extensive in fine-grained sediments and sedimentary rocks (e.g., shales) than in coarse-textured sedimentary rocks (e.g., sandstones). Shales and slates are usually rich in the fine-grained, illitic-type micas. Illitic-type micas are also important minerals in limestones. Much illite in sedimentary rocks is apparently detrital. However, some illite in these rocks may also have been developed or affected by authigenic or diagenetic processes. The contents and species of micas in more recent, unconsolidated parent materials such as glacial tills, loess, and alluvium vary with their origin.

Micas represent a major source of the macronutrient K and thus play an important role in plant nutrition. If the soil solution is low in K^+ activity, K near the edges of micaceous minerals may be released into solution by exchange with H^+, Na^+, Mg^{2+}, or Ca^{2+}. When the readily exchangeable K is exhausted, fixed K from the interlayer position can also be released. Estimating the power of micaceous minerals to supply K to the soil solution is thus critical for predictions of plant nutrition and growth.

Micas exhibit a strong preference for Cs^+. This strong affinity of micas for large, weakly hydrated cations such as Cs^+ has an important environmental application in determining the fate of some radioactive waste. Radioactive isotopes of Cs have been added to soils by disposal of radioactive wastes and by deposition of fallout from both nuclear weapon testing and accidents at nuclear energy facilities. The mobility and bioavailability of radiocesium in mineral soils is limited by nearly instantaneous sorption of $^{137}Cs^+$ at the frayed edges of mica particles followed by slower fixation of $^{137}Cs^+$ ions diffused into interlayer sites within mica crystals. Therefore, micas play a role in restricting the contamination of $^{137}Cs^+$ to the terrestrial food chain and the impact on human health.

Structural Fe contents of micas may be substantial. For example, Fe accounts for approximately 23% by mass of ideal biotite. Structural Fe can participate in electron-transfer reactions in soils. Three examples of mica involvement in environmentally significant electron-transfer reactions are the reduction of NO_3^- to NH_4^+, the reduction of Cr(VI) to Cr(III), and the reductive degradation of chlorinated hydrocarbons in soils and groundwater.

Common Accessory Primary Minerals

Besides quartz, feldspars, and micas, other common primary minerals are olivines, pyroxenes, and amphiboles. These minerals are accessory primary minerals, present in the sand- and silt-sized fractions of soils.

Olivines occur as the principal constituents of some igneous rocks. In the upper lithosphere, however, their concentration is certainly smaller than that of pyroxenes and amphiboles. These three groups of minerals belong to the accessory minerals of soils and are present in heavy specific-gravity fractions.

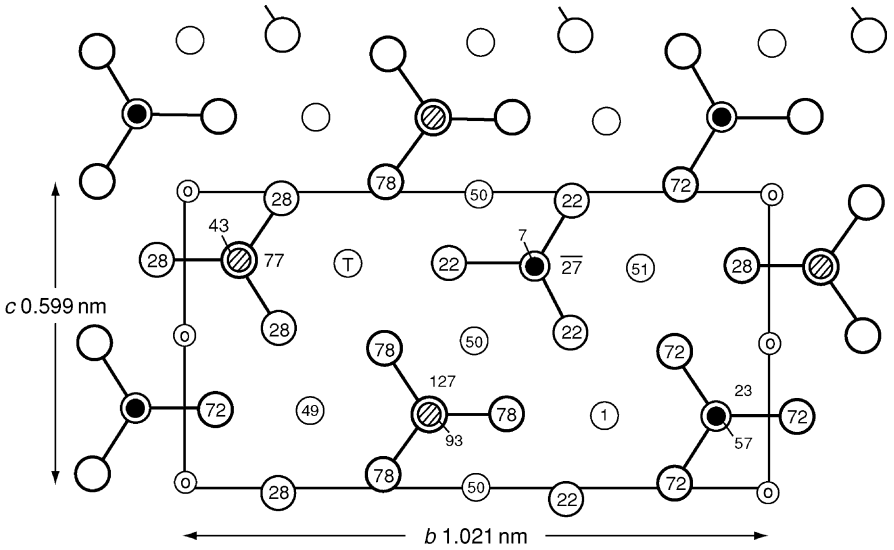

Figure 8 The structure of forsterite, Mg_2SiO_4, projected on the (100) plane. The largest circles are O, the smallest circles Mg, and the black or shaded circles Si; Si-O bonds mark out the SiO_4 tetrahedra. The kinds of positions of atoms are indicated by heights as shown by the numbers inside or beside the circles. Table 4 Certain members of olivine, pyroxene, and amphibole groups

Mineral	*Specific chemical formula*[a]
Olivines	
Forsterite	$(Mg_{0.96}Fe_{0.04})_2SiO_4$
Fayalite	Fe_2SiO_4
Tephroite	Mn_2SiO_4
Monticellite	$CaMgSiO_4$
Pyroxenes	
Enstatite	$MgSiO_3$
Hypersthene	$(Mg_{0.88}Fe_{0.12})Si_2O_6$
Orthoferrosilite	$FeSiO_3$
Clinoenstatite	$MgSiO_3$
Clinoferrosilite	$FeSiO_3$
Diopside	$CaMgSi_2O_6$
Pigeonite	$(Ca_{0.04}Mg_{0.45}Fe_{0.48})SiO_3$
Hedenbergite	$CaFeSi_2O_6$
Johannsenite	$(Ca_{0.45}Mg_{0.03}Fe_{0.05}Mn_{0.47})SiO_3$
Acmite-augite	$(Ca, Na)(Fe, Mn, Zn, Mg)(Si, Al)_2O_6$
Aegirine (acmite)	$NaFeSi_2O_6$
Jadeite	$NaAlSi_2O_6$
Spodumene	$LiAlSi_2O_6$
Amphilboles	
Anthophyllite	$(Mg, Fe)_7Si_8O_{22}(OH)_2$
Cummingtonite	$(Fe_{0.6}Mg_{0.4})_7Si_8O_{22}(OH)_2$
Tremolite[b]	$Ca_2Mg_5Si_8O_{22}(OH)_2$
Arfvedsonite	$(Ca, Na, K)_{2.64}Fe_{1.42}(Fe, Mn, Mg, Ti)_{3.54}(Si, Al)_8O_{22}(OH)_{2.15}$
Glaucophane	$Na_2(Mg, Fe, Al)_5Si_8O_{22}(OH)_2$
Riebeckite	$(Na, Ca, K)_{2.2}(Fe^{2+}, Mg, Mn, Zn, Cu, Li)_{3.0}(Fe^{3+}, Al, Ti)_{2.0}(Si, Al)_{8.0}O_{22.1}(OH, F)_{1.9}$
Hornblende	$(Ca, Na)_{2.26}(Mg, Fe, Al)_{5.15}(Si, Al)_8O_{22}(OH)_2$

[a]The specific chemical formulas are compiled from the *Data Book* (after Joint Committee on Powder Diffraction Standards (1974) *Search Manual. Selected Powder Diffraction Data for Minerals, Data Book*, 1st edn. Swarthmore, PA: International Center for Diffraction Data).
[b]The division between tremolite and actinolite is arbitrary: tremolite is the low-iron end of the series and actinolite comprises the high-iron members. Reproduced with permission from Huang PM (1989) Feldspars, olivines, pyroxenes, and amphiboles. In: Dixon JB and Weed SB (eds) *Minerals in Soil Environments*. Madison, WI: Soil Science Society of America.

Weathering of these minerals is one of the major processes in the geochemical cycles of Mg and Fe. The variety of isomorphous substitution possible in these minerals and their relative ease of weathering make them excellent source minerals for Ca, Mg, and trace elements in soils. Furthermore, the catalytic power of Mn-bearing nesosilicates and inosilicates in the abiotic formation of humic substances in soils merits attention.

Olivines

Members of forsterite-fayalite series, $(Mg, Fe)_2SiO_4$, comprise the most abundant naturally occurring olivines. The structure of forsterite is shown in Figure 8. The O atoms lie in approximately hexagonally close-packed sheets parallel to (100). The SiO_4 tetrahedra point alternately in opposite directions along the *a*- and *b*-axis. Every Mg atom is octahedrally coordinated by six O atoms. In the structures described above, Fe^{2+} may replace Mg^{2+}, because the two have identical charge and similar ionic radii. The specific chemical formulas of selected minerals in the olivine group are given in Table 4.

There is complete solid solution between forsterite and fayalite in nature. The Mg-rich olivines are predominant in basic rocks and the Fe-rich varieties in intermediate and acidic igneous rocks. Tephroite occurs mainly in metasomatic rocks and in Mn deposits.

The weatherability of olivines in soils is very high. Due to their relatively easy weatherability, olivines contribute to nutrient levels of Mg and Fe. The extent of weathering of these minerals is an indication of the intensity of chemical weathering of soils in cool humid regions. Where leaching is only moderate, olivines may alter to serpentine or trioctahedral smectite (presumably of the saponite type), nontronite, and various ferric hydrates and gels. In an environment where leaching is intense, the degradation products are poorly crystallized smectite, kaolinite,

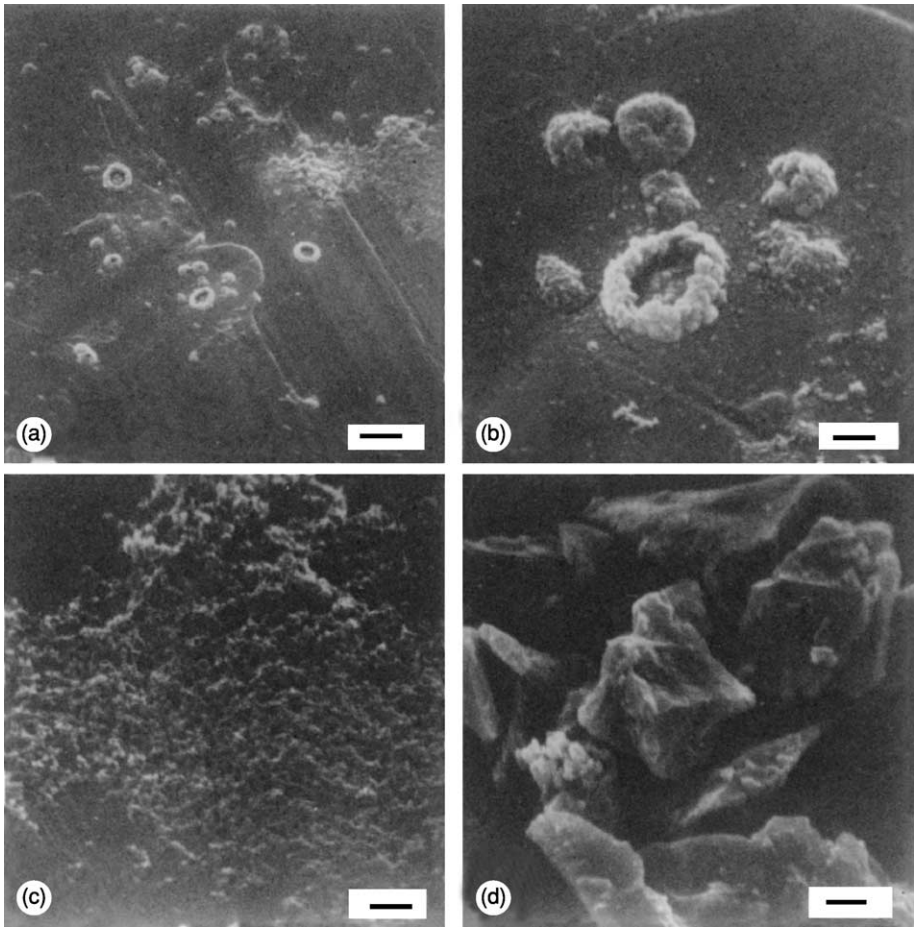

Figure 9 Scanning electron microscope micrographs of hydroquinone polymers in the supernatant and mineral particles settled in the tephroite system at the ratio of mineral to hydroquinone solution of 0.01 at the initial pH of 6.0 at the end of 7 d. (a–c) Hydroquinone polymers; (d) tephroite particles after reaction with hydroquinone. (a) Bar scale 10 μm; (b–d) 2 μm. halloysite, and Fe oxides such as goethite, hematite, or the noncrystalline precursors of these minerals.

Olivines have the ability to accelerate the abiotic polymerization of hydroquinone to humic substances. The catalytic power of tephroite, which is an Mn-bearing olivine, in the polymerization of polyphenols such as hydroquinone to humic acids with a high degree of humification is especially noteworthy. The scanning electron micrographs of the hydroquinone-derived humic polymers formed in the presence of tephroite reveal various morphological configurations (Figure 9a–c). The surface features of these polymers are similar to those of soil humic and fulvic acids. Furthermore, the infrared (IR) spectra of these humic polymers with molecular weights of approximately 3500 and greater are similar to those of humic substances. The association of hydroquinone-derived polymers with the surfaces of tephroite is not evident (Figure 9d), indicating that most humic polymers formed in the tephroite system are present as discrete particles.

Pyroxenes and Amphiboles

Pyroxenes and amphiboles are closely related structurally. Pyroxenes consist of single chains of linked SiO_4 tetrahedra, each of which shares two O atoms with its neighbor; in amphiboles, double chains of the tetrahedra are linked together by O atoms and the tetrahedra share alternately two and three O atoms (Figure 10). The chains are indefinite in length. When viewed at right angles to the chain and parallel to the base of the tetrahedra, pyroxenes and amphibole chains look alike, as depicted in Figure 10c. The pyroxene and amphibole chains are parallel to the *c*-axis of the crystal and their planes of basal O atoms are perpendicular to (010).

The chains of pyroxenes and the double chains of amphiboles are linked together by various cations. The general chemical formula for pyroxenes is $R_2[Si_2O_6]$ and that for amphiboles is $R_{14}[(OH)_4 Si_{16}O_{44}]$. In these formulas, R is Mg, Fe^{2+}, or Ca and, in many cases, A1, Fe^{3+}, Ti^{3+}, Mn^{3+}, Na, K, or Li. The bond between the O atoms and the cations linking the chains is relatively weaker than that between the O and the Si. Therefore, cleavage takes place diagonally through the crystal and does not rupture the Si-O chains. The principal members of pyroxene and amphibole groups are listed in Table 4.

Three series of pyroxenes – the enstatite-hypersthene, diopside-jadeite, and augite series – occur in

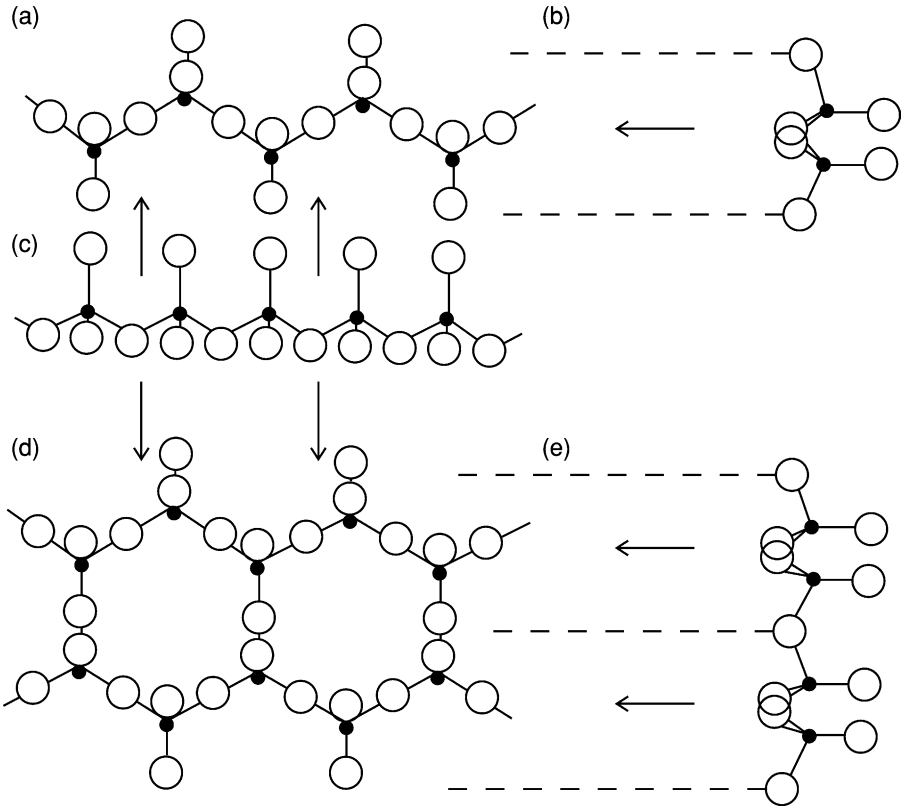

Figure 10 Si-O chains in structures of pyroxenes and amphiboles: (a–c) the pyroxene chain as seen in plane, in elevation, and end-on view, respectively; (c–e) the amphibole chain from the same three aspects. (Reproduced from Bragg L and Claringbul GF (eds) (1965) *Crystal Structures of Minerals: The Crystalline State*, vol. IV. London, UK: G Bells and Sons, Ltd.)

igneous rocks. In nature, pyroxenes are often mixtures. Among the three series of pyroxenes, the augite series is geochemically more important than the others. Its members are among the most important constituents of igneous rocks. Many amphiboles are absent in primary igneous rocks or may occur as minerals of secondary origin. The main primary amphiboles of igneous rocks are the Mg-poor riebeckites and the Si-poor basaltic and common hornblende. Hornblendes are widely distributed in igneous rocks from syenite and granite to gabbro, and in metamorphic rocks such as gneiss, hornblende schist, and amphibolites. Pyroxenes and amphiboles are largely confined to the sand and silt fractions of soils. Some of them may occur in the clay fraction of soils that are developed from glacial rock flour and have not been subjected to intensive weathering. The variety of isomorphous substitution in these minerals and their easy weatherability make them excellent sources of trace elements and Ca and Mg in soils.

Pyroxenes tend to weather to chlorite or smectite or both, through partial dissolution of Mg, Ca, and Fe^{2+}. Calcite may develop in the environment where the rate of dissolution of Ca is higher than the rate of complete breakdown of the pyroxene. As the chemical weathering proceeds further, all the Ca and Mg, and part of the Si are lost, resulting in progressive enrichment of the residue in kaolinite, ferric oxides and oxyhydroxides, and anatase. Amphiboles appear to have a weathering sequence similar to pyroxenes.

Pyroxenes (e.g., augite) and amphiboles (e.g., hornblende) have the ability to catalyze abiotic polymerization of polyphenols such as hydroquinone to humic substances. Therefore, these minerals along with olivines merit attention in the abiotic formation of humic substances in soil environments. These accessory primary minerals thus play a role in catalyzing humification and protecting soil C against mineralization and loss to the atmosphere as CO_2.

Introduction

Soil morphology is defined as the branch of soil science that deals with the description, using standard terminology, of *in situ* spatial organization and physical properties of soil regardless of potential use. Precise descriptions, using conventional terms, are necessary to all of the areas of science included in the field of soil science. The basic descriptors used today have been developed over the past 50 years and are continually added to. Prior to utilization of standard terminology, soils were described as clayey, sandy, stony, sedimentary, saline, marshy, dry or moist, heavy or light, soft or compact, fatty, friable, or lean. Soil horizons were described by terms such as 'gray watery sand' or 'rusty brown clay.' While these terms illustrate a fundamental understanding of soil properties, they do not impart any specific knowledge about the soils in question and cannot be compared with other soils described by other scientists. An objective, complete description of the soil is essential, because it serves as a basis for soil identification, classification, correlation, mapping, and interpretation.

The basic tools used by field soil morphologists are very simple and usually include a knife, tape measure, water bottle, Munsell color book, $\times 10$ hand lens, 10% HCl, and a clinometer or Abney level. A description of a soil profile, a vertical cross-section of the soil, represents a three-dimensional pedon. A pedon is the smallest volume that is recognized as a soil. Field morphology of a soil profile is best determined from a recently opened pit; however, a fresh roadside cut may be used. Field descriptions begin by organizing and subdividing a vertical exposure (soil profile) into reasonably distinct layers or horizons. At a minimum, a soil description includes a site characterization and the horizon depth intervals, horizon boundary characteristics, color, texture, structure, consistence, roots and pores, pH, and effervescence; and special descriptions of special features for each horizon.

Site Description

The soil pedons that are described at a site will have been affected by five soil-forming factors: parent material, biota, climate, topography, and time. A brief description of the parent material is desirable, because of inherited soil properties. It is necessary to record the observable features in the landscape that impart information about a soil. The geomorphic information needs to be described as precisely as possible, including the physiographic location, geomorphic description, and surface morphometry. The physiographic information includes: (1) physiographic division; (2) physiographic province; (3) physiographic section; (4) state physiographic area; and (5) local physiographic or geographic name. The geomorphic information includes: (1) landscape, (2) landform, (3) microfeatures, and (4) anthropogenic features. The surface morphometry includes: (1) elevation; (2) slope aspect; (3) slope gradient; (4) slope complexity; (5) slope shape; (6) geomorphic components; and (7) microrelief. The vegetation type is described, listing the common names of the plants and their scientific names when possible. The latitude and longitude, in degrees, seconds, and minutes, are most commonly used to record the geographical location of the soil as precisely as possible.

Horizons

Soil horizons may be the most distinctive visual features of a soil profile. According to the *Soil Survey Manual*, a soil horizon is a layer approximately

parallel to the surface of the soil, distinguishable from adjacent layers by a distinctive set of properties produced by the soil-forming processes. The term 'layer,' rather than 'horizon,' is used if all the properties are believed to be inherited from the parent material or no judgment is made as to whether the layer is genetic.

The depth to and thickness of the horizon should be recorded as well as the horizon designation. Horizons are labeled according to diagnostic features and interpretations. A master horizon label is given which represents characteristic properties. As an example, the system developed by the US Department of Agriculture (USDA) uses O, A, E, B, C, and R as master horizon labels. These labels correspond to:

1. O horizons and layers: Layers dominated by organic material. Some are saturated with water for long periods or were once saturated but are now artificially drained; others have never been saturated.
2. A horizons: Mineral horizons that formed at the surface or below an O horizon which exhibit obliteration of all or much of the original rock structure and that show one or more of the following: (1) an accumulation of humified organic matter intimately mixed with the mineral fraction and not dominated by properties characteristic of E or B horizons; or (2) properties resulting from cultivation, pasturing, or similar kinds of disturbance.
3. E horizons: Mineral horizons in which the main feature is loss of silicate clay, iron, aluminum, or some combination of these, leaving a concentration of sand and silt particles.
4. B horizons: Horizons that formed below an A, E, or O horizon, contain soil structure, and show one or more of the following: (1) illuvial concentration of silicate clay, iron, aluminum, humus, carbonates, gypsum, or silica, alone or in combination; (2) evidence of the removal of carbonates; (3) residual concentration of sesquioxides; (4) coatings of sesquioxides that make the horizon conspicuously lower in value, higher in chroma, or redder in hue than overlying and underlying horizons without apparent illuviation of iron; (5) alteration that forms granular, blocky, or prismatic structure if volume changes accompany changes in moisture content; or (6) brittleness.
5. C horizons or layers: Horizons or layers, excluding hard bedrock, that are little affected by pedogenic processes and lack properties of O, A, E, or B horizons. The material of C layers may be either like or unlike that from which the solum presumably formed.
6. R layers: Hard bedrock.

Soil horizons can be dominated by properties of one master horizon but have subordinate properties of another; in which case, the master horizons may be combined to denote this interpretation (i.e., AB, EB, CB, BC, etc.). Where soil material from two horizons is within the same horizon, a virgule (/) is used to indicate two materials within that same horizon that can be described separately with regard to color, texture, and structure (i.e., Bw/A, Bt/A, C/Bt, etc.).

Table 1 Suffix symbols used by the USDA for master horizons

Suffix	*Horizon*
a	Highly decomposed organic material
b	Buried genetic horizon
c	Concretions or nodules
d	Physical root restriction
e	Organic material of intermediate decomposition
f	Frozen soil or water
ff	Dry permafrost
g	Strong gleying
h	Illuvial accumulation of organic matter
i	Slightly decomposed organic material
j	Accumulation of Jarosite
jj	Evidence of cryoturbation
k	Accumulation of carbonates
m	Cementation or induration
n	Accumulation of sodium
o	Residual accumulation of sesquioxides
p	Tillage or other disturbance
q	Accumulation of silica
r	Weathered or soft bedrock
s	Illuvial accumulation of sesquioxides and organic matter
ss	Presence of slickensides
t	Accumulation of silicate clay
v	Plinthite
w	Development of color or structure
x	Fragipan character
y	Accumulation of gypsum
z	Accumulation of salts more soluble than gypsum

Reproduced from Soil Survey Staff (1998) *Keys to Soil Taxonomy*, 8th edn. USDA, Natural Resources Conservation Service. Washington, DC: US Government Printing Office.

Designations of soil horizons are supplemented with suffixes or subscripts to convey more information about a horizon. Description systems vary slightly; however, as an example the suffixes used by the USDA are listed in Table 1.

Soil horizons and layers have been developed based on central concepts observed from field investigations. The properties between soils vary greatly and are a continuum of properties. There are no definitions that are rigorously followed to label each horizon. The labeling is an interpretation based on observations of the scientist; however, the classification of the soil, which is based on the description, does follow criteria definitions.

Soil Texture

Soil texture is one of the most common features used by scientists and laymen to describe soils. Texture

refers to the relative abundance, by weight, of the size fractions – sand, silt, and clay. In all textural classification systems, the sum of all particles (by weight) less than or equal to 2 mm is equal to 100% (Figure 1), and is referred to as the 'fine-earth fraction.' There are several textural classification systems used, with varying ranges of particles sizes (Figure 2).

Textural descriptions are commonly used, because it is cumbersome to give the percentage of sand, percentage of silt, and percentage of clay within a description. Commonly, field estimates of sand, silt, and clay are used, and the soils are placed into textural classes. These textures are verified by laboratory analysis. The mineralogy of the clay may affect estimates of clay in field textures. The kaolinitc clays expand less and tend to be less expressed than smectitic clays which may result in an underestimation of the percentage of clay.

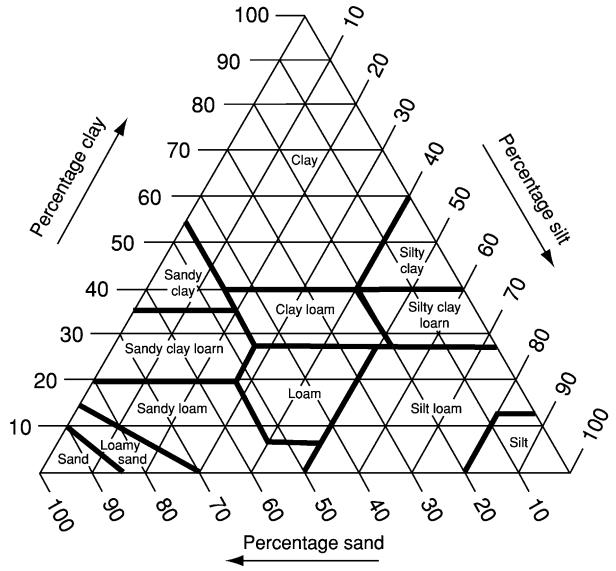

Figure 1 USDA soil textural triangle.

Soil texture relates to many of the ways a soil performs. If a soil is coarse (sandy), water tends to move through it quite well, but it may not retain enough water for plant growth. If a soil is clayey, water will probably move slowly but it should retain water for plant growth. The shrink–swell potential of clayey soils varies quite widely depending on the type of clay minerals present. If the soil is high in smectitic clay minerals, it will shrink and swell as the moisture content of the soil changes. If the shrinking and swelling are not considered in the design of infrastructure, it will cause problems for roads and foundations. However, if the clay mineral is primarily kaolinite and other low-activity minerals, construction on such soils should not be a problem. Also, if the particles larger than 2 mm are of sufficient quantity to be important, the textural classes are prefixed with modifiers. These separates are classed as gravel, cobbles, or stones (Figure 2). (*See* **Texture**.)

Soil Color

Soil colors are used to infer pedogenic processes in soils. The main pigmenting (coloring) agents in soils are organic matter, iron, and, to a lesser extent, manganese. When these agents are not covering the mineral grains, the natural color of the grains is visible. Most mineral grains are naturally gray. The contrast of color is shown in Figures 3 and 4, where two soils

USDA	Clay	Silt			Sand							Gravel				Cobbles		Stones				
		Fi.		Co.	V.Fi.		Fi.		Med.		Co.	V.Co.	Fi.		Med.		Co.					
	0.002			0.05							2						76		250 mm

Figure 3 Highly developed soil in a well-drained convex position.

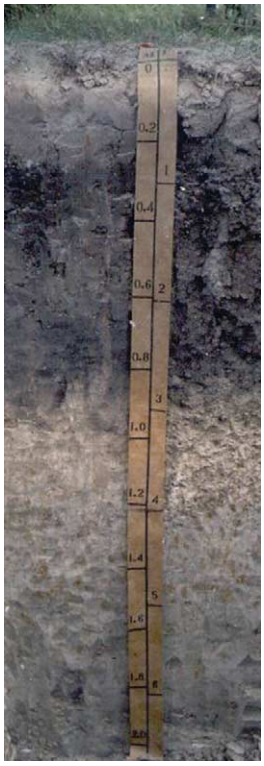

Figure 4 Highly developed soil in a poorly-drained concave position.

have similar texture and structure yet differ in color scheme. When a soil horizon has more than one color, the dominant color by volume is the matrix color.

Soil colors are most conveniently measured by comparison with a soil color chart. The one generally used is a modification of the Munsell color chart that includes only the portion needed for soil colors, about one-fifth of the entire range of color. The arrangement is by hue, value, and chroma – three simple variables combine to give all colors. Hue is the dominant spectral (rainbow) color; it is related to the dominant wavelength of the light. Value refers to the relative lightness of the color and is a function (approximately the square root) of the total amount of light. Chroma is the relative purity or strength of the spectral color and increases with decreasing grayness.

In the soil color chart, all colors on a given card are of a constant hue, designated by a symbol in the upper right-hand corner of the card. Vertically, the colors become successively lighter by visually equal steps; their value increases. Horizontally, they increase in chroma to the right and become grayer to the left. The value and chroma of each color in the chart are printed immediately beneath the color. The first number is the value and the second is the chroma. As arranged in the chart, the colors form three scales: (1) radial, or from one card to the next, in hue; (2) vertical in value; and (3) horizontal in chroma.

The matrix color is the first color described in a soil horizon or layer, since it is by definition the most dominant color. The moisture status of the soil color must be taken into account when describing soil color, i.e., moist or dry. To determine soil color, a fresh ped (a unit of soil structure) interior is used to eliminate the possibility of describing the color of a ped surface coating.

Redoximorphic Features and Mottles

The lack of uniformity of soil color may give insight regarding the pedogeneis of the soil. In the USDA description terminology, the generic term 'mottle' was changed to 'redoximorphic feature' when describing features in the soil resulting from reduction–oxidation reactions. The term 'redoximorphic feature' is a more descriptive term used when the pedogenic processes of reduction and oxidation are interpreted. 'Mottles' is a term used for spots in the soil and infers no pedogenic process.

Redoximorphic Features

Soil colors are greatly affected by the oxygen supply in the soil. As long as there is sufficient oxygen for microbial activity, the soils are usually brown or red and frequently have a single dominant color.

However, when soils become wet (saturated with water), the oxygen supply cannot flow as freely and the supply becomes insufficient for many microbes. Insufficient oxygen in the soil results in reduction – a process by which iron and manganese gain electrons.

Figure 5 Iron depletions illustrated in the subsoil.

Reducing conditions in soils are precursors to redoximorphic features, which are multicolored. Reduction of iron and manganese greatly increases their solubility, thus allowing them to dissolve into solution and move with the water, i.e., become mobile. Features caused by reduction or reduction and subsequent reoxidation are also called 'redoximorphic features.'

When the iron in the soil goes into solution, it uncoats the mineral grains, resulting in zones called 'depletions,' where the color is that of the mineral grains – usually gray. When air reenters the soil, the iron and manganese are oxidized and precipitate into brownish to reddish to blackish forms called 'concentrations.' Thus depletions are caused by removal of iron coatings, and concentrations are caused by oxidation and precipitation of previously reduced forms of iron and manganese. Both depletions and concentrations require reduction, but only concentrations require subsequent reoxidation.

Concentrations and depletions are described by kind, size, abundance, and color. Depletions are usually lighter colored than the matrix (**Figure 5**), and concentrations are usually browner, redder, or blacker than the matrix (**Figure 6**). There are several kinds of concentrations, which are described as finely disseminated materials, masses (noncemented), nodules, or concretions (cemented). Masses are noncemented concentrations of iron and manganese. Concretions and nodules are both cemented accumulations of iron and manganese, but differ in their internal structure: concretions have concentric rings, whereas nodules do not (**Figure 7**). There are two types of depletions: (1) iron depletions, which are primarily a lighter color

Figure 6 Iron concentrations.

Figure 7 A manganese nodule in a loess soil.

than the matrix; and (2) clay depletions, which have the same color change but also have lost clay and thus are grainier.

Mottles

Mottles (areas of color that differ from the matrix color) are commonly lithochromic or lithomorphic colors. Commonly these features are inherited from the geologic parent material rather than pedogenesis. Also included in mottles are relic redoximorphic features, which are features that formed in a pluvial environment or in landscape that has been naturally or anthropogenically altered and permanently affects the drainage of the soil. Description of mottles may include abundance, size, contrast (to matrix), color, and name of object boundary.

Soil Structure

An undisturbed soil forms several levels of structure that can be divided into primary, secondary (compound), and tertiary structure. The primary structural units are the basic structural units used in morphological descriptions. Secondary and tertiary structure are defined as: (1) the size, shape, and arrangement of the primary peds, their interpedal voids, and associated interpedal pedological features in a soil material; (2) the size, shape, and arrangement of the secondary peds of a sol material (compound peds resulting from the packing of primary peds), their interpedal voids and associated interpedal pedological features. Soil structure refers to units composed of primary particles. The cohesion within these units is greater than the adhesion among units and is a product of processes that aggregate, cement, compact, or unconsolidate soil particles. Under stress, the soil mass tends to rupture along predetermined planes or zones. The peds form repetitive, quasi-uniform shapes.

Clods and fragments stand in contrast to peds, for which soil-forming processes exert weak or no control on the boundaries. A clod is caused by disturbance, such as plowing or digging, which molds the soil to a transient mass that slakes with repeated wetting and drying. Fragments include: (1) units of undisturbed soil with bounding planes of weakness that are formed on drying without application of external force and which do not appear to have predetermined bounding planes; (2) units of soil disturbed by mechanical means but without significant rearrangement to a denser configuration; and (3) pieces of soil bounded by planes of weakness caused by pressure exerted during examination, with size and shape highly dependent on the manner of manipulation.

Some soils lack structure and are referred to as structureless. When structureless soils are ruptured, soil fragments, single grains, or both may result. Structureless soil may be termed either ‘massive’ or ‘single grain.’ Massive soils tend to form fragments when disturbed, and single grain soils are usually sandy and are loose in 50% or more of the mass.

Shape

Several basic shapes of structural units are recognized in soils. Supplemental statements about variations in shape of individual peds are needed in detailed descriptions of some soils. Table 2 and Figure 8 describe the possible shapes of soil structure.

Table 2 Types of soil structure

Structure	*Description*
Natural soil structural units (pedogenic structure)	
Granular	Small peds, with rounded or very irregular faces
Angular blocky	Peds with faces that intersect at sharp angles
Subangular blocky	Peds with sub-rounded shapes and lacking sharp angles
Platy	Flat plate-shaped units
Wedge	Elliptical, interlocking lenses that terminate in acute angles, bounded by slickensides; not limited to vertic materials
Prismatic	Vertically elongated peds with flat tops
Columnar	Vertically elongated peds with rounded tops
Structureless	
Single grain	No structural units; entirely noncoherent; e.g., loose sand
Massive	No structural units; material is a coherent mass

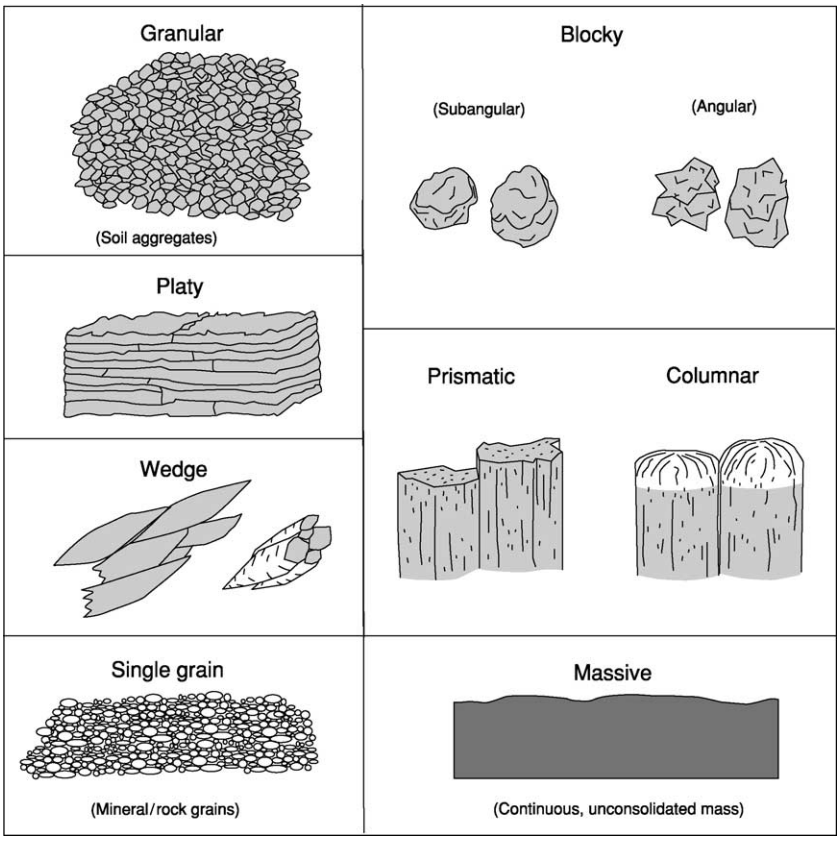

Figure 8 Shapes of soil structure. (Reproduced from Schoenberger PJ, Wysocki DA, Benham EC, and Broderson WD (eds) (2002) *Field Book for Describing and Sampling Soils*, version 2.0. Natural Resources Conservation Service. Lincoln, NE: National Soil Survey Center.)

Size

There are five classes that are used to describe the size of structural units: very fine, fine, medium, coarse, and very coarse. The size limits vary according to the shape of the unit. The size limits refer to the smallest dimension of plates, prisms, and columns.

Grade

The distinctness of units is described by the grade. Criteria are based on the ease of separation into discrete units and the proportion of units that hold together when the soil is handled.

Weak Units that are barely observable in situ are termed 'weak.' When gently disturbed, the soil material parts into a mixture of whole and broken units and much material that exhibits no planes of weakness. Faces that indicate persistence through wet–dry–wet cycles are evident.

Moderate Units graded as moderate are well formed and evident in undisturbed soil. When disturbed, the soil material parts into a mixture of mostly whole units, some broken units, and material that is not units. Peds part from adjoining peds to reveal nearly entire faces that have properties distinct from those of fractured surfaces.

Strong Units that are distinct in undisturbed soil are graded 'strong.' They separate cleanly when the soil is disturbed. When removed, the soil material separates mainly into whole units.

The distinctness of individual structural units and the relationship of cohesion within units to adhesion between units determine grade of structure. The degree of disturbance required to determine structure grade depends largely on moisture content and percentage and mineralogy of clay. Only slight disturbance may be necessary to separate the units of moist sandy loam having strong granular structure, while considerable disturbance may be required to separate units of a moist clay loam having strong blocky structure.

The designation of structure grade, size, and shape can be modified with other appropriate terms when necessary to describe other characteristics. Surface characteristics of units are described separately. Special structural units, such as wedge-shaped units of high-potential shrink–swell soils, are described in appropriate terms.

Compound Structure

'Secondary structure' is another term for 'compound structure,' where smaller structural units may be held together to form larger units. Grade, size, and shape are given for both, and the relationship of one set to the other is indicated. 'Strong medium blocks within moderate coarse prisms' and 'moderate coarse prismatic structure parting to strong medium blocky' are examples of compound structure.

Soil Consistence

Consistence refers to the cohesion and adhesion within a soil or its resistance to deformation or rupture. The consistence of soils changes greatly as the soil moisture changes. There are many expressions of consistence, such as rupture resistance, surface crust, manner of failure, stickiness, plasticity, penetration resistance, and others.

The most commonly used parameter of consistence is field evaluation (i.e., rupture resistance), which is conducted by placing a specimen 25–30 mm on each side between the thumb and first finger and applying pressure. Again, the moisture content of the soil sample is very important.

Soils in humid and subhumid climates may form brittle subsurface horizons. The degree and percentage of brittleness of the soil are described. Soils may also be hardened due to cementation. In this case, the materials accumulated causing the cementation, such as carbonates, gypsum, humus, iron, and/or silica are listed. In addition, the percentage, cementation of soil and the strength of the cementation are noted.

Roots and Pores

The roots and pores that can be observed in the field are among the larger pores in the soil. These pores are mostly noncapillary pores, i.e., pores that cannot hold water against the force of gravity. These pores are of major importance in moving water and air within the soil. After a major wetting of the soil (rainfall, snowmelt, irrigation, etc.), these pores must transmit the water throughout the soil to the smaller capillary pores. The noncapillary pores should redistribute the water in a few days, because they must drain in order also to distribute oxygen (air) into the soil. If soil oxygen is depleted for more than a few days, many plants will die or at least be harmed, although some plants thrive in oxygen-deprived soils.

Normally soils with a mixture of noncapillary and capillary pores are preferred, because they both drain well and retain water for plant growth. When describing roots and pores, at least the abundance of each size class is assigned; for example, common fine roots or many medium pores.

Chemical Response

pH

The acidity or alkalinity can infer much information about a soil. The pH of a soil can be estimated with a simple field test kit. There are several soil pH class systems used to categorize soil pH. Each horizon or layer within a pedon is tested as pH may vary dramatically due to pedogenic or lithogenic properties.

Effervescence

A simple field technique may be used to check for the presence of free carbonates. A 10% solution of HCl added to the soil produces a gaseous response when

$CaCO_3$ is present. The gaseous response of the HCl will vary depending on the amount of carbonates in the soil. The degree of effervescence is noted in the description.

Reaction to Alpha,Alpha′-Dipyridyl

In soils that are actively reducing at an Eh (redox potential) or pE (relative electron activity) low enough to produce ferrous iron, a 0.2% concentration of alpha,alpha′-dipyridyl (also listed as 2,2′-bipyridine) may be used. This solution is applied to the soil within minutes of exposure in the absence of sunlight. If Fe^{2+} is present, the alpha,alpha′-dipyridyl will change to a red or pink color; if only Fe^{3+} is present, the solution will remain clear. This solution will react with a few parts per million of Fe^{2+}, so care should be used when extracting soil. The Fe^{2+} from a knife blade or spade contact with the soil will produce a false-positive response. This solution should only be used when reducing conditions are suspected.

Special Features

Pedon Features

Pedon features occur throughout the pedon and may cross adjacent horizons. These features are described using standard technical terms; however, some added language is sometimes used to supplement the description (Table 3).

Horizon or Layer Features

Concentrations are identifiable bodies within the soil that have been formed due to the pedogenic processes of chemical dissolution and/or precipitation, transport, accrual, and physical and/or biological removal. Concentrations may be finely disseminated materials, masses, nodules, concretions, crystals, biologic concentrations, and/or inherited minerals. The kind, size, abundance, and color are used when describing concentrations. In some soils, supplemental information is needed to describe concentrations fully.

Ped Surface Features

Surface features occur from a variety of pedogenic processes and result in differences from the matrix soil in composition, orientation, or packing. Surface features include: (1) coats of a variety of substances unlike the adjacent soil material and covering part or all of surfaces; (2) material concentrated on surfaces by the removal of other material; and (3) stress formations in which thin layers at the surfaces have undergone reorientation or packing by stress or shear. Descriptions of surface features may include kind, location, amount, continuity, distinctness, and thickness of the features. Where the features are thick and there are contrasting colors, this is noted. Table 4 lists some common ped surface features found in soils.

Location

Surface features may vary in the coverage of peds or may coat other soil constituents such as gravel or rocks.

Amount

The number should be noted as a percentage or a percentage range. Some horizons have more than one surface feature. In those cases, each surface feature is noted with the percentages of each feature.

Table 3 Common pedon features

Pedon feature	*Description*
Cracks	Fissures other than those attributed to soil structure
Desert pavement	Natural concentration of polished gravel and stones at the soil surface primarily in arid and semiarid climates
Ice crystals, lenses, layers (veins), wedges	Features occurring in soils of Arctic, Antarctic, and Subarctic regions
Jarosite mottles	Yellow jarosite mineral accumulations due to oxidation of sulfidic accumulations
Krotovinas	Irregular tubular streaks of soil material within a horizon or layer transported to another horizon or layer due to biologic activity
Lamellae	Thin banded illuviated clay
Microbiotic crust	Thin surficial zone exhibiting more mechanical continuity of the soil fabric than the subjacent soil
Stone line	Natural accumulation of coarse fragments below the surface extending through the pedon
Tongues of albic material	Lobes of eluviated soil that extend into the soil horizon from overlying horizons

Reproduced with permission from Schoenberger PJ, Wysocki DA, Benham EC, and Broderson WD (eds) (2002) *Field Book for Describing and Sampling Soils*, version 2.0. Natural Resources Conservation Service. Lincoln, NE: National Soil Survey Center.

Table 4 Common ped surface features

Ped feature	*Description*
Clay films	Layers of oriented, translocated clay ('clay skins')
Clay bridges	Links between mineral grains found primarily in sandy soils
Stress surfaces, pressure faces	Smooth, shiny or smeared surfaces formed through rearrangement of particles resulting from shear forces
Slickensides	Stress surfaces that are polished and striated; direction of movement can be determined from striations
Other features	Coats of iron, aluminum, or manganese oxides, organic matter, salts, or carbonates

Reproduced from Schoenberger PJ, Wysocki DA, Benham EC, and Broderson WD (eds) (2002) *Field Book for Describing and Sampling Soils*, version 2.0. Natural Resources Conservation Service. Lincoln, NE: National Soil Survey Center.

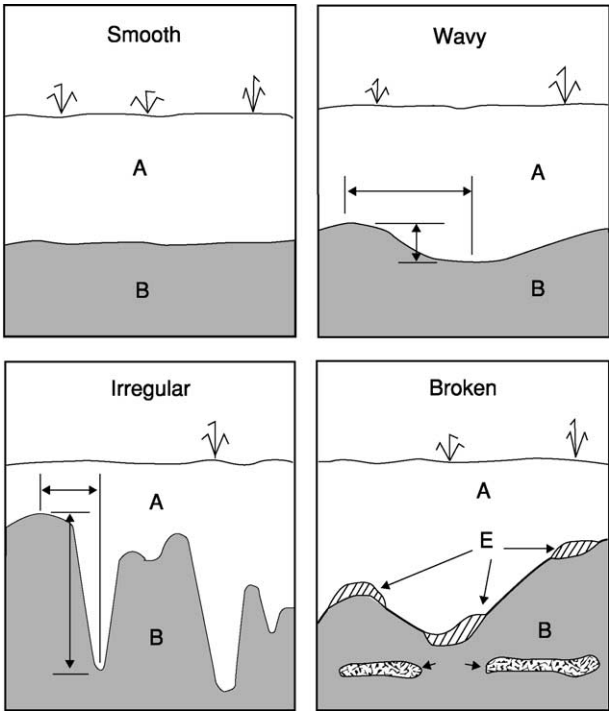

Figure 9 Boundary nomenclature of soil horizons. A, A horizon; B, B horizon; E, E horizon. (Reproduced from Schoenberger PJ, Wysocki DA, Benham EC, and Broderson WD (eds) (2002) *Field Book for Describing and Sampling Soils*, version 2.0. Natural Resources Conservation Service. Lincoln, NE: National Soil Survey Center.)

Boundary

The horizons or layers may be parallel to the surface; however, in some soils the bottom boundary may vary depending on the pedogenesis. In most description systems, the bottom boundary of the soil horizon or layer is described as smooth, wavy, irregular, or broken (Figure 9). The distance in which the boundary grades into or changes is normally described also. The boundary classes are abrupt (0–2 cm), clear (2–5 cm), gradual (5–15 cm), and diffuse (more than 15 cm).

Soil Micromorphological Description

The discussion in this chapter has focused on the macromorphological description of soils in the field. There is a discipline devoted to micromorphological descriptions in the laboratory using soil thin sections. These descriptions are valuable for classification and elucidating pedogenesis in soils. Where possible a micromorphologic investigation is used to supplement and verify features in the macromorphological description.

MULCHES

C L Acharya, K M Hati, and K K Bandyopadhyay,
Indian Institute of Soil Science, Bhopal,
Madhya Pradesh, India

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Mulch means a layer of dissimilar material separating the soil surface from the atmosphere, and mulching is the artificial application of mulch, practiced to obtain beneficial changes in the soil environment. Mulch may be organic (crop residues, stubble mulch etc.) or inorganic (plastic sheet, gravels etc.) in nature. It may be grown *in situ* like previous crop residue mulch left on the soil surface, produced by a cover crop or it may be living mulch like perennial legume mulch. It may also be grown or produced *ex situ* and brought in for field application, e.g., straw, sawdust, plastic products etc.

The practice of mulching has been widely used as a management tool for centuries in many ancient civilizations. The Great Plains region of the USA, which was once considered to be a dust bowl, has been turned into the granary of the world through the adoption of conservation tillage, the practice of leaving crop residues as the surface stubble or flattened straw mulch. The idea of using plastics as mulch originated in Hawaii, where it was used in pineapple cultivation with considerable success.

Mulch has a buffering effect and it dampens the influence of environmental factors on soil. The magnitude of the buffering effect of mulches depends upon the quality, quantity and durability of mulch material, soil type and the climatic conditions. Mulching influences the soil hydrothermal regime by influencing the radiation balance, rate of heat and water vapor transfer, and heat capacity of soil. Mulching improves the physical condition of soil by enhancing soil aggregation and helps in conservation of water by checking evaporation, increasing infiltration and retarding runoff loss. It favorably modifies the soil thermal regime, retards soil erosion, and improves soil chemical environment and biological activity in soil. Modification of the soil microclimate by mulching favors seedling emergence and root proliferation and suppresses weed population. Organic mulches add nutrients to soil when decomposed by microbes and help in carbon sequestration. Favorable soil edaphic environment under mulch improves crop productivity, enhances input-use efficiency and checks environmental pollution. From the conservation viewpoint, mulch simulates the effect of a plant cover. It is most useful as an alternative to cover crops in dry areas where insufficient rain prevents the establishment of a ground cover before the onset of heavy rain or strong winds, or where a cover crop competes for moisture with the main crop.

However, improper application of mulches leads to creation of an anaerobic environment under a heavy rainfall situation, leading to loss of nitrogen through denitrification. It may cause disease and pest infestation and some allelopathic materials produced in some crop residues retard the crop growth. So proper site-specific methodology needs to be followed under different soil, crop and climatic conditions for efficient mulch management to achieve sustainable crop production.

How Mulching Influences the Soil Environment

Mulching improves the physical conditions, chemical environment and biological activities of soil. Favorable modification of the soil hydrothermal regime, improvement of soil aggregation and retardation of erosion and soil loss enhance the physical condition of soil under mulch. Improvement in the soil chemical environment and biological activities by mulching is mainly attributed to the enrichment of soil organic matter through organic mulching and improvement of the physical condition of soil under both organic and inorganic mulches.

Soil Moisture Regime

Mulching favorably influences the soil moisture regime by controlling evaporation from the soil surface, improving infiltration and soil-moisture retention and facilitating condensation of water at night due to temperature reversals.

Controling evaporation from the soil surface Direct evaporation of water from the soil surface is an important process, particularly in the case of bare soils or in areas where summer fallow is practised. Mulching reduces evaporation from the soil surface by retarding the intensity of the radiation and wind velocity on the mulched surface. It is effective in retarding the evaporation mainly during the initial energy-limited stage of drying. However, mulching is not very effective in controling evaporation during the falling-rate or supply-controled stage of evaporation. During this stage, the soil surface dries under the mulch and the vapor transfer of water to

the atmosphere is inhibited more by the dry soil than by the overlying vegetative mulch. Higher mulch rate retards the energy reaching the soil surface and hence limits the evaporation at the constant-rate stage (Figure 1). The retardation of initial evaporation can also enhance the process of internal drainage and thus allows more water to migrate downward into the deeper parts of the profile, where it is conserved longer and is less likely to be lost by evaporation.

Mulching also affects the pattern of evaporation by offering resistance to water vapor flow from the soil surface to atmosphere and by increasing the thickness of the relatively non-turbulent air zone above the soil, thus changing the boundary layer conditions of the soil–air interface. The relative magnitude of evaporation reduction for different mulch rates is much greater under high evaporative demand. The cumulative evaporation reduction due to mulching follows a quadratic relationship with time. The magnitude of maximum evaporation reduction and the time when it is reached depends on the rate of mulching, soil type, magnitude of evaporative demand and the method of residue application (Figure 2). The orientation of the residue, i.e., flat or matted versus standing, affects the porosity and thickness of the layer and thus the rate of evaporation from the soil surface. As the amount of standing residue increases, greater wind speed is needed to initiate water loss through evaporation; in addition, the water loss rate at a given wind speed decreases with increased amounts of standing residue. Residue position also affects soil temperature (Table 1), which in turn affects the evaporation rate through its influence on the vapor pressure of the soil water.

Water-saving under mulching is prominent if rains are frequent. However, under extended dry spell periods, mulch may keep the soil surface moist for longer periods and hence prolong the first stage of evaporation and thus produce no net saving of water.

Improving infiltration rate Mulching with organic materials improves the infiltration rate because it serves as a barrier for runoff, which provides more opportunity for water to infiltrate into the profile. Secondly, mulch intercepts the rainwater, protects the soil from its biting action and checks splashing of the soil. It prevents crust formation due to clogging of soil pores, which increases infiltration rate. Furthermore, organic mulches improve the macroporosity and stability of the structural aggregates of soil

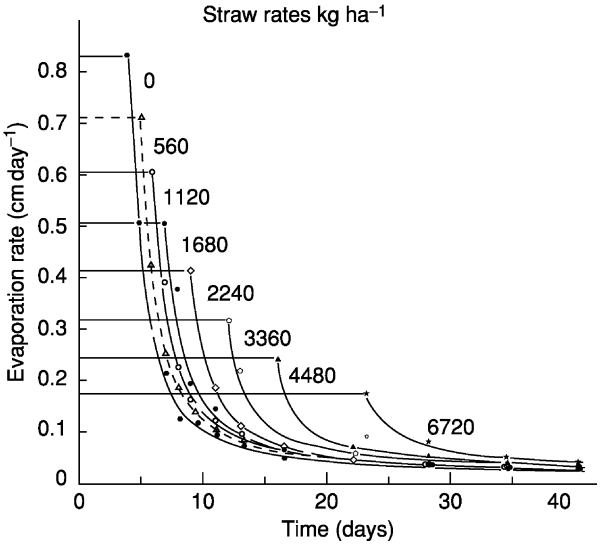

Figure 1 Temporal variation of soil water evaporation rate as influenced by rates of straw mulch application. Straw rates range from 0–6720 kg ha^{-1}. Reproduced with permission from Bond JJ and Willis WD (1969) *Soil Science of America Proceedings* 33: 446.

and thereby improve the water transmission properties (Table 2), which facilitate better infiltration and recharge of the soil profile. Straw mulch application increases soil water storage and storage efficiency. The amount of water storage in the soil profile, the storage efficiency, total water use and water-use efficiencies of dryland crops increase with increase in the mulch rate (Table 3). The increase in infiltration that results from mulch is found to be more important in some situations than its effect on reduction in evaporation for conservation of water in the profile.

Soil moisture retention Mulching improves the moisture retention properties of soil through its effect on pore-size distribution and soil structure. Higher mulch rates increase soil-water retention more at lower suctions (Table 4) due to an increase in macropores and interaggregate pores caused by enhanced soil organic matter content and higher activity of soil fauna, e.g., earthworms and termites in mulched plots.

Table 2 Effect of mulch rate on water transmission properties of an Alfisol

Water condensation at night Stone and gravel mulches induce lateral movement of heat and vapor, which could in turn collect water under the stones, due to condensation of vapor at night, in amounts sufficient enough to serve as the source of water for some species of desert plants.

Controlling Runoff and Soil Erosion

Mulching invariably decreases soil erosion and often reduces the rate and amount of runoff. Mulch cover protects the soil from raindrop impact and surface sealing, increases the infiltration rate and decreases runoff velocity through physical resistance to water flow. In general, loss of water through runoff decreases exponentially with increase in mulch rate (Table 5). For some soils, mulch does not substantially decrease runoff and drastically reduces soil erosion. The runoff water gets filtered through the mulch and is often clear with little sediment. Mulching decreases sediment concentration in runoff water through the protective effect of crop residues against raindrop.

The rate of soil loss decreases exponentially with the increase in the percentage area covered by mulch. The mulch factor (MF), defined as the ratio of soil loss with mulch to that without mulch, is related to the percentage residue cover (RC) or mulch cover by the following expression:

Table 4 Effect of mulch rate on moisture retention properties of 0–5 cm layer of an Alfisol

	Moisture retention (% w/w) at different suction (bar)			
Mulch rate (Mg ha^{-1})	0.03	0.06	1	15
0	27.3	26.1	5.5	3.2
2	29.1	26.1	6.5	5.1

$$MF = e^{-aRC}$$

where, 'a' ranges in value from 0.03 to 0.07 and 0.05 is generally used. The exponential relationship is applied only for rill erosion whereas the interrill erosion decreases linearly with the mulch cover. Since for most soils the contribution of the interrill erosion to the total soil loss is quite small for slope length in excess of 25 m and for all but very low percentage residue covers, the above equation may be used to compute the mulch factor. This mulch factor is multiplied with the 'C' factor values for calculating the effect of mulching in the universal soil loss equation. It has been observed that a minimum of 50% soil cover is required to achieve reduction in soil loss. Ideally a mulch should cover 70–75% of the soil surface. The optimum mulch rate can be computed for a pre-selected set of conditions using the Manning's equation for flow velocity. The relationship between Manning's n and mulch rate is given below:

$$\text{Manning's equation:} \quad n = (r^{0.67} \times S^{0.5})/v$$

where, r = hydraulic radius, S = slope and v = desired maximum flow velocity.

The value of n due to mulch has been described as $n_m = (n^{3/2} - n_s^{3/2})^{2/3}$ where, n_s = Manning's n for a particular soil.

Mulch rate (M, kg m^{-2}) is related to the Manning's n for mulch (n_m) by the following relationship.

$$n_m = 0.071\, M^{1.12} \quad \text{for interrill erosion}$$
$$n_m = 0.105\, M^{0.84} \quad \text{for rill erosion.}$$

Experimental evidence shows that an adequate quantity of crop residue mulch can mitigate the effect of the degree of slope in reducing soil loss.

Mulching is also effective in reducing soil erosion by wind. It reduces the wind velocity on the soil surface when the mulch is fixed to the soil, so that soil particles do not get blown up by wind. Standing crop residues are more effective than flattened surface mulches in reducing wind erosion. The effectiveness of standing crop residues depends upon the number of stalks per unit area and their size.

Modifying Soil Thermal Regime

Mulch has a moderating influence on the soil thermal regime and the effect varies among soils, climate, kind of mulch materials used and rates of application. It increases soil temperature during cooler weather and decreases it during hot spells. In general, mulch has a damping effect on the amplitude of the diurnal fluctuations in soil temperature. Organic mulching enhances the soil temperature at night and early morning hours but it decreases the daytime temperature as compared to unmulched plots (Figure 3).

Mulching is commonly practiced in some fruit crops, like strawberry, to keep the fruit clean by avoiding direct contact with soil and to moderate the soil hydrothermal regime for better productivity and quality of fruit. Transparent polythene mulch raises the maximum soil temperature whereas organic mulches like pine needle and grass mulches lower it. Black polythene mulch, however, does not alter the maximum soil temperature appreciably (Figure 4). The application of straw mulch can lower maximum soil temperature due to the interception of incoming solar radiation, high reflectivity and low heat conductivity, the magnitude of which depends upon soil wetness, incidental radiation, rate of mulch application as well as period of the year (Table 6). The lowering of maximum soil temperature by straw mulching during the early stage of growth of sugarcane can significantly improve the yield.

Soil Aeration

Crop residue mulch improves soil aeration by promoting free exchange of gases between the soil and the atmosphere. This is facilitated by improvement of structural stability, total porosity and macroporosity, decrease of surface crusting and by improving the overall soil drainage. Oxygen diffusion rate is higher under mulch than under unmulched conditions. The gaseous composition of soil air under mulch depends on the nature of the mulch material (C:N ratio), its rate of decomposition, the soil moisture regime and the climatic condition. Plastic mulch is practically impervious to carbon dioxide (CO_2), a gas that is of prime importance for photosynthesis. Very high levels of CO_2 build up under the plastic, as the film does not allow it to escape. It has to come through the holes made in the plastic for the plants and a 'chimney effect' is created, resulting in localized concentrations of abundant CO_2 for the actively growing leaves that accelerates the growth of the crop.

Improving Soil Structure

Mulching improves soil structural properties directly by preventing raindrop impact and indirectly by promoting biological activity. Organic mulching improves the total porosity, macroporosity and mean weight diameter of water-stable aggregates, because of addition of organic matter upon decomposition by soil microorganisms. The mean-weight diameter of water-stable aggregates increases with increase in the mulch rate (Table 7).

In general, under mulched conditions, the bulk density of the soil is lower than that under unmulched

conditions. Bulk density decreases with increase in residue mulch rate. One of the reasons for the decrease in bulk density with increase in mulch rates is high earthworm activity in mulched plots.

Improving the Soil Chemical Environment

Organic mulches add organic matter and plant nutrients to soil upon decomposition. Thus, they improve carbon sequestration. The volatilization and leaching

loss of nitrogen is reduced under mulched conditions. During decomposition of organic mulches, soil mineral nitrogen is immobilized by microbes and thus its loss is minimized. Cation exchange capacity is substantially influenced by organic matter content in soils containing predominantly low-activity clays. Improvement in the cation exchange capacity of soil improves the fertility status of these soils. Furthermore, decomposition of organic mulches adds organic acids to the soil resulting in low soil pH, which influences the bioavailability of many plant nutrients, e.g., Fe, Mn, Zn, Cu, etc. Mulches also influence the availability of nutrients through their influence on physical conditions, hydrothermal regime and biological activity of the soil.

Improving Biological Activity in Soil

Soil biological activity is either directly influenced by the supply of food substrates by organic mulches or indirectly influenced by both organic and inorganic mulches through alteration of the soil hydrothermal regime. The activity and diversity of soil organisms is substantially influenced by the quality of mulch material and the rate of its application. The soil microorganisms (bacteria, fungi and actinomycetes) and soil fauna (earthworm, millipede, centipede etc.) help in the decomposition of soil organic matter and hence the availability of nutrients. However, mulching with materials of high C:N ratio results in immobilization of nitrogen by microorganisms. Mulching with organic residues of weeds like wild sage (*Lantana camara*) or eupatorium (*Eupatorium adenophorum*) under conservation tillage practices enhances the earthworm population due to supply of food substrate and a better hydrothermal regime under mulch (Table 8).

Types of Mulches

There are different types of materials ranging from natural plant residues, to gravel to various industrial products such as paper or plastic sheets, which are used as mulch. These can broadly be categorized into two groups i.e., organic mulch and inorganic mulch.

Organic Mulches

Organic mulches include living mulch, cover crops and mulches whose materials are derived from natural sources, such as field crops, trees, or natural waste products. These include hay, straw, wood chips, bark, sawdust, wood shavings, peat moss, compost, grass clippings, paper, and materials such as cocoa shells and buckwheat hulls. Organic materials for mulching should be a stable material that will remain in place at least through the growing season of an annual crop and longer for perennial crops. More durable organic material provides longer-lasting benefits as mulches than readily decomposable plant residues. Durability of organic mulch material depends upon its composition. Factors influencing the rapidity of residue decomposition include the nature of the material like the C:N ratio, cellulose and lignin content, climatic conditions, and types and population of soil microorganisms. The decay rate of surface-applied plant residues indicates that the high lignin and cellulose-containing cereal straws produce more weather-resistant mulch than do legumes.

The effectiveness of organic or vegetative mulches also depends upon the thickness of the mulch. A lesser covering does not adequately protect the soil while a greater covering suppresses plant growth. Vegetative mulches, due to their low thermal conductivities,

decrease the conduction of heat into and out of the soil, causing the soil underneath to be cooler during the day and warmer during the night than bare soil. Thus it acts as an insulating agent on the soil surface. Vegetative mulches significantly affect soil temperature through their effect on the radiant energy balance of the system. The radiation balance is influenced by reflection of incoming radiation by surface residues, differential heating of soil and air and alteration of evaporation of soil water from the surface. Soil temperature generally decreases as reflectance increases. The insulating effect of mulches improves with increase in thickness of the surface residue layer. Age of the residue, color, geometry (standing, flattened or matted), distribution and amount are the main characteristics that affect radiation reflection. Reflection is normally greatest from bright residues like wheat straw and decreases with residue aging (discoloration) and decomposition. As a result, temperature differences between residue covered and bare soils are greatest when residues are bright and decrease as they age and decompose.

Organic mulches have the advantage of being biodegradable. In time, they are broken down and consumed by microorganisms, adding to the soil's organic matter content and improving soil structure or tilth. The vegetative mulches reduce the rate of evaporation from the soil surface, but the effectiveness of vegetative mulching in the reduction of evaporation depends upon the thickness, type, orientation and color of the residue. The rate of evaporation decreases with an increase in mulch thickness. As the material density of mulch affects the thickness and surface coverage obtained with a given weight of material, a low-density material such as wheat straw reduces evaporation more effectively than higher-density materials such as sorghum stubble or cotton stalks. To obtain a reduction in evaporation similar to that obtained with wheat straw on a weight basis, about twice as much sorghum stubble and more than four times as much cotton stalks are needed.

Living or cover crop mulch is also an important organic mulch used for some specific crops. Living mulch is a covering of living plant material, which is planted or allowed to remain living on the land after another crop has been planted. The live mulch system is based on the principles of mixed cropping. Here a perennial legume is established with the objective of smothering weeds and a seasonal grain crop is grown in small strips through the established live cover crop. The system works if the live mulch is a low-growing, nonclimber and does not compete for light, moisture or nutrients with the main crops. The live mulch system is more successful in humid and sub-humid regions with little or no water deficit than in semiarid or arid regions. This system imparts some of the benefits similar to surface-applied organic mulches such as increased soil carbon content, increased rainwater infiltration and reduced soil erosion. Cover crop mulches suppress weed growth through modification of the microclimate and release of allelochemicals. By land-surface coverage, mulches block the light stimulus required for germination of many small-seeded weed species. However, drastic yield suppression of the food crops has been reported in some studies due to allelopathic effects of the cover crop on the main crop and competition for moisture during periods of drought stress. Some important crops like cereal rye (*Secale cereale* L.) and hairy vetch (*Vicia villosa* Roth) can be used as cover crop mulch. Cereal rye is one of the best winter-hardy cover crops grown in the mid-western USA. Perennial ryegrass (*Lolium perenne* L.), a potential cover crop, is commonly used as a living mulch for some vegetables like cabbage.

Paper mulch is an important organic mulch produced from recycled paper. It has been evaluated as an available biodegradable alternative to plastic mulch. Paper does not require disposal at the end of the season and the use of recycled paper can reduce solid waste as well as energy costs. But paper may decompose too rapidly to maintain season long ground coverage. This can be checked by treating the paper with waste cooking oil, which delays the breakdown and enhances soil warming by increasing the paper's translucency to sunlight.

Inorganic Mulches

Different inorganic materials such as plastic film, gravels, crushed rocks etc. are used as mulch. Inorganic materials used for mulches do not add nutrients or humus to soil and do not decompose except after long exposure to weathering. Otherwise these materials are effective mulches and several of them are permanent and quite attractive.

Plastic mulch Plastics are the most widely used inorganic mulch materials. Mulching with the help of plastic film has played a major role in plant cultivation by creating some measure of mechanical protection at the soil surface and a microclimate favorable from the aspects of temperature distribution, retention of humidity and the supply of carbon dioxide to the stomata of lower leaves of small plants. Plastic mulch has been used commercially for vegetable production since the early 1960s. It can be used very effectively with trickle or drip irrigation, particularly for the cultivation of vines and strawberries where it encourages the lateral development of the root system.

In many of the developed countries plastic film, such as low-density polyethylene (LDPE) film is rapidly replacing conventional vegetative mulching because of its effectiveness and commercial viability, particularly in the case of high-value crops. In this method around 30–60% of the cultivated area is covered with a thick polythene film (30–150 μm). The plants are allowed to grow through the holes made in the LDPE film. In ornamental plants it is often used under gravel or stone mulches. The effectiveness of the plastic mulch depends upon the color of the mulch. Color determines the energy-radiating behavior of the mulch and affects the surface temperature of the mulch and the underlying soil temperature.

Recent new innovations in plastic technology manufacturing have resulted in the production of new plastic products for the farmers, e.g., photodegradable mulch, co-extruded mulch (black/white), and different colored mulches that serve specific purposes like maintenance of cool soil temperature during summer in tropical countries, increased warming of soil in spring in temperate regions and repelling aphids with silver-colored mulch. By raising the soil temperature in the planting bed, plant growth is accelerated, producing earlier yields in the temperate region. Black plastic mulch can result in harvest 7–14 days earlier while clear plastic accelerates harvest by 21 days in some conditions. For enhancing the earliness of vegetable crops in temperate regions, the mulch should maximize the transmission of the soil-warming portion of sunlight (the near infra-red radiation) and minimize the amount of visible light transmitted, as this visible light increases the weed growth under the mulch.

Due to the high cost of the cover and the difficulty of keeping it in place, plastic mulches are mainly used for some high-value vegetable and cash crops where these are found to be cost-effective. Muskmelons, tomatoes, peppers, cucumbers, squash, eggplants, watermelons and okra are some of the vegetable crops that have shown significant increases in earliness, yield, and fruit quality when grown on plastic mulch. Some less-valuable crops like sweetcorn, snap beans, southern peas and pumpkins have also shown similar responses in temperate climates. Based on the ability to transmit, absorb or reflect specific wavelengths, plastic mulches are divided into the following categories.

Black plastic mulch: Black is the most commonly used color of polyethylene mulch. This is chosen more often than clear polythene mulch because of its ability to control weeds by excluding photosynthetically active radiation. Black polythene placed in direct contact with the soil can warm the soil down to a depth of about 8–10 cm. Under black plastic film the temperature of the soil during the day is not significantly higher and in certain cases it is even lower than in the bare ground but during the night the temperature is always higher by 0.5–4°C than uncovered ground. This is desirable for warm-season vegetables such as peppers, tomatoes, eggplants etc. It is also widely used for the cultivation of pineapples in Hawaii, USA for reaping a higher yield.

Transparent/clear plastic mulch: Clear plastics have the greatest warming potential. They are transparent to incoming radiation and trap the longer wavelengths re-radiating from the soil, thereby producing a greenhouse effect that warms the soil underneath. Under transparent plastic film during daytime, soil temperature remains 2–10°C more than the bare ground while at night a difference of 2–4°C is observed, depending on the season, soil type and its moisture content. For warm-season crops, such as vine crops, earlier and higher yields can be achieved with clear mulch. However, as clear mulch is transparent to visible light, weed infestation under this mulch poses some serious problems, which may negate the benefits of soil warming.

White plastic mulch: Under white plastic mulch the temperature always remains lower than the uncovered ground due to its high reflectance and low transmittance of solar radiation. Since energy exchange is very poor, this film is used either in regions with a high level of sunshine where it is required to reduce the energy and lower the soil temperature or in regions of low luminosity where the amount of reflected light is to be increased on the lower and middle leaves of crop plants.

Colored plastic mulch: These are opaque, like black plastics, and are made with many different pigments. They do not allow light to pass through, but rather, reflect specific wavelengths of light up into the crop canopy. These mulches may be useful for enhancing crop production. For example, red mulches are effective in promoting growth of tomatoes. The other response observed with different mulch colors is the increase or decrease in insect population depending on reflected light and possibly temperature. Yellow appears to attract insects, especially cucumber beetle, and silver appears to repel aphids. The possibility of utilizing yellow mulch to monitor insect populations in a field of non-yellow plastic mulch shows promise. In addition, reduction of pesticide applications could be possible if only rows of yellow mulch (one row of yellow for every five or six rows of other-colored mulch laid) were sprayed with insecticide to control

high populations of pests. Thus, yellow plastic mulches can be used to attract insects, much like a trap crop.

Infrared transmitting mulches (IRT): These have been developed recently and are wavelength-selective mulches. IRT mulches warm the soil intermediate to clear and black polythene mulches. These mulches are pigmented to reduce the amount of visible light transmitted and thereby reduce weed growth underneath. Thus, they blend the soil-warming characteristics of clear mulch with the weed-control ability of black mulch. IRTs contain very specific pigments that give them the unique ability to transmit a maximum of near-infrared radiation and a minimum (14–16%) of visible light. Some visible light is required to be transmitted in order to maximize soil warming. The benefits of IRTs are greatest for early-season plantings in temperate regions. Though these mulches are more expensive than black or clear plastics, some growers find them useful for high-value, heat-loving crops like melons.

Gravel mulch Gravel mulching is an age-old practice and can be very effective in water conservation (both in enhancing infiltration and in suppressing evaporation, even in layers as thin as 5–10 mm). Pea gravel is an attractive permanent mulch that is usually applied 5–10 cm deep and can be reused indefinitely. These are particularly good for rock garden plantings. The problem of this type of mulches is that once applied, gravels cannot be removed, do not decompose and might hinder future farm operations or land uses. Another issue is its high cost of mining, transportation and application in the field.

Crushed rock Crushed volcanic rocks or stones are available in many colors or sizes and make a permanent cover. These materials are especially useful around plants subject to crown rot. The color of the rocks influences the temperature of the soil underneath. Black rock absorbs heat and keeps the soil temperature warmer than normal, while white rock reflects sunlight and thus maintains a cooler temperature underneath. However, white rock can generate too much heat for the above-ground portion of some plants to survive.

Other materials used as mulch Sprayable preparations of latex, asphalt, oil, fatty alcohols etc. are also used as mulch for certain high-income crops such as strawberries. They inhibit evaporation by forming monomolecular films on the soil surface. Some water-proofing chemicals like silicone on application to clods on the soil surface form a layer of water-repellent aggregates. These aggregates then constitute a dry mulch that serves as an evaporation barrier. This layer also enhances infiltration by allowing the treated surface zone to act as a detention reservoir to prevent runoff.

Methods of Mulch Application

Proper methodology and timing of mulch application should be followed to realize the full benefit of mulching. The methods of mulch application vary with soil type, climate, crop and type of mulch material used.

Paper and plastic mulches are generally spread and fastened down either between the rows or over the rows of the crop. The plant seedlings in the latter case are allowed to grow through suitable openings made in the mulch material. Plastic mulches in commercial crop cultivation are generally applied by mulch applicators, which are available commercially or can be manufactured. They generally consist of a plastic-roll holder, two furrow-openers, and two land wheels followed by two furrow-closers mounted on a tool bar. The furrow-openers create a trench on either side of the mulch. The two land wheels follow the furrow-openers and hold the plastic in the furrow. The two furrow-closers refill the trench, firmly anchoring the plastic. A 15–23 cm border of plastic is usually buried leaving 76–91 cm of mulch exposed. Rototilling prior to installation creates a smooth lump-free surface, which helps to ensure a tight union between the plastic and the soil for more efficient heat transfer.

Organic mulches are normally spread a few centimeters thick on the soil surface. The depth of mulch depends upon the mulch material and types of crop on which they are applied. Thicker layers of mulch are normally placed around trees and shrubs, while finer and smaller materials are generally used for small flowers and vegetables. Ten centimeters of loose fibrous materials work well around trees and shrubs. The finer and smaller the particle size, the thinner the layer needs to be. Thick layers of very fine material block air to the roots of plants. For trees, mulch cover should reach at least to the tree's drip line or the outer perimeter of the branches. It should preferably be kept at least 15 cm away from the tree trunk and a couple of centimeters away from plant stems.

Mulches are normally applied and spread uniformly on the soil surface except in the case of vertical mulching. In vertical mulching crop residues, stubbles of the previous crop or other agricultural waste materials are dumped in vertical trenches dug at few-meter intervals in the field with the main objective to recharge the profile and conserve moisture in low

rainfall areas of the semiarid tropics. The few centimeters-protruded portions of the stubble from the trenches also reduce the runoff and sediment loss from the field.

Impact of Mulching on Crop Growth and Input-Use Efficiency

Modification of Crop Growth

The effect of mulches on crop growth response depends on the combination of climate, type of crop and soil. Mulching influences three principal factors affecting crop growth, i.e., weed competition, seedling emergence and root growth, which in turn influence crop productivity.

Weed competition Straw mulching suppresses weed growth through delayed emergence, reduced weed count and smothering effects. Effectiveness of weed control is dependent on the type of mulch material used. Black plastic mulches are more effective for weed control than organic mulches in thin layers as light does not penetrate through black plastic mulches.

Seedling emergence Lack of moisture or unfavorable soil temperature in the seed zone often limits seedling emergence even though there may be sufficient water in the lower part of the profile. Mulch keeps the surface layers wetter for longer periods and thus enhances seed germination and seedling emergence. The times required for initiation of emergence and maximum emergence are shorter under mulching than under no mulch. Straw mulch significantly increases percentage of seedling emergence both under dry spell and rainfall situations (Table 9). Under dry-spell conditions, seedling emergence increases with mulching due to lowering of maximum temperature and reduction in evaporation loss of water. Under rainfall conditions the seedling emergence increases under mulching due to retardation of crust formation, which otherwise hampers seedling emergence.

Table 9 Effect of wheat straw mulching on seedling emergence in cotton and soybean in a sandy loam soil

	Percent seedling emergence			
	Cotton		*Soybean*	
Treatment	*No rain*	*Simulated rain*	*No rain*	*Simulated rain*
No mulch	25	9	19	0
Mulch	31	23	30	20

Root growth Mulching favorably influences root growth and distribution in the upper soil layer due to favorable soil temperature and higher soil water content under mulch. Higher soil water content in the surface layer reduces the mechanical resistance to growing roots, which helps in their proliferation. Application of organic mulches to the previous standing crop after the recession of rains helps in conservation and carry-over of higher amounts of residual soil moisture at the time of sowing of the subsequent rainfed crop, leading to better root proliferation and higher crop yield in regions where the weather starts cooling in the post-rainy season (Table 10). This carry-over effect is more prominent under conservation tillage than under conventional tillage.

Improvement of Input-Use Efficiencies

The favorable effects of mulching on crop growth and yields through an improved soil environment enhance both water and nutrient-use efficiency. Increase in water availability in the upper layers due to a reduction in evaporation and runoff losses under mulch is one of the reasons for increased input-use efficiency. Furthermore, modification of the soil hydrothermal regime under mulch favors root proliferation, which can tap water and nutrients from a larger soil volume, thus improving water and nutrient-use efficiency. Mulching results in better coordination of demand and supply of water resulting in complete extraction of profile-stored water, which improves the water-use efficiency. As grain yield-water use relation is linear within the domain of limited water supplies, any increase in water supply, beyond a minimum threshold would be directly reflected in increased grain yield as well as water-use efficiency (WUE).

Higher soil water content particularly in the initial stages of crop growth results in greater total water use by the crop, leading to higher plant growth and greater yield. Another factor contributing significantly to higher yield is more efficient use of growing season precipitation when the surface is covered with mulch. The final consequence of a higher yield with a relatively small increase in total water use is higher WUE with mulching than under unmulched conditions.

Application of pine needles, a waste product from pine forests, as mulch at the time of sowing of some tuber crops like potato improves the yield and water-use efficiency and results in savings of nitrogen fertilizer and irrigation water (Table 11). Hence, within certain limits, mulches can act as a substitute for both irrigation water and nitrogen fertilizer.

Table 10 Effect of tillage and nitrogen on root growth and grain yield of rainfed wheat in a silty-clay loam soil (Typic Hapludalf)

Mulch tillage (T)	Nitrogen	Root mass density ($kg\,m^{-3}$)		Grain yield ($Mg\,ha^{-1}$)

With increased water availability under mulching, crop response to fertilizer increases, thereby improving the fertilizer-use efficiency. Enrichment of soil with plant nutrients through organic mulching materials boosts crop production. Furthermore, mulching helps in moderating the soil thermal regime, which has a profound influence on nutrient transformations in soil, root growth and nutrient uptake by crop plants. Thus it enhances the nutrient-use efficiency by crops.

Limitations of Mulching

Despite the positive aspects, the following are limitations, which must be taken into account while following the practice of mulching.

1. If mulch is applied before sowing it hinders sowing and many post-sowing operations like fertilizer applications, irrigation etc. Mulch poses special problems for the arable farmer because tillage tools become clogged with the residue, thus planting under the residue is not always successful. Some specific equipment is required for post-sowing operations in mulched plots.

2. In shallow potato planting if mulch is improperly managed it may lead to a greater percentage of stolon becoming aerial shoots and more tubers becoming sunburned. The mulch layer in potato fields should be removed once full canopy is achieved, to avoid disease and pest infestation.

3. In areas of high rainfall, thick mulching may lead to water-logging conditions and provide an environment for disease infestation. If the soil is too wet under mulch, an increase in denitrifying bacteria may cause loss of N.

4. The effectiveness of a mulch depends upon the depth and extent of its coverage. However, if the mulch is applied too thickly it may hinder seedling emergence through the deep impenetrable barrier.

Therefore, it is suggested to use a thin layer of mulch at planting so as not to impede emergence and to follow with a thicker application once the seedlings are established.

5. Plastic mulches usually require pick-up and disposal at the end of the season and their manufacture and disposal entail significant environmental costs, as these are not biodegradable. Plastic mulch can interfere with the recharge of the soil profile by rain or overhead irrigation, which can lead to water deficits in vegetables if drip irrigation is not used.

6. Numerous phytotoxic substances associated with various crop residues have been shown to limit growth of several crop species reportedly through exudation, leaching or microbial production of allelopathic chemicals.

7. There are competing demands for crop residues for other uses in the semiarid tropics of developing countries. Where most of the plant residues are used as cattle fodder, farmers may not adopt mulching under conditions of scarce fodder. In the tropics, crop residues are also used for fencing, roofing and as a source of household fuel. Mulching is thus practiced under conditions where the marginal return from this practice is higher than its other competing demands.

8. The crop residue mulches reduce the temperature of the surface soil layers. In cool climates, this reduction in soil temperature shortens the growing season of the arable crops, while in wet areas higher soil moisture may induce gleying and anaerobic conditions. The limiting problem of using residue mulch on soils in temperate regions is its inability to remove excess water to allow the soil to warm up in time for planting the next crop.

9. The mulch competes with the main crop for nitrogen as it decomposes if the C:N ratio of the material is very high due to immobilization of the soil nitrogen by the microorganisms.

10. The surface residue mulch may generate a more favorable habitat for soil and surface-dwelling insects and pathogens. The residue left at the surface reduces water loss, moderates temperature extremes and provides food resources for the pests and may increase their infestation. Besides this, for many plant pathogens, residues provide a source of food, a place to live and a place to reproduce. A significant proportion of root-infecting organisms, for example, depend upon crop residues for their survival in soil. Root diseases caused by *Pythium* species are favored by wet soils and cool temperatures, especially in corn production.

Introduction

Mycorrhizae ('fungus roots') are an almost universal terrestrial mutualism between plant roots and certain soil fungi, the oldest fossil evidence of which is in the rhizomes of early vascular plants from approximately 400 My ago. Most mycorrhizae are mutualistic, i.e., the fungi provide soil resources to the plant in exchange for photosynthates. Six major types of mycorrhizae are recognized: ectomycorrhizae (EM), arbuscular (AM), monotropoid, arbutoid, orchid, and ericoid (Table 1; Figure 1a). These categories are based largely on differences in phylogenetic, structural, or ecophysiological differences among fungal–plant relationships. We focus on AM and EM, the most common types.

AM are unique in that they are the only monophyletic mycorrhizal lineage that has coevolved with land plants (Table 1; Figure 1b). Although there are relatively few species of AM fungi (approx. 175 species to date), they associate with a wide diversity of plants in grasslands, many tropical forests, and some temperate forests. AM are particularly efficient at the uptake and transfer of nutrients under conditions of low soil moisture or fertility, especially immobile nutrients with low diffusion rates or adsorbed to soil particles (phosphorus, P), and mobile mineral species (NH_4).

EM and the remaining mycorrhizal types demonstrate polyphyletic lineages that represent parallel or convergent evolution, interspersed with saprophytic relatives, and multiple lineages that have gained or lost the capacity to form mycorrhizae. These associations are formed by a vast array of fungal taxa (more than 5000 species; Table 1; Figure 1b). However, compared with AM associations, a mere 3% of plants are EM, most of which are woody trees and shrubs in boreal, temperate, and some tropical forests. These mycorrhizae also demonstrate the capacity to acquire N in a variety of forms (proteins, peptides, NH_4) and sources (weathered rock, leaf litter), and P by producing extracellular acid phosphatases that release P from organic complexes in the soil.

The remaining types are confined to specific plant families and/or habitats. Arbutoid mycorrhizae are a variant of EM and found in ericaceous plants. Ericoid and orchid mycorrhizae coexist with specific plant groups and harbor specialized fungal symbionts that promote plant growth by directly mineralizing organic substrates, often at low soil pH, by releasing enzymes into the substrates (Table 1; Figure 1b). Monotropoid mycorrhizae demonstrate the evolution toward increased host control over their fungal partners (mycoheterotrophy). Typically, the host plant is dependent on fungi for mineral nutrients and energy (carbon substrates), because they lack photosynthetic apparatus and/or substantial roots, but the fungi derive little or no benefit from these associations.

Apart from the construction of fungal structures on or in the root, mycorrhizae invest resources in producing hyphae, microscopic threads 2–10 μm in diameter, which grow out into the soil from the mycorrhizal root (Figure 1). These external hyphae ramify the soil and increase plant nutrient and water supply by extending the volume of soil accessible to plants, act as a sink for carbon, bind soil particles into soil aggregates, and provide food for animals. Mycorrhizal benefits can include greater plant yield and nutrient accumulation. Moreover, hyphal linkages shared by two or more plants may facilitate the transfer of resources in a community, or assist in seedling establishment.

For the most part, being mycorrhizal thus represents a considerable C expense to the plant. In community and ecosystem structure and functioning, a large proportion of plant photosynthate production is allocated to mycorrhizal roots, resulting in a large flux of C into the belowground detrital system. In fact, as mycorrhizal fungal tissue grows, between 3 and 20% of a plant's net primary productivity is transferred from the host plant and allocated to the pool of live fungal tissue. The obligate fungal requirement for host-derived C means that any environmental factor that affects plants also affects their fungal mutualists. Then again, mycorrhizal diversity also determines the competitive balance between plant species and the overall diversity and productivity of plant communities, because each fungal species may differentially enhance (or restrain) survival, growth, and nutrient acquisition among host plants. Accordingly, each change in the soil physical or chemical environment that influences mycorrhizal functioning may also affect the host plant. Such interdependencies or linkages typically characterize the central paradigm of complexity,

Table 1 Summary of the principal evolutionary and ecologic characters of the major mycorrhizal types

	Arbuscular	*Ectomycorrhizae*	*Ericoid–arbutoid–monotropoid*[a]	*Orchid*
Evolution				
Age of association (My)	>400	>100	±80	±100

Character states: +, present; −, absent; *, not known.
[a]Members of the Ericales are host to arbutoid, ericoid, and monotropoid mycorrhizae. For clarity, these types are considered as one group.
[b]All orchids are achlorophyllous in the early seedling stages; however, the extent of chlorophyll development varies among adults.

from the Latin *complexus*, meaning 'entwined' or 'twisted together.'

Complexity

What is complexity? What does it mean to have a complex mycorrhizal system? Traditionally, mycorrhizal functioning has been evaluated by empirical and descriptive studies or by theoretical concepts, mathematical models, and deductive structures, i.e., analytic versus synthetic models. Most experiments are also reductionist. In other words, they successively reduce a mycorrhizal system into smaller and simpler components that are studied in isolation and in a formulated manner. In contrast, the complexity approach is rich and holistic. The individual components within a mycorrhizal system mean little on their own, but together they give rise to the collective responses or emergent patterns of the whole system, and how this system interacts with its environment (Figure 2). This tenet is also central to ecology, or the totality of relations between organisms and their environment.

Mathematically, such systems exist 'on the edge of chaos,' or somewhere between perfect order and complete randomness, where a small change in one component can lead to widely varying results overall. Moreover, complexity *per se* has been allied with terms such as 'fractals,' 'cellular automata,' 'genetic algorithms,' 'order and hierarchy,' to name just a few. Such terms, however, simply emphasize the many different approaches that may be used to understand complexity. Can one use the science of complexity to understand mycorrhizal systems better? Conventional approaches based on linear causality and stochastic properties, while illustrative of the individual components, are inappropriate, because by their very nature mycorrhizal systems are dynamic processes rather than static entities. The canon is complex interplay. Conceptual models might provide

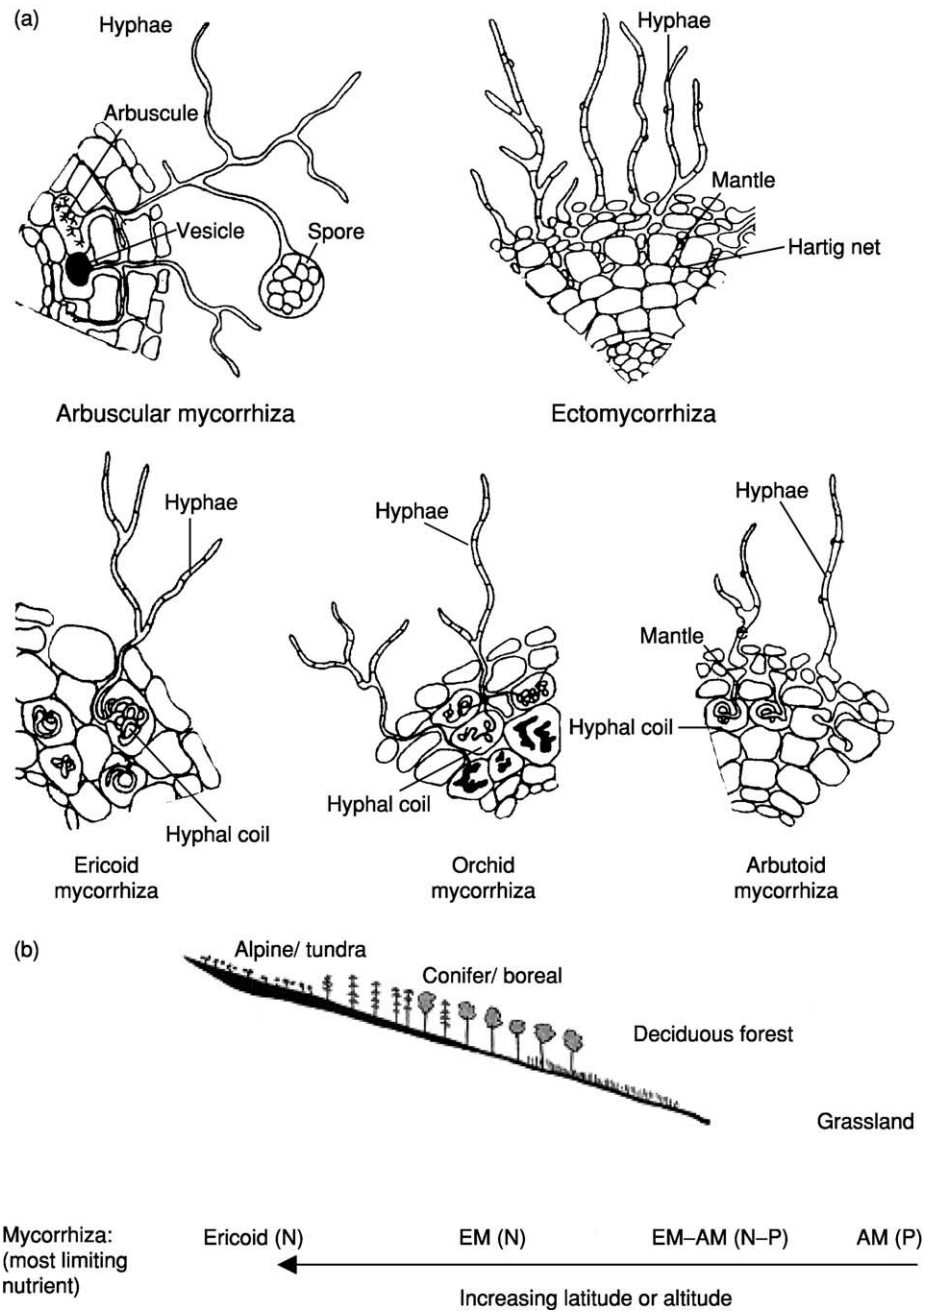

Figure 1 (a) Differential relationships between fungal and plant structures for each of the main types of mycorrhizal associations. frameworks for the identification of processes, structures, and relationships within complex systems.

Defining the Mycorrhizal System and Participants

The system is a specified region in space or a dynamic surface that changes over time (Figures 2 and 3). For example, the oak woodland bounded by grasslands and the hyphal network can both be considered as mycorrhizal systems. They are persistent and respond to the environment or repeated instances of similar or related conditions. Mycorrhizal systems repeatedly demonstrate a negative response to N fertilization and a positive response to elevated atmospheric CO_2. The environment includes organic and mineral nutrients, water, carbon, and influences such as urbanization and global change.

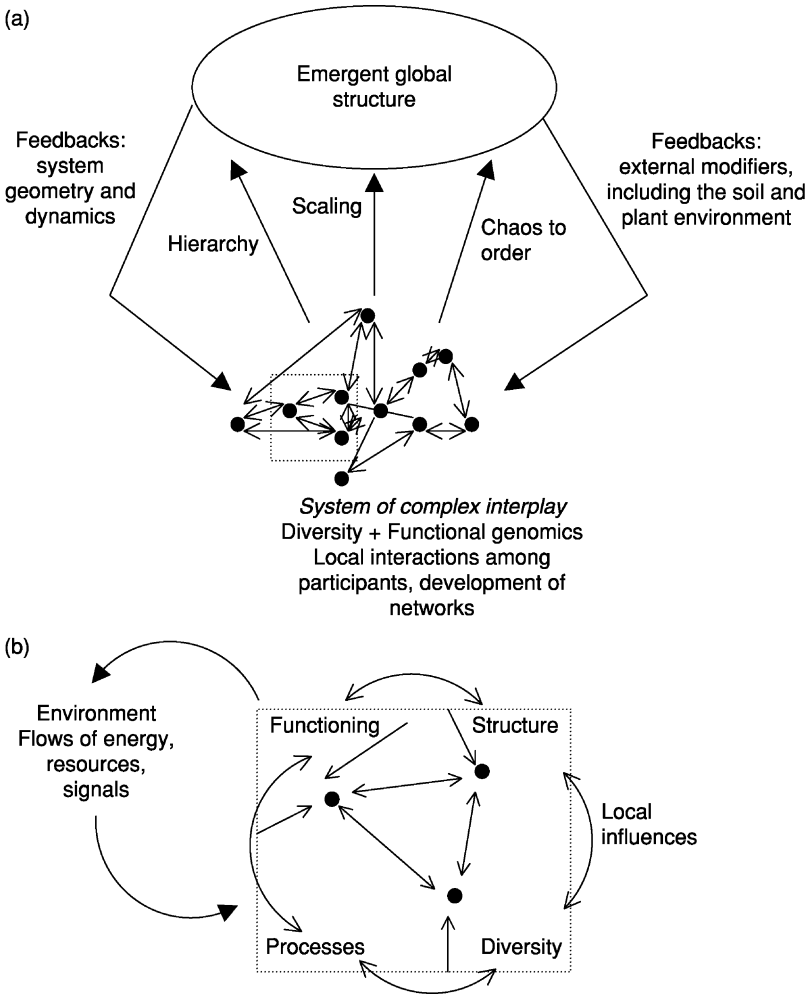

Figure 2 (a) Conceptual model of complexity as a framework for developing analyses in mycorrhizal systems; (b) components of the interactions between the mycorrhizal systems and the environment.

The system is composed of fungal and plant participants. The fungal participants may consist of single-species situations or a set of interacting species. The plant participants are networked into the system by fungi such that the system consists of a lattice (hyphal network) with a discrete agent (host plant) at each lattice site or node (Figure 3a,b). In the field, each mycorrhizal fungus attaches to as many plants as it encounters. For example, there is considerable overlap of EM associated with Ponderosa pine, Douglas fir, Tan oak, Grand fir, and Madrone. Every plant within the network interacts because any transition or change in one fungal partner leads to changes in the neighboring or connected plants. Adding new individuals progressively alters the size and degrees of connectedness within the network in a geometric fashion (Figure 3b). Connections among networks can result in increasingly complex configurations (Figure 3c). The journey into mycorrhizal complexity starts with ecologic diversity, and the structural and functional genomics of the symbiosis.

Governance of the System

Diversity and the Delivery of Ecosystem Services

The potential global taxon richness is extremely high for both plants and fungi forming mycorrhizal systems. The measures of α, β, and γ relate the number of species to area: α is the number of species per hectare (local), β, the number of species per 10–1000 ha (regional) and γ, the number of species in more than 10 000 ha (landscape). Both α and β diversity are similar among habitats and appear to reach upper limits of 5–20 species ha^{-1} for α diversity and 30–50 species for β diversity. Hence, there may be some limit to the system services provided by mycorrhizal fungi. At the γ level, patterns of diversity

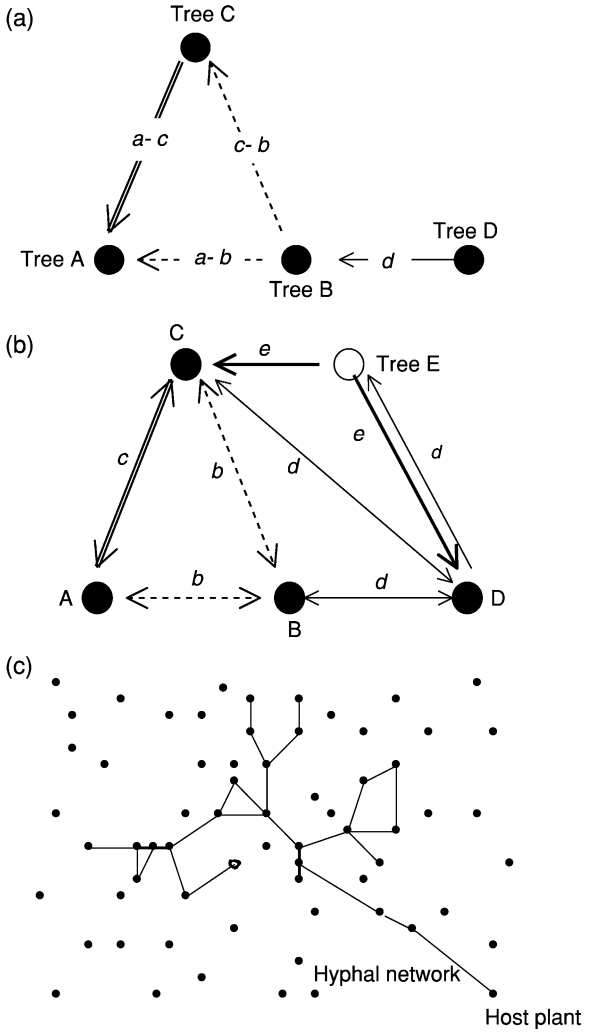

Figure 3 (a) The simplest configuration of a network among three trees; (b) the addition of another host tree and associated fungi increases the number of potential links in the network; (c) the addition of subsequent host plants further increases the complexity of links among plants and the system as a whole. Upper-case letters and filled circles denote the host tree; lower-case letters denote fungus or fungi associated with a host tree. Arrows denote the potential hyphal linkages among plants.

among mycorrhizal types diverge. Forty-eight species of AM fungi have been recovered from *Artemisia tridentata*, although only 175 species have been described globally. In contrast, more than 2000 EM species associate with Douglas fir, but worldwide the number of described EM species approaches many thousands.

What is being measured? Molecular approaches measure species and population genetic diversity, whereas sporocarp (mushroom) and morphotype estimates are responsive to host species or environment. Thus, sporocarp diversity is unlikely to reflect the diversity of EM fungi on the root tips. In *Quercus* woodlands, only three species of EM sporocarps per

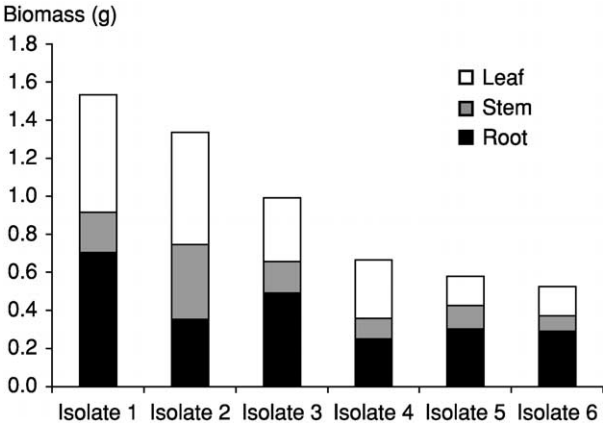

Figure 4 Biomass accumulation in the leaves, stems, and roots of *Quercus* plants grown with six different cultures of *Cortinarius* that were isolated from one clump of sporocarps.

tree have been collected compared with seven to nine morphotypes and up to 20 molecular types per tree. In addition, a few widespread species of fungi account for more than 50% of mycorrhizal abundance and the majority of species are rarely detected. In Douglas fir, 69 morphotypes of EM have been recovered, of which nine types colonize 67% of the root tips.

Fungi also separate both spatially and temporally even when associated with the same host plant. Spatial variation within a system is high because the dominant fungi vary considerably among trees. Fungi may also be spatially segregated to the undercanopy, edge of canopy, and interspace areas. From the temporal perspective, EM formed by certain species of *Laccaria*, *Amanita*, and *Hebeloma* persist in small genets for an average of 1–2 years. In contrast, large genets that last decades are formed by species of *Suillus* and *Cortinarius*. It follows that all species have the potential to contribute to system functioning, although not necessarily in synchrony.

Increasing the diversity of fungi within a system can increase the diversity, productivity, and stability of the plant community. Douglas fir grows better when supported by multiple mycorrhizal fungi, and especially in competition with Ponderosa pine. Different fungi can also undertake different ecologic roles across space and time. For example, six isolates of *Cortinarius* isolated from a single group of sporocarps produce different biomass allocation patterns in their host plant (Figure 4). Certain fungi may preferentially acquire organic nitrogen (N) (*Boletus*) and others, inorganic N (*Pisolithus*, *Laccaria*). *Cenococcum geophilum* exploits the local soil for resources, whereas *Pisolithus* forms extensive hyphal networks that run from one resource patch to another. *Rhizopogon subcaerulescens* persists deep within the soil profile, survives fire, and thus forms

mutualisms in the postfire environment, whereas the upper-profile dweller, *Thelephora*, does not. Such patterns of diversity have important implications for system functioning.

Multiple Genes Coordinate the Development of Mycorrhizae

Both the fungal and plant partner engage in a precisely orchestrated developmental sequence that results in the expression of distinct fungal or plant genes exclusively or predominantly within the symbiosis. In *Eucalyptus globulus–Pisolithus tinctorius* EM, 65 genes record the dialogue of the early development of the fungal mantle. Mycorrhizal development results in the upregulation of the translation initiation factor eIF4A gene, a high-molecular-weight (MW) protein complex, in *Pisolithus tinctorius*, sequences coding for classes of symbiosis-regulated (SR) genes, particularly the cysteine-rich hydrophobins and multigene SRAP32 families, and more recently proline-rich proteins and proteophosphoglycans. eIF4A is essential for translation and cell growth, whereas the structural proteins encoded by SR genes are usually involved in membrane synthesis and function. Similarities to genes encoding proteins involved in primary metabolism and transport (carbon, H^+-ATPase), the cell cycle, deoxyribonucleic acid (DNA) replication, cell structure (β-tubulin), fungal structure (arbuscule degradation, hyphal proliferation), signal transduction, and the suppression of plant defense genes have also been recovered from AM. In addition, mutants unable to sustain AM (Myc^-) were also unable to associate with N-fixing Rhizobium (Nod^-). Conserved signal transduction pathways may thus be common to both mutualisms during their early development

Genomic Hegemony over Nutrient and Carbon Transport

Just as many genes can be ascribed to development of the symbiosis, so can the expression of other functional genes record the dialogue of carbon and nutrient transfer in mycorrhizae. For example, the monosaccharide uptake system in *Amanita muscaria* requires a transporter, AmMST1. AmMST1 contains the open reading frame for a 56-kDa protein that is expressed when *A. muscaria* is axenically cultured at a glucose concentration of less than 5 mmol l^{-1}(the threshold expression level) for 18–24 h, and in *A. muscaria–Picea abies* and *A. muscaria–Populus tremula* × *tremuloides* mycorrhizae. The expression of AmMST1 and any subsequent increase in the import of monosaccharides by fungus triggers an increase in the supply of photoassimilates from the host. Phenylalanine ammonia lyase (AmPAL), a key enzyme of secondary metabolism (phenolics), is also involved in plant defense against pathogenic microbes. Phosphoenolpyruvate carboxylase (PEPC) is expressed in regions of intense mycorrhizal development; PEPC moderates the assimilation of NH_4 in fungi and the transport of amino acids such as glutamine from fungus to plant. However, many genes in fully sequenced genomes are of unknown function, because mycorrhizae are typically studied in a synthetic environment and outside the ecologic context in which they evolved.

Functional Genomics

Responses of a mycorrhizal system to specific environmental cues are tightly coordinated by a physiologically appropriate subset of its genes. Nutrient transport from soil to plant via the mycorrhizal fungus has been the hallmark of mycorrhizal studies for more than a century. One gene that may be involved in P transport efficiency of AM is a fungal membrane P transporter, which moves P from the soil into the hyphae. This gene is regulated by the availability of P in the soil environment, but the fungal partner controls the synthesis of polyphosphate (polyP) and thus the amount of P available in the root and shoot. In turn, *in vivo* ^{31}P nuclear magnetic resonance (NMR) illustrates that mycorrhizal plants typically accumulate P as supramolecular aggregates of polyP (chain length 5–11 units), whereas nonmycorrhizal plants accumulate solely inorganic P (P_i). In mycorrhizae, polyP represents much of the mobile P reservoir.

Mycorrhizal fungi are also capable of utilizing many forms of N and along a variety of pathways. A putative nitrate-transporter gene has been isolated from mycorrhizal *Medicago* in which the expression is downregulated by some, but not all, AM. NMR reveals that NH_4 is predominantly incorporated by glutamine synthetase/glutamate synthetase pathway (GS/GOGAT), with a small proportion by the glutamate dehydrogenase (GDH) pathway. AM may also accelerate the decomposition of organic matter and acquire N directly from these substrates. ^{15}N pulse-chase studies show the incorporation of labeled N into arginine, which is consistent with the ornithine cycle. In turn, the N is stored in relatively immobile complexes with polyP in vacuoles.

Fractionation of N during N uptake by fungi results in considerable shifts in ^{15}N abundance such that ^{15}N abundance in fungal tissues is unlikely to reflect those of the original soil N. The patterns of fractionation are also fungus and N source-specific. Intense fractionation against ^{15}N in ericoid systems results in a ^{15}N-enriched plant, whereas EM systems discriminate against ^{14}N (^{15}N-depleted plant). In

addition, δ^{15}N values for EM sporocarps in a *Quercus* woodland range from 2 to 11. Thus, organic and inorganic N compounds can be accessed differentially by fungi. ^{15}N natural abundance also demonstrates that the strict functional boundaries between mycorrhizal and decomposer fungi may be less clear-cut than previously considered (δ^{15}N 5.29% in mycorrhizal *Boletus*; 6.03% in saprobic *Bovista*).

Spectra from ^{1}H- and ^{13}C-NMR assays in AM *Gigaspora* demonstrate that fungal spore germ tubes, extraradical hyphae, and intraradical hyphae differ in their lipid (triaglycerol) and carbohydrate (hexose) metabolism. Spore germ tubes are sites of lipid breakdown and gluconeogenesis. In intraradical hyphae, hexose is transported into the cytoplasm, where lipid synthesis occurs. Extraradical hyphae act as sink for lipids, and the lipids are converted to carbohydrates (trehalose) and occasionally glycogen, and stored in spores or vesicles. Fungi convert the simple sugars to trehalose or other complex sugar to prevent or reduce reabsorption. Changes in root phytohormone composition also occur in tandem with the loading and unloading of C.

Nutrient fluxes may also be coregulated because the translocation of nonlimiting nutrients such as magnesium (Mg) depends on simultaneous long-distance translocation of P. Combined mass balance (P, potassium, K) and stable isotope analyses (^{25}Mg) show that hyphae can transfer up to 5% K and 3–4% Mg as long as P fluxes through the system.

The factors regulating the amounts of resources transported between fungi are poorly understood. Virtually all studies to date have concentrated on demonstrating the presence and form of elemental transport from soil to plant via the fungal hyphae. As a result, there is little quantitative work on the mechanisms regulating the transport of resources among fungi.

Games and Models for Mapping Causality

Knowing the structure of water yields no clues as to why water goes down a drain in a vortex. Similarly, in mycorrhizae, the genes are expressed and the metabolic machinery produces parts of the system, but they provide no information on how structure in mycorrhizal systems is generated. Mapping is a way of generalizing dynamics and establishing conceptual illustrations and models using simple input/output diagrams. The cognitive system map (Figure 5) draws a causal relationship among components and predicts how complex events might play out. Each arrow defines a causal link where 'plus' is an increase or enhanced response, 'minus' is a decrease,

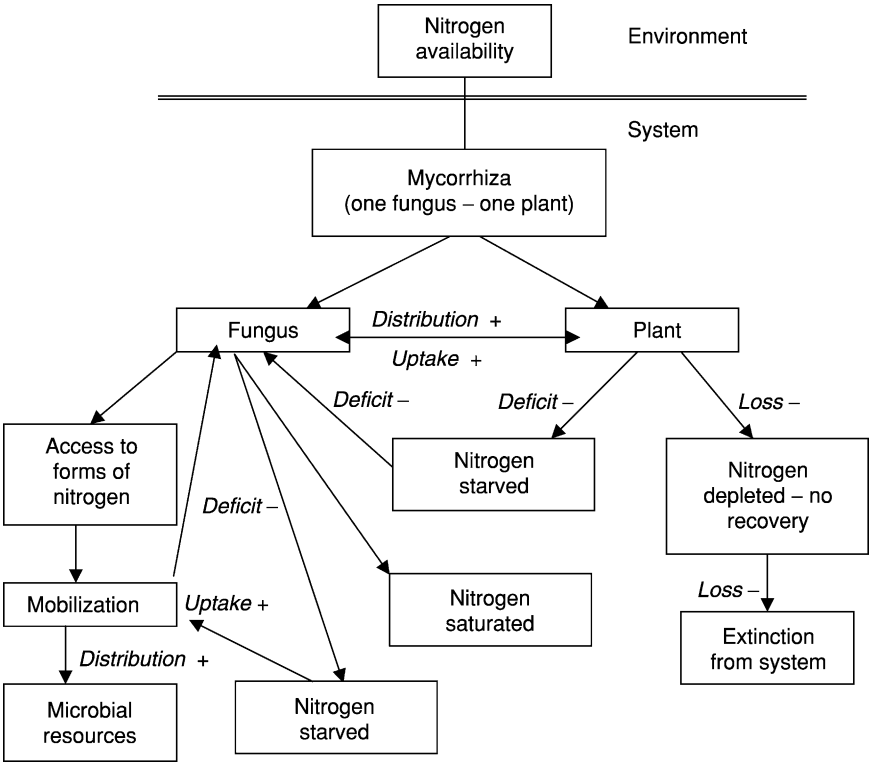

Figure 5 A single-state model of the relationship between the environment and the mycorrhizal system in response to soil nitrogen status.

or negative response, and 'zero' is stasis. The final cognitive map defines the nonlinear dynamic system.

This single-state map for a one plant–one fungus mycorrhizal system and its response to soil N availability illustrates that the fungal response is enhanced by plant nutrient stress and decreased by an increase in nutrient availability and drought. The plant response is enhanced by P availability and decreased by drought. The overall model is the 'If condition, then action,' which has the same meaning as statements in programming language. If the condition portion is satisfied, then the action is triggered and other rules are activated. This is the 'bucket brigade' algorithm (*sensu* J.H. Holland), where signals are passed down the line to reinforce a chain of effect. This is also similar to path analysis. Calculations of the potential outcomes (fungus, plant, system, or 3^n) from the model (Figure 5), indicate that if soil N is limited, then the fungus transports approximately 64% of N to plant, or strengthens the importance of the fungus to the system. However, if soil N increases then the fungus transports only approximately 34% of plant N.

Adding more participants into the system increases the number of possible outcomes exponentially. A two-fungus system responds quite differently to the environment than a one-fungus system. Fungal respiration is depressed in each of *Rhizopogon* and *Suillus* mycorrhizae by 72% and 30%, respectively, after the addition of NH_4 (Figure 6). An additive cognitive map, however, indicates that NH_4 may have a bigger negative effect on respiration in *Rhizopogon–Suillus* in concert than on a single species or the edges where they meet. Using mapping rules as patches also demonstrates the nonlinear nature of the sporocarp $\delta^{15}N$:$\delta^{13}C$ divide between mycorrhizal and saprobic fungi (Figure 7). In particular, when $\delta^{15}N$ is ± 0, $\delta^{13}C$ in mycorrhizal fungi is depleted, whereas $\delta^{13}C$ in saprobes is enriched.

As more knowledge emerges, so do more rules and a more elaborate model that is connected to actual observations. For example, the N needs of the fungus and plant are determined by the level of internal N reservoirs that are depleted at a rate that keeps the fungus and plant functioning, so that low N implies a high need for the resource. The N level in the reservoir may only be increased by providing the correct signal molecule or transporter. Adding these new parameters into Figure 6 increases the number of potential iterations and outcomes and, in turn, the complexity of the system. Such complex systems are controlled by feedback mechanisms between plants and their mycorrhizal mutualists and soil microbes, and local host-dependent preferences for certain communities of fungi.

Hierarchy and Scaling

Complex adaptive systems are hierarchically nested because they are large systems that are comprised of progressively smaller systems, etc.; these large

	Respiration (μg C mg^{-1} ergosterol h^{-1})		
Species	*Control*	*NH_4*	*% decrease*
Rhizopogon sp.	5.1	1.4	72

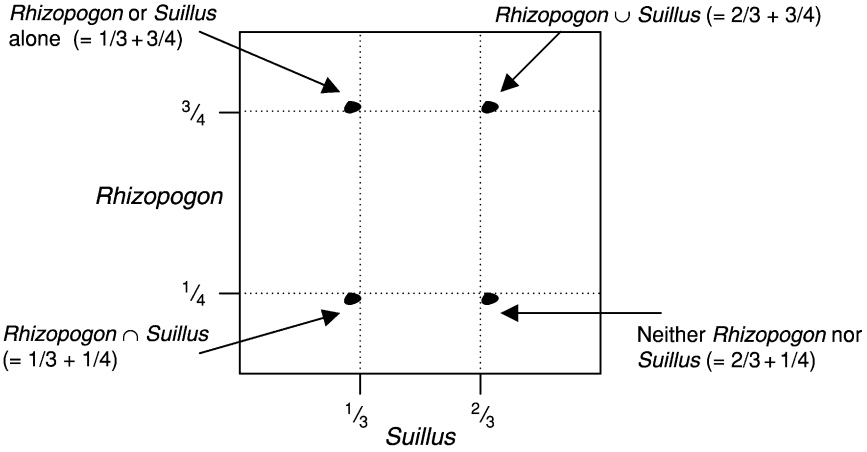

Figure 6 An additive map of the predicted interactions between the ectomycorrhizal fungi, *Rhizopogon* and *Suillus*, after media enrichment with ammonia. Ranking of analysis (highest to lowest effect) shows that NH_4 influences: two species together in culture (*Rhizopogon* ∪ *Suillus*, 17/12); single-species cultures (*Rhizopogon* or *Suillus* alone, 13/12); fungal contaminants (neither *Rhizopogon* nor *Suillus*, 11/12); patches where each species intersects (*Rhizopogon* ∩ *Suillus*, 7/12).

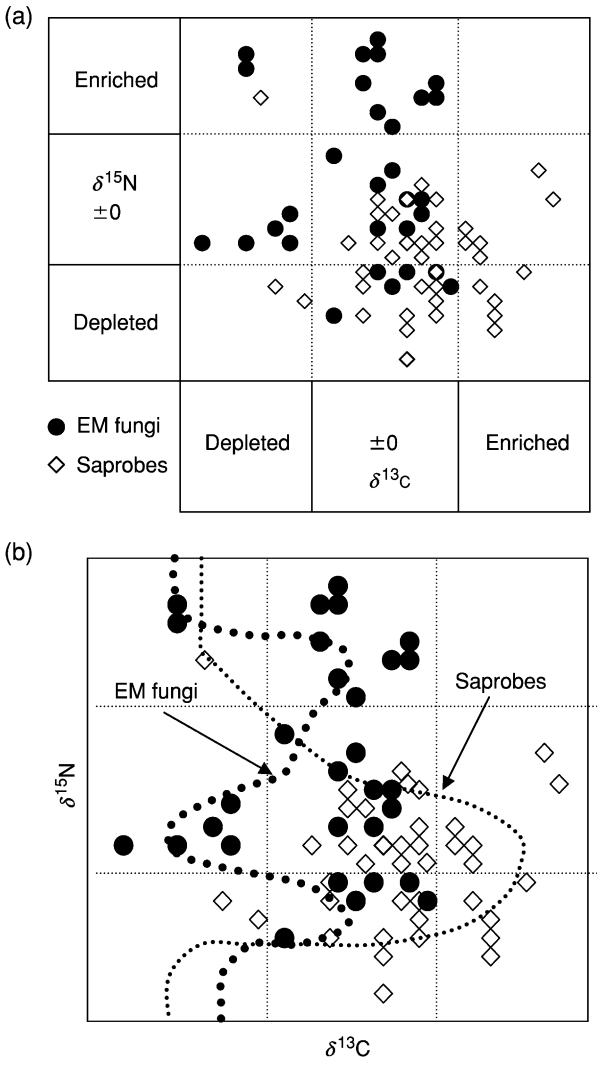

Figure 7 (a) Ratio of δ^{15}N:δ^{13}C in sporocarps of mycorrhizal and nonmycorrhizal (saprobic) fungi; (b) additive patch map of δ^{15}N:δ^{13}C in mycorrhizal and nonmycorrhizal fungi. EM, ectomycorrhizae.

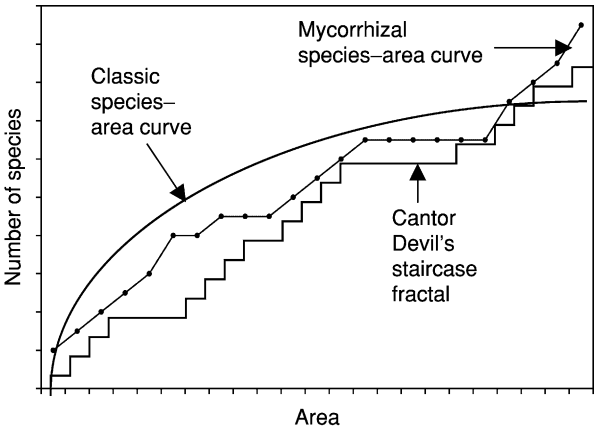

Figure 8 Overlap of the asymptotic (classic) species–area curve, the species–area relationship for morphotypes in oak woodlands, and the Devil's staircase fractal.

systems can interact with each other as well. The issue of scaling and translating information from small-scale patterns and processes to understanding of large-scale problems, such as global change, is essential. This is captured in a simple way in the study of chaos and fractals. Chaos is a rich description of a complex nonlinear system that can include the coupling of different scales over time or space and where a small, seemingly insignificant change in one of the attributes of a single agent can have a widely varying effect on the system as a whole. A fractal is a noninteger semidimension, and one of its traits can be self-similarity at different scales.

Quantifying global species' diversity from measurements of local diversity (species, transcripts, sequences) is typically summarized as a function of sample size and area, i.e., a species–area curve (Figure 8). The classic species–area curve asymptotically approaches the total diversity in the collection. On the contrary, species–area curves for EM morphotypes typically proceed in a step-wise fashion and bear a stronger resemblance to the Cantor (or Devil's staircase) fractal. An inverse relationship exists between species diversity and D, the dimension of the Cantor function. Therefore, systems with high diversity have low D ($\dim \rightarrow <0$), and conversely, mycorrhizal systems with low diversity possess a high D ($\dim \rightarrow <1$). Relating D to issues in global-change biology suggests that an increasing input of N may correspond to a progressive increase in D, while elevated atmospheric CO_2 may correspond to lower D.

Dimensionality within the Cantor function also appears to corresponds with the transition from order to chaos, because entropy (disorder) and enthalpy (energy) are inextricably linked to chaos as follows: maximum diversity: $\dim \rightarrow 0$: minimum order: maximum disorder: minimum energy. This follows from Shannon–Wiener's adaptation of Newton's second law of thermodynamics as applied to information theory. A commonly used measure of diversity, the Shannon–Wiener index, is also calculated using exactly the same formula as for statistical entropy. Thus, calculations of diversity are simply reflections of system order or disorder (chaos), where the higher the diversity index the greater the level of chaos within a system.

Autonomous Networks

Fungal and plant species differ in mutualistic functioning and tolerance to the environment, but, when networked, the benefits of each are distributed

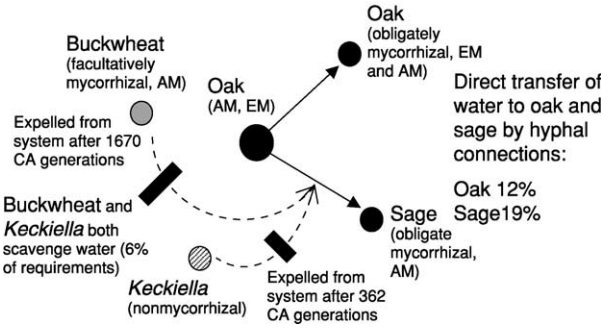

Figure 9 Model estimates of the time and sequence of plant species elimination from a fungal network based on simple cellular automata (CA) rules of water sharing and host mycorrhizal status. AM, arbuscular mycorrhizae; EM, ectomycorrhizae.

throughout the system. Fungal networks allow both plants and fungi to share resources, including carbon and water (Figure 9).

Network models based on cellular automata (CA) are appropriate in nonlinear systems. Traits or variables such as diversity (entropy) may be used for CA and, in turn, a set of cellular automata may form a Cantor set. In the simplest case, a CA consists of fungal hyphae that evolve in a series of time steps and according to simple specific rules. Even though the rules may be very simple in the initial state, the pattern produced is self-similar (or fractal). Fractal analysis derives the models of hyphal growth. EM hyphae demonstrate branching in a binary tree in which each of the nodes has two branches and operations are restricted to a two-way choice (left or right, great or less). *L*-systems describe system growth and efficiency. Because EM fungi follow the Twig model and AM fungi follow Weed models, the *L*-system can be used to describe mathematically or simulate mycorrhizal growth patterns. This is packing efficiency, or the manner in which mycorrhizal systems can squeeze a great deal of hyphal length and surface area into a finite volume and, in turn, resource acquisition. Because the production of extraradical hyphae differs significantly among mycorrhizae, packing efficiency may be a useful indicator of system functioning.

Integrating this knowledge into mycorrhizal functioning indicates how the network might proceed. Plants joined by a hyphal network may share water by either direct or indirect transfer (Figure 9). Using a CA with simple water-sharing rules, nonmycorrhizal *Keckiella* is eliminated from the group after 362 generations and facultative mycorrhizal *Eriogonum* after 1670 generations. Only plants that are directly connected by fungal hyphae remain in the system, because packing efficiency (resource transfer) increases within the networked area.

The extent of network development and the transfer resources among plants is still an open question. Spanning trees may be useful in calculating these outcomes. In addition, multiple transfers of resources suggest redundancy. Different fungal species, and possibly communities, may be capable of the same processes even though there may be different versions of the gene(s) that encode for a certain purpose, e.g., N acquisition.

Summary

Lovelock's Gaia hypothesis conceptualized biodiversity and mutualism in their most advanced and elegant integration. In mycorrhizae, diversity and mutualistic functioning unite successive systems into networks and complex systems. In order to show that complexity has increased overall, it is sufficient to show, that – all other things being equal – connections have increased in at least one dimension. What is lacking is the ability to make predictions about how complexity in mycorrhizal communities will change their function as the systems and/or their environment is altered by human impacts and global change. Combining molecular, metabolic, and biochemical data with nonlinear mathematical models might provide the foundations and rules for understanding mycorrhizal complexity. The limitations and utility of any data, however, remain in developing data-mining and complexity-modeling tools and techniques to utilize effectively the information from a local and global perspective, because data are gathered on scales from molecules to genomes, organelles, cells, tissues, and organs. Bioinformatics is the acquisition of knowledge by means of computational tools for the organization, management, and mining of genetic biological data. These analytical tools are generally applied to the oceans of data collected by molecular biology, e.g., the Human Genome project. A more appropriate term for mycorrhizal systems may be 'ecoinformatics' or the accumulation of ecologically based data sets appropriate to mycorrhizae *in situ*, followed by data integration. In doing so, it will then be appropriate to say that diversity and mutualism provide ecosystem function and what that functioning may be.

FOUR-VOLUME SET

by Daniel Hillel (Editor-in-Chief)

Hardcover: 2200 pages
Publisher: Academic Press; 1 edition (November 8, 2004)
Language: English
ISBN-10: 0123485304
ISBN-13: 978-0123485304

Book Description

More than ever before, a compelling need exists for an encyclopedic resource about soil the rich mix of mineral particles, organic matter, gases, and soluble compounds that foster both plant and animal growth. Civilization depends more on the soil as human populations continue to grow and increasing demands are placed upon available resources.
The Encyclopedia of Soils in the Environmentis a comprehensive and integrated consideration of a topic of vital importance to human societies in the past, present, and future.

This important work encompasses the present knowledge of the world's variegated soils, their origins, properties, classification, and roles in the biosphere. A team of outstanding, international contributors has written over 250 entries that cover a broad range of issues facing today's soil scientists, ecologists, and environmental scientists.
This four-volume set features thorough articles that survey specific aspects of soil biology, ecology, chemistry and physics. Rounding out the encyclopedia's excellent coverage, contributions cover cross-disciplinary subjects, such as the history of soil utilization for agricultural and engineering purposes and soils in relation to the remediation of pollution and the mitigation of global climate change.

This comprehensive, yet accessible source is a valuable addition to the library of scientists, researchers, students, and policy makers involved in soil science, ecology, and environmental science.

Also available online via ScienceDirect featuring extensive browsing, searching, and internal cross-referencing between articles in the work, plus dynamic linking to journal articles and abstract databases, making navigation flexible and easy. For more information, pricing options and availability visit www.info.sciencedirect.com.

* A distinguished international group of editors and contributors
* Well-organized encyclopedic format providing concise, readable entries, easy searches, and thorough cross-references
* Abundant visual resources — photographs, figures, tables, and graphs — in every entry
* Complete up-to-date coverage of many important topics — essential information for scientists, students and professionals alike

FOREWORD

The *Encyclopedia of Soils in the Environment* is a vitally important scientific publication and an equally important contribution to global public policy. The *Encyclopedia* brings together a remarkable range of cutting-edge scientific knowledge on all aspects of soil science, as well as the links of soils and soil science to environmental management, food production, biodiversity, climate change, and many other areas of significant concern. Even more than that, the *Encyclopedia* will immediately become an indispensable resource for policy makers, analysts, and students who are focusing on one of the greatest challenges of the 21st century. With 6.3 billion people, our planet is already straining to feed the world's population, and is failing to do so reliably in many parts of the world. The numbers of chronically poor in the world have been stuck at some 800 million in recent years, despite long-standing international goals and commitments to reduce that number by several hundred million. Yet the challenge of food production will intensify in coming decades, as the human population is projected to rise to around 9 billion by mid-century, with the increased population concentrated in parts of the world already suffering from widespread chronic under-nourishment.

Unless the best science is brought to these problems, the situation is likely to deteriorate sharply. Food production systems are already under stress, for reasons often related directly to soils management. In Africa, crop yields are disastrously low and falling in many places due to the rampant depletion of soil nutrients. This situation needs urgent reversal, through increasing use of agro-forestry techniques (e.g. inter-cropping cereals with leguminous nitrogen-fixing trees) and increasing the efficient applications of chemical fertilizers. In other impoverished, as well as rich, parts of the planet, decades of intensive agriculture under irrigation have led to salinization, water-logging, eutrophication of major water bodies, dangerous declines of biodiversity and other forms of environmental degradation. These enormous strains are coupled with the continuing pressures of tropical deforestation and the lack of new promising regions for expanding crop cultivation to meet the needs of growing populations. Finally, there looms the prospect of anthropogenic climate change. Global warming and associated complex and poorly understood shifts in precipitation extremes and other climate variables all threaten the world's natural ecosystems and food production systems in profound yet still imperfectly understood ways. The risks of gradual or abrupt climate change are coupled with the risks of drastic perturbations to regional and global food supplies.

The *Encyclopedia* offers state-of-the-art contributions on each of these challenges, as well as links to entries on the fundamental biophysical processes that underpin the relevant phenomena. The world-scale and world-class collaboration that stands behind this unique project signifies its importance for the world community. It is an honor and privilege for me to introduce this path-breaking endeavor.

PREFACE

The term 'soil' refers to the weathered and fragmented outer layer of our planet's land surfaces. Formed initially through the physical disintegration and chemical alteration of rocks and minerals by physical and biogeochemical processes, soil is influenced by the activity and accumulated residues of a myriad of diverse forms of life. As it occurs in different geologic and climatic domains, soil is an exceedingly variegated body with a wide range of attributes.

Considering the height of the atmosphere, the thickness of the earth's rock mantle, and the depth of the ocean, one observes that soil is an amazingly thin body – typically not much more than one meter thick and often less than that. Yet it is the crucible of terrestrial life, within which biological productivity is generated and sustained. It acts like a composite living entity, a home to a community of innumerable microscopic and macroscopic plants and animals. A mere fistful of soil typically contains billions of microorganisms, which perform vital interactive biochemical functions. Another intrinsic attribute of the soil is its sponge-like porosity and its enormous internal surface area. That same fistful of soil may actually consist of several hectares of active surface, upon which physicochemical processes take place continuously.

Realizing humanity's utter dependence on the soil, ancient peoples, who lived in greater intimacy with nature than many of us today, actually revered the soil. It was not only their source of livelihood, but also the material from which they built their homes and that they learned to shape, heat, and fuse into household vessels and writing tablets (ceramic, made of clayey soil, being the first synthetic material in the history of technology). In the Bible, the name assigned to the first human was Adam, derived from 'adama,' meaning soil. The name given to that first earthling's mate was Hava (Eve, in transliteration), meaning 'living' or 'life-giving.' Together, therefore, Adam and Eve signified quite literally 'Soil and Life.'

The same powerful metaphor is echoed in the Latin name for the human species – Homo, derived from humus, the material of the soil. Hence, the adjective 'human' also implies 'of the soil.' Other ancient cultures evoked equally powerful associations. To the Greeks, the earth was a manifestation of Gaea, the maternal goddess who, impregnated by Uranus (god of the sky), gave birth to all the gods of the Greek pantheon.

Our civilization depends on the soil more crucially than ever, because our numbers have grown while available soil resources have diminished and deteriorated. Paradoxically, however, even as our dependence on the soil has increased, most of us have become physically and emotionally detached from it. Many of the people in the so-called 'developed' countries spend their lives in the artificial environment of a city, insulated from direct exposure to nature, and some children may now assume as a matter of course that food originates in supermarkets.

Detachment has bred ignorance, and out of ignorance has come the delusion that our civilization has risen above nature and has set itself free of its constraints. Agriculture and food security, erosion and salination, degradation of natural ecosystems, depletion and pollution of surface waters and aquifers, and decimation of biodiversity – all of these processes, which involve the soil directly or indirectly – have become abstractions to many people. The very language we use betrays disdain for that common material underfoot, often referred to as 'dirt.' Some fastidious parents prohibit their children from playing in the mud and hurry to wash their 'soiled' hands when the children nonetheless obey an innate instinct to do so. Thus soil is devalued and treated

as unclean though it is the terrestrial realm's principal medium of purification, wherein wastes are decomposed and nature's productivity is continually rejuvenated.

Scientists who observe soil closely see it in effect as a seething foundry in which matter and energy are in constant flux. Radiant energy from the sun streams onto the field and cascades through the soil and the plants growing in it. Heat is exchanged, water percolates through the soil's intricate passages, plant roots extract water and transmit it to their leaves, which transpire it back to the atmosphere. Leaves absorb carbon dioxide from the air and synthesize it with soil-derived water to form the primary compounds of life. Oxygen emitted by the leaves makes the air breathable for animals, which consume and in turn fertilize plants.

Soil is thus a self-regulating bio-physio-chemical factory, processing its own materials, water, and solar energy. It also determines the fate of rainfall and snowfall reaching the ground surface – whether the water thus received will flow over the land as runoff, or seep downward to the subterranean reservoir called groundwater, which in turn maintains the steady flow of springs and streams. With its finite capacity to absorb and store moisture, and to release it gradually, the soil regulates all of these phenomena. Without the soil as a buffer, rain falling over the continents would run off entirely, producing violent floods rather than sustained river flow.

Soil naturally acts as a living filter, in which pathogens and toxins that might otherwise accumulate to foul the terrestrial environment are rendered harmless. Since time immemorial, humans and other animals have been dying of all manner of disease and have then been buried in the soil, yet no major disease is transmitted by it. The term *antibiotic* was coined by soil microbiologists who, as a consequence of their studies of soil bacteria and actinomycetes, discovered streptomycin (an important cure for tuberculosis and other infections). Ion exchange, a useful process of water purification, also was discovered by soil scientists studying the passage of solutes through beds of clay.

However unique in form and function, soil is not an isolated body. It is, rather, a central link in the larger chain of interconnected domains and processes comprising the terrestrial environment. The soil interacts both with the overlying atmosphere and the underlying strata, as well as with surface and underground bodies of water. Especially important is the interrelation between the soil and the climate. In addition to its function of regulating the cycle of water, it also regulates energy exchange and surface temperature.

When virgin land is cleared of vegetation and turned into a cultivated field, the native biomass above the ground is often burned and the organic matter within the soil tends to decompose. These processes release carbon dioxide into the atmosphere, thus contributing to the earth's greenhouse effect and to global warming. On the other hand, the opposite act of reforestation and soil enrichment with organic matter, such as can be achieved by means of conservation management, may serve to absorb carbon dioxide from the atmosphere. To an extent, the soil's capacity to store carbon can thus help to mitigate the greenhouse effect.

Thousands of years are required for nature to create life-giving soil out of sterile bedrock. In only a few decades, however, unknowing or uncaring humans can destroy that wondrous work of nature. In various circumstances, mismanaged soils may be subject to erosion (the sediments of which tend to clog streambeds, estuaries, lakes, and coastal waters), to leaching of nutrients with attendant loss of fertility and eutrophication of water bodies, to waterlogging and impaired aeration, or to an excessive accumulation of salts that may cause a once-productive soil to become entirely sterile. Such processes of soil degradation, sometimes called 'desertification,' already affect large areas of land.

We cannot manage effectively and sustainably that which we do not know and thoroughly understand. That is why the tasks of developing and disseminating sound knowledge of the soil and its complex processes have assumed growing urgency and importance. The global environmental crisis has created a compelling need for a concentrated, concise, and definitive source of information – accessible to students, scientists, practitioners, and the general public – about the soil in all its manifestations – in nature and in relation to the life of humans.

INTRODUCTION

The *Encyclopedia of Soils in the Environment* contains nearly 300 articles, written by the world's leading authorities. Pedologists, biologists, ecologists, earth scientists, hydrologists, climatologists, geographers, and representatives from many other disciplines have contributed to this work. Each of the articles separately, and all of them in sequence and combination, serve to summarize and encapsulate our present knowledge of the world's variegated soils, their natural functions, and their importance to humans.

Concise articles surveying specific aspects of soils (soil genesis, soil chemistry and mineralogy, soil physics and hydrology, and soil biology) are complemented by articles covering transdisciplinary aspects, such as the role of soils in ecology, the history of soil utilization for agricultural and engineering purposes, the development of soil science as a discipline, and the potential or actual contributions of soils to the generation, as well as to the mitigation, of pollution and of global climate change.

This comprehensive reference encompasses both the fundamental and the applied aspects of soil science, interfacing in general with the physical sciences and life sciences and more specifically with the earth sciences and environmental sciences.

The *Encyclopedia of Soils in the Environment* manifests the expanding scope of modern soil science, from its early sectarian focus on the utilitarian attributes of soils in agriculture and engineering, to a wider and much more inclusive view of the soil as a central link in the continuous chain of processes constituting the dynamic environment as a whole. Thus it both details and integrates a set of topics that have always been of vital importance to human societies and that are certain to be even more so in the future.

Introduction – Life in a Soil Pore

Few people are aware of the most numerous of all soil-dwelling animals, the nematodes. These minute, unsegmented roundworms are actually aquatic organisms, inhabiting water films (1–5 μm thick) that coat and surround soil particles. (This chapter focuses on nematodes that typically complete their entire lifecycle within terrestrial soils or within plant roots. Numerous parasites of vertebrates have soil-dwelling stages, but their development is dependent on entering an appropriate host species. Vertebrate nematode parasites include hookworms, intestinal roundworms, pinworms, whipworms, and other serious pests of humans and domesticated animals. Information about vertebrate parasites is readily found in textbooks of parasitology.) Their size, typically 0.40–1.0 mm in length, is ideal for navigating this porous matrix. Although fully functional within a water film, they are ultimately bounded by soil structure, restricted in movement within soil pores less than 30 μm diameter.

Nematodes are simple organisms (Figure 1). Comprised of approximately 1000 somatic cells in the adult stage, these worm-like organisms are an example of functional and anatomical economy. Lacking eyes, appendages, and true segmentation, nematodes use mechanosensory and chemosensory neurons embedded in the cuticle to orient and respond to a wide range of environmental stimuli. At the nematode's anterior end is a circlet of sensilla arranged around an oral opening. These sensilla, including two larger, laterally placed chemosensory organs called 'amphids,' detect subtle chemical gradients, providing directional information to the nematode (Figure 2). Plant-feeding nematodes respond to slight variations in CO_2 and root exudates. A positive chemosensory signal initiates a snake-like sinuous movement characteristic of most nematodes, created by longitudinal body muscles working in apposition to a hydrostatic skeleton. Directional movement more than a few centimeters per day is unlikely in the soil environment. Once they contact the root surface, plant-feeding nematodes will probe with their stylet, a hollow, protrusible, hypodermic needle-like feeding tube (Figure 3a). Some plant-feeding nematodes will feed externally to the root surface, using this stylet to puncture cells, withdrawing the cytoplasmic contents. Others will penetrate the root and establish permanent feeding sites within the root cortex, or migrate cell-to-cell, leaving a trail of damaged necrotic tissue.

Free-living nematodes also occupy the interstitial spaces in soil. Unlike the plant-feeders, free-living nematodes are seldom sedentary, continually moving to feed on a diverse array of food, including bacteria, algae, fungi, protozoa, small invertebrates, and other nematodes. They use the same set of sensilla to track their food source; however, their feeding structures are modified to suit their meal. Bacterial-feeders graze using a relatively simple tubular mouthpart,

although the cuticle surrounding the oral opening may be modified elaborately to direct food toward the stoma (Figure 4). Predators may be adorned with 'teeth,' used to puncture or shred the integument of various invertebrates (Figure 5). Fungal-feeders and omnivores have a stylet similar in appearance to that of plant-feeders, distinguished by the lack of stylet 'knobs,' points of muscle attachment for stylet protrusion (Figure 3b).

Early observations of nematodes by light microscopy led scientists to refer to nematodes as a 'tube within a tube.' Food entering the nematode is channeled quickly into a tubular esophagus and then passed into an intestine that comprises the bulk of the body cavity. Waste products are eliminated through a posterior ventral anus. There is no circulatory or respiratory system within the nematode. In addition to the alimentary system, the reproductive system is a conspicuous feature in the adult nematode (Figure 6). Females and hermaphrodites are characterized by a branched genital system, which produces eggs that exit the body via a ventral genital opening in the body wall. Males possess a spicule, a cuticularized, protrusible modification of the genital system that guides sperm into the female for internal fertilization (Figure 7). Many nematodes are strictly bisexual, but parthenogenesis and self-fertilizing hermaphroditism are also common among species. Regardless of mode of reproduction, nematodes are prolific animals. Some species complete a life-cycle of 3 or 4 days. Others require several months to go from egg to egg-laying female. *Meloidogyne* spp., an economically important group of plant parasites, will typically begin to produce eggs within 3 weeks of hatching; each female is capable of producing hundreds of eggs during an adult life.

Nematode Distribution and Abundance

The hallmark of Phylum Nemata is the exceptional abundance and ubiquitous presence of nematodes (Table 1). It is a challenging exercise to identify a habitat not occupied by a diverse community of nematodes. Consider the dry valleys of Antarctica, an environment considered so extreme that it is thought to provide the bare minimum for sustaining life on earth. There, in McMurdo Valley, three nematode species occupy the top levels in the soil food chain, two bacterivores and a third species, *Eudorylaimus antarcticus*, that feeds on the two bacterivorous species. Soils of the high Arctic are populated so heavily with nematodes that biologists have searched for explanations for an Arctic nematode biodiversity that exceeds that of the humid tropics. Temperate grasslands appear to sustain the greatest levels of diversity and abundance in the phylum. On Konza Prairie, one of the last remaining large stands of true tallgrass prairie in North America, each handful of soil is likely to contain 50–100 different nematode species. An estimated 1.5 million nematodes can be extracted from a square meter of soil, just within the surface 10 cm. Some researchers have considered the plant-feeding or herbivorous species as 'belowground buffalo,' referring to their impact as grazers of plant roots. Nearly all researchers agree that the approximately 25 000 described species of nematodes represent a small percentage of the species that actually exist in nature.

Finding agreement on those factors responsible for extraordinary nematode abundance and diversity is not so simple. Clearly, the evolutionary age of nematodes has provided considerable time for nematode diversification. Recent molecular studies indicate that the roots of the nematode evolutionary tree are hundreds of millions of years older than the corresponding tree for insects. Marine nematodes, which inhabit even the deepest ocean floors, have a nucleotide diversity that suggests nematodes flourished before life

Table 1 Nematode communities in selected studies

NA, not available.

colonized land. The same nematode survival mechanisms that allowed them to be among the first colonizers of land most likely contribute to a competitive advantage in current-day harsh environments.

Physiology

Although nematodes depend on free water for normal functioning, under harsh conditions such as freezing or drying many nematodes are capable of entering a cryptobiotic state, essentially a reversible state of suspended animation until favorable conditions return. Anhydrobiotic success, the ability to withstand the lack of moisture, depends on a slow rate of dehydration, rapid decline in cuticle permeability, and accumulation of compounds such as trehalose and glycerol to stabilize phospholipids and proteins. Species including *Acrobeloides* spp., *Aphelenchus avenae*, and *Scutellonema brachyurum* start to enter anhydrobiosis by coiling at gravimetric water contents of 3.7% (−300 kPa), 9% (−30 kPa), and 15% (−10 kPa), respectively. It is unknown how long nematodes may persist in this state and still survive hydration. Specimens of the wheat gall nematode *Anguina tritici* have been revived after more than 30 years in anhydrobiosis.

Nematodes are not alone among invertebrates in their ability to enter a cryptobiotic state. Therefore, additional clues to their successful colonization of soil are found in their physiological versatility. Physiological adaptations have allowed nematodes to invade habitats in which few other animals can survive and avoid interspecific competition and many environmental selection pressures. Nematodes are capable of regulating their uptake of oxygen over a wide range of partial pressures from 100 to 5%. When oxygen falls below 5%, nematodes convert their use of energy reserves. For example, *Aphelenchus avenae* uses reserves of neutral lipids under aerobic conditions and glycogen under anaerobic conditions. Not only does a hydrostatic skeleton facilitate movement, but also an ability to expand or contract body size in response to gradual changes in concentration of solutions containing sodium, calcium, magnesium, and/or potassium ions. The adjustment process, osmoregulation, is possible by modifying the permeability of their cuticle. Furthermore, nematodes can tolerate a wide pH range, with some species capable of withstanding strong acids or bases (pH 1.6–11.0). Nematode tolerance for temperature is equally remarkable. In hot springs, nematodes live at temperatures as high as or higher than any other Metazoa. *Aphelenchoides parietinus*, a cosmopolitan species, has been reported from 58°C springs in Chile and 61°C springs in New Zealand.

Ecology

Although nematodes have adapted mechanisms to survive extremities of climate, their activity is stimulated by the return of more moderate conditions. For example, communities of nematodes are revived after rain in desert soils or after a relatively warm period in soils of polar regions. Species are found interacting with other organisms in a variety of occupations including competitor, opportunist, parasite, host, predator, or prey. As a competitor, nematodes rival protozoa for access to bacterial food sources. However, differences in size and generation time can alleviate competition by specializing on microhabitats fine-tuned to minute spatial and temporal scales. As opportunists, nematode species are phoretically transported by insects, adhering to their bodies, providing an opportunity to reach food sources at a longer distance than they would be capable of reaching alone. For example, Psychodidae flies carry nematodes to fermenting organic matter; dung beetles carry nematodes to fresh dung; and Scolytidae bark beetles transport Tylenchida and Rhabditida to their tunnels, where they feed on bacteria and fungi. Nematodes that are parasites of plants include both specialists and generalists.

Host ranges may extend to hundreds of plant species or be restricted to a single plant variety. Some nematodes specialize in precise feeding sites along the root. Plant-parasitic nematodes affect primary productivity of plants by altering uptake of water and nutrients. These abnormalities may result from changes in root morphology and/or physiology resulting in reduced productivity. Other nematodes infect insects, killing them within 48 h by releasing insect-pathogenic bacteria into the insect. The insect host dies from the bacterial infection, and nematodes feed on the bacteria and develop and reproduce inside the insect cadaver. In this case, the nematode and bacteria have a mutualistic association. Sometimes, a nematode finds itself in a role reversal, becoming the host or target of fungi specialized for trapping nematodes, using constricting rings, sticky knobs, or hyphal nets. Being in the middle of a food chain, nematodes eventually become prey to higher-order consumers. Nematodes provide a portion of the diet for many kinds of small soil arthropods. For example, a symphylan can hold seven large nematodes in its gut at one time. In 1 day, a mite may consume two large nematodes or several smaller nematodes.

Genetic diversity, nematode abundance, and the variety of niches occupied by nematodes has led to the assessment of nematode communities as a means of making predictions about past or present soil conditions. The species composition and relative nematode abundance of species comprising a nematode community allow nematodes to serve as biological indicators for soil disturbance as well as 'soil health.'

Monitoring

Nematodes contribute directly to biogeochemistry of soils by regulating processes such as decomposition and nutrient cycling. Nematodes do not feed on decaying organic matter directly, but on bacteria, fungi, algae, and actinomycetes that colonize and decompose decaying plant and animal debris. Indirectly, nematodes control availability of nutrients by regulating the abundance or activity of these organisms, releasing nitrogen and phosphorus from microbes they digest, immobilizing nutrients in their live tissues, and excreting excess nitrogen as ammonium. Under field conditions, bacterial-feeding and predatory nematodes contribute 8–19% of nitrogen mineralization in conventional and integrated farming systems, respectively.

Nematode community structure and function are known to change in response to land-management practices such as nutrient enrichment through fertilization by organic or inorganic nitrogen, cultivation, liming, drainage, plant community composition and age, and toxic substances such as heavy metals, pesticides, and polycyclic aromatic hydrocarbons. Disturbance can affect the survival of individuals directly, or indirectly by changing resource levels. For example, a larger ratio of fungal-feeding to bacterial-feeding nematodes suggests less effect by cultivation than a smaller ratio. Any disturbance that results in compaction reduces soil porosity, and the numbers of relatively large-sized nematodes. General biocides such as methyl bromide can nearly eliminate nematodes, returning the ecological succession of soil communities to that assembling a depauperate soil matrix. Although recovery occurs eventually, abundance and diversity of nematode communities may take years to achieve prefumigation levels. Alternatively, some herbicides affect nematodes indirectly by reducing vegetation and smaller additions of organic matter to soil.

The composition of nematode communities may reflect the frequency of disturbance to soil, whether the disturbance is primarily physical and/or chemical in origin. This concept is based on the principle that different species have contrasting levels of sensitivity or tolerance to stress because of unique survival and/or reproductive traits. Smaller values of an index that integrates relative abundance of species within each sensitivity/tolerance class are indicative of a more disturbed environment, and larger values may indicate a less-disturbed environment. Ideally, indicators of soil health would correspond with ecological processes occurring in soil. Because initial experiments have been correlative in nature, it is too soon to claim such an association with great confidence.

The concept of nematodes as indicators of soil condition and their predictive use in soil management represents a tremendous shift in emphasis in the science of nematology. Formerly a science focused on the control of parasitic and harmful species, now nematodes are seen as an integral and potentially useful component of soil systems. In light of this new perspective, it is likely that the study of nematodes will contribute significantly to our understanding of biological processes in the soil.

Introduction

Soil water makes land-based life possible by satisfying plant water requirements (e.g., for crops and forests), by serving as a medium for nutrient movement to plant roots and nutrient cycling (e.g., fungal and microbial decay, mineralization, fertilization), and by controlling the fate and transport of contaminants in the soil environment. Therefore, understanding the dynamics of plant growth, nutrient cycling, and contaminant behavior in the soil requires knowledge of the soil-moisture status as well as its spatial and temporal variability.

The neutron probe (also known as the neutron moisture meter) is a popular instrument for measuring soil-water content. The probe emits high-energy neutrons and measures the low-energy neutrons that result from interactions with the soil constituents. What makes a neutron probe viable for measuring soil water is that hydrogen nuclei, which are part of the water molecule, play a dominant role in normal soils in reducing the energy level of neutrons.

The neutron probe measures soil-moisture status without the need to collect innumerable soil samples. This feature alone is one of the main reasons the technique is popular, because it allows researchers and farm managers to monitor the water content at multiple soil depths at the same location repeatedly without disturbing the soil. Thus, neutron probes make it possible to conduct long-term studies 'on the same plot of land' without fear of altering the plot by repetitive sampling. Neutron probes are easy to deploy for studies of spatial variability, thus overcoming the cost and destructiveness of sampling or the cost, disturbance, and inflexibility of weighing lysimeters. Another reason for the rise in popularity of the neutron probe is the large sensing volume, which nominally approximates a sphere with a 15- to 30-cm radius. The large sensing volume reduces the influence of small-scale variability in the soil, the number of measurements needed, and the sensitivity to soil disturbance caused by installation.

The idea of using neutrons to measure soil conditions arose in the 1940s, and the first use of a neutron device in a borehole was reported in 1947. By the 1950s, researchers around the world were extending neutron probe technology to agricultural conditions and reporting success in measuring water content in laboratory and field experiments. Since then, the neutron probe has become a standard field method for measuring soil-water content. As shown in **Figure 1**, the agriculture community uses neutron probes to monitor field water status in croplands and identify when irrigation is needed to meet plant water requirements. The environmental community uses neutron probes to monitor water conditions in and around waste disposal sites. The academic research community uses neutron probes to study and understand the hydrologic cycle.

Theory and Instrumentation

The neutron is an elementary particle with a mass similar to that of a proton. Unlike the proton, the neutron has no charge, which allows it to interact primarily with atomic nuclei. A free neutron eventually decays according to:

$$ {}^{1}_{0}\mathrm{n} = {}^{1}_{1}\mathrm{H} + \beta \qquad [1] $$

Figure 1 Neutron probe in use in a field containing soybean stubble. Photo courtesy of Steve Evett, USDA–ARS, Soil and Water Management Research Unit, Bushland, Texas.

with a half-life of 10.4 min and a β energy of 0.782 MeV.

Neutrons are produced by the transformation from one radionuclide to another. Three modes of transformation suitable for soil and environmental studies are spontaneous fission, alpha-neutron (α-n) interactions, and neutron generation. Of these, the α-n mode has proven to be most effective for agricultural soils.

The α-n method for generating neutrons involves mixing two materials: one material to provide a source of alpha particles, the other material to provide a source of neutrons when exposed to alpha particles. Potential sources of alpha particles include americium, californium, polonium, plutonium, and radium. The americium decay reaction is:

$$^{241}_{95}\mathrm{Am} = ^{237}_{93}\mathrm{Np} + ^{4}_{2}\alpha + \gamma \qquad [2]$$

which generates an α with an energy of 5.48 MeV. The material typically chosen to provide the neutrons is beryllium, although lithium has also been used. For the americium–beryllium (Am-Be) combination, the equation is:

$$^{4}_{2}\alpha + ^{9}_{4}\mathrm{Be} = ^{12}_{6}C + ^{1}_{0}\mathrm{n} + \gamma \qquad [3]$$

The optimum material combination from the standpoint of commercial application is americium–beryllium, which has the desirable characteristics of a long half-life (458 years), a moderately high neutron-emission rate of 67.6 n s^{-1} MBq^{-1} (2500 n s^{-1} mCi^{-1}), and a low gamma dose rate of 2.78 nSv s^{-1} at 1 m (1 mrem h^{-1} at 1 m) under a fast neutron flux of 10^6 n s^{-1}. The long half-life ensures that a sealed source will last many years with negligible decay. The high emission rate ensures that enough neutrons will be present to make detection feasible. The low gamma dose rates and moderate fast neutron fluxes make it relatively safe to use.

The energy of neutrons generated by the Am-Be source ranges from 1 to 14 MeV and averages approximately 4.5 MeV. Neutrons at these energy levels are classified as fast neutrons. As they permeate the surrounding medium, fast neutrons interact with nuclei in scattering (both elastic and inelastic) and absorption events. The probability that a nucleus will interact with a free neutron can be statistically determined and represented using the microscopic cross-section (σ); the standard unit of measurement is the barn, which is 10^{-28} m^2 per nucleus. The ability of a soil to interact with neutrons will be a function of the soil's elemental composition, the σ values associated with each element, and the element density (atoms per volume).

In elastic scattering events, the neutron strikes the nucleus and rebounds; energy and momentum are conserved. This type of scattering is colloquially referred to as 'billiard ball scattering' and is the dominant process for slowing down neutrons under normal soil conditions. In inelastic scattering events, the neutron strikes the nucleus and rebounds with a loss of energy via gamma-ray emission. In absorption events, neutrons strike and react with the nucleus, resulting in the release of additional radiation (e.g., α, β, γ, n). Both inelastic scattering and absorption of fast neutrons are minor neutron-slowing processes relative to elastic scattering.

Table 1 shows that soil constituents differ in their efficiency at slowing down neutrons by elastic scattering. Hydrogen, which is present primarily in soil water, requires the least number of collisions to thermalize a 14 MeV neutron. Table 1 shows that, although the slowing-down power of the elements is a function of the energy range, hydrogen consistently has the greatest potential.

After repeated scattering events, the energy level of the neutron decreases to less than 1000 eV, at which point the neutron is classified as a slow or thermalized neutron. The petroleum industry uses slow neutrons in the energy range from 1000 to nearly 0.025 eV for geophysical measurements (e.g., petroleum reservoir

Table 1 Fast and thermal neutron information for the most common soil constituents

Element	Nominal soil fraction (wt %)	Estimated no. collisions to thermalize neutron from 14 MeV to 0.01 eV	Estimated fast neutron slowing-down cross section 10–0.183 MeV (barn)	Estimated fast neutron slowing-down cross section 0.183 MeV to 1.44 eV (barn)	Thermal capture cross section at 0.0253 eV (barn)

characterization); these slow neutrons are called epithermal neutrons. Slow neutrons near or below the energy level of 0.025 eV are called thermal neutrons because they are in an energy condition similar to thermal equilibrium with their environment.

The density of thermal neutrons that forms around the probe is balanced between thermal neutron creation (via thermalization of fast neutrons) and the processes of thermal neutron capture, decay, and diffusion away from the probe. Once formed, thermal neutrons do not travel far; the diffusion length is highly variable but is on the order of centimeters. If a fast neutron encounters many nuclei close to the source, the neutron will be reduced to thermal conditions while it is still relatively close to the source. If a fast neutron encounters few nuclei close to the source, the neutron will tend to migrate further from the source before it is reduced to a thermal energy level. In other words, the nature of the medium dictates how far from the source the thermal neutrons are created. Because hydrogen (and thus water) has such a high macroscopic cross-section relative to all other normal soil constituents, water content is the primary controller of the density of thermal neutrons near the probe and thus determines how much of the medium is sensed. This phenomenon is called the volume of influence. Figure 2 shows how the volume of soil sensed by the neutron probe decreases as the water content increases. The radius of influence is typically 15 cm for wet soil and as much as 30 cm for dry soil.

Thermal neutrons can be detected using the ionization products that form when the neutron is captured by an element. Early detectors used gas-filled tubes containing boron trifluoride (BF_3), but modern detectors tend to use the helium isotope ^{3}He, which reacts as follows:

$$^3_2\mathrm{He} + {}^1_0\mathrm{n} = {}^3_1\mathrm{H} + \mathrm{p} \qquad [4]$$

The ^{3}He isotope has a higher thermal cross-section (5400 barns) than ^{10}B (3840 barns) and can be stored in the detector tube to a greater density. For both the B and He detectors, the ionization products within the gas in the tube alter the current through the tube, thus allowing the thermal neutrons to be detected and counted. These detectors are insensitive to fast neutrons.

Radioactive decay is a random process that affects the rate of fast neutrons emanating from the probe. To overcome the randomness of the source, neutron probes are designed to count the number of thermal neutrons for a specific duration. Repeated measurements under the same conditions, such as in a standard medium, produce a sample population of counts that resembles a Poisson distribution, which has the property that the standard deviation of the finite sample population can be approximated by the square root of

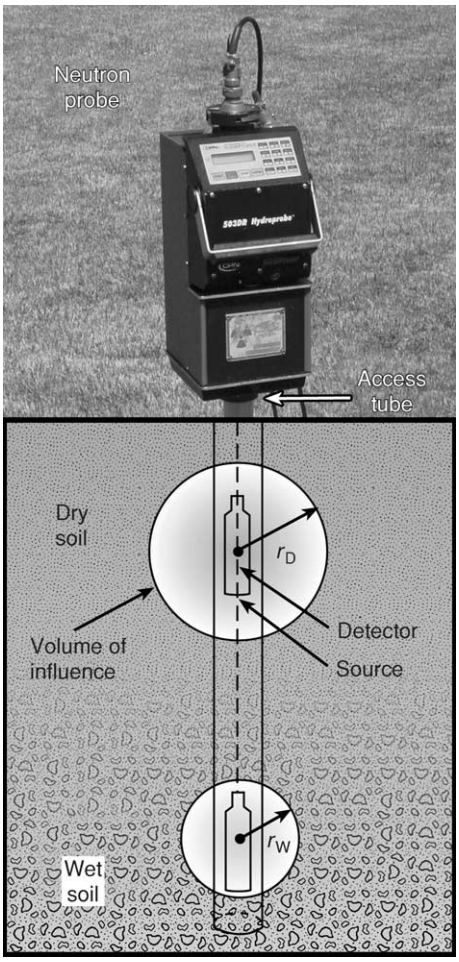

Figure 2 A neutron probe volume of influence in wet soil and dry soil.

the mean count. Because a Poisson distribution can be approximated with a normal distribution (given sufficient counts), the mean count and standard deviation can be used to describe the sample distribution. Thus, they can be used to control measurement precision by estimating the counting time needed to achieve a specific precision. They can also be used for quality control by comparing the results with a normal distribution to detect abnormal amounts of fluctuation that would indicate a malfunctioning probe.

Neutrons emitted by a neutron probe have the potential to activate (make radioactive) some of the elements (e.g., Na, Mg, Cl, Si, Al, Fe, Mn) in the soil and access tube. For example, the aluminum in an aluminum access tube can become activated as follows:

$$^{27}_{13}\mathrm{Al} + ^{1}_{0}\mathrm{n} = ^{28}_{13}\mathrm{Al} \qquad [5]$$

The resulting aluminum isotope has a short half-life (2.3 min) and yields a beta particle during decay. Other activation product half-lives range from seconds to hours. The probability of significant activation is very low because the concentrations in the soil are generally so small and the neutron flux is relatively low (more than an order of magnitude lower than required to cause measurable activity). Because activation products are belowground and of short duration, the risk of exposure is extremely small.

Field Methodology

To use a neutron probe to measure soil moisture requires an access hole in the soil into which the probe can be inserted. Ideally, the hole should be just wide enough to permit entry of the probe while minimizing excess air gaps. In reality, drilling a uniform-width hole and keeping it open and unchanging is highly unlikely, even under the best of field conditions. Therefore, the commonly accepted practice is to install a rigid-wall tube (or pipe, conduit, casing) that allows the probe to access the soil repeatedly without degrading the hole geometry.

The access-tube material should be chosen based on ease of installation, durability, availability, and minimal impact on neutron flux. Thin-walled tubing made of aluminum, schedule-10 galvanized steel, or schedule-40 polyvinyl chloride (PVC) is the preferred choice, but thicker iron well casing has been shown to be acceptable for specific applications. Successful installation requires that air gaps and packing material (e.g., grout) be minimized or, even better, eliminated and that the installation procedure be used consistently for all tubes. The key to choosing the correct access-tube material and installation method is to demonstrate, through calibration, that the probe and access-tube combination retains sufficient sensitivity to be an effective soil-moisture measurement system.

The most common orientation for access tubes is vertical so that the operator can monitor the depth distribution of soil water. However, access tubes can also be installed at an angle, or even horizontally, to allow the operator to monitor beneath an object such as a buried storage tank. Access tubes can become damaged during installation; once installed, the tube should be tested with a dummy probe to determine its integrity. Dummy probes are inert objects, usually made of metal, that are shaped like a real probe but slightly larger. If the dummy probe can be passed through the access tube, the operator can be assured that the neutron probe will not become lodged.

In addition to protecting the access tube, the operator must protect the access-tube site from compaction by foot and vehicular traffic. Relative to the tube surroundings, compaction increases the density of

neutron-affecting minerals, alters the soil hydraulic properties, and affects plant growth and behavior. The seriousness of compaction can increase if the site is used for multiyear tests involving many site visits.

Calibration

A neutron probe detects and measures thermal neutrons to indicate soil-moisture status. In addition to soil water, the formation and maintenance of a cloud of thermal neutrons within the sensing volume of the probe depends on the mineral composition of the soil matrix, bulk density, bound water, soil-water constituents, and organic matter. Table 1 shows how the major soil elements vary in their ability to slow down fast neutrons as well as capture thermal neutrons. Clearly, hydrogen has the greatest potential to thermalize neutrons and capture them, and thus control the thermal neutron density around the probe. As noted above, increases in bulk density translate directly into increases in the density of neutron-affecting minerals. Bound (or structural) water is part of the soil matrix (e.g., between clay lamella). Bound water affects neutron thermalization just like free water, but it is not available to plants and does not interact with free-flowing soil water.

Natural soil-water constituents are generally present in concentrations too low to affect a neutron probe and are normally not considered during probe calibration and use. However, operators should be cognizant when soils are subject to significant fertilization, salts (e.g., carbonate and sulfate deposits in semiarid and arid soils), sludge amendments, or waste disposal. Under these conditions, the soil water could contain constituents with significant thermal neutron-capture cross sections (e.g., B, Cl, Fe, Mn) that would render the probe calibration less representative unless modified.

Another soil component normally not considered during probe calibration and use is organic material, which includes living plant roots and associated subsurface plant components, dead and decaying plant parts, and fully developed organic matter. The key feature of organic material that could affect probe sensitivity is the presence of water, either as part of living plant tissue or in response to changes in the water-holding capacity of the soil. These factors should be assessed seasonally and in special zones in the soil where plant root changes are greatest (e.g., soil surface and soil-layer interfaces with contrasting soil texture).

Because they are affected by conditions such as mineralogy, bulk density, and sediment discontinuities, neutron probes should be calibrated for the specific conditions under which they will be used in the field. In a typical field calibration, multiple access tubes are emplaced to allow access to the entire thickness of soil. The neutron probe is lowered to different depths in each access tube and readings performed. Immediately subsequent to collecting neutron readings, the soil is excavated to collect multiple undisturbed soil samples directly adjacent to the tubes and at the same probe-measurement depths. The undisturbed samples are then analyzed in the laboratory to determine the measured volumetric water contents and bulk densities for those depths. These values are then related to the neutron-probe counts taken at the respective depths. The key to a successful calibration is to collect data under wet and dry conditions in each soil layer to cover the complete range of expected water contents.

The thermal neutron count rate is converted to soil moisture using a calibration equation. Separate equations may be required for different soil horizons. The most common calibration equation is a linear function of the form:

$$\theta = m(\mathrm{CR}) + b \qquad [6]$$

where θ is the volumetric moisture content, CR is the thermal neutron count ratio, and m and b are calibration parameters. The count ratio is the thermal-neutron count in the soil relative to the thermal-neutron count in a standard medium. The rationale for referencing to a standard medium is to minimize the impacts caused by changes in the probe source and electronics due to aging and decay that might not be readily apparent to the probe operator. The standard medium must have neutron-slowing properties and the properties must remain constant. Typical standards are the probe shield or a sealed barrel containing nonchanging material such as water or wax. If the probe shield is used, it ought to be located 0.8 m from the ground surface and up to 3 m from structures, vehicles, and people to minimize interferences. The distance recommendations are less stringent if the larger standards such as water- or wax-filled barrels are used. Figure 3 shows a typical linear calibration equation and the supporting field measurements.

Equation [6] has been shown to be appropriate for a wide variety of soils and moisture conditions, but other forms of calibration equations have been proposed and used for special cases. These other equations include multiple regression equations that use other soil information such as bulk density and quadratic equations that allow for a better fit of data for specific cases (e.g., very low water contents; large-diameter, iron-cased wells).

Applications

The output of the neutron probe is converted to soil moisture data. These data are used to assess the depth distribution of water, the overall soil-water status, and the movement of water in the soil profile. When collected on multiple occasions, the temporal data can reveal long-term changes such as withdrawal of water by plants, loss of water by evaporation, and responses to weather and irrigation conditions. Figure 4 shows a typical variation in water-content profile determined with a neutron probe.

Safety and Care

Human health is affected by exposure to radiation. The nature and degree of health effects depend on the type of radiation and the length of time one spends in the radiation field. Although the radioactive source in a neutron probe is sealed and unreachable by the operator (barring the use of force to overcome the seal), the probe operator is subject to the radiation emitted through the seal and the probe housing. Emissions from neutron probes consist of neutrons and gamma rays at various energy levels. Measurements adjacent to the probe shield have shown that dose rates are dominated by the fast neutron flux. Thus, most probe monitoring efforts focus on measuring the fast neutron flux. The impact to an operator can be seen in the following example. The radiation field at a distance of 5 cm from the shield of a 3.7-GBq (100 mCi) Am-Be source was measured and found to be $0.12\,\mathrm{mSv\,h^{-1}}$. At that dose rate, a neutron probe operator could be 5 cm from the shield for 8 h every week of the year and not exceed the International Standard worker limit of 50 mSv in any single year.

Radiation from a neutron probe is generally not a health hazard to someone within the radiation field if ALARA (as low as reasonably achievable) principles are followed. For example, the radiation field strength can be reduced by limiting the size of the source and surrounding it with a shield. Typical shields are composed of hydrogenous material to reduce neutrons. The dose from a 3.7-GBq (100 mCi) Am-Be source is reduced by approximately 20% when behind a 7-cm-thick plastic shield; the resulting dose is primarily from fast neutrons ($0.1\,\mathrm{mSv\,h^{-1}}$ ($10\,\mathrm{mrem\,h^{-1}}$) versus $0.01\,\mathrm{mSv\,h^{-1}}$ ($1\,\mathrm{mrem\,h^{-1}}$) from gammas and thermal neutrons). The dose from more modern probes is less because the source activities have been reduced, e.g., 0.37 GBq (10 mCi) and 1.8 GBq (50 mCi). Operators can reduce exposure further by using distance and time to advantage. For example, the radiation filed is inversely proportional to the distance squared. By doubling the distance to the probe, the operator can reduce the radiation field by a factor of four. The operator can also reduce the radiation field to some extent by using intervening material (e.g., shielding between a truck cab and the truck bed when the probe is transported). In addition to increasing distance to the

probe, the operator can also reduce exposure by minimizing the time spent within the radiation field. Prior planning, quality-assurance procedures, and efficient work habits can reduce the amount of unnecessary time spent lingering near the probe.

Modern neutron probes are robust but, because of the radioactive source and the electronics, these probes require administrative oversight and care in handling. The International Atomic Energy Agency (IAEA) promulgates safety and regulatory requirements designed to ensure safe use of neutron probes. More than 125 nations belong to the IAEA and they use national organizations to address the IAEA requirements. These requirements include the need for routine periodic leak tests of sealed sources to look for particles of the source (thus indicating a failure of the source seal) and transportation and storage controls for safety, theft protection, and disposal.

Manufacturers provide guidance to operators for probe care, cleaning, and battery replacement. For maintenance and repair work, manufacturer recommendations differ. Some require sending the probe back to the factory; others allow the electronics to be disengaged from the source and sent to the factory while the source remains stored locally. A probe operator can prolong the life of the probe, cable, and electronics by taking care to avoid dropping them, subjecting them to extremes of temperature, pressure, and acceleration, and by minimizing their exposure to solar radiation and water. The operator should also prevent undue stress on the cable.

Access tubes can become damaged during use. Caps or covers on the access tubes help to limit accidental bumps as well as to keep out water, soil, and organic debris. Even so, the tubes should be periodically checked for dents, decay, and debris. Tube cleanliness can be maintained by using a cleaning rag on a pole. The radial uniformity of the tube should be checked occasionally using a dummy probe to ensure that the actual neutron probe will pass easily through the tube.

Future Use

After more than 50 years, neutron probes remain the most reliable tool available for field monitoring of soil-water content. Neutron probes provide integrated measurements over relatively large volumes of soil and, with proper access, allow for repeated sampling of the subsurface at the same locations. The limitations of neutron probes include costly and time-consuming manual operation, lack of data automation, and costly regulatory requirements. As more nonradioactive systems for soil-water monitoring are developed to provide automated profiling capabilities, neutron-probe usage will probably decline. Until then, neutron probes will continue to be a standard for reliable measurements of field water contents in soils around the globe.

Introduction

Nitrogen (N) is the element most often limiting plant nutrition in terrestrial ecosystems. The greatest source of available N is atmospheric dinitrogen (N_2), which is relatively inert and can only be used by symbiotic and free-living prokaryotic bacteria with the capacity for N_2 fixation (Table 1). For other plants and soil organisms, the slow release of N from rocks and minerals and cycling between organic and inorganic forms in soil is crucial to life. Unfortunately, some aspects of N cycling can be problematic. Nitrogen can be readily lost from terrestrial soils, leading to reduced fertility and surface- or groundwater contamination, and several transformations give rise to intermediate or final products that can have negative environmental consequences.

Properties and Forms of Nitrogen in Soil

There are two overriding chemical properties of the N atom worth noting. First, the dinitrogen molecule, N_2, is very stable. Once formed and lost from the soil environment, N_2 is relatively inert and requires considerable energy ($946\,kJ\,mol^{-1}$) to break the triple bond between N molecules and reintroduce N to biological systems. The second significant feature of N, owing to its atomic structure and electron configuration, is its ability to undergo changes in oxidation state from $+5$ to -3 depending on its environment. This property is important for soil transformations, because N, in its oxidized forms, can be an electron acceptor in anaerobic respiratory metabolism. N, in its reduced forms, can also be an energy source for various chemolithotrophic bacteria. The N cycle in soil is driven by these transformations between oxidized and reduced states and between organic and inorganic forms (Figure 1).

The principal soluble inorganic N forms in soil are NO_3^-, NO_2^-, and NH_4^+. The inorganic gaseous N forms in soil are N_2, N_2O, NO, and NH_3. Organic N takes many forms, such as amino acids (e.g., glycine, glutamine), amino sugars (e.g., glucosamine, galactosamine), nucleosides (e.g., adenine, guanine), peptides, phospholipids (e.g., phosphatidylethanolamine, phosphatidylserine), vitamins (e.g., niacin), and other compounds such as creatine, cyanide, allantoin, various alkyl amines, and urea. Unidentifiable forms of N are typically polymerized with soil organic matter fractions such as humic and fulvic acids.

N-Cycling Pathways

The major organic and inorganic N transformations that occur in soil can be grouped into five pathways: mineralization (ammonification), assimilation (immobilization), nitrification, nitrate reduction, and N_2 fixation.

Table 1 Global sources of available N

Source	*N content ($\times 10^{16}$ kg)*[a]	*Total (%)*
Atmosphere	386.000	87.0000
Oceans and lakes		
Dissolved N_2	2.190	0.5000
Soluble inorganic N	0.110	0.0200
Sediments	35.000–55.000	12.0000
Sea bottom organic N	0.054	0.0100
Terrestrial biosphere	0.028–0.065	0.0100
Terrestrial soils		
Organic N	0.022	0.0050
Clay-fixed NH_4^+	0.002	0.0005

[a]The data exclude N in the lithosphere such as igneous rocks, sediments, and coal that do not actively participate in global N cycling.

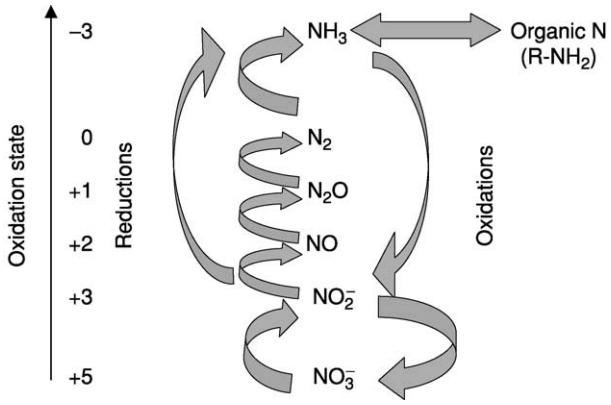

Figure 1 Oxidation–reduction transformations of nitrogen.

Mineralization (Ammonification)

During mineralization, organic N is hydrolyzed to release NH_3, which is subsequently protonated in the soil solution to become the cation NH_4^+ (eqn [1a]). Consequently, mineralization is frequently referred to as ammonification:

$$\text{Organic N (R-NH}_2) \longrightarrow \text{NH}_3 \longrightarrow \text{NH}_4^+ \quad [1a]$$

$$\text{Glutamate} + \text{NAD}^+ + \text{H}_2\text{O} \xleftrightarrow{\text{Glutamate dehydrogenase}} \alpha\text{-Ketoglutarate} + \text{NH}_4^+ + \text{NADH} + \text{H}^+ \quad [1b]$$

Another example of mineralization that has great importance in soil is urea hydrolysis by the seemingly ubiquitous enzyme urease, which is shown in eqn [2]. Urea is one of the dominant organic N forms excreted by animals, and it is also one of the most popular forms of solid fertilizer used on a global basis. Urea hydrolysis in soil is rapid, and the subsequent NH_3 formation can cause considerable N loss through volatilization. One of the immediate effects of urea hydrolysis is also a rapid increase in the soil pH:

$$\text{H}_2\text{O} + \text{NH}_2\text{CONH}_2 \xrightarrow{\text{Urease}} \text{CO}_2 + 2\text{NH}_3 \quad [2]$$

Assimilation (Immobilization)

Assimilation (immobilization) is the incorporation of inorganic N as NH_4^+, NO_3^-, or NO_2^- into biomass (eqns [3] and [4]). Immobilization can also refer to the binding of NH_4^+ to certain clays in soil and to the interaction of inorganic N with soil organic matter:

$$\text{NH}_4^+ \longrightarrow \text{Organic N (R-NH}_2) \quad [3]$$

$$\text{NO}_3^- \text{ or } \text{NO}_2^- \longrightarrow \text{NH}_4^+ \longrightarrow \text{Organic N (R-NH}_2) \quad [4]$$

Nitrification

Nitrification is the general term that describes oxidation of reduced inorganic and organic N and formation of NO_2^- or NO_3^-. It is an aerobic process that occurs by one of two pathways: autotrophic nitrification, carried out by chemolithotrophic bacteria, and heterotrophic nitrification, carried out by chemoheterotrophic bacteria and fungi.

Autotrophic nitrification Autotrophic nitrification is a two-step process that is carried out by chemolithotrophic bacteria, which obtain energy by oxidizing NH_3 to NO_3^- (eqn [5]).

$$\text{NH}_4^+ \underset{+\text{H}^+}{\overset{-\text{H}^+}{\rightleftharpoons}} \text{NH}_3 \longrightarrow \text{NO}_2^- \longrightarrow \text{NO}_3^- \quad [5]$$

The first step in the pathway, which is performed by NH_3-oxidizing bacteria such as *Nitrosomonas*, involves the sequential oxidation of NH_3 to hydroxylamine (NH_2OH) and then to NO_2^- (eqns [6a] and [6b]):

$$\text{NH}_3 + \text{O}_2 + 2\text{H}^+ \xrightarrow{\text{Ammonia monooxygenase (AMO)}} \text{NH}_2\text{OH} + \text{H}_2\text{O} \quad [6a]$$

$$\text{NH}_2\text{OH} + \text{H}_2\text{O} \xrightarrow{\text{Hydroxylamine oxidoreductase (HAO)}} \text{NO}_2^- + 5\text{H}^+ \quad [6b]$$

The second step in the pathway is performed by NO_2^- oxidizing bacteria typified by bacteria in the genus *Nitrobacter*. Nitrite oxidation is generally so rapid that NO_2^- rarely accumulates to any significant extent in soil:

$$\text{H}^+ + \text{NO}_2^- + \text{H}_2\text{O} \xrightarrow{\text{Nitrite dehydrogenase}} \text{NO}_3^- + 3\text{H}^+ \quad [7]$$

Autotrophic nitrification is believed to be the dominant type of nitrification occurring in agricultural soils. Nitrification is an acidifying process and use of reduced organic and inorganic N for plant nutrition will lower the soil pH with time because of nitrification.

Heterotrophic nitrification Heterotrophic nitrification is the oxidation of organic N and NH_3 by various chemoheterotrophic bacteria and fungi such as *Arthrobacter*, *Streptomyces*, and *Aspergillus*. Heterotrophic nitrification produces NO_2^- and NO_3^- in soils typically too acid to permit autotrophic nitrification (eqn [8a]).

$$\text{Organic N (R-NH}_2) \longrightarrow \text{NO}_2^- \text{ or } \text{NO}_3^- \quad [8a]$$

Products of heterotrophic nitrification also include nitroso-compounds, which have been identified as potential carcinogens (eqn [8b]):

$$\text{R-NH}_2 \longrightarrow \text{RNHOH} \longrightarrow \underset{\text{Nitroso-compound}}{\text{R-NO}} \longrightarrow \text{R-NO}_3 \longrightarrow \text{NO}_3^- \quad [8b]$$

Nitrate Reduction

In anaerobic or waterlogged environments, denitrification and dissimilatory nitrate reduction to ammonium (DNRA) are the two major pathways by which the NO_2^- and NO_3^- formed by nitrification can be subsequently reduced. Facultatively anaerobic bacteria perform these N transformations, although it has been suggested that some fungi are also capable of denitrification.

Denitrification Denitrification is the major reductive fate of NO_3^- in most soil environments. It is a respiratory process in which nitrogen oxides are used as terminal electron acceptors in place of O_2 and produces gas as the terminal reduction product (eqn [9]). Denitrification is a multistep process catalyzed by distinct enzymes for each step:

$$\text{NO}_3^- \xrightarrow{\text{Nitrate reductase}} \text{NO}_2^- \xrightarrow{\text{Nitrite reductase}} \text{NO} \xrightarrow{\text{Nitric oxide reductase}} \text{N}_2\text{O} \xrightarrow{\text{Nitrous oxide reductase}} \text{N}_2 \quad [9]$$

Dissimilatory nitrate reduction to ammonium The NH_4^+ produced during DNRA is not assimilated but is excreted into the environment (eqn [10]). The bacteria that perform DNRA are distinct from denitrifiers. They predominate in environments that are continuously saturated, anaerobic, and have high concentrations of available C relative to NO_3^-:

$$\text{NO}_3^- \longrightarrow \text{NO}_2^- \longrightarrow \text{NH}_4^+ \quad [10]$$

N_2 Fixation

Nitrogen fixation is an energy-demanding process by which prokaryotic bacteria reduce N_2 gas to NH_3 either independently or in symbiosis with various leguminous and nonleguminous plant species (eqn [11]). The most significant types of terrestrial nitrogen fixation are the legume/rhizobia symbiosis and the actinorhizal symbioses, which occur between woody shrubs and bacteria of the genus *Frankia*. In aquatic systems, photosynthetic cyanobacteria such as *Anabaena* and *Nostoc* are responsible for N_2 fixation.

$$\text{N}_2 + 16\text{Mg-ATP} + 8\text{H}^+ \xrightarrow{\text{Nitrogenase}} 2\text{NH}_3 + \text{H}_2 + 16\text{ADP} + 16\text{Pi} + 16\text{Mg}^{2+} \quad [11]$$

Nitrogenase is actually an enzyme complex consisting of dinitrogenase reductase and dinitrogenase, which are highly conserved, O_2-sensitive enzymes working in tandem to reduce N_2. Nitrogenase is somewhat nonspecific with respect to substrate, so it will also reduce H^+ to H_2, N_2O to N_2, and C_2H_2 to C_2H_4. The latter reduction is the basis for the acetylene reduction assay (ARA), which is used to detect and quantify N_2 fixation in different environments.

Fixed (Nonexchangeable) Ammonium

An important part of the inorganic soil N of some soils is fixed or nonexchangeable NH_4^+. Ammonium ions in soil exist in a chemical equilibrium as follows:

$$\text{NH}_4^+(\text{solution}) \leftrightarrow \text{NH}_4^+(\text{exchangeable}) \leftrightarrow \text{NH}_4^+(\text{fixed})$$

Figure 2 shows the crystalline structure of a weathered, micaceous silicate clay mineral, such as illite, showing the locations of solution, exchangeable, and fixed NH_4^+. Much of the fixed NH_4^+ can be slowly available to growing plants and soil

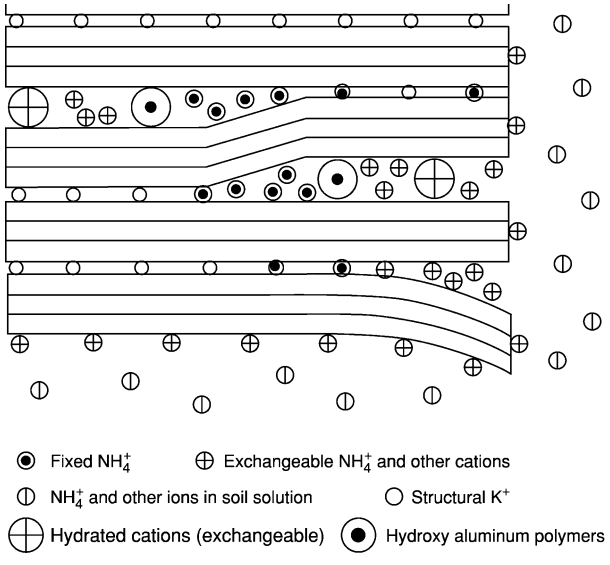

Figure 2 Schematic of micaceous-type soil clay (vermiculite, hydrous mica) showing wedge-shaped zones and weathered edges where NH_4^+ can be fixed. Adapted from Dixon JB and Weed SB (eds) (1989) *Minerals in Soil Environments*, 2nd edn. Soil Science Society of America Book Series 1. Madison, WI: Soil Science Society of America with permission.

microorganisms. As plant uptake or biomass immobilization depletes the readily available NH_4^+, i.e., solution NH_4^+ and exchangeable NH_4^+, fixed NH_4^+ is released by cation replacement, especially with K^+. Conversely, when NH_4^+ is added to the soil from any source, more NH_4^+ is fixed to establish a new equilibrium. Therefore, the fixed NH_4^+ sites serve as a reserve source of N and as a sink for excess NH_4^+.

Regulation and Environmental Control

Nitrogen transformations between organic and inorganic forms in soil depend on the type and availability of inorganic N and on the relative availability of inorganic N to mineralizable C.

Cellular and Environmental Regulators of N Transformations

Microorganisms in soil will preferentially assimilate NH_4^+ rather than NO_3^- or NO_2^-. Even low NH_4^+ concentrations in soil solutions will quickly stop NO_3^- uptake and, soon after, inhibit enzymes associated with assimilatory NO_3^- reduction (Table 2). If NH_4^+ concentrations in soil solutions exceed $1\,mmol\,l^{-1}$, assimilation by glutamate dehydrogenase will occur in which the first recognizable product is glutamate. If soil N is limiting, microorganisms will utilize an enzyme system referred to as GS/GOGAT (glutamine synthetase/glutamine oxoglutarylamino transferase) in which the first identifiable form of organic N is glutamine. Nitrate, if it is assimilated, will first be reduced to NO_2^- by assimilatory NO_3^- reductase and the NO_2^- subsequently reduced to NH_4^+ by assimilatory NO_2^- reductase. Thereafter, the pathways are the same as for NH_4^+ assimilation.

Organic N will be mineralized in soil in the absence of available inorganic soil N, although, as a general rule, N-containing compounds such as amino acids are not mineralized only to be subsequently resynthesized. Most N cycling in soil and inorganic N release is actually driven by the mineralization of soil C for biomass and energy; inorganic N accumulates in soil only when the microbial demand for N is met. When the C/N ratio of decomposing material exceeds approximately 30, net immobilization of inorganic N from soil occurs because there is insufficient N in the mineralizing material to sustain microbial biomass formation. In contrast, when the C/N ratio is less than 30, the N needs for microbial growth are met, and inorganic N is released into the soil environment. The decomposition of organic materials with very low C/N ratios can therefore cause inorganic N to accumulate briefly in excess of microbial and plant needs, with the potentially adverse effects of volatilization, runoff loss, or plant toxicity in the case of NH_4^+.

The three environmental factors that regulate nitrification in soil are NH_4^+ availability, aeration, and pH (Figure 3). As long as the oxidation–reduction potential (E_h) of soil exceeds approximately 400 mV, NO_3^- will remain oxidized and nitrification of NH_4^+ will proceed. In contrast to most other N transformation processes, autotrophic nitrification is extremely pH-sensitive. Below pH 5.5, NH_4^+ oxidation will not occur, and above pH 8 NO_2^- oxidation slows, because NH_3 inhibits NO_2^--oxidizing bacteria. Ammonification and urease activity can rapidly increase the NH_3 concentration in soil sufficiently to prevent NO_2^- oxidation and thereby cause brief NO_2^- accumulation. Plant toxicity can result.

In grassland and prairie environments, autotrophic nitrification is often minimal. Although it has been suggested that this is due to allelopathic effects of the native vegetation, the most likely explanation is

Table 2 Inhibition of NO_3^- assimilation by NH_4^+

NO_3^- concentration ($\mu g\ NO_3^-$-N ml^{-1})	*N source*	*Inhibition (%)*	*Response time (min)*

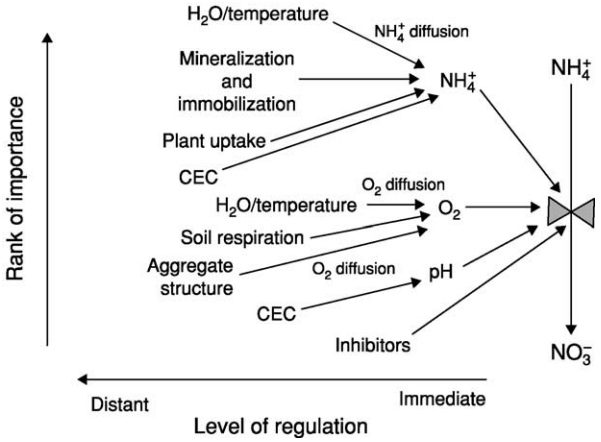

Figure 3 Regulators of nitrification in the soil environment. CEC, cation exchange capacity.

that intense competition from plant roots and heterotrophic microorganisms deprives nitrifiers of the NH_4^+ that they require for growth.

Nitrification slows and ceases as soils become increasingly saturated. The dominant fate of NO_3^- in most waterlogged soil environments is denitrification. Oxygen concentration is the overwhelming environmental factor controlling denitrification and DNRA (Figure 4). Limited C and NO_3^- availability will also slow denitrification and affect whether incompletely reduced intermediates such as NO and N_2O accumulate.

Environmental control over whether denitrification or DNRA predominates in an environment appears to be governed by the extent and duration of anoxia and by the relative proportions of soluble C and NO_3^- (Figure 5). Denitrifiers are more competitive when C is limiting because they obtain more energy through anaerobic respiration with NO_3^- than do NH_4^+ dissimilators (1121 versus 600 kJ mol^{-1} of NO_3^- reduced).

Nitrogen fixation is an energy-demanding process. Consequently, when N is available in the form of inorganic N or readily mineralizable organic N, the synthesis and activity of nitrogenase are suppressed. High soil N concentrations will also suppress the establishment of symbiotic N_2-fixing relationships between bacteria and plants.

Chemical Regulators of N Transformations

Chemicals have been developed that can effectively regulate (inhibit) two important N transformations on an agricultural field scale – nitrification and urea hydrolysis. A nitrification inhibitor slows the rate of autotrophic nitrification by selectively suppressing *Nitrosomonas* bacteria in the soil (eqn [5]). A urease inhibitor functions by interfering with the enzymatic activity of urease in catalyzing the hydrolysis of urea (eqn [2]). The use of these chemicals will be discussed later as part of management practices to decrease N losses.

Routes of N Loss From the Environment

The N transformations in soil inevitably result in intermediate or final products that can be lost from the soil environment through gaseous diffusion, leaching, or surface erosion (Figure 6). The route of N loss greatly depends on the type of transformation – whether oxidative or reductive.

Reductive Losses

The major reductive losses of N occur during denitrification, which produces N oxides such as NO and N_2O as intermediates and N_2 as a final product. All three compounds are gases that can be lost to the atmosphere. Nitrate reduction to NH_4^+ seemingly preserves N from loss; however, the NH_4^+ formed can still be leached in soils with low cation exchange capacities or lost through erosion.

Oxidative Losses

Autotrophic nitrification frequently results in the production of NO and N_2O as gaseous intermediates. The major concern with nitrification is the production of NO_3^-, which is readily leached from soil environments.

Volatilization

Ammonium exists in chemical equilibrium with NH_3. The pK for this equilibrium is approximately pH 9.5. Consequently, when the soil pH is sufficiently high, or

if NH_4^+ production is sufficiently rapid, aqueous NH_3 will be volatilized from soil and lost to the atmosphere as a gas. Animal manures, which contain readily mineralizable forms of organic N such as urea, can produce considerable amounts of volatile NH_3 due to this process.

Interaction of N with Soil Organic Matter

A significant fate of inorganic N is its interaction with soil organic matter. Although this can retard N loss from the environment, it also temporarily renders part of the inorganic N unavailable. Studies in California and Iowa have demonstrated that much of the inorganic NO_3^- and NH_4^+ added to soil can almost immediately become immobilized. Nitrification-mediated immobilization involves the reaction of NO_2^-, formed during the first step of nitrification, with soil organic matter at acidic and neutral pH to form nitrosophenols. Nitrite can also react with amino acids and other forms of reduced organic N to liberate gases as illustrated in eqns [12] and [13]:

$$NH_3 + HNO_2 \longrightarrow NH_4NO_2 \longrightarrow 2H_2O + N_2 \quad [12]$$

$$RNH_2 + HNO_2 \longrightarrow ROH + H_2O + N_2 \quad [13]$$

Management Practices to Decrease N Losses

Figure 6 shows the transformation pathways that potentially result in losses from the N cycle. Some of these losses, including soil erosion, NO_3^- leaching, denitrification, and NH_3 volatilization, can be managed to varying extents. Inhibiting nitrification and urease activity affects all of these pathways except erosion.

Nitrification inhibitors Several chemicals have been shown to inhibit nitrification (Table 3), but few have been proven agronomically and economically effective. The first nitrification inhibitor to be approved by the US Environmental Protection Agency was nitrapyrin, manufactured by Dow Chemical Company

and marketed as N-Serve. Nitrapyrin is 2-chloro-6-(trichloromethyl) pyridine. It may be used with any NH_4^+-N fertilizer, including anhydrous ammonia, urea, urea–ammonium nitrate solutions (UAN), ammonium nitrate, ammonium sulfate, and animal manures.

Nitrapyrin has a relatively high vapor pressure (2.8×10^{-3} mmHg at 23°C). Because of its tendency to volatilize, the manufacturer initially recommended incorporation into soil immediately after application. Research in Kentucky showed that nitrapyrin was effective when sprayed directly on to N fertilizer particles, which were then surface-applied for no-tillage corn. The researchers believed that the immediate proximity of nitrapyrin and NH_4^+ ions together at the sites of nitrification facilitated its effectiveness, even when surface-applied.

Dicyandiamide (DCD), also known as cyanoquanidine, is a water-soluble, organic amide that is both a slow-release N source and a nitrification inhibitor. The composition of DCD is $C_2N_4H_4$, and it contains at least 65% N. It is a fine-grained, nonhygroscopic, crystalline powder, which is easily incorporated into solid, solution, or suspension fertilizers.

Widespread research on nitrapyrin and DCD shows generally that both are very effective in suppressing nitrification in soil for several weeks after application. The ratio of NH_4^+ to NO_3^- is usually much higher in soils, and NO_3^- is lower in drainage water from soils following application of ammonical fertilizers treated with nitrapyrin or DCD than the same applications without a nitrification inhibitor. A crop yield response to a nitrification inhibitor, however, occurs only if N was lost by leaching or denitrification and then only if those losses resulted in N deficiency sufficient to reduce yields without the nitrification inhibitor. Rarely are yield increases observed if nitrification inhibitors are used with much higher than optimum application rates of N. The environmental benefits of decreasing NO_3^- leaching with a nitrification inhibitor would none the less be present and even more important where an excess of N was applied.

Urease inhibitors As in the case of nitrification inhibitors, several chemicals inhibit urease activity. Because mechanical incorporation is usually not practical, a urease inhibitor must suppress hydrolysis of broadcast-applied urea to the surfaces of soil and plant residues for no-tillage agriculture, or growing plants in pastures, forage fields, or lawns, and the effect must last long enough to allow rainfall to leach the urea molecules into the soil, where hydrolysis can occur with little risk of NH_3 volatilization loss from most soils.

Table 4 Corn yield response to urease inhibitors with fertilizers surface applied for no-tillage corn

	Grain yields (Mg ha^{-1})	
Fertilizer[a]	*Pennsylvania*[b]	*Kentucky*[c]
UAN	6.96	5.14
UAN + ATS	7.03 NS	–
UAN + NBPT	7.40*	5.52*
Urea	6.65	5.27
Urea + NBPT	7.53**	6.15**
Ammonium nitrate	7.59	5.96

[a]UAN, urea ammonium nitrate solution; ATS, ammonium thiosulfate; NBPT, *N*-(*n*-butyl) thiophosphoric triamide.
[b]From Fox and Piekielek (1993).
[c]Unpublished data, Department of Agronomy, University of Kentucky.
NS, not significantly different ($P \geq 0.10$) by LSD.
Significantly different by LSD: *$P \leq 0.10$, **$P \leq 0.01$, respectively.

In many research studies (examples shown in Table 4), one urease inhibitor has been shown to be particularly efficacious for urea fertilizer management. Allied Chemical Corporation patented *N*-(*n*-butyl)thiophosphoric triamide (NBPT) as a urease inhibitor in 1985. Today, NBPT is marketed by Agrotain International as a technology entity that includes a practical means of treating solid urea or UAN solution with NBPT, or NBPT and DCD, at a fertilizer-blending facility and delivering the product in the field as a fertilizer application. The combination of NBPT and DCD provides urease and nitrification inhibition for a urea application.

Environmental and Health Consequences of N Cycling

The principal environmental and health concerns associated with N cycling in soil are the potential for trace gas production and its effect on global warming and ozone depletion, the potential for nutrient loss, and the movement of N to environments where it can cause eutrophication and potential health problems.

Global Warming and Ozone Destruction

Nitrous oxide and nitric oxide are trace gases formed during nitrification and denitrification transformations of N in soil. Molecule for molecule, N_2O is 150 times more effective at adsorbing thermal radiation than is CO_2, the major greenhouse gas. Nitric oxide plays a well-known role in the destruction of stratospheric ozone as illustrated in the following reactions:

$$O_3 + h\nu \rightarrow O_2 + O\cdot \quad [14]$$

$$N_2O + O\cdot \rightarrow 2NO \quad [15]$$

$$NO + O_3 \rightarrow NO_2 + O_2 \quad [16]$$

$$NO_2 + O\cdot \rightarrow NO + O_2 \quad [17]$$

Nutrient Losses

Denitrification and NO_3^- leaching have been associated with the loss of up to 70% of the inorganic N in some fertilized fields. Ammonia volatilization occurring during hydrolysis of urea (eqn [2]) can result in losses of 10–50% of the N from surface-applied urea fertilizers. Ammonia volatilization due to urease activity is given as one explanation for the loss of 3–50% of the N in unincorporated manures such as poultry litter applied to neutral soils. Ammonia in high enough concentrations is a toxic gas, and its production in confined animal feeding operations (CAFOs) is a major concern. Unfortunately, venting such gases into the atmosphere is problematic for two reasons. First, the volatile N gases are odoriferous and generate nuisance complaints. Second, the volatile gases eventually return to soil or water as wet and dry deposition and can contribute to eutrophication in pristine environments.

Groundwater Quality

Groundwater is the source of drinking water for more than half of the USA, and in rural areas it represents more than 95% of the water used for domestic purposes. Nitrate-N concentrations in streams and groundwater are typically less than $2\,mg\,l^{-1}$ but have been steadily increasing in the USA and Europe. In the USA, for example, well-drained soils receiving high N inputs have median NO_3^--N concentrations approaching $5\,mg\,l^{-1}$ and up to 26% of sample wells have levels exceeding $10\,mg\,NO_3^-N\,l^{-1}$, which is the US Environmental Protection Agency (USEPA) and Public Health Service drinking water standard. Many drinking water systems in Europe currently exceed the EC limit of $11.3\,mg\,l^{-1}$.

The consequences of chronic consumption of NO_3^--contaminated drinking water and vegetation can be severe and include methemoglobinemia (blue-baby syndrome) and increased potential for stomach cancer due to nitrosamine formation.

The consequences of nitrification and subsequent NO_3^- leaching also have severe ecological consequences. The inability of growing plants to capture completely the N applied in fertilizer, and natural mineralization and nitrification in undisturbed soils opened to agriculture, grazing, and irrigation, has caused N pollution problems from the Chesapeake Bay in the eastern USA to the Baltic. The Gulf of Mexico, for example, receives drainage from approximately 41% of the continental USA via the Mississippi River and its tributaries. Due to nutrient leaching from agricultural watersheds, a hypoxic zone some 7000 square miles in size (approximately the same area as the state of New Jersey), which has significantly affected the shrimp and shellfish industries, has developed in the Gulf of Mexico off the Louisiana coast.

Conclusion

The N cycle in soil is dynamic and inherently leaky. Off-site losses of N gases, soluble ions, and organic compounds are virtually impossible to eliminate completely. Nevertheless, there are several management practices for erosion control and fertilizer use that can minimize N losses from soil, and the cycle itself can be used to preserve environmental quality. For example, biological N_2-fixation rather than commercial fertilization will generally retain more soil N. Nitrates and nitrites in groundwater have been remediated through denitrification on increasingly larger scales to preserve groundwater quality and public health.

List of Technical Nomenclature

Anoxia	Conditions in which O_2 is absent. Synonymous with 'anaerobic'
Autotrophy	Growth using inorganic elements as C and energy sources
Biomass	Living organisms in soil, whether plants, animals, or microorganisms
Eutrophic	Excessive growth typically associated with aquatic systems in which one or more limiting nutrients such as N or P is provided
Heterotrophy	Growth using organic C as the source of C for biomass production and for energy
Hydrolysis	Addition of water to chemical bonds during chemical reactions
Inhibition	Suppression or slowing of a process for an indefinite time, usually a few weeks

Nitrates

D S Powlson and T M Addiscott, Rothamsted Research, Harpenden, UK

© 2005, Elsevier Ltd. All Rights Reserved.

Under aerobic conditions nitrate (NO_3^-) is the final form of nitrogen produced in soil following the decomposition of soil organic matter or any added plant or animal material. It is the main chemical form in which nitrogen is taken up by plants, though most plants can also absorb N in the ammonium form (NH_4^+). Figure 1 shows the central position of soil nitrate within the nitrogen cycle. Nitrate is a natural product that is almost always present in soil. In natural or seminatural ecosystems nitrogen is usually cycled very efficiently between soil microbes, soil solution, and plants so the concentration of nitrate in soil at any time is normally low and losses are small. By contrast, in order to grow large yields of agricultural crops, nitrogen is required in large quantities. For example, winter wheat growing under UK conditions would typically take up about 200 kg N ha^{-1} and most agricultural crops, other than those grown under subsistence farming conditions, take up between 100 and 200 kg N ha^{-1}. Various practices are adopted in order to provide sufficient N and the use of inorganic fertilizers is particularly important, with almost 80 million tonnes of N being used annually worldwide (Table 1). Inorganic fertilizers either contain nitrate or forms of N such as ammonium or urea that are rapidly converted to nitrate by soil microorganisms. Alternatively N may be supplied by adding animal manure or by incorporating residues of plants rich in nitrogen, such as N-fixing legumes, which may have been grown as the previous crop, as a green manure or as part of a pasture which is then plowed up. In all cases, except in anaerobic conditions such as flooded rice, much of the N from these organic sources will be converted to nitrate before being absorbed by the crop. It is highly desirable to utilize N from organic materials but it is mistaken to assume that losses of nitrate are necessarily less than with inorganic fertilizers as the production of nitrate from organic sources is determined by the activity of soil microorganisms and not by crop demand – some nitrate is produced at times when crop uptake is small and the risk of nitrate loss is large.

The nitrate ion is extremely soluble in water and can easily be washed out of soil to natural waters. There are two main pathways by which nitrate ions dissolved in soil water are lost through the movement of water: (1) leaching – the vertical movement of water and its solutes through the soil profile to either groundwater or field drains; and (2) surface runoff – the horizontal movement of water and solutes over the soil surface until it reaches a river or lake. Surface runoff occurs where the soil is either compacted or is naturally poorly draining, e.g., due to high clay content. A variation on surface runoff is sometimes termed subsurface flow, in which water infiltrates the soil to some extent but then moves horizontally due to impeded drainage, for example due to compaction at the base of the plow layer in cultivated soil or because of a change in soil physical properties with depth.

Compared to natural ecosystems, the risk of nitrate loss through leaching, surface runoff, or denitrification is much greater in agricultural soils because: (1) nitrate concentration in soil is high for some periods of the year; and (2) at least with arable crops, soil is bare for part of the year so there is no removal of nitrate by plants. Any loss of N from agriculture is an economic loss for the farmer and a waste of a valuable resource for society, so much research over the last century has been directed at minimizing losses. Since about the 1970s issues of water pollution (some genuine and some not) have led to regulations and policies to limit the concentration of nitrate in water and this has become a main driver of research and a major influence on farming practice. In the European Union a limit of $50\,mg\,l^{-1}$ of nitrate (equivalent to $11.3\,mg\,l^{-1}$ of nitrate-N) has been imposed on any ground- or surface-water to be used as a source of drinking water and any surface water where eutrophication is considered to be a risk. In the USA the limit is $45\,mg\,l^{-1}$ of nitrate, equivalent to $10\,mg\,l^{-1}$ of nitrate-N. These limits have a significant influence on agricultural practices: for example, under the climatic and agronomic conditions of the UK, annual leaching losses from arable soils are rarely less than $20\,kg\,N\,ha^{-1}$ and often twice this. But in the drier eastern regions, which are important for arable cropping, excess winter rainfall is often only 200 mm or less: under these conditions a nitrate loss of only $20\,kg\,N\,ha^{-1}$ will cause the nitrate concentration limit in water to be exceeded.

In addition to issues of water pollution, nitrate can also be involved in the emission of environmentally damaging gases to the atmosphere. Under anaerobic conditions nitrate can be microbially reduced to the gas nitrous oxide (N_2O) which is a powerful greenhouse gas and also has a role in the destruction of ozone in the stratosphere; this provides a good reason for minimizing the amount of excess nitrate in the environment.

Chemical Structure and Physical Properties

The nitrate ion, NO_3^-, has a symmetrical planar trigonal structure. It is negatively charged and so is termed an anion. Salts formed by the nitrate ion with cations (e.g., Ca^{2+}, K^+, Na^+) are generally soluble and, in soil, are always present in solution. These salts are dissociated so it is the nitrate ion that is the entity of interest. The practice of referring to nitrates in soil or water is incorrect – nitrate is a unique species, not a plural.

Being an anion, nitrate is attracted to positively charged surfaces. Some acid soils contain positive surface charge that can retain nitrate ions, but this is the exception. In the vast majority of soil worldwide, especially those used for agriculture, nitrate is not retained in this way and remains in soil solution and moves through the processes of mass flow or diffusion.

Biological Transformations in Soil

Numerous organisms in soil are involved in the breakdown of organic matter to inorganic (mineral) materials, the process termed mineralization. During aerobic mineralization, C in organic materials is converted to CO_2 and N is initially converted to ammonium; this step of N transformation is termed ammonification and is carried out by a wide range of heterotrophic organisms including various fungi and bacteria. A much smaller range of autotrophic bacteria are responsible for the conversion of ammonium to nitrate via a two-step process, together termed nitrification. The first step is conversion of ammonium to nitrite; classically this is described as being mediated by bacteria of the *Nitrosomonas* species, but it is now known that the less-studied species *Nitrosolobus*, *Nitrosospira*, and *Nitrosococcus* are at least as important:

$$2NH_4^+ + 3O_2 \rightarrow 2NO_2^- + 4H^+ + 2H_2O + \text{energy}$$

Nitrite rarely accumulates in soil, which is fortunate as it is toxic to plants and many microbes. It is rapidly oxidized in aerobic soils to nitrate by *Nitrobacter* species:

$$2NO_2^- + O_2 \rightarrow 2NO_3^- + \text{energy}$$

Although the nitrifying bacteria in soil cover a narrow group of genera, they are ubiquitous, so it can be assumed that any ammonium (whether from added fertilizer or from mineralization) will be converted to nitrate within a period of days to weeks provided the soil is aerobic and conditions of temperature, moisture, and pH are conducive for general microbial activity. The first step of nitrification produces H^+ ions and is thus an acidifying reaction. This is illustrated in Figure 2, which shows changes in soil pH over a period of 150 years in a long-term grassland experiment at Rothamsted, UK. In the treatment where N fertilizer is applied as ammonium sulfate, pH decreased from 5.7 to 3.7. In the treatment receiving the same quantity of N in the nitrate form there was little change in soil pH.

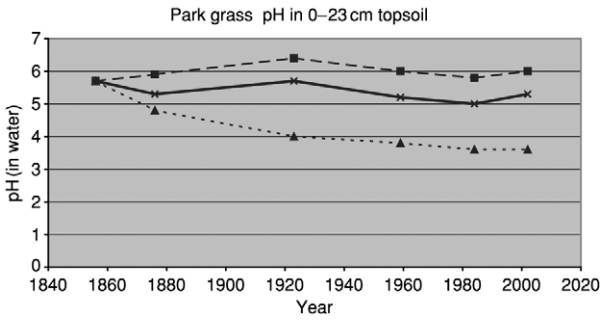

Figure 2 Influence of the long-term application of ammonium sulfate fertilizer on soil pH in the Park Grass grassland experiment at Rothamsted, UK. Plots received N as either ammonium sulfate or sodium nitrate every year since 1856. Nitrification of ammonium in the ammonium sulfate treatment caused an acidification of soil but application of N already in the nitrate form did not. × Control; ■ sodium nitrate; ▲ ammonium sulfate.

Nitrate in soil can be destroyed by the action of denitrifying bacteria when oxygen is in short supply. Under anaerobic conditions the nitrate ion can be used instead of O_2 as the acceptor of free electrons produced during respiration. The products are a mixture of nitrous oxide (N_2O) and nitrogen gas (N_2) – the sequence can be represented as:

$$NO_3^- \rightarrow NO_2^- \rightarrow N_2O \rightarrow N_2$$

The extent to which the reduction proceeds is strongly influenced by the pH and temperature of the soil. At a low temperature and a pH less than 5, the ratio of N_2O to N_2 is about 1, but at a temperature of 25°C or more and a pH greater than 6, most of the N_2O is reduced to N_2. Soils are not usually uniform and even in mainly aerobic soils there are often small localized anaerobic zones in which denitrification occurs. This spatial variability, together with the variable ratio of N_2O to N_2, makes denitrification very difficult to measure. It also implies that nitrification and denitrification may be occurring simultaneously close to each other in the soil. Nitrous oxide is also produced to some extent as a by-product of nitrification (Figure 3) and it is often difficult to distinguish between the sources. The environmental impacts of nitrous oxide are mentioned later.

Forms of Nitrogen Fertilizer

In Europe ammonium nitrate or calcium ammonium nitrate (CAN) is widely used. These forms supply 50% of their N as pure nitrate and so instantaneously increase the quantity of nitrate in topsoil from a very low value, typically about 10 kg nitrate-N ha^{-1}, to 50 kg nitrate-N ha^{-1} or more depending on the amount applied. A typical application of N to an arable crop in spring, at the beginning of the rapid crop growth period, might be 100–200 kg N ha^{-1}, but usually divided into two or more portions. The ammonium N is typically nitrified to nitrate over a period of 1–4 weeks. Worldwide, urea is by far the most commonly used form of nitrogen fertilizer. Before becoming available for plant uptake, the N in urea first has to be converted to ammonium (the process of urea hydrolysis) but this occurs within a few days. The ammonium is then nitrified within 2–3 weeks. Thus, in practice, the difference between urea and ammonium nitrate or CAN in terms of impact on soil nitrate is fairly small. These transformations can be studied by labeling the N in urea or either the ammonium or nitrate parts of ammonium nitrate with ^{15}N, the heavy isotope of nitrogen. In some experiments in northern France in which ^{15}N-labeled fertilizers were applied to field plots of winter wheat in April, intact urea molecules were virtually undetectable in soil within a week of application. All of the N derived from urea was either converted to ammonium or nitrate, absorbed by the crop, or immobilized by soil microorganisms within 2 weeks of application. Where ammonium nitrate was applied, the majority of the ammonium had been converted to nitrate or absorbed by plants or microorganisms within 2 weeks. For applications in March, when soil temperatures were lower, the transformations were slower but the trends the same.

A small but potentially significant difference between urea and nitrate-containing fertilizers is that the peak concentration of nitrate in soil is likely to be less with urea. Thus urea may give a decreased risk of nitrate loss by leaching or denitrification shortly after application. However, with urea some N may be lost as ammonia gas under some circumstances and slightly more may be absorbed by microorganisms as they tend to take up ammonium rather than nitrate if both are available. Overall agronomic experiments show only small differences in crop utilization of N from urea compared with nitrate-containing fertilizers.

A number of additives are available commercially that retard either urea hydrolysis or nitrification, so retaining a greater proportion of N from fertilizer in the ammonium form and decreasing the amount as nitrate. In principle these additives (urease inhibitors or nitrification inhibitors) should decrease the losses associated with nitrate by decreasing the quantity in soil. Whilst this can be useful for nitrate coming from fertilizer, the impact of inhibitors on overall nitrate loss is likely to be small because it is nitrate derived from the mineralization of soil organic matter that is usually the main source. Also, until now, their high cost has precluded their use from normal agricultural crops; they are used to some extent to make fertilizer N slowly available to certain high-value horticultural crops.

Management of Nitrate in Agriculture

Loss of Nitrate from Fertilizer During the Crop-Growing Period

The period immediately after N fertilizer application is a time of high risk of nitrate loss. During this period nitrate concentration in soil is high as a result of the added fertilizer and the mineralization and nitrification of N derived from soil organic matter. The concentration rapidly declines as crop uptake proceeds. One method of measuring the total loss of N from fertilizer during the growing season of a crop is to apply N fertilizer labeled with ^{15}N, the heavy isotope of nitrogen. In this way N derived from fertilizer can be distinguished from N derived from soil organic matter or other sources in soil as these are predominantly composed of ^{14}N. ^{15}N is a stable isotope, so is not radioactive and can be used in field or laboratory experiments without the need for special safety procedures. Figure 4 shows the results of such an experiment in which about 170 kg N ha^{-1} was applied in spring to autumn-sown wheat in south-east England. The N was applied as ammonium nitrate with both the ammonium and nitrate parts labeled with ^{15}N, i.e. $^{15}NH_4$ $^{15}NO_2$. About two-thirds of the applied ^{15}N-labeled N derived from fertilizer was recovered in the above-ground parts of the crop when it was harvested. A further 20% was retained in the soil, almost entirely as organic forms as this N had

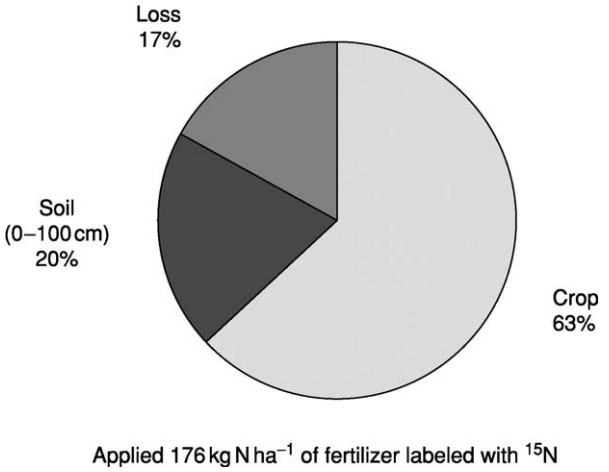

Figure 4 Fate of ^{15}N-labeled fertilizer (double-labelled ammonium nitrate, $^{15}NH_4$ $^{15}NH_3$) applied to winter wheat in south-east England. N was applied as a single dressing in spring (April) to a healthy crop of winter wheat, sown the previous autumn. The crop and soil were sampled at the time of harvest in August.

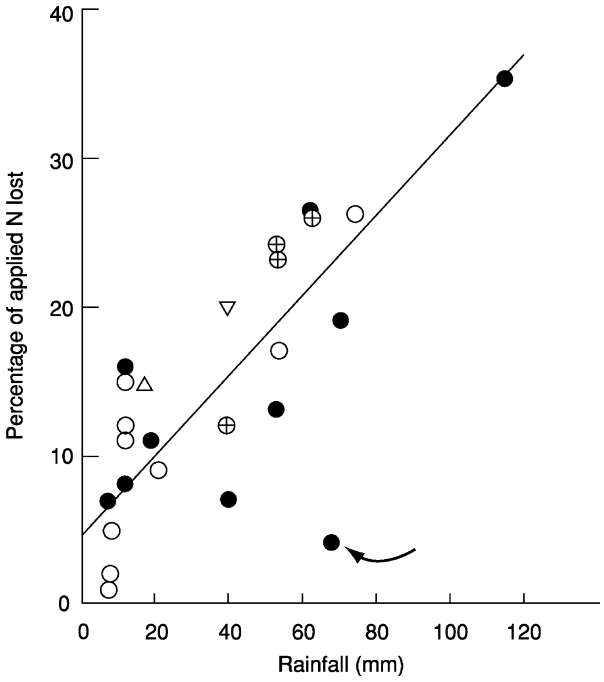

Figure 5 Relationship between loss of ^{15}N-labeled fertilizer applied to crops in spring and rainfall in the 3-week period following application. All circles (●, ⊕, ○) refer to winter wheat crops. Different symbols indicate crops receiving rates of fertilizer N known to be above (⊕) or below (○) that giving maximum grain yield. All other wheat crops indicated by ●. Arrowed result excluded from regression. Results included for experiments with forage maize (▽) and canola (oilseed rape, △) but used in calculating regression: Percentage of applied N lost = 5.0 + 0.264 (rainfall in 3 weeks after N application, mm). Reproduced with permission from Powlson DS, Hart PBS, Poulton PR, Johnston AE and Jenkinson DS (1992) Influence of soil type, crop management and weather on the recovery of 15N-labelled fertilizer applied to winter wheat in spring. *Journal of Agricultural Science, Cambridge* 118: 83–100.

been incorporated into wheat roots, soil organisms, and soil organic matter – this can also be seen in Figure 6, later. About 17% of the applied N had been lost – it could not be found in the crop or in soil to a depth of 1 m. This result is typical for healthy well-managed winter wheat growing in a temperate climate. In other experiments in similar environments losses ranged from less than 5% of applied fertilizer N to a maximum of 35%. Other studies indicated that in this environment dentrification was the major and most common cause of loss; but in years when rainfall was particularly heavy soon after N fertilizer application nitrate leaching became more important, as expected, especially in sandy soils. Taking together results from a series of similar field experiments in south-east England, there was a correlation between the percentage of the applied fertilizer N lost during the growing season and the total quantity of rain falling in the 3-week period following fertilizer application (Figure 5). This emphasizes the importance of the vulnerable period for loss when much nitrate is present in soil because crop uptake is not yet complete. It has also been found that any factors such as disease or weeds that inhibit crop growth (and uptake of N) tend to increase N losses from soil.

Although losses of fertilizer N can be relatively low in some situations, as described above, this is not universally the case. There are many examples of much lower recoveries, implying losses of 50% or sometimes even more. In some cases this is because of high rainfall in the period soon after N application – if this is an occasional event there is little that can be done to avoid it other than for the farmer to take note of local weather forecasts and for meteorologists to improve these as much as possible. There are, however, some measures that can be taken to decrease the risk of loss. For some crops and growing conditions it is common to apply N fertilizer at the time of sowing the crop, or even before. This means that nitrate is present in soil for a prolonged period as uptake by the crop will not start until seeds have germinated and the plants reached a certain size; depending on the crop and climatic region this could be as long as 2 months, allowing considerable opportunity for losses by leaching or denitrification unless it is a region where rainfall is very low at that time. Eliminating N applications at a time when the crop is not growing rapidly is one means of decreasing N losses and increasing the efficiency of use of nitrate derived from fertilizers.

An example of inappropriate timing of N application is shown in Table 2. In these experiments ^{15}N-labeled potassium nitrate was applied to winter wheat at the time of sowing the crop in autumn. Under the climatic conditions of north-west Europe

wheat grows to a limited extent in autumn and early winter, typically taking up about 20 kg N ha^{-1}, and then no more until the main growth period in spring. Thus, in most conditions, little of the applied nitrate is taken up during the winter period and is exposed to loss, mainly by leaching or surface runoff as low temperature in winter limits denitrification. In maritime climates rainfall in winter exceeds evapotranspiration so water can move through the soil and cause leaching of nitrate, either continuously or intermittently. In continental climates soil is frozen during much of the winter so leaching does not occur. When the soil thaws in spring, a large amount of leaching (and/or surface runoff) occurs in a short period but the overall effect on nitrate loss is similar. Table 2 shows that between 39 and 78% of the autumn-applied N was lost from the crop/soil system, almost certainly by nitrate leaching. In the past it was thought that applying fertilizer N at the time of sowing was beneficial for early growth of the crop and 'seedbed' applications were recommended. It is now known that there is no benefit and it simply causes an unnecessary loss of N, and is a waste of money. A similar inappropriate timing of N fertilizer is the situation where N is applied at about sowing time of a crop and is immediately followed by irrigation. In this situation some of the nitrate in soil, not yet taken up by the newly established crop, can be leached below rooting depth or denitrified depending on soil and climatic conditions.

Losses of Nitrate Derived from Soil or Fertilizer Outside the Main Crop Growth Period

Although some losses of fertilizer-derived nitrate do occur during the growing period of agricultural crops, in most environments the largest losses by nitrate leaching or surface runoff occur when crops are not actively growing or are not present at all. The examples discussed above of fertilizer being applied at the time of sowing rather then just before the main growing period illustrate this. It is obviously important to know the source of nitrate in soil during these periods of high risk. It is commonly assumed that it is unused fertilizer but much research has shown this is not usually the case for the major arable crops in

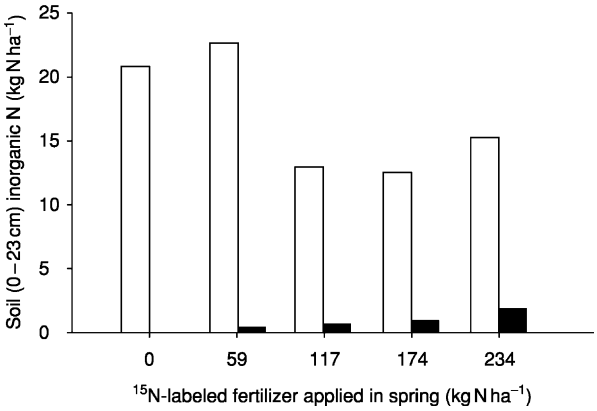

Figure 6 Labeled and unlabeled nitrate in plow-layer soil (0–23 cm) at the time of harvesting winter wheat. A range of rates of fertilizer N, labeled with ^{15}N, was applied in spring. Almost all the nitrate present in soil at the time of harvest was unlabeled, indicating that it was derived from the mineralization of soil organic N, not from fertilizer. Additional nitrate was present in deeper soil layers, almost all unlabeled. This soil-derived nitrate, plus additional nitrate from later mineralization, is the main source of nitrate leaching to water during the subsequent winter. □ unlabeled N; ■ labeled N. Reproduced with permission from Macdonald AL, Powlson DS, Poulton PR, and Jenkinson DS (1989) Unused fertilizer nitrogen in arable soils–its contribution to nitrate leaching. *Journal of the Science of Food and Agriculture* 46: 407–419. © Society of Chemical Industry.

the world or for pasture. Short-season horticultural crops can be exceptions to this generalization as they are often given very large rates of fertilizer N and this can be used inefficiently, leaving significant residues unused in the soil.

Experiments using fertilizer labeled with ^{15}N have been informative in identifying the sources of nitrate in soil in autumn and winter. Figure 6 shows the quantities of nitrate in soil at the time of harvesting a winter wheat crop in England. The fertilizer applied in spring had been labeled with ^{15}N, but the results show that very little of the nitrate left in soil after harvest in late summer was derived from this – the vast majority of the nitrate present at this time, and subject to leaching during the forthcoming winter, was unlabeled because it was derived from the mineralization of organic matter in the soil. Similar results have been obtained from numerous other studies with crops such as wheat, barley, and maize in Europe, North America, and elsewhere.

Winter losses of nitrate by leaching arise because the soil microbes responsible for mineralization and nitrification are active when conditions of temperature and moisture are suitable, which does not always coincide with crop uptake – this is illustrated in Figure 7. N mineralized and nitrified in spring does coincide with the major period of N uptake for most crops but that mineralized in autumn or early winter, before low temperature stops the process, is likely to remain in soil and be exposed to a high risk

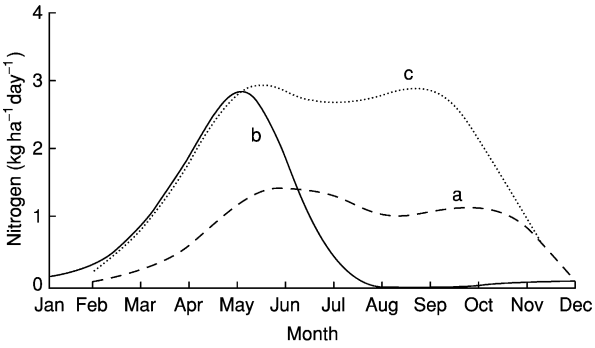

Figure 7 Representation of the time course of (a) mineralization of soil organic N to produce nitrate, (b) N uptake by an autumn sown arable crop and (c) N uptake by grass. — wheat; ····· grass; - - - mineralization. of leaching. Leaching may occur intermittently during winter (as in maritime climates where soil is not frozen during winter) or in a shorter period after the spring thaw in continental climates, as described above for autumn-applied fertilizer. Unfortunately, many agricultural practices that are beneficial for crop nutrition and soil quality tend to worsen the problem of winter nitrate loss. For example, additions of organic manures lead to increased production of nitrate at all periods of the year – partly when it will be absorbed by the growing crop (spring and summer) but partly when it will be at high risk of loss due to low crop uptake and the movement of water through soil (autumn and winter). Similarly, plowing up pasture in a mixed grassland/arable rotation such as organic farming brings both benefits and problems. Nitrate produced during the growing season of the subsequent crop substitutes for inorganic fertilizer that would otherwise be needed, but that produced too late for uptake in summer or too early for spring uptake will be subject to leaching.

Winter leaching losses from grass can be less than from arable crops as the plants are present throughout the year and able to absorb nitrate later in the autumn than an arable crop and start earlier in the spring, as the grass will already have a well-established root system. In this sense, grassland is more like a natural ecosystem with plants present throughout the year. However, low leaching is generally only the case with cut grass. In grassland that is grazed by animals, or has slurry applied, mineralization of these organic inputs can lead to nitrate formation in late autumn that is not taken up by the grass and is at risk of being leached.

As a general principle, arable crops that are sown in autumn rather than spring minimize the opportunity for leaching losses during winter – some nitrate is taken up in autumn before leaching begins and roots are already present in spring. With a spring-sown crop, the soil is bare during winter and there is a period of several weeks after sowing in the spring before the crop takes up nitrate in significant quantity. This trend is generally shown when measurements of drainage are made from arable fields or nitrate losses are estimated from measurements of nitrate concentration in soil water made using porous ceramic cups. However, it cannot be assumed that the presence of an autumn-sown crop solves the problem as the extent to which the crop is an effective sink for nitrate is highly dependent on the time of sowing and on weather conditions. A crop sown rather late in autumn and slow in establishing may only absorb $10\,kg\,ha^{-1}$ of nitrate before winter leaching begins and thus have little impact on the amount of nitrate lost. By contrast, a vigorously growing early-sown crop may absorb 30–$50\,kg\,ha^{-1}$ of nitrate and greatly decrease losses. Where spring crops are grown, a management practice sometimes used to decrease nitrate loss is a winter cover crop or 'catch crop.' This is a crop grown specifically to absorb nitrate during the period from late autumn to early spring that is incorporated into the soil before sowing the spring crop. Cover crops can sometimes be very effective at decreasing nitrate leaching, although they do introduce additional agronomic difficulties. Also, as the incorporated plant material is mineralized it is common for rather little of it to become available to the subsequent spring-sown crop – mineralization is usually fairly slow, occurring over several years, and some contributing to nitrate leaching in the next winter.

In a series of experiments using hydrologically isolated plots in central England (the Brimstone Farm experiment), varied crop rotations and management practices were compared for their influence on winter leaching of nitrate. Drains were installed under each plot so that water could be collected and analyzed for nitrate. Losses were greatest when soil was bare prior to a spring-sown crop. They could be decreased in that year by growing a cover crop but this led to increased leaching in later years. The only way to decrease nitrate loss greatly was to abandon arable cropping and convert the land to unfertilized grass. Overall it was concluded that, under the soil and environmental conditions of the site, continuous autumn cereals were the best compromise between decreased nitrate movement to water and profitable agriculture.

Improving the Management of Inorganic Fertilizer

Although it is generally true that nitrate from mineralization of organic matter in soil, or added to soil, is the major source of nitrate losses, there are

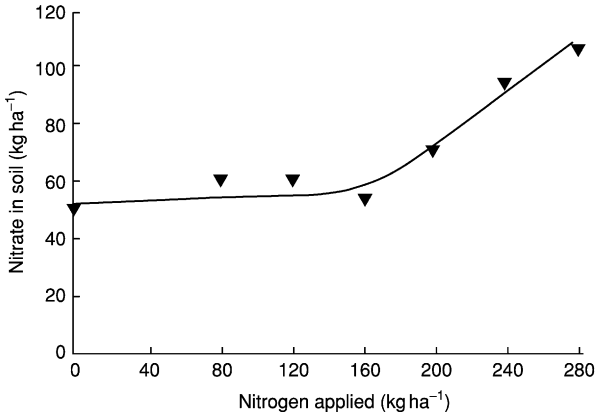

Figure 8 Mean quantities of nitrate in soil to a depth of 90 cm after harvesting winter wheat at eight sites in central and eastern England. Reproduced with permission from Cheney K (1990) Effect of nitrogen fertilizer rate on soil nitrate nitrogen content after harvesting winter wheat. *Journal of Agricultural Science, Cambridge* 114: 171–176.

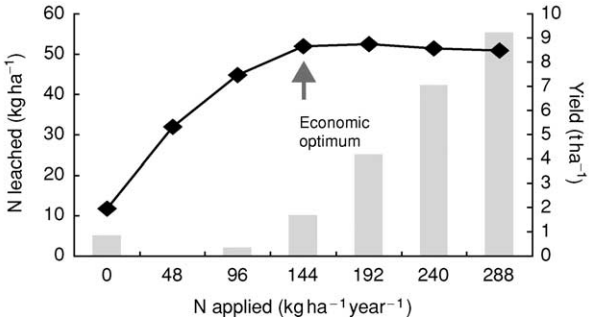

Figure 9 Nitrate lost in drainage water from plots of the long-term Broadbalk Experiment at Rothamsted that have received uniform applications of inorganic N fertilizer for many years. ◆, wheat grain yield; ▮, N leached. exceptions. If more inorganic fertilizer is applied to a crop than is required, some of the excess may be left in the soil and contribute to the pool of nitrate liable to be lost in the period after crop harvesting – an example is shown in Figure 8. The amount of nitrate in the soil profile (to a depth of 90 cm) was measured after harvesting winter wheat at eight sites in central and eastern England. A range of fertilizer N rates, including zero, had been applied in spring. Figure 8 shows the mean nitrate quantities for the eight sites. For rates of fertilizer N between zero and 160 kg N ha^{-1} (the average rate giving maximum crop yield), about 60 kg ha^{-1} of nitrate-N remained in soil but when this application was exceeded, residual nitrate rapidly increased to over 100 kg ha^{-1} of nitrate-N. It should be noted that, even where no fertilizer N had been applied, 50 kg ha^{-1} of nitrate-N remained in the soil, so small decreases in applications below a rate likely to give approximately maximum yield will have little influence on residual nitrate and nitrate leaching.

Figure 9 shows the measured amounts of nitrate lost in drainage water during winter from plots of the long-term Broadbalk wheat experiment at Rothamsted, UK. Each plot has received a specific rate of N fertilizer annually for many years. Up to the rate of N fertilizer corresponding to maximum grain yield (and also the calculated economic optimum rate), nitrate losses were about 10 kg N ha^{-1} or less but after this fertilizer N rate was exceeded, losses increased greatly. Other studies have shown that a plot receiving organic manure annually loses the largest amount of nitrate. To avoid excessive amounts of fertilizer being applied it is necessary to estimate in advance two quantities, both of which are difficult to predict: (1) the likely requirement of N by the specific crop; and (2) the amount of N likely to become available to the crop from mineralization or other sources. Estimating crop N requirement is best achieved by referring to the yields achieved on that field or region in the past. Of course, the value obtained will only be an estimate as weather in the coming growing season will be unknown at the time. For estimating N supply from sources other than fertilizer the following approaches are currently used or being developed:

1. Using computer models of N cycle processes to estimate the production of inorganic N from mineralization based on soil type, past cropping, past inputs of organic manures and either average or expected climatic conditions for the site. Such models also include estimates of likely N losses based on soil type, timing of agronomic operations, and weather. Modeling systems may also include a model for crop growth or this may be estimated separately. Decision support systems based on computer models have been developed in many regions of the world over the last 20 years and, in principle, can be highly site-specific. The availability of home computers and computerized farm record-keeping has made this approach realistic in many countries. The models used range from simple nutrient balances to complex descriptions of the main N cycle processes. The more complex the model, the more detailed data are required to run it – a judgment has to be made between simplicity and complexity.
2. Using tables of typical N supply values based on runs of models for a range of conditions or measurements from specific experiments. This system can never be as site-specific as a modeling system but is often very effective, low-cost, and requires a minimum of specialist personnel.
3. Measurements of inorganic N in the soil profile before the main crop-growing period. This is often termed the N_{min} method. Assumptions have to be made regarding the rooting depth of the crop and amount of inorganic N that will be lost and so not

be available to the crop. In regions with fairly stable weather conditions (e.g., continental areas within Europe) and soils that contain few stones and so are easy to sample (e.g., loess), this method has proved successful. The measurements can also be used to adjust predictions based on models or tables.

4. Variable N applications. In some situations, where fields are large and soils are not uniform, it may be helpful to adjust N applications according to the variations in soil type and crop growth – giving larger applications where growth can reasonably be expected to be most vigorous and small applications where it is constrained. The technology for variable applications is now readily available but the limitations to its use are: (1) insufficient understanding of the factors influencing crop growth in a particular year; and (2) insufficient data on soil variability. Maps of yield variation from previous years are easy to obtain with modern combine harvesters but it is often difficult to interpret their significance for fertilizer use in future years.

Regulations Affecting N Use in Agriculture

In many parts of Europe and North America concern about nitrate entering water has led to regulations being imposed on agricultural practices. In the European Union areas subject to regulation are termed 'nitrate-vulnerable zones' (NVZs). The regulations are based on current understanding of the causes of nitrate loss, especially the need to minimize nitrate in soil during the vulnerable winter period. The measures adopted in NVZ regulations include the following:

1. Closed periods for N applications. No applications of organic or inorganic forms of N during specified periods in winter appropriate for climate and growing conditions in the area (about 5 months, e.g., 1 September to 1 February for inorganic fertilizer to arable land in the UK). The closed season is shorter for grassland, recognizing that N uptake is possible over a longer period than for arable crops.

2. Limits on quantities of N applied. The farmer is required to use a recognized method for assessing crop requirement and this must not be exceeded. For organic manures the maximum allowed application decreases after 4 years, recognizing that the continued use of organic manure will increase the amount of mineralizable N in soil. For example, in the UK the maximum for grassland is initially $250\,kg\,ha^{-1}$ of total N in manure but decreases to $170\,kg\,ha^{-1}$.

3. Application controls. Limitations on applications when weather conditions could lead to runoff to adjacent surface waters, e.g., because soil is frozen or waterlogged. Also ensuring that applications are made accurately and evenly.

4. Slurry storage. Ensuring that a farm with animals has sufficient capacity to store slurry during the closed period.

5. Record-keeping. Keeping adequate records on N applications, cropping and animal numbers for at least 5 years.

Nitrate and Health

One of the main drivers for agricultural measures to decrease losses of nitrate from soil to water has been the claim that nitrate in drinking water is a cause of two serious diseases. The evidence for the link has never been strong and medical research now indicates that it does not exist at all. There is also evidence that some intake of nitrate has a positive effect on health.

Stomach Cancer

In the past it was claimed that nitrate (NO_3^-) from drinking water or vegetables was reduced to nitrite (NO_2^-) by bacteria in the mouth and that when nitrite entered the stomach it could react with amines from the breakdown of proteins to form N-nitrosamines, which are known to be carcinogenic. One early epidemiological study appeared to support this as it showed a higher incidence of stomach cancer in an area of the UK having high concentrations of nitrate in drinking water. However, a later and much larger study, published in the mid-1980s, contradicted this result. Nitrate concentration in saliva was measured in people from two areas in the UK, one with an unusually high incidence of stomach cancer and one with an unusually low incidence. The results were the opposite of what would be predicted if nitrate was associated with stomach cancer – nitrate concentrations in saliva were about 50% higher in the low-cancer-risk area. Such evidence in itself can neither prove nor disprove a link but it clearly indicates that any link must be weak and outweighed by other factors. Several other studies have shown a negative correlation between nitrate and incidence of stomach cancer. One study was based on the number of deaths of workers in a factory manufacturing ammonium nitrate fertilizer over a 35-year period. Because of the ammonium nitrate dust in the factory, the workers had a larger intake of nitrate than the general population and this was shown by increased concentrations of nitrate in their saliva. However, the number of deaths from stomach cancer among these workers between 1946 and 1981 was exactly the number expected on the basis of incidence in the general population. It can be concluded that there is now no medical evidence to suggest any link between nitrate intake and stomach cancer.

Methemoglobinemia (Blue-Baby Syndrome)

Methemoglobinemia or blue-baby syndrome is a serious disease that can kill infants less than 1 year old. Nitrite derived from the reduction of nitrate can react with hemoglobin and block the site that normally transports oxygen around the body. The first report of the problem in the USA in 1945 referred to 'well-water methemoglobinemia,' and all the cases identified in a 1991 review were caused by water from wells, 98% of which were described as 'privately dug.' It is now thought that the condition only occurs when water is contaminated by gastroenteritic bacteria from sewage or manure heaps, as can occur if a shallow well is dug on farm premises. In such cases nitrate and bacteria both contaminate the water. The condition is currently known in parts of Africa where surface waters are used for human consumption but are contaminated by animal excreta, introducing both bacteria and nitrate. The publisher of the original report was well aware that both bacteria and nitrate were involved in the condition, but the possible role of the bacteria seems to have been played down subsequently. It is now seems likely that it is the bacterial contamination that is the main factor. There are no reports of blue-baby syndrome associated with bacteriologically clean water from a mains supply.

Beneficial Effects of Nitrate on Health

Recent medical research has indicated that nitrate can protect humans and animals from gastroenteritis. It has shown that nitrate is reduced to nitrite by denitrifying bacteria in the mouth, similar to those in soil. It also now appears that the human metabolic system actively secretes nitrate into saliva for this purpose if the intake of nitrate from water or vegetables is insufficient. The proposed reaction between nitrite and amines in the stomach (mentioned above in relation to the proposed link with stomach cancer) probably does not occur because the acid conditions in the stomach destroy nitrite and nitric oxide, NO, is formed. A great deal is now known about the physiological role of NO, one of which is the killing of bacteria such as *Salmonella* and *Escherichia coli* which can cause gastroenteritis. In this way it is now thought that nitrate is a key precursor for NO and thus plays an important role in the body's defense against stomach disease.

Impacts of Nitrate on Ecology of Surface Waters

Any nitrate escaping from agricultural soil to streams, rivers, or lakes can increase the growth of water plants and thus alter the ecology of aquatic systems. This is undesirable in itself and can also interfere with fisheries and navigation for shipping by clogging the waterway with large quantities of water weed. Nitrate can also contribute to the growth of algae in surface waters which are unsightly and some of which are toxic. When algae die the bacteria decomposing them use oxygen dissolved in the water, thus deoxygenating the water with adverse consequences for fish and other organisms. In freshwaters phosphate is usually the limiting factor controlling the growth of algae, but nitrate is also required. In river estuaries and sheltered seas (e.g., the Baltic Sea and the Gulf of Mexico), nitrate is probably the controlling factor. Thus the impact of nitrate on the ecology of natural waters is a genuine and significant reason for controlling losses from agriculture.

Conclusions

Nitrate is the most common form of inorganic nitrogen in soil, being the final product of the decomposition of organic materials under aerobic conditions. It is the form normally taken up by plants, though most plants can also take up ammonium. If sufficient food is to be grown for the current world population of over 6 billion and its expected growth during the twenty-first century, greatly increased amounts of nitrogen will be needed. It will be necessary to use increasing amounts of inorganic fertilizers in addition to better utilization of organic manures and other wastes and improvement in the use of legumes to supply nitrogen to crops. This continued intensification of agriculture will inevitably lead to further losses of nitrate to natural waters. The considerable amount of research conducted over recent decades can help to decrease these losses, both by increasing the efficiency of use of inorganic fertilizers and by better retaining nitrate from organic matter mineralization within the soil/plant system. However, losses can never be entirely eliminated as the nitrate ion is soluble and is always at some risk of being washed out of soil. It can also be converted to nitrous oxide, a powerful greenhouse gas. The ecological impacts of nitrate on aquatic ecosystems can be serious so, for a range of environmental reasons, it is important to minimize nitrate losses from agricultural soils as much as possible. This is in addition to the economic and sustainability reasons for avoiding waste of a vital resource. However, the proposed adverse health impacts of nitrate in water that have been the main driver for limiting nitrate loss now appear to be unfounded. Indeed, the opposite appears to be the case – there is evidence from medical research that some intake of nitrate has beneficial effects on health through the production of nitric oxide in the stomach and its role in the control of gastroenteritis.

Nitrification

J I Prosser, University of Aberdeen, Aberdeen, UK

Introduction

Nitrification is the oxidation of reduced forms of nitrogen, ultimately to nitrate. It is carried out by three microbial groups: (1) autotrophic ammonia oxidizers, (2) autotrophic nitrite oxidizers, and (3) heterotrophic nitrifiers. Autotrophic ammonia and nitrite oxidizers are characterized by their ability to oxidize ammonia sequentially to nitrate under aerobic conditions, but these organisms possess a wider metabolic diversity. This has significant consequences for their ecology, for the occurrence and kinetics of nitrification, and for interactions with other organisms. The major sources of reduced forms of soil nitrogen are excretion and decomposition of organic nitrogen, derived from animals and plants, and application of ammonia-based fertilizers. Many microorganisms and plants require ammonium for growth, while others assimilate nitrate. For both groups, nitrification is important in regulating the supply or loss of nitrogen from the environment. While ammonia has a propensity to bind to soil particles, its conversion to nitrate leads to significant losses of soil nitrogen through leaching and conversion to gaseous forms through denitrification. Nitrification also contributes to soil acidification, with consequent increases in

mobilization of toxic metals, particularly in heavily fertilized and poorly buffered soils. In addition, nitrifiers are involved in production and conversion of a number of greenhouse gases.

Autotrophic Ammonia-Oxidizing Bacteria

Taxonomy

Autotrophic ammonia oxidizers are Gram-negative bacteria, traditionally placed within the *Nitrobacteriaceae* and characterized by their ability to oxidize ammonia. Further classification is based on a limited number of characteristics, including cell shape, internal membrane structures, flagella, inclusion bodies, salt tolerance, urease activity, and substrate affinity and inhibition. Confirmation of taxonomic groupings and species descriptions is by DNA:DNA hybridization of pure cultures. The type strain, *Nitrosomonas europaea*, has been the subject of the majority of biochemical, physiological, and genomic studies.

More recently, analysis of sequences of 16S ribosomal ribonucleic acid (rRNA) and *amo* A genes (encoding the active subunit of ammonia monooxygenase) has enabled phylogenetic classification of cultured ammonia oxidizers. This places *Nitrosococcus oceanus* in the γ-proteobacteria and other known autotrophic ammonia oxidizers in seven lineages within a monophyletic group within the β-proteobacteria: *Nitrosospira*, *Nitrosomonas europaea/Nitrosococcus mobilis*, *Nitrosomonas communis*, *Nitrosomonas marina*, *Nitrosomonas oligotropha*, *Nitrosomonas cryotolerans*, and *Nitrosomonas* sp. Nm143. Difficulties in cultivating ammonia oxidizers limit available physiological data, but links exist between these phylogenetic groups, their physiological characteristics, and their environmental origin. Analysis of 16S rRNA gene sequences also indicates evolutionary relationships with photosynthetic bacteria and other groups possessing intracytoplasmic membrane structures, suggesting that ammonia oxidizers evolved from photosynthetic organisms. 16S rRNA sequence analysis suggests only peripheral associations with methane oxidizers, but similarities exist between *amo*A genes of γ-proteobacterial ammonia oxidizers (*N. oceanus*), and *pMMO* (particulate methane monooxygenase), suggesting a common ancestral origin.

Biochemistry

Ammonia oxidation by β-proteobacteria involves two steps:

$$NH_3 + O_2 + 2H^+ + 2e^- \rightarrow NH_2OH + H_2O$$
$$NH_2OH + H_2O \rightarrow NO_2^- + 5H^+ + 4e^-$$

In the first step, ammonia is oxidized to hydroxylamine by a membrane-bound ammonia monooxygenase. The reaction is endergonic and requires oxygen and a source of reducing equivalents. Hydroxylamine is then oxidized to nitrite by hydroxylamine oxidoreductase, using oxygen from water in an exergonic reaction. Two electrons are required for ammonia oxidation, while the remainder pass down the electron transport chain. The NO_2^-/NH_3 redox potential is -340 mV and reduced nicotinamide adenine dinucleotide (NADH) is synthesized by reverse electron flow using adenosine triphosphate (ATP). Hydrogen ions generated by the second step lead to acidification of unbuffered growth medium, limiting sustained growth.

An alternative mechanism for the first step has recently been proposed, involving nitrogen dioxide and tetroxide, based on studies of *N. eutropha*:

$$NH_3 + N_2O_4 + 2H^+ + 2e^- \rightarrow NH_2OH + 2NO + H_2O$$
$$2NO + O_2 \rightarrow 2NO_2(N_2O_4)$$

This mechanism does not appear to involve ammonia monooxygenase, and studies have also demonstrated reduction in lag phase and the stimulation of growth, activity, and cell yield in cultures supplied with nitric oxide. Any reduction in lag phase will provide ammonia oxidizers with advantages in soil where ammonia supply is intermittent.

Carbon Metabolism

Organic carbon is obtained by nitrifiers via carbon dioxide fixation, and all strains studied as of 2003 possess type I Rubisco genes, but with sequence variation between strains. Rubisco enzymes in some strains are located in carboxysomes. Energy generated by ammonia oxidation is only just sufficient for growth, particularly as carbon dioxide fixation requires significant reducing equivalents, and generation of reducing equivalents consumes ATP.

Ammonia monooxygenase has broad substrate specificity, and ammonia oxidizers can oxidize and assimilate, but not grow on, a number of organic compounds, including methanol, bromoethane, ethylene, propylene, cyclohexane, benzene, and phenol. Acetate, formate, and pyruvate can increase biomass yield by as much as 130%, but higher concentrations inhibit growth. The ecological implications for this are not clear, but assimilation of soil organic carbon may provide a selective advantage, while ammonia oxidizers may be important in biodegradation of organic pollutants in oligotrophic environments, where alternative carbon sources are scarce.

Ammonia monooxygenase is similar to the membrane-bound methane monooxygenase of methanotrophic bacteria. Ammonia oxidizers can oxidize but

not grow on methane and carbon monoxide, and the enzymes have common inhibitors. Incorporation of methane is inhibited by ammonia, and vice versa, and complete methane oxidation may be prevented by inhibition of hydroxylamine oxidation by formaldehyde, produced during methane oxidation. In general, ammonia oxidizers have higher oxidation rates and lower K_m values for ammonia than methanotrophs, while the converse is true for oxidation and affinity for methane. Competition between the two groups for ammonia and methane therefore appears unlikely, but high levels of ammonia-based fertilizer may suppress methanotroph activity. Despite these considerations, ammonia oxidizer 16S rRNA and *amo*A sequences have been found in ^{13}C-labeled nucleic acids extracted from grassland soils treated with ^{13}C-labeled methanol and methane, suggesting their role in soil methane oxidation. Ammonia oxidizers may also have a role in the oxidation of another greenhouse gas, carbon monoxide. They have greater affinity for carbon monoxide than carboxydobacteria, and may provide an important carbon monoxide sink. Carbon monoxide oxidation only occurs during ammonia oxidation, which is required as an energy source, even though carbon monoxide and ammonia compete for the ammonia monooxygenase enzyme.

Ammonia Oxidation under Anaerobic Conditions

Although traditionally considered to be aerobic, autotrophic ammonia oxidizers maintain activity at low oxygen concentrations and under anaerobic conditions. *N. europaea* possesses a nitrite reductase and can denitrify nitrite under anaerobic conditions using hydrogen or organic compounds as electron donors. (They can also denitrify under oxic conditions, using ammonia as electron donor.) This results in the production of nitric and nitrous oxides, and dinitrogen gas. At atmospheric oxygen concentrations, nitrogen oxides constitute 0.1–0.5% of the total N oxidized, but proportions rise to 2.5–10% at low oxygen concentrations.

Anaerobic ammonia oxidation by *N. eutropha* has recently been demonstrated in which nitrogen dioxide or nitrogen tetroxide acts as an electron acceptor, generating nitric oxide and hydroxylamine. The latter is converted to nitrite with release of dinitrogen gas. In addition, anaerobic ammonia oxidation is carried out by autotrophic planctomycetes, which utilize nitrite as an electron acceptor, generating nitrate and nitrogen, with hydrazine and hydroxylamine as intermediates. The process is sensitive to oxygen and nitrite, and the calculated mass balance is:

$$NH_4^+ + 1.32NO_2^- + 0.066HCO_3^- + 0.13H^+ \rightarrow 0.26NO_3^- + 1.02N_2 + 0.066CH_2O + 0.5N_{0.15} + 2.03H_2O$$

However, neither of these anaerobic processes has been detected in soil, where their significance is unclear. Both require substrates which are produced under oxic conditions (nitrogen dioxide and nitrite) but the processes may occur at oxic–anoxic interfaces, such as in biofilms formed on soil particulate material.

Autotrophic Nitrite-Oxidizing Bacteria

Nitrite oxidizers are classified into four genera within the proteobacteria: *Nitrobacter* (the most studied; α-proteobacteria), *Nitrococcus* (γ-proteobacteria), *Nitrospira* (δ-proteobacteria), and *Nitrospina* (forming its own subdivision). *Nitrobacter* strains are related to several denitrifying organisms, while *Nitrobacter* and *Nitrococcus* possess intracytoplasmic membranes and are related to photosynthetic bacteria. δ-Proteobacterial nitrite oxidizers do not contain intracytoplasmic membranes and are not related to photosynthetic organisms. Only *Nitrobacter* and *Nitrosospira* have been detected in soil. Nitrite oxidation is catalyzed by nitrite oxidoreductase, the NO_3^-/NO_3^- redox potential is 430 mV, and reducing equivalents are generated by reverse electron flow, consuming ATP:

$$NO_2^- + H_2O \rightarrow NO_3^- + 2H^+ + 2e^-$$

Nitrite oxidizers fix CO_2 for growth but, unlike ammonia oxidizers, many are capable of mixotrophic and heterotrophic growth on a range of simple organic substrates. Heterotrophic growth is slow (doubling times of 30–150 h) but leads to greater biomass yields. Nitrite oxidoreductase enables heterotrophic growth under anaerobic conditions, with nitrate as the electron acceptor and production of nitrite and ammonia, and nitrogen oxides. This metabolic versatility may explain greater abundance of nitrite oxidizers than ammonia oxidizers in soil.

Heterotrophic Nitrification

Heterotrophic nitrification is the oxidation of inorganic and organic reduced forms of N, to nitrate, by a wide range of fungi and heterotrophic bacteria. In some organisms, the mechanism is similar to that in autotrophic ammonia oxidizers and is linked, in some strains, to aerobic denitrification. The second mechanism, termed fungal nitrification, is linked to lignin degradation and involves reaction of reduced organic compounds with hydroxyl radicals produced in the

presence of hydrogen peroxide and superoxide. There is little evidence that heterotrophs gain energy or other benefit from nitrification, and cellular rates of heterotrophic nitrification activity are significantly lower than for autotrophs. Nevertheless, it may be important in acid soils or where C:N ratios and heterotroph biomass are high.

Analysis of Nitrifiers and Nitrification

Nitrification Activity and Rates

Nitrification rates in soil are traditionally measured as ammonia consumption or nitrite plus nitrate production during incubation of soil or soil slurry. Zero-order kinetics result from short-term measurements at nonlimiting ammonia concentrations and measure potential nitrification, which can be used to estimate nitrifier abundance. Short-term measurements at limiting substrate concentrations generate Michaelis–Menten kinetics. Long-term incubation of nonenriched soil leads to exponential increases in nitrite plus nitrate owing to unrestricted growth, at nonlimiting substrate concentrations, or growth at submaximal and decreasing rates at limiting substrate concentrations. Nitrate-production kinetics are frequently fitted to the logistic equation. Kinetics can be interpreted differently, however, if nitrifiers are considered to be distributed heterogeneously, as clusters growing on discrete sources of ammonium within the soil. If nitrification is measured in individual soil aggregates, the observed nitrate production curves fit well with the cumulative distribution curves for lag periods. Bulk nitrate concentrations therefore reflect not cumulative product of a uniformly growing population but the continued activation of clusters of nitrifying bacteria. The increase in nitrate concentration then depends on the distribution of lag periods prior to the onset of nitrification. Further evidence for heterogeneous distribution of ammonia oxidizers in soil is provided by molecular analysis of communities in grassland soils. Regular application of inorganic nitrogen fertilizer reduces heterogeneity in ammonia oxidizer communities, in association with similar reduction in the heterogeneity of soil pH and ammonia concentration. Analysis of nitrification kinetics during incubation is therefore important in providing information on soil population levels and substrate concentrations. Growth parameters are more easily obtained from laboratory cultures and typical values are given in Table 1.

Other nitrogen cycle processes, e.g., denitrification, immobilization, and ammonification, will influence concentrations of ammonium, nitrite, and nitrate. Rigorous measurement of soil nitrification rates, and distinction between autotrophic and heterotrophic nitrification therefore necessitate the use of metabolic blocks and ^{15}N-based techniques. The former involve measurement of nitrate production in the presence of specific nitrification inhibitors e.g., nitrapyrin and acetylene. The second involves applying ^{15}N as NH_4^+ or NO_3^- and following changes in the concentration of label in the respective pools.

Enumeration

Dilution-plate enumeration of viable nitrifiers is not feasible because of poor growth on solid media and enumeration is traditionally achieved using the most probable number (MPN) method. This involves multiple inoculation from dilutions of a soil suspension into mineral-salts medium containing ammonium and a pH indicator. After incubation for several (typically 4) weeks, growth is assessed by nitrite production, ammonium loss, and/or acidification, and cell concentrations are calculated using statistical tables. The requirement for laboratory cultivation leads to underestimation of cell concentrations. In addition, growth may be biased by ammonium concentrations in the medium, with inhibition of some strains at high concentrations (Figure 1). MPN counts for typical soils range between 10^3 and 10^5 cells g^{-1}

Table 1 Reported ranges for kinetic constants derived from pure cultures of ammonia and nitrite oxidizers

	Ammonia oxidizers	*Nitrite oxidizers*
Maximum specific growth rate (h^{-1})	0.02–0.088	0.018–0.058
Doubling time (h)	8–35	12–39
Biomass yield (g biomass mol^{-1} substrate)	0.42–1.72	1.11–1.51
Cell yield (cells mol^{-1} substrate)	1.85–10.6	
Carbon yield (ratio of CO_2 fixed: NO_2^- or NO_3^- produced)	0.014–0.096	0.013–0.031
Cell activity (fmol NO_2^- or NO_3^- $cell^{-1}$ h^{-1})	0.9–31.3	5.1–42
Biomass activity (fmol NO_2^- or NO_3^- g $biomass^{-1}$ h^{-1})	4–200	15.7–25.2
Saturation constant for growth (mmol l^{-1} NH_4^+ or NO_2^-)	0.12–14	0.045–0.178
Saturation constant for activity (mmol l^{-1} NH_4^+ or NO_2^-)	0.05–0.07	1.6–3.6

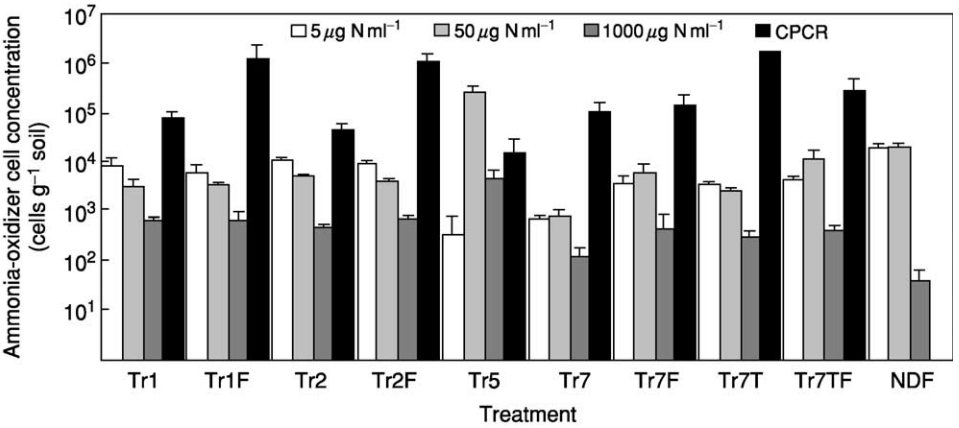

Figure 1 Enumeration of ammonia-oxidizer cells in long-term ecological research (LTER) soils using the most probable number (MPN) method with medium containing 5, 50, or 1000 mg of NH_4^+-N ml^{-1} and competitive polymerase chain reaction (C-PCR). Treatments are: Tr1, conventional tilling; Tr2, no tilling; Tr5, *Populus* perennial cover crop; Tr7, historically tilled; NDF, natural deciduous forest. Error bars represent the standard errors. Suffixes 'T' and 'F' indicate tillage and fertilization, respectively. (Reproduced with permission from Phillips CJ, Harris D, Dollhopf SL *et al.* (2000) Effects of agronomic treatments on the structure and function of ammonia oxidising communities. *Applied and Environmental Microbiology* 66: 5410–5418.)

soil for ammonia oxidizers, with nitrite oxidizers slightly more abundant. Quantitative molecular techniques (e.g., competitive PCR (cPCR), real-time PCR) avoid cultivation bias and detect the total nitrifier populations, giving cell concentrations 1–2 orders of magnitude greater than MPN counts (Figure 1).

Enrichment and Isolation

Autotrophic ammonia-oxidizing bacteria are readily enriched by inoculation of an inorganic medium, containing ammonium with soil, and incubation for several weeks. Isolation of pure cultures is more difficult, due to faster growth of heterotrophs on organic carbon contaminants or by-products of nitrifier growth. This typically takes several months and cultures frequently do not survive continued subculturing. Laboratory selection also reduces the likelihood of obtaining dominant or representative environmental strains, but enrichment of a strain is necessary for unequivocal evidence of its presence and viability in a particular soil.

Soil Communities and Diversity

Information on 16S rRNA and *amo*A gene sequences from cultured ammonia oxidizers has led to the design of oligonucleotide polymerase chain reaction (PCR) primers specific for β-proteobacterial autotrophic ammonia oxidizers. These have been used to amplify ammonia-oxidizer gene fragments from nucleic acids extracted directly from soil. Gene fragment sequences may then be analyzed by cloning, sequencing of clone library representatives, and phylogenetic analysis. Alternatively, fingerprinting techniques such as denaturing or temperature gradient gel electrophoresis (DGGE, TGGE) and terminal restriction fragment length polymorphism (T-RFLP) analysis may be used. These approaches do not require laboratory cultivation and thereby eliminate many of the disadvantages of cultivation-based techniques, and difficulties in purifying and identifying ammonia-oxidizing bacteria.

The application of molecular techniques has greatly expanded our knowledge of nitrifier communities in soils. Phylogenetic analysis of amplified sequences reveals considerable diversity within soil ammonia oxidizers. Duplicate sequences and sequences identical to pure cultures are rarely obtained, although this partly reflects the few pure culture sequences in databases and, potentially, sequencing and cloning errors. Sequences are sometimes homologous to those of laboratory cultures enriched from the same environment and the majority fall within the lineages obtained with sequences from cultivated organisms. One exception is the possible subdivision of *Nitrosospira* into four clusters, and there is evidence of differences in physiological characteristics of pure and enriched cultures representative of these different *Nitrosospira* clusters.

Soils are dominated by β-proteobacterial ammonia oxidizers, with γ-proteobacterial sequences apparently restricted to marine environments. The links between 16S rRNA-defined lineages and physiological characteristics aid in the interpretation of the distribution of these organisms under different soil conditions. This approach also indicates that *Nitrosospira* may be more abundant than *Nitrosomonas* in

soil. If so, more studies are required of *Nitrosospira* physiology, rather than basing interpretation on information on *Nitrosomonas europaea*.

Fingerprinting techniques, particularly DGGE, have been used to study the effects of environmental factors and soil treatments on ammonia-oxidizer communities. This provides more rapid assessment and greater replication than cloning and/or sequencing approaches. In addition, bands of interest on DGGE gels may be excised, cloned, and sequenced and information on identity obtained by comparison with database sequences. These approaches can also be used to assess quantitative or semiquantitative changes in ammonia-oxidizer community structure.

Comparison of 16S rRNA gene sequences in enrichment cultures with those amplified from nucleic acids extracted from the same soil provides an indication of selection during laboratory cultivation. The relative abundances obtained using these two approaches differ but, in one study, 16% of sequences were common to both enrichment cultures and clones analyzed. Molecular analysis of cultures obtained during MPN enumeration also indicates selection, with frequent domination by *Nitrosomonas* strains in samples from environments which appear, from molecular analysis, to be dominated by *Nitrosospira*. Molecular- and cultivation-based techniques therefore provide different views of diversity and species composition within soil ammonia-oxidizer communities. However, molecular techniques are also subject to bias and additional techniques are required. In this respect, direct detection of cells using fluorescent *in situ* hybridization (FISH) with specific ammonia-oxidizer probes would be useful. This approach, however, is limited by autofluorescence and the relatively low cell concentrations of ammonia oxidizers in soil.

Influence of Soil Characteristics on Ammonia-Oxidizer Communities

Soil pH

Ionization of ammonia at low pH values reduces substrate availability for ammonia oxidizers, and laboratory batch growth of ammonia oxidizers does not occur at pH values of less than 6.5. However, autotrophic ammonia oxidizers with neutral pH optima are frequently isolated from acid soils, and autotrophic nitrification has been demonstrated in soils with pH values as low as 3.5. In some situations, nitrification in acid soils is due to heterotrophic nitrification. Coupled denitrification–nitrification by heterotrophic nitrifiers is unlikely, due to the requirement for high substrate concentrations, and heterotrophic nitrification involving ammonia monooxygenase-based reactions suffers from reduced ammonia availability at low pH. However, acidophilic fungal heterotrophic nitrifiers have been characterized and fungal nitrification is significant in some acid soils. Nevertheless, use of specific inhibitors of autotrophic ammonia oxidation and ^{15}N-based studies have demonstrated active, autotrophic ammonia oxidation in acid soils.

One explanation for this phenomenon is the possession by some ammonia oxidizers of urease activity, enabling growth on urea as a sole nitrogen source. Urease activity and growth on urea are independent of pH in the range 4–8, possibly through uptake by passive diffusion. Laboratory studies show that, under these conditions, ammonia oxidation can proceed at pH values as low as 4, until urea is exhausted, after which it ceases, even if ammonium is present in solution. This has been demonstrated in a strain of *Nitrosospira* that cannot oxidize ammonium at pH values less than 7 (Figure 2). Urease activity therefore provides

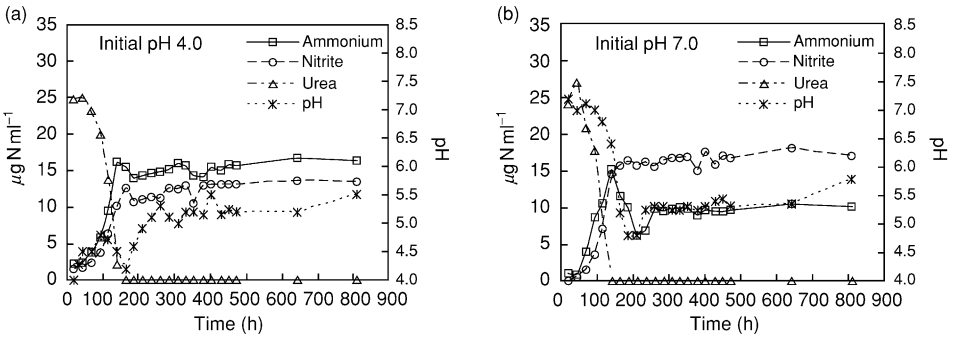

Figure 2 Changes in pH and in concentrations of urea, ammonium, and nitrite during growth of *Nitrosospira* strain NPAV in liquid batch culture on poorly buffered medium containing urea, at initial pH values of (a) 4 and (b) 7. (Reproduced with permission from Burton SAQ and Prosser JI (2001) Autotrophic ammonia oxidation at low pH through urea hydrolysis. *Applied and Environmental Microbiology* 67: 2952–2957.)

the potential for acidophilic ammonia oxidation, but is not a prerequisite for ammonia oxidizers isolated from acid soils.

Autotrophic ammonia oxidizers appear to be protected from low pH in soil when occurring at high cell concentrations and associated with particulate matter. High cell concentrations can be achieved in aggregates, which when inoculated into liquid medium can nitrify at low pH, and nitrification at pH 4 has been demonstrated for cells immobilized in alginate. Biofilm formation on surfaces such as glass slides, glass beads, ion-exchange resin beads, and clay minerals can reduce the pH minimum for growth and activity of *N. europaea* by up to 2 pH units. Surface growth protection increases with the cation exchange capacity of the particulate material and lag phases prior to growth of stationary-phase or starved cells are reduced for attached cells. Protection from low pH may result from preferential growth and nitrification at the clay surface, due to adsorption of ammonium. It is greatest when the only source of ammonium is that bound to clay minerals. This has been demonstrated by growth on ammonia-treated vermiculite (ATV), in which ammonia is fixed to the vermiculite by high-temperature exposure to ammonia. In the presence of ATV, *N. europaea* growth occurs without a lag phase and with greater nitrite yield than for suspended cells, but with no decrease in the pH of the medium. This, and the other clay effects, suggests localized buffering; ammonium released from the clay surface is utilized by adsorbed cells and H^+ ions are effectively inactivated by exchange for ammonium ions. It is not clear why biofilm growth should reduce the lag phase, but this presents a significant ecologic advantage in competing for transient supplies of ammonium. A possible mechanism involves cell–cell signaling molecules, acyl homoserine lactones, which will accumulate at high cell concentrations. When *N. europaea* biofilms established on glass beads are starved and then resupplied with ammonia, oxidation occurs immediately. However, supply of ammonia to suspended, nonbiofilm cells in liquid medium results in a lag period, prior to ammonia oxidation. The lag period increases with the length of the preceding starvation period but is significantly reduced by addition of acyl homoserine lactones. Signaling compounds are produced by a wide range of soil microorganisms and affect a number of ecologically important processes. These compounds may therefore mediate interactions between nitrifiers and other soil microorganisms, particularly in biofilms and in the rhizosphere, where biomass concentrations are sufficient to lead to high concentrations of signaling molecules.

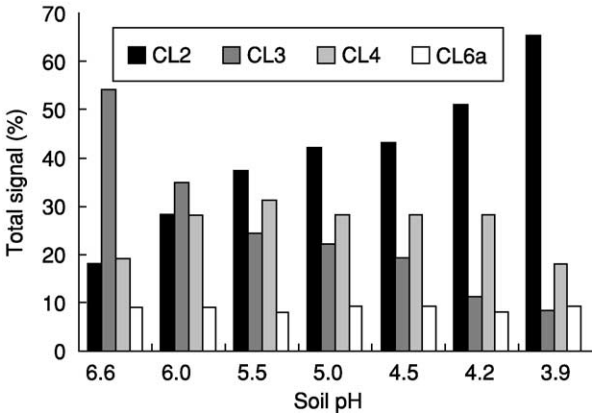

Figure 3 The influence of soil pH on the relative abundances of *Nitrosospira* clusters 2 (CL2), 3 (CL3), and 4 (CL4), and *Nitrosomonas* cluster 6a. Abundances are calculated as relative intensities of denaturing gradient gel electrophoresis (DGGE) analysis of ribosomal ribonucleic acid (rRNA) genes amplified from DNA extracted from soil maintained at a range of pH values, using ammonia oxidizer-specific primers. (Reproduced with permission from Stephen JR, Kowalchuk GA, Bruns MA *et al.* (1998) Analysis of β-subgroup ammonia oxidiser populations in soil by DGGE analysis and hierarchical phylogenetic probing. *Applied and Environmental Microbiology* 64: 2958–2965.)

The development of molecular techniques has enabled assessment of the influence of soil pH on ammonia-oxidizer communities. In one study, DGGE analysis was carried out on β-proteobacterial 16S rRNA gene fragments amplified from DNA extracted from soils maintained for 36 years at pH values in the range 3.9–6.6. Relative abundances of different clusters were assessed as relative intensities of DGGE bands and showed a greater proportion of *Nitrosospira* cluster-2 sequences in acid soils and a greater proportion of *Nitrosospira* cluster 3 at higher pH (Figure 3). Other clusters detected were *Nitrosospira* cluster 4, which may have increased in relative abundance at pH 5.5, and *Nitrosomonas* cluster 6a, which was independent of pH. Molecular studies of agricultural, grassland, and forest soils provide further evidence for the association of *Nitrosospira* cluster-2 sequences with acid soils. However, lack of information on distinctive physiological characteristics specific to representatives of this group, and of physiological diversity within ammonia oxidizers in general, prevents establishment of links between species diversity, functional diversity, and mechanisms for nitrification at low pH.

Nitrogen Fertilization

Sustained nitrogen fertilization and liming increase nitrifier population size, as indicated by cell counts (MPN and cPCR) and nitrification potential

measurements. In addition, evidence from molecular studies of nitrifiers in long-term ecological research (LTER) sites subjected to a number of different fertilization and cultivation conditions indicates an influence on the ammonia-oxidizer communities. Tilled soils were dominated by *Nitrosospira* cluster-3 sequences, while never-tilled soils contained *Nitrosospira* clusters 3 and 4, and *Nitrosomonas* cluster 6. Similar effects of fertilization on the relative proportions of *Nitrosospira* cluster-3 and -4 sequences have been found in chalk grassland soil. Little is known about the persistence of changes after perturbations.

Nitrogen supplied as inorganic fertilizer or, in grazing systems, as animal urine leads to localized, high ammonia concentrations. These concentrations are sufficient to inhibit ammonia-sensitive groups of ammonia oxidizers, while permitting growth of more tolerant strains. Soil microcosm experiments have demonstrated that the kinetics of nitrification of ammonia derived from synthetic sheep urine applied to grassland soil depends on the relative abundances of ammonia-sensitive and ammonia-tolerant strains. Low numbers of the latter result in significant lag periods before nitrification, impact significantly on maintenance of high levels of ammonia for plant growth, and reduce nitrogen losses associated with leaching and denitrification of nitrate.

Inhibition of Soil Nitrification

Specific inhibitors of autotrophic nitrification (e.g., nitrapyrin, dicyandiamide, etridiazole) have been used in the field to reduce losses of fertilizer nitrogen and to reduce nitrate pollution. Inhibitors, particularly acetylene, are also used as metabolic blocks when measuring nitrification rates. Higher concentrations of these compounds are required for inhibition in soil than in laboratory culture because of inactivation and degradation and because attachment of nitrifiers to soil surfaces protects cells from inhibition. Protection is greater with expanding clays with high cation exchange capacity. In many mature coniferous soils, nitrogen is present as ammonium rather than nitrate and net nitrification rates are low. This has led to suggestions of allelopathic inhibition of nitrification by polyphenolic compounds released by roots, which can inhibit laboratory growth of nitrifiers. However, use of ^{15}N-based techniques has demonstrated high gross nitrification rates in these soils and low nitrate levels are more likely due to greater immobilization of nitrate. There is little direct evidence for specific effects of plant diversity and community structure on ammonia-oxidizer communities, although plants can exert indirect effects through their influence on soil ammonium concentrations.

Summary

Nitrifying bacteria convert the most reduced form of soil nitrogen, ammonia, into its most oxidized form, nitrate. In itself, this is important for soil ecosystem function, in controlling losses of soil nitrogen through leaching and denitrification of nitrate. Nitrifiers also contribute to other important processes, including nitrous oxide production, methane oxidation, degradation of organic compounds, and carbon monoxide oxidation. The development of ^{15}N-based techniques has increased significantly our ability to dissect soil nitrogen transformations and their rates, while molecular techniques now enable characterization of soil nitrifier community structure and changes in species composition. These approaches are increasing our understanding of the ecology of soil-nitrifying bacteria and provide the potential for determining relationships between diversity, community structure, and ecosystem function in this important group of organisms.

Plant Uptake

A Hodge, University of York, York, UK

Introduction

Nitrogen (N) is essential for life because it is a component of nucleic acids and amino acids and thus peptides and proteins. In addition, plants also require N for chlorophyll. In most terrestrial ecosystems, N is the primary limiting nutrient. In soils, N is present predominantly in organic form, and inorganic N is made available by the mineralization of organic N to ammonium (NH_4^+) and subsequent oxidation to nitrate (NO_3^-). Both these inorganic N sources can be taken up by plant roots, but roots have to compete with soil microorganisms as well as other plant roots for this N. Recent evidence suggests that plants may be able to access simple organic N sources directly without the need for the mineralization process to release inorganic N, but these N sources also have to be captured in a competitive environment. The distribution of N sources in soil, particularly organic N forms, is both spatially and temporally heterogeneous. Plant roots respond to this heterogeneity in a number of ways in order to capture N from the soil system.

Plant–Microbial Competition for N

Mineralization of organic material to NH_4^+ is carried out by a wide range of soil animals and microorganisms. However, mineralization and the subsequent conversion of NH_4^+ to NO_3^- are generally considered to be the rate-limiting steps in the terrestrial N-cycle. Due to their rapid turnover times and rapid adaptation rate, microorganisms are generally thought to utilize inorganic N sources first, with the plant only being able to access what is left over after microbial uptake. Exceptions are plants such as legumes and alder which form symbiotic associations with rhizobium and *Frankia* bacteria, respectively. These symbionts form nodules on the roots which are capable of fixing dinitrogen and thus supply the plant with N directly. The majority of plants, however, do not form N_2-fixing symbiotic associations and must rely on N uptake via their roots or mycorrhizas.

Most transformations of N also depend on the supply of carbon (C), and thus these two nutrient cycles are closely linked. The C:N ratio of the substrate determines the rates at which N (and C) are released and mineral N made available for plant uptake. Also influential are the composition of the decomposer microbial community and its requirements for N. Fungi tend to have a higher substrate assimilation efficiency and a lower N requirement per unit of C assimilated than bacteria. Thus, if the decomposer population is predominantly fungal, more N may be released than if it was predominantly bacterial. However, fungi also tend to turn over less rapidly than bacterial populations, so the N contained in their structural components will be locked up for a longer time than bacterial N. Generally net mineralization, resulting in the release of N, occurs if the C:N ratio of the substrate being decomposed is lower than approx. 25:1. At higher C:N ratios, net immobilization occurs and the microbial decomposer community requires additional N from the soil system to decompose the substrate.

Net immobilization of N reduces the N available for the plant and can reduce overall plant growth. Although other factors influence the release of N, for example lignin content of the substrate, there is a strong inverse relationship between the amount of plant N captured from organic substrates and the C:N ratio of the substrate, as shown in Table 1.

In addition to microorganisms soil animals also play an important role in the mineralization process through physical, chemical, and biological processes. Soil animals can physically break up and redistribute organic materials in the soil. They also ingest organic materials which are subsequently broken down by a range of enzymes and/or by microflora present in their guts. Much of the C they consume is used for metabolic processes and the excreted waste products, in the form of NH_4^+, urea, or amino acids, are a much more readily available form of N for plant uptake than the organic material originally ingested. Soil animals feed on microorganisms as well as other soil animals. The plant benefits from the regulation of the size and activity of the microbial population, and from the release of more N into the soil–plant system. An increase in plant N capture of up to 75% has been reported as a result of protozoa grazing on soil microorganisms. Thus, although microorganisms may

initially sequester inorganic N, protozoa grazing ensure that this N is released back into the root-soil environment and becomes available for root uptake.

Inorganic N

The fate of N into different pools in the soil can be measured by addition of materials labeled (or enriched) with the stable isotope ^{15}N. Short time scales (i.e., a few hours to days) are used to measure flow rates between pools, because recycling of labeled material over longer incubations may occur and lead to underestimations of the total flux through the pool. Such short-term studies on partitioning of labeled inorganic N sources added to soils have been used to measure the competition between microorganisms and plants (Table 2). Generally, a larger percentage of the ^{15}N-labeled inorganic N material is detected in the microbial biomass than plants, indicating that, at least in the short term, microorganisms are the superior competitors. These types of studies also indicate how rapid the flux is through the inorganic pools in soil. Thus the size of the pool, which is typically measured to estimate available N, does not reflect the N that is actually available to the plants and soil microorganisms if that pool has a high flux rate.

The studies summarized in Table 2 added N compounds enriched with ^{15}N in order to trace the uptake of N by the different groups of organisms (i.e., microorganisms or plants). Another method used by some investigators is to measure differences in the natural abundance of ^{15}N among different pools of N in soil to determine the source of N that plants or microbes are utilizing. This technique, however, is complicated by fractionation of ^{15}N by biochemical processes and mixing of N among the various soil pools. In addition, there is evidence that the $\delta^{15}N$ of plants is affected by their mycorrhizal status. Thus, some investigators have concluded that plant $\delta^{15}N$ values cannot be used to identify the N source that a plant is accessing in the soil. Although natural abundance techniques have considerable potential, many technical difficulties need to be resolved before the technique can be effectively used in a wide range of environments.

Some plants, such as members of the Ericaceae, prefer to take up NH_4^+ over NO_3^-. There is some evidence to suggest that these plants may lack the capability to reduce large quantities of NO_3^- in their tissues. These plants generally grow in acidic soils, where nitrification of NH_4^+ to NO_3^- is inhibited and NH_4^+ accumulates, and this may explain their inorganic N source preference. If NH_4^+ accumulates inside the plant it becomes phytotoxic, thus NH_4^+ is rapidly transformed to amide or amino acid form after absorption. For most plants, NO_3^- is the major form of N absorbed and nitrate is then reduced to nitrite (NO_2^-) and to NH_4^+ by the linked enzymes nitrate and nitrite reductase. When NO_3^- is mixed with a small amount of NH_4^+ (rather than just NO_3^- alone), plant growth generally increases. These conditions reflect the availability of inorganic N in most fertile soils but of course this will also depend on soil type. In soil solution, NH_4^+ concentrations are generally lower than NO_3^- concentrations because of rapid transformation to NO_3^- or because NH_4^+ is strongly held on to negatively charged particles such as soil organic materials and clays, and so unavailable for plant uptake. The uptake of a particular inorganic N source may also vary depending on the time of

Table 2 Data from field studies following the partitioning of inorganic N between plants and the microbial biomass after addition of ^{15}N-labeled sources

year, as it is well established that NO_3^- uptake is more sensitive to low temperature than is NH_4^+.

In addition, plants can absorb N through their foliage. Foliar additions of N in the form of urea, ammonium nitrate, and potassium nitrate are added to some crops, although this practice is not widespread. Plant foliage can also absorb nitrogenous gases such as NO, N_2O, and particularly ammonia (NH_3) from the atmosphere or volatilized from the soil surface. Losses of N via NH_3 volatilization can be considerable, i.e., approx. 50% of the N in animal slurries and manures can be lost in this way. Ammonia volatilization is increased under dry conditions, high temperatures, high air movement and in soils of alkaline pH and low organic matter or clay content. The presence of plants helps to reduce NH_3 losses because their roots compete for NH_4^+ in the soil, preventing its transformation and subsequent loss as NH_3. Also their foliage directly absorbs volatilized NH_3 from the soil surface. Foliar absorption of NH_3 is of considerable importance to the plant's N uptake in some terrestrial N cycles. However, cell membranes are highly permeable to NH_3 and the local, rapid increase in pH within the plant cell may irreversibly damage it. Thus although this mechanism can contribute to the plant's total N uptake, at high absorption levels NH_3 becomes toxic to the plant.

Another input of N is emission of NH_3 and other gases including nitrogen oxides (NO_x; i.e., NO and NO_2) and N_2O from intensive agricultural and industrial sources, and their subsequent deposition elsewhere via wet (largely in the form of nitrate and ammonium) or dry (largely in the form of NO_x and ammonia) deposition. This redistribution of N can have a positive effect on plant productivity in N-limited systems. However, excessive levels can cause soil acidification and adversely affect plant diversity.

Plant Inorganic N Uptake and Rhizosphere pH

The form of inorganic N taken up by the plant can strongly influence the pH of the rhizosphere. To maintain the electrochemical gradient between root cells and soil (cells typically have electrochemical potentials of less than −100 mV) which drives cation uptake, plants taking up N as nitrate will release bicarbonate (HCO_3^-) and/or hydroxyl (OH^-) ions, causing the rhizosphere pH to increase. In contrast, plants taking up ammonium as the main form of N will tend to release protons, causing the rhizosphere pH to decrease. However, even when grown on nitrate as the sole source of N, the rhizosphere pH of some plants (such as chickpea) can decrease. This decrease is almost certainly due to a higher ratio of cation to anion uptake. Leguminous plants with active N_2-fixing nodules also tend to have a large cation to anion uptake ratio and so a tendency to excrete protons and so decrease the pH of their rhizosphere soil. Thus the consequences for the rhizosphere pH will depend not only on the form of N (i.e., NH_4^+, NO_3^- or N_2 fixation) the plant is taking up but also on the plant species present and the buffering capacity of the soil.

Organic N

In some ecosystems such as the arctic, alpine, and boreal forest, annual plant N uptake is higher than should be available through inorganic N capture

alone. This has led to the conclusion that many of the plant species in these ecosystems are accessing organic N sources directly without the prior need for microbial mineralization. Forms of organic N in these soils range from the complex (e.g., humus) to the simple (i.e., amino acids and urea), although most of the evidence for plant uptake of intact organic N comes from studies on amino acid N. Some amino acids are present in the dissolved organic nitrogen (DON) fraction, but the majority are protected from uptake by adsorption on to soil particles or humic substances. Environmental fluctuations such as freeze–thaw and drying–rewetting events can result in the disruption of these soil particles and some of this bound amino N may subsequently be released. These environmental events can also disrupt microbial cells, leading to the death of a large fraction of the microbial community and a competitive advantage for the plant providing the plant itself is not also adversely affected by the same environmental events. The advantage to the plant is due not only to a decline in the number of microbial competitors but an increase in N supply through the release of bound amino N forms from soil particles and from the lysis of the microbial cell contents.

Studies using plants grown in solution culture or excised roots have demonstrated that uptake of organic N can occur at levels comparable with, or even in excess of, N uptake from inorganic sources. However, in such studies the uptake of organic N is maximized because, unlike in soil, these N compounds are freely available rather than physically or chemically bound and the plant does not have to compete with microorganisms for these N sources. Although a number of amino acid transporters have been identified on plant roots, amino acids in soil have to move across the rhizosphere, a zone of high microbial activity. Many of these microbes also possess amino acid transporters. The exception is with plants that form mycorrhizal associations, in which case uptake by the fungal hyphae may occur. In these cases, transport across the hyphosphere (the volume of soil influenced by the external mycelium of the mycorrhizal fungus) instead of the rhizosphere occurs. How significant organic N is as a source of N to the nonmycorrhizal plant is questionable. Nevertheless studies conducted in soil microcosms or under field conditions have demonstrated that uptake of intact amino acids can occur regardless of the mycorrhizal status of the plant. The amino acid is generally labeled with both ^{13}C and ^{15}N (i.e., 'dual'-labeled) so that uptake of intact organic N can be distinguished from uptake of mineralized N. If N was being taken up by the plant in mineralized form, ^{15}N levels would be enriched in the plant tissue but there would be no ^{13}C enrichment; whereas, if N was being taken up in organic form, both ^{13}C and ^{15}N would be enriched in the plant tissue. The uptake of the amino acid glycine has been used widely to demonstrate such an uptake mechanism (Table 3). However, glycine is a relatively poor substrate for microbial growth and the amounts of glycine added in such experiments generally far exceed levels normally found in the soil solution. Thus, what has been observed in these studies may not be applicable to ambient conditions. Moreover, although the uptake of glycine in intact organic form is high in plants harvested a few hours or days after glycine addition, in the longer term, plants probably capture more total N from glycine in the form of mineralized N (Table 3). Further progress in understanding plant uptake of organic N sources requires advances in analytical techniques and also measurement of amino acids at more realistic concentrations.

Root Responses

Root systems are modular which allows them to be very plastic in their response to prevailing environmental factors, including the distribution of nutrient resources. When N availability is low, plants generally increase their root weight ratio (RWR; ratio of root weight to total plant weight) because more biomass is allocated to the root system. However, the RWR is not necessarily the best root trait to measure in order to assess the ability of plants to capture water, N, and nutrients in general. The RWR will include old lignified roots not actively involved in nutrient uptake *per se*, and also changes in the architecture of the root system in response to nutrient availability can occur independent of changes in root biomass. Uptake of nutrients is more closely related to root length than root mass. Roots can only absorb ions from the soil that are transported to them by diffusion and mass flow. Beneficial physiological changes in ion uptake rates by roots can enhance uptake of mobile ions such as nitrates. In contrast, more immobile ions (e.g., phosphate) are limited more by diffusion to the root rather than uptake at the root surface so would be less affected by changes in root uptake rates. The diffusion coefficient for NO_3^- in the soil environment is approx. $10^{-10}\,m^2\,s^{-1}$ and, in contrast, the diffusion coefficient for phosphate is approx. 10^{-13}–$10^{-15}\,m^2\,s^{-1}$. The lower diffusion coefficient of phosphate is due to insoluble complexes formed by phosphate ions with cations such as Al^{3+}, Fe^{3+}, and Ca^{2+}. Diffusion coefficients for NH_4^+ range between approx. 10^{-10} and $10^{-12}\,m^2\,s^{-1}$, but the availability of NH_4^+ is further reduced by sorption in soil. Thus, the distribution of NO_3^- in soils should be more uniform than

Table 3 Uptake of intact glycine from various studies

Plant species	*Harvest time after addition of glycine*	*Glycine added taken up in intact form (%)*	*Mycorrhizal status*	*Comments*
Vaccinium myrtillus[a]	Few hours to 7 days	91	Ericoid mycorrhizal	Glycine injected into the mor layer of a boreal forest. Rates of glycine uptake were similar to those of [^{15}N]ammonium

that of phosphate and, in principle, even a relatively low root length density (RLD) should be enough to capture sufficient N from the soil when present in the form of NO_3^-. In actuality, plants have to capture N (and indeed other nutrients) in competition with other plant roots as well as soil microorganisms, also a large number of inputs in natural systems occur in organic form via leaf litter, dead roots, and animals, leading to a heterogeneous distribution of resource supply both spatially and temporally. Thus, the distribution of resources in soil, even of NO_3^-, is not uniform but patchy.

Root systems can respond to nutrient-rich zones or patches through proliferation of roots as demonstrated in the classic experiments conducted by Drew and colleagues in the 1970s. Barley roots exposed to a localized supply of nitrate, ammonium, and phosphate increased both the initiation (i.e., number) and extension (i.e., length) of first- and second-order laterals within that localized zone. Moreover shoot weight was only slightly depressed when these nutrients were supplied locally compared with controls receiving a uniformly high supply of these nutrients throughout their entire root system. However Drew's experimental system involved plants grown in sand units supplied with nutrient solutions and did not reflect the complexity of the soil environment. Nevertheless, the study demonstrated that roots respond, often spectacularly, to inorganic N as well as phosphate-rich zones (**Figure 1**).

Although root proliferation has been widely reported, it has only recently been demonstrated to have a benefit in terms of N capture in soil. When two different plant species are grown in competition for resources from an organic N-rich patch (grass shoots dual-labeled with the stable isotopes ^{15}N and ^{13}C) added to soil, plant ^{15}N capture was related to RLD produced in the patch. No ^{13}C enrichments were detected in the plant tissue, thus N must have been taken up as mineralized N. Thus, when in competition for N, even mineralized N, which can be highly mobile in soil, RLD is important, because the supply of N from the organic patch is finite. In contrast, in the absence of plant–plant competition, the supply of N can be thought of as invariant and RLD is less important.

The timescales to construct new roots in these nutrient-rich zones are generally weeks rather than days (**Figure 2**). In contrast, microbial populations can respond much more rapidly in time scales of hours to days. Thus, root proliferation responses are considered to be more important in terms of plant–plant competition rather than plant–microbial competitive interactions. High-order laterals produced upon root proliferation also tend to have higher N concentrations and thus are more expensive to

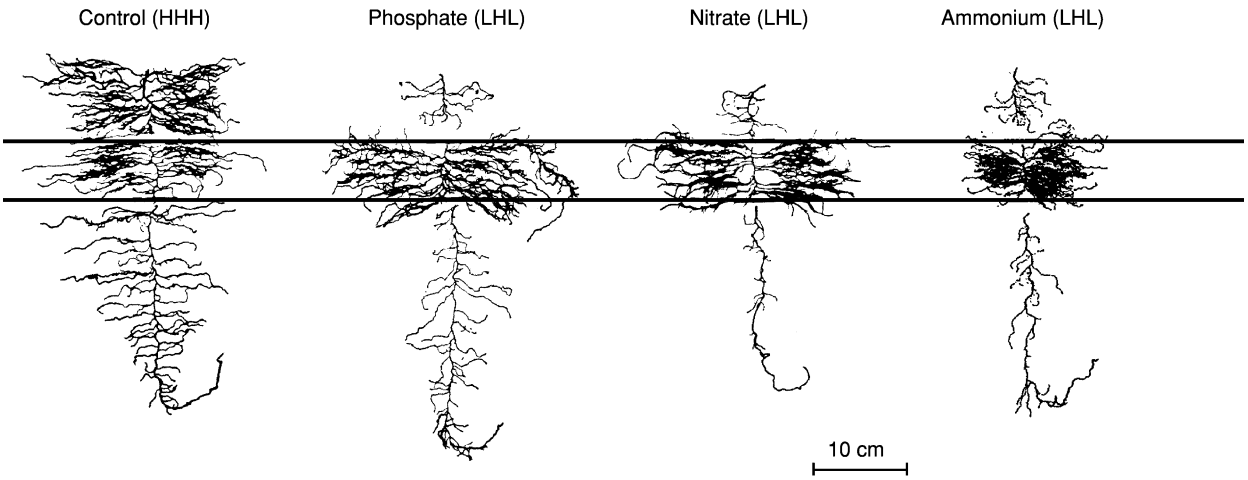

Figure 1 The proliferation of primary and secondary laterals of barley (*Hordeum vulgare*) root systems when supplied with a 100-fold greater concentration of phosphate, nitrate, or ammonium to their middle part of their root system (indicated by the lines). H, high; L, low, which refer to the nutrient concentrations of phosphate, nitrate, or ammonium received by the top, middle, and bottom of the root system, respectively. The control which received uniformly high levels of nutrients to all parts of its root system is shown as a comparison. Reproduced with permission from Drew MC (1975) Comparison of the effects of a localized supply of phosphate, nitrate, ammonium and potassium on the growth of the seminal root system, and the shoot, in barley. *New Phytologist* 75: 479–490, with kind permission of the trustees of the *New Phytologist*.

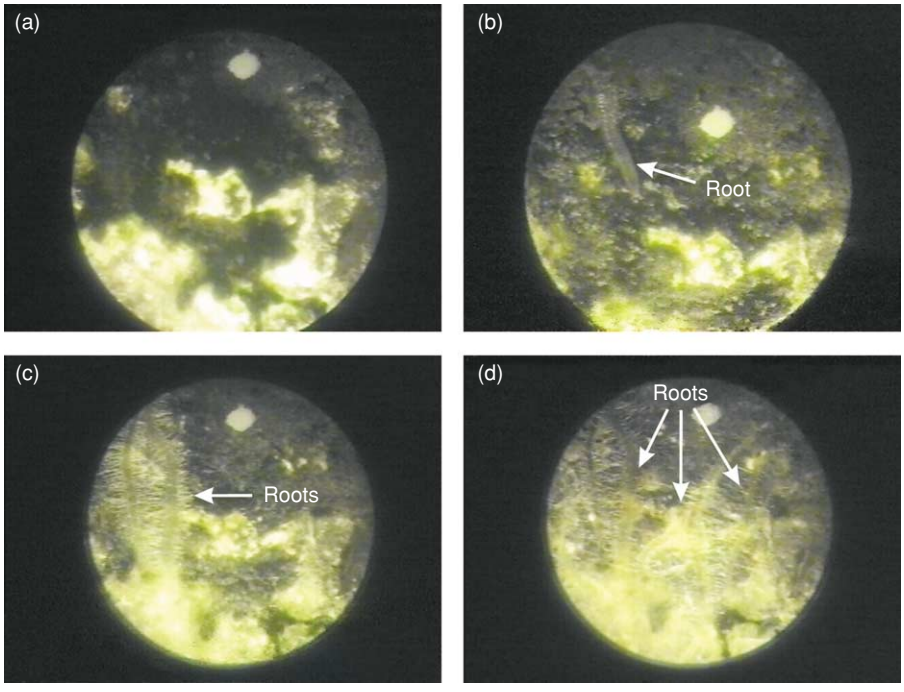

Figure 2 Root growth and proliferation in an N-rich organic material added as a spatially discrete patch and comprising lyophilized algal cell organic material patch (C:N ratio of 3.2:1). (a) One day after the patch was added, no roots in the patch zone were observed; (b) 21 days after the patch was added, a single root was seen growing into the N-rich zone. (c) The same image 25 days and (d) 48 days after the patch was added: increased root production and root-hair development in the N-rich zone was clearly observed. After 49 days, the plants were harvested and found to contain 54% of the N orginally added in the algal cell patch in their tissues. Are microorganisms more effective than plants at competing for nitrogen? pp. 304–308. © 2000, with kind permission from Elsevier Science.

construct but presumably the benefits of exploiting a nutrient-rich patch and the capture of N from it outweigh the disadvantages of these roots' construction costs. Moreover, increased root turnover, i.e., a decrease in root longevity, is often observed in both fertile soils and fertile patches, but again presumably the advantages of having a young population of roots actively involved in nutrient-uptake processes outweigh the disadvantages of high root turnover rates.

Mycorrhizal Contribution to Plant N Uptake

Most plants form mycorrhizal associations under natural conditions. Mycorrhizal symbiosis is discussed in detail elsewhere so only the benefit of mycorrhizas for plant N uptake will be considered here. Mycorrhizal associations may be expected to enhance N uptake from inorganic N sources because, by virtue of the extension of the fungal mycelium in the soil, they should be better able to compete with the soil microbial community for these N sources compared with plant roots. Many of the fungi involved in the ectomycorrhizal and ericoid mycorrhizal associations have been demonstrated to have a preference for NH_4^+ rather than NO_3^- when grown in pure culture. The reasons for this are probably the same as the preference for inorganic shown by plant roots in that it reflects the dominant inorganic N source under which these fungi usually form their associations. In addition, the arbuscular mycorrhiza (AM), ericoid, and ectomycorrhizal associations have all enhanced N capture for their host plant when supplied with NH_4^+. Mycorrhizas are probably more effective at enhancing N capture when supplied with NH_4^+ than NO_3^- because of the differences in mobilities of these ions. As NH_4^+ is much less mobile than NO_3^-, NH_4^+ uptake can be enhanced in the same manner that phosphate (which is even more immobile) is enhanced by mycorrhizal colonization, whereas the very mobile NO_3^- diffuses readily to the root surface. However, under certain circumstances, such as drought conditions, when ion mobility is restricted, mycorrhizas have also been demonstrated to enhance NO_3^- uptake for their host plant. In addition, AM colonization of legume roots has been demonstrated to have a positive effect on N nutrition for these plants when their hosts are in a tripartite symbiosis with N_2-fixing *Rhizobium* spp. but in this case the enhanced N nutrition of the plant is believed to be a consequence of increased plant P status and uptake of other micronutrients which may have indirectly enhanced the N_2-fixation process in addition to improving overall plant growth. AM mycorrhizal fungi have also been suggested to play a role in the redistribution of N within a plant community via fungal connections from legume to nonlegume plants, allowing transfer of N-containing products to the nonlegume host. However, it is unlikely that such a mechanism alone would be sufficient to meet the N demand of the nonlegume host.

The ectomycorrhiza and ericoid mycorrhizas also enhance N nutrition for the host plant by accessing organic N sources. These fungi produce hydrolytic enzymes which mineralize complex N forms, such as chitin and proteins, and then absorb the NH_4^+ liberated. Uptake of N from simple organic sources such as amino acids and peptides has also been demonstrated. However, there is considerable variability among species and even among different strains of the same species in their ability to acquire N from organic sources. For example ectomycorrhizal fungi such as *Suillus bovinus*, *Paxillus involutus*, and *Hebeloma crustuliniforme* are classified as 'protein fungi' because their growth yields on organic N are the same, or in excess of, yields on ammonium, whereas the so-called 'nonprotein fungi' *Laccaria laccata* and *Lactarius rufus* grow poorly and have low yields on organic N (gliadin and bovine serum albumin, BSA) sources. Once the more-complex organic N sources are cleaved by the mycorrhizal fungi, this may aid capture of N in more simple organic form by either different mycorrhizal fungi or plant roots. The ability of AM associations to use organic N sources to any great extent is controversial, although it has been shown that AM fungi can access such N sources and transfer the N to their host plant.

There is much current interest in the uptake of intact organic N sources by plants; however, its significance as a major N-acquiring system in most ecosystems is still unclear. For plants, the availability of N whether in inorganic or organic form will be determined by the activities of the microbial community in soil and, thus, plant uptake of N cannot be studied independently of these microorganisms. Plants are effective at competing for N with microorganisms because of their much slower tissue turnover times. Also, by remobilization of N from senescing tissues, plants can reduce their losses of N back into the soil system.

Introduction

Nitrogen-fixing bacteria are known to form symbiotic associations with some members of all major groups of plants, as well as with some fungi. Although there are numerous reports of nitrogen-fixing bacteria occurring in animals, for example termite guts, the significance to their hosts remains to be proven. In global terms, nodulated plants (both legume and actinorhizal) fix most nitrogen, but many of the other symbioses are very important within their own ecosystems. All nonnodulated nitrogen-fixing symbioses have cyanobacteria as their endosymbiont.

Common features to most symbiotic systems that have been studied in detail are: first, that given a supply of combined nitrogen (nitrate, ammonium, organic N) from the soil, they will tend to use this in preference to fixing N_2; in most cases this partially or completely excludes the development of the symbiosis, a situation frequently described in agricultural systems, but which is likely to occur also in natural ecosystems; second, that the host plant assimilates the ammonium produced by the nitrogen-fixing endophyte. Thus a series of control mechanisms is invoked whereby the plant host supplies organic carbon, amino compounds, and mineral elements in exchange for ammonium. The only exception is in lichens, where the fungal component is probably responsible for supplying minerals from the soil or other substratum, and carbon fixation is carried out by either a green alga or the nitrogen-fixing endophyte (see Table 1).

Where estimates of fixed nitrogen are given, these are subject to large errors because of limitations of available methods for use on a field scale.

Cyanobacterial Symbioses

Table 1 lists the major types of symbiosis between cyanobacteria and plants. Nitrogen-fixing cyanobacteria usually have nitrogenase located in specialized cells known as heterocysts, and this is true of almost all symbiotic forms studied.) Exceptions to this observation are those listed in Table 1 as having 'coccoid forms' of endophyte. Shortly after infection, heterocyst frequency may be similar to that of free-living forms, but subsequently it increases markedly as the endophyte fixes nitrogen using carbon fixed by the host, making photosynthesis by vegetative cells unnecessary. Further, in many systems, the cyanobacteria do not receive light, although they continue to produce photosynthetic pigments. Only in two membered lichens (Table 1) does the cyanobacterium need to fix both CO_2 and N_2.

Another common feature to all except some diatoms is that water is necessary for infection by motile filaments (hormogonia) of the cyanobacterium. In bryophytes *Azolla* and *Gunnera*, these invade cavities in the host plant: *Azolla* also has a means of dispersing its endophyte during spore production. Within cavities, host cells make close contact with their symbionts and often undergo structural modifications enabling the efficient interchange of nutrients. The need for water may be one of the reasons why cyanobacterial symbioses are limited in number. Only lichens are found in very dry areas.

Lichens

Identification of the fungi involved in lichen formation is difficult, but it is likely that about 20% of known fungi can be found in lichens. Of these, the vast majority are ascomycetes. No phycomycetes are known to form lichens, although one coenocytic species, *Geosiphon pyriforme*, produces bladders that can house *Nostoc punctiforme*. This interesting association may

Table 1 Major categories of nitrogen-fixing symbioses involving cyanobacteria

Category	*Genus of host*	*Genus of cyanobacterium*	*Comments*
Diatoms	*Bacteriastrum*	*Richelia*	Includes both marine and freshwater genera. Marine genera may be important in vertical translocation of organic carbon in oceans
	Chaetoceros	*Richelia*	
	Denticulata	Coccoid form	
	Epithemia	Coccoid form	
	Hemiaulus	*Richelia*	
	Neostreptotheca	Coccoid form	
	Rhopalodia	Coccoid form	
	Rhizosolenia	*Richelia*	
	Rupertia	*Nostoc*	
	Streptotheca	Coccoid form	
Lichens	*Collema*	*Nostoc*	Lichens are important in boreal and temperate forests, in arid areas, and on rocks, often in coastal areas. They may have only two components (fungal, cyanobacterial), or three, when a green alga is also present. In the former the cyanobacterial member fixes both CO_2 and N_2, in the latter, only N_2. Some lichens have unicellular endophytes
	Dendriscocaulon	*Scytonema*	
	Dictyonema	*Scytonema*	
	Ephebe	*Fischerella*	
	Leptogium	*Nostoc*	
	Lichina	*Calothrix*	
	Lobaria	*Nostoc*	
	Massalongia	*Scytonema*	
	Nephroma	*Nostoc*	
	Pannaria	*Nostoc*	
	Parmelia	*Nostoc*	
	Peltigera	*Nostoc*	
	Placopsis	Uncertain	
	Placynthium	*Dichothrix*	
	Polychidium	*Scytonema*	
	Pseudocyphellaria	*Nostoc*	
	Solorina	*Nostoc*	
	Stereocaulon	*Nostoc*	
	Sticta	*Nostoc*	
Hornworts	*Anthoceros*	*Nostoc*	The cyanobacteria are located in pockets in the thallus
	Phaeoceros	*Nostoc*	
	Notothylas	*Nostoc*	
	Dendroceros	*Nostoc*	
Thalloid liverworts	*Blasia*	*Nostoc*	The cyanobacteria are located in pockets in the thallus
	Cavicularia	*Nostoc*	
Ferns	*Azolla*	*Anabaena*	Although '*Anabaena*' is in common use, it is really a *Nostoc* and is found in leaf pockets
Cycads	*Bowenia*	*Nostoc* is very common, other reports include *Calothrix*	All extant cycads are symbiotic. Cyanobacteria are found in specially modified roots, usually referred to as 'coralloid,' but sometimes called 'nodules'
	Ceratozamia		
	Cycas		
	Dioon		
	Encephalartos		
	Lepidozamia		
	Macrozamia		
	Microcycas		
	Stangeria		
	Zamia		
Angiosperms	*Gunnera*	*Nostoc*	All extant species are symbiotic. Unlike all the above, except some diatoms, cyanobacteria are intracellular

well represent another type of symbiosis for which more examples remain to be discovered.

In some areas, lichens are responsible for significant inputs of fixed nitrogen into soils, either directly or indirectly. Two of the most widely studied systems are the boreal forests and arctic tundra, where nitrogen-fixing lichens (often thalloid *Sterocaulon* spp.) may be the dominant component of the ground flora, as in parts of Scandinavia and northern Canada. Although the total amount of nitrogen fixed may seem low by agricultural standards (1–2 compared with up to $400\,\mathrm{kg\,N\,ha^{-1}}$ per year), when set against the requirements of growth at low temperatures, it may be sufficient not only for the lichens, but, following

mineralization, for other organisms in the ecosystem. Similar arguments can be applied to the epiphytic lichen *Lobaria oregana* found on old-growth Douglas fir in the Pacific Northwest of the USA, where it contributes 3–4 kg N ha^{-1} per year, which may enter the soil via stem flow. In dry areas, both cold and hot, ranging from Antarctica to the tropics, lichens and free-living cyanobacteria may be among the few photosynthetic organisms found. Lichens can survive years of desiccation then resume growth and both CO_2- and N_2-fixing activity. However, little fixed nitrogen may be released into the soil, as the lichens are part of a tightly controlled ecosystem where the presence of bacteria and other organisms suggest that the entire nitrogen cycle occurs within it. Similar arguments apply to crustose lichens occurring on rocks (and buildings).

Bryophytes

This category includes the hornworts and thalloid liverworts of Table 1. They are found in all parts of the world on bare, nitrogen-deficient soils that are very moist but not flooded. Botanically they are interesting because of their life cycle and the means of transport between the gametophyte and sporophyte generations. Figure 1a shows the main features of a hornwort, *Anthoceros*. A relevant question relating to this association is: Why are there so few bryophytes with nitrogen-fixing symbionts? Current molecular evidence suggests that extant symbiotic forms arose from an ancient branch of the bryophyte lineage. Many modern bryophytes, particularly mosses, have adapted to live in harsh environments, including dry areas. As water is essential for the cyanobacteria to enter pockets of the developing thallus, there may have been a selective disadvantage to symbiotic forms.

Ferns

Azolla is an unusual fern in being both aquatic and having a nitrogen-fixing endophyte (Figure 1b). Being aquatic, it is not strictly relevant to a discussion on soils, but, as it has been and still is widely used as a nitrogen fertilizer for wetland rice, it will be mentioned. Its agricultural use has been the subject of many reviews. These have taken different standpoints

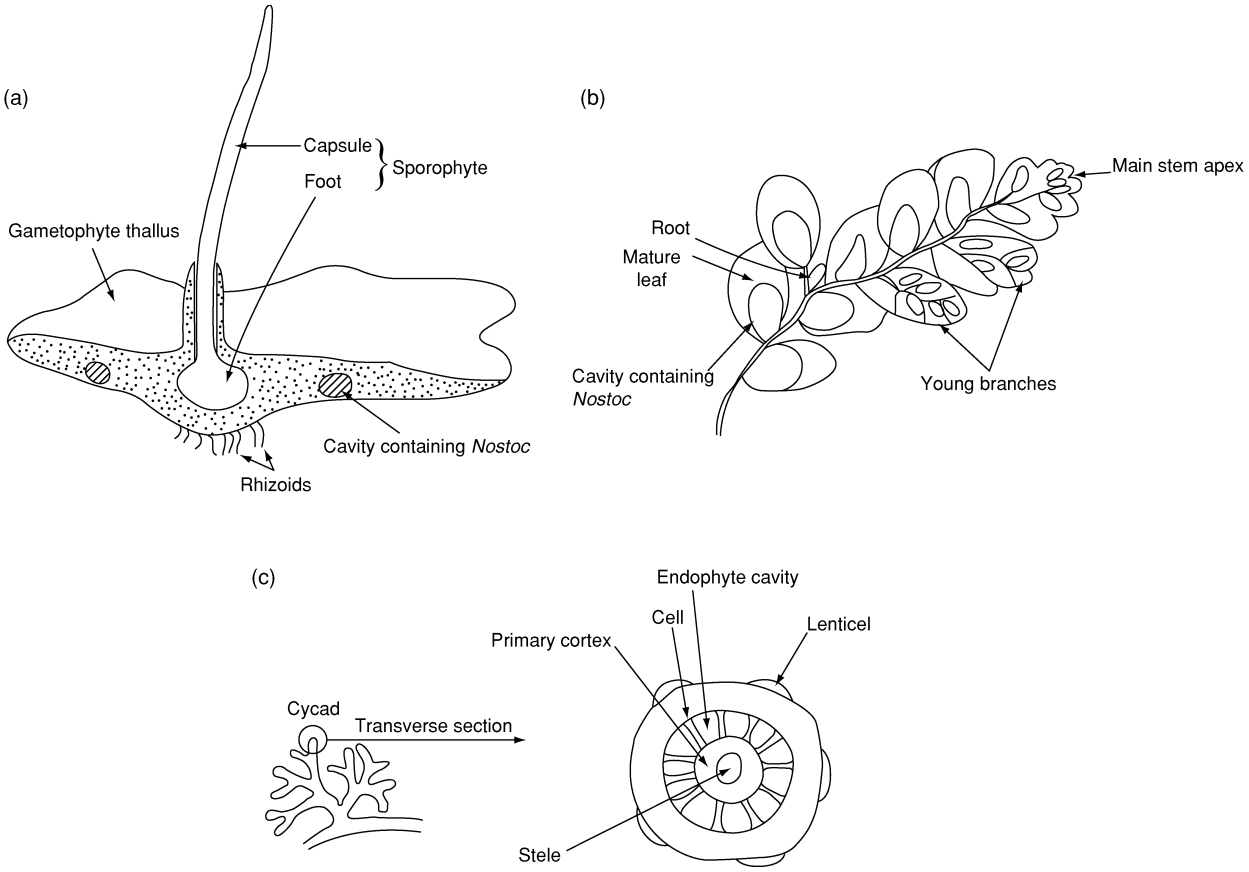

Figure 1 Some cyanobacterial symbioses with plants: (a) the hornwort *Anthoceros*, approximately ×10 natural size; (b) *Azolla*, ×10 natural size; (c) generalized cycad, approximately natural size; and magnified transverse section. © J Sprent.

as to the practicality of the use of *Azolla* in modern rice-growing, although there is general agreement that it can yield significant amounts of easily mineralized N. However, in many areas of the world where *Azolla* has been introduced, for example South Africa, it can also be a nuisance by blocking water channels. Recently attention has been given to control of *Azolla* by insects and other agents, and in its use for feeding fish, poultry, and pigs.

Why only one genus of fern is known to have a nitrogen-fixing symbiosis is not clear. Current fossil evidence is that *Azolla* evolved comparatively recently compared with other ferns, suggesting that it may have been a 'one-off' event to fill a particular need.

Cycads

Many texts state that cycads are only found naturally in the southern hemisphere, but this is not true. Although their frequency may be greater in the southern hemisphere, cycads occur in tropical and warm temperate areas of both hemispheres. This distribution can be traced through the fossil record, which shows that cycads were around at least 230 million years ago, before Pangaea broke up into Gondwana (which moved south) and Laurasia (which moved north). It is possible that the comparative rarity of natural stands of cycads in the northern hemisphere relates to destruction of their habitat. Certainly several of them are listed as endangered. Biologically, cycads are particularly interesting in that all extant and fossil forms appear to be symbiotic and yet no evolutionarily related groups of plants (for example gymnosperms) have nitrogen-fixing members. There must have been pressure toward symbiosis at an early stage in the evolution of cycads. This may have been a shortage of combined nitrogen, but evidence supporting this hypothesis is not yet clear. Many of the most abundant cycads today live in dry environments with low-nutrient soils, but others are found in rainforests and seasonally dry areas.

Hormogonia apparently invade gaps in the cortex of cycad root and stimulate the formation of a much-branched structure, the coralloid root (**Figure 1c**). Within this, *Nostoc* is found in cavities between the primary and secondary cortex. It is very easy to find coralloid roots in cycads grown as pot plants, as they are near to and often protrude from the surface of the soil. However, in other cycads, for example *Macrozamia reidlii*, coralloid roots are found well below ground level (down to 1 m). This species is common in areas of Western Australia that are prone to fire. *M. reidlii* can regenerate after fire from subterranean tubers and the deep-seated coralloid roots remain functional. In some eucalypt forests, cycads apparently provide an important source of nitrogen, equivalent to that of understorey legumes in other eucalypt forests. The largest genus of cycads is *Encephalartos*, widely distributed in a variety of habitats in east and southern Africa. Some species are fire-resistant, others frost-tolerant, and one at least is deciduous. Many standard textbooks describe cycads as 'living fossils.' Whilst they may not be as dominant as in former times, in areas such as parts of Australia and South Africa and in the everglades of Florida they are still a prominent component of natural vegetation. However, as they are widely collected for use in horticulture, some species are now threatened.

The list of cycad genera given in **Table 1** is conservative. Other genera have been proposed, of which the most often cited is *Chigua*, with two species native to Colombia; however, some workers believe that these should be included in *Zamia*. The division of cycads into families is also an area of current uncertainty. However, as far as soils are concerned, it is probably safe to assume that, at any site where cycads grow, there will be an input of symbiotically fixed nitrogen.

Angiosperms

Gunnera is the only genus of angiosperm known to have a symbiotic association with a cyanobacterium, in this case *Nostoc punctiforme*. Taxonomically, *Gunnera* appears to be isolated, placed in its own family, and far removed from other angiosperms with nitrogen-fixing symbioses. There are approximately 40 species and all contain *Nostoc* in modified glands (sometimes referred to as nodules) at the base of petioles. Plants are herbs that vary in size from those with leaves over 1 m in height to small creeping forms. In common with other angiosperms, the endophyte of *Gunnera* is intracellular, in that it is contained within the volume surrounded by a plant cell wall, but extracellular in that it is confined within a membranous sac (now often called a symbiosome). Transport of material into and out of the glands is via phloem, unlike nodulated plants in which outward transport is via the xylem. *Gunnera* appears to lack nitrate reductase, so is unable to use nitrate. All studies suggest that *Nostoc* is capable of fixing enough nitrogen for the needs of its host and hence, in the longer term, is likely to be a good source of N for soil mineralization. There is abundant fossil pollen evidence that *Gunnera* is of ancient origin and its present distribution, largely in the southern hemisphere, is restricted to areas with high humidity. This may have been its downfall if it was unable to adapt to the increasingly dry conditions that spread over much of the world since angiosperms first evolved. However, *Gunnera* appears to be very important in some of its present locations, where nodulated legumes and actinorhizal plants are

scarce or absent. An extreme case of this is in the Malvinas (Falkland Islands) off the coast of Argentina, where *Gunnera magellanica* is the only native angiosperm with a nitrogen-fixing symbiont. Here it is common and widespread, being found from sea level to all elevations, and clearly has a vital role to play.

Nodulated Angiosperms

These fall into two categories, based on the nature of the endophyte. *Frankia*, a filamentous bacterium belonging to the actinomycetes, nodulates a variety of plants (Table 2). Legumes and the Ulmaceous genus *Parasponia* are nodulated by unicellular bacteria from the α- and β-proteobacteria, collectively known as rhizobia (Table 3). Recent molecular evidence has placed all nodulated plants in a distinct group, known as the Rosid I clade. However, the clade also contains many genera that lack the ability to nodulate. If, as is generally assumed, all members of the clade have some predisposition to form nodules, why is it only expressed in certain genera? The implications of this for the evolution of nodulation are an area of intense current interest, especially as the internal structure of nodules in the two groups is different.

A problem common to all aerobic nitrogen-fixing organisms, including the symbiotic *Frankia* and rhizobia, is to reconcile the need for oxidative phosphorylation to fuel the nitrogen fixation with the fact that the enzyme is inactivated by oxygen. Nodules have a number of ways of controlling the rate of oxygen diffusion to the active enzyme so that nitrogen fixation is balanced with the supply of fixed carbon. In some cases this means reducing the concentration of oxygen from the 20% found in air, by means of fixed and/or variable diffusion barriers. Once a sufficiently low level (about 1%) is reached, there may be a need to maintain a constant flux of oxygen; this is achieved by plant forms of hemoglobin. It has been known for many years that hemoglobin gives most active

Table 2 Genera of plants known to be nodulated by *Frankia*. These are grouped according to family (numbers in parentheses indicate the total number of genera in the family); families are arranged in four groups, separated by an additional line space, according to their position in the Rosid 1 clade of angiosperms. The first group also contains the Ulmaceae, in which *Parasponia*, the only genus outside the legumes known to nodulate with rhizobia, is placed. It should be noted that there are six groups in this clade. Of the other three, two contain no nitrogen-fixing members and the other, the legumes. All groups have nonnodulating members

Family	*Nodulating genera*	*Comments*
Elaeagnaceae (3)	*Elaeagnus* *Hippophae* *Comptonia*	Where known in this group, infection is intercellular and no nodule rootlets are formed. Vesicles in the first two families are spherical and septate, with the exception of *Ceanothus*, where they lack septa. In the Rosaceae, vesicles are elliptical and aseptate. Within the whole group, Rosaceae is sister to the other two families
Rhamnaceae (55)	*Ceanothus* *Colletia* *Discaria* *Kentrothamnus* *Retanilla* *Talguenea* *Trevoa*	
Rosaceae (100)	*Cercococarpus* *Chamaebatia* *Cowania* *Dryas* *Purshia*	
Betulaceae (6) Myricaeae (3)	*Alnus* *Comptonia* *Myrica*	In this group, infection is through root hairs. Nodule rootlets are present in all genera except *Alnus*
Casuarinaceae (5)	*Allocasuarina* *Casuarina* *Ceuthostoma* *Quadrangula* *Gymnostoma*	Vesicles are absent from *Allocasuarina* and *Casuarina* nodules. *Quadrangula* has recently been proposed for two species previously included in *Casuarina*. In all other genera vesicles are septate, but vary in shape from spherical to club-shaped (Myricaeae)
Coriariaceae (1) Datiscaceae (3)	*Coriaria* *Datisca*	Details of infection in this group are still unclear. Nodule rootlets occur in *Datisca*. Vesicles are filamentous and aseptate. Nodules on these genera have several other distinct features

legume nodules their pink internal color, but it is now apparent that the pigment is also a necessary part of the functioning of some actinorhizal nodules. Species living in waterlogged conditions may also need an anatomical pathway that allows air to pass through a series of spaces from above the water level to the nodule. This may be achieved by negatively geotropic nodule rootlets, as in *Myrica*, or by a continuous layer

Table 3 Currently recognized bacterial genera and species known to form nitrogen-fixing root nodules in association with legume roots (sometimes stems). All except those indicated are in the α-proteobacteria, but not all are in the same branch. The genera *Agrobacterium* and *Allorhizobium* may be incorporated into *Rhizobium*

Genus	*Species*	*Examples of legumes nodulated and comments*
Agrobacterium	?	Some nodulating bacteria appear to belong to this genus, but their exact nature has not been confirmed
Allorhizobium	*undicola*	*Neptunia natans*
Azorhizobium	*caulinodans*	*Sesbania rostrata* stems
Blastobacter	Not determined	*Pterocarpus erinaceous*, *P. lucens*
Bradyrhizobium	*elkanii*	*Glycine max*
	japonicum	*Glycine max*
	liaoningense	*Glycine max*
	sp. (host genus)	Several potential species e.g., sp. (*Lupinus*) are currently defined by their hosts
Burkholderia	Two spp.?	*Aspalathus carnosa*
		Machaerium lunatum
		In the β-proteobacteria
Devosia	*neptuniae*	*Neptunia natans*
Mesorhizobium	*amorphae*	*Amorpha fruticosa*
	chacoense	*Prosopis alba*
	ciceri	*Cicer arietinum*
	huakuii	*Astragalus sinicus*
	loti	*Lotus corniculatus*
	mediterraneum	*Cicer arietinum*
	plurifarium	*Acacia senegal*
	tianshanense	*Glycyrrhiza pallidiflora*
Methylobacterium	*nodulans*	Some *Crotalaria* spp.
Ralstonia	*taiwanensis*	*Mimosa* spp. In the β-proteobacteria. Now renamed *Wautersia taiwanensis*
Rhizobium	*etli*	
	bv. phaseoli	*Phaseolus vulgaris*

	bv. sesbaniae	*Sesbania rostrata* roots

of aerenchyma, as in a number of wetland legume genera.

Within the two groups of nodulated angiosperms, individual genera and species are nodulated by different strains of either *Frankia* or rhizobia, in other words there is specificity between the partners. In order for nodulation to proceed, the endophytes must recognize and be recognized by their hosts, gain entry into roots (occasionally stems in legumes), by-pass the host's defense reaction, and stimulate production of nodule tissue. The recognition process involves a series of exchanges of key molecules produced by the host and the endophyte, following which various nodulation genes in each partner are induced. Some cell division in host roots often starts toward the end of this recognition pathway. Entry may be gained via root hairs, as in many legumes and actinorhizal genera such as *Alnus* or by penetration between epidermal cells or at the point of emergence of lateral roots (adventitious roots in stem-nodulating legumes). Subsequent to the initial infection, nodule development in legumes and actinorhizal plants proceeds in different ways. The common feature of all actinorhizal nodules and those induced by rhizobia on *Parasponia* is that the vascular system is central and the infected tissue cortical. In legume nodules the vascular system is cortical and the infected tissue is central. Even so, there is increasing evidence that similar nodulation genes may be involved in both types, consistent with a common predisposition for nodulation.

Actinorhizal Plants

Plants nodulated by *Frankia* are collectively referred to as actinorhizal. Technical difficulties, coupled with a lack of funding for nonagricultural species has resulted in research on these plants lagging behind that on nodulated legumes. However, progress is now rapid and the important role of these plants is increasingly being recognized. Table 2 lists the currently agreed actinorhizal genera, and this list is unlikely to be radically altered, as close relatives of the nodulating genera have been extensively examined in almost all areas of the world. However, there have been isolated (unconfirmed) reports of nodules on members of the familes Cucurbitaceae and Zygophyllaceae, both of which are in the Rosid I clade. Molecular evidence has grouped actinorhizal plants in a way that fits well with the known variations in infection pathways and nodule characters, as can be seen in Table 2. All nodules have indeterminate growth (Figure 2), most are perennial, and older parts may become very woody, with the active regions confined to the tips of nodule lobes. It is now generally agreed that nodulation with *Frankia* has evolved on a number of different occasions. One question that is now being addressed is whether or not there is a relationship between particular host plants and the type of *Frankia* with which they nodulate. Although host–endophyte specificity has been shown in a number of cases, it varies widely. On balance it is probably true to say that there is more evidence for coevolution between host plants and *Frankia* than there is for legumes and rhizobia.

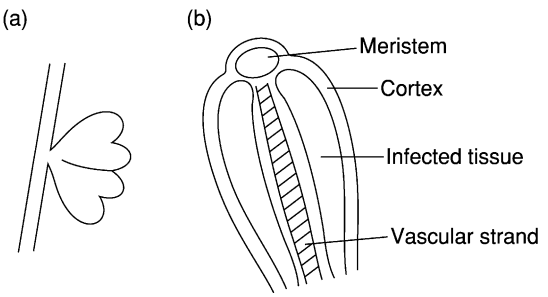

Figure 2 Actinorhizal nodules. (a) A young nodule as found in *Alnus*. Nodules branch repeatedly, forming a woody coralloid structure up to 8–10 cm in diameter; (b) longitudinal section through the tip of a lobe of a generalized nodule; in some genera this also produces a nodule rootlet (Table 2). The detailed structure of the infected tissue varies greatly with genus, and not all nodules have lobes which are symmetrical in longitudinal section. © J Sprent.

Growing *Frankia* in pure culture from crushed nodules has proved a difficult task and one that has still not been achieved for all host genera. Molecular methods have enabled more detailed studies of *Frankia* in soil to be undertaken and it now seems likely that, as with rhizobia, it has a saprophytic stage that may tide it over during periods when no compatible host is present. Being filamentous, *Frankia* has the potential for differentiation. This may occur in the production of vesicles and of spores. Vesicles are usually swollen structures formed at the ends of filaments under conditions of low oxygen concentration. Where present they are the site of nitrogenase activity and the thickness of their lipid-based walls is adjusted to prevent oxygen reaching the enzyme. The location of vesicles within the infected host cells varies considerably between genera. Some strains of *Frankia* form spores within nodules; others do not. Evidence that spores are effective perennating structures is not strong and spore-positive nodules often show lower nitrogenase activity.

Actinorhizal plants are mainly woody in nature, most being shrubs or trees. They are found worldwide from the arctic (*Dryas*, an unusual genus in that it nodulates in some areas but not others) to the tropics (members of the Casuarinaceae), on high mountains (Himalayan alder) and in lowland bogs (*Myrica gale*). The major type of vegetation from which they seem to

be absent is tropical rain forest. Many are drought-resistant (*Cercocarpus* and other shrubs from the rain shadow of the US Rocky Mountains), a factor often coupled with saline tolerance (some species of *Casuarina*). They are used in a variety of ways, including forestry (both as a nitrogen input, e.g., *Ceanothus* and as a source of timber, e.g., *Alnus*, *Casuarina*), for land reclamation (*Casuarina*) for animal browse (e.g., *Purshia*), as an agricultural crop (*Hippophäe*), and for pharmaceutical purposes (*Myrica*). The amounts of nitrogen fixed when they are growing in their natural environment or when planted is related to soil and climatic conditions, but is similar in magnitude to that of legumes in similar environments (up to approximately $100\,kg\,N\,ha^{-1}$ per year). As with legumes, optimum nitrogen fixation may need formation of other structures such as endo- and/or ectomycorrhizas and cluster (proteoid) roots.

Legumes

The Leguminosae, also known as the Fabaceae, is the third-largest family of flowering plants. However, only a small number have been exploited by humans, and our knowledge of nitrogen fixation (if any) by most of them ranges from nonexistent to sparse. A great deal of effort has gone into describing legumes from around the world, but not many plant taxonomists look beneath their feet, generally using only characters such as flowers, fruit, and habit that are visible above ground. Most taxonomists agree that the family should be divided into three subfamilies, Caesalpinioideae, Mimosoideae, and Papilionoideae, with a possible fourth currently being considered. It is also widely understood that nodulation is rare in the first, common in the second, and virtually always present in the third. Recent work has not altered this understanding (Table 4), but has identified some closely related groups, mostly trees, from each subfamily that lack the ability to nodulate. All known naturally nonnodulating legumes are from tropical and subtropical regions, although some are cultivated at higher latitudes. Their distribution within the family is consistent with the suggestion that nodulation in legumes arose at least twice, possibly three or four times.

Legume nodules are found in a variety of shapes, sizes, and structures (Figure 3). As with actinorhizal plants, nodule features tend to be uniform with taxonomic groupings. Some have determinate growth, with only a transient meristem; these are relatively short-lived. Most are indeterminate, with a distinct apical meristem, often showing branching. These are usually longer-lived and may be perennial. They are generally better able to withstand adverse conditions, because they can resume growth and produce new nitrogen-fixing tissue after periods of stress such as drought or low temperature. Studies with agricultural species such as clovers, alfalfa (lucerne), and beans generally show that nodulated plants are less able to withstand environmental extremes than the same species grown in soil containing combined nitrogen. Many commercial cultivars respond well to 'starter nitrogen,' i.e., a small dose of nitrogen fertilizer at planting. To some extent this reflects the fact that until recently most plant breeders raised crops on very fertile soils and thus may have been inadvertently selecting against efficient nitrogen fixation. Around the beginning of the twenty-first century, there was a major effort to raise legume cultivars that would produce economic yields on less-fertile soils and under environmental stresses such as drought and salinity. However, it is also important to go back to the field and look for wild legumes that grow well in extreme environments (Table 5). The only conditions where nodulated legumes do not seem to occur naturally is in sea water, although some may grow well in saline areas and others submerged in fresh water. In human terms, perhaps even more importantly, it is now being recognized that there are many nodulated legumes that have been used by native peoples for millennia that can provide food often under very adverse conditions. Early settlers in the USA made great use of tubers of *Apios americana*, a species used by American Indians. In dryland Africa, many tubers are used for food and even water under dry conditions. Whilst most of these

Table 4 Genera in legume subfamilies which can and cannot nodulate and for which there is no information. Since legume taxonomy is currently undergoing many rearrangements, all numbers must be regarded as very approximate. Many of the genera for which there are no reports are monotypic. Only three genera are known so far in which there is good evidence for both nodulating and nonnodulating species, *Acacia* and *Pentaclethra* (Mimosoideae), and *Pterocarpus* (Papilionoideae)

	Number of genera			
Subfamily	*Total*	*Nodulated*	*Nonnodulated*	*Unknown*
Caesalpinioideae	157	8	72	76
Mimosoideae	78	38	9	31
Papilionoideae	479	353	27	99

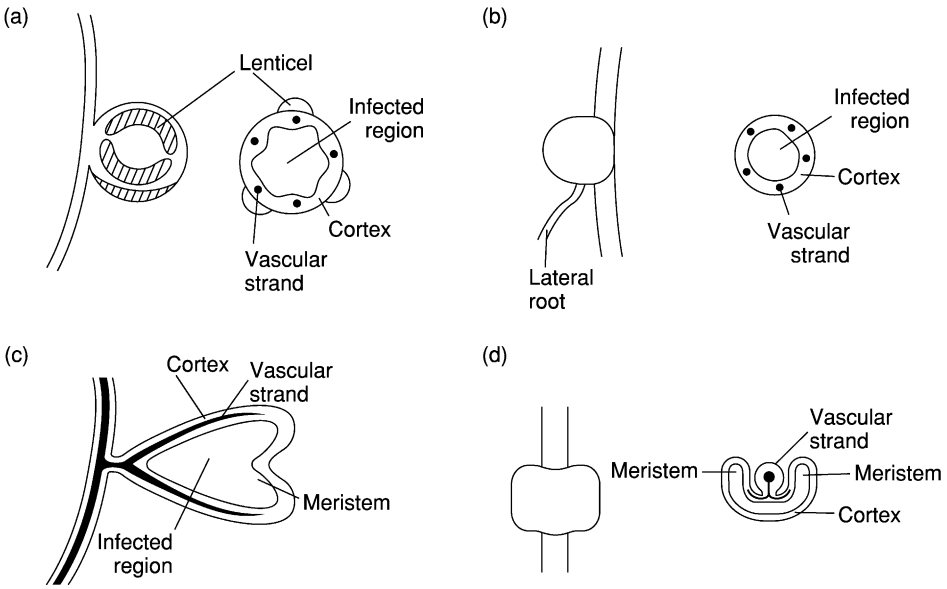

Figure 3 Legume nodules, drawn from field material, and showing the major types of nodule formed. (a, b, d) Left, whole nodules; right, transverse sections through these nodules; (c) a longitudinal section. (a) Determinate nodule of the desmodioid type, as found in soybean and related genera. Size varies from 2–7 mm in diameter. Lenticels on the surface facilitate gaseous exchange; (b) determinate nodule of the aeschynomenoid type, always associated with lateral or adventitious roots. They are found in many genera, including peanut and important tree genera such as *Dalbergia* and *Pterocarpus*, and on stems of some legumes, such as certain species of *Aeschynomene*. Size is usually between 2 and 6 mm in diameter. The infected tissue lacks the uninfected cells present in desmodioid nodules; (c) indeterminate nodule, drawn from a species of *Acacia*. This is the commonest type of nodule and occurs in all three subfamilies. It is characterized by an apical meristem, and the infected tissue has a gradation from young, inactive cells through active, nitrogen-fixing cells to (in older nodules) an inactive senescent region. They vary greatly in ratio of length to breadth and in the degree of branching (if any). Size varies from 2–3 mm in length to complex coralloid structures which may be more than 5 cm in diameter; (d) lupinoid nodules. These are not common, but are typical of many species of *Lupinus*. They have a lateral meristem which gradually encircles the root, forming a collar. As with other indeterminate nodules, there is a gradient of cells in the infected region. © J Sprent.

Table 5 Some environmental constraints to nitrogen fixation by legumes used in agriculture and examples of wild legumes which appear adapted to such conditions

Constraint	*Wild legumes showing tolerance*
Low temperature	*Astragalus alpinus*, *Hedysarum arcticum*, *Oxytropis sordida*
Shade	Some *Inga* spp., *Ormosia countinho*, *Poecilanthe hostmannii*
Flooding	*Discolobium pulchellum* (requires flooding for nodulation), some *Astragalus* spp., some *Neptunia* spp.
Salinity	*Halimodendron halodendron*, *Prosopis tamarugo*, *Vigna marina*
Drought	Some *Acacia* spp., *Faidherbia albida*, some *Vigna* spp.
Low available P	Some *Acacia* spp., *Crotalaria grahamiana*, *Cajanus cajan*
Low soil pH	Some *Astragalus* spp., some *Lupinus* spp.
High soil Al	*Dioclea guianensis*, some *Stylosanthes* spp.

can nodulate, there are exceptions, such as the marama bean, *Tylosema esculentum*. If 'old' new crops are to be sustainably exploited, it is essential to know: First, can it nodulate; and, second, will it nodulate under the conditions under test?

The soil contains a large number of bacterial genera known to nodulate legumes (Table 3). What is not clear from Table 3 is that one strain of rhizobia may nodulate one or many hosts, and that some hosts are nodulated by one strain, others by many. These variations raise a number of theoretical and practical questions. Whereas early studies placed great emphasis on host–rhizobial specificity, assuming that the two partners had coevolved, this is now much less clear. Most of the early work on legume nitrogen fixation was carried out on temperate crop plants and in these the 'rules' usually apply. The main exception is the common bean *Phaseolus vulgaris*, now known to nodulate with several different rhizobial genera (Table 3). Since about 1989, there has been a major thrust toward examining rhizobia from tropical areas. This is when the rules start to break down. New phenomena such as stem-nodulating legumes, photosynthetic rhizobia, new combinations of growth rate and acid/alkali production, and many more have been discovered. Many examples of broad host-range rhizobia have been discovered, adding to the classic one, originally referred to as the 'cowpea miscellany.' At that stage, broad host

range and slow growth were thought to be associated, but there is now a fast-growing strain, NGR 234, isolated from Papua New Guinea, that can nodulate at least 70 genera, including some from each of the three legume subfamilies. This and other findings have challenged the idea of coevolution. We now know that clusters of bacterial genes, called 'symbiotic islands,' are capable of lateral transfer in the soil between genera, and this may account for the growing number of new rhizobial genera which are being discovered. It may also help to explain the close relationship between some rhizobia and plant and animal pathogens.

If it is possible to make any generalizations about nodulated legumes, it may be that, when radiating into higher latitudes, legumes tend to be herbaceous, always to nodulate, and to have a recognizable level of host–rhizobial specificity. Nodules are also usually indeterminate, a benefit in areas with a markedly seasonal climate. In low latitudes, there are many nonnodulating legumes and, of the nodulating ones, many are nodulated by a wide range of rhizobia, producing nodules that vary greatly in their ability to fix nitrogen (effectivity). From the bacterial perspective, infectivity may be more important than effectivity.

The Importance of Nitrogen-Fixing Symbioses to Soil Fertility

One of the problems with trying to estimate biological nitrogen fixation is the lack of suitable methods for field use, especially where trees are involved. As a result, published estimates for global nitrogen fixation vary widely. The true value may lie in the range 100–200 Tg N per year. In recent years, the availability of cheap fertilizer N has reduced both the amount of biologically fixed nitrogen in agriculture and also the amount of field research on the subject in the developed world. However, the rise in the organic movement and fears about nitrate pollution have provided a stimulus for renewed study. Developing countries have no doubt about the significance of nitrogen fixation for the well-being of their peoples and their economies. It is now very clear that optimization of nitrogen fixation in these countries requires much more research, as many of the procedures used in developed countries are inappropriate. To take a simple example, the diversity of rhizobia found in tropical soils poses major problems for the production of effective, competitive inoculant strains.

What is the fate of nitrogen fixed by symbiotic systems? Initially it is to supply the partners, but in the real world plants do not live on their own. We have little idea of how much, if any, of nitrogen fixed by plants that are also mycorrhizal (which most, including bryophytes, are) is exchanged for other nutrients (phosphorus, fixed carbon, trace elements) with nonfixing plants via hyphal connections. If this occurs, then selective harvesting of, for example, large nodulated trees could have a major effect on other plants in the ecosystem. Harvesting crops can also lead to loss of soil N if the amount removed in the crop exceeds that fixed. Even the benefits of crop rotation have been reassessed. A concomitant of nitrogen reduction by nitrogenase is the simultaneous production of hydrogen.) Although the energy so wasted may be partly recovered in some systems by an uptake of hydrogenase, there is little evidence that plants lacking such a system are at a disadvantage. A recent suggestion is that hydrogen evolution in the soil alters the microbial flora in such a way that plants may benefit from improved nutrition. This could help to explain some of the benefits of crop rotation which cannot be accounted for by improved soil fertility and/or reduction of pest and pathogen load.

NUCLEAR WASTE DISPOSAL

G W Gee, P D Meyer, and A L Ward, Pacific Northwest National Laboratory, Richland, WA, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Nuclear wastes are by-products of nuclear weapons production and nuclear power generation, plus residuals of radioactive materials used by industry, medicine, agriculture, and academia. Their distinctive nature and potential hazard make nuclear wastes not only the most dangerous waste ever created by humanity, but also one of the most controversial and regulated with respect to disposal. Nuclear waste issues, related to uncertainties in geologic disposal and long-term protection, combined with potential misuse by terrorist groups, have created uneasiness and fear in the general public and remain stumbling blocks for further development of a nuclear industry in a world that may soon be facing a global energy crisis.

Categories

High-Level Waste

The category 'high-level waste' (HLW) consists of either used (spent) nuclear fuel or the waste generated by reprocessing spent nuclear fuel. HLW generates much heat and radiation and requires remote handling and significant shielding, using materials such as lead, concrete, soil, or water, to prevent excessive radiation exposure to workers. Spent-fuel waste consists of fuel elements removed primarily from commercial reactors, after 3 or 4 years, when their useful life is over and they no longer generate electricity efficiently. The spent fuel assemblies from nuclear power plants are stored on-site, where they are typically submerged in large, water-filled pools, awaiting final disposal. In contrast, reprocessing wastes are stored mainly at nuclear weapons production facilities in liquid form in large underground storage tanks. Figure 1 shows construction of large (1 million gallons, approx. 3.6 million liters) storage tanks buried at the Hanford Site in Washington state, USA. In some cases, the liquid wastes have been calcined into a dry granular form. In the USA, all HLW liquids will be solidified (vitrified) and shipped in secure canisters to a deep geologic repository. Similar plans exist for other countries.

Figure 1 Underground million-gallon (3.6 million liter) storage tanks for nuclear waste at the Hanford site in Washington State, USA.

Transuranic Waste

Transuranic waste (TRU) is derived from the reprocessing of spent fuel and the use of plutonium in fabricating nuclear weapons. TRU is waste contaminated with alpha-emitting radionuclides of atomic number greater than 92 (i.e., greater than uranium, hence the term 'transuranic') and half-lives greater than 20 years in concentrations greater than 3700 $\mathrm{Bq\,g^{-1}}$. TRU typically generates less heat and emits less radiation than HLW, but it remains toxic for centuries and thus requires the same long-term isolation as HLW. TRU in the USA is stored at the Waste Isolation Pilot Plant near Carlsbad, New Mexico.

Low-Level Waste

The category 'low-level waste' (LLW) includes all radioactive waste other than HLW and TRU. Uranium mill tailings, a special form of LLW, are discussed separately. Most LLW contains relatively short-lived nuclides and has less radioactivity than found in HLW. LLW comes from a wide range of institutions, including nuclear power plants, government laboratories, test reactors, hospitals, laboratories, and industrial plants. LLW takes a wide variety of forms, including materials from medical research and treatments; contaminated rags and protective clothing; paper towels, filters and filter residues; and hand tools and equipment. Radiation from LLW can be high enough to require shielding for handling and shipping. Figure 2 show disposal of LLW in concrete (shielded) containers at the Hanford LLW disposal site, USA.

LLW is classified into four groups according to degree of hazard. LLWs that can be disposed of by near-surface burial are classed as A, B, and C types, ranging from the lowest hazard (A) to the highest (C). The US Nuclear Regulatory Commission (NRC) provides requirements for packaging and the form of burial for each of these classes. LLW too hazardous to bury in near-surface facilities is termed 'Greater-Than-Class-C' waste and requires disposal in a deep geologic repository. LLW also includes radioactive materials from natural sources, including radium-226, radium-228, radon-222, plus other radioactive elements from terrestrial sources. Discrete and diffuse sources are part of the LLW inventory. Discrete waste sources include spent industrial gauges, radium needles (used in medical equipment), and exchange resins (e.g., those that separate radium and other radionuclides from contaminated waters). Diffuse LLW can include such things as coal ash, phosphate waste from fertilizer production, and contaminated water and drilling equipment from oil and gas production. Some LLW has been reused for construction backfill and road-building activities and thus spread over long distances. While these radiation levels are relatively low, they produce conditions that can be a detriment to human health. As an example, uranium tailings high in radium can produce significant levels of elevated radon-222 gas. People in homes with basements surrounded by tailings or other radium sources can be exposed to radon gas levels that exceed permissible limits (e.g., 0.74 $\mathrm{Bq\,m^{-2}\,s^{-1}}$).

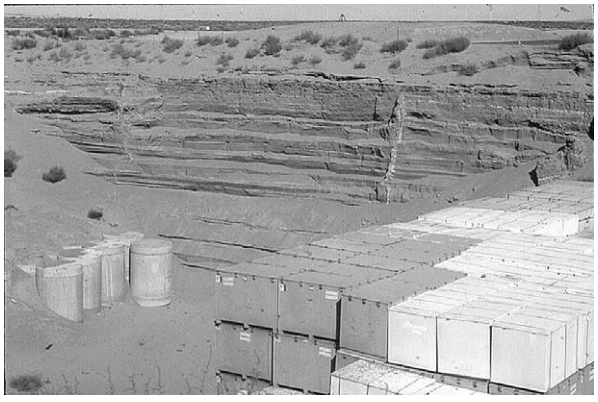

Figure 2 Low-level waste storage at the Hanford low-level waste facility in Washington State, USA.

Uranium Mill Tailings

This special category of LLW consists of residues in the form of fine sands and silts generated from the mining and milling of uranium ore. Large volumes of uranium tailings exist (more than 118 million cubic meters in the USA alone) containing low concentrations of naturally occurring radioactive materials, including thorium-232, radium-226, and its decay product, radon-222. Radon gas is the largest single radiation hazard from uranium mill tailings. Soil covers placed over uranium tailings piles have generally reduced the probability of radon escaping from them. Other environmental concerns include elevated uranium, sulfate, nitrate, and ammonia concentrations in groundwater beneath tailings piles.

Mixed Waste

Waste that contains both hazardous chemicals and radioactive wastes (generally those in the LLW category) is termed 'mixed waste.' In the USA, mixed waste is subject to both NRC and Environmental Protection Agency (EPA) regulations. Sites where chemical contaminants such as dense, nonaqueous-phase liquids (DNAPLs, e.g., carbon tetrachloride), or heavy metals (e.g., chromium, lead, mercury) are mixed with radionuclides are more difficult to clean up than sites where radionuclides are the

sole contaminant, because of the complex nature of the mixed waste coupled with the heterogeneous nature of the subsurface soils and sediments in which the wastes reside.

Waste Inventories and Environmental Discharges

Since the end of World War II, large amounts of nuclear wastes have accumulated in temporary waste repositories around the world. Table 1 shows the volumes of HLW, TRU, and LLW that have accumulated in the past and are projected to accumulate in the USA by the year 2030. Uranium mill tailings are also shown for comparison. In terms of shear volume, uranium mill tailings contribute by far the largest volume of waste (over 157 million cubic meters), with LLW contributing approximately one-fifth of the total volume (or nearly 38 million cubic meters of LLW). Nearly double the USA volumes have been generated in the former Soviet Union (FSU), with lesser volumes in other countries. Decay of radionuclides reduces the massive amounts of nuclear waste but does not eliminate the hazard, because long-lived radionuclides dominate in later years. As shown, the hazard of radioactive waste remains in perpetuity, so treatment or indefinite containment strategies are needed.

In addition to stored wastes, considerable volumes of wastes have been previously discharged directly to the environment. These environmental insults range from approximately 1.4×10^{19} Bq (390 million curies [where 1 Ci $= 3.7 \times 10^{10}$ radioactive disintegrations per second]) in the USA (primarily from liquid discharges during weapons production) to more than 6.3×10^{19} Bq (1700 million curies) in the FSU. At nuclear facilities, the discharges have been directly to the soils and adjacent waterways, burdening them with radioactive decay products whose half-lives range from a few years to millions of years. Long-term environmental consequences from these waste discharges focus primarily on inventories of carbon-14 (half-life of nearly 6000 years), technetium-99 (Tc-99) (half-life of 213 000 years) and iodine-129 (I-129) (half-life of nearly 16 million years). The chemical forms in which Tc-99 and I-129 are present are not strongly sorbed in most sediments so they tend to move to groundwater. Concentrations in excess of 7400 Bq l^{-1} of Tc-99 (more than 100 times permissible limits) have been found in the deep groundwater under waste tanks at the US Department of Energy (DOE) Hanford Site in Richland, WA, USA.

Table 1 Current and projected volumes of various types of nuclear waste in the USA

	Volume of waste ($\times 10^3$ m^3)		
Types of waste	*Year 2000*	*Year 2010*	*Year 2030*
High-level waste			
Commercial-liquid wastes	0.24	0.24	0.24
Commercial-spent fuel	17	24	35
Defense (total)	395	335	346
Transuranic			
Defense/environmental cleanup	275	297	191
Low-level waste			
Commercial	1722	2055	2508
Defense/decommissioning/ cleanup	4707	22 777	36 524
Uranium mill tailings			
Commercial and defense wastes	152 400	155 400	157 400

Radiation Exposures

Figure 3 shows the major pathways through which radioactivity from nuclear sources can affect living organisms. While the impact on the environment has been significant, immediate health effects to the general population have been small. Exposure to materials from the nuclear fuel cycle (including nuclear waste) is less than 0.2% of the total annual radiation dose to the general population. In contrast, dental and medical diagnosis and therapy account for more than 90% of all doses from nonnatural sources. Some occupations and geographic settings expose an individual to a greater-than-average radiation dose. A person living in Denver, CO, USA (1.5 km above sea level) is exposed to nearly twice as much cosmic radiation as a person living at sea level in San Diego, CA, USA. Individuals living in Spokane, WA, USA are exposed to higher concentrations of radon from the soil than those living in Midland, TX, USA. The question for many is that, while radiation doses to the general public are currently small, as nuclear waste discharges continue and dispersal to the environment proceeds, what future risks to the human population can be expected? What are the long-term risks? What can be done to ensure the risks are minimal and that, in the immediate and foreseeable future, the human race is protected against undue and unnecessary health risk from nuclear waste?

Waste Storage and Disposition

Most HLW, including spent fuel rods, and reprocessing wastes are in temporary storage (Table 2). No permanent repository for HLW has been licenced anywhere in the world to date (2004). Spent fuel rods are largely contained at sites near nuclear reactors. These

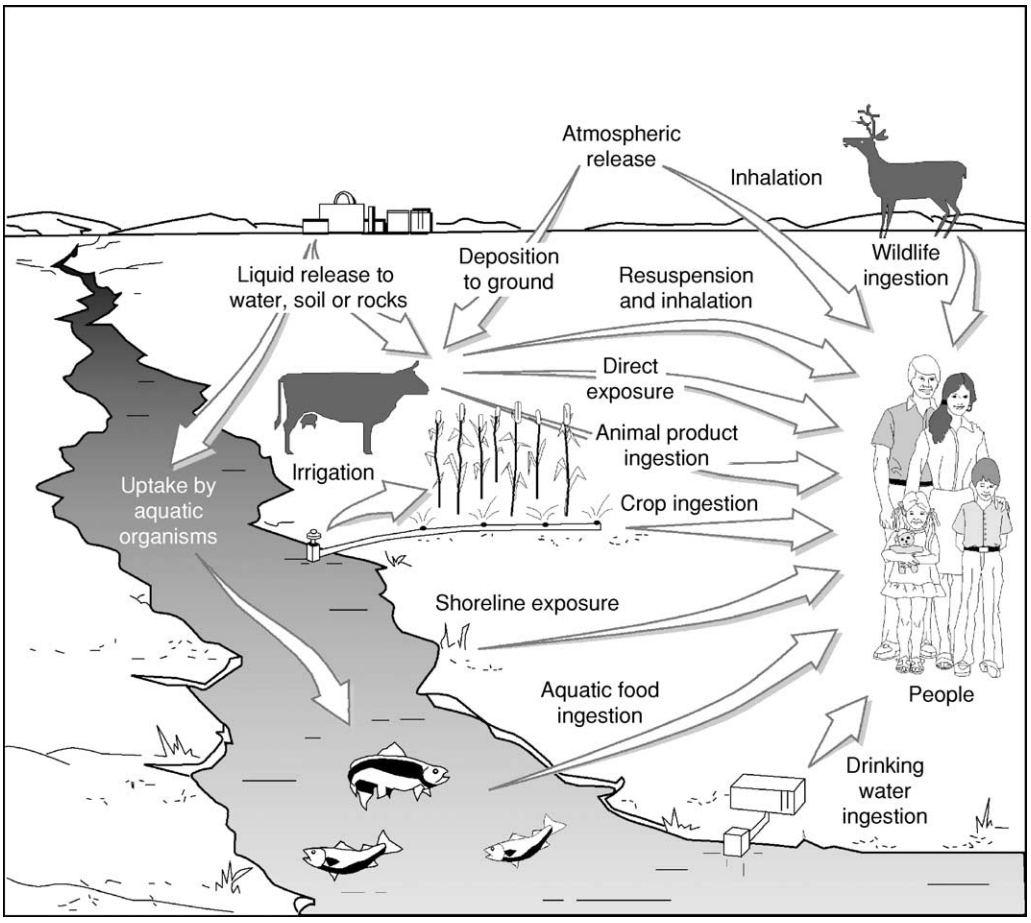

Figure 3 Potential radionuclide pathways from nuclear wastes.

Table 2 High-level waste burial programs in various countries

Country	*Earliest planned year*	*State of program*
Belgium	2020	Underground disposal in clay at Mol, Belgium
Canada	2025	Bury irradiated fuel in granite at yet-to-be identified site
China	Undetermined	Fuel to be reprocessed. Burial planned for Gobi Desert
Finland	2020	Field studies conducted – final site selection not made
France	2010	Two sites selected and studied with final selection in 2006
Germany	2008	Gorleben salt dome site only site studied
India	2010	Fuel to be reprocessed – granite repository to be selected
Italy	2040	Fuel to be reprocessed – storage for 50 years before burial in clay or granite
Japan	2020	Cooperative study at a Chinese research facility
Netherlands	2040	Interim storage for 50 – 100 years before burial sub-seabed or exterior
Russia	Undetermined	Uncertain
Spain	2020	Burial in clay, granite, or salt formation
Sweden	2020	Aspo granite site selected near Oskarshamn nuclear facility
Switzerland	2020	Burial in granite or sedimentary formation to be selected
United States of America	2010	Yucca Mountain – deep vadose zone, federally recommended site
United Kingdom (Great Britain)	2030	Interim storage approved through 2022. Options include sub-seabed burial

fuel rods pose a threat to humanity because they can be reprocessed for plutonium, a key component of nuclear weapons, so permanent disposal is highly desirable. Many billions of dollars have been spent by the US government on characterizing Yucca Mountain as a potential repository for more than $70\,000\,m^{-3}$ of nuclear wastes, including spent fuel rods. The US Department of Energy is currently

proceeding with a license application to store nuclear wastes at the Yucca Mountain site. Should a license be approved, no nuclear waste will be stored there until well after 2010. Issues of transportation, monitoring, and final waste configurations remain to be resolved. In the interim, most of the spent fuel remains in relatively vulnerable locations, often near large urban centers where nuclear terrorism may be difficult to prevent and where consequences of such acts of terrorism could be deadly and have long-range consequences. These issues suggest that action be taken soon to finalize waste repositories at locations that effectively control access to waste, particularly HLW that can be converted into weapons.

After reprocessing wastes are removed from underground storage tanks, some residual contaminants will remain. Several options are being considered for containing the waste and leaving the tanks, contaminated soil, piping, and support structures in place. The following options are being considered:

- Stabilization: tanks would be stabilized to prevent dome collapse by filling with inert material such as bentonite, sand, gravel, cement, or a combination of these materials;
- Immobilization: subsurface injections of either reactive chemicals, to immobilize contaminants and prevent them from moving, or physical barriers (low-permeability grouts, including bentonite and mineral wax), to retard the migration of the contaminants to the water table;
- Decontamination: chemical or mechanical decontamination by using high-pressure water or frozen carbon dioxide blasting, or in-place solvent washes and extractions;
- Flushing: a combination of a subsurface barrier and a soil-flushing treatment where chemicals such as carbonate solutions would extract contaminants. Subsurface barriers made of grout or polymers would minimize the chance of flushing the contaminants and mixing with groundwater;
- *In-situ* vitrification: this process uses heated electrodes to melt the waste in place. The waste and surrounding soil are vitrified (turned into glass) at temperatures exceeding 1500°C and when cooled resemble natural glass obsidian. Volatile organics would be destroyed and heavy-metal contaminants and radionuclides would be physically bound in the glass. This process has been successfully demonstrated for LLW and mixed wastes at a number of locations throughout the world;
- Surface barriers: after the empty tanks are treated in place, aboveground barriers could be placed over the tanks to protect the area against intrusion, wind and water erosion, and net water infiltration. If successful, such efforts would ensure that any residual contaminants not fully treated would tend to remain in the subsurface for thousands of years. Long-term surface barriers (intended to have a lifetime of at least 1000 years) consisting of specially designed soil layers have been tested and show promise for deployment at the Hanford Site in the USA. Figure 4 shows a schematic picture of a backfilled storage tank covered by a 1000-year soil barrier.

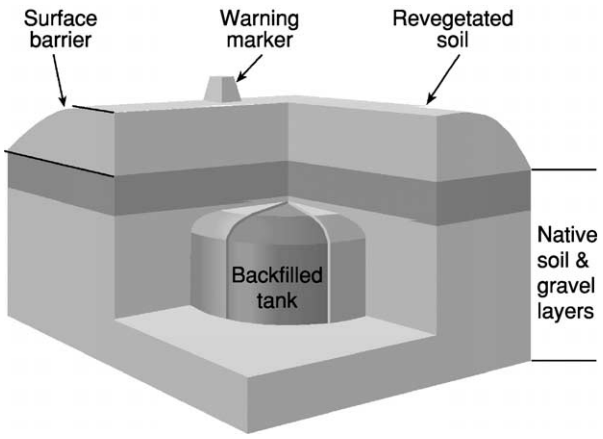

Figure 4 Schematic of a surface barrier consisting of natural earthen materials placed over an evacuated and stabilized high-level waste tank. The surface barrier is designed to last at least 1000 years and protect against plant and animal intrusion, wind and water erosion, and water infiltration.

LLW disposal actions remain site-specific. Under present regulatory guidance, there will be minimal waste treatment, with site closures depending on cover systems that can provide control of erosion, intrusion, and minimization of water invasion into the waste. Longevity for such cover systems remains largely unproven, since most conventional landfill designs are built to last decades not millennia. Efforts to develop innovative and scientifically sound, long-term performance tests are still in their infancy at the beginning of the twenty-first century.

Environmental Uncertainties

One of the characteristics of nuclear wastes is their potential to cause adverse health and environmental effects for many thousands of years. For nuclear waste disposal facilities and sites contaminated with radioactive materials, there is consequently a need to assess safety far into the future. In the USA, regulatory limits for the disposal of HLW and TRU are required to be met over a 10 000-year time period; a 1000-year period is used in analyses for decommissioning nuclear materials sites. Decisions that are intended to apply that far into the future rely, in large part, on models that predict radionuclide

transport in the environment. Because such predictions are inherently uncertain, a variety of strategies have been adopted to provide confidence in decisions about nuclear waste disposal:

- Reliance on natural systems to limit transport (e.g., stable rock formations, arid sites);
- Redundant design of engineered components (to prevent catastrophic behavior if one component fails);
- Site-specific characterization of processes potentially affecting transport (to provide understanding of site behavior and to develop and parameterize models);
- Natural analog studies (e.g., of uranium transport);
- Accelerated degradation studies (e.g., of glass waste forms);
- Peer review;
- Monitoring of site behavior and comparison with model predictions;
- Sensitivity and uncertainty analyses of predictive models.

The extent of analyses conducted to support decisions on nuclear waste disposal varies significantly. In the USA, the disposal of HLW at Yucca Mountain, a remote site in southern Nevada, USA, and the disposal of TRU at the Waste Isolation Pilot Plant have been supported by large budgets, detailed site-characterization studies, complex modeling analyses, and extensive site monitoring. In contrast, decommissioning of nuclear materials sites may rely on very limited, site-specific data and relatively simplified modeling analyses. Regardless of the level of effort, however, predictive modeling of radionuclide transport in soils and sediments plays an important role. Assessing the uncertainty inherent in model predictions supports decision-making by increasing the credibility of the modeling analyses, improving the predictability of consequences, avoiding worst-case assumptions, and focusing data collection on variables most valuable in improving predictions and reducing uncertainty.

The sources of uncertainty that potentially have an impact on predictions of radionuclide transport in the environment are many. In a general sense they arise from:

- Measurement or sampling errors in characterizing the system;
- Spatial and temporal variability in the system's properties;
- Disparity among the scale of the system's features, events, and processes and the scales at which sampling and simulation occur;

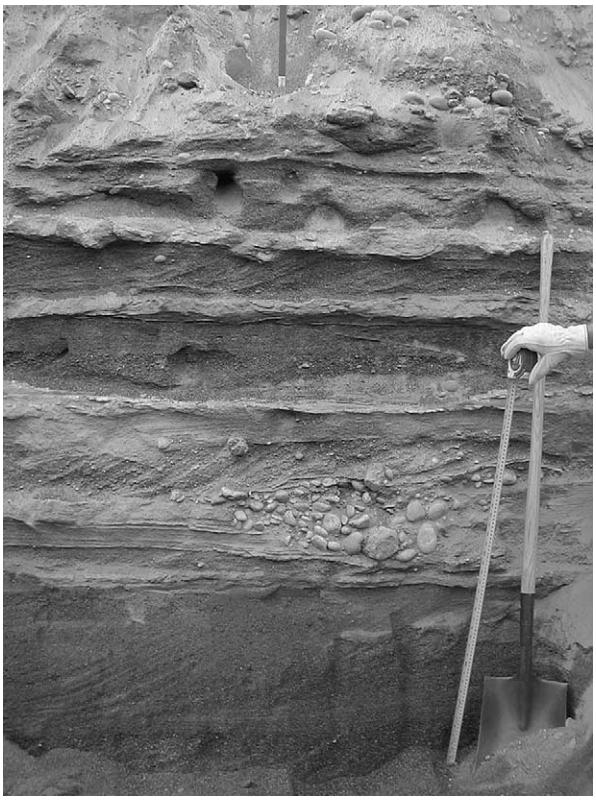

Figure 5 Exposed trench face of layered, heterogeneous sediments in which nuclear wastes are stored at the Hanford Site, Washington state, USA. (Photo courtesy of John Selker, Oregon State University.)

- Randomness in the system's stresses, particularly transient external stresses often occurring over a short period of time (e.g., floods, earthquakes);
- Incomplete knowledge of the system being analyzed (i.e., ignorance of significant features, events, or processes).

The issues of variability and scale are demonstrated in Figure 5, which shows the spatial variability of sediments on a trench face at a location on the Hanford Site (Washington, USA). Fine, silty layers only a few centimeters thick lie between coarse, sand layers with varying amounts of gravel. Parameters describing flow and transport vary over a wide range at this site (by several orders of magnitude in the case of hydraulic conductivity). A small-scale measurement with a sample size of 30 cm or so (such as a neutron-probe measurement of water content) would probably sample over distinctly different materials. In a model, it would not be unlikely that the area of the entire photograph would be represented by a single parameter value. Uncertainty is thus introduced both in the interpretation of measured quantities and in the assignment of parameter values.

Transport of radioactive contaminants through the vadose zone (i.e., the zone between the ground surface and the water table) depends on the magnitude and variability of geochemical and hydrologic parameters. These parameters include particle-size distribution, specific surface area, cation-exchange capacity, chemical retardation factors, water retention, and unsaturated hydraulic conductivity, all of which control fate and transport of chemicals and radionuclides in the vadose zone, and all have significant levels of uncertainty associated with them at a given waste site. For example, understanding how leaks from HLW tanks move through soils presents a formidable challenge. Wastes are often hot, highly saline, and chemically reactive. Waste plume movement is both spatially and temporally affected by geochemical interactions as well as hydrologic controls. Concentrated water flow from water-line leaks and meteorologic sources (winter rains and snowmelt) can cause contaminants to move in preferential flow paths that may accelerate downward movement. On the other hand, horizontal layering of sediments can cause plumes to spread laterally, delaying their arrival at the groundwater table.

In modeling the performance of nuclear waste disposal sites, it is convenient to classify uncertainties into three basic types: scenario uncertainty; model uncertainty; and parameter uncertainty. Scenario uncertainty addresses the possibility that the future state of the system may be significantly different from what is assumed as the initial case. This may be the result of direct human activity (e.g., irrigation or groundwater extraction) or a more natural event (e.g., increased precipitation due to climate change).

Model uncertainty arises when a complex system is conceptualized for the purpose of modeling and when that concept is implemented as a mathematical model for the purpose of prediction. It is frequently the case that multiple conceptual models can be proposed for a single site to explain observed behavior and that site data are insufficient to determine which model best represents reality. An example is the case of flow and transport in the unsaturated zone at the Yucca Mountain site. Understanding of the relative importance of fractures versus the rock matrix in contributing to seepage and radionuclide transport, and the best way to represent the fracture and/or matrix flow and transport processes, has evolved over time in response to improved analyses and additional site data.

Parameter uncertainty addresses our inability to specify precisely the parameters of the models developed to describe flow and transport of radionuclides in the environment. Even if the models are accurate representations of the actual system processes, it is impossible to measure exhaustively the required model parameters due to their spatial andtemporal variability and apparent randomness. Worse yet, the quantities that are often measured are only indirectly related to model parameters and may be on a scale different (either larger or smaller) from the scale of the model parameters. Model calibration (minimizing the difference between observed system behavior and model-predicted behavior by systematically varying parameter values) is an important method to reduce and quantify parameter uncertainty.

Parameter uncertainty is most amenable to characterization using formal probabilistic methods. In soils, this generally means using measured data and/or expert judgment to specify probability distributions for flow and transport characteristics. Because measurement of these characteristics is frequently expensive and time-consuming, more easily measured soil characteristics are often used to infer distributions of the desired parameters. Examples include soil texture measurements, to infer unsaturated hydraulic properties, and soil mineralogy (along with other quantities), to infer chemical effects on radionuclide transport (i.e., adsorption). Model uncertainty is generally quantified by comparing flow and transport results from alternative models, potentially weighting these results by estimates of the relative probability of the models. Scenario uncertainty can be similarly quantified, although in this case it is possible that absolute probabilities of alternative scenarios can be derived (e.g., the probability of a flood occurring in a given time-period).

In relatively extensive studies of uncertainty (such as for Yucca Mountain and the Waste Isolation Pilot Plant), parameter, model, and scenario uncertainties have all been found to contribute significantly to the overall system uncertainty (e.g., uncertainty in the performance of the nuclear waste disposal facilities). In addition, results of the uncertainty analyses have been used to identify model components and parameters that have the greatest impact on system performance. This information has been used to target data collection to provide the greatest reduction in system uncertainty.

Summary

Nuclear waste disposal is a global concern. Discharges to the environment have been significant, with radioactive production and subsequent dispersal of billions of curies. To date these waste inventories have been largely confined to locations near nuclear-production facilities primarily in the USA and FSU. Dispersal from global fallout and from nuclear accidents have produced measurable radiation doses to the global population, but compared with natural

sources have contributed only a small fraction of total annual dose and, as of 2004, do not present a significant health risk to the general public. However, the public needs to be informed of hazards that remain in those areas where soils and waters have been exposed to nuclear waste discharges and remain highly contaminated.

Safe disposal of nuclear waste is a priority among most nations and will continue to be a major expense for those nations involved in past nuclear weapons production or with past and current nuclear-power generation. Treatment, immobilization, and containment are methods that are being proposed to handle nuclear wastes until they decay to harmless levels. Vitrification is an expensive but viable technology for immobilizing high-level radioactive waste, and deep, geologic storage is a scientifically sound method for ensuring long-term public protection. Low-level radioactive waste disposal in shallow landfills, covered by soil covers, is allowed (in 2004) and should be acceptable if longevity of these disposal facilities and their isolation capabilities can be demonstrated. This remains a scientific challenge.

NUTRIENT AVAILABILITY

N K Fageria, EMBRAPA, Santo Antônio de Goiás, GO, Brazil

Introduction

Agricultural production and productivity are directly linked with nutrient availability. For sustained high crop yields, the application of nutrients is required. The term 'nutrient availability' has been used and defined in many ways. Hence, any use of the term needs to be accompanied by an appropriate definition. The Soil Science Society of America has defined available nutrients: (1) the amounts of soil nutrients in chemical forms accessible to plant roots or compounds likely to be convertible to such forms during the growing season, and (2) the contents of legally designated available nutrients in fertilizers determined by specified laboratory procedures which in most states constitute the legal basis for guarantees.

Soil productivity and nutrient availability are interrelated. Soil productivity is the capacity of a soil to produce a certain yield of crops or other plants with a specified system of management. Management of nutrients is an important aspect of maintaining soil productivity. Quantity of nutrient present in the soil is defined in terms of soil fertility, and, generally, soil

analysis is used as a criterion to make fertilizer recommendations for field crops. Nutrient availability is evaluated by observations and tests which are used to predict the response of plants and management of nutrients. The presence of sufficient total quantities of essential nutrients in a soil does not guarantee the availability of these nutrients to growing plants, because other factors such as soil-moisture content, soil temperature, pH, soil physical conditions, presence of toxic elements and/or salts may be limiting. Hence, adequate levels of nutrients alone do not guarantee soil productivity. A productive soil is one that has optimal total environmental conditions for plant growth. Since soil is a continuum, it is a matrix in constant change. It is very difficult under practical conditions to have all crop production factors at an optimal level; hence, most of the crop production factors are usually at a suboptimal level.

In modern agriculture, maximizing and sustaining crop yields are the main objectives. One of the major problems constraining the development of an economically successful agriculture is nutrient deficiency for crop production. As much as 50% of the increase in crop yields worldwide during the twentieth century was due to the adoption of chemical fertilizers. Soil infertility (natural element deficiencies or unavailability) is probably the single most important factor limiting crop yields worldwide.

Essential Nutrients for Plant Growth and Their Functions

The supply and absorption of chemical elements needed for growth and metabolism may be defined as nutrition, and the chemical elements required by an organism are termed 'nutrients.' Sixteen nutrients are essential for plant growth and development. On the basis of quantity required by plants, nutrients are divided into macro and micro groups. The essential nutrients such as carbon (C), hydrogen (H), oxygen (O), nitrogen (N), phosphorus (P), potassium (K), calcium (Ca), magnesium (Mg), and sulfur (S) are known as macronutrients; whereas iron (Fe), manganese (Mn), zinc (Zn), copper (Cu), boron (B), molybdenum (Mo), and chlorine (Cl) are termed micronutrients. Further, the essentiality of silicon (Si), sodium (Na), vanadium (V), and cobalt (Co) has been considered but is not yet proven. Plants obtain C, H, and O from air and water, and the remaining nutrients are absorbed from soil solution as inorganic ions or oxides by growing plant roots. Nutrient absorption by plants is usually referred to as 'ion uptake' or 'ion absorption,' because it is the ionic form in which nutrients are absorbed. Cations and anions may be absorbed independently and may not be absorbed in equal quantities: however, electroneutrality must be maintained in the plant and in the growth medium; therefore, ionic relationship achieves major importance in plant nutrition. The majority of cations in plant tissues are in the inorganic form, predominantly K^+, Ca^{2+}, and Mg^{2+}, and the majority of anions are in the organic form. The organic ions are synthesized within the tissue, while inorganic ions are absorbed from the growth medium. Generally, the monovalent cations are absorbed rapidly, whereas the divalent cations, especially Ca^{2+}, are absorbed more slowly. Similarly, the monovalent anions are generally absorbed more rapidly than polyvalent anions. The so-called physiological acidity or alkalinity of a salt depends upon which ion of the salt, the cation or the anion, is absorbed most rapidly. Thus a salt such as K_2SO_4 would be physiologically acid, since the K would enter the roots more rapidly than the SO_4^{2-}. By the same token, $CaCl_2$ should be physiologically alkaline, since the Ca^{2+} enters slowly and the Cl^- rapidly.

Mineral nutrients can also be absorbed by higher plants when applied as foliar sprays in appropriate concentrations. However, in modern high-yielding cultivars, nutritional requirements (macronutrients) are rarely met with foliar applications. Furthermore, foliar application of macronutrients requires several sprays and can be washed off by rain. The plant needs sufficient leaf area for absorption, and leaf damage by high nutrient concentrations is a serious practical problem. Despite these drawbacks, under some situations foliar application is the most effective method to correct a nutritional disorder. For example, iron deficiency in calcareous soils can be corrected by foliar application of ferrous sulfate solution more efficiently than the soil application of iron sources.

The macro- and micronutrient classification is simply based on the amount required: macronutrients are needed in relatively larger quantities than micronutrients. Each of these essential nutrients performs a specific biophysical or biochemical function within plant cells. Hence all nutrients are equally important for production of higher crop yields. If any one of these nutrients is deficient in the growth medium, plant growth is reduced. The low requirements of plants for micronutrients can be explained by the participation of these elements in enzymatic reactions and as constituents of growth hormones rather than as components of major plant products such as structural and protoplasmic tissue. To obtain higher yields, essential nutrients should be present in adequate concentrations and in available form, as well as in appropriate balance. An imbalance results when one or more nutrients are present in either deficit or excess supply. Table 1 shows forms of absorption and functions of essential plant nutrients.

Table 1 Forms of absorption and functions of essential nutrients in plants

Nutrient	*Forms taken up by plants*	*Functions*
Carbon	CO_2	Basic molecular component of carbohydrates, proteins, lipids, and nucleic acids
Hydrogen	H_2O	Hydrogen plays a central role in plant metabolism. Important in ionic balance and as main reducing agent; plays a key role in energy relations of cells
Oxygen	H_2O, O_2	Oxygen is like carbon in that it occurs in virtually all organic compounds of living organisms
Nitrogen	NH_4^+, NO_3^-	Nitrogen is a component of many important organic compounds ranging from proteins to nucleic acids
Phosphorus	$H_2PO_4^-$, HPO_4^{2-}	Central role in plants in energy transfer and protein metabolism
Potassium	K^+	Helps in osmotic and ionic regulation. Functions as a cofactor or activator for many enzymes of carbohydrate and protein metabolism
Calcium	Ca^{2+}	Calcium is involved in cell division and plays a major role in the maintenance of membrane integrity
Magnesium	Mg^{2+}	Component of chlorophyll and a cofactor for many enzymatic reactions
Sulfur	SO_4^{2-}	Sulfur is like phosphorus in that it is involved in plant cell energetic reactions
Iron	Fe^{2+}, Fe^{3+}	An essential component of many heme and nonheme Fe enzymes and carriers, including the cytochromes (respiratory electron carriers) and the ferredoxins. The latter are involved in key metabolic functions such as N fixation, photosynthesis, and electron transfer
Zinc	Zn^{2+}	Essential component of several dehydrogenases, proteinases, and peptidases, including carbonic anhydrase, alcohol dehydrogenase, glutamic dehydrogenase, and malic dehydrogenase
Manganese	Mn^{2+}	Involved in the O_2-evolving system of photosynthesis; is a component of the enzymes arginase and phosphotransferase
Copper	Cu^{2+}	Constituent of a number of important oxidase enzymes, including cytochrome oxidase, ascorbic acid oxidase, and lactase, and important in photosynthesis, and protein and carbohydrate metabolism
Boron	$B(OH)_3^0$	Activates certain dehydrogenase enzymes, involved in carbohydrate metabolism, synthesis of cell wall components; is essential for cell division and development
Molybdenum	Mo	An essential component of nitrate reductase and N_2-fixation enzymes; is required for normal assimilation of N
Chlorine	Cl^-	Essential for photosynthesis and as an activator of enzymes, involved in splitting water, and functions in osmoregulation of plants growing on saline soils

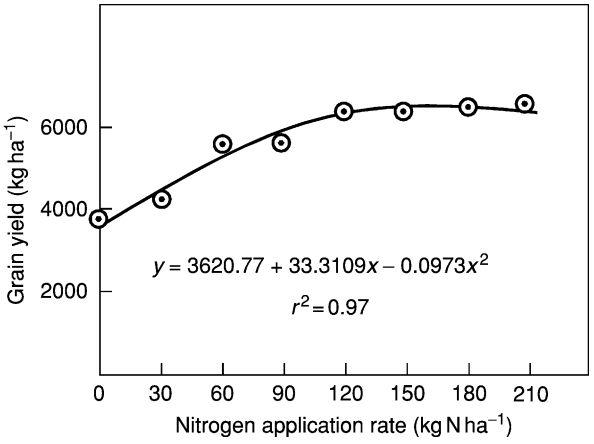

Figure 1 Response of lowland rice to nitrogen fertilization grown on an Inceptisol of central Brazil.

Nutritional disorders (deficiency and/or toxicity) limit crop yields in all types of soils around the world. For example, in Brazilian Oxisols and Inceptisols, deficiency of N, P, K, and Zn limits the yield of almost all field crops. Figure 1 shows the importance of N application in increasing yield of lowland rice grown on a Brazilian Inceptisol. It is clear from Figure 1 that yield of this important field crop increases with increasing levels of N until an adequate level in the soil is achieved. To obtain good yields of crops, nutrient disorders must be corrected. The first step in this direction is to identify the nutritional disorder.

Diagnostic Techniques for Nutrient Availability

Diagnostic techniques for nutrient availability refer to the methods for identifying nutrient deficiencies, toxicities, or imbalances in the soil–plant system. Nutritional deficiency can occur when there is insufficient nutrient in the medium or when it cannot be absorbed and utilized by plants as the result of unfavorable environmental conditions. Table 2 shows soil conditions associated with nutrient deficiencies. Nutritional deficiencies are very common in almost all field crops worldwide. The magnitude varies from crop to crop and region to region. Even some cultivars are more susceptible to nutritional deficiencies than others within a crop species. Four methods assess nutrient availability or sufficiency of mineral nutrients for plant growth: (1) visual symptoms, (2) soil testing, (3) plant analysis, and (4) crop growth response. These four approaches are becoming

Table 2 Soil conditions inducing nutrient deficiencies for crop plants

Nutrient	*Conditions inducing deficiency*
Nitrogen	Excess leaching with heavy rainfall; low organic matter content; burning the crop residue
Phosphorus	Acidic, organic, leached, and calcareous soils; high rate of liming
Potassium	Sandy, organic, leached, and eroded soils; high liming application, intensive cropping system
Calcium	Acidic, alkaline, or sodic soils
Magnesium	Acidic, alkaline, or sodic soils
Sulfur	Low organic matter content of soils; use of N and P fertilizers containing no sulfur; burning the crop residue
Iron	Calcareous soils; soils high in P, Mn, Cu, or Zn; high rate of liming
Zinc	Highly leached acidic soils; calcareous soils; high levels of Ca, Mg, and P
Manganese	High organic matter content; calcareous soils
Copper	Sandy soils; high liming rate in acid soils
Boron	Sandy soils; naturally acidic leached soils; alkaline soils with free lime
Molybdenum	High podzolized soils; well-drained calcareous soils

Table 3 Nutrient-deficiency symptoms in field crops

Nutrient	*Symptoms*
N	Chlorosis starts in old leaves; in cereals tillering is reduced; under field conditions, if deficiency is severe, whole crop appears yellowish and growth is stunted
P	Growth is stunted; purple–orange color of older leaves; new leaves dark green; in cereals tillering is drastically reduced
K	Older leaves may show spots or marginal burn starting from tips; increased susceptibility to diseases, drought, and cold injury
Ca	New leaves become white; growing points die and curl
Mg	Marginal or interveinal chlorosis with pinkish color of older leaves; sometimes leaf-rolling, like drought effect; plants susceptible to winter injury
S	Chlorosis of younger leaves; under severe deficiency whole plant becomes chlorotic and similar to appearance in N deficiency
Zn	Rusting in strip of older leaves with chlorosis in fully matured leaves; leaf size is reduced
Fe	Interveinal chlorosis of younger leaves; under severe deficiency whole leaf becomes first yellow and finally white
Mn	Similar to iron deficiency; at advanced stage necrosis develops instead of white color
Cu	Chlorosis of young leaves, rolling, and dieback
Mo	Mottled pale appearance in young leaves; bleaching and withering of leaves
B	Pale green tips of blades, bronze tints; death of growing points

widely used separately or collectively as nutrient-availability, -deficiency or -sufficiency diagnostic aids. They are extremely helpful, yet are not without limitations.

Visual Symptoms

When the supply of a particular nutrient is at an inadequate level in the soil or when plant roots are not able to absorb required amounts, owing to unfavorable conditions in the rhizosphere, plants show certain growth disorders. These disorders may be expressed in reduced height, reduced tillering in cereals, leaf discoloration, reduced root growth, and reduced growth of newly emerging parts of the plant. Table 3 summarizes the symptoms of nutritional deficiency in crop plants. Using visual symptoms is the cheapest method of diagnosis for nutritional disorders. However, this technique needs a lot of experience on the part of the observer, because deficiency symptoms can be confused with problems caused by drought, insect and disease infestation, herbicide damage, soil salinity, soil acidity and inadequate drainage. Sometimes, a plant may be on the borderline with respect to deficiency and adequacy of a given nutrient. In this situation there are no visual symptoms, but the plant is not producing at its capacity. This condition is frequently called 'hidden hunger.'

Deficiency symptoms normally occur over an area and not on an individual plant. If a symptom is found on a single plant, it may be due to disease or insect injury or a genetic variation. Also, the earlier symptoms are often more useful than late, mature symptoms. Some nutrients are relatively immobile in the plant, while others are more mobile. In general, deficiency symptoms caused by immobile nutrients first appear on the younger or upper leaves. The older leaves don't show any symptoms because immobile nutrients do not move or translocate from older to newer leaves. Immobile nutrients are Ca, Zn, B, Cu, Fe, Mn, and Mo.

In contrast, when there is a deficiency of a mobile nutrient, the symptoms first appear on the older leaves of the plant. This is because the mobile nutrients move out of the older leaves to the younger part of the plant. The mobile nutrients are N, P, K, and Mg. S may behave as a mobile or an immobile nutrient. However, in rice plants S deficiency first appears in younger leaves.

The use of visible symptoms has the advantage of direct field application without the need of costly equipment or laboratory support services, as is the case with soil and plant analysis. A disadvantage is that sometimes it is too late to correct deficiency of a given nutrient, because for some disorders considerable yield loss may have already occurred by the time visible symptoms appear.

Soil Testing

In a broad sense, soil testing is any chemical or physical measurement that is made on a soil. The main objective of soil testing is to measure soil nutrient status and lime requirements in order to make fertilizer and lime recommendations for profitable farming. Soil testing is an important tool in high-yield farming but produces best results only when used in conjunction with other good farming practices:

> There is good evidence that the competent use of soil tests can make a valuable contribution to the more intelligent management of the soil

This statement was made by the US National Soil Test Workgroup in its 1951 report and is still applicable today.

Soil testing involves collecting soil samples, preparation for analysis, chemical or physical analysis, interpretation of analysis results, and finally making fertilizer and lime recommendations for the crops.

The use of soil analysis as a fertilizer recommendation method is based on the existence of a functional relationship between the amount of nutrient extracted from the soil by chemical methods and crop yield. When a soil analysis test shows low levels of a particular nutrient in a given soil, application of that nutrient is expected to increase crop yield. Generally, nutrient analysis is arbitrarily classified as very low, low, adequate, high, and excessive. At very low nutrient levels, relative crop yield is expected to be less than 70% and a larger application of fertilizer for soil-building purposes is required. After the application of the nutrient, growth response is expected to be dramatic and profitable. At the low fertility level, relative yield is expected to be 70–90%. Under these conditions, annual application of fertilizer is necessary to produce maximum response and increase soil fertility. The increased yield justifies the cost of fertilization. When soil analysis testing shows adequate levels, relative crop yield under this situation is expected to be 90–100%. Normal annual applications to produce maximum yields are recommended. In this case more fertilizer may increase yields slightly, but the added yield would not pay back the expense of the additional fertilizer. At high levels of nutrient, there is no increase in yield, but small applications of fertilizer maintain soil level. The recommended amount may be doubled and applied in alternative years. When soil testing shows very high or excessive nutrient levels, yield may be reduced due to toxicity or imbalances of nutrients. In this situation there is no need to apply nutrient until the level drops back into the low range. To get such a nutrient level and yield relationship, it is necessary to conduct fertilizer yield trials in several locations in a given agroecologic region for different crops. Some specific recommendations for soil analysis are summarized here:

1. Soil samples must be representative of the land area in question. The recommendation is to take a minimum of one composite sample per 12–15 ha for lime and fertilizer evaluations. A representative soil sample is composed of 15–20 subsamples from a uniform field with no major variation in slope, drainage, or past fertilizer history. Any of these listed factors, if changed, will have an effect on the number of samples and unit area from which the sample is obtained;
2. Depth of sampling for mobile nutrients such as N should be 60 cm and, for immobile nutrients such as P, K, Ca, and Mg, 15–20 cm. For pasture crops, a sampling depth of 10 cm is normally sufficient to evaluate nutrient status and make liming and fertilizer recommendations;
3. The appropriate extractor must be selected. Three extracting solutions, $0.05\,\mathrm{mol\,l^{-1}}$ HCl + $0.025\,\mathrm{mol\,l^{-1}}$ H_2SO_4 (Mehlich 1), $0.03\,\mathrm{mol\,l^{-1}}$ $NH_4F + 0.025\,\mathrm{mol\,l^{-1}}$ HCl (Bray-P1), and $0.5\,\mathrm{mol\,l^{-1}}$ $NaHCO_3$ at pH 8.5 (Olsen) are the most commonly used extractants for P at the present time and are generally adequate to cover a broad range of soils. Commonly used extractants for K, Ca, and Mg are double acid (Mehlich 1), $1\,\mathrm{mol\,l^{-1}}$ NH_4Ac at pH 7, and NaOAc at pH 4.8. Multielement extracting reagents are replacing the more familiar, single-element extractants. After mixing with an appropriate aliquot of soil, the obtained extract is assayed by an inductively coupled plasma emission spectrometer (ICP-AES). A flow-injection analyzer (FIA) is another multielement analyzer capable of assaying these soil extracts;
4. Optimum soil test values for macro- and micronutrients, which vary from soil to soil, crop to crop, and extraction to extraction, are required. They are usually approximately greater than $10\,\mathrm{mg\,P\,kg^{-1}}$, greater than $50\,\mathrm{mg\,K\,kg^{-1}}$, greater than $600\,\mathrm{mg\,Ca\,kg^{-1}}$, greater than $120\,\mathrm{mg\,Mg\,kg^{-1}}$, and greater than $12\,\mathrm{mg\,S\,kg^{-1}}$ for producing satisfactory results for most soils and crops. For micronutrients, the critical values reported are: Fe, 2.5–5 $\mathrm{mg\,kg^{-1}}$; Mn, 4–8 $\mathrm{mg\,kg^{-1}}$; Zn, 0.8–3 $\mathrm{mg\,kg^{-1}}$; B, 0.1–2 $\mathrm{mg\,kg^{-1}}$, Cu, 0.5–2 $\mathrm{mg\,kg^{-1}}$, and Mo, 0.2–0.5 $\mathrm{mg\,kg^{-1}}$, respectively;
5. pH values should be ascertained; the pH of agricultural soils is in the range of 4–9. It is difficult to define optimum pH values of different plant species. Most food crops grow well in acid soils of pH approximately 6. Lime is called the foundation of crop production or 'workhorse' in acid soils;
6. Fertilizer field trials establish nutrient requirement and are the most important part of the overall

diagnostic process of a nutrient disorder, whereby the full interplay of soil, plant, climate, and management factors can occur.

Plant Analysis

Plant analysis is based on the concept that the concentration of an essential element in a plant or part of a plant indicates the soil's ability to supply that nutrient. This means it is directly related to the quantity in the soil that is available to the plant. For annual crops, the primary objective of plant analysis is to identify nutritional problems or to determine or monitor the nutrient status during the growing season. If deficiency is identified early in the growth stage of a crop, it is possible to correct it during the current season. Otherwise, steps should be taken to correct it in the next crop. Plant analysis can be useful for the prediction of nutrient needs in perennial crops, usually for the year following the time of sampling and analysis. Like soil analysis, plant analysis also involves plant sampling, plant tissue preparation, analysis, and interpretation of analytical results. All these steps are important for a meaningful plant analysis program.

Many factors such as soil, climate, plant species, and their interactions affect absorption of nutrients by growing plants. However, the concentrations of the essential nutrients are maintained within rather narrow limits in plant tissues. Such consistency is thought to arise from the operation of delicate feedback systems, which enable plants to respond in a homeostatic fashion to environmental fluctuations. Table 4 shows average adequate concentrations for essential nutrients in important field crops. No doubt these values vary with soil, climate, crops, and management practice, and it is very difficult or not logical to make generalizations. Generalized values (Table 4) do give the reader some idea about what adequate levels of nutrients are in crop plants.

For the interpretation of plant analysis results, a critical nutrient concentration concept has been developed. This concept is widely used in the interpretation of plant analysis results for diagnosing nutritional disorders. Critical nutrient concentration is usually designated as a single point within the bend of the curve when crop yield is plotted against nutrient concentration where the plant nutrient status shifts from deficient to adequate. The critical nutrient concentration has been defined in several ways: (1) the concentration that is just deficient for maximum growth; (2) the point where growth is 10% less than the maximum; (3) the concentration where plant growth begins to decrease; and (4) the lowest amount of element in the plant accompanying the highest yield. The above definitions are similar, but not identical. It is well known that there is a good relationship between concentration of a nutrient and yield of a given crop. This is shown in Figures 2 and 3, which show a highly significant correlation ($R^2 = 0.94$ and $R^2 = 0.78$) between N in lowland rice plants (*Oryza sativa* L.) and average yields of lowland rice from three field experiments in the central part of Brazil. Similarly, N uptake (N concentration × dry weight) in shoots as well as in grain has a significant quadratic relationship with shoots as well as grain yield in lowland rice (Figures 4 and 5). In addition to the critical nutrient-concentration approach, tissue

Table 4 Average concentration of essential nutrients in dry matter sufficient for adequate growth of field crops[a]

	Concentration	
Nutrient	*g kg^{-1} or mg kg^{-1}*	*μmol g^{-1}*
Carbon	450	37 500
Oxygen	450	28 125
Hydrogen	60	60 000
Nitrogen	14	1 000

nutrient status can also be diagnosed by the diagnosis and recommendation integrated system (DRIS) and composition nutrient diagnosis (CND).

Nutrient concentrations in plant are generally expressed in milligrams per kilogram or grams per kilogram. Sometimes there is confusion between concentration and accumulation. Concentration is content per unit dry weight of plant tissue, whereas accumulation is concentration multiplied by dry matter. Nutrient accumulation is generally expressed in kilograms per hectare. Table 5 shows nutrient accumulation by important field crops. Nutrient accumulation is related to crop yield and crop species. Nitrogen and potassium are accumulated in higher quantities as compared to P, Mg, and S. Uptake and absorption are also very common in expressing plant analysis results. Uptake or absorption normally refers to the process of elemental movement into and within plants and not to quantitative-based terms such as concentration or total accumulation.

Data related to the quantity of nutrients accumulated during a cropping season give an idea of fertility depletion and help in managing soil fertility for the succeeding crops. The best time to determine nutrient accumulation is at flowering or at harvest, when

Table 6 Methods of correcting nutrient deficiency and Al and Mn toxicity

Nutrient/element	*Corrective measures*
Nitrogen	Addition of organic matter to the soil; application of N fertilizers, including legumes in the crop rotation; use of foliar spray of 0.25–0.5% solution of urea
Phosphorus	Adjustment of extreme pH; application of phosphorus fertilizers
Potassium	Application of potassium fertilizers, incorporation of crop residues
Calcium	Liming of acid soils; addition of gypsum or other soluble calcium source where lime is not needed; foliar spray in acute cases with 0.75–1% calcium nitrate solution
Magnesium	Application of dolomitic limestone; foliar application of 2% magnesium sulfate solution
Sulfur	Use of fertilizer salt containing sulfur such as ammonium sulfate and single superphosphate; application of gypsum or elemental sulfur
Zinc	Addition of zinc sulfate to soil; foliar spray of 0.1–0.5% solution of zinc sulfate
Iron	Foliar spray of 2% iron sulfate or 0.02–0.05% solution of iron chelate; use of efficient cultivars
Copper	Soil application of copper source of fertilizer or foliar spray of 0.1–0.2% solution of copper sulfate
Boron	Soil application of boron source or foliar spray of 0.1–0.25% solution of borox
Molybdenum	Liming of acid soils, soil application of sodium or ammonium molybdate; foliar spray of 0.07–0.1% solution of ammonium molybdate
Manganese	Foliar application of 0.1% solution of manganese sulfate
Aluminum/ manganese	Application of lime; use of tolerant species or cultivars

accumulation is expected to be maximum. Grains as well as straw should be analyzed and their weights per unit area determined to calculate total accumulation.

Crop Growth Response

Soil and plant analyses are the common practices for identifying nutritional deficiencies in crop production. The best criterion, however, for diagnosing nutritional deficiencies in annual crops is through evaluating crop responses to applied nutrients. If a given crop responds to an applied nutrient in a given soil, this means that the nutrient is deficient for that crop. Relative decrease in yield in the absence of a nutrient, as compared to an adequate soil fertility level, can give an idea of the magnitude of nutrient deficiency. For example, research conducted on Oxisols of central Brazil provides evidence of which major nutrient is most limiting for upland rice, common bean, corn, soybean, and wheat. The conclusion was that P deficiency was the primary yield-limiting nutrient for annual crop production. Methods for correcting nutrient deficiencies and AL and Mn toxicities are summarized in Table 6.

Summary

Soil is our most precious nonrenewable resource in food production. In the long run we must make sure that the productivity of the soil is maintained or improved. Maintaining adequate level of nutrients is one way to achieve this objective. Historically, the study of soil fertility has focused on managing soil nutrient status to create optimal conditions for plant growth. The amount and availability of soil nutrients are determined by physical, chemical, and biological processes, which are often managed in an attempt to increase or optimize uptake of nutrients and yields. There are 16 essential nutrients for plant growth and their presence in the soil at an adequate level and proportion is fundamental for obtaining higher yields. The important criteria in evaluating nutrient availability or deficiency or sufficiency are visual symptoms, soil testing, plant tissue testing, and crop response to applied nutrients. Soil testing is generally recognized as the best available method for diagnosing soil nutrient limitations before a crop is planted so that correction can be made in that year by appropriate fertilization.

Soil fertility is measured in terms of quantity of available nutrient in a given soil. However, plant nutrition involves transport of nutrients from soil to plant roots, absorption by roots, translocation from absorbing site to various parts of the plants, and finally utilization in the growth and development processes of plants. This means it is a very dynamic process and influenced by soil, climate, and plant factors. A thorough knowledge of these factors is essential to understand properly the subject of mineral nutrition of plants.

Integrated nutrient management systems should be used to improve the overall nutrient availability and use efficiency by crops. Successful application of many practices which are part of the integrated nutrient management can increase the profitability and minimize the environmental impacts of nutrient use, the fundamental goal of supplying adequate amounts of nutrients in appropriate proportions for higher yields.

NUTRIENT MANAGEMENT

G D Binford, University of Delaware, Newark, DE, USA

Introduction

The management of nutrients in soils is important for both economic and environmental reasons. Plants require certain amounts of each essential nutrient to maintain optimum health. During the production of crops, it is important to have enough of each nutrient present in the soil to optimize productivity and maximize profitability. These nutrients come primarily from native soil minerals, the application of fertilizers, nitrogen fixation, or the application of animal manures. Although these nutrients are essential for optimum plant growth and crop production, it is important from an environmental standpoint that these nutrients are not applied in excess of what is required by the plant. When excessive amounts of nutrients, primarily nitrogen (N) and phosphorus (P), are applied to the soil, these nutrients can leak from the soil and move into nearby water supplies. As surface waters increase in concentrations of N and P, these increases can result in accelerated growth of water plants. An overabundance of plants growing in the water can result in a process known as eutrophication, which can be detrimental to the overall health of the water ecosystem. Excess N, as nitrate, can also leak from soils and get into groundwater supplies, which can be a concern for both human and animal health.

The potential for losses of nutrients is especially great in areas with intensive concentrations of animals, because the animal wastes from these facilities contain significant quantities of nutrients. As a result, proper nutrient management is an especially major concern in areas with large animal production facilities. These animal wastes are usually land applied to provide nutrients for the crops to be grown on the land. These wastes, however, often contain a higher P:N ratio than the ratio needed by the crop. In addition, because N is often needed in relatively high amounts for crops such as corn, when these manures are applied to meet the N demands of the crop, the amount of P applied is much greater than that required by the crop. As a result, after decades of similar applications, P concentrations in soils become quite excessive. Research has shown that, when P concentrations of soils reach a certain level, the risk of P loss from the soil to nearby water supplies greatly increases.

Losses of nutrients are not only confined to operations with intensive livestock operations. In fact, nutrients can be lost from any soil when nutrients are present at levels greater than growing plants can utilize and/or the soil can hold. This can occur on farms, golf courses, lawns, or any other place nutrients are applied to soils. Also, poor application techniques can lead to nutrient losses from soils. For example, nutrients that are applied accidentally to impervious surfaces such as roads or sidewalks will most likely be lost in runoff and could impact surface-water quality.

In recent years, the concept of nutrient-management planning has been promoted as a practice that will help prevent overapplication and improper application of nutrients to the land. The primary goals of nutrient-management planning are to maximize profitability of crop production and to prevent a buildup of excess nutrients on the land, thereby reducing the potential for nutrient losses from land to water.

Nutrient-Management Planning

There is a specific process that is typically followed in the development of a sound nutrient-management plan. It is important that a nutrient-management plan be developed by someone who understands both soil and crop sciences, so that both an environmentally sound and an economically feasible nutrient-management plan can be prepared. The process of developing a nutrient-management plan can be broken down into several steps. These steps include:

1. Development of a map for the operation;
2. Determination of crop or plant nutrient requirements;
3. Inventory of nutrient production on the operation;
4. Determination of nutrient balance on the operation;
5. Emergency action plan;
6. Record keeping.

Step 1: Creating Maps

Detailed maps of the operation are developed and these maps include:

1. Identification of property boundaries;
2. Identification of field boundaries with field identification codes;
3. Location of any areas sensitive to nutrient loading, such as surface waters or wellheads;
4. Direction of flow for any streams on the property;
5. Identification of all soil types where nutrients are applied;
6. If present, location of animal production facilities;
7. Location of nutrient storage (fertilizer and/or manure);
8. Location of roads, neighboring homes, or public facilities.

These detailed maps are important for understanding the layout of the operation; they can be used to guide nutrient applications near areas that are critical to nutrient loading such as surface waters. If necessary, these maps can also be used as a guide to limit applications of animal wastes near public roads, neighboring homes, or areas of public gatherings. The maps with field identification codes are also helpful to the person implementing the plan so that the appropriate nutrient recommendation can be applied to the corresponding area of the field. Maps can be drawn by hand, with computer software, or created from aerial photographs.

Step 2: Nutrients Required by Crops or Plants

Identifying which nutrients are required includes:

1. Determining the crop rotation or plants to be grown on the facility;
2. Determining crop/plant nutrient requirements;
3. Soil testing and/or plant analysis;
4. Nutrient credits for animal waste applications, if applicable;
5. Nitrogen credits for previous legume crops, if applicable;
6. Nitrogen credits for nitrate in irrigation waters, if applicable.

The first step in determining plant nutrient requirements is deciding on what type of crop or plants will be grown and the rotation of crops or plants for the period of the nutrient-management plan. After this decision has been made, a determination of the required nutrients is needed. The primary procedure for making this determination in most situations is by soil testing.

Soil testing is the best method available for determining how much nutrient is needed for optimum production of most crops. For some crops, the use of plant analysis may be the preferred method of determining crop nutrient needs. Making nutrient-application decisions without soil testing or plant analysis can be a risky endeavor because this will probably result in reduced profitability from either under- or overapplying nutrients; in addition, overapplication of nutrients can result in reduced water quality. It is important to follow recommended procedures for taking soil and plant samples.

When making N recommendations for many crops, the determining factor on how much N to apply is based on the expected yield of the crop. The best method for determining expected yield is from previous yield records. It is important to use an expected yield that is realistic, because if an expected yield is used that is much greater than can be achieved realistically then more nutrient will be applied than the crop can utilize. Applying excess nutrient increases the risk of nutrients getting into nearby water supplies and jeopardizing water quality. At the same time, using an expected yield that is too low can limit yields due to nutrient deficiencies, which reduces profitability of crop production.

Once the recommended rate of fertilizer has been determined, it is important to make any adjustments in the recommended rate for nutrient credits from animal wastes, previous legume crops, and N that is present in irrigation water. These credits can be determined for animal wastes by having a nutrient analysis done by a laboratory. Quantification of nitrates in irrigation water can also be determined by a laboratory. Credits for previous legume crops are usually standard values that have been determined by crop-management and soil-fertility research.

Because a nutrient-management plan is typically written to make fertilizer recommendations for all crops throughout the rotation, it is important to estimate the amount of nutrients that will be removed when a crop is harvested. Estimating the amounts of nutrient removed from the soil by a crop will usually be necessary for making appropriate fertilizer recommendations for subsequent crops in the rotation, unless soil samples are taken for each crop. Typically, soil samples for soil testing are taken every 2–3 years depending on the rotation and soil type. In some situations, a crop grower will apply enough nutrients (i.e., nonmobile nutrients) to meet the nutrient requirements of the current crop and the subsequent crop, which reduces application costs. An example of this practice would be a corn–soybean rotation, where a grower may often apply enough P and potassium (K) to the corn crop so that this application not only meets the requirements of the corn crop but also meets the P and K requirements of the following soybean crop.

Step 3: Inventory of Available Nutrients on the Operation

It is only necessary to make an inventory of available nutrients for operations that have animals and are producing animal waste; if no animals are present, then this step will not be needed. If an operation has no animals, such as a golf course or a grain production farm, then there are no nutrients (i.e., animal waste) being generated on the operation, so all nutrient needs on an operation of this type are fulfilled by importing nutrients to the operation. If animals are present on the operation, then it is important to determine quantities of nutrients (i.e., waste) being generated on the operation so that these nutrients can be utilized most appropriately so that potential losses of these nutrients to the environment are minimized and the economic value of these nutrients is maximized.

The first phase in determining nutrient inventory is to determine how much animal waste is being produced on the operation. If there are no records from past animal waste production from the operation, it is necessary to use average animal waste production values for the development of the nutrient-management plan. These average production values have been generated from previous research and can be found through most University/Cooperative Extension programs. To improve the accuracy of determining the amount of animal waste being generated on an operation, records can be kept on the amount of manure that is removed from the operation. These amounts can be determined by weighing each load of animal waste as it leaves the animal production facility or by determining the volume of animal waste as it leaves the facility and then converting this volume to an estimated weight. Actual measurements from the animal operation would be the most accurate and reliable method for determining nutrient inventory on an animal operation, as compared to just using established book (i.e., average) values.

In addition to determining the quantity of animal waste being produced, the nutrient content of the animal waste should be determined. This can be done by sending a representative sample of the animal waste to a laboratory for analysis. It is important to make sure a representative sample is taken and also that the sample is handled properly before sending to the laboratory. The laboratory should be able to provide details on the proper procedure for taking a representative sample of animal waste; procedures vary depending on the type of animal waste being sampled. It is also possible to obtain average book values for the nutrient content of animal wastes; however, laboratory analyses provide a better determination for each specific animal operation than an average book value.

It is important to remember when calculating the amount of available nutrient present on the operation that the availability of N in animal manures will be dependent on how the manure is handled before and during application. For example, significantly less N will probably be available for future crops when manure is applied on the soil surface and not incorporated compared with manure that is applied and

incorporated immediately; this is because of potential volatilization of N from the nonincorporated manure. General guidelines have been developed for determining the amount of N that is potentially available to crops after the manure has been field-applied. It is important to remember that these are just guidelines and that weather conditions have a major impact on the amount of N that is potentially available to subsequent crops. Because of this potential variability in the amount of plant-available N that is present from field-applied manures, it is advisable to use diagnostic tools (e.g., the pre-sidedress soil nitrate test or PSNT, plant tissue analyses, and chlorophyll meters) to monitor the N status of the growing crop when deciding how much additional N to apply as fertilizer to the growing crop. The use of such tools helps to reduce excess applications of N, which reduce profitability and increase potential environmental harm.

Step 4: Nutrient Balance

As in the previous step, balancing of nutrients is only needed if animals are present on the operation. If no animals are present, then this step is also unnecessary. After determining the quantity of nutrients needed by the planned crop rotation through proper soil testing and the quantity of nutrients that are being produced from the animal production facility, the next step is to evaluate the nutrient balance. The main question that has to be answered before the nutrient balance can be calculated is to determine whether the nutrient management plan will be an N- or P-based plan. In some situations, it may be appropriate to have a metals-based plan. In other words, the animal waste is applied based on the metal content of the waste. In the development of the plan, it is necessary to assess each management area (i.e., area from which the soil sample is taken) for its nutrient needs and whether that area will require an N-based or P-based plan.

Historically on many operations, animal waste has been applied at rates to meet the N demands of the crop or at even higher rates in situations where the waste has been considered a disposable by-product of the animal production facility. In recent years, the concept of P-based planning has become popular. This popularity in P-based planning has resulted from areas where animal wastes have been applied at P rates much greater than the amounts of P removed in the harvested portion of the crop. As a result, after decades of this practice, soil-test P levels have increased to levels that are considered a potential threat for off-site movement of P into nearby water supplies.

Before deciding whether a P-based plan should be used, the criteria to be used to define when the risk of P loss warrants the use of P-based planning instead of N-based planning must be determined. Simply defining a soil-test level that is considered too high is one method; however, a method usually referred to as a P site index probably makes more sense and would be more representative of P-loss potential from a soil. There is currently a great deal of research being conducted on the development of an appropriate P site index. It is important that a P site index be adapted and developed for local conditions. A P site index evaluates all aspects of potential P transport from soil to water and not just the current level of P in the soil (i.e., soil test P). A P site index provides a relative risk of P loss from a soil and takes into account such things as soil erosion potential, distance from water, P loading rates, soil-test P, and subsurface drainage.

A farm balance of nutrients can be determined after a decision has been made on which areas will need a P-based plan and which areas will need an N-based plan. The total nutrient requirements of the crops to be grown can be calculated by summing the total nutrient needs of each area that was soil-sampled. The difference between the total supplies of nutrients produced by the animal operation can then be compared with the total nutrient needs of the crops to be grown. If an excess of nutrients (i.e., animal waste) is available on the operation, an alternative plan should be developed for transporting the excess animal waste from the operation. It is also important to consider when the animal waste will be removed from the animal production facility and when it will be applied to the land or removed from the operation so that appropriate storage can be planned.

It is likely that significant future improvements in nutrient farm balances can be achieved through diet modifications of livestock. Currently, many livestock operations are adding P to animal diets at rates greater than needed for optimal animal health. As a result, much of this added P ends up in the manure and has to be land-applied. New technologies in diet formulations and animal genetics also offer opportunities for reducing the P content of animal manures. For example, recent work in Delaware and Maryland, USA, has shown that significant reductions can occur in the P content of poultry manure by utilizing phytase enzyme and low-phytate corn in the feed ration of the birds. In fact, it is possible that future use of these new technologies and with improved feed management the ratio of P:N in animal manures could be much more in balance with the ratio of P:N that is needed by crops. This would allow manures to be applied at rates equal to the amount of nutrient that will be removed by the crop, which would eliminate nutrient buildup in

soils, thereby, reducing the potential for nutrient losses from land to water.

Step 5: Emergency Action Plan

As a part of the overall nutrient-management plan, it is important to have a planned course of action in the event of a nutrient spill during transport or storage. This action plan should be in place for either manure or fertilizer that is collected, stored, transferred, or applied on the operation. This emergency plan should include telephone numbers for reporting a spill and for seeking assistance. The plan should also show anticipated flow paths in the event of a spill or discharge of nutrients. To be most helpful as a part of this action plan, the anticipated flow path should be shown on the overall site map of the operation.

Step 6: Record Keeping

Maintaining detailed records is an important part of having a useful nutrient-management plan. Development of future nutrient-management plans is improved and less time-consuming if detailed records are maintained concerning the operation. Detailed records also provide documentation on procedures used on the operation, which could be helpful should the need arise to prove activities used on the operation. Many of the needed records for determining animal waste production may not be available the first time a nutrient-management plan is written, which will require the use of average book values. Future nutrient-management planning, however, will be made easier and more site-specific if on-site records are available from the operation.

The end result of nutrient-management planning is the same result of any planning process. It does not matter if we are talking about a business plan, a financial plan, or a nutrient-management plan: the more time and effort put into the planning process, the better the results. A well-written and detailed nutrient-management plan should result in an improved efficiency of nutrient use. This improved efficiency should result in an operation that has increased potential profitability and decreased potential damage to the environment.

Summary

Nutrient management planning offers a systematic process for determining amounts of nutrients produced (i.e., animal wastes) and amounts of nutrients needed for optimal plant growth. Any operation that applies nutrients to land should have a nutrient-management plan prepared by an individual with a sound understanding of plant and soil sciences. There are six basic steps to follow when developing a nutrient management plan; however, the details involved with each step will vay depending on the type of operation. It is important to remember that, for normal growth and development, plants must acquire nutrients from soils through root uptake. Therefore, if soil testing indicates a need for nutrients, then nutrients must be added to the soil to support optimal plant growth. Nonetheless, if too much nutrient is applied to land, these excess nutrients can leak from soils and result in water-quality concerns. Therefore, the overall goal of sound nutrient management is to optimize plant health, while minimizing environmental harm.

ORGANIC FARMING

C A Francis, University of Nebraska, Lincoln, NE, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

One of the most rapidly growing sectors of the food industry is organic products, in both the USA and Europe. Market share in 2002 was 2% in the USA and up to 5% in other countries. In part this growth is due to increasing concern in the general consumer population about the amounts of chemical pesticides that may be carried over from field production on the surface of fruits and vegetables and eventually find their way into the human food chain. Another concern comes from a recent series of outbreaks of foot and mouth disease, as well as bovine spongiform encephalitis in domestic animals in northern Europe, events that have caused many to begin buying meat from animals produced using organic methods. There are ambitious national goals in Europe to make 10–20% of all agriculture organic and/or ecologic before 2012.

Organic farming is defined as production of crop, animal, and other products without the use of synthetic chemical fertilizers and pesticides, transgenic species, or antibiotics and growth-enhancing steroids, or other chemicals. This is called 'ecological farming' in some northern European countries. It involves a philosophy of improving soil fertility, protecting crop plants and animals through natural methods and system design, maintaining the rural environment as a desirable place to live, and showing concern for the distribution of benefits from agriculture and the food system. In a sense, organic farming is an ancient art that evolved with the first farmers and dominated food production up until approximately 100 years ago. Before that, fossil fuel-derived pesticides or fertilizers were not available, and food was produced essentially by organic methods in most of the world. The landmark book *Farmers of Forty Centuries*, by F.H. King of the US Department of Agriculture, describes the systems used in China, Korea, and Japan, and these would qualify today as organic production systems. What we today call 'organic farming' has its roots in these ancient and highly sustainable systems in Asia.

Organic farming practices have depended on limited scientific research and extensive practical experiences by farmers and proponents of this approach. There are important precedents in Rudolph Steiner's lectures on biodynamic farming in Germany, as well as Sir Albert Howard's extensive observations and experiments in India on composting and improving soil humus. Developments in organic farming over recent decades have included increased attention to building soil fertility, fine-tuning methods of pest management, and emergence of certification organizations that provide a specific label to guarantee the authenticity of food produced by organic methods. Interest in ecologic agriculture in the Nordic region and throughout Europe has been especially intense in recent years. Useful sources that document this history are shown in Table 1 and in the Further Reading section. These books describe the evolution of agricultural practices as well as the growing popularity of organic products over the last century.

Building on a brief history, this article continues with discussions of how organic farmers maintain and build soil fertility, and how they design systems to protect against pest problems, especially weed management. Important to development of organic farming are the contributions of the biodynamic movement and integrated systems research. Although organic crop yields generally are lower per unit area, many people speculate that this is due to less research and development invested in these systems. In fact, the best organic growers often have yields equal to or better than country or regional averages for crops, and most farmers benefit from lower production costs and premium prices. Labeling and marketing are important issues in the commercialization of organic food, and these must include discussion of claims for nutritional benefits from the products of organic farming practices. Finally, there is intense discussion about the industrialization of organic farming and food products, and this will continue as a contentious issue into the future.

Building Soil Fertility

Organic farmers build and maintain soil fertility through a number of practices that mimic the natural ecosystem, rather than supplying crop needs through application of chemical, fossil fuel-derived commercial fertilizers. One characteristic of organic farmers is their strong belief in the soil as a complex place that is home to a living ecosystem of billions of organisms that work together to provide cycling of nutrients, and not merely a physical medium that holds plants upright and provides a place to store chemical nutrients until they are taken up by plants. The care of this living system and the cycling of its nutrients in field crops, vegetables, pastures, and domestic animals are central to the philosophy of organic farming and a foundation on which farmers build sustainable systems.

Crop diversity, careful soil management, legumes, and animals in the system are key strategies for the design of efficient and sustainable nutrient relationships in each field. These diverse components can enhance the process of nutrient cycling within the system and contribute to minimizing the losses of nutrients. There is no special formula for creating more nutrients within the organic farming system, but rather a logical planning to minimize extraction or loss of nutrients from the field and farm, and to replace those nutrients using internal resources on the farm (see Table 2). The crop sequence and mixture are designed to maximize nitrogen fixation and preservation of organic matter, efficient cycling of nutrients, and retention of nutrients where they are needed on the farm. Some organic farmers maintain that it is impossible to design an efficient system without including ruminant animals, while others increase the proportion of legumes in the system and use this strategy to accomplish the same goals. The bottom line is to incorporate continuously as many nutrients as the amount extracted in harvest and removal from the farm. A goal is to increase organic matter and nutrients to a more healthy level for soil and plants when these factors are deficient, but not to a level that creates a risk for erosion or leaching of soluble nutrients. The concept of balance is paramount, and crop rotation is essential. (*See* **Crop Rotations**.)

Soil organic matter is central to nutrient storage and cycling in the soil, and to providing nutrients to crop and pasture plants at the right time in their growth cycles. Along with the clay mineral fraction of the soil, organic matter provides negatively charged sites for cations (positively charged nutrient ions such as potassium, calcium, and magnesium) to be adsorbed, thus contributing to the cation exchange

Table 2 Nutrient-management practices and processes used by organic farmers to maintain soil fertility adequate for efficient and economical plant growth

Practice or process	*Description and impact on soil quality and crop production*
Legumes in rotation	Nitrogen fixation, contributions to soil organic matter, fibrous root systems contribute to loosening soil and quality
Manure application	Provides nitrogen and other nutrients, increases level of soil organic matter, improves soil tilth and quality
On-farm cycling	Use of primarily green manure crops and animal manure produced by feeding grain or forage on same farm helps balance
Cover crops	Provide cover over the ground surface during much of the year to prevent erosion, trap nutrients, contribute organic matter
Timely seeding	Synchronize crop planting and growth cycle with availability of nutrients from soil reserve
Reduced tillage	Maintains crop residues on top of soil, where they break down more slowly and provide nutrients when needed by later crops
Crop–Ley rotation	Rotation of crops with perennial pastures and grazing animals provides manure, fixed nitrogen, and green biomass to soil
Contour planting	Seeding crops on contours or terraces reduces soil erosion and thus reduces nutrient losses with eroding soil
Crop–animal systems	Integration of a diverse array of animal enterprises provides an internal market for forages and helps cycle nutrients

capacity of the soil. Organic matter is increased by incorporating green manure crops and growing forage crops or pastures, as long as they are fed to ruminants and manure recycled in the field, and these crops are not harvested and sold off the farm. The important organic matter is the active fraction that is being broken down by soil organisms and chemical reactions in the soil solution, thus releasing nutrients available to crops.

Algae are the only soil organisms to capture energy directly from sunlight, while all the others (bacteria, fungi, actinomycetes, and a host of macroorganisms) are dependent on breakdown of organic matter to provide their energy and nutrients, which they release and make available to crop and pasture plants. Soils that are too acid or too basic have lower levels of microbial and macroorganism activity, and thus break down soil organic matter more slowly. Most soil organisms such as earthworms are sensitive to soil acidity, and most have optimum activity at near-neutral soil conditions (pH = 7.0). Organic systems are designed to achieve this balance and build soil organic matter. 'Humus' is a term used for a combination of decomposed organic matter and high-molecular-weight compounds that are generally more resistant to biological decomposition than the active organic matter. Preserving organic matter by preventing erosion, minimizing extraction from the field (such as hay or silage harvest), and increasing the proportion of crop residues or green-manure crops in the sequence can enhance the long-term soil organic matter levels and overall soil quality. Higher levels of soil organic matter also help break the force of rain drops, especially when there is residue on top of the soil surface, and contribute to water storage by acting like a large sponge above and within the total soil mass. Thus soil organic matter contributes nutrients and increases water-holding capacity.

Organic systems depend on legumes as a key to maintaining soil nitrogen and other nutrients at levels adequate for successful crop and pasture-plant growth. The atmosphere is approximately 78% elemental nitrogen, and this can be fixed in plants by symbiotic bacteria, which live on the roots of legumes, and made available to subsequent crops when nitrates are excreted into the soil solution or when the legumes or parts of them are incorporated into the soil as green manure or as crop residues. In conventional farming, nitrogen is supplied primarily by application of chemical forms of nitrate, and higher levels applied in this way actually suppress the nitrogen fixation by legumes. It is possible to fix more than 100–150 $kg\,ha^{-1}$ nitrogen in 1 year from an appropriate legume such as alfalfa or clover. It is also possible to lose 25–150 $kg\,ha^{-1}$ of nitrogen in 1 year if this is applied as a soluble chemical, especially if there are high-rainfall events and low-organic-matter levels in the soil. In organic farming systems, the key is to fix and store adequate nitrogen for crop or pasture needs, while not having an excessive amount from legumes that exceed crop needs. The soluble nitrate ions are susceptible to leaching during rainfall events that exceed the ability of soil to hold this moisture.

Elements such as phosphorus, potassium, sulfur, calcium, magnesium, and others are also important for crop and pasture growth, but are less soluble and thus more tightly stored in the soil profile. Potassium is adequate in most agricultural soils and not easily leached out, and in pastures most is returned to the soil by grazing ruminants. Phosphorus is highly insoluble, and its availability is enhanced by the presence of fungal species called 'mycorrhizae' that infect plant roots and help in absorption of phosphate. Since there are often adequate supplies of phosphorus deep in the soil profile, deep-rooted crops with a strong tap root can 'mine' this element from lower soil strata. These elements and others can be supplied from organic sources, especially straw or feed that is cycled back

to the field as manure from animals, and again the balance in the system is the important goal. A smaller amount of these other elements is needed for plant growth compared with nitrogen, but their management is no less important due to serious effects of deficiencies in some soils. A number of soil-management practices, such as contour planting and reduced tillage, are useful to preserve nutrients in the field, in both organic and conventional production.

Protecting Plants against Pests

Similar to the strategies used for maintaining soil fertility, there are comparable lessons from natural ecosystems that help inform our design of agroecosystems to tolerate debilitating or completely destructive pest populations. Many of these principles relate to cropping diversity in each field and on the farm. Genetic resistance to insects and pathogens are commonly used in both organic and conventional farming systems. Well-adapted and healthy crop, pasture, and domestic animal species with tolerance to prevalent pest problems promote the least-expensive control methods, since this alternative may require no further management costs after the crop is planted or the basic animal enterprise is established. Other practices can be incorporated into the management strategy that will control or minimize losses to pests (see Table 3).

Crop rotations are desirable in most production systems, and these are both prescribed in organic rules and widely used to enhance soil fertility, reduce weed populations, and protect against many insects and plant pathogens. Rotations of unalike crop species will favor different weed species in each season or year and thus break the reproductive cycles of these weed species or aid in their control by mechanical means. Different summer crops such as maize and soybean have different growth habits and timing of competition with weeds, their root systems, and patterns of nutrient uptake, thus favoring a somewhat distinctive weed complex. Rotations of summer with winter crops further exploit this principle, since winter annual weeds that develop with the winter crop can be easily controlled in a subsequent summer crop, and vice versa. Rotating annual crops with perennial crops also provides a means of weed management, since the perennial weeds that develop with perennial crops can often be controlled mechanically in the next annual crop. Lastly, allelopathic species such as winter rye can suppress many weed species that will not be a problem in the succeeding summer annual crop. Cucurbits such as squash grown with maize and beans in the well-known, historical three-sisters crop combination in Central America control many weeds both by shading and by exudates from the leaves and roots. Crop varieties that are rapidly growing early in their cycle can quickly shade weeds and provide a measure of control. These are all methods used by organic farmers. (*See* **Crop Rotations**.)

Spatially diverse cropping patterns such as strip-cropping and intercropping are used to diversify the field planting pattern, confuse some insects that enter from the air, and disrupt their movement once they have entered the field. These patterns in organic agriculture may interrupt or discourage pest reproduction and reduce damage to crops. Pathogens likewise may have more difficulty in dispersion when they occur in a diverse system, compared with their rapid dispersion in monoculture. Diverse agroecosystems may include the added diversity potential of flowering

Table 3 Pest-management practices and processes used by organic farmers to maintain crops, pastures, and domestic animals in a cost-efficient and environmentally sound manner

Practice or process	*Description and impact on pest populations and production*
Crop rotation	Breaks the reproductive cycle of many pest species, provides natural controls through diverse crops in most available niches
Cultivation	Reduces weed populations by mechanical means and reduces their potential for reproduction and spread
Competitive species	Choice of highly competitive crop and pasture species and varieties that will use resources quickly and outgrow weeds
Resistant crops	Genetically resist insects and pathogens that would normally attack susceptible species or crop varieties
Planting dates	Adjustment can allow additional cultivation prior to planting (weeds) or avoidance of problems (insects)
Strip-cropping	Adds spatial diversity to field, habitats for some predators and parasites to aid control of unwanted species
Intercropping	Diversity in the field provides more competition for weeds, also reduces pest outbreaks due to resistance of many individual plants
Allelopathy	Planting certain crops such as winter rye, sorghum, and cucurbits that suppress weeds through chemicals excreted by roots or leaves
Summer–winter crop	Rotation of crops that grow in different seasons disrupts weed reproductive cycles and allows mechanical control
Annual/perennial	Rotation of crops with different life cycles helps control weeds that become more abundants in either species grown continuously
Genetic resistance	Crop or animal resistance or tolerance to pathogens or insect problems is an effective and inexpensive means of control
Floral fencerows	Field borders that are biologically diverse and provide a range of flowering species can harbor predators that reduce crop pests

wild species in fencerows, windbreaks, and field borders, providing habitats for predators and parasites that also help control unwanted pests in the adjacent production fields.

These combinations of genetic resistance, spatial and temporal diversity, and different crops in the field can be combined with adequate nutrient management to produce healthy organic crops. When crops and pasture species are growing rapidly, they often outgrow competition from small weed populations and are more resistant to insect pests and plant pathogens. Likewise, a healthy herd or flock of domestic animals is less susceptible to disease or insect problems. When these animal species in organic systems are allowed free range in pastures and crop residues, they also have fewer problems than the same species raised in confinement. Organic production practices favor this type of outdoor management whenever possible for domestic animals, and appropriate regulations assure the humane treatment of all livestock.

Conversion to Organic Production and Certification

The transition or change from conventional production systems to an organic system is called 'the conversion process,' and this requires 2 years in the UK and 3 years in the USA to complete before a farmer can apply for certification. Most advisors who have worked with farmers say that the most important and often difficult step in the conversion is a psychological change, an embracing of the concept that nonchemical farming is possible, achievable, practical, and economically viable. Armed with this confidence, gained by talking with current organic farmers, reading, attending workshops, or finding motivation from some other source, a farmer is ready to undertake the often considerable changes in farming system design and attendant practices that are required for certification.

Often a number of innovations or major changes are needed in planning the system. It is necessary to plan a conversion to nonchemical methods of providing adequate nutrients for crop and pasture growth. Most often this requires introducing more legumes and green-manure crops, or putting fields to pasture. Farmers often embark upon conversion by planting a forage crop that has no additional nutrient needs or complicated protection against pests. Animal numbers need to be adjusted to fit the carrying capacity of the available area of the farm, since it is highly desirable to minimize the amount of purchased feed or fodder that increases costs. In European countries, there are rules about the amount of nonorganic grains and fodder that can be used for animals while maintaining organic certification. There are also rules in the USA about what is permitted in animal production, and, although these vary somewhat among the private certification groups, there is a basic standard in the new organic legislation that must be followed by all groups. In the overall organic system, there needs to be a balance of areas in crops, in pastures, and in green-manure species to provide a sustainable level of fertility for optimum crop and animal growth, and profitability.

This balance may be achieved by either converting the entire farm at one time, or by converting a fraction of the farm each year over a period of years. The former is desirable because it is possible to take advantage of organic premiums in the marketplace much sooner if all fields are certified after the minimum waiting period. However, it may be too difficult to convert the entire farm at once if this requires planting forage crops in every field and there is not an adequate market for this product. Also, if there is an expected reduction in production until the organic system is established and in balance, it may be too difficult financially to make such a change in all fields at the same time. A more rational approach may be to convert some proportion of the farm each year, perhaps 33% or 25%, so that the process can be completed in 3–4 years. This spreads the risk as well as the reduced income over a longer period of time, and allows for the learning that must take place in making necessary changes.

In addition to changes in crops, cropping sequence, and use of inputs, there are likely to be modifications needed in field equipment, additions of facilities for processing or packaging products, and the development of innovative marketing channels. These changes are not all necessary for every farmer who converts to organic production, and the amount of modification in practices and sales options depends on the number of new enterprises added, the distance to markets and complexity of marketing, and the decisions to add more value to products by some direct sales. If there is a modest change in the balance of crops already grown on the farm, it is possible that no new field equipment will be needed. If there is diversification of current enterprises it is likely that additional equipment for new and specialized uses will be essential. How much processing, packaging, and direct sale will take place on the farm will determine whether additional buildings or equipment are needed for these activities. There is always an option of leasing equipment, time-sharing with neighbors, or custom work on operations that would not justify purchase of equipment for a specialized job. Yet this reduces the opportunity to bring return to a farmer's labor, and most operations are probably

done more economically by the owner or manager of each farm. Each of these steps may require new information, and this can be acquired by reading, from the Internet, or from workshops and classes (offered by Cooperative Extension in the USA), or through a certifying organization. People starting in organic farming may underestimate the need for additional information that will help them make the transition and avoid catastrophes in the field.

Biodynamic Farming, Biological Farming, and Integrated Systems

Several other schools of thought and specific groups have contributed to current philosophy and practices in organic farming. Biodynamic farming grew from the lectures and philosophy of Rudolph Steiner in Germany, founder of the movement called 'anthroposophy.' His teachings embrace a holistic and spiritual interpretation of agricultural systems, and especially the central and special role of humans in those systems. In this movement, the farm is viewed as a self-contained and dynamic organism that can be managed using internal resources and special chemical preparations (called 'preparats') that are essential to the health and vitality of composts, the farm, and its surroundings. The practices reflect a belief in cosmic as well as terrestrial forces on the biological rhythms on the farm. Although most organic farmers do not accept the tenets of Steiner, they do embrace the holistic view of the farm, the rejection of chemical fertilizers and pesticides, and the sound management techniques that were fundamental to the original lectures.

Biological farming includes a range of other movements from the USA, Europe, and India that focus on efficient use of animal manures and compost, green-manure crops, and careful attention to nutrients and soil fertility. Concentration on the humus fraction of soil and its importance in supplying nutrients is central to most systems, and soil health is often related to livestock and human health for those practicing the systems. Such studies have led to more research on the composting of human wastes, a practice long accepted in Asia but not a part of most European or Western Hemisphere fertility strategies in recent years. These systems evolved to include integrated management, a focus that continues today. Integrated farming is currently a strategy that takes into account balance of livestock and crop production, organization of the whole farm into a system that cycles nutrients and provides efficient production of several enterprises, and embraces diversity in those plans. It is easy to see how many of these approaches and strategies for farming overlap and complement each other, although they have different names and are vigorously pursued as different strategies by their supporters.

Marketing and Consumption of Organic Products

The organic food industry is growing rapidly in response to consumer demand and due to the new availability of organic crops and livestock. Countries with the largest areas in organic production include Australia (7.5 million ha), Argentina (3 million ha), Italy (1 million ha), and the USA (900 000 ha) in the year 2000. Those countries with the highest per capita consumption of organic products include Denmark, Switzerland, and Austria. Approximately two-thirds of organic foods marketed are fresh vegetables and fruits, with lower sales in processed and packaged foods. The majority of sales still take place from natural-food stores, although this is changing rapidly as the mainstream supermarkets explore this new and enticing market with their customers. There has been a lack of balance between supply and demand in organic food, for example in the USA there has been more demand than supply, and many farmers are increasing production to meet this demand by the public. In some European countries, such as Germany, there has been adequate production for domestic markets and enough available for organic cereal export to the Nordic region. National planners and farmers in this region are responding by moving toward incentives for producing ecologic grains that can substitute for these imports.

Premiums for organic products are highly variable, ranging from less than 10% where there is limited demand to more than 100% when a product is scarce. A review by Donald Lotter illustrates this spread in great detail. Fresh products in the US market for an average of 60% higher price than comparable conventional foods, while processed organic products may cost 100–300% more. In the European Union (EU) these price spreads are more in the order of 10–50%, depending on the product, country, and nature of subsidies for production. These subsidies for both the conversion process and for continuing to grow organic products have helped to narrow the differences in prices between the two. However, the support programs differ among countries, although the EU is slowly making these more uniform, and are so complicated that a Swedish farmer was heard to

say that the most important advisor in his organic farming business was the one who could help him fill out all the EU forms for subsidies. In this realm, both organic and conventional farmers are in the same situation, with a high dependence on external subsidies to maintain profitability.

Consumer demand for organic products has been studied in a number of countries. It is generally found that more affluent customers, those with higher levels of education and smaller families, are more apt to buy organic food. Consumers appear to be motivated by two major factors, that organic foods are more healthy for them and that the organic systems that produce them are more environmentally safe. A recent consumer survey in Hedmark County in Norway found that people who regularly purchased organic food were similar in most ways to those who purchased conventional food products, although they were more concerned about conditions under which the food was produced, the importance of local production, and animal welfare on the farm. There is a general concern about GMOs (transgenically modified organisms) among those who practice organic farming and those who purchase the products, and these new crops and performance-enhancing products for livestock are not allowed by any of the organic certification organizations, nor in the new national US legislation on organic labels.

There is great public interest and continuing debate about the safety and the health benefits of organic food products compared with those considered conventional. There is no question about the research, and surveys that have shown less pesticide residue (most often zero) on organic than on conventional produce. Thus organic food is a safer product than the general offering of vegetables and fruits in the marketplace. In terms of food value, there are numerous claims by organic proponents of better taste, freshness, and nutritional quality of organic foods. These qualities are difficult to substantiate, although it is obvious when produce comes from a local farmer and is purchased quickly and directly by the consumer that it will be fresher and probably have a better taste than a comparable product that has traveled 1000 km or 1500 miles (average distance that US food travels from production to consumer). Definitive clinical comparisons of nutritive value generally fail to show differences between organic and conventional food, results that are broadcast by the large food companies to support their claims of no differences and despaired of by organic food enthusiasts who are convinced of the nutritive value of their chosen products. This is still a valuable area for further research.

Future Perspectives for Organic Farming and Foods

If consistent growth in markets over a period of nearly two decades is any indication, there is a large potential for the expansion of organic food production and sale. One of the best indications of the growth potential for this sector is the current interest of larger corporations and multinationals in acquiring smaller organic processing and distributing companies. In the International Federation of Organic Agriculture Movements (IFOAM) Congress held in Victoria, BC, Canada, in August of 2002, there was extensive debate about the entrance of large corporations into the production and marketing of organic foods. The concern in traditional organic circles is that large corporations (both large farms and large processors and marketers) may fulfill the legal requirements of no pesticides or chemical fertilizers, thus producing a 'clean' product, but they are not in step with the goals of the majority of smaller organic producers to create local food systems that will promote the local food economy and establish personal relationships between farmers and producers. This industrialization of organic foods is likely to be the center of long debates in the near future, as people weigh the importance of organic certification versus food produced locally that meets more of the social goals that are part of the original organic agriculture movement.

Other questions embedded in the organic farming debate include the value and desirability of subsidies for organic production, whether price premiums will disappear if organic foods are widely grown, and the potentials for organic agriculture to feed a growing world population. Proponents of the completely free market argue that consumers will sort out food values in the marketplace, and thus there is no need for subsidies. Opponents argue that there are additional costs and limited research to support their conversion to organic farming, and financial incentives are still needed for farmers to begin organic farming to meet the obvious demands. If there is widespread adoption of organic farming techniques and there are many more organic products on the market, it is likely that price differentials will be reduced, but it is unlikely that they will disappear completely. On the issue of global food production, the best organic farmers today produce yields equal to those on conventional farms, although average production is 10–15% lower on organic farms. Part of this is due to lack of research and adequate extension recommendations in organic systems, and part is due to a lower intensity of resource use in organic farming

where there is dependence on internal resources and limited import of fossil fuel-derived materials from outside the farm. An organic farming strategy can be profitable if the production costs are lower and if price premiums are available. There is general agreement that the major problem contributing to hunger on a global scale is inadequate distribution of benefits from today's food system, i.e., that poverty is more to blame than lack of production. This will not be solved by producing more, argue some supporters of organic farming; and we can save the environment by reducing applications of pesticides and fertilizers that reduce water quality and quality of life for many rural residents.

The unique model of Cuba illustrates what can be done when fossil fuel supplies are severely limited in agriculture, and an entire country embraces organic farming and gardening as a major strategy for local food production. The majority of food consumed in major cities in Cuba – fruits, vegetables, small animals and their products – is produced within or adjacent to the city limits. Most are marketed directly from farmers to consumers. In 2002 Cuba enjoyed a healthy diet based on this food system, after some difficult years of adjustment or 'conversion' in their entire agricultural system. This is one model embedded in a unique political system, including diversity in land ownership, wide participation in food production, and a reliance on primarily internal resources to produce an adequate diet for the entire population. In conclusion, this is a model that should be studied as a specific case where organic farming is highly successful.

Introduction

The presence of organic matter (OM) distinguishes the soil from a mass of rock particles and allows it to become a living system. Soil organic matter (SOM) serves as a soil conditioner, nutrient reservoir, substrate for microbial activity, preserver of the environment, and major determinant for sustaining and increasing agricultural productivity. The OM content of soils ranges from less than 1% in desert soils to close to 100% in organic soils. A typical agricultural soil may contain between 1 and 5% OM in the top 15 cm.

The main emphasis of this article is on the analytical characteristics of SOM fractions and on studies on their chemical structure. Based on the results of extensive researches, a two-dimensional humic acid (HA) model structure was formulated which has been subsequently converted, with the aid of computational chemistry, to a three-dimensional HA model structure.

The term 'SOM,' as used in this article, refers to the sum total of all organic carbon-containing substances in soils. The major components of SOM are humic substances, especially HA; other significant components are carbohydrates, proteinaceous materials, and lipids.

Extraction and Fractionation of Humic Substances

Extraction of Humic Substances from Soils

Because, in soils, humic substances and inorganic soil constituents are closely associated, it is necessary to separate the two before either can be examined in greater detail. The most efficient extractants for humic substances are either dilute base (0.1–0.5 mol l^{-1} NaOH solution) or dilute neutral salt solutions such as aqueous 0.1 mol l^{-1} $Na_4P_2O_7$.

Fractionation of Extracted Humic Substances

Most soil OM chemists partition the humic substances extract into the following three fractions: (1) HA, which is that fraction of the extract that coagulates when the extract is acidified to pH 2; (2) fulvic acid (FA), which is that fraction of the extract that remains in solution when the alkaline extract is acidified, that is, it is soluble in both alkali and acid; and (3) humin, which is that humic fraction that remains with inorganic soil constituents, that is, it is insoluble in both alkali and acid.

A number of objections have been raised to the use of alkaline extractants. The latter may extract silica from minerals, protoplasmic components from organic tissues, and bring about the auto-oxidation of some organic components, and the condensation of amino groups of amino acids with carbonyl groups of reducing sugars to form Maillard-type reaction products. Some of these changes can be minimized by doing the extractions in atmospheres of inert gases, but not all possible changes can be excluded.

In Situ Analysis of SOM

Cross-polarization magic angle spinning ^{13}C nuclear magnetic resonance (CP-MAS ^{13}C NMR) and pyrolysis-field ionization mass spectrometry (Py-FIMS) are used for the *in situ* analysis of OM in soils. These methods identify the major chemical components of SOM without extraction and fractionation and yield valuable information on the main chemical structures of these materials. The major chemical components of SOM that have so far been identified include carbohydrates, phenols, lignin monomers and dimers, saturated and unsaturated fatty acids, alkanes and alkenes, alkyl monodi- and triesters, alkyl benzenes, methyl naphthalenes, methyl phenanthrenes, amino acids, and heterocyclic N-compounds. While the *in situ* analysis of OM in whole soils by the two methods referred to above does away with the extraction of OM from soils and its subsequent fractionation into HA, FA, and humin, it defines instead SOM in terms of its chemical makeup. In contrast to earlier workers, who thought

that HA and FA were chemically pure substances that were well separated by the extraction procedure, we know now from chemical, ^{13}C NMR, and mass spectrometric analyses that the assumptions of workers prior to the early years of the twentieth century are incorrect. HA, FA, as well as humin, are not distinct chemical substances. Each of these fractions consists of hundreds of compounds, which appear to be associated at molecular levels by mechanisms not yet well understood.

If soil chemists want to retain the extraction and fractionation approach, they need to define each fraction not on the basis of color and solubility or insolubility in base or acid, but by its ^{13}C NMR spectrum, its infrared (IR) spectrum, its mass spectrum, its elemental and functional group analyses, and so on.

Analytical Characteristics of HAs and FAs

Elemental Composition and Functional Group Content

The elemental composition and oxygen-containing functional group analysis of a typical HA (extracted from the Ah horizon of a Haploboroll) and a FA (extracted from the Bh horizon of a Spodosol) are shown in Table 1.

A more detailed analysis shows that: (1) the HA contains approximately 10% more C, but 36% less O than the FA; (2) there are quantitatively smaller differences between the two materials in H, N, and S contents; (3) the total acidity and COOH content of the FA are significantly higher than those of the HA; (4) both materials contain per unit weight significant concentrations of phenolic OH, alcoholic OH, and ketonic and quinonoid C=O groups; (5) the HA is richer than the FA in quinonoid C=O groups, while both materials contain relatively few OCH_3 groups; (6) about 74% of the total O in the HA is accounted for in functional groups, but all of the O in the FA is similarly distributed; and (7) the E_4/E_6 ratio (ratio of absorbances at 465 and 665 mm) of the FA is almost twice as high as that of the FA, indicating that the FA has lower molecular weight than the HA.

Table 1 Analytical characteristics of a Haploboroll humic acid and a Spodosol fulvic acid

	HA	*FA*
Element (g kg^{-1})		
C	564	509
H	55	33
N	41	7
S	11	3
O	329	448
Functional groups (cmol kg^{-1})		
Total acidity	660	1240
COOH	450	910
Phenolic OH	210	330
Alcoholic OH	280	360
Quinonoid C=O	250	60
Ketonic C=O	190	250
OCH_3	30	10
E_4/E_6	4.3	7.1

HA, humic acid; FA, fulvic acid.

Infrared and Fourier Transform Infrared Spectrophotometry

IR and Fourier transform IR (FTIR) spectra of HAs and FAs show bands at 3400 cm^{-1} (H-bonded OH) 2900 cm^{-1} (aliphatic stretch), 1725 cm^{-1}(C=O of COOH, C=O stretch of ketonic C=O), 1630 cm^{-1} (COO^-, C=O of carbonyl and quinone), 1450 cm^{-1} (aliphatic C–H), 1400 cm^{-1} (COO^-), 1200 cm^{-1} (C–O stretch or OH deformation of COOH), and 1050 cm^{-1} (Si–O of silicates). The bands are usually broad because of extensive overlapping of individual absorbances. IR and FTIR spectra of HAs and FAs reflect the preponderance of oxygen-containing functional groups, i.e., COOH, OH, and C=O in these materials. Some FTIR spectra show the presence of C=C and polysaccharides. While IR and FTIR spectra provide useful information on the functional groups and their participation in metal–humic as well as pesticide–humic interactions, they tell us little about the chemical structure of these materials.

Chemical Structure of SOM

^{13}C NMR Spectroscopy

One of the most important methods currently available for elucidating the chemical structure of organic substances is ^{13}C NMR. For the analysis of SOM and fractions derived from it such as HA, FA, and humin as well for the direct *in situ* analysis of OM in whole soils, CP-MAS or solid-state ^{13}C NMR is especially useful. CP-MAS ^{13}C NMR spectra of a Mollisol HA and a Spodosol FA are shown in Figure 1. Both the HA and FA show distinct resonances in the aliphatic (0–105 ppm), aromatic (106–150 ppm), phenolic (155–169 ppm), and carboxyl (170–190 ppm) regions. The signals in the HA spectrum at 17, 21, 25, 27, and 31 ppm are probably due to alkyl C. The resonance at 17 ppm is characteristic of terminal CH_3 groups and that at 31 ppm of $(CH_2)_n$ in straight paraffinic chains. The peak at 40 ppm could include

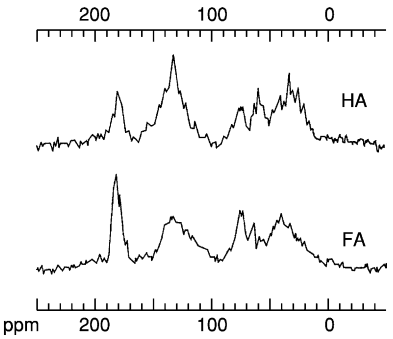

Figure 1 Cross-polarization magic angle spinning ^{13}C nuclear magnetic resonance (CP-MAS ^{13}C NMR) spectra of HA (extracted from the Ah horizon of a Haploboroll and FA (extracted from the Bh horizon of a Spodosol). Table 2 Distribution of C (%) in a Haploboroll HA and a Spodosol FA as determined by ^{13}C NMR

	% of C	
Chemical shift range (ppm)	*HA*	*FA*
0–40	24.0	15.6
41–60	12.5	12.8
61–105	13.5	19.3
106–150	35.0	30.3
151–170	4.5	3.7
171–190	10.5	18.3
Aliphatic C (0–105 ppm)	50.0	47.7
Aromatic C (106–150 ppm)	35.0	30.3
Phenolic C (151–170 ppm)	4.5	3.7
Aromaticity[a]	44.1	41.6

[a]((Aromatic C + phenolic C)/(aromatic C + phenolic C + aliphatic C)) × 100. Reproduced with permission from Schnitzer M (2000) A lifetime perspective on the chemistry of soil organic matter. *Advances in Agronomy* 68: 1–58, © Academic Press, San Diego.

contributions from both alkyl C and amino acid C. The broad signal at 53 ppm and the sharper one at 59 ppm appear to be due to OCH_3. Amino acid C may also contribute to this region. Carbohydrates in the HA would be expected to produce signals in the 60–65, 70–80, and 90–105 ppm regions; also other types of aliphatic C bonded to O could do so. The aromatic region contains a relatively sharp peak at 130 ppm due to alkyl aromatics. The signal at 155 ppm shows the presence of O- and N-substituted aromatic C (phenolic OH and/or NH_2 bonded to an aromatic C). The broad signal near 180 ppm is due to C in COOH groups, although amide C and C in esters could also contribute to this resonance.

The CP-MAS ^{13}C NMR spectrum of the FA (Figure 1) consists of a number of aliphatic resonances in the 20- to 50-ppm region, followed by signals due to C in OCH_3 groups, and C in amino acids. Signals due to carbohydrate C are present between 50 and 85 ppm. Broad signals between 130 and 133 ppm indicate the presence of C in alkyl aromatics. The strong signal between 170 and 180 ppm shows the presence of C in COOH groups. In general, fewer sharp signals are observed in the spectrum of the FA than that of the HA, possibly because of more H-bonding in the FA.

The CP-MAS ^{13}C NMR data for the HA and FA are summarized in Table 2 in terms of the distribution of C in the different spectral regions. An examination of the data shows similar C distributions in the two humic materials. The HA is slightly more aromatic than the FA, but the FA is richer in COOH groups, which appears to be the main difference between the two substances. Other differences are that the HA is richer in paraffinic C but poorer in carbohydrate C than the FA. However, on the whole, the main structural features, as well as the aromaticity and aliphaticity, are similar so that the HA and FA have similar chemical structures.

As far as the CP-MAS ^{13}C NMR spectrum of humin, that portion of SOM that stays behind after extraction of the soil with dilute alkali or neutral salt solution, is concerned, the spectrum, after extensive leaching, is very similar to that of HA. This indicates that humin is essentially HA-bound strongly to soil minerals.

Electron-Spin Resonance Spectroscopy

Humic substances contain free radicals that can participate in a wide variety of organic–organic and organic–inorganic interactions. The electron-spin resonance (ESR) spectrum of a typical HA consists of a single line devoid of hyperfine splitting. From the magnitudes of the *g*-values (the spectroscopic splitting constant), the prominent free radicals in humic materials appear to be semiquinones or substituted semiquinones. The latter can be produced either by the reduction of quinones or the oxidation of phenols. Except for indicating the presence of phenols, semiquinones, and quinones in these materials, ESR spectroscopy has so far contributed little to our understanding of the structural chemistry of these substances. The main reason for this is that it has been difficult to split the signal.

It is also known that there are two types of free radicals in humic materials: (1) permanent free radicals with long lifetimes, and (2) transient free radicals with relatively short lives (several hours). Transient free radicals in humic substances can be generated in relatively high concentrations by chemical reduction, irradiation, or increases in pH.

Oxidative Degradation

The oxidative degradation of HAs, FAs, humins, and whole soils under a wide variety of experimental conditions produces aliphatic carboxylic, phenolic, and benzene carboxylic acids. Among aliphatic oxidation products are mono-, di-, tri-, and tetracarboxylic acids. Major phenolic acids include aromatic rings substituted by one to three OH groups and by one to five COOH groups, while major benzene carboxylic acids are the di-, tri-, tetra-, penta-, and hexa-forms. From the oxidation products identified and from CP-MAS ^{13}C NMR spectra of humic substances, it appears that the aromatic rings are cross-linked by paraffinic chains. Oxidation converts CH_3 and CH_2 groups closest to the aromatic rings to COOH groups, whereas CH_2 groups in alkyl chains are oxidized to mono- and dicarboxylic acids and/or to CO_2. The formation of significant concentrations of CO_2 from the oxidation of side chains may explain the low oxidation yields of aliphatic acids compared with phenolic and benzene carboxylic acids.

The model structure shown in Figure 2 has an aromaticity of 50% if functional groups are excluded. Of special interest are the following: (1) isolated aromatic rings are important structural components of all humic substances; (2) aliphatic chains link aromatic rings to form an alkyl aromatic network; and (3) the structure contains voids of various dimensions that can trap organic and inorganic soil constituents. These characteristics are typical of soil humic substances.

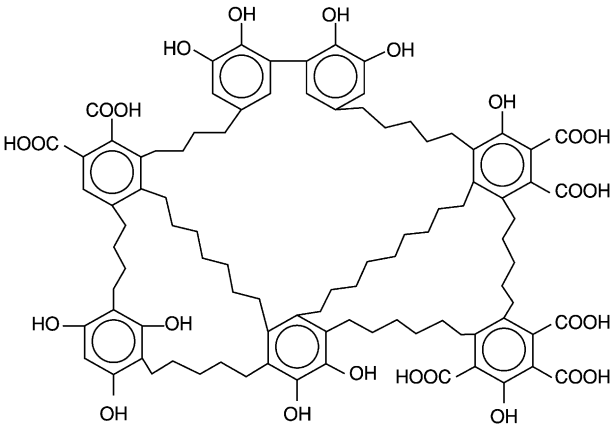

Figure 2 Chemical structure of humic substances based on oxidation products. (Reproduced with permission from Schnitzer M (2000) A lifetime perspective on the chemistry of soil organic matter. *Advances in Agronomy* 68: 1–58, © Academic Press, San Diego.)

Reductive Degradation

Relatively mild reduction of humic substances with Na amalgam produces phenols and phenolic acids. But the harsher Zn-dust distillation and Zn-dust fusion yield methyl-substituted naphthalene, anthracene, phenanthrene, pyrene, and perylene. The methyl groups on the polycyclics are probably the remains of longer alkyl chains linking the polycyclics in HA, FA, and humin structures.

Pyrolysis-Field Ionization Mass Spectrometry of HAs, FAs, and Humins

Compounds identified in the Py-FI mass spectra of a whole soil, an HA, an FA, and a humin are summarized in Table 3. The most abundant compounds identified in all three fractions are carbohydrates, phenols, lignin monomers, lignin dimers, *n*-fatty acids, *n*-alkyl diesters, and *n*-alkyl benzenes. Minor components include *n*-alkyl monoesters, methylnaphthalenes, methylphenanthrenes, and N-compounds. HA tends to be enriched in *n*-fatty acids and the whole soil and the humin in *n*-alkyl diesters and *n*-alkyl benzenes.

Curie-Point Pyrolysis–Gas Chromatography/Mass Spectrometry of HAs and FAs

Curie-point pyrolysis–gas chromatography/mass spectrometry (Cp Py-GC/MS) of HAs and FAs indicates the presence of relatively high concentrations of aromatic rings substituted by alkyl chains. Of special significance is the identification of a series of C_1–C_{22} *n*-alkyl benzenes. In addition, ethylmethyl benzene, methylpropyl benzene, methylheptyl benzene, methyloctyl benzene, and methylundecyl benzene are also detected. Other compounds identified

are trimethyl- and tetramethyl benzenes, alkyl naphthalenes, and alkyl phenanthrenes. The alkyl substitution on the naphthalenes ranges from one to five methyls, whereas that on the phenanthrene rings ranges from one to four methyls.

Other Characteristics

From surface pressure, surface tension, and viscosity measurements at different pHs and varying concentrations of HA and neutral electrolytes, it appears that, under conditions normally prevailing in most agricultural soils, HA behaves like a flexible, linear polyelectrolyte. Additional support for this view comes from transmission electron micrographs of HA which show that in dilute aqueous solution HA forms flat, elongated, multibranched filaments, 20–100 nm in width. With increasing pH or HA concentration, a finely woven network of elongated fibers is formed which then coalesces into a sheet-like structure, perforated by voids of varying dimensions. The overall impression is that of a relatively flexible and open structure.

Model Structures of HA

Two- and Three-Dimensional Model Structures of HA

The two-dimensional HA model structure of HA shown in Figure 3 is based on long-term chemical, ^{13}C NMR spectroscopic, degradative, electron-microscopic, X-ray, Py-FIMS, and Cp Py–GC/MS studies. In this structure, *n*-alkyl aromatics play a significant role. Oxygen is present in the form of COOH, phenolic and alcoholic OH, ester, ethers and ketones, whereas nitrogen occurs in nitriles and hetercyclic structures. The carbon skeleton contains voids of various dimensions which can trap and bind other organic and inorganic soil constituents as well as water. The molecular formula of the HA is $C_{308}H_{328}C_{90}N_5$, its molecular weight is 5540 Da, and its elemental analysis is 66.8% C, 6.0% H, 26.0% O, and 1.3% N. It is assumed that carbohydrates and proteinaceous materials are adsorbed on external HA surfaces and in internal voids and that hydrogen bonds play an important role in their

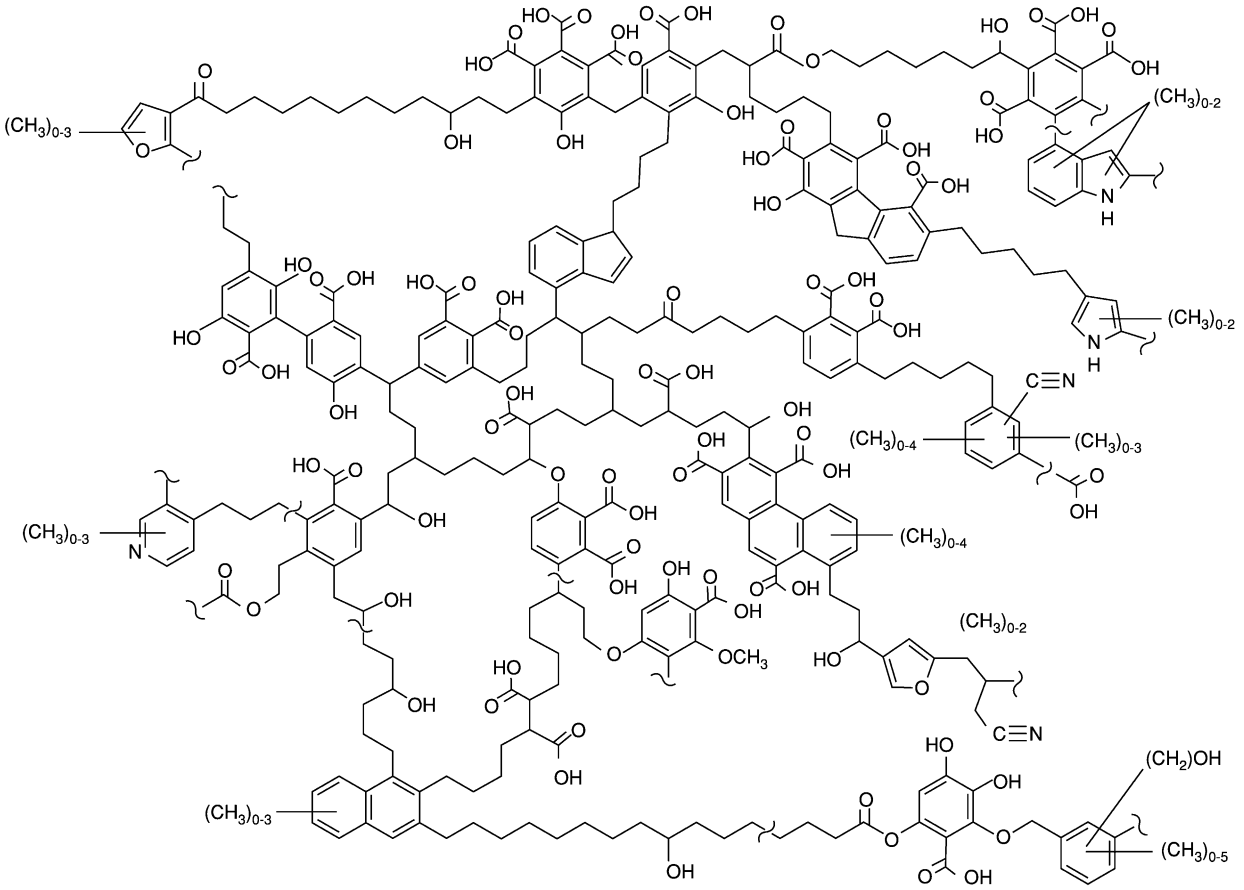

Figure 3 Two-dimensional HA model structure. (Reproduced with permission from Schulten H-R and Schnitzer M (1993) A state of the art structural concept for humic substances. *Naturwissenschaften* 80: 29–30, Fig. 1, © Springer-Verlag, Heidelberg.)

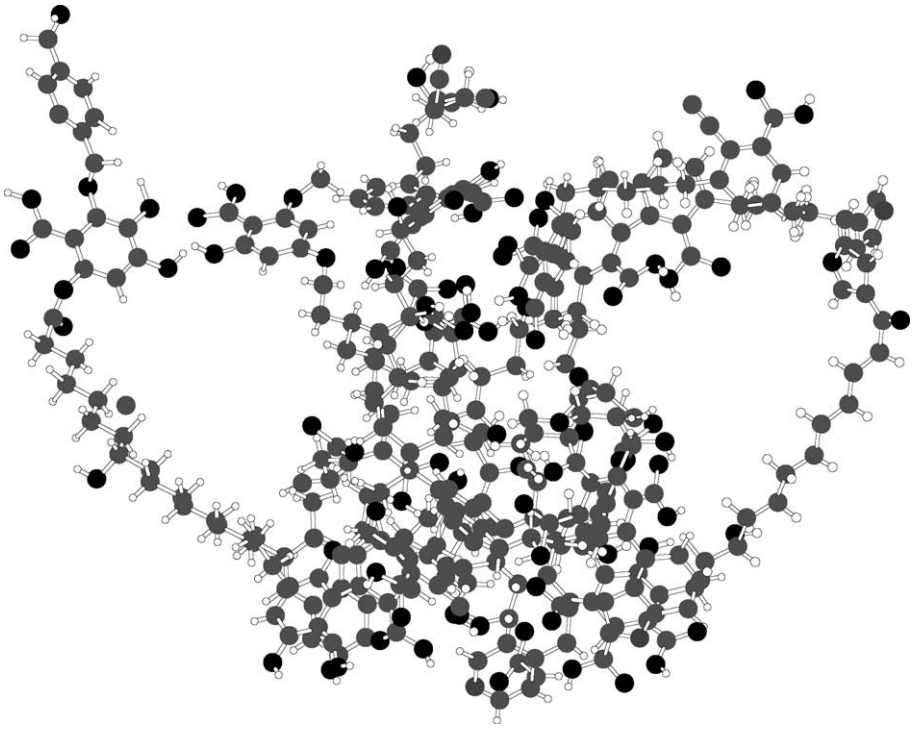

Figure 4 Three-dimensional humic acid model structure. Element colors are: carbon (light gray), hydrogen (white), oxygen (black), and nitrogen (dark gray). (Reproduced from Schulten H-R and Schnitzer M (1997) Chemical model structures for soil organic matter and whole soils. *Soil Science* 162: 115–130, © Lippincott, Williams & Wilkins, Baltimore.)

immobilization. Aside from carbohydrates and proteinaceous materials, the voids can also trap and bind lipids and biocides, as well as inorganics such as clay minerals and hydrous oxides.

The conversion, with the aid of HyperChem software, of the two-dimensional HA structure (**Figure 3**) to a three-dimensional HA structure is shown in **Figure 4**. The three-dimensional HA model structure has a molecular weight of 5547 and an elemental analysis of 66.7% C, 6.1% H, 26.0% O, and 1.3% N.

It is likely that applications of computational chemistry to the development of SOM structural models will increase in the future and lead to a better understanding of the spatial arrangements of the molecular constituents of SOM. A more comprehensive knowledge of the chemistry and reactions of SOM will certainly be beneficial to a sustainable agriculture and help to protect the environment.

Reactions of SOM with Metals and Organics

Formation of Water-Soluble Metal–Organic Complexes

Reactions in water near pH 7 between di- and trivalent metal ions and HAs and FAs are likely to proceed via one or more of the mechanism shown in **Figure 5**, taking a divalent metal ion M^{2+} as an example. According to eqn [1] in **Figure 5**, one COOH group on the HA or FA reacts with one metal ion to form an organic salt or monodentate complex. Equation [2] in **Figure 5** describes a reaction in which one COOH and one adjacent OH group react simultaneously with the metal ion to form a bidentate complex or chelate. According to eqn [3] in **Figure 5**, two adjacent COOH groups interact simultaneously with the metal ion to form a bidentate chelate. Equation [4] shows the metal ion M^{2+} linked to the HA or FA not only by electrostatic bonding, but also through a water molecule (water bridge) in its primary hydration shell to a C=O group of the ligand. The latter type of interaction is especially important when the cation has a high solvation energy and so retains its primary hydration shell. Equations [2] and [3] in **Figure 5** describe the formation of strong, inner-sphere complexes, whereas eqn [4] refers to the formation of a weaker, outer-sphere complex. While a number of workers have published stability constants of water-soluble metal–HA and metal–FA complexes, problems have been encountered with the analysis and interpretation of the data. Probably the most serious obstacle to progress in this area is our lack of knowledge of the chemical structures of HAs and FAs, the ligands.

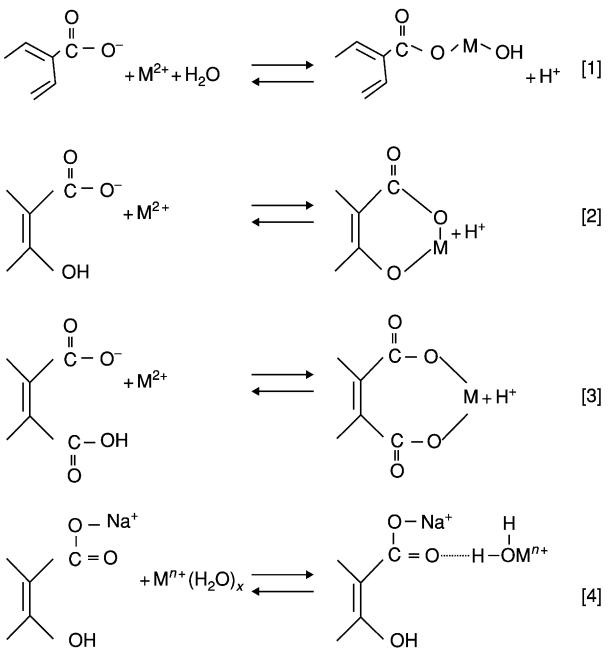

Figure 5 Major metal–HA and –FA reaction mechanisms. (Reproduced with permission from Schnitzer M (1986) Binding of humic substances by soil colloids. In: Huang PM and Schnitzer M (eds) *Interactions of Soil Minerals with Natural Organics and Microbes*, pp. 77–101. Special Publication No. 17. Madison, WI: Soil Science Society of America.)

Other Types of Metal SOM Interactions

The formation of mixed-ligand complexes of the type M^{2+}–FA – secondary ligand (Y) is known to occur in soils. Secondary ligands (Y) can be citrate tartrate, salicylate, phosphate, bicarbonate, sulfate, aspartate, glycinate, etc. In neutral to weakly acid solutions, these complexes are more stable than simple complexes. The formation of mixed ligand complexes prevents the precipitation of metal ions by hydrolysis at elevated pHs.

Due to their ability to complex di-, tri-, and tetravalent metal ions, dilute aqueous FA solutions and aqueous HA solutions at pH >6.5 can attack and degrade minerals to form water-soluble and water-insoluble metal complexes. Thus, the weathering of minerals in soils and sediments is often enhanced by the action of naturally occurring organic substances, especially FA. Because of its abundance in soils, its solubility in water, and its ability to complex with metal ions and interact with silica, the latter may increase the concentrations of these soil constituents in aqueous solutions to levels that far exceed their normal solubilities. In this manner, aqueous FA solutions may not only bring about the dissolution and degradation of existing minerals, but also lead to the synthesis of new minerals by permitting the complexed and dissolved metals and silica to form new combinations. Conversely, active surfaces of inorganic soil constituents may catalyze either the degradation or synthesis of HAs and FAs.

The extent of adsorption of HA and FA on mineral surfaces depends on the characteristics of the surface, the pH of the system, and its water content. For example, sepiolite, which has a channel-like surface, readily adsorbs FA. In untreated sepiolite, these channels are filled by bound and/or zeolitic water, which can be displaced by undissociated FA in aqueous solution at pH 3.

The interlayer adsorption of FA by expanding clay minerals is pH-dependent, being highest at low pH but no longer occurring at pH >5. The FA cannot be displaced from the clay interlayers by leaching with $1\,\mathrm{mol\,l^{-1}}$ NaCl; an inflection is observed in the adsorption–pH curve near the pH corresponding to the p*K* of the acid species of FA so that the adsorption can be classified as a ligand-exchange reaction. In this type of reaction, the anion (FA) is thought to penetrate the coordination shell of the dominant cation in the clay and displace water coordinated to the dominant cation in the clay interlayer.

Nitrogen in Soils and SOM

Almost 95% of total soil N is associated with SOM. This N occurs in the forms of amino acids, peptides, proteins, amino sugars, heterocyclic N compounds, and ammonia. The amino acid composition of soils and SOM from widely differing origins is remarkably similar and resembles that of bacteria. This appears to indicate that microbes play a major role in the synthesis of amino acids, peptides, and proteins in soils. The most prominent amino sugars in soils and SOM are D-glucosamine and D-galactosamine. Present in smaller amounts are muramic acid, D-mannosamine, *N*-acetylglucosamine, and D-fucosamine.

By Py-FIMS and Cp Py-GC/MS, more than 100 heterocyclic N compounds have been identified in soils and SOM. These N compounds include nonsubstituted and substituted pyrroles, pyrrolidines, imidazoles, pyrazoles, pyridines, pyrazines, nitriles, indoles, quinolines, isoquinolines, benzothiazoles, and pyrimidines. Low-mass N-compounds detected are hydrocyanic acid, dinitrogen, dinitrogen monooxide, isocyanomethane, acetamide, and hydrazoic acid. N-derivatives of benzene detected include benzamine, benzonitrile, and isocyanomethylbenzene. According to the latest estimates, the distribution of total N in soils and SOM is as follows: proteinaceous materials (amino acids, peptides, proteins), 40%; amino sugars, 5–6%; heterocyclic N (including purines and pyrimidines), 35%; and NH_3-N, 19%. Thus, proteinaceous materials and N heterocyclics are the major N components. While there are indications that the

proteinaceous materials and amino sugar are strongly adsorbed on the HA and SOM surfaces and in the voids, the heterocyclic N components appear to be chemically bonded to HA and SOM components; that is, they are integral structural components of HAs and SOM.

Phosphorus and Sulfur in Soils and SOM

According to current estimates, about 75% of the total P in soils occurs in organically bound forms. Principal organic P forms include inositol phosphates, phospholipids, nucleic acids, phosphoproteins, and metabolic phosphates. Other organic P compounds identified by ^{31}P NMR in soils and SOM are alkyl phosphonic esters, alkyl phosphonic acids, choline phosphate, and orthophosphate mono- and diesters.

It is estimated that more than 90% of the total soil S in most noncalcareous soils occurs in organic forms. These include phenolic sulfates, sulfated polysaccharides, choline sulfate, and sulfated lipids. Also present are S-containing amino acids (cystine and methionine), cystathionine, djenkolic acid, taurine, biotin, and thiamine. In poorly drained soils, the decomposition of organic S compounds produces volatile compounds such as carbon disulfide, carbonyl sulfide, methyl mercaptan, diethyl sulfide, dimethyl sulfide, and dimethyl disulfide.

Interactions of SOM with Pesticides and Herbicides

The persistence, degradation, bioavailability, leachability, and volatility of pesticides and herbicides in soils are directly related to the concentration of SOM. The pesticides and herbicides may sorb on SOM and be retained by van der Waals forces, hydrophobic bonding, hydrogen bonding, charge transfer, ion exchange, and ligand exchange. Pesticides and herbicides may also be adsorbed unchanged on external SOM surfaces or in internal voids. SOM can promote the nonbiological degradation of pesticides and herbicides in addition to chemically binding residues arising from their biological and chemical degradation. These processes may play important roles in the detoxification, protection, and preservation of the environment.

List of Technical Nomenclature

Ah	humus-enriched A horizon
Bh	humus-enriched B horizon
^{13}C	carbon-13
C=O	carbonyl group
COOH	carboxyl group
CO_2	carbon dioxide
CP-MAS ^{13}C NMR	cross-polarization magic angle spinning carbon-13 nuclear magnetic resonance spectroscopy
CP Py-GC/MS	Curie-point pyrolysis–gas chromatography/mass spectrometry
cmol kg^{-1}	centimoles per kilogram
E_4/E_6	ratio of absorbances at 465 nm and 665 nm
ESR	electron-spin resonance spectroscopy
FA	fulvic acid
FTIR	Fourier-transform infrared spectrophotometry
g kg^{-1}	grams per kilogram
HA	humic acid
N	nitrogen
NaOH	sodium hydroxide
$Na_4P_2O_7$	sodium pyrophosphate
OCH_3	methoxyl group
OH	hydroxyl group
OM	organic matter
P	phosphorus
Py-FIMS	pyrolysis-field ionization mass spectrometry
ppm	parts per million
S	sulfur
SOM	soil organic matter
TII	total ion intensity
Zn	zinc

Introduction

The primary sources of soil organic matter (SOM: all organic C-containing compounds in the soil) are dead plant materials in the form of leaves, straw, twigs, roots, and other plant litter materials. The global biomass of higher plants amounts to approximately 500–700 Gt C (1 Gt = 10^9 t) and contributes approximately 100 Gt C in litter annually in the soil, either on the surface or deposited belowground as rhizodeposition. About the same amount of carbon is annually released from soil as CO_2. The dead plant material consists of lignocelluloses with an average composition of 15–60% cellulose, 10–30% hemicelluloses, 5–30% lignin, and 2–15% protein. Minor components are phenols, sugars, amino acids, and peptides, as well as numerous secondary metabolites. Most of the compounds are used as nutrient and energy sources for microbial growth.

SOM is a natural product resulting from microbial activity in the inorganic and/or organic soil environment. The amount and accumulation of SOM are controlled by the composition and amounts of the plant residues, by climatic conditions, and soil texture. Other important factors are microbial activity, soil redox conditions, and other soil chemical and physical properties.

Soils may contain several tons of SOM per hectare. Most of it can be only slowly degraded and metabolized by soil organisms as a consequence of both its physical and chemical stabilization. Plant debris, with structural relationship to its origin, may become resistant to microbial degradation by interaction with minerals, whereas its completely humified products are produced by random condensation of refractory plant and microbial products. Their diversity and lack of regular polymeric structures do not favor efficient enzymatic degradation and energy production. Therefore, chemical composition and structure of the humified residues and their physical protection by spatial distribution are equally important for accumulation of soil carbon, which amounts to approximately 1400–1600 Gt C on a global scale.

Combining the concepts of chemical stability and physical protection, it is assumed that there are two categories of natural organic matter: labile (readily degrading) and resistant (slowly degrading). Furthermore, there are three categories of microenvironments: free unprotected particles, particles occluded or entrapped in an inorganic or organic microenvironment, and particles attached or adsorbed to surfaces by physical or chemical mechanisms. This gives rise to six categories of SOM:

1. Free particulate, intrinsically labile;
2. Free particulate, intrinsically resistant;
3. Occluded particulate, potentially labile but currently protected as a result of inaccessibility;
4. Occluded particulate, intrinsically resistant and further protected by its inaccessibility;
5. Adsorbed, potentially labile, but currently protected by adsorption;
6. Adsorbed, intrinsically resistant and further protected by adsorption.

Soil Fabric and its Impact on SOM Stabilization

Transformation and Stabilization Processes of Free and Occluded Particulate Organic Matter

The location of organic matter within the soil structural units has been demonstrated to control SOM dynamics by physical or chemical mechanisms. Crushing of macroaggregates (greater than 250 μm) provides plant-derived material from roots or leaves colonized by microorganisms, which decompose

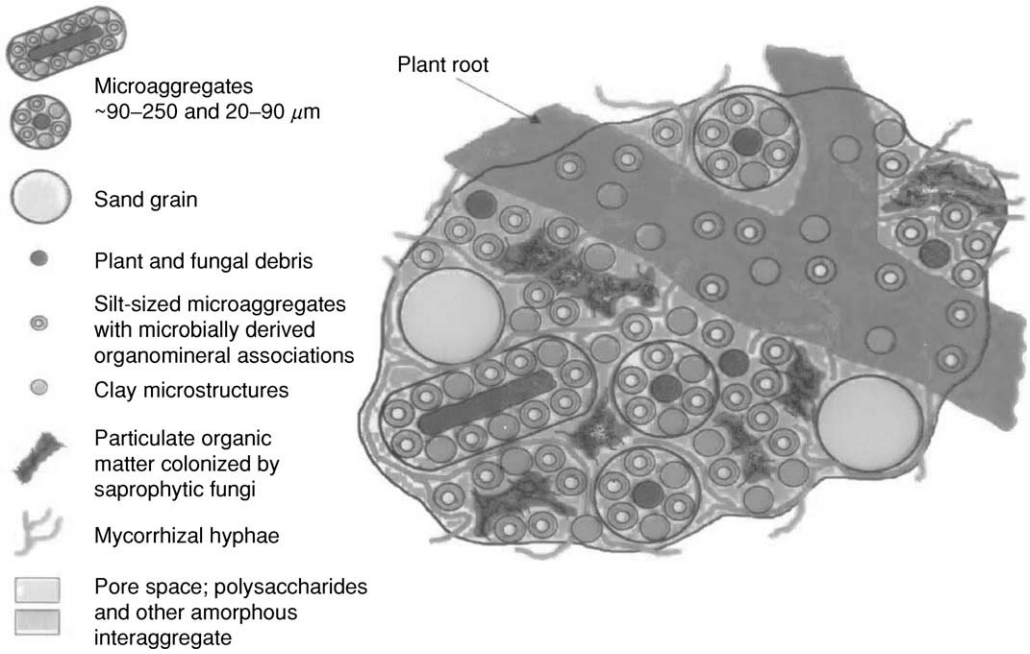

Figure 1 Mineral and organic components within a macroaggregate. (Adapted from Jastrow JD and Miller RM (1998) Soil aggregate stabilization and carbon sequestration: feedbacks through organomineral associations. In: Lal R, Kimble JM, Follett RF, and Stewart BA (eds) *Soil Processes and the Carbon Cycle*, pp. 207–223. Boca Raton, FL: CRC Press.)

them and form humified material, microaggregates (less than 250 μm), and sand grains (Figure 1).

Microscopic and electron-microscopic evaluation gives direct access to the origin and the degree of decomposition of SOM within the different fractions. Mostly large, undecomposed root and plant fragments exist in the 500–2000-μm aggregate fractions; whereas, in the 10–100-μm aggregate fractions, more decomposed materials have been observed.

Proportions of free particulate organic matter vary widely and are affected by land use, vegetation and soil type, climate, and other factors. Its accumulation is favored in cold and dry climates and in continuously vegetated soils with a large input of plant litter, e.g., as in grass or forest vegetation areas. There, free particulate SOM can account for 15–40% of the total SOM in surface horizons, whereas in tilled soils it contributes less than 10% of the total SOM and reflects differences in cropping sequences and tillage. Free particulate SOM also includes organic particles which adhere loosely to surfaces of organomineral complexes. This type of particulate SOM can be recovered by minimal dispersion (e.g., density fractionation) of soil samples in which aggregates remain intact. It consists either of partly decomposed litter particles from recently deposited crop residues or of older, uncomplexed SOM previously occluded in aggregates but released by their destruction. These particles tend to be readily depleted when soils previously under a permanent native vegetation are brought into cultivation.

Plant-derived materials in soil are rapidly colonized by microorganisms. Microorganims and their mucilages are attached to clay particles and form microoaggregates which slow their biodegradation. With time the materials in macroaggregates become more fragile and mainly humified material is adsorbed on mineral surfaces in microaggregates, where it is hardly available to microorganisms and stabilized for a long time (Figure 2).

Many studies on different soil types have shown that macroaggregates contain younger C than microaggregates. Examples from investigations in Oxisols, Alfisols, and Inceptisols, where C3 vegetation was replaced by C4 vegetation, are shown in Table 1. The photosynthetic switch and the corresponding differences in $\delta\,^{13}$C-values from C4 to C3 vegetation are frequently used to calculate average turnover times of aggregate-associated organic matter. The average turnover time for old C4-derived C is approximately 400 years for microaggregates compared with an average turnover time of approximately 140 years for macroaggregates.

Stabilization of SOM by Sequestration in Microporous Structures or on Hydrophobic Surfaces

Physical factors confer biological stability to organic matter in soils through the constraints they place on the opportunities for reactions between substrates and enzymes or decomposer organisms. Microbial

access to substrates when located in small pores or sorbed on solid surfaces may be limited, because they are inaccessible to microorganisms and their enzymes, and are thereby protected from rapid decomposition. Carbohydrates, lignin-degradation products, and nitrogenous substances can interact with soil colloids by sorption, polymerization, or entrapment in voids of inorganic or organic soil constituents.

Xenobiotics such as pesticides or polyaromatic hydrocarbons can be sorbed in the microporous structure of SOM or minerals. Similarly to xenobiotics, also natural SOM can be sorbed in micropores. Since such sorption sites are limited, the

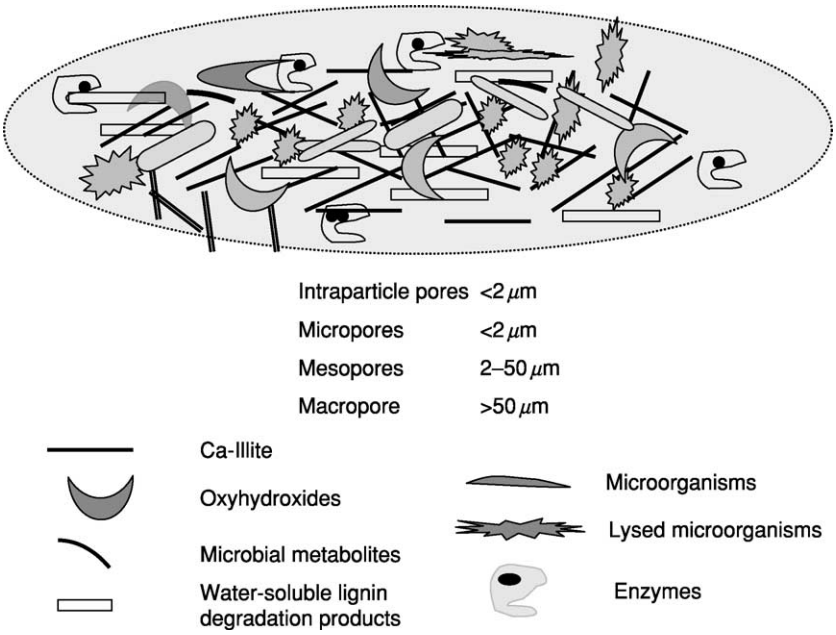

Figure 3 Conceptual model of stabilization of soil organic matter within nanopores.

mineralization of phenols or phenolic acids, of amino acids, and of glucose or other carbohydrates can be more strongly retarded at low concentrations (10 ppm or less) than at higher concentrations. It can be presumed that the observed continuous decline in bioavailability (and extractability) is associated with a slow diffusion of the molecules to more remote sites. Intraparticle and intraorganic diffusion into nanopores is believed to account for these slow phases of sorption and desorption of nonionic molecules. Dissolved organic matter (DOM) can diffuse into nanopores of primary particles or sorb on active surfaces. Within pores less than 8 nm, DOM is inaccessible to exoenzymes. A conceptual model of the stabilization of sorbed SOM within nanopores is shown in Figure 3.

Chemical Information About Organic Matter in Aggregates and Organomineral Complexes

Microscopic evidence suggests that SOM in the coarse sand fraction is mainly composed of little-decomposed plant residues, whereas that associated with fine sand consists of quite well-altered organic debris and fine particles of roots. This is corroborated by chemical analyses. Significantly lower C-to-N (C/N) ratios in fine fractions than in the coarser ones indicate a more pronounced microbial alteration in the fine-size separates (Figure 4a). This is also obvious from the pattern of monosaccharides released upon acid hydrolysis in the fractions. Individual sugar monomers released from SOM upon acid hydrolysis culminate in sand and clay separates and have their minimum in the silt-size fraction. There is a shift from primarily plant-derived monosaccharides in the coarse fractions to a dominating microbial contribution in the fine fractions (Figure 4b). Ratios of (galactose + mannose) to (arabinose + xylose) and of (rhamnose + fucose) to (arabinose + xylose) increase from sand to silt to clay, indicating primarily plant-derived polysaccharides in the sand-size separates and larger fractions of microbial polysaccharides in the clay. Amino acids, in particular diaminopimelic acid, which is confined to the peptidoglycans of cell wall of the prokaryotes, are recovered in elevated yields from clay. Because most of the bacterial biomass has been found in the vicinity of clay, high concentrations of bacterial-derived compounds (diaminopimelic acid, muramic acid) in the clay-size separates may be caused by a high production of microbial-derived substances.

As revealed by CuO-oxidation products, particle-size fractions of soils differ in the contribution of lignin to total organic carbon, but also in the degree of lignin alteration. Highest lignin contents obtained by the CuO-oxidation method are measured in the coarse fractions and decrease continuously with decreasing particle size (Figure 4c). A higher degree of oxidative alteration of lignin in finer-size separates compared with coarser fractions suggests that lignin in finer fractions had undergone more intensive microbial degradation.

Cross-polarization/magic angle spinning (CP/MAS) ^{13}C nuclear magnetic resonance (NMR) spectroscopy

is, at present, probably the most favored tool for detecting individual forms of C. Although this method is problematic with respect to quantification, it provides important insights into the chemical structure of SOM associated with different primary-particle fractions (Figure 5).

In general, O-alkyl resonances, mainly derived from carbohydrates or from ether bonds in degraded lignin predominate across the entire textural range, but they are minimized in the silt fraction. The strongest O-alkyl signals are always observed in the sand fraction, and spectra of the organic matter associated with sand strongly resemble those of fresh plant litter. Aromatic C, and in particular the aromatic C with other C substituents, is maximal in silt but is lowest in the clay fraction(s). Alkyl C steadily increases with decreasing particle size and represents the major or the second major C species in the clay(s). Long-chain aliphatic material derived from natural waxes is a major component of this alkyl C. Furthermore, microorganisms also synthesize long-chain aliphatic compounds.

Using the natural ^{13}C-labeling technique where there is a shift in the photosynthetic pathway from C3-vegetation to C4-vegetation or vice versa (see also Table 1), it was shown that particle-size fractions represent SOM pools with different turnover times. Organic compounds in sand-size fractions are turned over rather rapidly within several years, whereas organic matter associated with silt and clay particles show markedly higher turnover times, thus being involved in mid- and long-term dynamics.

Stabilization of SOM by Humification

As well as stabilization by spatial separation of organic matter particles with structural relationships to plant tissue material at different stages of microbial decomposition, the chemical stabilization of the completely humified products of the particles together with microbial compounds makes an important contribution to SOM. Accumulation of refractory humic compounds can be caused by preferential sorption of refractory fractions of organic matter in the dissolved stage (DOM). It results from leaching of dead plant residues, particularly those of the litter layer, with water or by solubilization of already humified compounds in the soil solution. Only small proportions of DOM can be identified in the form of organic acids, sugars, amino acids, and phenols. But most DOM is complex humified organic matter. The carbohydrate fraction of DOM contains a higher proportion of hexose and deoxysugars, which are typical for a microbial origin.

Adsorption of DOM on mineral phases results in a drastic decrease in its microbial degradability. Laboratory studies show that soil samples can adsorb DOM rapidly and there is evidence of a fast and strong adsorption of DOM to Al and Fe oxides and hydroxides. Sorption of the hydrophobic DOM fraction is strongly favored over the binding of the hydrophilic fractions in soils and on hydrous oxides. Furthermore, ^{13}C NMR spectroscopy shows that the sorption of DOM to soil material leads to a preferential depletion of carbonyl and aromatic C, whereas alkyl C accumulates in the soluble portion. Also a preferential sorption of N compounds to oxides and clay minerals has been reported. Especially in the

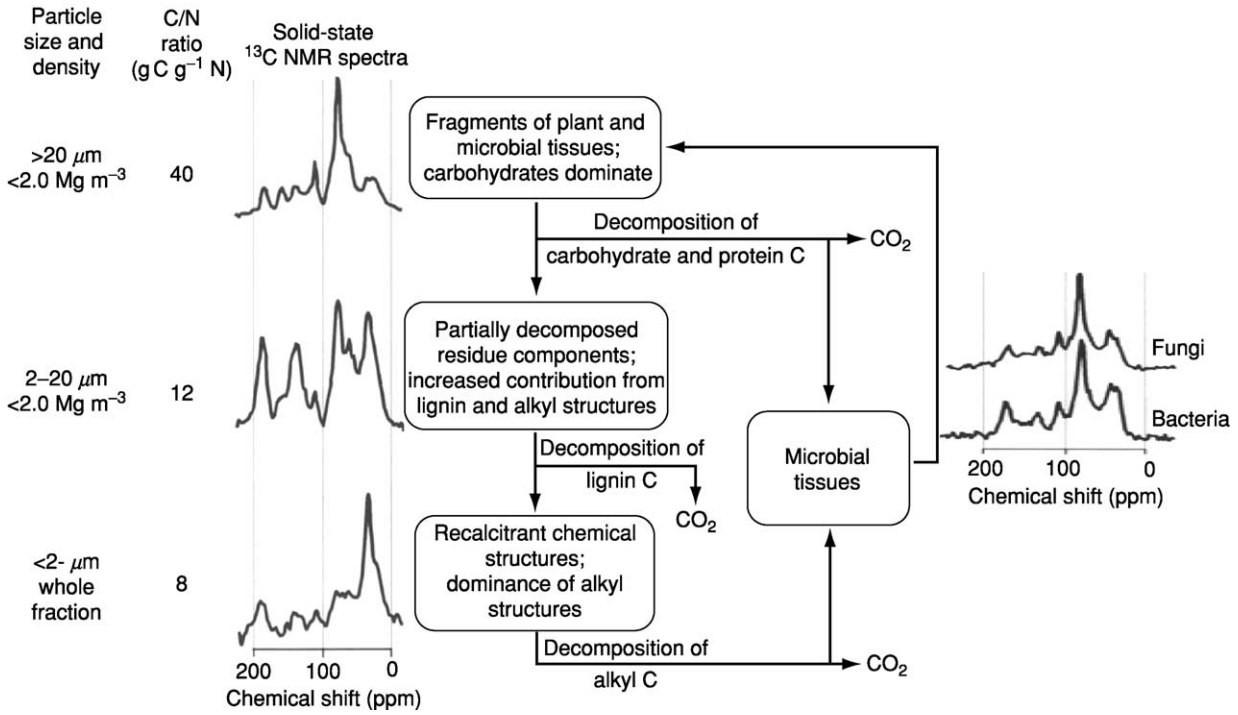

Figure 5 Cross-polarization/magic angle spinning ^{13}C-NMR spectra of the organic matter associated with different particle-size fractions. (Adapted from Baldock JA and Skjemstad JO (2000) Role of the soil matrix and minerals in protecting natural materials against biological attack. *Organic Geochemistry* 31: 697–710, with permission.)

deeper layers of the forest floor and in the A-horizon, low rates of DOM decomposition are found, which qualifies DOM as a source for the formation of stable humic substances. Sorption of DOM can create hydrophobic surfaces which limit microbial access by the reduction of wettability.

Biochemical Stabilization Mechanisms of Main Components from Plant Residues in SOM

Polysaccharide-related materials With respect to quantity, polysaccharides account for 5–25% or more of soil organic carbon. Although most plant polysaccharides are readily decomposed, several microbially synthesized polysaccharides are relatively resistant against decomposition. Based on model experiments, mechanisms for their stabilization have been proposed, which may be caused by a close association with mineral colloids, an interaction with metal ions through uronic acid and mannose units, or by their interaction with tannins. Polysaccharides that are stabilized in such ways may represent a stable fraction of SOM. A further protection against rapid degradation arises from the special role of polysaccharides as 'bridges' between mineral particles, being directly involved in the formation of stable aggregates. There are indications that even more stable products of microbial resynthesis are also involved in the stabilization of SOM. One substance of importance is 'glomalin,' a glycoprotein with N-linked oligosaccharides, which is produced by hyphae of arbuscular mycorrhizal fungi and which is abundant and stable in soil.

Lignin-related materials Lignin, which is the second most abundant component of plant residues in terrestrial ecosystems, is relatively recalcitrant by itself, and degradation rates of lignocellulosic materials are negatively correlated to their lignin content or to their lignin-to-N ratio. Lignin as an aromatic biomolecule is degraded at a much slower rate than cellulosic and noncellulosic polysaccharides, and proteins. This recalcitrance is caused by the presence of nonhydrolyzable C–O–C and C–C bonds between the phenylpropanoid units, and the structural heterogeneity of stable ether and C–C bonds, which can only be cleaved by oxidative mechanisms through ligninolytic enzymes. These enzymes are directly or indirectly involved in the generation of lignin radicals by removing electrons from phenolic units. The resulting unstable radicals subsequently undergo a variety of spontaneous rearrangement reactions. During these reactions, water and oxygen molecules, and thereby additional hydroxyl, carboxyl, and C=O functions are introduced, which increase the oxygen content in the remnant lignin. Another peculiarity of

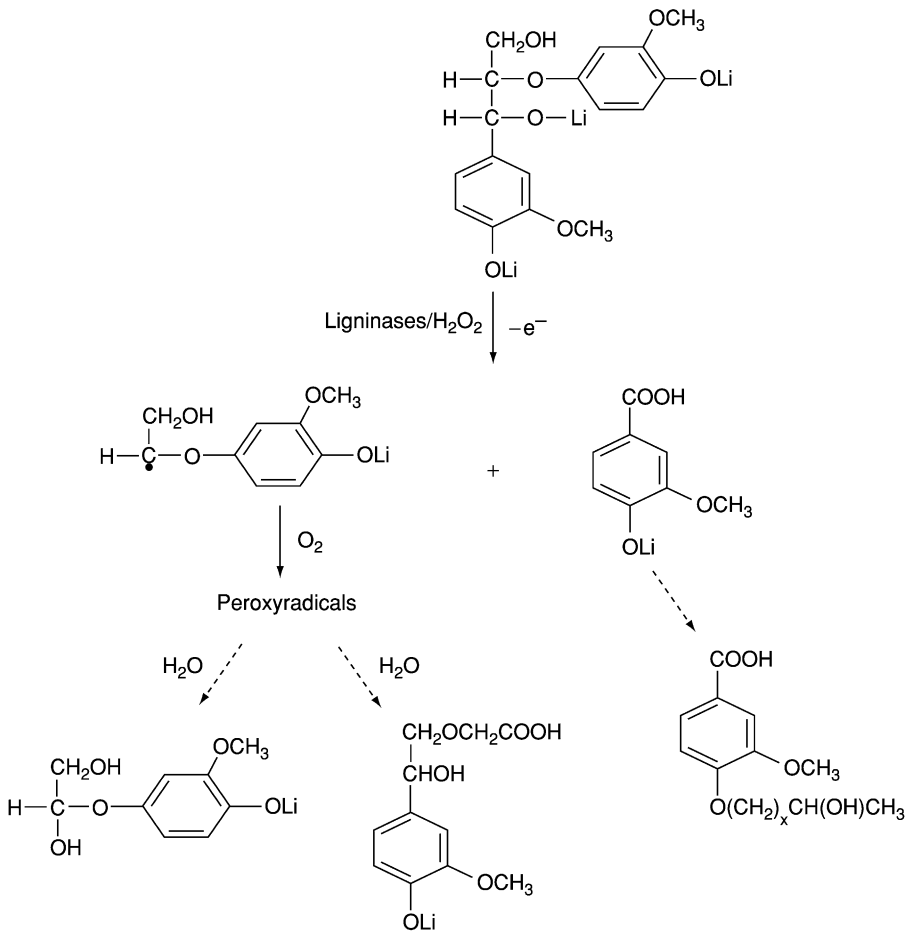

Figure 6 Structural features of a microbially attacked lignin. Li, residues of lignin; •, radical (unpaired electron). (Adapted from Haider K (1992) Problems related to the humification processes in soils of temperate climates. In: Stotzky G and Bollag J-M (eds) *Soil Biochemistry*, vol. 7, pp. 55–94. New York: Marcel Dekker.)

lignin biodegradation, compared with other plant compounds, is the cometabolic character of the degradation process, by which it does not provide a source of energy or carbon for ligninolytic organisms. Thus, for an effective lignin degradation, a readily metabolizable cosubstrate such as carbohydrates is required.

Preservation of lignin constituents in humic substances has attracted attention for many years. Similarities and differences in structure and chemical reactivity between lignin and humic compounds have been reviewed recently in terms of existing humification hypotheses. ^{13}C-NMR spectroscopy of microbially degraded lignin in soils, its oxidative CuO-splitting or its reductive HI-splitting products, pyrolysis in combination with previous chemolysis by tetramethylammonium hydroxide (TMAH) indicate that intact or only demethylated lignin does not appear to be stabilized in the long term in soils or in any of its fractions. However, the latter method reveals that phenolic structures characteristic for altered lignin structural units contribute significantly to the stable SOM pool in soils.

Based on investigations with ligninolytic organisms, enzymatic lignin degradation is a result of random peroxidative splitting of the lignin macromolecule in the α-β and other bonds of the side chain and in the aromatic rings, and by demethylation of the methoxyl groups (Figure 6). Thereby, the compact and hydrophobic structure of the lignin molecule becomes dispersed and, by introduction of additional carboxyl and hydroxyl groups, more hydrophilic. Additional hydroxyl and carboxyl groups in vicinal positions are apt to form complexes with metal ions in solution or on surfaces of clays or metal oxides.

Impact and Function of the Soil Microflora in Relation to SOM Stability

In order to understand the role of microorganisms in the generation and turnover of refractory SOM, a better knowledge of population structure and the activity of the microbial communities in the soil

habitat is necessary. Soils generally contain several tons of organic matter per hectare, but soil microorganisms can degrade most of this SOM pool only very slowly.

Models to describe the turnover of SOM assume the presence of easily and less-easily degradable pools in soil. These pools are, however, not clearly separated, but exist in a continuous sequence of overlapping residence times. Approaches to characterize SOM pools with different turnover rates distinguish between active, slow, and passive pools. The active or easily degradable pools with mean residence times of 0.1–4 years consist of free or only loosely adsorbed particulate organic matter (e.g., the light fraction, the microbial biomass). The slow-degrading SOM pools with mean residence times between 25 and 50 years consist of physically stabilized organic matter, i.e., occluded or sequestered in small aggregates. The passive or stable SOM pool contains the chemically stabilized humic materials, sorbed to fine silt and/or to clay, and has mean residence times of approximately 400–3000 years. On average, approximately 5–10% of the total C in SOM is involved in the active pools, and approximately 20–40% in the slow pools. To maintain a relatively constant nutrient level and release by mineralization, the pools have to be renewed continuously by fresh plant residues. The balance between decay and renewal processes controls nutrient availability and is sensitive to management practices. The slow pools are also affected by cultivation, as physical disturbance (caused, e.g., by ploughing) destroys macroaggregates and larger microaggregates and thus releases physically protected SOM. The passive pools contain the most stable SOM, which is protected by chemical and physical mechanisms. A strict distinction between physical and chemical effects of soil minerals on the stabilization of SOM can often not be made. The passive pool represents 50–70% of the total C in SOM and is seldom affected by management practices.

Whereas the compounds in the active and also some of the ingredients in the slow pools are used by microorganisms for metabolic and energy-producing processes, the great SOM portion of humic compounds in the passive pool is not readily available to microorganisms as a source of energy and products for microbial biosynthesis. On the other hand, small amendments of readily available substrates such as glucose or fructose, but even more in the form of cellulose, wheat straw, root exudates, or green manure, cause 2–5 times more C to be released from soil as CO_2 than was added with the substrate. This effect is termed the 'priming effect.' It arises either immediately or very shortly after the addition of available substrates and is caused by microbial activity, since similar effects have never been observed under sterile conditions. In the case of a 'positive priming effect,' the extra mineralization originates at least partly from the labile humus fractions or by an enhanced turnover of the native soil microbial biomass. In the case of a passive soil fraction, an increased induced enzyme production leading to a cometabolic decomposition has been found.

As for lignin, the completely humified products consist of randomly condensed intermediate compounds. In the case of a passive humus fraction, they represent refractory plant and microbial residues. Their diversity and lack of regular polymeric structures and the large number of enzymatic steps necessary to release CO_2 do not allow efficient enzymatic degradation and energy production. The slow decomposition of the passive SOM, however, becomes accelerated by small inputs of available substrates. Even when these inputs are relatively small compared with the large size of the passive fraction in most soils, they 'trigger' the synthesis of enzymes for the cometabolic degradation of a portion of the otherwise passive SOM fraction. This priming effect only lasts for a relatively short period after addition and disappears after metabolization of the added substrates. It can be hypothesized that this effect may limit the ultimate accumulation of passive SOM.

Interactions with Metals

N Senesi and E Loffredo, Università di Bari, Bari, Italy

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Metal ions in soil are rarely found in the free state, but mostly occur in interactions with other soil organic, inorganic, and biological components, in the liquid and solid phases. The distribution and speciation of metal ions in soil, especially in trace concentrations, are extremely complex and are governed by a variety of reactions, among which complexation with soil organic matter (SOM) plays a key role.

Thus, understanding the molecular, mechanistic, and quantitative aspects of metal–SOM complexation is extremely important in the prediction of processes in which metals are involved in soil. These include: pedogenesis, mobility and transport, fixation and accumulation, chemical and biological reactivity, bioavailability, and toxicity to higher plants and microorganisms. The topic is also of considerable practical interest because of the continuous and increasing release of various metals in soil by numerous modern agricultural practices.

Molecular and Mechanistic Aspects

Metal Reactivity, SOM Binding Sites, and Complexation Stoichiometry

Metal cations may be subdivided into three classes with respect to their reactivity with organic ligands: (1) 'hard' cations such as alkaline-earth metals Ca^{2+} and Mg^{2+} that are mainly involved in electrostatic interactions and may form rather weak, outer-sphere complexes only with hard oxygen ligands; (2) 'soft' cations such as Cd^{2+}, Pb^{2+}, and Hg^{2+} that possess a strong affinity for and tend to form covalent bonds with intermediate (N) and soft (S) ligands; and (3) 'borderline' cations, including most transition metals such as Fe^{3+}, Cu^{2+}, Zn^{2+}, and Mn^{2+} that have a character intermediate between hard and soft metals, and possess appreciable affinity for both hard and soft ligands.

The most important metal-binding functional groups present in SOM, classified according to their affinity for hard, borderline, and soft metals, are listed in Table 1. For hard cations the order of donor atom affinity is: O > N > S, whereas a reverse order is observed for soft metals. For bidentate ligand sites, affinity for a given hard metal decreases with the overall hardness of the donor atoms, in the order: (O, O) > (O, N) > (N, N) > (N, S); whereas this order is reversed for soft metals. In general, the competitive reactions for a given ligand essentially involve hard and borderline metals for O sites, and borderline and soft metals for N and S sites, with competition between hard and soft metals being weak. However, the type, source, and concentration of SOM can affect metal-binding affinity, and the relative affinities are often dependent on the method used to measure metal bonding and pH.

Humic substances (HS), i.e., humic acids (HA) and fulvic acids (FA) are universally recognized to

Table 1 Most important metal organic ligands of soil organic matter classified according to their preference for hard, borderline, and soft metals

Ligands preferred by hard cations (hard bases)	*Ligands preferred by borderline cations*	*Ligands preferred by soft cations (soft bases)*
 (Ester)	$-NH_2$, $=NH$, $\equiv N$	R^-
(Carboxylate)	(Primary, secondary, tertiary amino groups)	(Alchil anion)
–OH (Alcoholic and phenolic)		$-SH$, $-S^-$
	(Amide)	(Sulfhydryl, sulfide)
		–S–S–, –S–
(Carbonyl) (Ether)		(Disulfide) (Thioether)

represent the most numerous (between 70 and 80%) and most metal-reactive SOM components. This is because they contain a large number of binding sites per molecule and thus behave as natural 'multiligand' systems.

Metal ion–HS interactions may yield mononuclear complexes, with the central group being either the HS macromolecule or the metal ion, and polynuclear complexes of various stoichiometries. Accumulated evidence shows that aromatic carboxyls and phenolic groups play a prominent role in the 1:1 binding of metal ions by HA and FA, by forming chelates that involve two COOH groups in a phthalic-type site (**Figure 1a**) and both COOH and phenolic groups in a salicylate-type site (**Figure 1b**). Nonaromatic carboxyl and hydroxyl sites, e.g., pyruvic and glycolic acid sites (**Figure 1c, d**), may also be involved in metal ion binding by HA and FA. The most stable complexes are believed to be formed with the more strongly acidic COOH groups, whereas the less stable complexes involve weakly acidic COOH and phenolic OH groups. Other possible combinations involve two phenolic OH, quinone, NH_2, and sulfhydryl groups, and conjugated ketonic structures (**Figure 1e**). Metal ions may also coordinate with ligands belonging to two (or more) HS molecules, forming 2:1 complexes (**Figure 1f, g**) and/or chelates (**Figure 1h, i**). Eventually, a chain structure (**Figure 1j**) may be produced that may result in the aggregation and precipitation as the chain grows at high metal-to-HS ratios.

Two main types of complexes may be formed between metal ions and HS, which are: (1) inner-sphere complexes that result in the formation of bonds with some covalent character between the ligand atom(s) and the metal ion, both completely or partially dehydrated; and (2) outer-sphere complexes that result in the electrostatic attraction between the ligand(s) and the metal ion that remains completely hydrated. For simplicity, **Figure 1a–j** shows formation of inner-sphere complexes, but they may represent outer-sphere HS complexes if the cation remains solvated (e.g., **Figure 1k**).

A number of molecular properties of HS and physical and chemical characteristics of the surrounding medium govern metal–HS binding processes. These include: polyfunctionality, polyelectrolyte character, hydrophilicity/hydrophobicity and extent of ionization of major acidic groups of HS, electronic and steric environment of the HS ligand site, and pH, ionic strength, and metal concentration of the medium.

Experimental Evidence

Spectroscopic techniques such as infrared (IR), ultraviolet-visible (UV-VIS), fluorescence, electron-spin or electron paramagnetic resonance (ESR or EPR), X-ray absorption (XAS), Mössbauer, and nuclear magnetic resonance (NMR) spectroscopies have provided a number of important molecular and mechanistic insights of the chemical and physical nature of HS binding sites and metal–HS interactions.

IR, UV-VIS, and fluorescence spectroscopies Fourier transform IR (FT IR) and diffuse reflectance FT IR (DRIFT) spectroscopies, often in conjunction with selective group blocking techniques and/or with

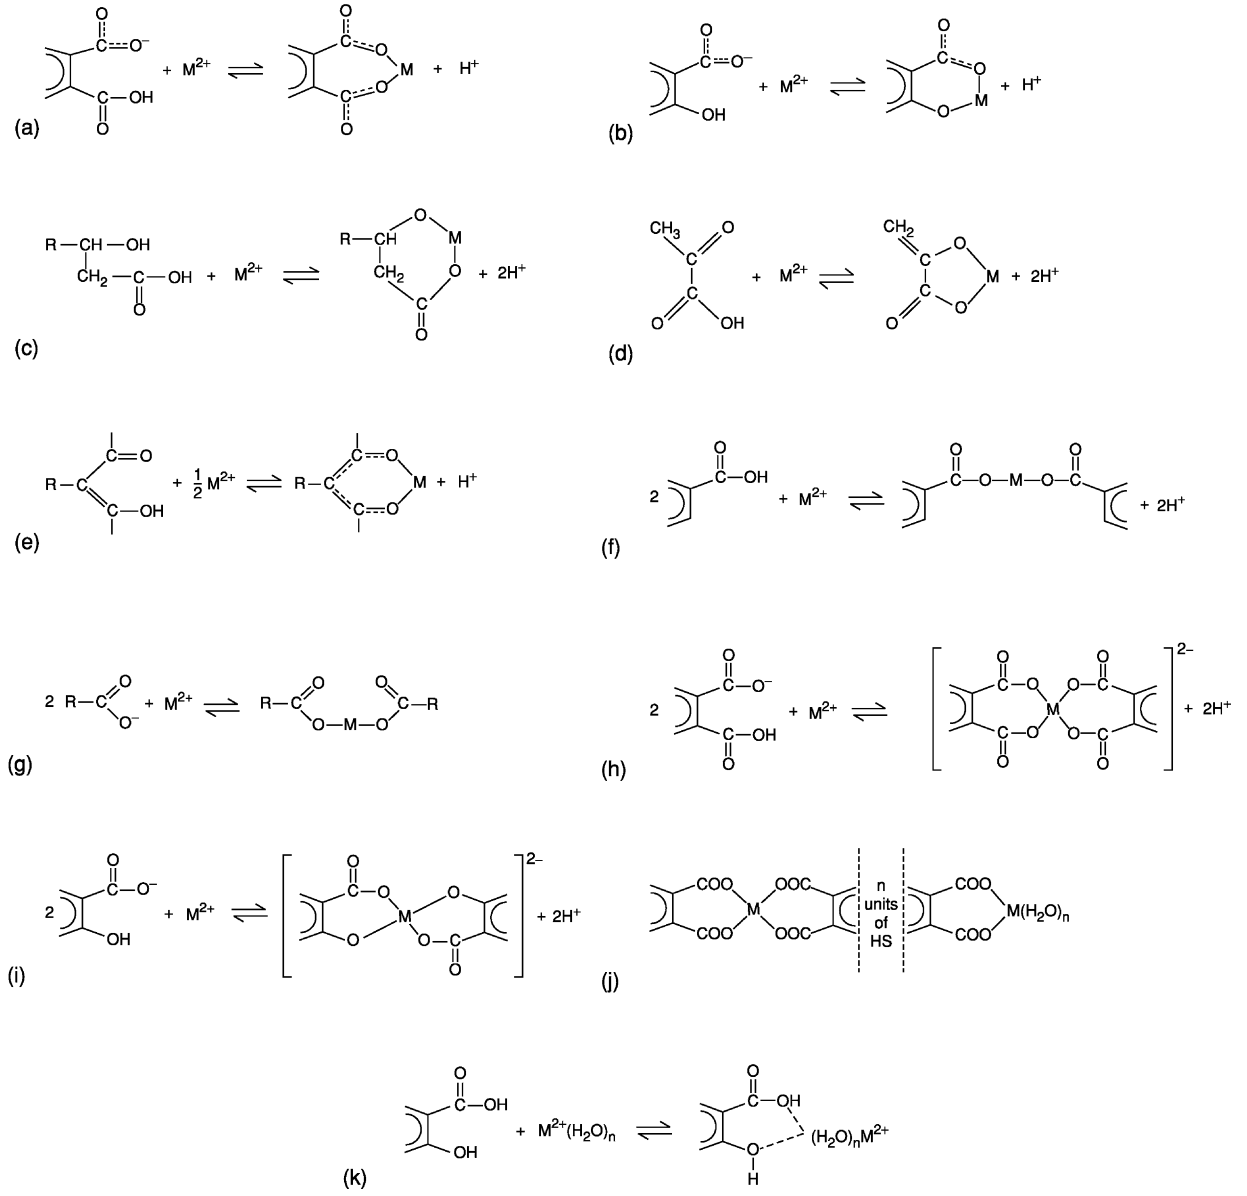

Figure 1 The most common binding sites for metal ions in humic substances and stoichiometries of complexation: (a) a phthalic-type binding site; (b) a salicylate-type binding site; (c) a pyruvic acid binding site; (d) a glycolic binding site; (e) a conjugated ketonic binding site; (f) a 2:1 aromatic carboxyl complex; (g) a 2:1 aliphatic carboxyl complex; (h) a 2:1 phtalic-type chelate; (i) a 2:1 salicylate-type chelate; (j) a chain structure; (k) a salicylate-type outer-sphere complex.

chemical derivatization methods, have provided useful information about the nature and reactivity of HS functional groups that interact with metal ions.

The prominent role played by COOH groups of HA and FA in the complexation of several metal ions, including Cu^{2+}, Mn^{2+}, Zn^{2+}, Pb^{2+}, Co^{2+}, Ni^{2+}, Ca^{2+}, Mg^{2+}, Sr^{2+}, Fe^{3+}, and Al^{3+}, has been demonstrated by the strong reduction or disappearance of the typical IR absorption bands of COOH groups at approximately 1710 and 1200 cm^{-1}, and the simultaneous reinforcement or appearance of the typical IR bands of COO^- groups near 1600 and 1380 cm^{-1}, upon reaction of HA and FA with the metal (Figure 2). The extent of COO^- to COOH conversion varies in the decreasing order: $Fe^{3+} > Cu^{2+} > Al^{3+} > Ca^{2+} > Mg^{2+}$. The increase in COO^- vibration frequency for a number of metal–HA and –FA complexes suggests that high-covalent bonds are preferentially formed at low levels of metal ion, whereas bonding becomes increasingly ionic as the system is enriched with the metal. The large separation measured between the frequencies at approximately 1600 and 1380 cm^{-1} for the COO^- group complexed by Cu^{2+}, Fe^{3+}, Co^{2+}, and Zn^{2+}, with respect to that of

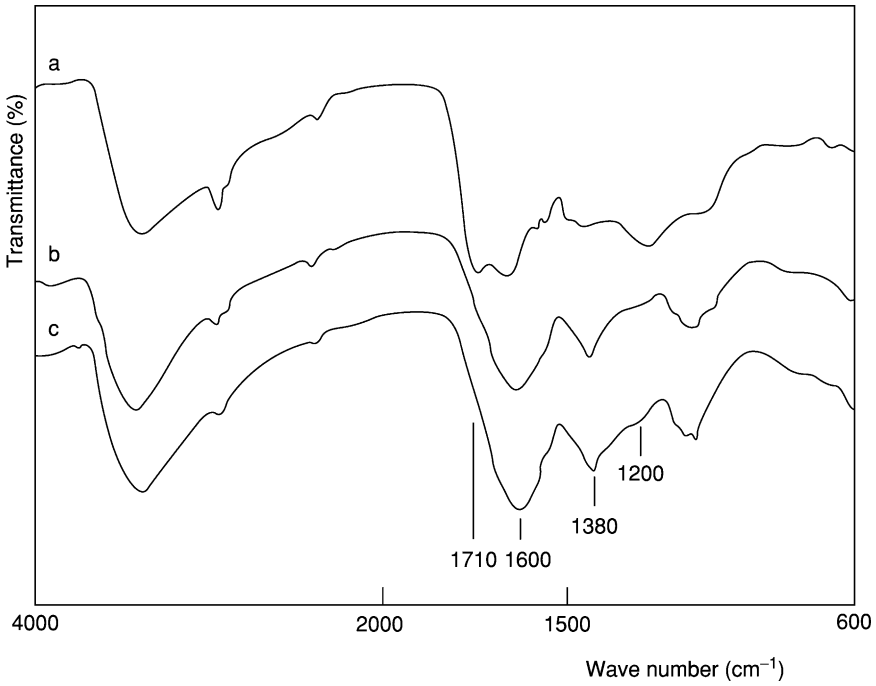

Figure 2 Infrared spectra of a soil humic acid (HA) (a) and its complexes with Cu^{2+} (Cu^{2+}:HA = 0.04) (b), and Cu^{2+} and Fe^{3+} ((Cu^{2+} + Fe^{3+}):HA = 0.08) (c). (Adapted from Senesi N, Sposito G, and Martin GP (1986) Copper (II) and iron (III) complexation by soil humic acids: an IR and ESR study. *Science Total Environment* 55: 351–362, with permission.)

the uncomplexed COO^- ion, suggests the preferential formation of unidentate metal complexes.

The net IR shift of the OH band, from 3500–3400 cm^{-1} in HA and FA to 3300–3200 cm^{-1} in their complexes with Zn^{2+}, Fe^{3+}, Cu^{2+}, Pb^{2+}, Co^{2+}, and Mn^{2+} is ascribed to the involvement of phenolic and/or alcoholic OH groups in metal binding. The extent of the OH stretching shift toward lower frequencies follows the order: Fe > Cu > Co > Mn. Modification of the typical band at approximately 1070 cm^{-1} ascribed to OH groups of polysaccharide components of FA suggests that these structures are also involved in metal complexation. The shift to a lower frequency measured for the band at 1610 cm^{-1} in Cu^{2+}–FA complexes is attributed to the involvement of conjugated ketones in Cu^{2+} binding. IR evidence is also provided for metal binding sites involving amide N (and possibly amide C=O) and sulfonic groups by N- and S-rich HS. Finally, the very sharp IR bands observed in the region 1130–1080 cm^{-1} and at between 890 and 697 cm^{-1} for HA and FA complexes with Cu^{2+}, Zn^{2+}, Al^{3+}, or Fe^{3+} are attributed to the metal–O vibration of bound hydroxylated and/or hydrated metal ions.

The stoichiometry of metal–HS complexes has been investigated by UV-VIS spectroscopy based on the Job method. For example, the ions Cu^{2+}, Fe^{3+}, and Al^{3+} form 1:1 complexes with FA at pH 3; whereas, at pH 5, Cu^{2+} and Fe^{3+} form 2:1 molar complexes with the FA, and Al^{3+}–FA complex composition remains at 1:1.

The capacity of paramagnetic transition metal ions such as Cu^{2+}, Fe^{3+}, Fe^{2+}, Mn^{2+}, Cr^{3+}, and VO^{2+} to quench efficiently the natural fluorescence of some HS ligands is attributed to their capacity to form strong, inner-sphere complexes with HS, involving strongly acidic carboxyl groups in bidentate salicylic- or phthalic-type chelation sites. In contrast, the low fluorescence-quenching ability exhibited by cations such as Mn^{2+}, Co^{2+}, Ni^{2+}, Pb^{2+}, and Al^{3+} suggests the formation of weak, outer-sphere complexes with HS. The quenching effect generally increases with increasing pH (Figure 3). Fluorescence-quenching studies also suggest the involvement of aromatic amino acidic groups such as tyrosine and phenylamine moieties, and citrate and malonate moieties in the complexation of Cu^{2+} by FA.

ESR, XAS, Mössbauer, and NMR spectroscopies The ESR technique applied to HA and FA complexes with paramagnetic transition metals of major importance in soil, including Fe, Cu, Mn, and V, has provided useful information about oxidation states of metals bound, symmetry and type of coordination sites in HS, binding mechanisms of metals to HS, and identity of ligand atoms and groups involved in metal complexing.

The representative ESR spectrum of a soil HA shown in Figure 4a exhibits a number of patterns

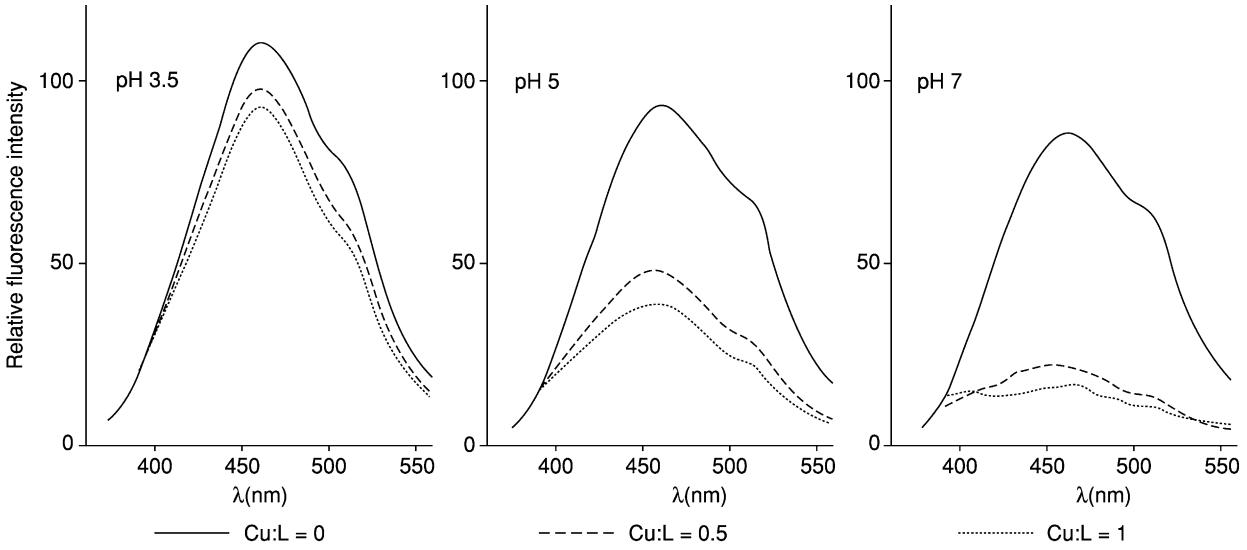

Figure 3 Fluorescence emission spectra ($\lambda_{exc} = 355$ nm) of a soil fulvic acid (FA) and its complexes with Cu^{2+} obtained at three pHs and two different Cu^{2+}-to-FA ligand (L) ratios. Propriétés fluorescentes et colloidales d'une solution organique de podzol au cours du processus de complexation par le cuivre. *Advances in Soil Science*, vol. 14, pp. 77–130. New York: Springer-Verlag.)

that can be resolved, analyzed, and attributed to various metal–HS complexes. The asymmetrical, isotropic resonance line appearing at low magnetic field is consistent with high-spin Fe^{3+} ions in tetrahedral or octahedral sites of rhombic symmetry bound to O functional groups, possibly carboxylic and/or phenolic groups of HA. This form of Fe exhibits considerable resistance to proton and metal exchange, and to chemical reduction, thus suggesting that Fe^{3+} is strongly bound and protected in inner-sphere complexes in HS. The broad signal often exhibited by soil HS at higher field is preferentially ascribed to Fe^{3+} ions in slightly distorted octahedral sites. Iron in such sites is easily reduced by chemical agents and easily extracted by complexing agents, thus suggesting a weak binding of Fe^{3+} on external surfaces of HS.

The richly structured pattern exhibited at higher field (Figure 4a), which is better analyzed using the enlarged spectrum of the region (Figure 4b), can be resolved into two distinct, overlapping rigid-limit spectra of the 'axial' type. One comprises the typical anisotropic pattern ascribed to Cu^{2+} ions held in inner-sphere complexes with ligands arranged in a square planar (distorted octahedral) coordination site (tetragonal symmetry), involving either only O functional groups (carboxyls, phenolic hydroxyls,

carbonyls, and often water molecules) of HS, or both O and N ligands, or even only N atoms (i.e., a tetraporphyrin site). The other pattern is consistent with a VO^{2+} ion rigidly bound in HS as an inner-sphere complex in a square planar coordination site to O ligands, mostly phenolate, or possibly water molecules and, more rarely, N ligands.

ESR spectral parameters also provide evidence of a high covalent bond for Cu^{2+} and VO^{2+} complexed in HS, which renders Cu^{2+} and VO^{2+} ions difficult to remove from these sites, even with acid leaching. Covalent bonding is favored by low metal loadings in HS, where complexation to N-containing groups is preferred to O-containing ligands, whereas at high loadings the metal is bound largely to O-containing ligands and has a higher degree of mobility.

The ESR spectra of some soil HA and FA feature a well-resolved isotropic pattern consistent with high-spin, hexahydrated Mn^{2+} bound by electrostatic forces as outer-sphere complexes in a distorted octahedral environment to six O atoms of negatively charged carboxylate and phenolate groups. However, at pH > 8, or temperature $T > 50°C$, Mn^{2+} can enter inner-sphere, multiligand complexation sites. Thus, the type and stability of Mn^{2+}–HS complexes and, in turn, their ease of exchangeability and bioavailability in natural systems are strongly dependent on pH and temperature.

ESR evidence has been provided that HS possess a high residual binding capacity toward added Cu^{2+}, Fe^{3+}, VO^{2+}, and Mn^{2+} ions that can form complexes of various stability against various physical and chemical treatments. Most of the added metal is bound to surface sites in relatively labile and exchangeable forms.

In general, ESR analysis shows that high pH values that generate a greater availability of negatively charged O ligands favor inner-sphere complexation for metals, whereas, at lower pH, metals are preferentially retained as hydrated ions. Inner-sphere coordination is also preferred when competing water ligands are removed by dehydration, thus forcing the metal to enter into direct bonding with HS ligands. ESR data confirm that the more electronegative the metal ion, the stronger the metal bound to HS, the higher the degree of bond covalency. The ESR-related, electron-nuclear double resonance (ENDOR) and electron spin-echo envelope modulation (ESEEM) spectroscopies have the potential to overcome some limitations and yield more information than the classic ESR approach about the chemical environment of paramagnetic metal ions.

The XAS techniques, X-ray absorption near-edge structure (XANES) and extended X-ray-absorption fine-structure (EXAFS) spectroscopies, have yielded additional details about the coordination of the central ion to HS ligands and values of bond lengths and distances of metal-ligand also for nonparamagnetic metal ions that cannot be revealed by ESR. Analysis of XANES spectra, radial structure function (RSF) plots derived from EXAFS spectra, and corresponding simulations for Cu^{2+} bound to HS at various pHs (Figure 5) indicate the presence of a tetragonally distorted octahedral binding site for Cu^{2+} in HS, involving four equatorial O (or N) atoms at a mean distance of 1.92–1.97 Å and two axial O atoms at a mean

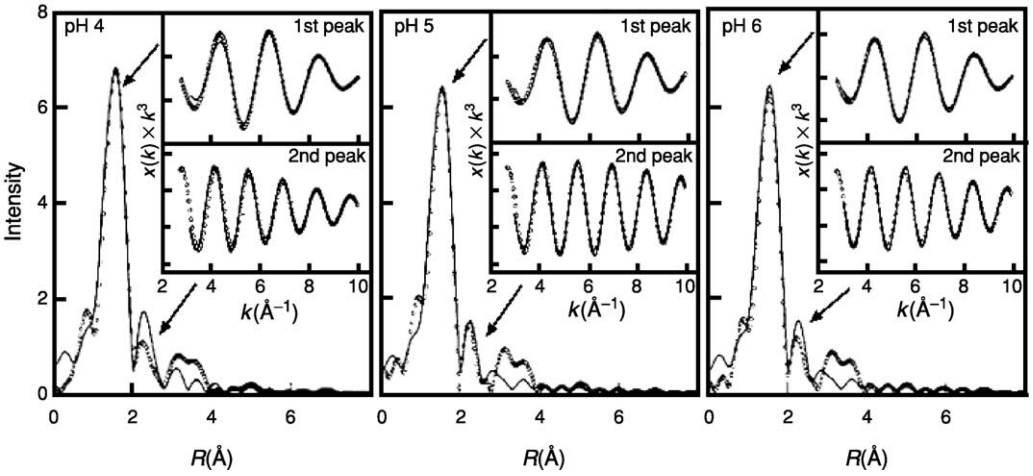

Figure 5 Experimental radial structure function for Cu^{2+}–humic substance complexes at pH 4, 5, and 6 (dotted line) and simulations (solid line) for an adjusted model of the coordination site derived from bond network analysis. The inset shows plots of experimental (dotted line) and fitted (solid line) inverse Fourier-transformed scattering curves for the first atomic shell (Cu–O) and second atomic shell (Cu–C). *R*, distance (in Å) of the ligand atom from Cu^{2+}. (Reproduced with permission from Xia K, Bleam WF, and Helmke PA (1997) Studies of the nature of Cu^{2+} and Pb^{2+} binding sites in soil humic substances using X-ray absorption spectroscopy. *Geochimica Cosmochimica Acta* 61: 2211–2221.)

distance of 2.02 Å in the first coordination shell, and four C atoms at a mean distance of 3.13 Å in the second shell. Similar XANES and EXAFS studies of Pb^{2+}–HS complexes indicate that Pb^{2+} is bound to four O atoms in the first shell at mean distances, decreasing from 2.46 to 2.32 Å, with increasing pH from 4 to 6, and two C atoms at a mean distance of 3.26 Å in the second shell. These results suggest inner-sphere bonding of Pb^{2+} to two O-containing, possibly salicylate- and catechol-type functional groups of HS. Complexes of Ni^{2+}, Co^{2+}, and Zn^{2+} with soil HS at pH 4 are interpreted as inner-sphere octahedral coordination, with six O atoms in the first shell for Ni^{2+} and Co^{2+}, and with four O and two S atoms for Zn^{2+}. The bond distances for Ni—O and Co—O are 2.10 Å and 2.04 Å, respectively, and for Zn—O and Zn—S are 2.13 Å and 2.33 Å, respectively. There is one C atom in the second shell for Co, at a distance of 2.87 Å, and there are two for Ni and Zn, at a distance of 2.94 Å and 3.29 Å, respectively. At very high Zn^{2+} concentration, however, most of the Zn (80–90%) is found to be bound as an outer-sphere complex. XANES and EXAFS spectra of Fe^{3+} and Mn^{2+} complexes with HA suggest that both ions are held in HA by six nearest-neighbor O or N atoms at a distance of 2.01 ± 0.05 Å and 2.20 ± 0.04 Å, respectively, and that Fe^{3+} occupies more than one binding site. Detailed EXAFS studies of Hg^{2+} complexation by soil HA suggest a two-coordinate binding environment for Hg^{2+}, with one O atom and one S atom in the first coordination shell at distances of 2.02 and 2.38 Å, respectively, and one C atom and a second S atom in the second shell at 2.78 and 2.93 Å, respectively. These results suggest thiol, disulfide/disulfane, COOH, and phenol OH groups of HA as ligands for Hg complexation.

Although Mössbauer spectroscopy is highly specific for the isotope ^{57}Fe, this technique is able to distinguish unambiguously between Fe^{3+} and Fe^{2+} ions that occur mostly in high-spin forms in combination with HS. Mössbauer parameters calculated from the representative Mössbauer spectrum of a soil HA shown in Figure 6a suggest the presence of three sites for Fe^{3+} ions in the HA, two with octahedral and one with tetrahedral coordination. Chemical reduction with hydrazine of the HA sample results in a Mössbauer spectrum in which one of the two doublets assigned to Fe^{3+} ions in octahedral sites disappears (3a in Figure 6a), and a new doublet appears that is typical of Fe^{2+} ions in the same type of sites (3b in Figure 6b). Mössbauer studies of several Fe^{2+}–HA complexes suggest the presence of Fe^{2+} ions either as a completely hydrated form in outer-sphere complexes or as a partially hydrated form bound to COO^- and phenolic and alcoholic OH- and N-containing groups of HA in elongated octahedral arrangements in inner-sphere, chelate-type complexes. Mössbauer evidence of partial oxidation of Fe^{2+} to Fe^{3+} is obtained on exposure to air of some Fe^{2+}–HA complexes.

The slight decrease observed in the line widths of the water NMR signal in a water solution of soil FA and Mn^{2+} suggests the formation of outer-sphere complexes of hexahydrated Mn^{2+} ion with FA in a slightly distorted octahedral environment. Differently, the great decrease measured in solutions of FA with Fe^{3+} or Cu^{2+} suggests the formation of inner-sphere coordination of these ions with FA. The involvement of O- and N-containing groups is suggested by ^{113}Cd-NMR in Cd complexation by soil FA in acidic conditions. Modern, two-dimensional NMR techniques such as total correlation (TOCSY), nuclear Overhauser effect (NOESY), heteronuclear Overhauser effect (HOES), and inverse-detection heteronuclear multiple quantum coherence (HMQC) spectroscopies are very promising in the studies of metal–HS interactions.

Quantitative Aspects

Metal-Binding Capacity of HS

In general, the binding or complexation capacity (CC) of a multiligand system such as HS is defined as the maximum capacity of the system for binding metal ions. To a good approximation, the CC of HS may be considered as the weighted average of the complexation capacities of the individual ligands $(CC)_i$ in the system, according to:

$$CC = \frac{\sum (CC)_i [\text{weight}]_i}{\sum [\text{weight}]_i} \qquad [1]$$

where $[\text{weight}]_i$ is a weighting factor related to the relative abundance of the ligand in the multiligand system. Given the relative abundance of acidic functional group ligands, primarily COOH, and the low concentrations of other O-, N-, and S-containing ligands in HS, the maximum binding capacity of HS approximates the total acidic functional group content.

In practice, the measured complexation capacity of HS is dependent on experimental conditions, being a function of various factors that include pH, ionic strength, HS concentration and properties, and nature of the metal ion. The effect of pH on metal–HS complexation results from both changes in the extent of ionization of COOH groups and hydrolysis reactions of the metal ion involving the formation of oxyhydroxides. In general, the complexation capacity

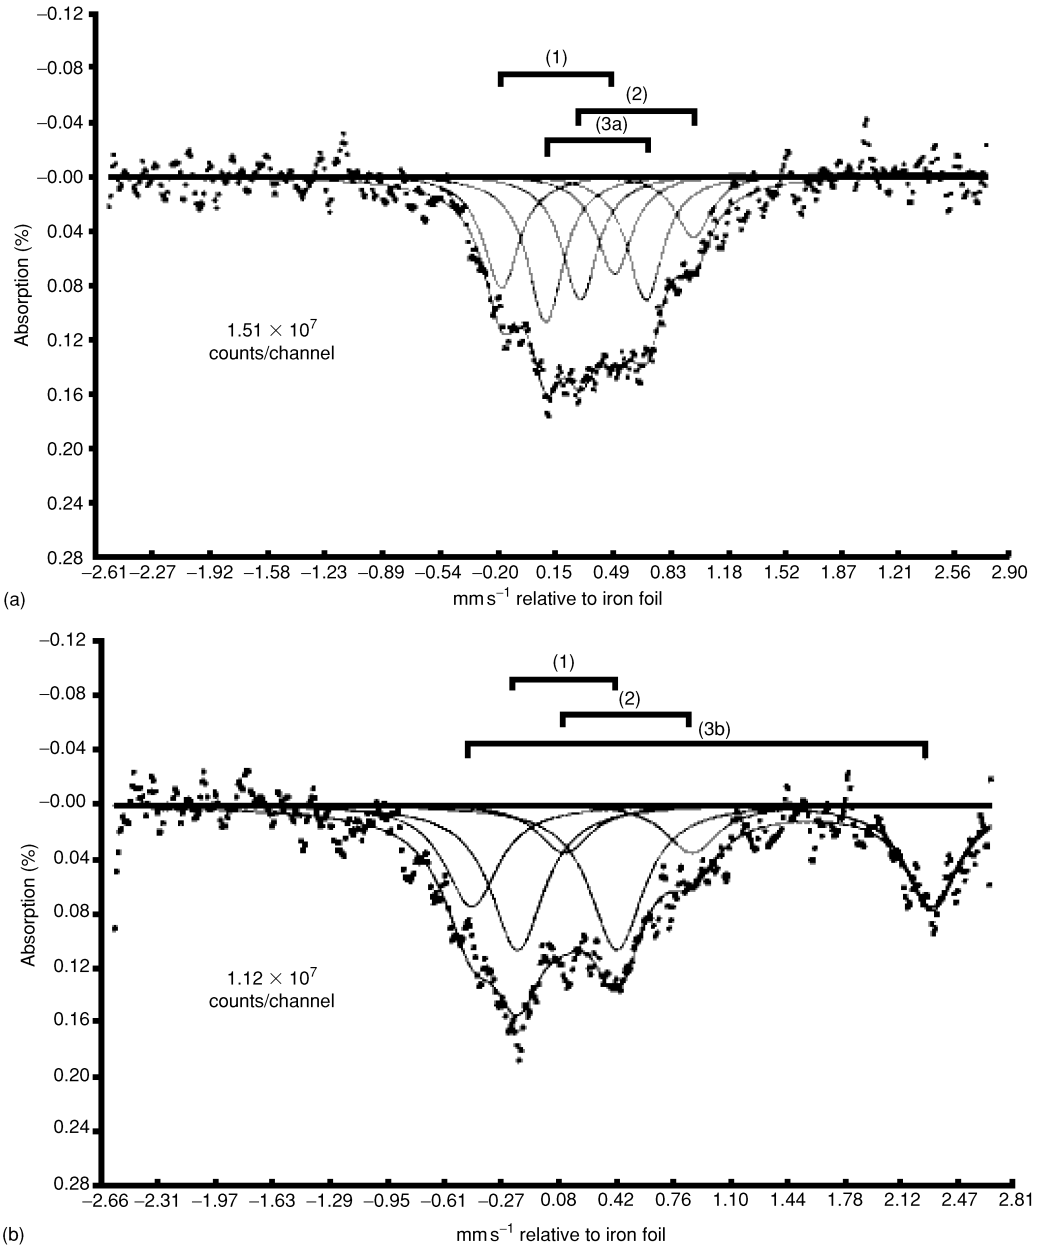

Figure 6 Mössbauer spectra of a soil humic acid (HA) (a) and the same HA after reduction with hydrazine (b). Doublets (1), (2), (3) refer to three different sites for Fe in HA. Doublets (3a) and (3b) refer, respectively, to Fe^{3+} and Fe^{2+} ions in similar octahedral sites. (Reproduced with permission from Senesi N, Griffith SM, Schnitzer M, and Townsend MG (1977) Binding of Fe^{3+} by humic materials. *Geochimica Cosmochimica Acta* 41: 969–976.)

of HS is reported to increase with increasing pH from acidity up to approximately neutrality and increasing HS concentrations, to decrease at high ionic strength, and to vary with the nature of the metal ion. For any given pH and ionic strength, trivalent cations are bound in greater amounts than divalent ones, of which those forming strong coordination complexes (e.g., Cu^{2+}) are bound to a greater extent and at stronger binding sites than those forming weak complexes (e.g., Mn^{2+}).

Stability Constants and Related Parameters of Metal–HS Complexes

The stability constant is probably the most important quantitative parameter for the characterization of a metal–ligand complex in that it provides a numerical

index of the affinity of the metal cation for the ligand. Several different theoretical and experimental approaches have been attempted for the determination of stability constants of metal–HS complexes.

The overall reaction of a single metal ion (M) and a single ligand (L) to form the complex M_mL_n:

$$mM + nL \rightleftarrows M_mL_n \qquad [2]$$

can be described by:

$$K = \frac{\{M_mL_n\}}{\{M\}^m\{L\}^n} = \frac{[M_mL_n]}{[M]^m[L]^n} \times \frac{\gamma_{M_mL_n}}{(\gamma_M)^m(\gamma_L)^n} = K_c \times \Gamma \qquad [3]$$

where braces and square brackets denote activities and concentrations, respectively, γ-values are activity coefficients, K is the true 'overall thermodynamic stability (equilibrium) constant,' K_c is the 'concentration quotient,' and Γ is the activity coefficient ratio. For convenience, the charges on the metal, ligand, and complex are not shown explicitly, even if their values are extremely important.

Most experimental investigations of metal–HS complexation reactions yield concentrations, rather than activities, of reactants and products. Thus, thermodynamic constants cannot be measured directly but must be indirectly obtained by calculation or by extrapolation methods from the concentration quotients whose values are not constant but depend, as well as those of the activity coefficient ratios, on the ionic concentration (ionic strength) of the solution. Basic electrostatic considerations (Debye–Hückel theory) indicate that Γ equals 1, and thus K_c values equal K values, at zero ionic strength; and Γ increases, and K_c tends to decrease, with increasing ionic strength. The concentration of the complex M_mL_n is thus expected to decrease upon addition of a background electrolyte to the solution of metal and ligand.

Competition from side reactions, especially the acid–base chemistry of both the metal ion and the ligand, i.e., hydrolysis of the metal ion to produce hydroxy complexes and protonation of the ligand, is another factor that affects the extent of complexation of M by L, which must be duly considered. In general, protonation of ligands occurs at low pH, and hydrolysis of metals at high pH. Thus, the most favorable condition for measuring the complexation of M by L is at intermediate pH values.

Metal–ligand complexation reactions are usually investigated at constant pH and using experimental techniques that are able to distinguish the metal–ligand complex from the uncomplexed metal and all forms of the ligand that are not bound to the metal ion. Thus, a 'conditional stability constant,' or more precisely a 'conditional concentration quotient,' K_c^*, can be written:

$$K_c^* = \frac{[M_mL_n]}{\frac{[M]^m}{(\alpha_M)^m} \times \frac{[L]^n}{(\alpha_L)^n}} = (\alpha_M)^m(\alpha_L)^n \frac{[M_mL_n]}{[M]^m[L]^n}$$
$$= (\alpha_M)^m \times (\alpha_L)^n \times K_c \qquad [4]$$

where α_M and α_L are the side-reaction coefficients of the metal ion and the ligand, respectively. Eqn [4] describes the formation and stability of the complex relative to all other forms of the metal and ligand that may exist under the actual experimental conditions. Further, eqn [4] shows that the conditional concentration quotient, K_c^*, includes a pH-invariant but ionic strength-dependent term, K_c, and pH-dependent terms, α_M and α_L.

Assuming for simplicity a 1:1 stoichiometry for all ML_i complexes, the complexation reaction of a single metal ion M with a multiligand system such as HS containing a number of ligands L_i can be described by an 'average stability constant,' or, more appropriately, an 'average concentration quotient':

$$\bar{K}_c = \frac{\sum[ML_i]}{[M]\sum[L_i]} \qquad [5]$$

where $\sum[ML_i]$ and $\sum[L_i]$ are, respectively, the sum of the concentrations of all 1:1 complexes and all uncomplexed ligands in the system. In practice, the metal ion will distribute itself among the various ligands on the basis of its stability constant with each ligand and of the relative concentration of that ligand. The metal ion will thus tend to complex preferentially with ligands having the highest stability constant and/or highest concentration.

Similar to single-ligand systems, an 'average conditional concentration quotient,' also called 'stability function,' $\bar{K}_c^*$, that takes pH effects into account, can be defined for multiligand systems such as HS. This quantity is a measure of the overall binding of a single metal ion to a multiligand system. However, it cannot be calculated rigorously for HS, because there is not sufficient information available to enable the full description of side reactions and the calculation of side-reaction coefficients of HS for which individual components are unknown. Thus the function $\bar{K}_c^*$ is often calculated directly from experimental data as:

$$\bar{K}_c^* = \frac{C_M - [M]}{[M](C_L - C_M + [M])} \qquad [6]$$

where C_M and C_L are the total stoichiometric concentrations of the metal and ligand in the system examined and [M] is the concentration of the free metal ion. The value of $(C_M - [M])$ corresponds to the sum

of the concentrations of all complexes formed between M and the multiligand system, and is calculated by neglecting the presence of inorganic metal complexes. The quantity $(C_L - C_M + [M])$ represents the sum of the concentrations of all binding sites that are not associated with M, and is calculated assuming an average 1:1 metal-to-ligand stoichiometry for the total of binding sites. Stability functions can also be defined for complexes of stoichiometries other than 1:1.

Mean $\bar{K}_c^*$ values are ultimately functions of ionic strength, pH, and degree of saturation of the multiligand system with the metal ion. At a given pH and ionic strength, $\bar{K}_c^*$ will decrease steadily as the total metal-to-ligand ratio (C_M:C_L) increases. At low metal-to-ligand ratios, the occurrence of preferential reactions of stronger ligands will determine the functional nature of $\bar{K}_c^*$. Thus, it is not possible to obtain true stability constants for metal–HS complexation, and reported values are not actually constant, because the functional dependence is a fundamental feature of systems such as HS, which cannot be eliminated by any experimental method unless total fractionation be achieved into pure ligands that can be studied separately.

In conclusion, the ill-defined nature of multiligand and polyelectrolytic HS systems and of the types, concentrations, and strengths of their several nonidentical binding sites prevent metal–HS complexation reactions to be described in rigorous mathematical terms. However, the stability function concept provides an important overview and useful insights into the nature of metal binding by HS, and may also provide useful indications for the most appropriate experimental methods with which to investigate metal–HS interactions.

Modeling and Models

The large body of field and laboratory data accumulated on the binding of metal ions and protons by HS has determined the development of chemical speciation models that could encapsulate the ample knowledge and information acquired, and allow applications to 'real-world' situations. The prevalent effort of any modeling approach is the quantitative description of the relative concentrations and strengths of the many nonidentical binding sites contained in HS. The various models applied to describe metal–HS complexation can be classified as 'discrete' ligand models and 'continuous' multiligand models.

In the discrete ligand approach, only a few ligands or binding sites are required to fit the experimental data. Since early modeling work, the competition for HS binding sites between metal ions and protons has been recognized, and metal binding has been estimated from displacements of pH titration curves. Successively modified and refined discrete models have incorporated site heterogeneity effects, i.e., variability in the intrinsic binding strengths among sites, and electrostatic effects related to the net negative charge of HS. Recently, a simplified and improved model (model VI), also based on the discrete-site/electrostatic formulation but moving toward a more distributional approach in describing binding sites for metals, has been developed and applied with success to describe published data sets on a range of metals.

The continuous multiligand distribution models are based on the assumption that a large number of heterogeneous ligands with a range of binding affinities are involved in metal binding with formation of complexes characterized by a continuous (e.g., Gaussian) distribution of the stability constants. The initial, noncompetitive Gaussian distribution models that do not account for proton–metal competition have been extended in the competitive Gaussian distribution models that characterize HS binding-site heterogeneity by using a continuous distribution of equilibrium constants, together with electrostatic submodels, and by assuming monodentate binding of metals to proton-binding sites. The most recent of these models is the NICA (nonideal competitive adsorption)–Donnan model that fits very well extensive experimental data sets obtained for a wide range of metal ion concentrations. The incorporation of multidentate sites into the NICA-Donnan model is under consideration.

A conceptually simple and calculation-convenient model is the 'quasiparticle' model, which includes previous concepts and models, and describes mathematically an aqueous system containing HS by replacing it with a set of hypothetical, average noninteracting molecules whose behavior mimics that of the actual HS system.

Since the primary purpose of any metal–HS binding model is to perform chemical speciation calculations for field situations, validation of the model on field data is required. Models formulated have been applied with variable success. More recent models reproduce trends quite well but lack of knowledge still exists on some key factors, and empirical adjustment of these factors is necessary to fit the data. Thus, more extensive field-testing is required to establish the usefulness or otherwise of any model of metal–HS binding.

Experimental Methods

A variety of separation and nonseparation methods have been used to speciate metal ions in the presence of HS, to assess the complexing capacity of HS, and to calculate conditional stability constants or quotients

of metal–HS complexes. Most commonly used separation approaches include: (1) proton-release titration; (2) cation exchange with synthetic resins; (3) gel filtration or permeation chromatography (GPC); (4) high-performance cation exchange chromatography (HP-CEC); (5) conventional dialysis and equilibrium dialysis–ligand exchange (EDLE); (6) ultrafiltration (UF); and (7) capillary electrophoresis (CE).

Separation approaches generally present the great advantage of allowing measurement of nearly any metal ion by sensitive techniques such as atomic absorption and plasma spectrometries. However, dialysis and chromatographic methods suffer from the disadvantages of disturbance of complexation equilibria and adsorption of interacting species on the membrane or chromatographic material, whereas equilibrium dialysis and cation exchange present uncertainties in the definition of chemical forms actually measured by the method. An important advantage of the UF methods is that they do not take such a long time to carry out as dialysis and do not disturb the complexation equilibria.

Most important nonseparation methods include: (1) ion-selective electrode (ISE) potentiometry; (2) voltammetric techniques such as anodic-stripping voltammetry (ASV); and (3) various spectroscopic techniques, including fluorescence, ESR, and NMR spectroscopies. Some nonseparation methods such as ISE and ASV, although being the most sensitive and advanced, also suffer from the problems of adsorption and shifts in equilibria. Further, these methods are applicable adequately only to a limited typology of metal ions, e.g., Cu^{2+}, Cd^{2+}, Pb^{2+}, and Zn^{2+}.

The fluorescence method presents a number of advantages over other methods. Titration curves of HS fluorescence quenching versus concentration of added metal quencher have allowed direct measurement of the complexing capacity of HS ligands and the stability constants of HS–metal complexes. The method is relatively rapid, since no separation is required between bound and free metal ion, thus errors associated with the separation step in most speciation methods are avoided. Neither supporting electrolyte, nor buffer, nor adsorbing material are required to be added to the sample; it is even more sensitive than ASV and ISE potentiometry and is sensitive enough for application to unmodified, natural organic ligands without preconcentration. The major disadvantage of fluorescence spectroscopy is, however, its efficiency only with strongly binding, paramagnetic metal ions such as Cu^{2+}. This limitation can be overcome by the use of fluorescent probes, such as in the lanthanide ion probe fluorescence spectroscopy (LIPS), where HS samples are titrated by Eu^{3+} ions, and the titration plot of the ratio of the intensities of two emission lines of Eu^{3+} is used to estimate the amount of bound and free species of the probe ion.

The ESR approach allows the determination of the free metal ion concentration and therefore of its degree of complexation with the ligand. ESR spectroscopy has been applied to obtain stability constants and stoichiometries in aqueous solution of VO^{2+} and Mn^{2+} complexes with FA. On these bases, the VO^{2+}–FA complexes are modeled as bis(phthalato)(salicylato)-oxovanadium (IV) and mono(salicylato)-oxovanadium (IV). The K_c values measured for Mn^{2+}–FA complexes by ESR are in excellent agreement with K_c values determined by an ion-exchange method. Major advantages of ESR spectroscopy are its high sensitivity and the minimal or no-sample pretreatment required, whereas its intrinsic limitation is applicability only to paramagnetic metal ions such as Cu, Fe, Mn, and V.

Few NMR experiments have been conducted to relate structure of HS to their metal-binding capacity. The positive correlation found between aromaticity of several HA determined by solution-state ^{13}C-NMR and stability constants of their complexes with Cd^{2+} and Zn^{2+} ions suggests the involvement of phenolic groups in the complexation of these metals. The higher content of carboxylate groups in a soil FA than in a soil HA measured by distortion enhancement by polarization transfer (DEPT)-^{13}C-NMR and quaternary-C only (QUAT) subspectra is consistent with the higher binding constant measured for Eu^{3+} with FA than with HA. Dipolar dephasing cross-polarization magic angle spinning (CPMAS) ^{13}C-NMR has shown that the stability constant of a Cd^{2+}–sediment HA is greater than that of Cd^{2+}–soil HA, probably due to the higher content and stronger binding of amino acidic N groups, in addition to carboxylic groups, of the sediment HA. Further, great metal stability constants of Zn^{2+}–HA and Cd^{2+}–HA complexes are found to be associated with a higher degree of substituted aromatic C groups, possibly due to chelation effects.

List of Technical Nomenclature

α_L	Side-reaction coefficient of the ligand
α_M	Side-reaction coefficient of the metal ion
Γ	Activity coefficient ratio
Å	Ångstrom (10^{-8} cm)
K	Thermodynamic stability (equilibrium) constant
$\bar{K}$	Mean stability constant or mean concentration quotient

K_c	Concentration quotient
K_c^*	Conditional stability constant or conditional concentration quotient
$\bar{K}_c^*$	Mean conditional concentration quotient or stability function
mT	Millitesla

ORGANIC RESIDUES, DECOMPOSITION

A J Franzluebbers, USDA Agricultural Research Service, Watkinsville, GA, USA

Published by Elsevier Ltd.

Introduction

Organic residues are carbon-containing compounds of biological origin. Decomposition is the breakdown of these complex organic materials into simpler components. Decomposition of organic residues in soil is an important ecological function whereby heterotrophic organisms consume various components, resulting in the physical and biochemical breakdown of organic materials and transformation and cycling of constituent elements. Biochemical composition, environmental factors, and diversity of organisms (*See* **Biodiversity**) play major roles in the dynamics and fate of organic residues in soil (*See* **Humification**; **Organic Matter:** Principles and Processes; Genesis and Formation). Decomposition is an important soil process that affects nutrient availability on a local scale (*See* **Nutrient Availability**) and environmental quality on a global scale by controlling carbon transformations (*See* **Carbon Cycle in Soils:** Dynamics and Management; **Carbon Emissions and Sequestration**), greenhouse gas emissions (*See* **Greenhouse Gas Emissions**), and nutrient fluxes (*See* **Nitrogen in Soils:** Cycle). The most common methods of determining decomposition are by mass loss of residues or by complete mineralization of organic constituents into end products of inorganic carbon (CO_2, CH_4), nitrogen (NH_4, NO_3), or phosphorus (PO_4).

Types of Organic Residues

Organic residues that enter the soil ecosystem are derived primarily from: (1) autotrophic organisms, including a wide diversity of plants, algae, and lichens; (2) animal tissue and manures; and (3) various organic additions from human activities, including pesticides,

oil products, and synthetic compounds (*See* **Pollutants:** Biodegradation). The presence of heterotrophic organisms in soil, such as fauna and microorganisms, contributes directly to the type of organic residues through synthesis of unique compounds in their bodies, as well as indirectly through transformations of organic residues during decay and subsequent humus synthesis (*See* **Bacteria:** Soil; **Fauna**; **Fungi**; **Nematodes**).

Plant residues are, by far, the most dominant input of organic residues to the soil ecosystem. The quantity of residues produced varies with environmental conditions, but typically ranges from 200 to 2000 $g \cdot m^{-2}$ per year. The allocation of total plant biomass between roots and shoots depends upon a number of factors, including annual or perennial vegetation, soil fertility, climate, and various other soil physical and chemical characteristics. Generally, annual plants tend to have shoot to root ratios of more than 1, while perennial plants tend to have lower shoot to root ratios. Rooting depth of plants depends upon factors similar to those affecting shoot to root ratio. In general, about 50% of total root biomass is found in the surface 20 cm of soil. Accurate characterization of root inputs is difficult because of the intimate contact between roots and the soil-decomposer community, which acts quickly on substrates that are unprotected in the moist soil environment. The portion of root biomass that decomposes rapidly and does not persist in soil is often called 'rhizodeposition.' Rhizodeposits are typically composed of sloughed root cap cells, organic acids actively secreted by growing roots, lysates of root tissues, and high molecular weight root mucilage.

Plant residues are composed of: (1) highly labile intracellular compounds such as protein, starch, fructan, and chlorophyll and other pigments; (2) moderately resistant structural compounds such as cellulose and hemicellulose; and (3) resistant structural compounds such as lignin, polyphenols, lipids, and cutin. If isolated from the whole plant, individual components would decompose at different rates due to their susceptibility to microbial utilization (Figure 1). The rate of decomposition of whole-plant materials varies in response to the relative proportion of different intracellular and structural compounds, as outlined in the following.

For many field crop residues, C concentration is relatively constant at 41% of dry matter (Figure 2a). Protein concentration (estimated as 6.25 times the N concentration), however, varies greatly among residues by species, plant part, age, and management. The amount of C and N mineralized from crop residues varying in N concentration during incubation in soil is highly related to the C to N ratio of residues (Figure 2b).

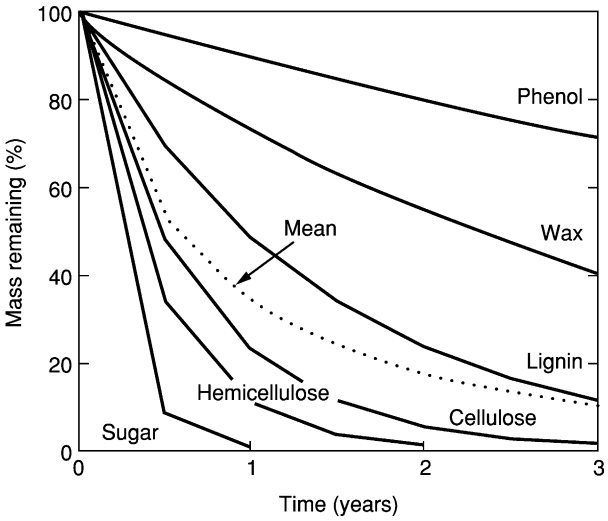

Figure 1 Theoretical decomposition of various components of plant cells, expressed as mass remaining during a 3-year period. Phenol, wax, and lignin groups decompose slower than the average rate of decomposition of plant material, and cellulose, hemicellulose, and sugar decompose faster. Mean proportion of the whole plant as phenol is 5%, as wax is 5%, as lignin is 40%, as cellulose is 20%, as hemicellulose is 15%, and as sugar is 15%. These proportions will vary depending upon plant species, age, fertility, and environmental conditions. Decomposition of organic residues typically follow first-order kinetics ($y_t = e^{-k \cdot t}$, where y = mass remaining at time t and k is a nonlinear rate constant). (Source: Minderman G (1968) Addition, decomposition and accumulation of organic matter in forests. *Journal of Ecology* 56: 355–362.)

Leguminous herbaceous and woody plant species are often applied to soil as mulch or incorporated as green manure to improve soil fertility, especially in the humid tropics where decomposition conditions are ideal. Decomposition of these materials is dependent not only upon N concentration (positive), but also on the concentration of polyphenolics (negative), which are reactive compounds that can form stable polymers with various N compounds and slow decomposition (Figure 3).

The amount of lignin in plant tissue has a negative impact on the rate of decomposition, although some tissues may have a high protein concentration (Figure 4). Lignin is a high molecular weight polymer composed of phenyl propane units in cell walls, giving plants rigidity and resistance to microbial attack. Aside from polysaccharides, lignin is one of the most abundant biopolymers in nature. Lignin is relatively resistant to microbial decomposition, being limited primarily to a group of white-rot fungi that can completely decompose it (*See* **Fungi**). In addition, a diverse community of soil organisms is able to work in concert to decompose parts of the lignin structure slowly (*See* **Biodiversity**).

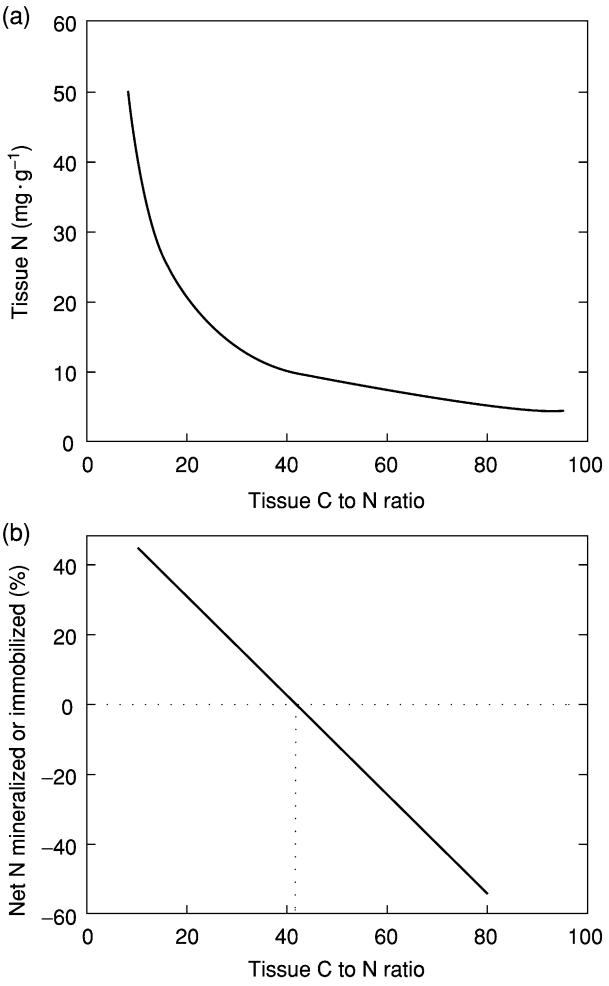

Figure 2 Relationship of C to N ratio of various crop residues with (a) N concentration and (b) net N mineralization during aerobic incubation. The close relationship between C to N ratio and N concentration (a) indicates uniform C concentration (410 mg·g^{-1}) and varying N concentration. Under defined incubation conditions (i.e., optimum temperature and moisture for 20 ± 10 weeks), the percentage of N mineralized from plant tissues varying in C to N ratio (b) is positive when the C to N ratio is less than 42 (i.e., net mineralization of N) and is negative when the C to N ratio is more than 42 (i.e., net immobilization of N). (Source: Vigil MF and Kissel DE (1991) Equations for estimating the amount of nitrogen mineralized from crop residues. *Soil Science Society of America Journal* 55: 757–761.)

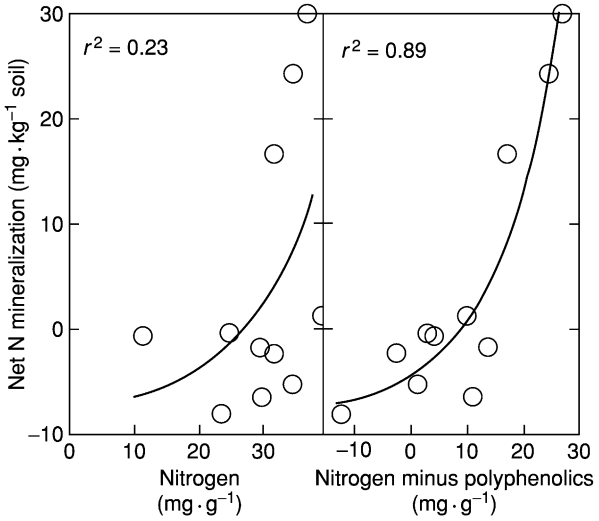

Figure 3 Relationship of N mineralization from different legume green manures (a) with N concentration and (b) with N concentration minus polyphenolic concentration. Although N concentration alone is typically a good predictor of potential N mineralization, condensation of N with polyphenolics can inhibit mineralization. Therefore, information on polyphenolic content of residues is needed to obtain a better prediction of N mineralization. (Source: Palm CA and Sanchez PA (1991) Nitrogen release from the leaves of some tropical legumes as affected by their lignin and polyphenolic contents. *Soil Biology and Biochemistry* 23: 83–88.)

Environmental Factors

Water directly affects decomposition through its controls on activity and transport of soil microorganisms, solubilization of organic constituents, oxygen supply, and soil pH (*See* **Microbial Processes:** Environmental Factors). An optimum water content for decomposition is within a range that is not too high to limit oxygen availability and that is not too low to limit substrate availability and mobility of soil microorganisms. The ideal soil moisture condition for decomposition is between −10 and −50 kPa (or 30–60% water-filled pore space). Fluctuating moisture conditions in soil are common, but they do not necessarily have a negative impact on the ability of microorganisms to respond quickly to available substrates upon rewetting (Figure 5).

Temperature controls the biochemical activity of intra- and extracellular enzyme activities, as well as metabolic activity of most soil organisms responsible for the biodegradation of organic residues. For every 10°C rise in temperature, decomposition generally increases one- to two-fold.

Oxygen is a requirement for the dominant heterotrophic soil organisms responsible for decomposition. Oxygen serves as the most efficient electron acceptor during microbial respiration. When oxygen becomes limiting in soil, decomposition proceeds at a much slower rate. Alternative electron acceptors, including NO_3^-, Fe^{3+}, Mn^{4+}, SO_4^{2-}, and CO_2, can be utilized by anaerobic bacteria such as denitrifiers, sulfate reducers, and methanogens.

Soil pH affects decomposition of organic materials because of its direct effect on the activity of heterotrophic microorganisms. As soil pH decreases to less than 4, microbial activity is severely retarded and accumulation of organic matter can occur, as

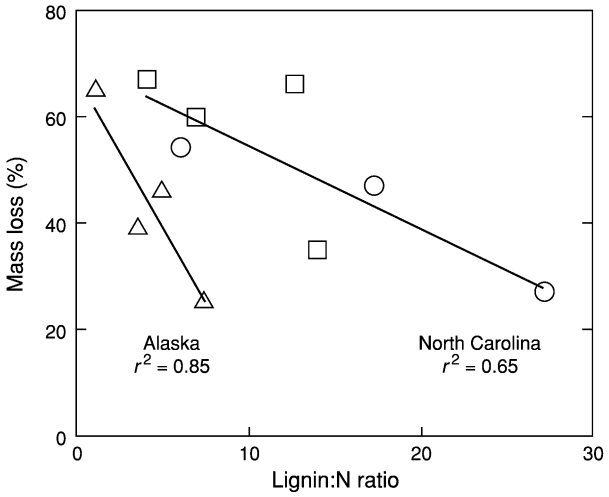

Figure 4 Decomposition of surface-placed residues as affected by their lignin-to-N ratio. Lignin is a polymer that is difficult for most soil microorganisms to decompose. Therefore, high lignin content reduces decomposition rate. At very low lignin content, decomposition of plant material would be similar whether the climate would be cold (Alaska) or warm (North Carolina). However, with increasing lignin content, decomposition is greatly reduced in a cold climate (Alaska) relative to a warm climate (North Carolina). Data from North Carolina are mass loss at the end of 1 year (circles: Blair JM (1988) Nitrogen, sulfur, and phosphorus dynamics in decomposing deciduous litter in the Southern Appalachians. *Soil Biology and Biochemistry* 20: 693–701.) and C loss at the end of 44 weeks (squares: Buchanan M and King LD (1993) Carbon and phosphorus losses from decomposing crop residues in no-till and conventional till agroecosystems. *Agronomy Journal* 85: 631–638.). Data from Alaska are mass loss at the end of 1 year. (Koenig RT and Cochran VL (1994) Decomposition and nitrogen mineralization from legume and non-legume crop residues in a subarctic agricultural soil. *Biology and Fertility of Soils* 17: 269–275.)

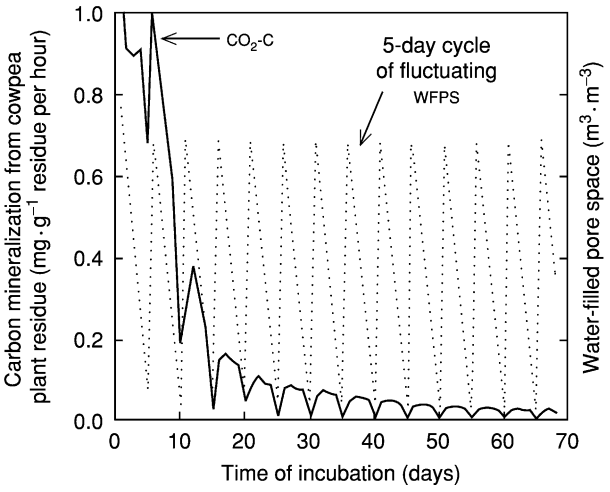

Figure 5 Carbon loss rate of decomposing leaf tissue during successive cycles of drying and wetting. Lowest points of each cycle have a water potential of −10 MPa. Extreme drying reduces decomposition, but decomposition resumes very rapidly upon rewetting. WFPS, water-filled pore space. (Source: Franzluebbers K, Weaver RW, Juo ASR, and Franzleubbers AJ (1994) Carbon and nitrogen mineralization from cowpea plants part decomposing in moist and in repeatedly dried and wetted soil. *Soil Biology and Biochemistry* 26: 1379–1387.)

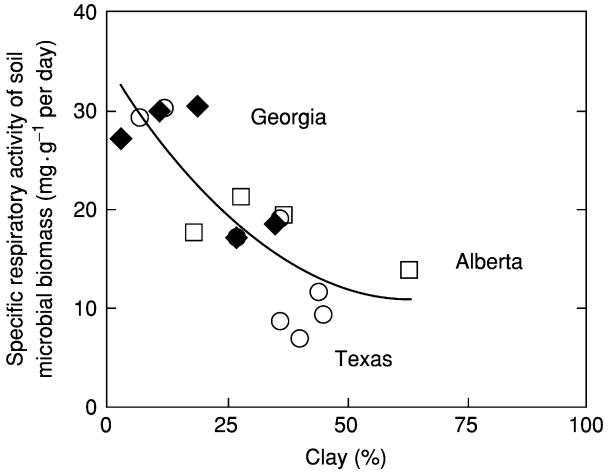

Figure 6 Relationship of microbial-specific mineralization with soil clay content (AJ Franzluebbers, unpublished data). Soils with fine texture have higher clay content and typically more aggregated soil that can protect a portion of the soil organic matter within aggregates. The higher specific respiratory activity of microbial biomass in coarse-textured soil than in fine-textured soil suggests a lower level of protection of the microbial community against predation by other microorganisms and by soil fauna.

especially evidenced by the thick litter layer that often develops under forests on acidic soils (e.g., mor).

Organic materials can become isolated, and even protected from decomposition to some degree, once they become incorporated into water-stable soil aggregates (*See* **Aggregation:** Microbial Aspects). Protection within these aggregates may be due to the physical barrier that limits soil faunal activity and, at times, due to low oxygen concentration that limits soil microbial activity (*See* **Structure**). Soil texture (*See* **Texture**) offers a similar physical limitation on organic matter decomposition, where the pores in coarse-textured soils are freely accessed by a wide variety of micro-, meso-, and macrofauna. Pores in fine-textured soils are often more diverse, with micropores that limit faunal activity and protect organic matter from decomposition typically not present in coarse-textured soil (Figure 6).

Soil management can have large impacts on residue decomposition by altering the physical environment and controlling the supply of substrates. Whether organic residues are left on the soil surface or incorporated into soil (*See* **Cultivation and Tillage; Conservation Tillage**) affects the moisture and temperature regimes they occupy. Generally, incorporated residues decompose faster owing to more consistent moisture

and temperature conditions in the soil than on the soil. The type of cropping can alter the timing, quantity, and quality of residues added to soil (*See* **Crop Rotations**). Residues that become available to soil organisms for decomposition during dry or cold periods will decompose at a different rate and possibly undergo different transformations because of different participating organisms than residues that become available during hot or wet periods of the year. Whether crops are perennial or annual can influence: (1) the level of soil disturbance, (2) the type, timing, and quantity of substrates supplied to the soil, and (3) the placement of residues.

Organism Interactions

Various types of organisms feed upon specific components of organic materials in soil. This complexity of interactions among organisms can be illustrated as a food web (Figure 7), where bacteria and fungi are principal decomposers at many points within the web and progressively larger organisms tend to feed on more specific components of organic material within the food web (*See* **Food–Web Interactions**). The soil microbial biomass plays a pivotal role in the decomposition of organic inputs from plant and animal residues and the breakdown and transformation of organic matter to and from slow and passive pools (Figure 8).

The presence of soil fauna (*See* **Fauna**) often facilitates decomposition by: (1) comminuting plant residues, which exposes a greater surface area to attack by soil microorganisms; (2) transporting organic residues to new locations in the soil, which facilitates decomposition, interaction with soil nutrients, and isolation from certain environmental conditions; (3) inoculating partially digested organic residues with specific bacteria and enzymes (*See* **Enzymes in Soils**); and (4) altering physical characteristics of soil by creating burrows, fecal pellets, and distribution of soil particles, which influence water (*See* **Water, Properties**), air (*See* **Aeration**), nutrient (*See* **Nutrient Availability**), and energy (*See* **Energy Balance**) retention and transport in the soil.

Nutrient Cycling

Nitrogen is a key element that is held within organic residues primarily as proteins and amino acids and released to the soil environment as NH_4^+ through the process of mineralization (*See* **Nitrogen in Soils:** Cycle). Decomposition of organic residues is

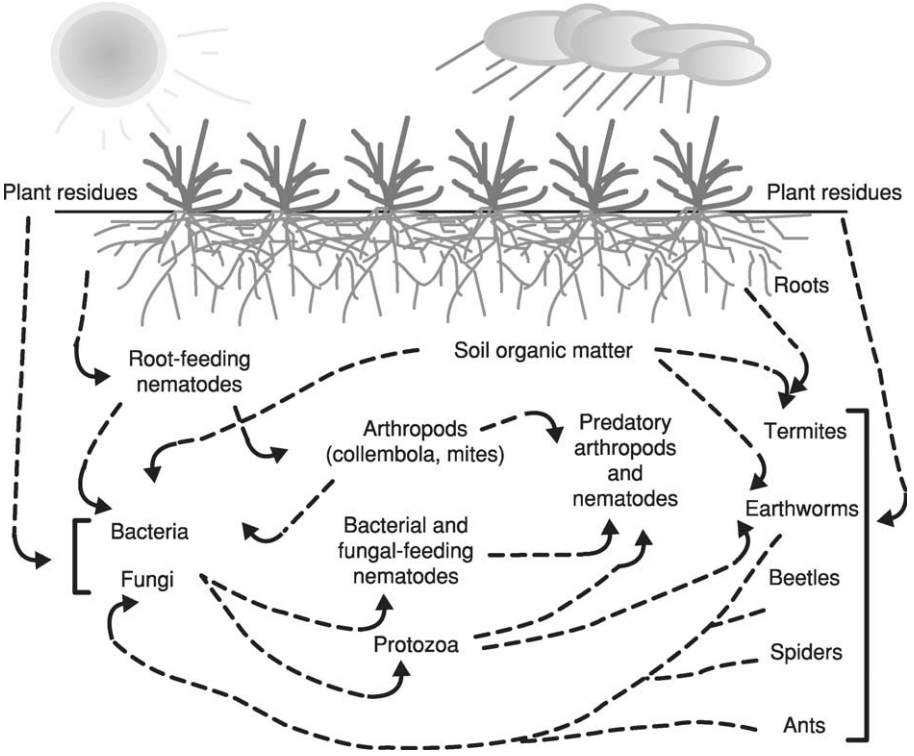

Figure 7 A soil food web. Plant residues are fed upon by various organisms residing in soil. In turn, the growth and remains of these organisms are fed upon by other heterotrophic organisms in soil until nearly all energy embedded within the organic molecules has been exhausted.

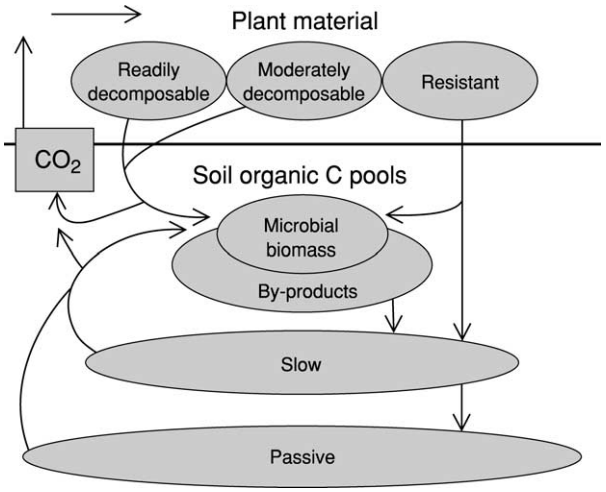

Figure 8 Pools of carbon in soil and the central role of microbial biomass in transforming organic residues into soil organic matter and releasing carbon dioxide into the atmosphere.

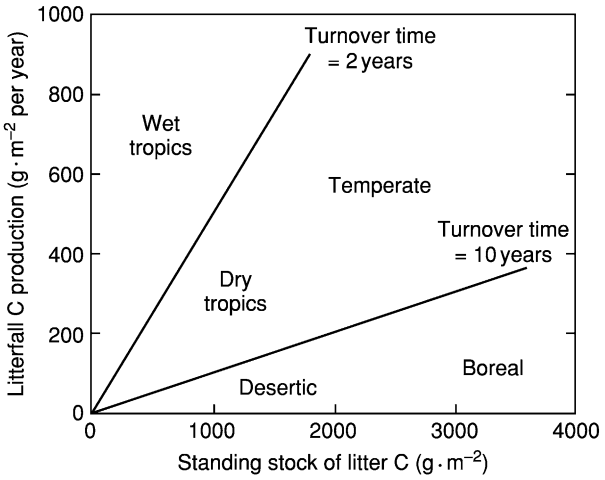

Figure 9 Decomposition estimates based on annual litterfall and standing stock of litter at the forest floor under different environmental conditions in the world. (Source: Olson JS (1963) Energy storage and the balance of producers and decomposers in ecological systems. *Ecology* 44: 322–331.) With high stock of litter at the forest floor and low litterfall production, slow decomposition occurs due to limited moisture or cold temperature. With low stock of litter and high litterfall production, rapid decomposition occurs due to plentiful moisture and warm temperature.

necessary to release organically bound N into inorganic N, which can then be taken up by plants.

Phosphorus is bound organically in plants primarily as deoxyribonucleic acid (DNA) and the energy-transfer molecules adenosine diphosphate (ADP) and adenosine triphosphate (ATP). Mineralization of P from organic residues can supply not only a portion of plant requirements, but also the rapidly growing microbial population that has a high demand for P to meet its ATP production requirements (*See* **Phosphorus in Soils:** Overview).

Carbon is the primary element in organic materials, representing 35–45% of the dry weight of most plant materials, 40–50% of the dry weight of animal manures, and 45–55% of the dry weight of soil humus. In general, C undergoes complete cycling from atmosphere to plants to soil organic matter to atmosphere (*See* **Carbon Cycle in Soils:** Dynamics and Management; **Greenhouse Gas Emissions**). The residence time of C in the terrestrial sphere can be relatively short in warm–moist environments and longer in cold–dry environments (Figure 9), but globally the quantity of C fixed within plant biomass each year is believed to be balanced by the quantity of C released to the atmosphere through decomposition.

Decomposition is an important process that returns organically bound nutrients back to nature for utilization and cycling. On a global scale, this vital ecosystem function balances the autotrophic production of organic matter through photosynthesis. An imbalance in these opposing processes would lead to either: (a) accumulation of organic residues, with a consequent reduction in plant-available nutrients, which could ultimately reduce net primary productivity without external nutrient inputs; or (b) depletion of soil organic matter reserves, which could facilitate greenhouse gas emissions and global warming, thereby depleting inherent soil fertility and reducing net primary productivity. Decomposition is a vital ecosystem function that sustains life on Earth.

Future Advances

Decomposition of organic residues has been historically and extensively studied, and yet much remains to be learned about the decomposition mechanisms and fate of residues in different environments. Of particular deficiency in our current knowledge are the dynamics and interactions with soil of plant root production and decomposition. More detailed chemical composition and fate of different organic residues are needed. Analytical techniques have relied in the past upon acid digestion procedures that are not particularly well suited for analyzing specific molecular classes of compounds. Future analytical techniques will probably rely more on a combination of spectroscopic, chemolytic, and thermolytic analyses to describe both initial chemical properties and the temporal changes in properties during decomposition.

List of Technical Nomenclature

%	Percent
ADP	Adenosine diphosphate

ATP	Adenosine triphosphate

ORGANIC SOILS

D L Mokma, Michigan State University, East Lansing, MI, USA

Introduction

Organic soils consist of organic materials derived primarily from plants, in contrast to mineral materials, from which most soils of the world formed. These soils form where production of organic matter exceeds decomposition, usually under conditions of water saturation: as a result, most organic soils are wetlands. Organic soil materials have more than 12–18% organic C depending on the clay content of the mineral fraction (Figure 1). Organic soils are commonly called peatlands. Several terms are commonly used to separate different organic soils. Highly acid organic soils are referred to as bogs. Less acid organic soils are called fens if they lack trees and are dominated by grasses and/or sedges, or swamps if they are at least partially forested. Marsh refers to wet mineral soils that are dominated by grasses and/or sedges.

Formation

The main soil-forming process active in organic soils is accumulation of organic materials. Paludization is the accumulation of organic materials under anaerobic conditions where preservation allowed a net gain

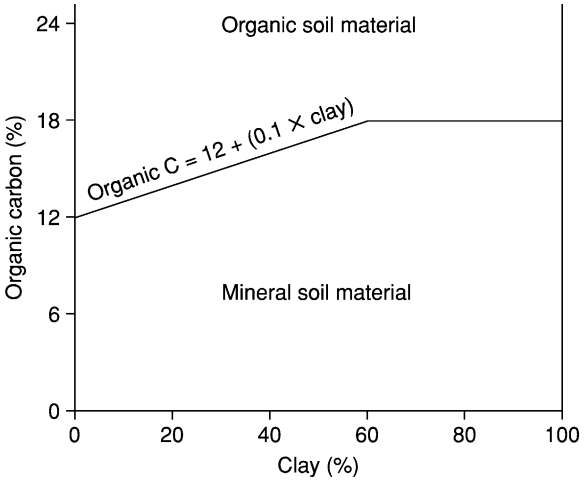

Figure 1 Organic carbon requirements for organic soil materials based on clay content.

through time. Little transformation of parent materials has occurred because of the anaerobic environment in which they form. Decomposition of organic materials is controlled by interrelated factors, primarily moisture content, temperature, acidity, microbial activity, composition of the deposit, and time. Organic soil formation began when microbial activity was promoted by entry of air into the organic deposit. The processes are physical, chemical, and biological ripening. Physical ripening involves a decrease in volume and depends on the nature of organic matter, content of mineral material, and depth of the water table. Chemical ripening is the decomposition of organic materials. Biological ripening involves the reduction in particle size and mixing of organic materials by living animals. The earth can be divided in two organic soil-forming zones, temperate zone and tropical zone. In temperate zones the median rate of organic soil formation is about 0.6 mm $year^{-1}$ and the carbon contribution is about 21.4 g m^{-2} $year^{-1}$. In tropical zones the rate of formation is about 2.2 mm $year^{-1}$ and the carbon contribution is about 128 g m^{-2} $year^{-1}$.

Parent Materials

Accumulated organic materials are primarily composed of plant remains. Small amounts of animal materials are included. The initial deposit of organic materials is considered geogenic rather than pedogenic. The deposit is the parent material. The dominant pedogenic process is the alteration of recognizable organic forms of leaves, stems, and roots, to unrecognizable organic materials. The characteristics of organic soils depend primarily on the nature of the vegetation that was deposited in the water and the degree of decomposition. Vegetation growing on organic soils varies with local climatic conditions, groundwater, and topography. Vegetation may differ in different portions of a single area. Changes in vegetation may also occur as the organic materials accumulate.

Topography

Organic soils may form in closed depressions, coastal marshes, on slopes where there is seepage, or blanket a dissected landscape. The common feature is water that may come from several sources. Climate controls where organic soils form on a regional scale; however, topography determines where they form on a specific landscape. Organic soils form on parts of landscapes where there is concentration of run-on, retention of precipitation, or discharge of groundwater. These conditions most often occur in topographic depressions or very flat areas.

Organisms

Organic soils in their natural environment can exhibit large numbers of contrasting flora. The flora includes those submerged and floating on water, growing along the shoreline and on the bog surface. The sequence of flora on the bog surface is usually meadow, heath, shrub, and finally forest association. Chemical composition of the organic and inorganic fractions, water level, and pH greatly affect plant associations. As a result, a single area of organic soil may have several plant associations at any one time. Differences in vegetative cover change organic soil characteristics that influence utilization of the soil. Generally, the first stage in organic soil formation is plankton growth in water and chara, hornwort and others in deep water and pond weeds and water lilies in shallow water (**Figure 2**). After some accumulation of organic materials, conditions become favorable for growth of sedges, reeds, and grasses (**Figure 3**). Later the area is covered with heath. Finally, succession leads to shrubs and forests (**Figure 4**).

Plant communities with high primary production usually have high decomposition rates, therefore, organic matter accumulation is negligible. Communities with low or modest primary production frequently have slow decomposition rates, therefore, organic matter accumulation is significant. The anaerobic environment of organic soils preserves pollen, therefore they contain a record of past climates and flora.

Climate

Organic soils can form in virtually any climatic region; however, water must be available in the region for the organic materials to accumulate. Accumulation of organic materials is favored by cold and wet climates because they inhibit decomposition of the materials. In the high latitudes of Asia, Europe, and North America average precipitation exceeds annual potential evaporation. In the northern part of these latitudes organic soils are not common because short growing seasons inhibit the production of organic materials. In lower latitudes organic soils are primarily limited to coastal plains that are nearly level with high annual precipitation and no dry season or to environments with high water tables maintained by tidal waters or coastal marshes. In arid, semiarid, and arctic areas, organic soil formation is very slow or negligible due to climate.

Time

Most organic soils have formed since the end of the last ice age. In high latitudes they are concentrated in regions that were covered by glaciers and formed

Figure 2 First stage of organic soil development: water lilies.

Figure 3 Sedges and grasses on organic soil.

following retreat of glaciers. In lower latitudes they were also impacted by glaciation. Large quantities of water were incorporated in glacial ice. Melting of glaciers caused sea level to rise at a rate that was more rapid than that of initial vegetation colonizing tidal regions. When the sea level rise slowed, marsh vegetation could become established and organic materials began to accumulate, producing the parent materials for organic soils. About 3.6 m of organic materials accumulated between 4400 BP and 1914 near Belle Glade, FL. In this low-latitude region the average rate of accumulation was about 1.4 mm year^{-1}. In Michigan, a more northern latitude, the average rate was 0.55 mm year^{-1}. In the slightly glaciated region of southwest Wisconsin, the average rate of accumulation was about 0.68 mm year^{-1}. In Iceland it was 0.39 mm year^{-1}.

Distribution

Organic soils comprise about 2% of the Earth's ice-free land surface. This includes 0.8% organic soils with permafrost. Organic soils can form in virtually any climate, even in arid areas, as long as water is available. They are most prevalent in the cool, humid boreal forest areas of northern Asia, Europe, and

Figure 4 Leather leaf on acidic organic soil.

North America. Every province of Canada and almost every state in the USA has organic soil. More than 95% of the total peat reserves of the world are located in the temperate zone of the northern hemisphere. In these areas precipitation usually exceeds evapotranspiration and summers are relatively cool. At lower latitudes organic soils occur locally on humid coastal plains, for example, South-East Asia, Indonesia, and east North America. These coastal areas are inundated by tidal waters.

In many central European countries organic soils have been extensively used and no longer qualify as organic soils. Nearly all organic soils in the Netherlands, Germany, and Switzerland have been lost. In more northern European countries the organic soils are relatively virgin. About 75% of Europe's remaining organic soil resources are located in Finland, Norway, and Sweden. Because of the loss of organic soils resulting from intensive utilization, it is difficult to obtain an exact amount of organic soil resources remaining.

Utilization

Most organic soils occur in wetland environments, thus they provide wetland functions of protecting surface and ground water quantity and quality, preserving biological diversity, reducing surface water runoff, assisting in flood protection, and providing erosion and sedimentation control. Early humans avoided organic soils because they were low, wet, and harbored pests. Malaria was a major problem in some areas. Some people believed evil spirits resided in these areas. Individuals seeking refuge from slavery or the law frequently used them. About the turn of the eighteenth century, interest in organic soils (Figure 5) was stimulated by the need for fuel. Wood,

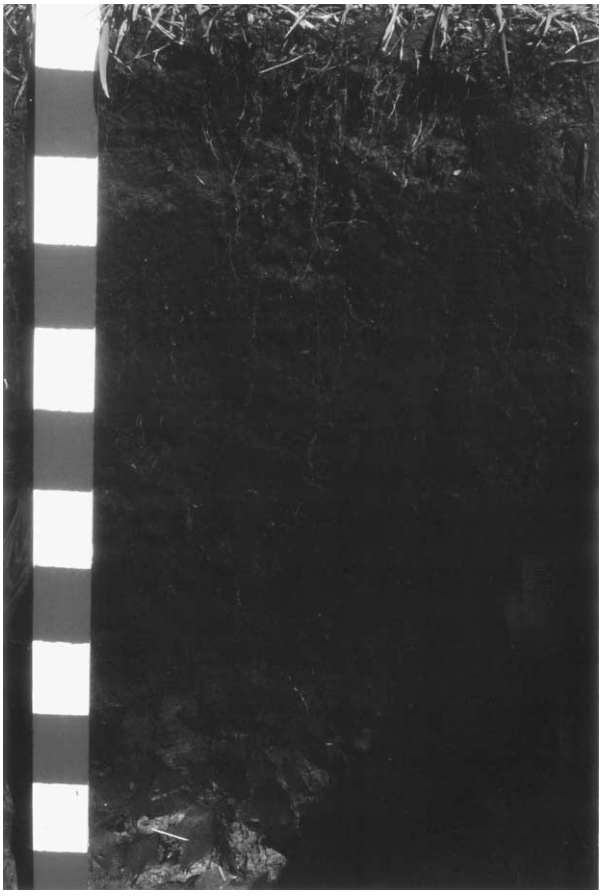

Figure 5 Profile of organic soil in Finland.

Figure 6 Use of organic soil for fuel.

the common fuel of that day was in short supply. Peat is still used for fuel (Figure 6) and for generation of electricity in some areas.

Utilization of organic soils is affected by several of their properties: soil reaction, cation exchange capacity, bulk density, water retention, water content, hydraulic conductivity, shear strength, and shrinkage. A profile description of a cultivated organic soil is given in Table 1. Selected physical and chemical properties of the same pedon are given in Table 2. The pH of organic deposits is largely a function of the nature of the water that flowed into the organic soil area and the vegetation. Organic soils in landscapes dominated by acid, sandy Spodosols are typically very acid and have a pH of less than 4.5. Also, organic soils that receive water only from precipitation, no groundwater flow, tend to be acidic. Coastal organic soils that received sulfur from seawater are usually very acid and may be acid sulfate soils. Organic soils in landscapes that receive subsurface flow that contains significant amounts of bases and/or bicarbonate are usually less acidic. Because organic soils are composed of primarily decomposed vegetative materials, composition of vegetation exerts a strong influence on soil reaction. Acid-loving plants, such as sphagnum moss (Figure 7), produce more acidic materials than base-loving plants. Very acid organic materials have low levels of microbial activity compared to less acidic materials. Less decomposed organic soil materials are more acidic than more decomposed materials. The availability of phosphorus and many micronutrients is dependent on pH. Acid organic soils are usually not limed above pH 5.5 in order to reduce the likelihood of causing micronutrient deficiencies in crops.

Table 1 Profile description of a cultivated organic soil

Oap	0–23 cm. Black (N 2/0), black (10YR 2/1) rubbed; about 5% fibers, 1% rubbed; weak fine granular structure; friable; few fine roots; estimated mineral content 20%; abrupt smooth boundary
Oa1	23–48 cm. Black (N 2/1), very dark brown (10YR 2/2) rubbed; about 20% fibers, 4% rubbed; weak coarse blocky structure; friable; few fine roots; estimated mineral content 25%; clear smooth boundary

Oa3	76–115 cm. Very dark brown (10YR 2/2) broken face and rubbed; about 25% fibers, 4% rubbed; weak thick platy structure; friable; estimated mineral content 15%; clear smooth boundary
Oa4	115–190 cm. Dark brown (7.5YR 3/2), very dark brown (10YR 2/2) rubbed; about 35% fibers, 7% rubbed; weak thick platy structure; friable; estimated mineral content 12%; clear smooth boundary

The cation exchange capacity of organic soils results primarily from carboxyl radicals. Other functional groups that contribute are phenolic, enolic, and quinonic hydroxyls and heterocyclic nitrogen structures. Organic soils have high cation exchange capacities compared to mineral soil. The cation exchange capacity is pH-dependent and ranges from 10 to 20 mmol per 100 g at pH 3.5–4.0 to 100–200 mmoL per 100 g at pH 7.0.

One of the most outstanding characteristics of organic soils is their generally low bulk density. Bulk densities range from as little as 0.02 to 0.30 g cm^{-3}. Some studies found that highly decomposed materials

Table 2 Selected properties of a cultivated organic soil

[a]Color of pyrophosphate extract.

Figure 7 Sphagnum moss.

have a greater bulk density than less decomposed materials; however, a recent study found no difference in bulk density with difference in degree of decomposition. Bulk density of organic soils increases with increasing mineral content.

Organic soils are wet not only because they exist in saturated conditions, but also because they have a great affinity to take up and hold water. Water retention is related to degree of decomposition. Large pores in slightly decomposed organic soil materials drain easily at low suction, whereas small pores in more decomposed materials retain water at low suctions. Water contents of organic soils are related to degree of decomposition. Fibric soil materials retain from 8.5× to more than 30× on a weight basis, hemic soil materials hold between 4.5 and 8.5×, and sapric soil materials usually retain less than 4.5×. Water contents ranged from 100% (by volume) for undecomposed, near-surface sphagnum moss peat to less than 80% for deeper, more decomposed peat. Hydraulic conductivity of organic soils is also related to degree of decomposition of the organic materials because of differences in pore size distribution. Saturated hydraulic conductivity of sapric material ranges from 0.5 to 15 $cm\ h^{-1}$, that of hemic materials ranges from 1.5 to 15 $cm\ h^{-1}$, and that of fibric materials is greater than 15 $cm\ h^{-1}$. Weakly or undecomposed peats had rather rapid hydraulic conductivities, whereas more decomposed peats had slow conductivities. After drainage, the hydraulic conductivity of an organic soil decreases, due in part to greater decomposition and in part to the decrease of the buoyant effect of the groundwater.

Shear strength is a measure of a soil's internal resistance to stress. In mineral soils, shear strength decreases as water content approaches saturation. In organic soils, this relationship is not as clear. Draining a fibrous peat reduces the water content but increases the shear strength because of the 'fibrous interlock.' However, drainage also increases decomposition that destroys the 'fibrous interlock.' As decomposition increases, organic soils behave more like mineral soils with respect to shear strength.

Most organic soils undergo considerable shrinkage upon drying. Well-decomposed organic soil materials may shrink 70% or more depending on the mineral content of the material. The degree to which the shrinkage is irreversible is partially related to degree of decomposition. Organic soils are vast reservoirs of carbon. Carbon is stored during formation of these soils. During warmer periods small amounts of organic materials accumulate, whereas during cool, moist periods considerable amounts accumulate. Excavation of organic materials for various purposes

(fuel, manufacture of peat products for agriculture and horticulture, medical applications) accelerates decomposition. Drainage leads to increases in decomposition of organic materials and emission of carbon dioxide. Methane and carbon dioxide stored in organic soils are released by drainage. Release of carbon dioxide as a result of these activities increases the concentration of greenhouse gases.

One of the early more intensive uses of organic soils was grazing, especially during the summer when water tables were naturally lower. Low bearing capacity and strength limited the usefulness of these soils. Artificial drainage not only lowered the water table but increased decomposition, thereby increasing bearing capacity and strength. Initially drainage was accomplished with open ditches and later with tile systems. Ditches have been constructed in some forests to increase productivity (Figure 8). Tile systems were more costly and required more intensive use of the land. Agronomic crops in high-latitude areas suffered frost damage in the spring after planting (Figure 9) and fall before maturity, thus the change from low-value crops fed to animals to high-value crops that tolerate frost or have a shorter growing season and are consumed by humans. Rice, carrots, onions, celery, potatoes, lettuce, mint, sugarcane, and

Figure 8 Ditch installed in forest to lower water table and increase production.

Figure 9 Frost damage of crop on organic soil.

cranberries are grown extensively on organic soils (Figures 10 and 11). Peat is also mined for use as a soil amendment in agriculture and horticulture. The low bulk density of organic soils makes them ideal for grass sod production (Figure 12) where large volumes of soil are moved long distances.

Utilization of organic soils requires careful management. Wise management of water is essential. In their natural state, organic soils are too wet. When they are drained, they become aerobic and organic materials decompose, causing rapid subsidence (Figure 13).

The most rapid subsidence occurs immediately after drainage. Subsidence in Hunts, England was 3.4 cm $year^{-1}$, Quebec, Canada 2.1 cm $year^{-1}$, Ontario, Canada 3.3 cm $year^{-1}$, Minnesota 5.1 cm $year^{-1}$, Indiana 3.0 cm $year^{-1}$, Florida 3.0 cm $year^{-1}$, and California 2.3 cm $year^{-1}$. An area in Michigan had to be retiled 28 years after it was established as a result of subsidence (about 3 cm $year^{-1}$). Organic soils have limited life expectancies. Rate of subsidence, degree of decomposition, and depth of organic materials determine the life of organic soils. Careful attention to wind erosion control and water table

Figure 10 Carrots growing on organic soil.

Figure 11 Organic soil used for cranberry production.

Figure 12 Low bulk density makes organic soil ideal for sod production.

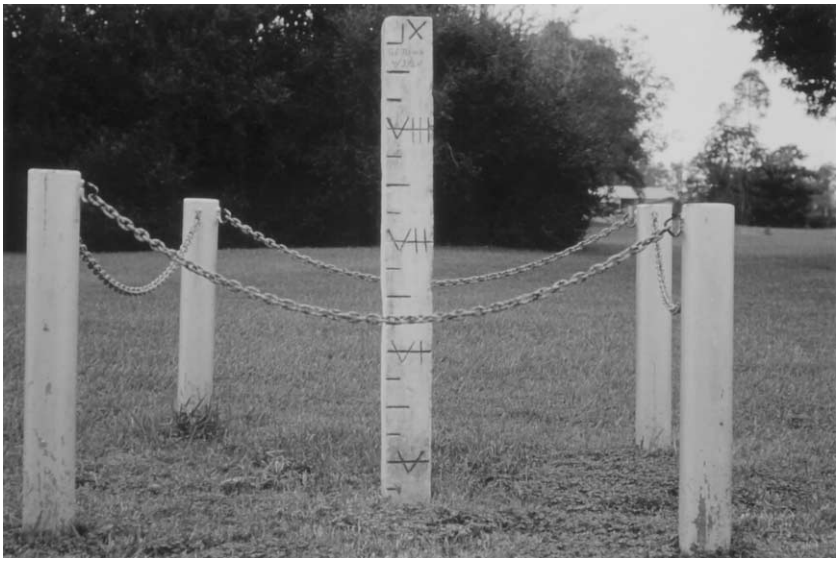

Figure 13 In 1924 this 9-feet (3-m) post was placed on the underlying bedrock with the top of the post at the surface of the organic soil at Belle Glade, FL. This photograph, taken in 1972, shows that subsidence has been about 2.5 cm year^{-1}.

height can pay dividends in conservation of organic soils. To minimize subsidence water tables should be maintained as high as crop and field conditions will permit. Raising the water tables to at or near the soil surface (Figure 14) during the noncrop period can be effective in reducing subsidence and wind erosion. After drainage, organic soils are very susceptible to wind erosion because of the low bulk density. Relatively low wind velocities cause movement of the light-weight materials if unprotected. When wind erosion is very severe, organic soil material in the air reduces visibility, thereby causing highways to be closed.

Fire hazard increases after drainage of organic soils. These fires are difficult to control and may burn underground for several months. Some fires were accidental, caused by sparks from rail locomotives or farm tractors. Other fires were deliberately started to reduce excess acidity and/or increase nutrient levels. Some pasture and old hay lands were burned to destroy unwanted plant residues and brush. As a result of fires, undesirable materials such as sand, gravel, clay, and marl were exposed. These fields usually had marked variability in pH. Some burned areas had greater than pH 8 because of marl or other calcareous materials. Marl in the plow layer

Figure 14 Raising water tables to at or near the organic soil surface will reduce subsidence and wind erosion.

Figure 15 Low bearing capacity of organic soils causes cracks in roads that require patching.

causes P and micronutrients to be unavailable for plant growth. In some Michigan fields available soil P levels ranged from 2 to 300 kg ha^{-1}. Levels below 10 kg ha^{-1} occurred in plow layers that contained marl, whereas the high levels occurred in plow layers that lacked marl. Fertilizer application in a field had been based on soil test analyses of the problem area.

The major engineering problem with the use of organic soils is compressibility. Compressibility is related to nature of the organic materials, degree of decomposition, water content, structure, and density. Compression and subsidence of organic soil materials continue for many years after loading. Construction of structures and roads on organic soils is usually difficult. Structures are usually constructed on piles that were driven into the underlying mineral soil to support foundations. Floating road designs have been used on large areas of organic soils. These roads frequently crack because of the low bearing capacity (Figure 15). If the area is not large, the organic materials can be removed and replaced with sand and gravel. Ultimately, structures are left standing above the ground level. Drainage accelerates decomposition and shrinkage of the organic materials, therefore subsidence of driveways, sidewalks, and/or lawns leaves structures perched above soil surfaces

Figure 16 Subsidence of lawns and sidewalks in Michigan necessitated addition of steps built on pilings to enter the apartment building.

Figure 17 Subsidence of lawn and driveway in New Orleans, Louisiana, requires capping of steps and decreases the accessibility of carport.

(Figures 16 and 17). Garages and carports may stand above the driveway and be inaccessible to cars. Many of these garages and carports have been converted into another room, since both the house and garage or carport were built on piles. Acidity of organic soils causes corrosion of concrete and metal materials. Organic soils have high porosity and high adsorptive capacity, therefore they are useful for treatment of wastewater. They have the potential to remove heavy metals and hydrocarbon. Mined peat is used for treatment of septic tank effluent before dispersing into soil.

All these activities have one thing in common – they bring stored carbon into atmospheric circulation.

Classification

Organic soils are saturated and have 40 cm or more of organic soil materials according to Food and Agriculture Organization of the UN–Unesco Soil Map of the World, Revised Legend and Soil Taxonomy. If the organic materials consist of at least 75% moss or have a bulk density of less than 0.1 g cm^{-3}, the thickness must be at least 60 cm. The World Reference

Table 3 Criteria used in the classification of organic soils

Food and Agriculture Organization of the UN Unesco	*Soil Map of the World, Revised Legend*
Soil units	Presence of permafrost
	Presence of a sulfuric horizon or sulfidic materials
	Degree of saturation
	Degree of decomposition of organic materials
World Reference Base	
Soil units	Presence of permafrost

OVERLAND FLOW

T S Steenhuis, L Agnew, P Gérard-Marchant, and M T Walter, Cornell University, Ithaca, NY, USA

Introduction

For many years, it was believed that the occurrence of surface runoff is primarily controlled by the infiltration characteristics of the ground. Specifically, runoff is generated whenever rainfall or irrigation water is applied to the ground at a higher rate than the soil's infiltration capacity. Robert E. Horton was responsible for some of the early foundational work behind this concept and hence the process is ubiquitously referred to as 'Hortonian runoff.' The synonymous term 'infiltration-excess overland flow' is also widely used, again emphasizing that surface runoff occurs when precipitation exceeds the infiltration capacity of the soil. This process is very important in many areas of the country: arid areas (where significant soil crusting and/or surface sealing occurs during rain events), in irrigated fields, in urban areas, and more generally during storms with very high rainfall intensities.

However, the Hortonian runoff concept does not meaningfully explain storm runoff in many regions where the infiltration capacity of the ground is typically much greater than the average rainfall intensities. Many researchers have found that hydraulic conductivities published in soil surveys, usually based on disturbed soil samples, underestimate, by a factor of 10 or more, the conductivity in the field for vegetated soils which contain preferential flow paths in the form of worm channels and root passages. Consequently, only the most intense summer storms can produce runoff under the Hortonian runoff scenario. This is in direct contrast to observations of stream response to almost all rain, even small storms, during the set periods of the year, which means that there must be some other mechanism generating runoff.

In many regions, runoff is most commonly generated on relatively small portions of the landscape that are susceptible to becoming completely saturated. Once the soils in these areas saturate to the surface, any additional rainfall (irrespective of intensity) becomes overland flow. This process is termed 'saturation-excess overland flow.' Therefore, the propensity of an area to produce runoff is largely independent of rainfall intensity. Instead, the total rainfall amount and landscape factors such as soil depth (i.e., available water storage capacity), upland watershed area, and local topography are the important factors determining whether or not a particular area in a watershed will generate runoff. Moreover, as rainfall continues, the saturated area grows in extent, increasing the area generating runoff (hence the term 'variable source area,' VSA). This is in contrast to Hortonian or infiltration-excess runoff generation, which depends on soil type (infiltration rate versus rain intensity) and is independent of position in the landscape, i.e., with the runoff generating area is always the same. Examples of regions in the USA where VSA hydrology is significant include the Northeast and the Pacific Northwest, as well as forested mountain areas. It also occurs throughout the world in many similar areas.

Saturation-Excess Overland Flow

Saturation-excess overland flow comes from two distinguishable sources. In one case, rain falling on already saturated soil has no option but to run off – this case is termed 'direct precipitation on saturated areas' (DPSA). The other source, termed 'return flow,' occurs if the rate of interflow entering a saturated area from upslope exceeds the capacity for interflow to leave the area by flowing downhill through the soil. The excess interflow, thus, 'returns' to the surface as runoff, hence the term. Whereas DPSA runoff only occurs during and just after a rainfall event, return flow seepage can continue as long as an interflow excess exists.

Areas prone to saturation either have a high groundwater table or hard pan (fragipan) at shallow depth. Interflow results in the formation of saturated areas at the bottom of slopes, usually in concave areas, or it quickly resurfaces in seeps and ditches. Some hydrological processes observed in upstate New York, primarily the Catskill Mountains region, can further serve to elucidate mechanisms resulting in saturation. Soils in the Catskills are generally permeable (relative to rainfall intensity) and underlain by a shallow, low-permeable, restrictive layer, typically bedrock or fragipan. Rainwater easily permeates the soil and, by-and-large, runs laterally as interflow on top of the restrictive layer downslope. Many researchers have observed evidence of the accumulation of interflow water at the bottom of slopes in the Catskills during wet periods in the form of increased moisture content at hill bottoms relative to the steep parts of hills. Some common locations where saturation occurs are areas where the soil above the restricting layer is shallow, in places where the downhill topographic slope decreases such as the toe-slope of a hill, or in topographically

converging areas (Figure 1). All three incidences are locations in the landscape where the Darcy flow capacity, or interflow capacity, is reduced either by a decrease in hydraulic transmissivity or hydraulic gradient. When interflow capacity is sufficiently restricted, the soil will saturate. During periods of enhanced rainfall, interflow will be higher and often expand the extent of saturation around saturation-prone areas; conversely, dry periods will decrease interflow and extent of saturation. This is illustrated for wet and dry seasons in Figure 2.

VSA hydrology is an extension of the saturation-excess concept, recognizing that the extent of saturated areas in a watershed will expand and contract, i.e., vary temporally. The variation in the extent of saturated areas has been studied over a range of temporal scales, ranging from storm duration, hours and days, to seasons (Figure 2). Although the original, underlying concept for VSA hydrology was developed by the US Forest Service, the term 'variable source area' is often attributed to Hewlett and Hibbert. As stated above, VSA hydrology is applicable to many landscapes throughout humid regions that have undulating topography.

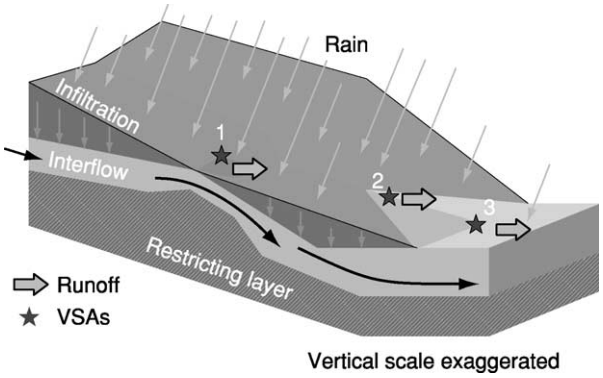

Figure 1 Incidence of saturation-excess hydrology: 1, shallow soil; 2, convergence area; and 3, decreasing downhill slope. VSA, variable source area.

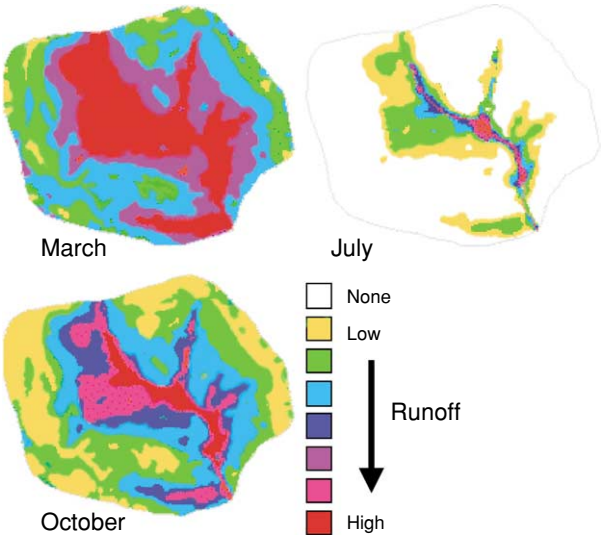

Figure 2 Seasonal changes of saturated areas (variable source areas) in a watershed in New York state. Color denotes areas more prone to saturation.

The VSA hydrology concept, thus, goes beyond conceptualizing the water–soil interface at or below the soil surface and making the simple assumption that water either runs off or infiltrates. The VSA hydrology concept includes the soil reservoir in a spatial landscape context to describe locations where the soil reservoir becomes saturated and begins to generate runoff. The soil reservoir methodology utilizes the bedrock, impermeable soil layers (relative to above layers), and/or the depth to the water table as the underlying hydrologic boundary instead of the soil surface. Thus, both hydrologic and soil water (i.e., porous media) concepts are combined to evaluate potential runoff areas in the landscape.

Calculation Method

TOPMODEL is used most often to predict the saturated-excess overland flow. It is based on calculating a groundwater table height that, when it intercepts the soil surface, will result in runoff. In TOPMODEL, the assumption is made that the watershed is underlain by a groundwater table. This is not realistic for many mountainous areas. However, since most of the saturated areas occur near streams, this limitation is not severe as a groundwater table is present in these areas. How the water gets to the groundwater is often inconsequential. An alternative method to find the saturated areas is the Soil Moisture Routing (SMR) model, a physically based, fully distributed, geographic information system (GIS) integrated code specifically designed for soils underlain by a hardpan. This model solves the water balance for cells in a grid that covers a watershed. What makes it different from most other models is that the spatial location of the grid cells is preserved in the landscape and water is routed by interflow from one cell to the next, resulting in the simulation of saturated areas within the landscape. This model, despite its simplicity, predicts the saturated areas in the landscape amazingly well.

TOPMODEL and SMR are admittedly more complicated than the popular Soil Conservation Service 'Curve Number' method (SCS-CN), which was developed in the 1950s and 1960s by the USDA Soil Conservation Service (currently the Natural Resource Conservation Service). The traditional SCS-CN

method is a rainfall-runoff model originally developed for predicting flood-flow volumes from ungauged watersheds for hydraulic engineering design. Despite the limited scope of intended application and several identified theoretical problems with the traditional SCS-CN method, it is ubiquitously used in water quality models to generate the fraction of rainfall that runs off. The original model was justified by Victor Mockus, to whom the traditional SCS-CN method is largely attributed, "on grounds that it produces rainfall-runoff curves of a type found on natural watersheds." Subsequently, hydrologists have shown that the basis of the method can be described in ways that are nominally consistent with both infiltration-excess theory and saturation-excess or VSA hydrology.

Figure 3 Manure deposition in exactly the wrong place from a hydrologically sensitive-area standpoint (courtesy of Glenn Warner).

Water Quality Impacts of Variable Source Area Hydrology

VSA hydrology has been shown to have significant consequences on surfacewater quality, having direct impacts on specific areas such as animal waste management, drinking water and human health, nutrient and pesticide management, pollution assessment and prevention, and watershed management. It is important that the development and implementation of the next generation of land-management practices for improving or preserving surface water quality be consistent with our most current hydrological understanding. Interestingly, many current practices aimed at reducing contaminant transport are based on Hortonian concepts. However, the effectiveness of these practices is diminished where Hortonian processes are not governing runoff generation.

Wherever VSA hydrology is a dominant process, there will be regions within a watershed that are more susceptible to producing runoff and delivering it to surfacewater bodies than other regions. These areas can be considered hydrologically sensitive areas (HSA). Recognizing the existence of HSAs allows watershed-scale water quality efforts to be focused on those areas where HSAs coincide with land uses that potentially contribute pollutants. The intersection of an HSA and a pollutant loading area is referred to as the 'critical management zone.' The most obvious best-management practice for this area would be to limit or prohibit potentially polluting activity from this region. A contrasting approach is finding methods and means of eliminating the hydrological sensitivity of the critical zones, although recent research suggests attempts to remove hydrologic sensitivity through drainage practices may simply reroute pollutants from overland flow to subsurface flow, with little reduction in concentration. In either case, the HSAs warrant primary attention when trying to preserve or improve water quality.

One example of where potential management practices derived from a recognition that VSA hydrology is in direct conflict with currently mandated management practices is whether dairy operators in the New York city watersheds should spread manure on steep slopes or in flat areas. The current dogma is to avoid spreading on steep slopes and to maximize spreading in flat areas. Under Hortonian flow, steep areas might arguably produce the most rapidly moving runoff and, therefore, the greatest potential for erosion and transport of manure. However, VSA hydrology is the dominant process in these watersheds and the steep slopes infiltrate essentially all rainwater and drain very rapidly, resulting in almost no substantial runoff. Conversely, the flat areas, especially at the base of hillslopes, are especially prone to saturation and, thus, prone to runoff generation. Figure 3 shows manure deposition in, from a HSA standpoint, exactly the wrong place. A manure-spreading policy that is more consistent with the recognized hydrology would promote spreading high in the watershed and minimize spreading on low, flat areas susceptible to runoff generation.

OXIDATION–REDUCTION OF CONTAMINANTS

C J Matocha, University of Kentucky, Lexington, KY, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

In the soil environment, inorganic and organic contaminants can be transformed by reduction and oxidation (redox) processes that can occur chemically, photochemically, or biologically. Historically, microbial oxidation of organic matter in soils and sediments ranks the sequence of oxidants as molecular oxygen (O_2) reduction, nitrate (NO_3^-) reduction, manganese dioxide (MnO_2) reduction, iron hydroxide ($Fe(OH)_3$) reduction, sulfate (SO_4^{2-}) reduction, and methane (CH_4) production. This reduction sequence is based on the oxidant yielding the most free energy change per mole of organic carbon oxidized and proceeds until all oxidants or all oxidizable organic matter are consumed in well-defined depth zones. It is well accepted that, in certain field situations, this thermodynamic reduction sequence is an oversimplification and does not coincide with the kinetic reduction sequence, because it provides no information about reaction rates and other potentially competing abiotic pathways.

In abiotic reaction pathways, the role of catalysis is important. Naturally occurring solid Fe and Mn oxides have been shown abiotically to catalyze transformations of organic and inorganic pollutants, which themselves could serve as electron donors and acceptors. Most reactions involving these metal oxides are heterogeneous, with complex, multistep processes such as adsorption, precipitation, electron transfer, and diffusion. The focus here is the role of reactive soil Fe and Mn species in the redox transformations of inorganic and organic contaminants.

Redox Status of Reactive Fe and Mn Species

Selected half-reactions and standard reduction potentials of important, solid-phase Mn(III,IV) and Fe(III) oxides in soils are compared below with other important redox half-reactions:

$$\frac{1}{2}\,\delta\text{-}MnO_x(s) + 2H^+ + e^- \rightarrow \frac{1}{2}\,Mn^{2+} + H_2O \qquad E_h^0 = 1.29\,V \qquad [1]$$

$$Fe(OH)_3(s) + 3H^+ + e^- \rightarrow Fe^{2+} + 3H_2O \qquad E_h^0 = 1.057\,V \qquad [2]$$

$$\frac{1}{4}\,O_2(g) + H^+ + e^- \rightarrow \frac{1}{2}\,H_2O \qquad E_h^0 = 1.229\,V \qquad [3]$$

$$\frac{1}{8}\,SO_4^{2-} + \frac{5}{4}\,H^+ + e^- \rightarrow \frac{1}{8}\,H_2S + \frac{1}{2}\,H_2O \qquad E_h^0 = 0.303\,V \qquad [4]$$

Birnessite (δ-$MnO_x(s)$) is the most commonly identified Mn(III,IV) oxide in soils, controlling solubility of plant-available Mn(II). Ferrihydrite, an amorphous Fe hydroxide ($Fe(OH)_3(s)$), is depicted as controlling Fe(II) solubility. Half-reactions are useful to represent the stoichiometry and thermodynamics of redox reactions. The standard state potential (E_h^0) in volts fixes the activity of reactants, products, and H^+ at unity by definition. The Nernst equation can be written for each half-reaction and E_h–pH diagrams constructed under more realistic environmental conditions ((Mn^{2+}), (Fe^{2+}), and $(SO_4^{2-}) = 10^{-5}\,mol\,l^{-1}$ and partial pressures of O_2 and H_2S of 0.02 and 0.0001 MPa):

1. δ-$MnO_x(s)/Mn^{2+}$: $E_h = 1.378 - 0.118\,pH$
2. $Fe(OH)_3(s)/Fe^{2+}$: $E_h = 1.352 - 0.177\,pH$
3. $O_2(g)/H_2O$: $E_h = 1.219 - 0.059\,pH$
4. SO_4^{2-}/H_2S: $E_h = 0.362 - 0.7375\,pH$

When summing two half-reactions, it is assumed that they are in equilibrium with one another (coupled). As long as the calculated E_h for the oxidant half-reaction is higher than that of the reductant half-reaction, the forward reaction is favorable. The free energy change, ΔG, of a redox reaction, can be assessed by knowledge of the standard reduction potentials of the half-reactions involved. E_h is directly related to ΔG of the system by:

$$\Delta G = -nFE_h \qquad [5]$$

where n is the number of electrons involved in the redox reaction and F is the Faraday constant ($F = 96\,500\,C\,mol^{-1}$). Redox reactions where $E_h > 0$ would give a negative ΔG and be thermodynamically favorable. Over a wide range of pH values, including those often encountered in soil environments (pH 4–8), oxidant strength from a thermodynamic point of view decreases in the order $O_2 > \delta$-$MnO_x > Fe(OH)_3 > SO_4^{2-}$ (Figure 1). Several lines of field evidence have shown that relying solely on thermodynamics to predict oxidant consumption can be misleading, and kinetic and catalytic factors need to be considered.

Sulfate reduction preceding Fe(III) reduction in lake pore-water sediments has been reported (Table 1). Overlap of these reduction sequences was ascribed to a wide range of Fe(III) oxide stabilities, giving rise to Fe(III) reduction rates that vary considerably and to the type of oxidizable organic C. The most unstable, poorly crystalline Fe oxides such as ferrihydrite are reduced preferentially to well-crystallized phases such as goethite (α-FeOOH). This situation is further complicated in soils containing Fe-rich phyllosilicate minerals that can undergo reduction and oxidation cycles.

Table 1 Pore-water chemistry with depth of Lake Greifen. Note the occurrence of sulfate reduction precedes that of Fe(III) reduction

Depth (cm)	*SO_4^{2-} (μM)*	*[H_2S] (μM)*	*Fe(II) (μM)*

Adapted from Wersin P, Hohener P, Giovanoli R, and Stumm W (1991) Early diagenetic influences on iron transformations in a freshwater lake sediment. *Chemical Geology* 90: 233–252.

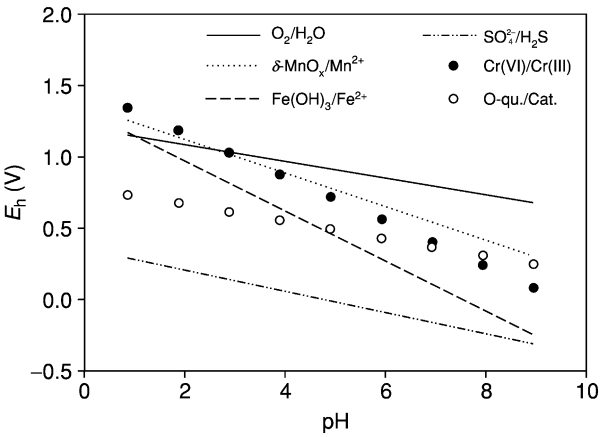

Figure 1 Relationship of redox potential (E_h) to pH for several important redox couples in soils compared with representative inorganic and organic (*ortho*-quinone (O-qu.)/catechol (cat.) couple) contaminants. Dissolved Mn, Fe, S, Cr, and organic species were assigned an activity of $10^{-5}\,mol\,l^{-1}$, and dissolved oxygen and sulfide were given values of 0.02 and 0.0001 MPa.

Reduced products from the primary redox reactions can participate in abiotic secondary reactions, affecting oxidant availability and organic matter degradation pathways. Consumption of dissolved O_2 is dependent on microbial activity and availability of suitable electron donors such as dissolved Fe(II) and Mn(II). Dissolved Fe(II) and Mn(II) can diffuse upwards from anaerobic environments into oxic zones. The thermodynamic driving force for capture of downward-diffusing O_2, which is in ample supply from the atmosphere, by dissolved Fe(II) and Mn(II) is favorable over a wide soil pH range. Yet at pH >6, Fe(II) oxygenation is rapid, while Mn(II) oxygenation occurs only after years and coexistence of dissolved Mn(II) and O_2 is not uncommon. Surface catalysis by hydrous oxides and microorganisms increases Mn(II) oxygenation rates, thus, only heterogeneous oxygenation of Mn(II) is included in reactive transport models because of the slow kinetics of homogeneous Mn(II) oxygenation. Depending on the environmental setting, as much as 50% of the dissolved O_2 can be consumed by these rate-limited secondary reactions and the remainder by microbial respiration.

Kinetics and Mechanism

The goal of collecting fundamental kinetic data is to derive an elementary rate expression with a rate constant and to propose a mechanism. The usefulness of the kinetic approach is that it expresses the rate as

changes in reactant and product concentration over time and empirically determines the reaction orders. Consider the following simple forward reaction:

$$A \xrightarrow{k_1} P \quad \text{rate} = -\mathrm{d}[A]\mathrm{d}t^{-1} = \mathrm{d}[\mathrm{P}]\mathrm{d}t^{-1} = k_1[A]^a \qquad [6]$$

where a is the power dependency or reaction order and k_1 is the rate constant, assuming the reaction stoichiometry is known and constant over the time period investigated. The value of k_1 should depend only on temperature, thus it should be specified, and be time-invariant. The rate expression is defined once the value of a is determined. If unity, then the reaction is first-order in A and first-order overall. Fractional-order rate expressions are not uncommon, particularly in multistep processes such as heterogeneous redox reactions. The rate, $-\mathrm{d}[A]\,\mathrm{d}t^{-1}$, is usually given in terms of moles per liter per second, and the units of k_1 for a first-order reaction are per second, per minute, or per hour. This information is used in reactive transport models that attempt to predict spatial and temporal distributions of redox-active species. It is important to realize that the empirical rate expressions may not always obey the overall reaction stoichiometry. Identification of the rate-limiting step, represented by the rate expression, is important because it represents the slowest step, thus any manipulation of it can either speed up (for instance adding a catalyst) or slow down the overall reaction.

For redox reactions to occur, the oxidant and reductant must encounter one another in order to allow the reaction to proceed. This is the case for both homogeneous and heterogeneous reactions. The general mechanism for heterogeneous redox reactions includes the following steps: (1) precursor-surface complex formation between oxidant and reductant, (2) electron transfer, and (3) product release. Both electronic and steric effects will influence the rate and extent of precursor complex formation, especially when considering sorption behavior at a surface. The precursor complex can involve a direct, inner-sphere bond between oxidant and reductant or an outer-sphere bond, where no bond breaking or making occurs and the transition state is unaffected. The rate-limiting step for outer-sphere electron transfer mechanisms is the electron-transfer step, while either precursor complexation or electron transfer can be rate-limiting in inner-sphere mechanisms. Bridging ligands with filled sigma (σ) and pi (π) orbitals such as oxo surface groups (O^{2-}, OH^-, and H_2O) on minerals can facilitate electron transfer for inner sphere mechanisms because the lone pairs of electrons function as 'bridges.' If the overlap of molecular orbitals for oxidant and reductant is perfect, then inner-sphere electron transfer mechanisms do not require a bridging ligand. Interfacial characteristics can also determine electron transfer rates, an additional consideration for heterogeneous reactions.

Rates of most redox reactions increase with temperature, and rate constants (k_{obs}) can be described by the Arrhenius equation to determine activation energies (E_a):

$$k_{obs} = A_f \exp^{-E_a/RT} \qquad [7]$$

where A_f is the frequency factor, R is the gas constant, and T is absolute temperature. Low E_a values ($<42\,\mathrm{kJ\,mol^{-1}}$) indicate that the rate-limiting step is a diffusion-controlled process, while high E_a values represent surface chemical control of the rate-limiting step. Conducting kinetic experiments over a temperature range of 4–40°C (277–313 K) can simulate conditions in aquifers and soil environments.

Thermodynamic considerations are an important first step in the appraisal of whether a given inorganic or organic contaminant will undergo redox reactions in a soil environment. Delineation of redox zones by analysis of soil solution and pore water for major redox-active species is also helpful in predicting the fate of the contaminant, particularly if rate expressions have been determined already for the specified redox couple.

Inorganic Contaminants

Manganese as an Oxidant

The importance of Mn(III,IV) (hydr)oxides environmentally lies in their ability to adsorb and in some cases oxidize certain trace metals. Chromium (Cr) is a well-known contaminant, and typical oxidation states are Cr(III) and Cr(VI). Hexavalent Cr is mobile in soils because it is an oxyanion and repelled by negatively charged soil particles. In contrast, Cr^{3+} is more strongly adsorbed and forms relatively insoluble oxide and hydroxide compounds. Chromium(III) and Cr(VI) speciation in solution are functions of pH, but will not be accounted for here. The half-reaction and standard reduction potential for the Cr(VI)-Cr(III) couple can be written as:

$$CrO_4^{2-} + 8H^+ + 3e^- \rightarrow Cr^{3+} + 4H_2O \qquad E_h^0 = 1.51\,\mathrm{V} \qquad [8]$$

where $E_h = 1.51–0.1573\,\mathrm{pH}$.

Oxidation of Cr(III) to Cr(VI) by O_2 is more energetically favorable than by Mn(III,IV) (hydr)-oxides or Fe oxides (Figure 1). However, rates of

Cr(III) oxidation by O_2 are slow over a wide pH range. Soil Mn oxides and laboratory-prepared Mn oxides can directly oxidize Cr(III) at faster rates than O_2 or Fe oxides, according to the following overall reaction:

$$Cr^{3+} + 1.5MnO_2 + H_2O \rightarrow CrO_4^{2-} + 1.5Mn(II) + 2H^+ \quad [9]$$

Typical rate equations and E_a values (more than $42\,kJ\,mol^{-1}$) indicate that the slowest step is either precursor-surface complex formation or electron transfer. Temporal variability in Cr(III) oxidation rates is observed as initial Cr(III) concentration and pH increases and is attributed to surface precipitation of $Cr(OH)_3(s)$ that inhibits the reaction. In some cases, formation of an intermediate Mn(III) oxyhydroxide phase is reported to retard the reaction also. These findings are significant because Cr(VI) is more mobile and toxic than Cr(III).

The coupling of Mn reduction with Cr(III) oxidation to Cr(VI) can be explained by frontier molecular orbital theory. Oxides and hydroxides of Mn(III) and Mn(IV) are kinetically better oxidants than O_2, because the lowest unoccupied molecular orbitals (LUMO) for Mn(III) and Mn(IV) are the e_g orbitals, which are of sigma (σ^*) symmetry and available to accept electrons from σ- and π-donor contaminant metals (Figure 2). For Mn(IV), with a $d^3(t_{2g}^3\ e_g^0)$ electronic configuration, both e_g orbitals are vacant and a concerted two-electron transfer can occur. In contrast, the LUMO for O_2 is of π^* symmetry (π_{2px}^{1*} π_{2py}^{1*}) and, being singly occupied, can only accept one electron at a time. Oxo groups present on the Mn oxide surface serve as bridging ligands, because they have filled orbitals of π and σ symmetry to make the Cr(III)-to-Mn(IV) electron transfer facile.

Other examples of Mn oxide-catalyzed oxidations of trace metal contaminants include oxidation of Co(II) to Co(III), As(III) to As(V), and Se(IV) to Se(VI). In all of these reactions, there is a rate dependence on reductant and oxidant concentration. The rates in oxygenated systems are negligible without the presence of the solid-phase Mn oxide.

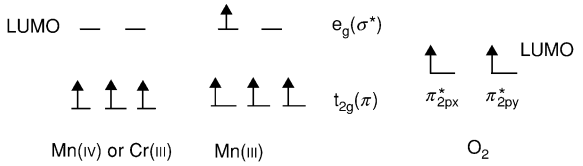

Figure 2 Lowest unoccupied molecular orbitals (LUMO) for Mn(III) and Mn(IV) are shown as e_g orbitals with σ^* symmetry. For O_2, the LUMO are antibonding π^* molecular orbitals resulting from overlap of 2px and 2py atomic orbitals.

Fe(II) as a Reductant

Rate studies of oxidation of Fe(II) in solution at pH > 5 shows a second-order dependence on OH^- concentration and first-order dependence on O_2 concentration:

$$-d[Fe(II)]/dt = k[Fe(II)][OH^-]^2[O_2] \quad [10]$$

because dissolved OH^- donates electron density to Fe(II) through the σ and π systems and enhances the metal's reducing power. Thus, O_2 reacts predominantly with the hydrolyzed species $FeOH^+(aq)$ and $Fe(OH)_2$ (aq) as the pH increases. Fe(II) coordinated with σ- and π-donating ligands, with oxygen as the ligating atom, such as oxo groups in minerals and dissolved organic matter, lowers the aqueous Fe(III)–Fe(II) reduction potential, making coordinated Fe(II) a better reductant than dissolved Fe(II). Naturally occurring, solid-phase Fe(II) minerals such as siderite ($FeCO_3(s)$), pyrite ($FeS_2(s)$), and sulfate green rust ($[Fe_4^{II}\ Fe_2^{III}\ (OH)_{12}]\ [SO_4 \bullet 3H_2O]$) are stronger reductants than aqueous Fe(II) also.

During reductive dissolution of Fe(III) (oxy)hydroxides or Fe-bearing phyllosilicates in in soils and sediments by either microorganisms or abiotic reductants, Fe(II) is released to solution. After initial release, one of the processes that dissolved Fe(II) can undergo is adsorption back on to the surface. Adsorbed Fe(II) is significant in anaerobic soil environments for two reasons. First, in pure mineral systems, dissolved Fe(II) resulting from microbial reduction of goethite has been shown to adsorb to remaining goethite surface sites and limit the extent of reduction. In Fe(III) oxide-rich subsoils with mixed mineralogy, dissolved biogenic Fe(II) adsorbs strongly to kaolinite to limit bioreduction. The second reason is that Fe(II) adsorbed as an inner-sphere surface complex is an effective reductant and can catalyze oxygenation. The conceptual model is shown in Figure 3, where >M—O represents a surface metal (Fe(III)) oxide or phyllosilicate mineral functional group. The oxide or hydroxide group behaves as a bridging ligand and 'pumps' electron density from adsorbed Fe(II) to the O_2. Surface OH groups on metal oxides and phyllosilicate minerals can catalyze electron transfer from Fe(II) to O_2 analogous to

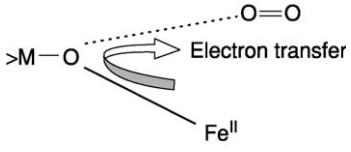

Figure 3 Conceptual model of adsorbed Fe(II) as an inner-sphere surface complex that enhances oxygenation.

dissolved OH^-. Therefore, adsorbed Fe(II) bound to surface OH groups in an inner-sphere surface complex is a better reductant than dissolved Fe(II). A kinetic estimate for the redox potential of adsorbed Fe(II) on goethite is $E_h^0 = 0.36$ V, similar in magnitude to $FeOH^+$ ($E_h^0 = 0.34$ V). Characterization of the reducing power of adsorbed Fe(II) on different mineral surfaces remains a challenge. Adsorbed Fe(II) species as reductants are important to consider in any environmental setting because, at the onset of anaerobic conditions, solid Fe(III) oxides are the most abundant oxidants, in concentrations approximately 60-fold greater than solid Mn oxides.

Investigators have recently shown that adsorbed Fe(II) coordinated to surface hydroxyl functional groups on metal oxides can catalyze the reduction of Cr(VI), nitrite (NO_2^-), uranium(U(VI)), and technetium(Tc(VI)). Reduction of toxic Cr(VI) by reduced Fe(II) species is beneficial because the solubility of Cr is lowered by formation of sparingly soluble Cr(III) precipitates. This multistep process is rapid in the presence of dissolved Fe(II), structural Fe(II), and adsorbed Fe(II). Rate expressions are typically second-order:

$$-\mathrm{d}[\mathrm{Cr(VI)}]/\mathrm{d}t = k_{\mathrm{obs}}[\mathrm{Fe(II)}]_x[\mathrm{Cr(VI)}] \qquad [11]$$

where k_{obs} is the second-order rate coefficient and $[Fe(II)]_x$ represents dissolved, adsorbed, or structural Fe(II). The values of k_{obs} for dissolved, adsorbed, and structural Fe(II) species can be compared qualitatively. Hydrous oxide surfaces such as goethite adsorb Fe(II) in an inner-sphere complex that is very reactive toward reduction of dissolved Cr(VI), with k_{obs} values ranging from 6.6 to 72 $l\,mol^{-1}\,s^{-1}$ (Table 2). Dissolved Fe(II) and solid-phase Fe(II) minerals such as green rust are also effective reductants of Cr(VI) (Table 2) and minimize contamination of soil and water supplies.

Nitrite reduction to N_2O by Fe(II) adsorbed to lepidocrocite (γ-FeOOH) is rapid, and the maximum rate of 10 $\mu mol\,h^{-1}$ occurs at pH 8.5. The postulated mechanism Fe(II) adsorbed as a bidentate inner-sphere complex with surface oxo groups provides an ideal environment for NO_2^- adsorption and subsequent N–N double-bond formation, similar to the function of the Fe metal center in nitrite reductase enzyme. No reduction of NO_2^- occurs in the absence of lepidocrocite or in the presence of dissolved Fe(II). The N_2O produced may take part in global warming and atmospheric ozone destruction, because it is a more potent greenhouse gas than CO_2 and represents an irreversible loss of N from soil.

Table 2 Chromate (Cr(VI)) reduction rates based on observed second-order rate coefficients (k_{obs}) by naturally occurring reactive Fe(II) species

Fe(II) species	k_{obs} *($l\,mol^{-1}\,s^{-1}$)*
Dissolved Fe(II)	3.7[a]
Solid Fe(II) (green rust)	6.3[a]
Adsorbed Fe(II)	
Goethite	6.6–72[a]
Aluminum oxide	3.5–7.5[a]

Organic Contaminants

Background

For reduction and oxidation processes to occur for organic compounds, the same general steps of precursor complexation, electron transfer, and product release are involved. Relevant structural properties of the organic compound that have to be considered are identity and location of functional groups, acidity and basicity of those groups, and overall molecular size and shape of the molecule. These properties in turn affect the water solubility of the organic compound and hence its ability to encounter the relevant oxidant or reductant in the soil environment. Active sites on organic compounds are the functional groups. Electron-donating functional groups that are able to form surface complexes, particularly chelate complexes, are effective reductants of oxidized Fe and Mn species. In general, removal of electrons from organic compounds can occur by two different pathways. The heterolytic pathway involves the transfer of two electrons, while homolytic pathways describe one electron transfer and are often referred to as free-radical pathways. Organic free radicals are usually reactive and unstable.

Oxidation and Reduction in Soil Organic Matter

Soil organic matter (SOM) consists of a wide range of compounds derived from algal, plant, and microbial material with different structures and consequently different properties. Primary functional groups in SOM include O- and N-containing groups that are electron-donating and undergo processes to form humic substances (HS), a subclass of SOM consisting of high-molecular-weight biopolymers that react profoundly with inorganic and organic contaminants. The exact structure of HS is unknown, and the humification process is not completely understood, yet it is a way of sequestering C. Characteristics of the precursor organic carbon and the transformations it has undergone are important factors influencing the

chemical properties of HS. Humification of natural SOM can also tie up organic contaminants which themselves often contain electron-donating functional groups through nucleophilic addition reactions. Implicit in the SOM-decomposition model is the paramount role of microorganisms, because they can derive energy from the reduced C source. Faster SOM degradation rates have been shown to result in greater overlap of reduction sequences with depth, indicating the likelihood of abiotic SOM oxidation.

Manganese and Iron as Oxidants

Direct reaction of organic compounds with O_2 is exceedingly slow, especially for organic pollutants. Solid-phase Mn(III,IV) (hydr)oxides can function as important electron acceptors of SOM, chlorinated phenols, and anilines. Catechol (1,2-dihydroxybenzene) is a suitable analogue of SOM, because semiquinones and quinones have been identified in soil HS. Catechol is known for its oxidation and reduction properties and represents a chelating and polymerizing polyphenol.

Naturally occurring birnessite (δ-$MnO_{1.7}$) catalyzes oxidation of catechol more rapidly than O_2 and FeOOH based on measurements of Mn(II) release (Table 3). Efficient dissolution of birnessite is probably aided by the ability of catechol to form a surface chelate during the precursor-surface complex step with metal center surface sites. In addition, electrons can be transferred immediately along the bonding axis as an inner-sphere process from the filled catechol p orbitals of σ symmetry to the vacant LUMO of σ^* symmetry of the Mn(III,IV) metal centers after precursor-surface complex formation. This proper symmetry overlap probably explains why Mn oxides are kinetically better oxidants than O_2 (see Figure 2) and Fe(III) oxides, because the LUMO for Fe(III) is singly occupied (d^5, t_{2g}^3 e_g^2).

Oxidation of substituted phenols by metal ion oxidants is complex, because product distribution and reaction rates are highly dependent on the nature of the oxidant, reactant concentrations, and reaction conditions. Several competing reactions may occur that accompany phenol oxidation and reductive dissolution of Mn(III,IV) (hydr)oxides, such as oxidative coupling of organic radicals or phenolic dimers which form complex mixtures of polymeric oxidation products. In fact, the rapid production of dissolved Mn(II) is accompanied by formation of polymeric reaction products via oxidative coupling reactions from the catechol precursor that resembles soil humic substances (Table 4). Spectroscopic indicators of humification are E_4:E_6 ratios, the ratio of absorbance at 465 nm to that at 665 nm. Lower E_4:E_6 ratios (approx. <5) correspond to higher organic radical

Table 4 Spectroscopic indicators of humification based on E_4:E_6 ratios for products of the birnessite–catechol mixture compared with extracted humic acid from a typical agricultural soil in Kentucky (Woolper silt loam)

Sample	E_4/E_6
Birnessite–catechol (pH 4)	20.3
Birnessite–catechol (pH 6.5)	3.1
Woolper humic acid	3.17

contents and a greater degree of humification and stabilization of soil humus. The E_4:E_6 ratios of filtrates for the birnessite–catechol reaction mixture at high pH are comparable with humic acid extracted in a typical Kentucky soil. Direct abiotic coupling of oxidizable organic carbon (C) with solid-phase Mn contributes to sequestration of C through humification processes.

Chlorophenols are well recognized as being highly toxic and represent an organic pollutant class that can be abiotically degraded by solid-phase Mn oxides. Their water solubility and reactivity decrease as the number of chloro substituents added to the phenol increase (Table 3). Detoxification of chlorinated phenols by Mn(III,IV) (hydr)oxides occurs by oxidation, dechlorination, and polymerization processes that can result in less-toxic products that can be biodegraded more readily in soils. During the oxidative coupling (polymerization) reactions, xenobiotic substances such as chlorinated phenols form insoluble precipitates that can be removed from water by sedimentation or filtration. Anilines, another organic pollutant class found in industrial byproducts and components in pesticides, can also be oxidized rapidly in the presence of birnessite (Table 3) and undergo further oxidative coupling reactions to form a variety of polymeric products. Although not as abundant, Mn oxides are more reactive catalysts than Fe oxides for a wide variety of organic pollutant redox reactions.

Adsorbed Fe(II) as a Reductant

In anaerobic soils and aquifers, Fe(II) species adsorbed on solid Fe(III) oxide sites are important reductants of oxidized organic contaminants such as halogenated solvents and nitroaromatic compounds. A common theme in past research in this area has been the greater reduction rates with Fe(II) adsorbed as an inner-sphere surface complex when compared with the presence of solid-phase or dissolved Fe(II) alone. Surface-bound Fe(II) is not only more reactive but also may be continuously regenerated by the activity of Fe-reducing microorganisms and subsequent adsorption from solution to form new

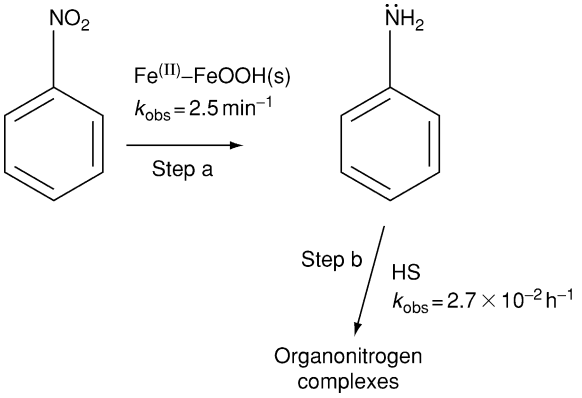

Figure 4 A two-step remediation strategy for nitrobenzene.

reactive Fe(II) species. The surface density of adsorbed reactive Fe(II) can be manipulated by varying pH values due to the pH-dependent sorption behavior. Thus, reduction rates typically increase with pH because of the greater surface density of reactive adsorbed-Fe(II).

For nitroaromatic compounds that are prevalent contaminants in the soil at munitions facilities, a two-step remediation strategy has been proposed. The first step involves the complete reduction of the nitroaromatic group to the corresponding aromatic amine compounds, followed by nucleophilic addition reactions such as oxidative coupling with natural SOM to form tight covalent bonds (bound residues) that pose minimal environmental threat. Both reduction and covalent binding reactions generally are scaled with pH. A generalized scheme is shown in Figure 4 for nitrobenzene. Adsorbed Fe(II)-goethite species reduce nitrobenzene at rapid rates (step a) to the reduced aniline product. Aniline is then reacted with natural SOM groups and incorporated into humic–organonitrogen complexes. Step b can be catalyzed by addition of Mn oxides to minimize environmental contamination of nitrobenzenes and anilines. Structural analyses of the products of these reactions have been made recently by state-of-the-art ^{15}N- and ^{13}C-labeled nuclear magnetic resonance techniques.

Introduction

Wetland rice or paddy soils provide the staple diet for nearly half the world's population. Worldwide, the total harvested rice area covers approximately 150 million hectares, and approximately 90% of this rice area is situated in Asia, with a similar share in rice production. The flooded soil environment is one of the specific characteristics associated with rice cultivation of the traditional rice-growing areas in the river deltas of China, Southeast Asia, and the Indian subcontinent. The term 'paddy soil' does not describe a specific soil type but rather denotes soils in lowland rice production systems with a prolonged period under submergence. 'Water regime' is used to classify the environment of paddy soils into broad ecosystems, distinguishing irrigated and rainfed rice grown predominantly in the lowlands, upland rice grown in the uplands under aerated soil conditions, and deep-water rice in flood-prone river deltas and coastal areas.

Cropping Environments in Asia's Lowlands

With an increasing demand for rice from a growing population, rice-cropping and paddy-soil management in Asia has undergone substantial intensification since the first modern high-yielding varieties with shorter growth periods, reduced height, and better fertilizer response were released in the early 1960s. Rice production tripled from 1948 to 1990 because of a larger physical land area cropped to rice, an increasing number of crops grown per year, and higher yields as a result of Green Revolution technologies such as improved germ plasm, irrigation infrastructure, water and pest management, and greater use of inorganic fertilizer. The intensification was accompanied by changes in chemical, biological, and physical processes in the soil–floodwater system. The duration of soil submergence and tillage operations increased, especially in the expanding double and triple rice-cropping systems. In such systems, periods of aerobic soil conditions are shorter and are mostly restricted to dry fallows. The duration of the dry fallow between two rice crops varies from a few weeks up to 2–3 months in the typical annual double rice-cropping system in Asia.

In the mid-1990s, the harvested area in Asia's rice ecosystems included 73 million hectares of irrigated rice, 46 million hectares of rainfed lowlands, 9 million hectares of upland rice, and approximately 4 million hectares of flood-prone rice ecosystems. While the overall physical rice area will probably not change much in the future, it is forecast that total rice production in Asia will have to increase by approximately 25% from 530 million tonnes in 1999 to 662 million tonnes in 2020 to meet the increasing rice demand in Asia (Table 1). Given the expansion of rice area with irrigation at the expense of upland rice area and the small potential for increasing rice yields in the uplands, yields in irrigated rice would have to increase from $5.3\,t\,ha^{-1}$ in 1999 to $6.7\,t\,ha^{-1}$ in 2020. The expected changes in rice demand, environment and socioeconomic conditions, and their effects on productivity and management of paddy soils in Asia's intensive rice systems are depicted in Figure 1. Most of the expected production increase will have to come from grain yield increases in the lowland rice ecosystems, and technologies developed in recent years provide substantial opportunities for farmers to increase productivity and profitability as rice demand increases. With sufficient investment, rice production can undergo an intensification that is environmentally sound and sustains the soil resource base. However, in some areas, crop management may change in response to environmental concerns, resource availability or low profitability, with possible adverse effects on rice yields and soils.

Table 1 Yield, area, and production of irrigated and nonirrigated rice for Asia in 1999, and required changes in yield based on projected changes in area and production requirements until 2020 (Dawe D, IRRI, personal communication.)

	Grain yield			*Area*			*Production*		
	t ha^{-1}			*10^6 ha*			*10^6 t*		
System	*1999*	*2020*	*Δ%*	*1999*	*2020*	*Δ%*	*1999*	*2020*	*Δ%*
Irrigated	5.36	6.72	+25%	76.0	78.4	+3.2%	406	527	+30%
Nonirrigated	2.08	2.39	+14%	59.5	56.5	−5.0%	124	135	+9%
Total	3.92	4.90	+25%	135.2	135.2	0.0%	530	662	+25%

Projected changes in area and production are adapted from Rosegrant MW, Sombilla MA, and Perez N (1995) *Global Food Projections to 2020: Implications for Investment. Food, Agriculture and the Environment.* Discussion Paper No. 5. Washington, DC: International Food Policy Research Institute.

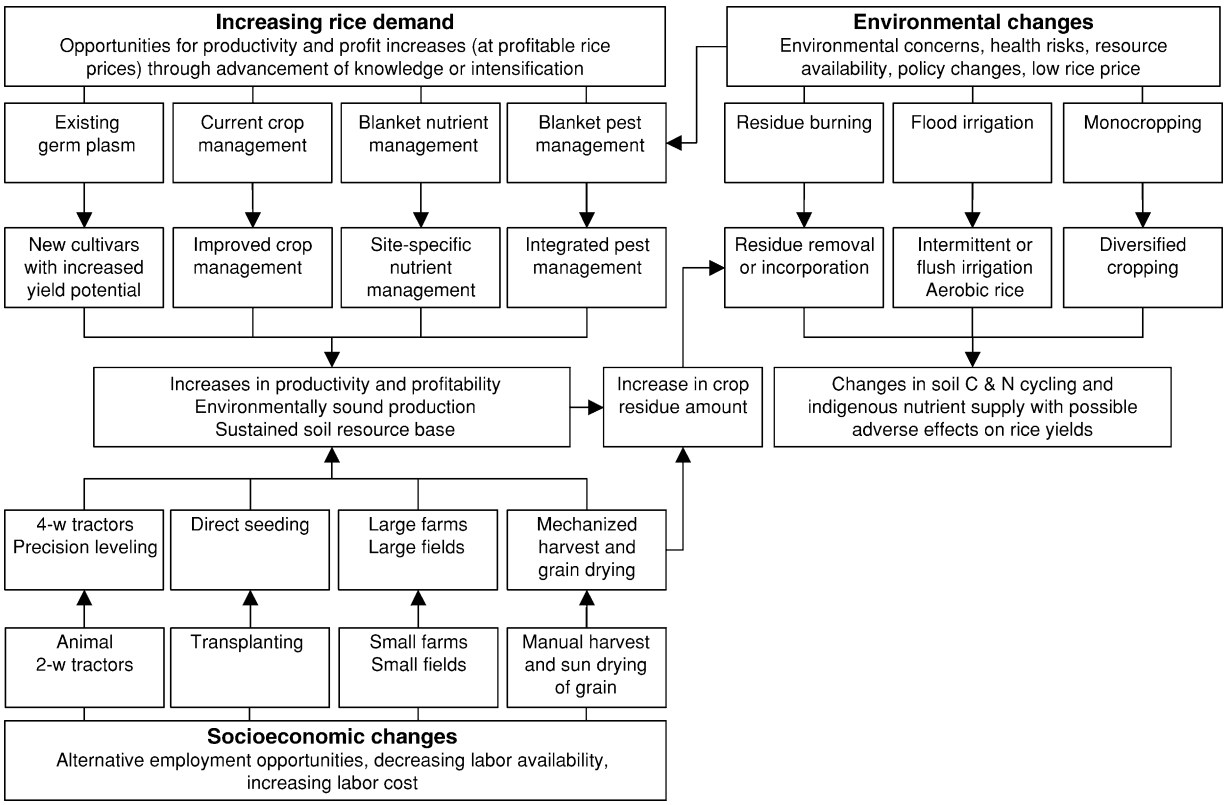

Figure 1 Expected changes in rice demand, environment, and socioeconomic conditions affecting the productivity and management of paddy soils in intensive rice systems in Asia. Some of these changes have already occurred or are in progress in certain areas. w, wheel.

Distribution and Important Characteristics of Paddy Soils

Paddy soils constitute an important group within the wetland soils, where water saturation dominates soil development and the types of plant and animal communities. Thus, paddy soils are defined as wetland soils with standing water in bunded and leveled fields used for cultivation of rice (bunds are small dikes around the field to keep the water from running off). Paddy soils may support an upland, nonrice crop in the dry season when soils are aerated, but insufficient drainage capacities often make rice the only possible crop choice in the lowlands of the humid tropics. Free surface water may occur naturally or rainfall, runoff, or irrigation water may be retained by field bunds and/or compacted subsoil layers.

According to the Food and Agriculture Organization of the UN (FAO) World Reference Base for Soil Resources, most paddy soils are designated as Anthrosols (having a puddled surface layer and a plow pan) or as Gleysols, Fluvisols, Planosols, Plinthosols, and Histosols. Smaller areas of paddy soils fall within the gleyic soil units of Arenosols, Andosols, Cambisols,

Solonetz, Solonchaks, Luvisols, Lixisols, Acrisols, and Alisols. Although Vertisols, Nitisols, and Ferralsols have no gleyic soil units, these soils may be artificially flooded and used for rice cultivation. The US Department of Agriculture Soil Taxonomy does not recognize wetland soils at the level of soil orders, but classifies soils with aquic conditions at the suborder level and soils with hydromorphism at the subgroup level. Most paddy soils would be assigned to the aquic suborders of Andosols, Oxisols, Vertisols, Ultisols, Mollisols, Alfisols, Inceptisols, and Entisols.

Natural or artificial flooding of paddy soils has marked effects on electrochemical, chemical, and microbial processes, which in turn affect soil fertility and thereby crop growth in a dynamic manner. The main electrochemical changes include a decrease in redox potential and changes in soil and solution pH, microbially mediated processes that are mainly controlled by organic matter and reducible Fe contents of the soil. With decreasing redox potential, oxidized forms of soil redox systems serve as electron acceptors in microbial respiration. The general sequence of reduction is O_2–NO_3^-–Mn(III, IV)–Fe(III)–SO_4^{2-}–CO_2–H^+. Some of these redox systems are overlapping (e.g., O_2, NO_3^-, and Mn(III, IV)), whereas others are not (e.g., O_2 and Fe(III); SO_4^{2-}, and CO_2). Reduction of CO_2 causes the emission of methane from flooded paddy soils in freshwater systems. The electrochemical changes induce a pH increase in most acid soils, whereas the pH decrease upon flooding of calcareous and sodic soils is due to the accumulation of carbon dioxide. Two distinctly different topsoil layers develop: a thin aerobic surface layer of a few millimeters depth caused by O_2 diffusion through the aerobic floodwater layer (and around the rice root surface due to O_2 transport through the rice plant's aerenchyma), and the anaerobic soil layer below, with a variable depth. Most roots are concentrated in the first 20 or 30 cm below the soil surface. The presence of aerobic and anaerobic soil compartments causes considerable soil N losses through mineralization–nitrification–denitrification reactions (Figure 2). In most soils, flooding increases the plant availability of P, K, Ca, Mg, Na, Mn, Fe, and Si at least temporarily. Reduction of Fe and Mn oxides releases sorbed and occluded elements such as P, Zn, Cu, B, and Mo. Increasing pH reduces plant availability of Zn and Cu, whilst the solubility of Mo increases. Reduction of SO_4^{2-} reduces plant-available S.

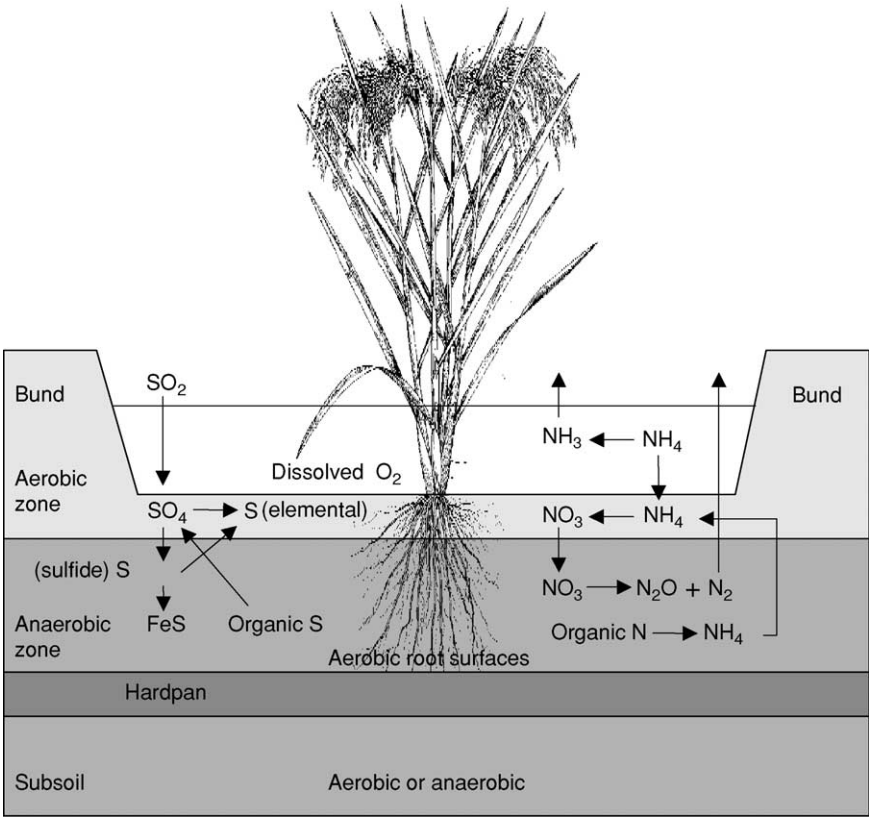

Figure 2 Aerobic and anaerobic soil compartments in a flooded paddy soil, and related sulfur and nitrogen dynamics. (Adapted from Greenland DJ (1997) *The Sustainability of Rice Farming*, pp. 1–273. Wallingford, UK: CABI Publishing/Manila, Philippines: International Rice Research Institute, with permission.)

A widespread and traditional soil-preparation practice in lowland production systems is puddling. Puddling refers to the practice of mixing surface soil with water to make it soft for transplanting, the traditional crop establishment method for rice. Other short-term puddling effects are the destruction of soil aggregates, irrigation-water savings due to reduced percolation, altered soil bulk density, increased soil water-holding capacity, decreased hydraulic conductivity, an acceleration of the electrochemical processes described above, and good weed control. A long-term effect of puddling is the development of a hardpan (plow pan, traffic pan) in the subsoil below the puddled layer, often associated with the accumulation of Fe, Mn, and Si. The puddled surface layer is often characterized by a coarser texture caused by clay mineral decomposition and/or transportation processes. Hardpan formation may take from 3 to 200 years, depending on soil type, climate, hydrology, and puddling frequency.

Paddy Soil Fertility and Nutrient Management

The nutrient-supplying capacity of paddy soils in the traditional rice-growing environments is largely determined by their parent material, the alluvial deposits in the river deltas and flood plains. Natural nutrient inputs are derived from sedimentation, irrigation and rainwater, organic residues or manure, biological N_2 fixation, and carbon assimilation by floodwater flora and fauna. Efforts to maintain soil fertility have historically centered around maintaining soil organic matter (SOM) through the addition of green manures, animal waste, and crop residues, but their significance has decreased continuously in the last decades.

The total annual C input in a double rice-cropping system may currently range from 4000 to 7000 kg C ha^{-1}, including inputs of 1000–2000 kg C ha^{-1} from the photosynthetic and heterotrophic biomass in rice fields. Despite high temperatures in the tropical soil floodwater environment and rapid initial breakdown of organic inputs, average SOM concentrations in paddy soils are higher than in aerated soils, mostly because of high organic matter inputs and a slower decomposition rate of humus. Crop intensification with prolonged soil flooding changes the nature of SOM toward more aromatic compounds (chemical structure with six C-atoms arranged in a ring) because of changes in the breakdown of organic matter under increasingly anaerobic conditions. These changes appear to have limited effects on yield stability under rice monocropping, except in systems with intensive triple cropping and nearly continuous soil submergence.

A recent analysis of yield trends in long-term experiments with intensive rice-based cropping systems in tropical and subtropical regions of Asia has suggested that yields in most experiments have remained stable with recommended fertilizer N, P, and K addition. There is also evidence that organic matter application does not improve grain yield trends in rice-based systems vis-à-vis a balanced mineral fertilizer application. However, the application of organic matter, unless purchased, is often profitable if used as a nutrient source complementary to inorganic fertilizer. The typical irrigated lowland rice soil maintains an average carbon concentration of approximately 1–2% and a nitrogen concentration of approximately 0.1–0.2%, but considerably lower concentrations are found in most rainfed lowland environments.

A unique contribution to the indigenous N supply of paddy soils derives from biological N_2 fixation (BNF), providing 15–50 kg N ha^{-1} per cropping cycle from blue-green algae in the floodwater and heterotrophic bacteria in the rice rhizosphere. The mineralization of algae and bacteria provides a constant supply of ammonium (NH_4^+), the dominating inorganic N form available to plants under anaerobic soil conditions. Because of efficient plant uptake of mineralized N, larger amounts of extractable NH_4^+ are found only after soil flooding during the initial decomposition of residues or if fertilizer N is applied (**Figure 3**).

The major N loss mechanism during the cropping season is ammonia (NH_3) volatilization from the flooded soil, particularly when NH_4^+ concentrations in the floodwater rise after N fertilizer application. Nitrogen is also leached, denitrified, and/or immobilized by soil microbial biomass and SOM. Approximately 70% of the fertilizer N applied by farmers is currently not recovered by crop N uptake, but N recovery efficiencies of applied fertilizers can reach 50% or more in farmers' fields with adequate real-time N management strategies. Considerable amounts of soil nitrate only accumulate in aerated soil during fallow periods or during upland cropping cycles in rice-based rotations. Almost all nitrate is lost after soil flooding because of leaching and denitrification. Including upland crops in rice-based systems affects mineralization, plant availability, and loss of inorganic N. Soil aeration also accelerates the turnover of SOM and changes its composition toward a less aromatic nature, with possible adverse effects on the amount of soil indigenous N supplied to rice. However, few long-term data are available from experiments that directly compare crop rotations.

Other anticipated future changes in crop management include mechanization of soil preparation and

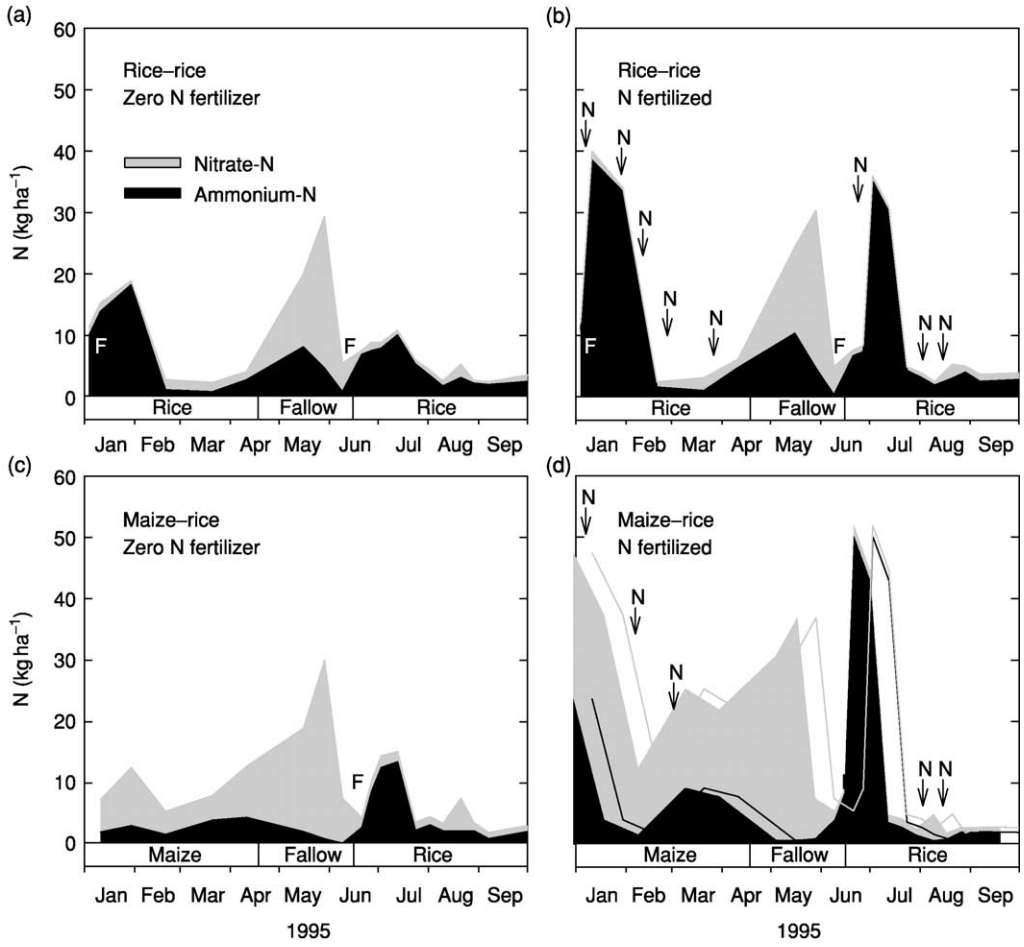

Figure 3 Nitrate (NO_3^-) and ammonium (NH_4^+) dynamics in a rice–rice and a maize–rice cropping experiment with and without fertilizer N application, IRRI experimental farm, 1995. Fertilizer N was applied in several split applications with a total of 190 kg N ha^{-1} in the dry season (Jan to mid-Apr) and 100 kg N ha^{-1} in the wet season (mid-Jun to early Oct). F, flooding; N, fertilizer N split application.

harvest operations, changes in water management toward increasing soil aeration, and larger amounts of crop residues remaining in the field for farmers to deal with (Figure 1). These changes will affect soil C and N cycling in paddy soils, and research currently aims to develop a portfolio of technology and management options to mitigate potential adverse effects.

Rice requires an adequate supply of nutrients from various sources to produce high and sustainable yields. A rice crop with a yield of 6 t ha^{-1}, for example, accumulates approximately 100 kg N, 18 kg P, 100 kg K, 0.3 kg Zn, 11 kg S, 480 kg Si, 21 kg Mg, 24 kg Ca, 3 kg Fe, and less than 0.1 kg Cu and B. Without fertilizer, the supply of indigenous N limits yield in most paddy soils. Other nutrients that have to be supplied with fertilizer in intensive rice systems include P and K, and in some areas also S and/or Zn. Required fertilizer rates are determined by the deficit between plant nutrient requirement and indigenous nutrient supply. This is particularly relevant for N, because residual effects of fertilizer N application are small and long-term trends show little change in indigenous N supply with time in farmers' fields. For nutrients other than N, fertilizer application is often recommended even in the absence of a yield response (maintenance rates) to avoid depletion of soil nutrient particularly at elevated yield levels at which nutrient removal with grain and straw is high. However, a comparison of current fertilizer rates used by farmers in seven major irrigated rice areas in Asia has shown that fertilizer use is often not in congruence with the deficit between yield level and indigenous nutrient supply (Table 2). On average, farmers use 90–140 kg N ha^{-1}, 10–25 kg P ha^{-1}, and 10–55 kg K ha^{-1} to achieve grain yields

Table 2 Average seasonal indigenous N, P, and K supply, fertilizer use, and grain yield in intensive rice systems of South and Southeast Asia. Ranges refer to interquartile ranges (25th, 75th percentiles) of on-farm data

of 4.4–6.2 t ha^{-1} in the typical annual double or triple rice-cropping systems of South and Southeast Asia. This is approximately 50–75% of the climate-adjusted, genetic yield potential of 8.3 t ha^{-1} that has been estimated for existing germ plasm across sites, seasons, and years. In general, yields and fertilizer rates are higher in the typical dry season, with greater solar radiation, than in the typical wet season, with greater cloud cover. The indigenous supply of N, P, and K in irrigated rice in Asia was on average 41–65 kg N ha^{-1}, 12–19 kg P ha^{-1}, and 61–102 kg K ha^{-1}, but varied widely with site, year, season, farm, and field. In rainfed lowlands, yields and fertilizer doses are generally lower, decreasing from favorable to unfavorable lowlands with increasing production risk.

Blanket fertilizer recommendations prevail in most of Asia's lowland rice areas without considering amount and spatial distribution of indigenous nutrient supplies. There is also concern that fertilizer P and K rates are not optimally adjusted to long-term needs. A typical input–output balance for P and K in farmers' fields is given in Table 3. On-farm measurements in irrigated rice have confirmed for a wide range of soils and growing environments that farmers' current fertilizer P and K management causes slightly positive P balances, while fertilizer K application is insufficient to balance K removal with grain and straw. Modern site-specific nutrient management (SSNM) strategies have been developed in recent years to manage nutrients more efficiently and supply fertilizers as required by the crop considering indigenous nutrient supplies. Estimates of indigenous nutrient supplies need to be verified if general crop management of paddy soils changes (Figure 1). Changes in fallow period and residue management or system diversification are likely to introduce changes in indigenous nutrient supplies that are sufficiently large to require fertilizer adjustments.

Table 3 Typical input–output balance for P and K during one cropping cycle in intensive irrigated rice systems in South and Southeast Asia

Parameters for P and K balance	*Unit*	*P*	*K*
Input with inorganic fertilizer	kg ha^{-1}	10–25	10–55
Input with irrigation water	kg ha^{-1}	0–1	10–30
Input with rainwater	kg ha^{-1}	0–1	0–10
Losses with percolation	kg ha^{-1}	0–1	5–15
Removal with grain and straw	kg ha^{-1}	10–15	50–65
Nutrient balance	kg ha^{-1}	0 to +11	−35 to +15

The deficiency of Zn is the most widespread micronutrient disorder in rice, not only on soils with a traditionally low supply of Zn (e.g., neutral and calcareous soils containing a large amount of bicarbonate), but increasingly also on other soils with intensive rice cropping. Sulfur deficiency occurs mainly in upland soils containing allophane (an aluminosilicate with primarily short-range structural order which occurs as exceedingly small spherical particles, especially in soils formed from volcanic ash), soils low in organic matter, highly weathered soils containing large amounts of Fe oxides, and sandy soils with high percolation. Lowland rice areas with common S deficiencies are located in Bangladesh, China, India, Myanmar, Pakistan, Sri Lanka, and Thailand. Other nutrient disorders are only of local importance.

Lowland Rice Systems and Declining Water Availability

Today, nearly 90% of the fresh water diverted for human use in Asia goes to agriculture and, of this, more than 50% is used to irrigate rice. With the growing demand for water for nonagricultural uses (domestic, municipal, industrial, and environmental), the proportion available for agriculture is projected to decline from 90% to 73% in developing countries in the near future. Indicators of a looming water crisis include falling groundwater tables in regions where mainly tube wells are used for irrigation and severe water shortages downstream of some major rivers in Asia (e.g., Yellow River, Indus, and Ganges). Figure 4 gives the current distribution of irrigated and rainfed lowland rice and major hot spots of groundwater depletion and reduced river water flows. The productivity of intensive rice systems depends strongly on the availability of sufficient irrigation water, and production is likely to decrease with water shortage unless suitable mitigation options are developed. By 2020, physical water scarcity is projected for wet-season irrigated rice in North China (2.5 million hectares), Pakistan (2.1 million hectares), and north and central India (8.4 million hectares), as well as on 2 million hectares of dry-season rice in central India.

Water productivity at the field level can be increased by: (1) increasing yield per unit cumulative evapotranspiration through the use of high-yielding, short-duration varieties and optimal, site-specific agronomic practices; (2) more effectively using rainwater by using dry-seeding rice technologies to synchronize the start of the cropping season with the start of the rainy season; and (3) reducing unproductive water losses (seepage, percolation, evaporation) through adequate soil and water management. Examples of the latter include saturated soil culture (daily flooding up to approximately 0.01 m water depth) or alternate wetting-and-drying regimes (flooding every 2–7 days up to 0.02–0.05 m water depth). These measures frequently cause a reduction in yield and profitability, although they often result in an increase in water productivity.

A more radical approach is to grow rice under permanently aerobic soil conditions by keeping the soil water content in the root zone always at or below field capacity, a technology called 'aerobic rice.' In contrast to 'upland rice,' this system is intended to be high-yielding, but more research is required to evaluate long-term effects on SOM and nutrient cycling. Such systems may gain local importance where water is limiting and rice prices are high, but yields may not reach those achieved in well-managed flooded systems. The adoption of such water-saving irrigation technologies is expected to cause a shift from mainly anaerobic soils to partly or even completely aerobic soils. Changes in the soil-moisture regime of paddy soils will have profound effects on SOM turnover, nutrient dynamics, carbon sequestration, soil productivity, weed ecology, and greenhouse gas emissions in irrigated systems. Water-saving technologies must therefore develop into integrated natural resource management approaches to maintain the productivity, profitability, and sustainability of the evolving systems.

Water productivity in rainfed lowland systems can be increased through more efficient and effective use of all inputs. A general increase in productivity will also reduce the pressure for more intensive management and area expansion of irrigated lands. Direct-seeding techniques offer further opportunities to achieve higher (water) productivity by timely crop establishment. Avoiding drought stabilizes yields, and a second, upland crop can be grown after rice using the residual soil-water content. Such crop intensification must be accompanied by balanced fertilization and adequate residue management on the often poor soils in rainfed systems to maintain or build up SOM and thereby the indigenous nutrient supply.

Sustainability and Environmental Issues

In general, rice cultivation is sustainable even where rice is continuously grown in monocropping at high production levels. The quality of the soil resource base can be maintained through adequate management practices, including proper crop residue and water management, tillage operations, soil aeration during fallows, and balanced fertilization. The sustainability of rice cropping may be at risk, however, where management-induced changes strongly influence soil characteristics and the soil environment. This may include prolonged soil submergence in intensive systems with three rice crops per year as well as prolonged soil aeration because of crop diversification (Figure 1). In the following, we focus on selected issues that are of general importance for sustainable paddy soil management and the environmentally sound production of rice.

When crops are grown with irrigation, the sustainability of agriculture is potentially threatened by several water-related processes such as salinization and alkalization. In the semiarid tropics, irrigation may cause salinization of soils by rising saline groundwater tables. Alkalization can occur when irrigation water with a positive residual alkalinity is used. However, ample irrigation can leach salts from the topsoil through percolation if sufficient drainage is given.

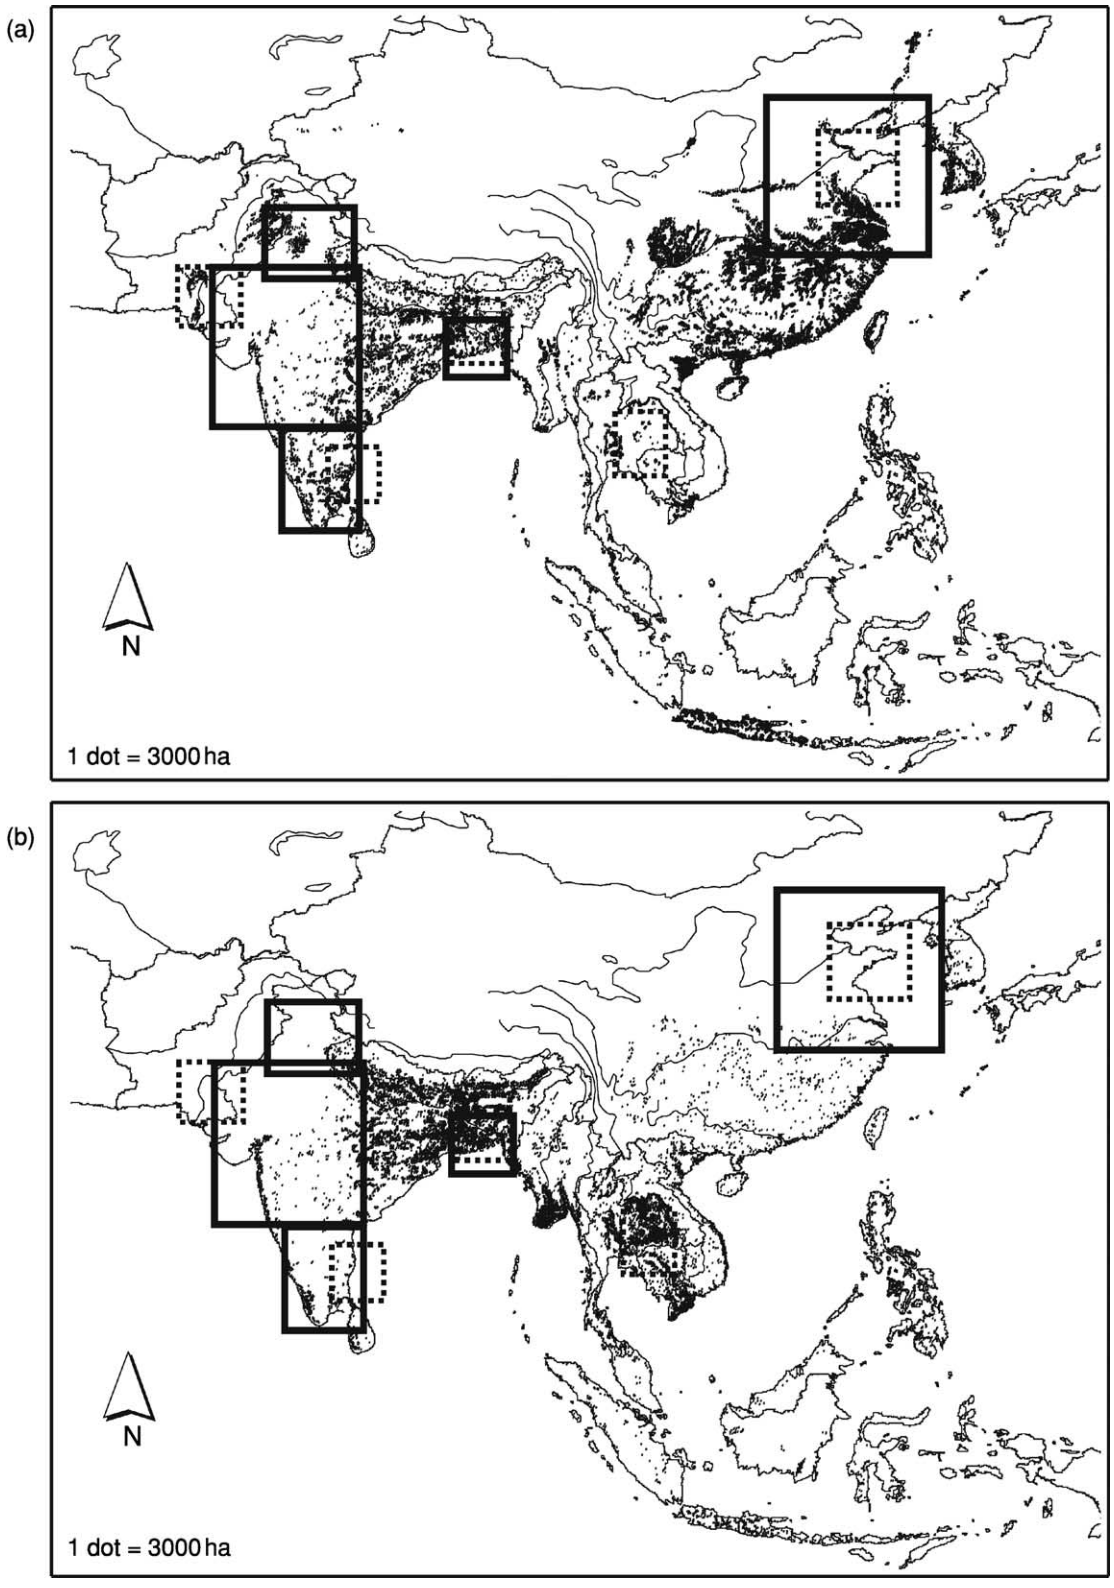

Figure 4 Current distribution of irrigated (a) and rainfed lowland rice (b) in Asia (Data source: Huke RE and Huke EH (1997) *Rice Area by Type of Culture: South, Southeast, and East Asia*. Manila, Philippines: International Rice Reasearch Institute (IRRI), and major hot spots of groundwater depletion (squares with solid lines) and reduced river water flows (squares with broken lines).

This makes irrigated rice a reclamation crop for such problem soils. A very different water-related problem is accidental flooding caused by inadequate irrigation control in some parts of tropical Asia, taking valuable land out of agricultural production; for example, this occurs in approximately 6 million hectares of arable land in India annually.

Other problem soils in the lowlands include Thionic Fluvisols or acid sulfate soils, which are widespread in Thailand, Vietnam, and Indonesia. Potential acid sulfate soils strongly acidify upon drainage, whereas actual acid sulfate soils are characterized by pH values of approximately 4. Rice cropping under submergence offers one of the few sustainable uses of these soils. Management strategies include: (1) complete soil oxidation through drainage and leaching of acidity from the crop root zone, which offers a permanent solution but may cause a contamination of surface water affecting crops, soils and aquatic organisms in surrounding regions; and (2) the limitation of soil oxidation by maintaining a permanent, high groundwater table, which requires sufficient irrigation water.

Environmental concern is increasing because the intensification of rice cropping in the past has led to an excessive use of fertilizer N and pesticides in many intensive rice-growing areas in Asia. This has been recognized, and much progress has been made in recent years in developing and disseminating adequate management strategies such as real-time N management and integrated pest management. Current changes in today's cropping environment include a shift from irrigated transplanted rice to direct seeding and/or the use of water-saving technologies. This causes greater weed pressure and may lead to an increased use of herbicides, particularly at sites with further intensification and mechanization because of labor shortages. Research efforts aim to integrate better water, nutrient, weed, and pest management approaches to enhance direct environmental and economic benefits for farmers.

Paddy soil environments have also caused global environmental concerns because methane (CH_4) is second in importance to CO_2 as a greenhouse gas and flooded paddy soils contribute approximately 10% of global CH_4 emissions. Although the CH_4 production of paddy soils is much smaller than originally assumed, it is still an important contribution. Methods to reduce this share include water-saving technologies as described above, improved crop-residue management, and direct seeding instead of transplanting. Care has to be taken to avoid significant increases in N_2O emissions, another greenhouse gas, which is 10 times more 'effective' than CH_4. Soil-moisture regimes keeping the soil redox potential between -100 and $+200$ mV could minimize both CH_4 and N_2O emissions.

Summary

Paddy soils are defined through their production environment, the typically irrigated and rainfed lowland rice-cropping systems. Cropping intensification since the 1960s has greatly increased rice yield and production, and further intensification is needed to achieve food security at the national and household level. Productivity increases at the farm level could be mainly achieved in two ways. One option is the continuing optimization of the existing rice-based cropping systems with two to three annual rice crops and short fallow periods. There is strong evidence that rice double-cropping in Asia can provide high, sustainable yields despite an increase in the duration of soil submergence and a shift from organic to inorganic nutrient sources since the 1960s. Sufficient inputs of external nutrients with fertilizer are necessary to match the insufficient supply of nutrients from indigenous sources, but inefficient fertilizer use, nutrient imbalances, and excessive pesticide use have become widespread and must be overcome through more site- and season-specific crop, soil, and water management to manage all inputs efficiently. The second option for farmers is to turn to crop diversification, adding more profitable, nonrice crops to the rice-based cropping system or to grow rice under aerobic soil conditions. Conditions imposed in the nonrice season will influence important characteristics of paddy soils and remove typical paddy soil characteristics temporarily or permanently. A key issue is whether the high productivity of current rice-cropping systems can be sustained in such diversified systems.

List of Technical Nomenclature

Indigenous N, P, and K supply ($kg\,ha^{-1}$)	The cumulative amount of a nutrient from all indigenous sources circulating through the soil solution surrounding the entire root system during one crop cycle. Indigenous nutrient supply is estimated as aboveground plant nutrient in plots where the element in question is the only limiting factor
Paddy	(1) Wetland rice; (2) bunded and leveled field used for cultivation of rice. The original meaning of paddy (Malay *padis*) is 'threshed, unhulled rice'

Introduction

Pedology has two meanings according to the *American Heritage Dictionary of the English Language*. The first is the study of the physical and mental development and characteristics of children, and the second is the scientific study of soils, including their origins, characteristics, and uses. The Greek word 'pedon' means ground and 'logy' means study. The International Union of Soil Scientists (IUSS) and many of the member scientists within the organization interpret 'pedology' as encompassing all scientific study of the soil, and hence all soil scientists are pedologists. In this encyclopedia the narrower definition of 'pedology' that characterizes it as the study of the formation, properties, classification, and management of soil is used. Others define pedology as "the earth science that quantifies the factors and processes of soil formation including the quality, extent, distribution, spatial variability and interpretation of soils from microscopic to megascopic scales."

Pedology is the study of soils in their natural setting (Figure 1) and has been equated with the study of soil genesis and soil classification. The people who study soils in these ways are pedologists. Pedology includes pedogenesis, the study of the origin and formation of soil; soil morphology, which is the characterization of the soil as a natural body; the distribution of soil on landscapes, which is soil survey; the organization of soil information into natural and technical classification systems; and the interpretation of soil properties for use and management of the soil resource. Pedology is "...an integrative and extrapolative science." Pedologists integrate understanding of landscapes, vegetation patterns, climate, and human activity into knowledge about soils, their distribution, mode of formation, and usefulness. Pedologists also extrapolate information from one scale to the next, to build a coherent model of soils from microscopic observations to the landscape scale. Integration and extrapolation are necessary because soils form a highly variable continuum over the Earth's surface.

History

Pedology is a relative newcomer to natural science, having emerged as a discipline in the nineteenth century. Although the agricultural value of soil and the importance of the chemical properties of soil were known well before the emergence of pedology, the concept that soil could be studied as a natural body was a nineteenth-century idea. A German scientist, A. Fallou, introduced the term 'pedology' in 1862. Most soil scientists credit the Russian soil scientist V.V. Dokuchaev as the person who made pedology a scientific discipline. He did so by recognizing that the five soil-forming factors (parent material, climate, biota, topography, and time) interact to produce the morphological properties of the three-dimensional soil individual, the pedon (see Figure 2, below). Hilgard is regarded as the first North American-based scientist to recognize pedology as an independent discipline. Hans Jenny is recognized as the nineteenth-century US soil scientist who took the

Figure 1 Pedologists examining a soil during the 2002 post-meeting field tour of the International Union of Soil Scientists, in Thailand.

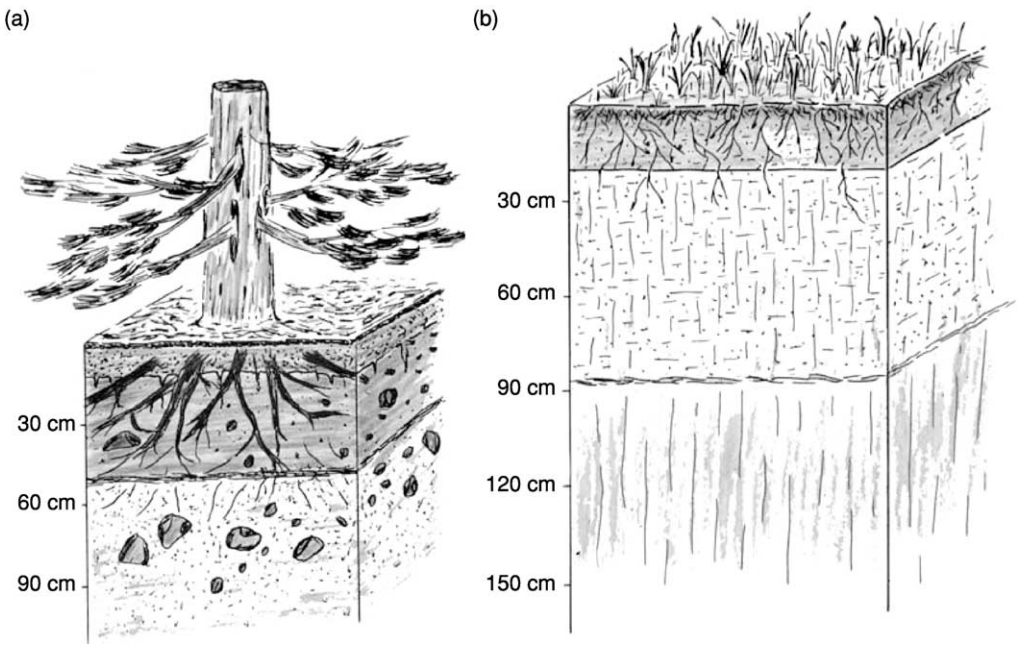

Figure 2 Soils forming under different climatic conditions with various types of vegetation develop different characteristics that are recognized by pedologists: (a) forest soil; (b) grassland soil.

concept of five soil-forming factors and gave it substance in his 1941 book *Factors of Soil Formation*. He further elaborated on his original text in his 1980 text *The Soil Resource*.

From these early beginnings, which were mostly centered on the mapping of soils and their description, emerged a science that built upon the early foundation and that today is a vibrant mix of individuals who study the soil as a natural body on landscapes, who are continuing to develop concepts about the development of soils through complex biogeochemical pathways, and who are looking for new ways to classify the soil to enhance and protect this resource. As scientists reach out to the moon and beyond, the definition of soil and the role of pedology are expanding.

Overview

Soil Classification

Why do we classify soils? The frequently cited reason is to utilize the large body of information about soil. Soil classification systems are grouped into natural and technical systems. Natural systems are those that classify what is seen on the landscape, while technical systems classify soils based on perceived strengths and weaknesses for specific uses. The entries in this encyclopedia focus on the natural classification systems from several countries. These represent diverse methods for categorizing the many kinds of soils that are recognized by pedologists. Although the language of natural soil classification appears foreign and esoteric to the casual reader, soil classification organizes soils with similar properties into useful groups. Most taxonomic systems are hierarchical, with the broadest groupings at the highest levels and the most narrow, most specific groupings at the lowest levels. The informed user can thus learn something about the properties of each group by understanding the construction of the system and the meaning of the terminology.

Classification systems reflect the interests and understanding of the soil scientists who create the systems. Hence the US system of soil classification Soil Taxonomy differs in structure from other systems, because it was developed from its own historical base. The US system has evolved over time, from a system based on perceived processes of soil formation and qualitative definitions that separated broad groupings of soils, to the present system that is based on quantitative definitions. Quantification is the path followed by all sciences and, as the discipline of pedology has matured, the various facets of the science have become more quantitative.

The IUSS has adopted the World Reference Base for Soil Resources (WRB) as the official system for correlating various national soil classification systems. It has also been developed to help users view broad divisions of soils and to facilitate understanding of soils throughout the world. Although each existing soil classification system is different, each is

based on carefully defined and quantified criteria that allow the system to be useful to the widest range of individuals.

Technical systems have also evolved throughout the world, with the intent of creating groups of soils with similar capabilities or limitations. These systems are not limited to agriculture; they exist for most of the common uses of soil. For example, systems exist for rating the usefulness of soils for on-site waste disposal, for construction of recreation areas, and as a source of material for road-fill. Because soil underlies and supports much of our civilization, technical systems are critically important guides to the proper selection of soils for different uses.

Soil Genesis

Soil genesis or pedogenesis is the study of the origin and formation of soil. Pedologists conceptualize soil as a natural, three-dimensional body on the Earth's surface (**Figure 2**). This three-dimensional body, the pedon, is large enough to include all of the properties of the soil individual. Typically the smallest pedon is 1 m^2 and 2 m deep. Pedons form within the framework of the five soil-forming factors. 'Parent material' is the term pedologists use to describe the starting material for soil genesis. The parent material may be consolidated (such as rock) or unconsolidated (such as wind-blown silt or sand). The amount of consolidation influences the rate at which water can enter the parent material and therefore the rate of soil formation.

Equally important are the constituent minerals that comprise the parent material. It is the size, crystalline nature, and chemistry of the minerals that determine the rates at which the inherited (or primary) minerals are changed to new minerals or are dissolved and removed from the parent material, thus creating soil. The mineralogy also determines the fertility of the parent material and soil and hence the biological activity on the parent material and soil. This oversimplifies the complexity of pedogenesis, which consists of many interacting processes, which proceed simultaneously at multiple rates.

A special case of how parent material greatly influences soil properties is the formation of soils on parent material rich in clay minerals. Such parent materials form soils that are rich in clay-size minerals and clay minerals. These soils, called 'shrink–swell soils,' tend to change volume greatly as they wet and dry, which makes use of the soils for agriculture and construction difficult.

Topography describes the landscape on which the soil is found. It typically includes the slope angle, slope shape (concave, convex, simple, or complex), and slope direction or aspect. Topography is complex in how it affects pedogenic processes. For example, in the northern hemisphere, a south-facing slope intercepts more solar energy than does a north-facing slope. In dry climates, the south-facing slope will be more water-limited than the north, and the south-facing slope is likely to have less organic matter accumulation, lower biological activity, less organic acid production, and slower mineral weathering than on a north-facing slope. In the southern hemisphere and in moist cold climates, the results are opposite.

The biotic factor includes animal and plant organisms of all sizes and their direct and indirect effects on pedogenic processes. Vegetation is part of the biotic factor of soil formation. Vegetation, under which soils form, mediates the cycle of carbon and nutrients into and through soil. The most obvious effect of plants is the input of carbon into and on to the soil through roots and litter fall. Plant roots and microorganisms respire large amounts of carbon dioxide that decreases soil pH, increases weathering, and has other important effects on soils. Plants also alter the chemistry of precipitation as it falls through the canopy and flows down the stems of plants. Animals mix the soil, consume and modify carbon, and create pores through which flow water and air. All of these processes and more are part of the biotic factor of pedogenesis.

Precipitation and annual temperature are two climatic factors that pedologists consider when studying soil genesis. Others are the timing of the precipitation (e.g., winter versus summer precipitation), rainfall versus snowfall as the dominant precipitation type, precipitation intensity as it affects soil destruction through erosion, and differences between winter and summer temperatures. The climatic factor is usually focused on mean annual temperature and precipitation, because these are the 'macro' climatic factors, but microclimate also influences the many soil-forming processes considered within the context of soil genesis.

Microclimate is the 'on-the-ground' climate that influences small areas of soil, compared with the regional climate. A topographic low that accumulates water and enhances weathering and translocation of weathering products creates a pedologically distinct 'climate' compared with upslope positions. Cold-air drainage into a valley can result in a distinctly different weathering regime than would be characterized by the general climate.

These factors describe the environment and conditions under which a soil forms and determine the properties of the 'product' of these processes. Time is the final natural soil-forming factor. Pedologists have shown that the net rate of soil formation is slow. The time required for horizons to form and for a soil to develop its distinct properties may be

thousands of years. Many processes contribute to the differentiation of the parent material into a vertically differentiated soil and they all act at different rates. Thus the question 'How old is this soil?' has no easy answer.

Soils record the history of the Earth's surface and sometimes soils that were once at the Earth's surface are buried. Once buried, they cease to form and they may represent climate and vegetation different from the modern climate and vegetation. These soils are paleosols and they are valuable records of natural history.

The influence of humans on soil development has become a growing area of interest to pedologists. This topic was not of major interest until the end of the twentieth century, when pedologists recognized the profound affect that humans were having on soils. Humans create new areas of soil, reclaim areas that have been destroyed through mining and road building, and destroy soils by modifying them for agriculture or urban uses. In particular, large areas of soil in the USA have been deep-plowed or ripped to remove horizons that are limiting to roots or water penetration. When this is done, the soil, as a natural body, is destroyed and the pedological clock is returned to the starting point.

Observing the vertical distribution of properties made visible by digging a hole or trench or removing vegetation on a vertical road excavation is typically the process used to study soil. Once the properties have been described and the horizons designated, samples are collected by depth increments or by horizon for laboratory analyses. Many chemical, physical, and biological analyses are performed on the samples. Interpretation of the analyses is used to reconstruct the pedogenic history from the time the parent material stabilized and pedogenesis began to the present. This method of studying soil has been referred to as 'static pedology.' Another method of study involves collecting and analyzing the soil solution from within horizons and at horizon boundaries. The data originating from these analyses are interpreted to indicate the types of processes extant in the soil profile. This method has been called 'dynamic pedology.'

Soil Morphology

Soils form a more or less continuous blanket over the terrestrial surface of the Earth and, in order to distinguish individuals from within this continuum, soil morphology is described in the field. Conceptually the pedon is the soil individual that is described (**Figure 2**), but in reality what is described is the two-dimensional slice through the pedon that soil scientists call the soil profile. These descriptions begin in the natural environment where the soil is observed, hence the morphological properties are those that can be measured or discerned by a trained observer. The field descriptions are supplemented and enhanced by laboratory analyses and micromorphological observations using thin sections and light and electron microscopes.

The major properties that are described in the field are the thickness, color, texture, and structure of individual layers, called 'soil horizons.' In addition, properties such as the physical behavior at different moisture contents (consistence), pH, boundaries between horizons, and presence of fragments larger than 2 mm in diameter are described. These properties characterize the soil individual, and they are interpreted to predict how soils behave when used for agriculture, recreation, urban development, and waste disposal.

Most pedologists study soils that are well drained. That is, they are well aerated and oxygen-rich for most of the year. The processes that form these soils and their morphology are better understood than the processes and morphology of soils formed under conditions where water remains and oxygen is in short supply for long periods of time. These hydric soils are described using the same properties as well-drained soils, although the soils themselves may look and act quite differently. Another group of soils found under wet, oxygen-poor conditions are the organic soils. Although the vast majority of soils are formed on mineral parent materials in which aluminosilicate minerals are the starting point for soil development, a small but important minority is formed from plant material that is slow to decay because the cold or wet conditions are unsuitable for microbial decomposition.

Organic soils or Histosols consist primarily of dead plant material in various stages of decay. The horizon nomenclature and morphology of these soils are different because of the different processes acting on the parent material. For example, rather than A, B, and C horizons that are standard for mineral soils, the organic soils consist of O horizons. An O horizon is one in which organic material is a major constituent. Each O horizon is given a subscript to denote its organic character. In the US Soil Taxonomy, for example, the subscripts a, e, and i are used to denote strongly decomposed, moderately decomposed, and mostly undecomposed plant material. The terminology used to describe soil morphology has sufficient breadth to encompass all soils. The breadth is accompanied by carefully crafted definitions that allow the specific characteristics of the soil profile to be described.

Modern pedology recognizes that the type of vegetation influences soil morphology, but that morphological properties are not purely a result of the vegetation under which the soil forms. Hence the familiar terms 'forest soil' or 'grassland soil' are more correctly 'soil formed under forest' or 'soil formed under grass' (Figure 2).

Soil Mapping

Pedology developed from the disciplines of agriculture and geology. Both require an understanding of the relationship between the soil individual and the landscape on which the individual is found. Creating soil maps that represent this relationship has been a more or less continuous process in the USA since the end of the nineteenth century. The process accelerated in the twentieth century as aerial photography replaced plane-table mapping and as new concepts of soil formation were learned and applied.

Soil mapping is not the sole provenance of the USA: the developing as well as the developed countries of the world make resource assessments on which development can be based. The Food and Agriculture Organization of the United Nations has led an international effort to create a soil map of the world to help nations and individuals understand the distribution of soil. Maps such as the world soil map are at a low level of resolution, and more detailed maps are required for resource management, but all scales of map are useful in displaying the distribution of soils.

Map scale determines the smallest area that can be easily identified on the map. The scale is selected based on the intended use of the map, the cost, and the finances available. Carefully designed transects across the landscape with many observations at close intervals is the mapping technique used to make very detailed maps. Such soil maps are made for construction projects or very-high-value crops. Fewer observations are made as map scales become less detailed. Soil classification follows the map scale with more general levels in the taxonomy used as map units on generalized maps and more detailed levels in the taxonomy used on more detailed maps.

Summary

Pedology, according to one broadly accepted definition, is the discipline that studies soil as a part of nature. Pedologists study the origin and formation of soil, the morphology of soil, the distribution of soil on landscapes, and the management of soil. The pedology entries in this encyclopedia bring to life these topics and explain the role of pedology in the study of the most important material of the Earth's surface, soil.

List of Technical Nomenclature

Aluminosilicates	Minerals with aluminum and silicon as major constituents. Examples include the clay minerals
Dynamic pedology	The study of soil formation processes by sampling and analyzing the soil solution in different horizons or at horizon boundaries
Histosols	Organic soils that have organic soil materials in more than half of the upper 80 cm, or that are of any thickness if overlying rock or fragmental materials that have interstices are filled with organic soil materials (an order in the US system of Soil Taxonomy)
Horizon	A layer of soil or soil material approximately parallel to the land surface and differing from adjacent genetically related layers in physical, chemical, and biological properties or characteristics such as color, structure, texture, consistency, kinds and number of organisms present, degree of acidity or alkalinity, etc.
Hydric soils	Soils that are wet for long enough to produce periodically anaerobic conditions, thereby influencing the growth of plants
Micromorphology	The study of soil morphology by microscopic (light optical and, less frequently, by submicroscopic) methods, often using thin-section techniques
Natural soil classification	The systematic arrangement of soils into groups or categories on the basis of their characteristics. Broad groupings are made on the basis of general characteristics and subdivisions are made on the basis of more detailed differences in specific properties
Paleosols	A soil that formed on a landscape in the past with distinctive morphological features resulting from a soil-forming environment that no longer exists at the site. A paleosol (or component horizon) may be classed as relict if it has persisted in a land-surface position without major alteration of morphology by processes of the prevailing pedogenic environment. An exhumed paleosol is one that was formerly buried and has been reexposed by erosion of the covering mantle
Parent material	The unconsolidated and more or less chemically weathered mineral or organic matter from which the solum of soils is developed by pedogenic processes

Pedogenesis	The processes that produce soils from parent materials
Pedologists	The individuals who study soils
Pedon	A three-dimensional body of soil with lateral dimensions large enough to permit the study of horizon shapes and relations. Its area ranges from 1 to 10 m^2
Soil-forming factors	Those external factors that control the kinds and rates of processes that form soils: parent material, climate, biota, topography and time and the five soil-forming factors
Soil taxonomy	The US system of soil classification
Static pedology	A method for studying soil formation by sampling the soil solid phase and measuring properties of the solids
Technical soil classification	A soil classification system that rates soils based on desired use of the soil

Dynamic

F C Ugolini, Università degli Studi di Firenze, Firenze, Italy

The expression 'dynamic pedology' was first introduced in the open literature in 1978. Later, in 1985, the term was adopted and the approach used to examine the genesis of a Gray Luvisol in the boreal forest of Canada. Dynamic pedology singles out pedological investigations conducted with the use of soil solution obtained in the field through lysimetry; it does not include experimental pedology where solution is obtained by leaching or displacement from soil columns, or laboratory experiments conducted to simulate weathering. Dynamic pedology is distinguished from traditional pedology or 'static pedology' in which only the solid phase is investigated. Paraphrasing a biological expression 'dynamic pedology' is equivalent to an *in vivo* versus an *in vitro* study of the soil.

The collection, analysis, and interpretation of the soil solution allow evaluation of the contemporaneity of the pedogenic processes and hence the dynamic aspect of the soil. In contrast, the analyses of the solid phase tend to average the sum total of all the processes that have occurred since the parent material was laid down. Furthermore, the proton donors considered responsible for the formation of soils can be identified in soil solution. If pedogenesis is defined as a combination of weathering and transportation processes occurring in the presence or absence of living and dead biota, proton donors initiate weathering reactions and participate in transport of ions released during weathering and biological activity. Questions inquiring about the nature and the actuality of the processes cannot be answered by traditional pedology. This is particularly crucial when processes are at their limits as the process of podzolization in the High Arctic or in those environments where soil formation is dictated by catastrophic events. In terrestrial ecosystem studies, the watershed approach has been useful for providing a balance of the ionic

inputs and outputs; however, it has not provided an insight to soil processes. In these studies the soil is considered as a black box placed between the incoming precipitation and the stream discharge. Dynamic pedology, by examining the soil solution exiting the genetic horizons, could, on the other hand, explain the changes in ionic composition caused by the processes occurring at the horizon level. The dynamic pedology approach is suitable to examine perturbations such as substitution of species, effects of fire, addition of fertilizers, pesticides, and pollutants. During the early 1970s, when acid rain became a large issue in Western Europe and North America, soil solution collected via lysimeters became the best way to monitor soil acidification and pollutants' movement in soils.

Early Stages of Soil Development on Recent Volcanic Ejecta

An example of soil development comes from a study conducted on an Entisol (Figure 1) developed on a pyroclastic flow emplaced during the 1980s eruption of Mount Saint Helens (USA). Soil solution collected between 1984 and 1986 shows that vapors of strong acids (H_2SO_4, HCl, HNO_3, and HF) produced by volcanic emanations during the eruption reacted with the airborne tephra, resulting in the formation of soluble salts that were promptly leached once the tephra was deposited on the ground. In addition, acid precipitation (pH 3.6–5.2) from gaseous emissions produced during the dome-building stage after the eruption has contributed to the introduction in the soil of proton donors, mostly H_2SO_4 and HCl. These strong mineral acids have been neutralized within the first 5 cm of soil (Figure 2). Calcium, Mg^{2+}, Na^+, and K^+ associated with SO_4^{2-}, Cl^-, and NO_3^- dominate the soil solution together with Si. Colonization by nitrogen-fixing lupine (*Lupinus lepidus*) has introduced a new regimen in the weathering and soil genesis. Soils under lupine plants show a pH higher than the near-barren sites. The increase in pH is due to the neutralizing effect of the acid deposition by the lupine foliage, which exchanges base cations with the H^+ of the rain. In the barren areas, the consumption of protons occurs in the first 5 cm; in the presence of lupines, a redistribution of the proton load occupies the entire rooting zone. Hydrogen ions are released by the roots in exchange for cations that buffer the acidity in the foliage. As a result of lupine invasion, the soil solution under these plants contains more dissolved organic matter (DOM), H_2CO_3/HCO_3^-, NH_4^+, and Cl^-.

In summary, in the proximity of an active volcano, soil development on pyroclastic material 4 years old must be interpreted as a function of those events that have occurred prior to, during, and after the deposition of volcanoclastic material. On the barren sites, strong mineral acids are the major proton donors, but they have been neutralized in the upper part of the soil (Figure 2). Under this weathering

Figure 1 Soil profile (Entisol) developed on Mount Saint Helens pyroclastic flow. The surface of the flow is visible in the background. The measuring tape is 1.0 m, with 10-cm intervals.

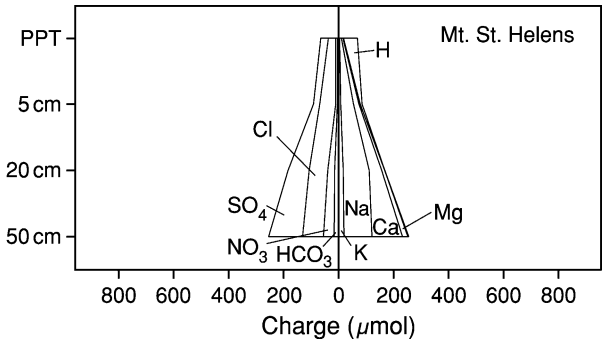

Figure 2 Charge balance for the precipitation (PPT) and for the soil solution of the Entisol, Mount Saint Helens. Concentrations of the different charged species as they exit the depths marked on the left. (Reproduced from Ugolini FC and Dahlgren RA (2002) Soil development in volcanic ash. *Global Environmental Research* 6: 73.)

regimen, there is a loss of Si, Ca, Mg, Na, and K; Fe and Al are not mobilized. With the colonization of nitrogen-fixing plants, the acidity of the incoming precipitation is neutralized by the foliage of the lupine rather than by the soil. Here, there is a shift in proton donors compared with the barren sites. Under the lupines, DOM and H_2CO_3/HCO_3^- are the major proton donors. The concentration of cations, anions, and Si under the lupines is higher than in the barren sites.

Migration of Particles in the Process of Podzolization

The unique morphology of Spodosols, supported by analytical data, has been attributed to the movement of DOM and metal cations in solution or suspension. Migration of clay particles has not been considered of importance in this process, although it has been detected in the early evolutionary stages of Spodosols. Lysimeters emplaced in well-developed Spodosols formed under Pacific silver fir (*Abies amabilis* (Dougl.) ex J. Forbes) forest, in the Washington Cascades (USA), have shown the existence of two distinct chemical compartments: the upper one starting from the top of the canopy and ending at the boundaries of the Bhs/Bs horizons, and the lower one below this boundary that reaches into the parent material. Weathering and ion transport in the upper compartment are governed by DOM that acidifies the soil (pH 3.8) and prevents the dissociation of the H_2CO_3. In the lower compartment, the pH is higher (approx. 5) than in the higher compartment, owing to the liberation of OH^- during the ligand exchange reactions between the DOM and the surface of amorphous materials. This compartment is dominated by HCO_3^- (Figure 3). Fulvic acid (FA) has been detected in the upper compartment, with 70% reduction across the Bhs/Bs. Electrodialysis, adsorption, molecular sieving, and other techniques indicate that FA is transported in solution in particulate form. However, direct evidence of their migration in soil is lacking. Lysimeters placed at the boundaries of the E, Bhs, and Bs of a Spodosol collect soil solution and suspended material, including humic substances. Upon filtration through a 0.1-μm Nucleopore filter, the suspended material is collected, lyophilized, and observed on a scanning electron microscope (SEM) equipped with energy-dispersive X-ray analysis (EDAX). Through the SEM it is possible to observe the presence of filaments 2–12 μm long extending from oblong bodies 2–3 μm wide. These bodies contain minor quantities of Al, Fe, P, S, and Si (Figure 4). Leachates collected below the Bs, on the other hand, show almost exclusively the presence of mineral particles ranging in size approximately from 2.0 to 22 μm.

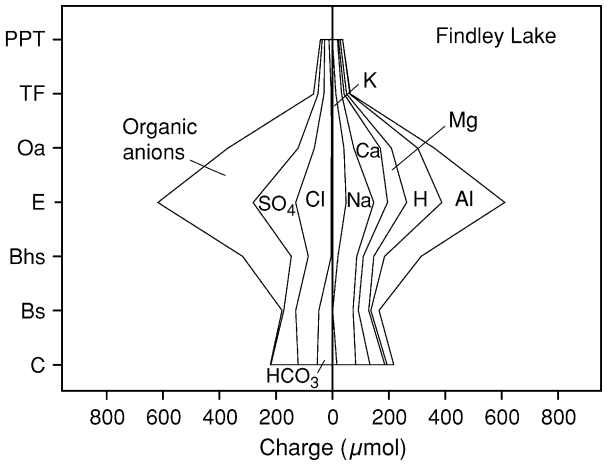

Figure 3 Charge balance for the soil solution of the Spodosol, Washington Cascades. Concentrations of the charged species for precipitation (PPT), canopy throughfall (TF), and the soil horizon solutions. The anion deficit was assumed to be due to organic anions. (Reproduced from Ugolini FC and Dahlgren RA (2002) Soil development in volcanic ash. *Global Environmental Research* 6: 73.)

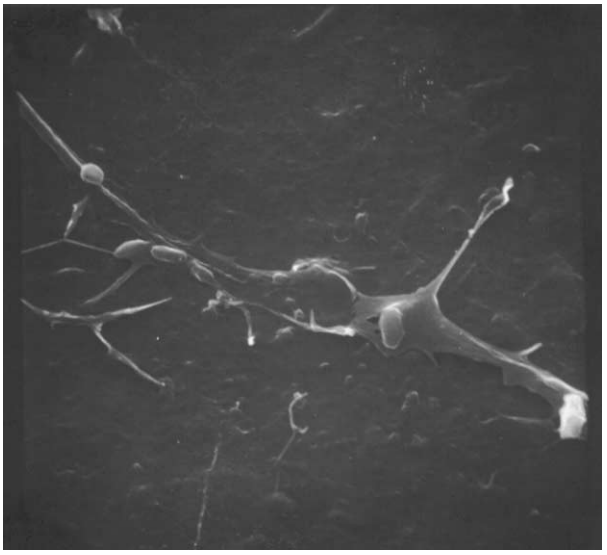

Figure 4 Scanning electron micrograph of an organic particle collected on 0.1-μm Nucleopore filter from soil solution obtained below the Oa horizon of a Spodosol, Washington Cascades. The filaments are 5–12 μm long, the oblong bodies are 2–3 μm wide (×5000).

EDAX spectra of these particles show that they are made of Si, Al with some Fe, Ca, and K, reflecting the composition of silicate minerals. This study indicates that the suspended material in the soil solution reflects the trend of the solution itself. The reduction of DOM across the Bhs/Bs is also verified by the presence of organic particles in the upper profile (Figure 4) and their absence below the Bhs/Bs (Figure 5). This study provides direct evidence for the mechanism of podzolization and the migration of particulate matter.

Evidence of Catastrophic Events and Horizon Inversion

Traditionally, soil formation is considered to be a relatively slow process, representing a continuum in time and space. In the absence of adequate techniques, short–term or catastrophic events in soil development have not been appreciated. However, improvement in soil-solution collection and analytical procedures has made the investigation of isolated events possible. At Walker Lake, Alaska (67° 09′ N and 154° 22′ W), the use of lysimeters has provided new evidence of threshold-controlled episodes associated with rapid solution-transport and particle migration. These events result in the formation of horizon inversion. At Walker Lake, in the boreal forest, the Spodosols have formed in the boreal forest on glacial drift deposited *c.* 13 000 BP. The horizon sequence shows a perplexing inversion of the Bhs below the Bs (Figure 6). From 25–28 July 1981, an intense storm followed by a prolonged leaching episode caused a radical departure from the average trend. The sequential change in solution composition shows a distinct flashing effect associated with normal leaching episodes. The flashing effect is a well-known phenomenon associated with antecedent moisture conditions, and it is typical of semiarid and subhumid climates. In the absence of complete

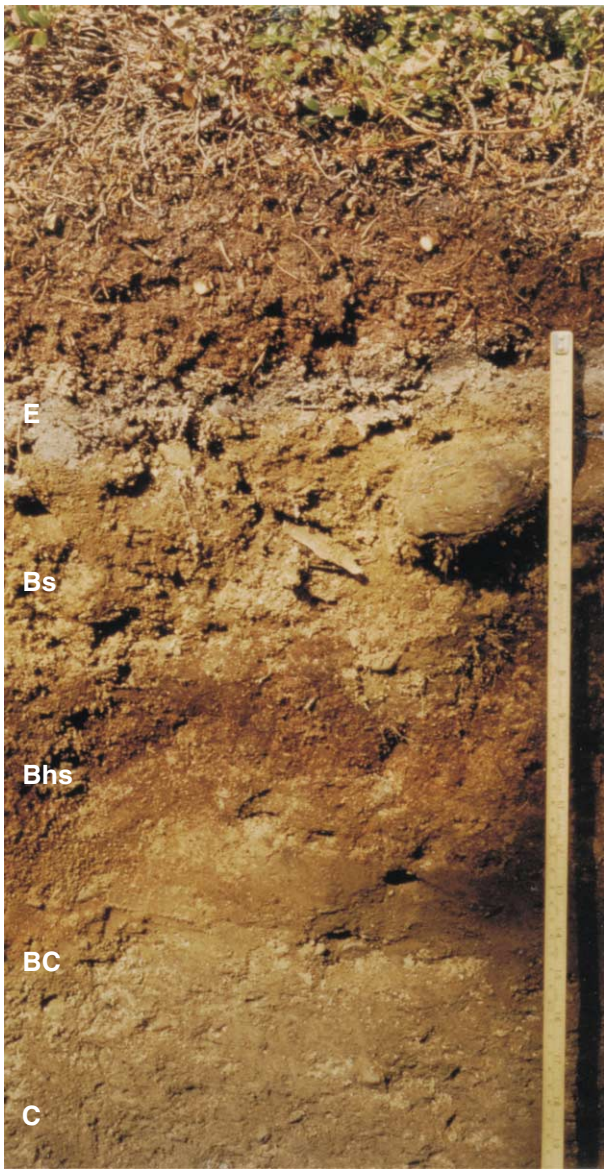

Figure 6 Boreal forest Spodosol showing an inverted sequence: a Bs over a Bhs; Walker Lake, Alaska. The yardstick is 50 cm long.

weather information for this remote site, sodium can be used as an indicator of antecedent moisture conditions. High initial concentrations of this ion indicate that a long period of drought has occurred. The high-intensity, low-frequency rainstorm delivered over 150% of the average total precipitation anticipated for the entire month. The pedogenic response was a progressive and dramatic surge in subsurface translocation processes (Figure 7). The successive stages in these processes, using iron as an indicator parameter, are shown in Figure 7. The first stage displays a normal leaching trend: depletion of Fe from the E horizon and accumulation into the Bs. After continuous leaching, phase 2 was initiated. In

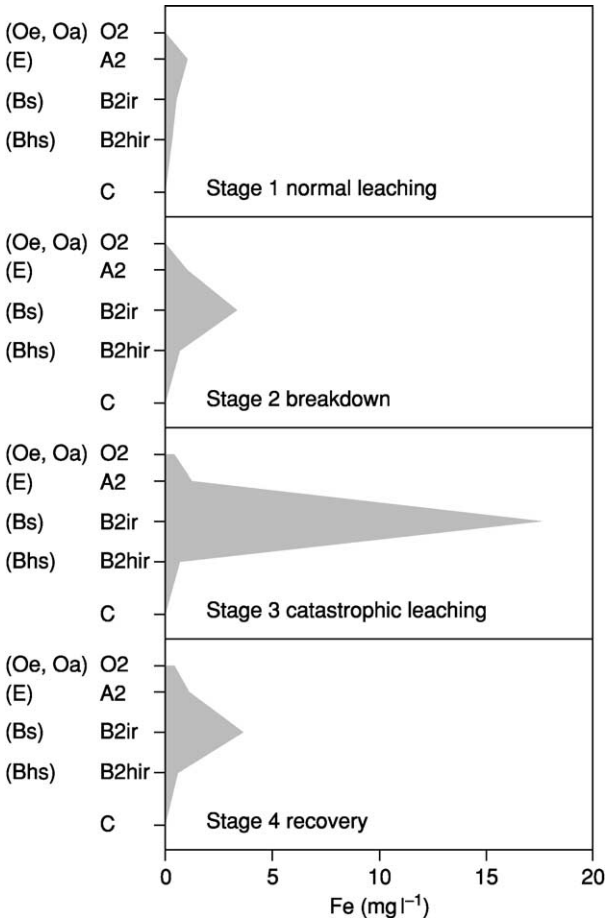

Figure 7 Dissolved iron (milligrams per liter) used as an indicator to separate the stages of a catastrophic leaching episode in a boreal forest Spodosol, Walker Lake, Alaska. (Adapted from Stoner MG and Ugolini FC (1988) Arctic pedogenesis. 2. Threshold-controlled subsurface leaching episodes. *Soil Science* 145: 49 © 1988, Lippincott Williams & Wilkins, with permission.)

this stage there is a depletion of metal cations and DOM from the Bs and translocation into the Bhs. Since no abnormal concentration of metal cations and DOM appears to leave the O and E horizon leachates, this surge indicates that the source is the Bs itself. Evidently, this horizon had been undergoing a degradation of the microstructure with the liberation of metal–organic (metal-organo) particles that had become suspended in the soil solution. Stage 3 shows a maximum liberation of particulate matter that leaves the Bs and is deposited in the Bhs. Filtered and unfiltered solutions show that 80% of Fe and Al is in particle form. This influx of suspended material tends to build up the Bhs horizon below the Bs. Stage 4 represents a recovery. This monitored response to a major rainstorm helps to explain the observed horizon inversion – the Bs over the Bhs – a feature observed in other Spodosols of the Arctic. Storms of less intensity are able to moisten only the upper part of the profile. During these episodes, the penetrating wetting front leaves mobile metal-organo complexes stranded in the upper Bs. These complexes are only temporarily detained, because their metal-to-C ratio is too low to induce their precipitation. This example serves to demonstrate the usefulness of lysimetry for capturing the impact of individual rainstorms. Further, it appears that in subhumid climates soil development occurs through episodic pulses corresponding to rainstorms of moderate magnitude. This trend is punctuated by catastrophic events that are responsible for the unusual migration of Fe, Al, and organic matter in particulate form. The catastrophic events are responsible for the observed B-horizon inversion. A similar horizon inversion has been observed for a Podzol located in the Massif Central (France). However, this phenomenon is explained by two separate pedogenic phases involving truncation and burial.

Effects of Species Substitution

Dynamic pedology is particularly useful when applied to study the impacts of replacement of species either naturally or anthropically induced. In northern Idaho, disturbed areas such as clearcuttings in the Grand Fir Mosaic Ecosystem are poorly revegetated by the native firs. Bracken (*Pteridium aquilinum* (L.) Kuhn) rapidly occupies the disturbed sites preventing the regeneration of the Grand Fir (*Abies grandis* (Dougl. ex D. Don) Lindley). Solutions collected under the bracken show a lower pH (minimum 4.8), a higher Al concentration (maximum 1.6 mg l^{-1}), and higher DOM than the undisturbed forest during 1994 and 1995.

Another study on the effects of species substitution has been conducted in northeastern Japan, in the Miyagi prefecture, to examine, through soil solution, the effects of Japanese oak trees (*Quercus serrata* Thumb.) on Alic Melanudands (nonallophanic Andisols). The oaks were established 50 years ago on a site originally occupied by Japanese pampas grass (*Miscanthus sinensis* Anders). The soil-solution composition collected under the Japanese oaks has been compared with that of the pampas grass growing in a plot next to the oaks (Figure 8). The acid precipitation (pH 4.8) caused by the presence of HNO_3 and H_2SO_4, of volcanic origin, and paddy fields is partially neutralized by the pampas grass canopy from pH 4.8 to 6.0, while the oak canopy increases the pH only to 5.4. As the canopy drip penetrates the soil, the soil solution tends to acquire a lower value (pH 4.6) in the upper 50 cm of the soil under oak than in the pampas grass (pH 5.5). Al concentrations, in the horizon under the oaks are significantly higher (38 μmol l^{-1}) than in the pampas

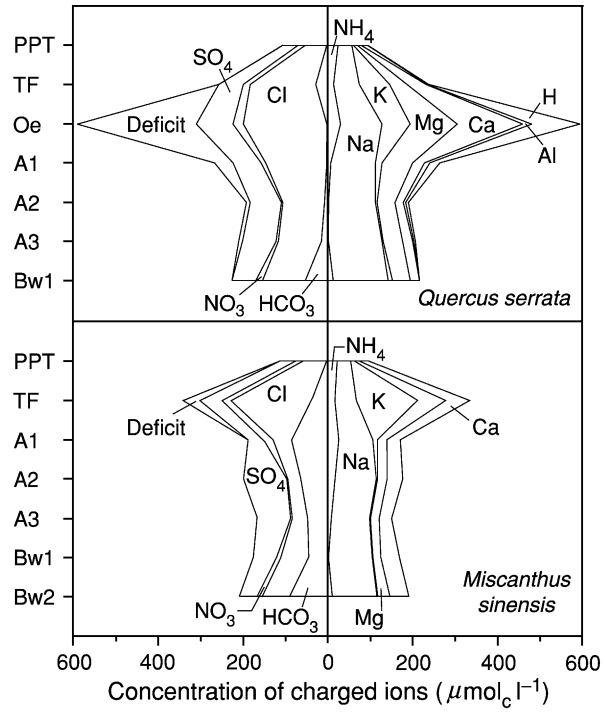

Figure 8 Charge balance for the soil solution of the Andisols developed under *Quercus serrata* and *Miscanthus sinensis*, Japan. The graph shows the concentrations of the charged species for precipitation (PPT), canopy throughfall (TF), and the soil horizon solutions. The anion deficit was assumed to be due to organic anions. (Reproduced with permission from Dahlgren RA, Ugolini FC, Shoji S, Ito T, and Slatten RS (1991) Soil-forming processes in Alic Melanudands under Japanese pampas grass and oak. (1991) *Soil Science Society of America Journal* 53: 1055.)

grass ($4\,\mu mol\,l^{-1}$). However, in both cases there has been no significant movement of Al into the B horizon. Iron concentrations are less than $1\,\mu mol\,l^{-1}$ in all horizons, except the Oe under the oaks, where a mean value of $0.4\,\mu mol\,l^{-1}$ has been recorded. Silicon concentrations under the oaks are high ($231\,\mu mol\,l^{-1}$) in the Oe due to biocycling. In the pampas grass plot, the highest levels are approximately $122\,\mu mol\,l^{-1}$ in the A horizon. Also, here the large amount of Si is due to the biocycling of silicon by the pampas grass. DOM concentrations reach a maximum of $3000\,\mu mol\,l^{-1}$ in the Oa of the oak site, but they decrease to less than $500\,\mu mol\,l^{-1}$ in the Al horizon. In the pampas grass site, the values are lower, approximately $1000\,\mu mol\,l^{-1}$, than under the oak. Under both species the mobility of DOM is limited to the surficial horizons. Uptake processes, in addition to the task of neutralizing the acid precipitation, mostly affect base cations (Na, K, Ca, and Mg). Calcium shows a higher concentration in the pampas grass, while Mg and Na are more abundant in the oaks. Anions show both differences and similarities between the two species. Chloride and sulfate show the highest concentrations. Sulfate reaches a minimum value in the B horizons, where it is retained by amorphous material.

Bicarbonate levels are higher under the pampas grass than under the oaks. In conclusion, the invasion of Japanese oak trees on a soil previously occupied by pampas grass has resulted in acidification of the soil solution in the upper 50 cm of the profile. This acidification has resulted in an increase in Al concentration and in a decrease in bicarbonate. Silicon tends to accumulate in the B horizon of the pampas grass, but with a net loss under the oaks. Also the oaks induce a greater cycling of Ca, Mg, K, and Cl. In spite of these differences, the process of andosolization, as characterized by *in situ* weathering in the B horizon and accumulation of organic carbon in the A, is still active under both species. The proton donors in the Oa of the oak site are the organic acids, while these acids have a lesser role in the pampas grass site, where carbonic acid prevails. Protons released by cation uptake dominate in the rooting zone of the oaks.

Impact of Burial by Volcanic Ash on Preeruption Soils

Regions in the proximity of active or dormant volcanoes are subjected to intermittent deposition of airfall tephra. These additions tend to rejuvenate the soil surface of the existing soils, bringing a high level of fertility and making these soils among the most productive in the world. The added volcanoclastic material varies in thickness, depending on many factors: volume of the ejecta, wind direction and velocity, and proximity to the source. Areas throughout the world that have received increments of airfall tephra display buried evidence associated with lithologic discontinuities. Although this phenomenon is widespread, there is a lack of information on the processes occurring when a new layer of fresh material is added to an existing soil. Dynamic pedology is the most suitable approach, because it provides an instantaneous record of the events and processes induced by the addition of tephra. Soils of the Pacific Northwest, USA, have been subjected, throughout the Holocene, to deposition of tephra produced by the volcanoes that dot the western part of the states of Washington, Oregon, and northern California. As recently as May 18, 1980, the eruption of Mount Saint Helens, western Washington, USA, provided an estimated $1.1\,km^3$ of airfall tephra that reached the soils along the fallout plume (Figure 9). In connection with this eruption, an experiment has been conducted by adding fresh tephra to soils that had received airfall tephra during the Holocene but had escaped the eruption of 18 May. Three metric tons of clean tephra have been

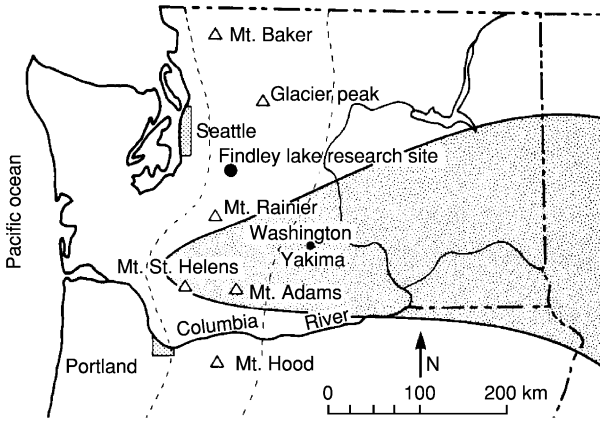

Figure 9 The shaded area indicates the approximate distribution of the 1980 Mt. St. Helens tephra. The location of the study, Findley Lake, Washington Cascades, is marked. (Adapted from Ugolini FC, Dahlgren RA, LaManna J, Nuhn W, and Zachara J (1991) Mineralogy and weathering processes in Recent and Holocene tephra deposits of the Pacific Northwest, USA. *Geoderma* 51: 279, with permission.)

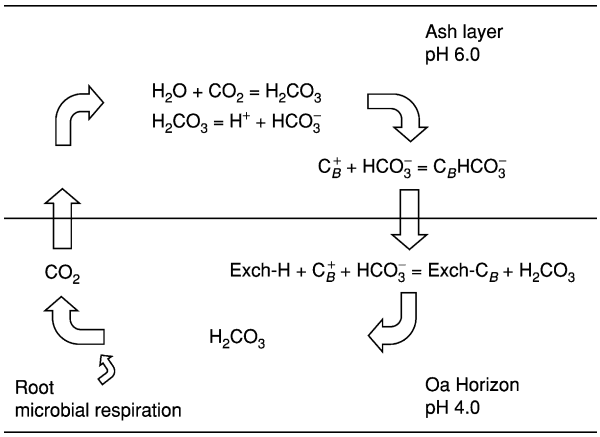

Figure 10 The CO_2–H_2CO_3–HCO_3 weathering and transport cycle between the added ash layer and the buried organic horizon (Oa). C_B, base cation. (Adapted from Dahlgren RA, Ugolini FC, and Casey WH (1999) Field weathering rates of Mt. St. Helens tephra. *Geochimica et Cosmochimica Acta* 63: 596, with permission.)

collected and applied in 5- and 15-cm increments to plots to be compared with those that had not received tephra. Hence a modern analog has been created of past burial episodes. The applied tephra contains soluble salts, mostly sulfates of Ca and Na formed while the ash was still airborne. These salts are readily leached once the tephra is exposed to the rainy and cool climate of the central Cascades, where the experiments have been carried out. The area receives 2300 mm of precipitation, two-thirds in the form of snow, and experiences a mean annual temperature of 5.5°C. The basic cations present in the leachates upon entering the buried forest floor displace H^+ and Al^{3+}. Consequently, solute entering the mineral soil (E horizon) have a low pH and a high concentration of soluble Al. Biological uptake, adsorption, and exchange reactions attenuate the pulse of basic cations. Calcium and K^+ are preferentially retained in the E horizon; Mg^{2+}, Na^+, and Cl^- are quickly removed from the solum. Sulfate is retained in the B horizon owing to ligand exchange reactions with imogolite/allophane material enhanced by the lowering of the pH. As the input from the fresh tephra of SO_4 decreases, most of the adsorbed SO_4 is desorbed from the B horizon. Al–bearing secondary minerals apparently control Al concentrations in the leachates collected below the B horizon. This *in vivo* experiment has revealed the mechanism of weathering in the newly added tephra layer. Carbonic acid is the major proton donor that liberates basic cations and Si and provides the conjugate base for their transport. Upon percolating through the acidic forest floor, the HCO_3^- gains a proton and is converted to H_2CO_3. At the low pH of the forest floor (approx. 4.0), volatilization of HCO_3 occurs, with the consequent diffusion of CO_2 upward into the tephra layer, where the pH (approx. 7.0) favors the formation of H_2CO_3, thus initiating a new weathering/transport cycle (Figure 10). This weathering scenario was observed during the first 4 months of monitoring the soil solution, but the process continued for 4 years. The information collected has allowed an estimation of field weathering rates, as well as of the weathering of the solid phase, after 10 years of exposure to the cool humid climate of the Cascades Mountains.

Testing New Theories of Soil Formation

From 1980 the classic theory of podzolization, also commonly known as the 'fulvate theory,' has been challenged by Farmer and his coworkers (Figure 11a). The fulvate theory holds that Al and Fe mobilization and transport occur through complexation with soluble organic acids. The new theory proposes that the migration of Al from the E horizon of Podzols occurs as positively charged, soluble hydroxyaluminosilicate sols called 'protoimogolite.' They are adsorbed/precipitated in the Bs and eventually transformed into imogolite (Figure 11b). Support for this process is the repeated presence of imogolite in the Bs horizons of Podzols/Spodosols derived from a variety of parent materials. However, in the absence of laboratory or field experiments that show the migration of protoimogolite from the E horizon, its presence in the Bs does not insure that it is derived from the E. It could have formed *in situ* in the Bs. Furthermore, previous experiments with aqueous solutions containing organic matter have shown the ability of

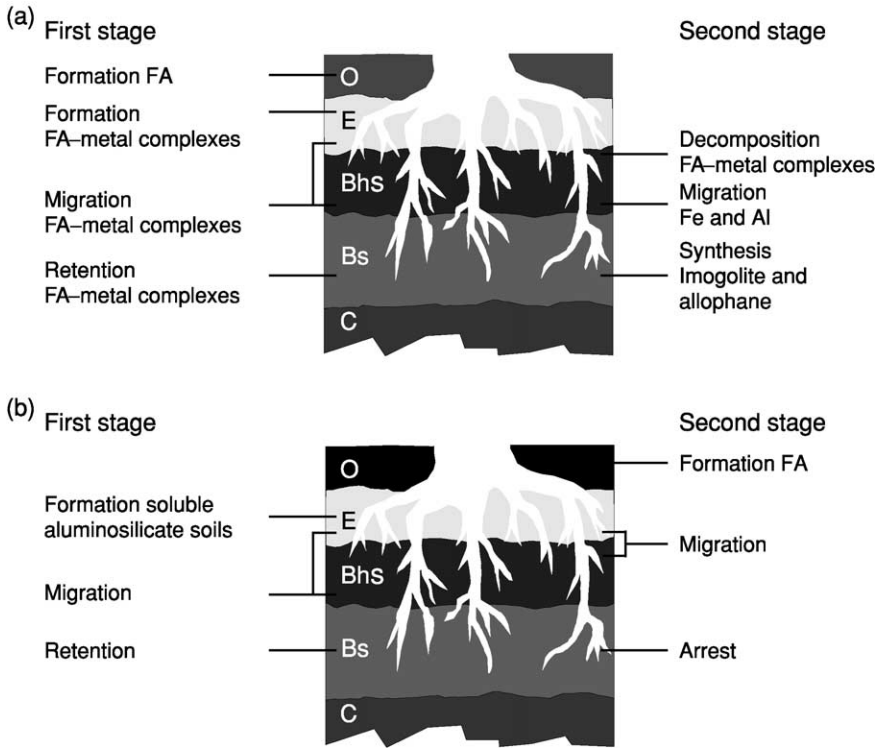

Figure 11 Schematic representation of the theories of podzolization: (a) fulvate theory; (b) protoimogolite theory. (Adapted from Ugolini FC and Dahlgren RA (1987) Mechanism of podzolization as revealed by soil solution studies. In: Righi D and Chauvel A (eds) *Podzols et Podzolization*. INRA, p. 196, with permission.)

these compounds to complex and mobilize Al and Fe. Also, soil solutions collected by lysimeters from a subalpine Podzol/Spodosol have evidenced the role of soluble organic matter in the process of podzolization. Nevertheless, to establish the validity of the proposed 'protoimogolite theory,' at least for the Pacific Northwest Podzols/Spodosols, it is crucial to answer a number of questions, such as: Does the Al migration occur in organic or inorganically complexed forms? Does protoimogolite migrate in the soil solution? Where is imogolite found in a subalpine Podzol/Spodosol? Is imogolite thermodynamically stable within the soil profile under the current weathering regimen?

To answer these questions it is necessary to collect soil solutions from the genetic horizons of a Podzol/Spodosol and to have available a method to fractionate the Al so as to establish the forms of this metal. Podzol/Spodosol profiles, located in the Cascades Mountains of Washington (USA), have previously been equipped with lysimeters and intensively studied. Soil solutions have been collected seasonally from this subalpine Podzol/Spodosol except in the summer because of low precipitation. Al fractionation is performed according to the technique proposed by Driscoll. This procedure partitions Al into three operationally defined fractions: strongly bound Al complexes, nonlabile monomeric Al, and labile monomeric Al. The labile monomeric Al includes aqueous Al as well as inorganic complexes. The Al^{3+} is estimated by speciating the labile monomeric fraction using GEOCHEM. The nonlabile monomeric fraction represents weakly held Al–organic complexes, while the strongly bound Al complexes appear to be a combination of colloidal Al or strong Al–organic complexes.

The first question is: In what form(s) does Al migrate from the E horizon? The answer is that between 73 and 100% of Al is organically complexed, mainly with the nonlabile monomeric form (Figure 12).

The second question asks whether protoimogolite migrates in the profile. The finding that Al in solution is organically complexed diminishes the role of inorganic Al forms and therefore of protoimogolite in the Al migration. However, an additional test has been carried out. Assuming, according to Farmer, that protoimogolite sols are present in the soil solution leaving the E horizon, being positively charged, they should have been retained on a cation exchange resin and hence decreased the Si concentrations of the solutions that had passed through the resin. However, statistical analysis of Si before and after passage through the cation exchange resin shows no change in Si concentration. This indicates the absence of

protoimogolite sols in the soil solution. Additionally, if the soil solution exiting the E horizon does contain protoimogolite, the value of the total Si, which includes also the Si in the aluminum silicate soils, should be higher than monomeric Si. However, the two values are the same; consequently, Si moves only in monomeric form and is not associated with Al. From these findings, apparently in these Podzols there is neither appreciable movement of inorganic Al nor migration of aluminum silicate soils.

To answer the question of whether imogolite is present in the Podzol under study, a search for this mineral has been made in all the inorganic horizons: E, Bhs, Bs, BC, and C. The methods used include selective dissolution, IR spectroscopy, scanning and transmission electron microscopy, and potentiometric titration. In the clay fraction, the minerals of short-range order represent less than 5% in the E horizon, while they range from 20 to 50% in the B and C horizons.

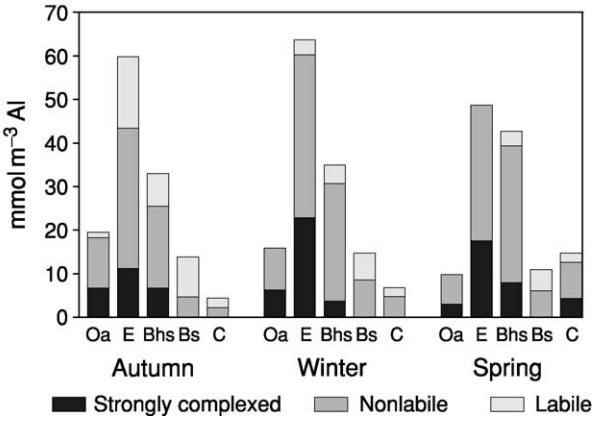

Figure 12 Aluminum fractionaton of soil solution from a Spodosol, Washington Cascades, into: strongly complexed, nonlabile monomeric and labile monomeric fractions. (Adapted from Dahlgren RA and Ugolini FC (1989) Aluminum fractionation of soil solutions from unperturbed and tephra-treated Spodosols, Cascade Range, Washington, USA. *Soil Science Society of America Journal* 53: 563, with permission.)

The final question is: Is imogolite thermodynamically stable in the soil studied? More specifically, is imogolite stable in the E horizon, where it should form according to the protoimogolite theory of podzolization? Chemical equilibria are used to determine the stability of imogolite and other minerals (Figure 13). The calculated saturation indices show that soil solution in the E horizon is undersaturated with respect to imogolite; consequently, the imogolite sols cannot be stable in this horizon. Soil solution from the Bs and C horizons appears to be in equilibrium with the hydroxyaluminum interlayer of 2:1 clay minerals and imogolite. The hydroxyaluminum interlayer seems to control Al activities, while imogolite controls H_4SiO_4 activities. From this study it appears that Farmer's proposed theory of protoimogolite to explain the process of podzolization is not applicable in Podzols/Spodosols developed in cool to cold forested environments, where organic acids tend to dominate the upper part of the profile where protoimogolite should form. Al is effectively complexed by the DOM and therefore not available for reacting with Si to form aluminum silicate sols.

Summary

Dynamic pedology, in the context of soil science, occupies a particular role. Based on collection, analysis, and interpretation of soil solution, dynamic pedology attempts to provide answers that traditional solid-phase investigations cannot give. It obtains an instantaneous picture of the ongoing processes and the impact of perturbations. However, a complete understanding of soil can be acquired by studying the liquid, the solid, and the gaseous phases. The adoption of dynamic pedology is restricted to those soils that experience percolative events, although collection of solution has been secured by irrigating the soil. Inherited limitations of dynamic pedology are obviously dependent on the collection of representative soil solution, which in turn is conditioned by the residence

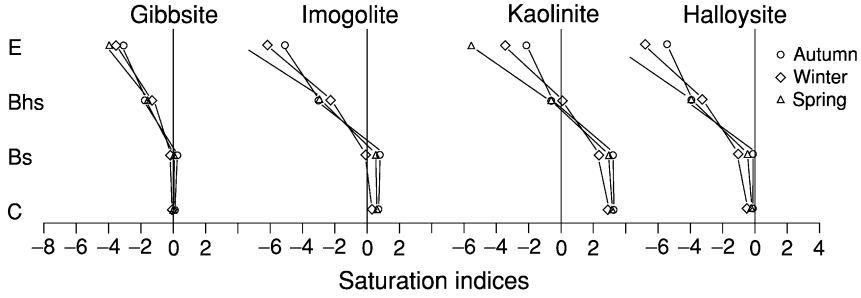

Figure 13 Saturation index of selected minerals calculated for the autumn, winter, and spring soil solutions collected from a Spodosol, Washington Cascades. (Adapted from Dahlgren RA and Ugolini FC (1989) Formation and stability of imogolite in a tephritic spodosol, Cascade Range, Washington, USA. *Geochimica et Cosmochimica Acta* 53: 1901.)

time of the water in the soil. Solution collected by gravitational means, zero-tension lysimeters, or tension lysimeters may differ. Seasonal variations in solution with tension lysimeters held at a constant of 10-kPa tension are few compared with solutions obtained with low (0–30 kPA)- and high-speed centrifuge (30–3000 kPa). Also the seasonal changes in solution composition determine the thermodynamic stability of minerals. Limitations in the use of dynamic pedology are therefore related to the sampling methodology and the time of sampling of the soil solution.

List of Technical Nomenclature

Concentrations:

μmol	Micromoles
$\mu mol_c l^{-1}$	Micromoles of charge per liter
mg l^{-1}	Milligram per liter
mmol m^{-3}	Millimoles per cubic meter

Length:

μm	Micrometer
cm	Centimeter
km	Kilometer
m	Meter
mm	Millimeter

Pressure:

kPa	Kilopascal

Temperature:

°C	Degrees Celsius

Volume:

l	Liter

PEDOMETRICS

I O A Odeh and A B McBratney, University of Sydney, Sydney, NSW, Australia

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

The term 'pedometrics,' first coined by McBratney in the late 1980s, 'is a neologism derived from the Greek roots pedos or $\pi\varepsilon\delta o\sigma$ (soil) and metron or $\mu\varepsilon\tau\rho o\nu$ (measurement).' It is used in a similar fashion to other words such as biometrics, psychometrics, econometrics, chemometrics, and, the oldest of all, geometry. Furthermore the term covers two main ideas – the 'soil' or 'pedo' part, which corresponds to that branch of soil science we call pedology, and the 'metrics' part, which is restricted to mathematical and statistical methods. Simply defined, pedometrics is the use of quantitative methods for the study of soil distribution and genesis, and as a sustainable resource. Another problem-oriented definition is 'soil science under uncertainty.' In this sense pedometrics deals with uncertainty in soil models that describe deterministic or stochastic variation, vagueness, and lack of knowledge of soil properties and processes (Table 1). Thus mathematical, statistical and numerical methods could be applied to resolve the uncertainty and complexity inherent in a soil system model, including numerical approaches to classification, which deals with supposedly deterministic variation.

Pedometrics is not new, as mathematical and statistical methods have been applied to soil studies since the 1960s and 1970s. However, it is now emerging as a technical branch of soil science complementing traditional pedology. Over time the use of computers has increased in both fields, and the difference between the two has decreased and, in some cases, overlapped. Due to new demands for quantitative soil information required for global-scale models, regional environmental planning, and field-scale agricultural land management, traditional pedology has become more quantitative through the increased use of computerized soil information systems. Concurrently, pedometrics has emerged as a collection of quantitative tools, which are increasingly being used to account for conceptual pedological models of soil variation. As of 2003, there is a strong and growing overlap and synthesis between 'traditional' pedology and quantitative pedology or pedometrics (as shown in Figure 1).

Methods and Problems

Pedometrics: Principles and Hypotheses

As the definition implies, pedometrics encompasses the whole quantitative approach to the study and description of soil, especially soil in the field. It also involves the use of mechanistic, stochastic, deterministic, and empirical models (Table 1). A more restricted form of pedometrics is one that involves applications of statistical and probabilistic modeling to soil variation. Pedometrics principles are therefore embodied in (geo-)statistical modeling of pedological processes and the associated phenomena as they influence soil variation, and the associated model uncertainty.

Pedometrics is therefore aimed at resolving a number of questions or hypotheses:

1. What is the pattern of soil distribution in multivariate space, i.e., soil taxonomy?
2. How does the soil vary spatially and temporally?
3. What are the utility and quality of soil?
4. What are the causal factors of soil, i.e., soil genesis?

Table 1 Types of quantitative models used for soil studies with examples and sources of uncertainty

Causality/ uncertainty	*Model*		
	Deterministic	*Stochastic*	*Nonstatistical*
Empirical	Generalized linear models, numerical taxonomy, Jenny functional relations and canonical ordination	Time series, spatial processes, temporal and spatial variation of soil properties	Fuzzy systems
Mechanistic	Flow and diffusion of soil plasmic materials, profile and landscape development	Indeterminate	Indeterminate
Uncertainty	Imprecise measurements, model uncertainty	Random process, probability	Vagueness, ambiguity, and fuzzy geostatistics

5. What is the uncertainty of modeling the spatial pattern of soil phenomena, i.e., is a model a true representation of reality?

With the exception of (5), these hypotheses dovetail well with the requirements of conventional pedology. Although in the past developments in pedometrics have been restricted to statistics and probability, increasingly mechanistic models are being applied to model soil processes.

Soil Measurements and Properties

In order to model soil quantitatively, we need to perceive it, i.e., sense it or measure some quality or quantity of it. In other words, how do we numerically represent soil properties in order mathematically and/or statistically to model their variation? Ever since the advent of modern environmental science, technological advances have improved immensely the way we characterize or measure the quality and/or quantity attributes of soil. Soil measurement techniques include direct measurements, visual observations, and remote sensing (including proximal, airborne, and space-based modes of sensing).

Soil color and spectroradiometry Measurement of soil color has gained tremendously from advances in technology, particularly in spectroradiometry. The human eye is capable of seeing colors made up of combinations of reflected wavelengths throughout the visible portion of the electromagnetic spectrum.

The Munsell System of Color Notation, a color order system invented by Albert H. Munsell in 1905, is the most-used soil color system prior to the development of a quantitative means of measuring soil color. It specifies a limited number of 'standard' colors, within an asymmetrical, 'cylindrical' color space. While the hue (H) describes the similarity to a dominant color (red, yellow, and blue) or a combination of any two, the value (V) is the color intensity (lightness) and chroma (C) is the relative purity of the dominant wavelength (saturation). The Munsell color notations are semiquantitative, requiring further transformation for quantitative data analysis.

In 1931 the CIE, or Commission Internationale de l'Eclairage, standardized color order systems by specifying the light source, the observer, and the methodology used to derive the values for describing color. The CIE system defines how to map a spectral power distribution to a set of tristimulus coordinates which describe the color space: a luminance component Y and two other 'imaginary' components of the primary spectra, X and Z (Figure 2a). These in turn could be mapped to xy coordinates of chromaticity (Figure 2b). More recently, in 1978 the CIE has provided additional transformations (CIELUV and CIELAB color spaces) to make color representation on a continuous numeric color space more amenable for pedometric analysis.

Optical properties of the soil are primarily a function of its mineral composition, since the soil is formed from the transformation of rocks. A soil reflectance spectrum is therefore superimposition of spectra of the soil mineral components. Thus a soil type has its unique spectral reflectance curve. *In situ* or reference data are often collected at the time of image acquisition. One form of reference data is the ground-based measurement of the reflectance of surface features to determine their spectral response patterns. This might be done in the laboratory or in the field using a spectroradiometer. This device measures, as a function of wavelength, the energy coming from an object within its view. It could be used to prepare spectral reflectance curves of many soil types for classification or comparison purposes (e.g., Figure 3). Pedometricians are currently investigating the predictive power of such spectra. Such analysis is well known in chemometrics.

Field properties: hard and fuzzy descriptors? Other than color, many soil morphological properties, required in routine soil surveys, are described in somewhat vague terms. For example, soil structure grade is described as 'structureless' or 'weak' or 'moderate' or 'strong' in many national soil survey handbooks. To make the grades more amenable to quantitative

analysis (e.g., multivariate statistical analysis) these terms are usually coded as 0, 1, 2, and 3, respectively. But because of the vagueness in the linguistic characterization, fuzzy coding, which accounts for uncertainty or lack of clear boundary between the grades, has been used. Other morphological descriptors such as soil aggregate (structure) size classes, e.g., 'fine,' 'medium,' and 'coarse,' may be given linguistic variables which could be fuzzified to determine the degree of truth that a given soil layer is characterized by. Simple examples of fuzzy coding are presented in Table 2.

Pedotransfer functions The term 'pedotransfer function' (PTF) is generally defined as translating the raw soil data into more useful information. It can also be defined as predictive functions of certain soil properties from other easily, routinely, or cheaply measured properties. The most readily available data come from soil survey, such as field morphology, texture, structure, and pH. PTFs add value to the basic soil data by translating them into predicates of other more laborious and expensively determined soil properties. These functions fill the gap between the available soil data and the properties, which are more useful or required for a particular model or quality assessment. A simple illustration of how to apply PTFs to practical problems is shown in Figure 4.

Quantitative Soil Geography – Classification Models

Soil Classification and Soil Map Units

The pattern of soil in the landscape is as a result of effects of soil-forming factors, namely: climate, organisms, parent material, topography, and time

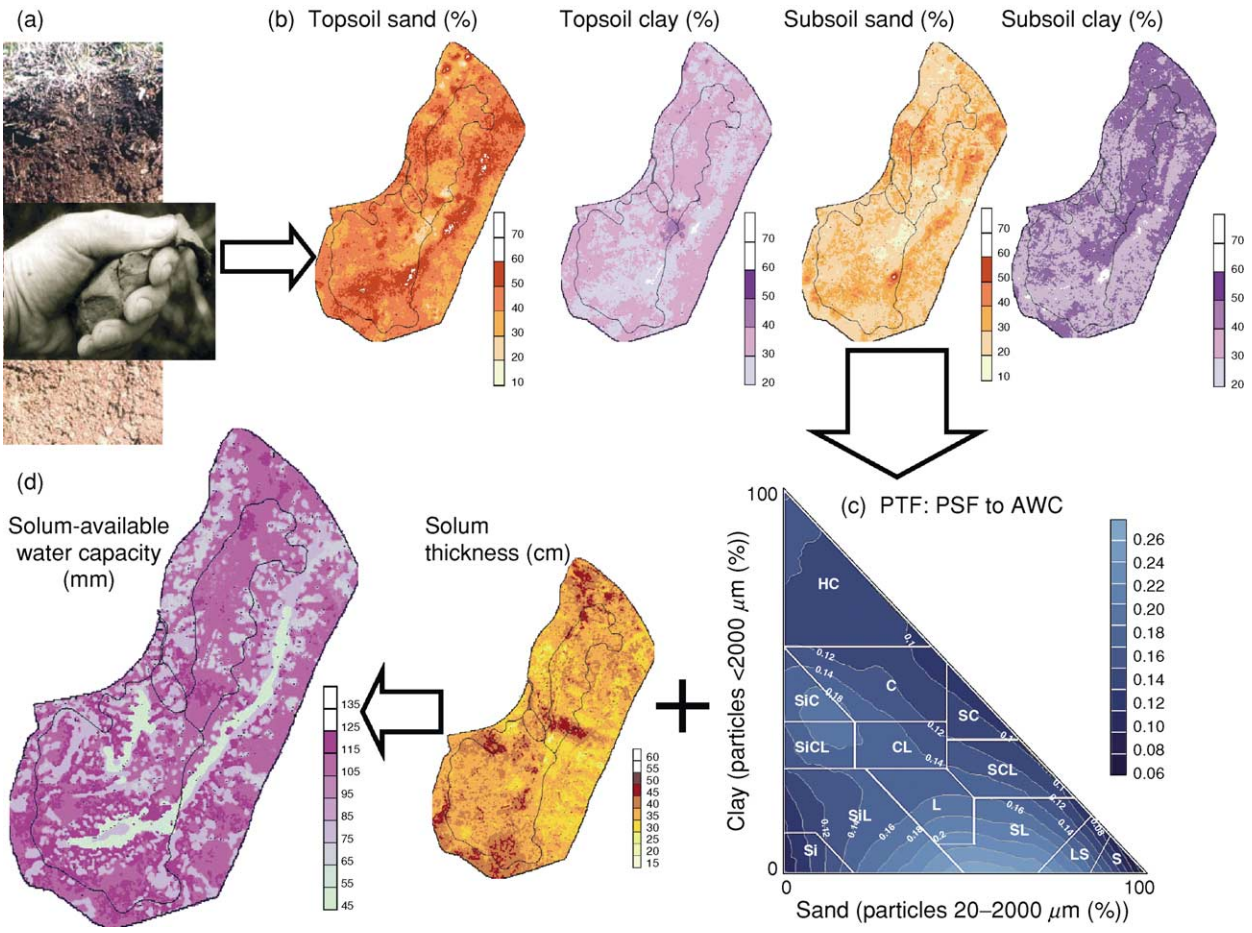

Figure 4 A simple example of pedotransfer functions (PTFs): (a) field texture was first determined by 'feel' method for topsoil and subsoil at each sample location; (b) particle-size fractions were then estimated from the textural classes and interpolated on to a fine grid; (c) horizon-available water capacity was in turn estimated through a PTF expressed as a function of particles sizes; (d) a combination of both horizons produces the solum-available water capacity. AWC, available water capacity.

(usually referred to as 'corpt,' but recently extended to 'scorpan' – see Eqn [2], below). These factors, particularly climate and parent material, produce broad patterns of soil in geographic space. The complex combination of these factors is what causes repetitive patterns of soil in the landscape, which form the basis for soil classification, identification, and mapping. In traditional soil classification, both the conceptual and real classes are qualitative and have no clear-cut boundary. Pedologists have, in the past, attempted to avoid these by applying numerical classification to complex soil data. Soil classification, in both geographical and taxonomic space, is a simple representation of complex, and sometimes repetitive patterns of soil in the landscape. Class identification, on the other hand, is aimed at matching classes that are conceptually described (usually in a classification system) with reality – represented by data obtained by soil morphological description and measurements.

A soil map unit is a collection of areas that are relatively homogeneous in soil constitution or miscellaneous areas that constitute different soil components or both. In a given survey region, a map unit differs in some respect from all others and can be uniquely identified on a soil map. A soil map delineation, on the other hand, is an individual area on the map, bounded by other delineations or the map boundary. Usually delineation contains the dominant components in the map unit name, but it may not always contain a representative of each kind of inclusion. Soil boundaries can seldom be shown with complete accuracy on soil maps; hence parts and pieces of adjacent polypedons are inadvertently included or excluded from delineations. This problem has been the stimulus for paradigm shifts in soil classification in the latter part of the 1990s; hence the applications of numerical hard and fuzzy classification systems in soil science.

Fuzzy classes and the breakdown of the classification paradigm Traditionally most classification systems are composed of mutually exclusive classes in order to conform to the discontinuous soil variation embedded in the traditional concept of soil map units. But soil variation is more continuous than discrete. The pioneer work in pedometrics, involving computer-based numerical classification, was designed to address this limitation among others. While the applications of numerical soil classification to soil studies are, to some extent, based on continuous representation of soil in space, their results are still interpreted in terms of 'hard' classes. There is also lack of any spatial coherence for the classes to be mapped. Recent advances are based on fuzzy sets for optimized prediction quality of the resulting classification, and which take cognizance of the continuous nature of soil variation and nonlinearity in the interattribute relationships.

The first application of fuzzy set theory in soil survey was principally for classification. Two different but complementary approaches to grouping individuals into fuzzy classes in soil science are: (1) fuzzy *c*-means (FCM, also known as 'fuzzy *k*-means'), and semantic import model (SI).

The FCM algorithm for improved predictive classification by providing for membership to an extragrade class is based on the objective function, defining the within-class sum-of-square errors, J_E, expressed as:

$$J_E(M,c) = \alpha \sum_{i=1}^{n} \sum_{j=1}^{c} m_{ij}^{\phi} d_{ij}^{2} + (1-\alpha) \sum_{j=1}^{c} m_{i*} \sum_{j=1}^{c} d_{ij}^{-2} \quad [1]$$

where c is the number of classes, n is the number of individuals or pedons; m_{ij} is the membership of an individual i in class j; φ is the fuzziness exponent $(1 < \varphi < \infty)$; d_{ij} is the character space between the feature value of an individual, i, and the feature centroidal value for class j; α is the parameter that determines the mean value of m_{i*}, which is the membership value of an individual, i, in the extragrade class.

The SI model was developed primarily for land evaluation. The need for using fuzzy set theory in land evaluation, such as defined in the Food and Agriculture Organization of the UN (FAO) framework, arises because basic soil information used for land evaluation is mostly described by seemingly vague terms such as 'poorly drained,' 'slightly susceptible to soil erosion,' and 'moderate nutrient availability.' Not even when these terms are defined precisely is the qualitative ambiguity removed. Usually, the land evaluator's aim is to produce a set of clearly defined classes of land qualities based on specified land use requirements. These subsequently provide the means of transferring information about the soil and its use. As land qualities are complex attributes that are derived from land characteristics such as topography, soil, water, or biological and human activity, subsequent Boolean logical operations in the process of land evaluation tend to throw away much useful information.

Spatial Prediction of Soil Classes

The corpt approach As previously stated, the 'corpt' methods are based on the empirical-deterministic models that originated from Han Jenny's *Factors of Soil Formation*. Jenny's state-factor equation, in its extended form, is expressed as:

$$S = f(s, c, o, r, p, a, n) \quad [2]$$

where S is some soil properties or soil type as a function of state factors: s as some other soil property at a point, c as climate, o as organisms, r as relief, p as parent material, a as time or age, and n as space or spatial position. Soil spatial variability is therefore considered as being causative realizations of the complex combinations of soil-forming processes as influenced by the soil-forming factors. The scorpan function (Eqn [2]) – in its original form, the corpt – earlier in the nineteenth century stimulated numerous studies, mainly quantitative prediction of soil attributes, which we shall treat in a later section. Until recently, because data on soil classes were nonquantitative, the scorpan methods were only restricted to predicting soil attributes measured on a continuous scale.

Models such as expressed in Eqn [2] can be derived for predicting soil classes or soil types using two different techniques: logistic regression and classification trees. Logistic regression is designed specifically for situations in which we have a dichotomous (nominal or ordinal) dependent variable (e.g., soil classes), in comparison to classical linear regression typically used for continuous dependent variables (e.g., soil pH value). Several problems arise when a dependent variable is binary: the error terms are nonnormal and their variance is nonconstant. Although the errors are not normal, this method still provides unbiased regression estimators that are approximately normal if the sample size is large. Classification tree algorithms, on the other hand, search for combinations of values of independent variables (e.g., Jenny's state factors or attributes derived from them) that best predict the value of the dependent variable (e.g., unordered factors such as soil classes). Prediction quality is based on criteria such as the within-group noises, variance, or statistical significance of the conditional frequency distribution of values for the dependent variable, conditioned on the answers

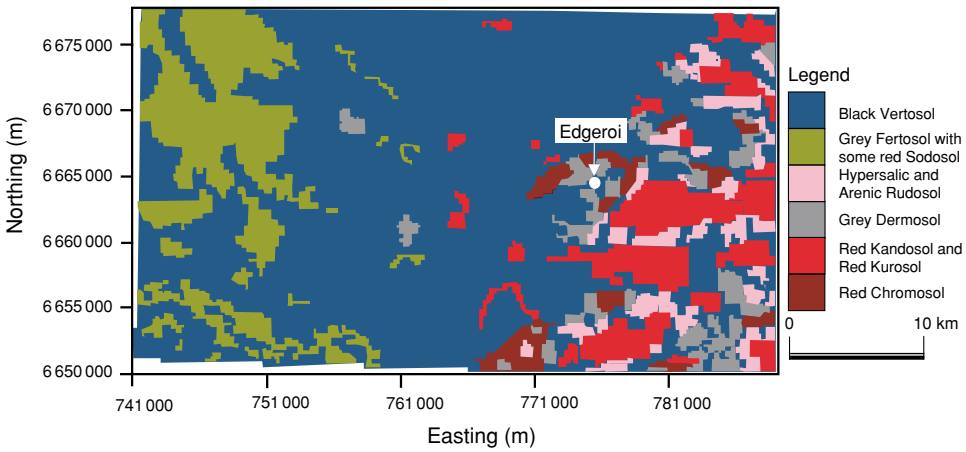

Figure 5 Predicted soil classes for the Edgeroi area in accordance with Australian Soil Classification. (Reproduced with permission from McBratney AB, Odeh IOA, Bishop TF, Dunbar MS, and Shatar TM (2000) An overview of pedometric techniques for use in soil survey. *Geoderma* 97: 293–327.)

to questions asked. A digital map of soil suborder classes, as produced by classification tree model, is shown in Figure 5.

Spatial Prediction of Soil Attributes

The scorpan approach The 'scorpan' approach (Eqn [2]) earlier in the nineteenth century stimulated numerous studies in quantitatively predicting soil attributes measured on a continuous scale. Much of the earlier studies, and indeed some recent examples, was based on general and bivariate-simple linear regression, although multiple polynomial regression models were occasionally applied. But due to nonlinearity in the correlations among many soil variables, and indeed of many of the soil variables with ancillary variables, robust methods such as generalized linear models (GLMs), generalized additive models (GAMs), and regression trees (RTs) have been developed and applied. Another development is the artificial neural network models, which are nonparametric modeling techniques that mimic the neural networks of the brain. The networks are composed of processing units, or neurons, which are organized into layers, i.e., input, hidden, and output layers.

But the problem is, while the classic models or the more robust methods may take care of the deterministic relations, they do not account for spatial autocorrelations of the soil properties, especially at the local level. To solve this problem, the pioneer pedometricians initiated the application of geostatistics (which was primarily developed for the mining industry).

Geostatistics Matheronian geostatistics is based on the theory of regionalized variables, which allows us to consider spatial variability of a soil property or even soil types, if quantified, as a realization of a random function represented by a stochastic model. The generic geostatistical method of spatial interpolation is termed 'kriging' in its various forms: simple, ordinary, lognormal, and disjunctive kriging.

In geostatistics, the semivariogram is a primary requirement for spatial prediction or kriging of a target geographical feature. The semivariogram can be obtained by processing a data set to produce empirical semivariances through the computation of the spatial correlation or covariance between pairs of samples at certain distances apart. The plot of the semivariance and the corresponding distance or lag at which the pairs are separated produce the semivariogram. The latter describes the magnitude, spatial scale, and the general form of variation of a given variable. An example of semivariogram is shown in Figure 6, with several spherical models based on different fitting methods.

The first major applications of kriging, in its ordinary and univariate form, for soil studies were in the early 1980s. Since then ordinary kriging has been widely used in various subfields of soil science, including soil reclamation, in soil classification, and soil pollution. Major limitations of the univariate geostatistics technique of kriging are due to the assumptions of stationarity, which are not often met by the field-sampled data sets and, of course, the often-cited requirement of large amounts of data to define the spatial autocorrelation. However, with increasing availability of ancillary information, the lack of adequate samples has been partially solved. The univariate usage of kriging is also limiting in situations of complex terrain where the soil-forming processes are themselves complex. In such situations there is the need to model both

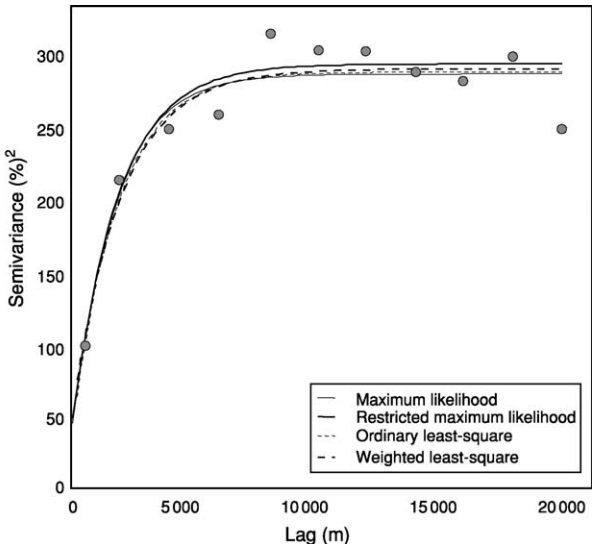

Figure 6 An experimental semivariogram fitted with spherical models based on different fitting techniques.

the structured and the spatially dependent components of the soil variable. Also there are economic and logistic reasons for including the ancillary variables influencing soil variability, especially if the latter are more readily and cheaply available. As both the soil and the exogenous factors are multivariate, the most obvious choices are appropriate combinations of multivariate or univariate analysis using the scorpan factors and the geostatistical methods. These combinations constitute the hybrid techniques.

The hybrid of scorpan and geostatistics The hybrid techniques for soil survey and mapping are based on various combinations of the geostatistical and multivariate or univariate scorpan methods. Let us suppose that a data vector describing a soil property is a random variable Z, determined at locations in a region, $X = x_1 \ldots, x_N$, and consisting of three components as:

$$Z = m + Z_1 + \epsilon \qquad [3]$$

where m is the local mean for the region, Z_1 is the spatially dependent component, and ϵ the residual error term, spatially independent. Now there may be situations where m is varying and dependent on some exogenous factors such as the scorpan factors. In other words it is deterministically related to some causative factors (in geostatistics parlance, the variable is said to exhibit a trend). Wherever trend exists, the ordinary univariate kriging is inappropriate. Several methods have been designed to accommodate the trend.

Universal kriging has been the commonly used method to accommodate the trend or 'changing drift,' as it is sometimes known, in a soil variable. Universal kriging is a combination of the standard model of multiple-linear regression and the geostatistical method of ordinary kriging, which is also analogous to combining scorpan methods with the univariate kriging, but only using the geographic coordinates as determining the drift (the n factor of the scorpan model). More recently, a more advanced approach, the intrinsic random function of order k (IRF-k), has been used to accommodate the varying nature of the trend in a regionalized soil variable. The term 'k' represents the order of polynomial trends: $k = 0$ means constant drift, and the IRF-k is equivalent to ordinary kriging system of equations. If $k = 1$, we have linear drift; $k = 2$ yields quadratic drift; but where there is no trend but deterministic relationships are with some known or readily available and inexpensive covariates (scorpan factors) or other easy-to-measure soil variables, co-kriging has played a major role in efficiently predicting the target soil variable. Universal co-kriging is also possible when considering the trend and covariation with one or more secondary variable.

Co-kriging is the multivariate extension of kriging that allows the inclusion of more readily available and inexpensive attributes in the prediction process. There are many instances in soil survey where the scorpan factors such as topography, time, and variable parent material, are easily discernible or are either readily available and/or are cheap to obtain. The most efficient way to predict the expensive-to-measure target soil variable, the variation of which is affected by the scorpan factors, is to use the factors in co-kriging the target soil variable, sampled at fewer locations, into dense grid nodes.

Regression-kriging (RK) is another hybrid method that combines either a simple or multiple-linear regression model (or a variant of GLM, GAM, and RTs) with ordinary, or simple, kriging of the regression residuals. The assumption here is that the deterministic component (m in Eqn [3]) of the target (soil) variable is accounted for by the regression model, while the model residuals represent the spatially varying but dependent component Z_1 in Eqn [3]). If the exogenous variables used in the regression equation are available at more dense locations than the target variable, the equation can then be used to predict the m on to those locations. The Z_1 can also be predicted to the same locations by simple kriging system of equations, and then added to the m to obtain Z^*. A variant of RK is kriging with uncertainty, which introduces regression residuals (as representing model uncertainty) into the kriging system used to predict the target soil variable. This reduces the extrema of the target soil variable and therefore produces a

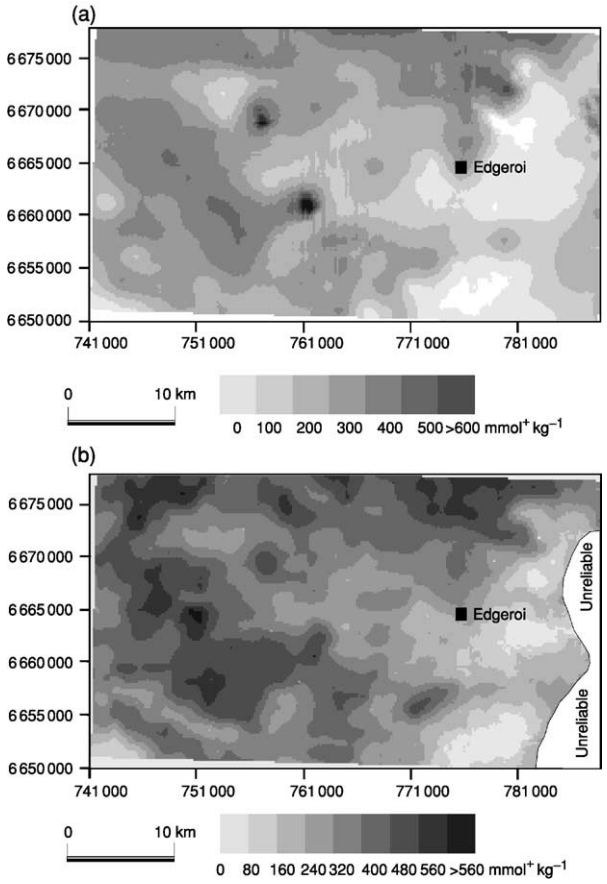

Figure 7 Predicted cation exchange capacity (CEC; millimoles per kilogram) for the Edgeroi area using (a) kriging with elevation as external drift and (b) regression-kriging. (Reproduced with permission from McBratney AB, Odeh IOA, Bishop TF, Dunbar MS, and Shatar TM (2000) An overview of pedometric techniques for use in soil survey. *Geoderma* 97: 293–327.)

smoother function of the predicted values. Another variant of RK, kriging with external drift (KED), is a hybrid technique that integrates the universality conditions into the kriging system using one or more of the ancillary drift variables. It is similar to universal kriging, but using an ancillary variable to represent the trend. As shown in Figure 7a, a regional digital map of cation exchange capacity (CEC) has been produced using KED with elevation as the external drift. Comparing this map with one produced using RK (Figure 7b) indicates a slightly more smoothed map produced by KED than the RK one.

Soil Utility and Quality

Land Evaluation, Soil Quality, and Soil Utility

Pedometrics has played a major role in advancing the role of land evaluation and, more recently, the quantification of soil quality for land management and sustainable use of land resources. Although 'soil quality assessment' is often used as a misnomer for 'land evaluation,' both could be regarded as the interpretative phase of soil survey. While land evaluation is concerned with the assessment of land performance when used for specified purposes, soil quality is defined as 'the capacity of a specific kind of soil to function, within natural or managed ecosystem boundaries, to sustain plant and animal productivity, maintain or enhance water and air quality, and support human health and habitation.' In considering productivity, environmental quality, and health as major functions of soil, this definition requires that values be placed on specific soil functions as they relate to the overall sustainability of alternate land-use decisions. Pedometric techniques (based on 'hard' and/or fuzzy techniques) are being used to quantify soil quality and associated uncertainty. For example soil quality can be assessed in terms of requirement for different specific uses such as shown in Figure 8. Many of the soil quality indicators are required at various scales and spatial extents in which pedometrics is playing a major role in spatially modeling them for incorporation into regional, catchment, and field-scale modeling. Another approach to soil quality analysis may be based on the concept of pedodiversity.

Recent Advances: Quantitative Pedogenesis

As stated above, soil variability is a function of factors of soil formation. Since the publication of Jenny's state factors, pedologists have attempted to develop pedogenetic (mathematical) functions that could explain soil variability and, in many instances, predict or even simulate the soil. A few examples are given here.

Process Models

The soil system is dynamic and regenerative under the influence of soil-forming processes. Since the soil is important for the survival of human civilization, it is imperative that researchers' interest in soil processes is ever-increasing. This has resulted in models of pedogenesis based on chemical and physical processes. The formulation of the process models and their applications are dependent on the scales in both the temporal and spatial dimensions. This modeling space–time continuum is determined by the complexity of the modeling process, which can be characterized in several ways. The first is based on computational complexity of the model, which ranges

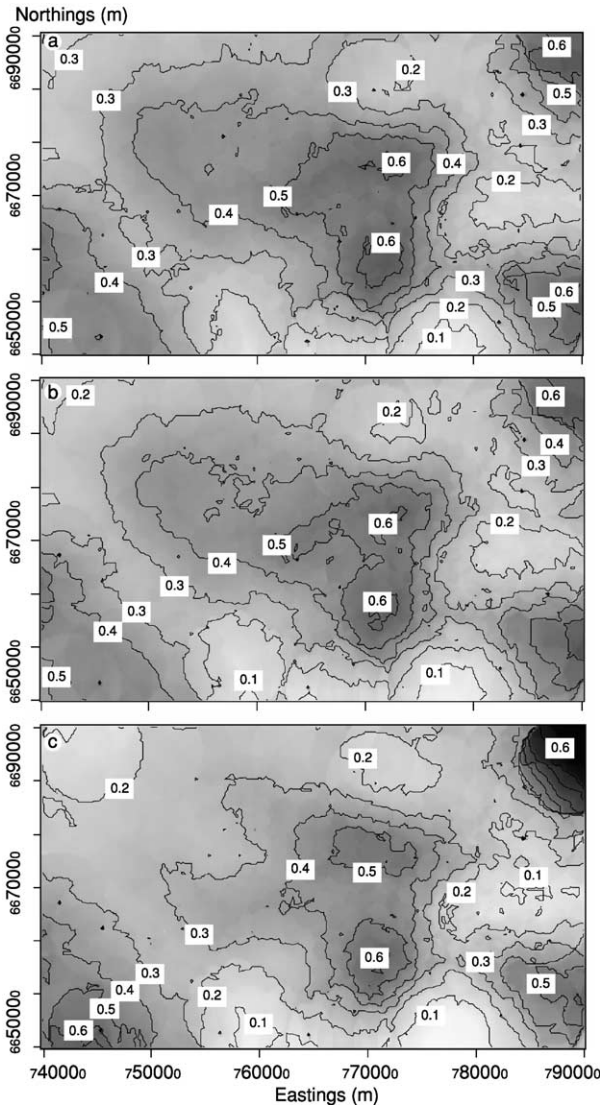

Figure 8 Interpolated suitability of (a) wheat, (b) sorghum and oats, and (c) dryland cotton. (Reproduced from Triantafilis J, Ward WT, and McBratney AB (2001) Land suitability assessment in the lower Namoi Valley of Australia using a continuous model. *Australian Journal of Soil Research* 39: 273–290.)

from purely qualitative (mental models) to highly quantitative, with the latter involving complex computer coding; the second is based on the complexity of the model structure, which distinguishes between mechanistic (highly complex) and empirical (simplified functional) models; and the last, but not least, is based on organizational hierarchy, which determines at which level a model is used to simulate the soil system. The hierarchical levels range from $i-4$ (molecular-level processes) to $i+6$ (global level). Each level is a subsystem of the level above it, therefore allowing room for upscaling.

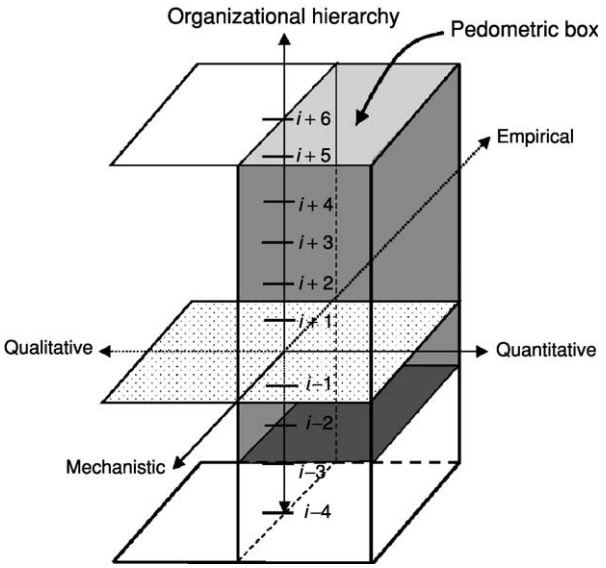

Figure 9 Pedometric box in the organizational hierarchy of pedogenetic modeling approach. (Adapted from Hoosbeek MR and Bryant RB (1992) Towards quantitative modeling of pedogenesis – a review. *Geoderma* 55: 183–210, with permission.)

The three characterizations above are well illustrated in Figure 9. It should be noted that pedometrics has played a dominant role in the quantitative half of the organizational hierarchy, particularly from and above the $i-3$ level, which is governed by material fluxes in the pores between the primary particles.

Recent developments in process modeling focus on mechanistic stochastic simulations, particularly at levels $i-3$ to i (Figure 9) and on how the latter can be upscaled to any of the higher hierarchies. For example: a mechanistic pedogenetic model, based on a digital elevation model (DEM), was used to simulate pedogenesis by a combination of several submodels: (1) physical weathering rate as exponential decline of soil thickness; (2) chemical weathering rate represented as a negative exponential function of both soil thickness and time; and (3) the movement of material as characterized by diffusion transport model. The upscaling result of such an analysis is illustrated in Figure 10, whereby, after 10 000 years, soil accumulation is predominant in the gullies compared with the ridges, where soil erodes.

Other emerging methods are geostatistical simulation models, e.g., indicator simulation, Gaussian simulation, etc. However, with increasing environmental concern, the development and applications of landscape dynamic models under different land-use scenarios may well dominate pedometric research in the first few decades of the twenty-first century.

The amount of water needed to ensure that a crop will provide the maximum yield possible in a given environment depends in a complex way on three main factors: prevailing weather, soil type, and the nature of physiological responses to the environment in general. Throughout the twentieth century, steady progress was made in measuring, quantifying, and interpreting these responses in terms of mechanisms. Towards the end of the century, developments in computing encouraged the building of 'models' that were intended to predict how the growth and yield of crops would respond to environmental factors in general and to weather in particular. Unfortunately, many of these models grew so rapidly that they shared the fate of the dinosaurs! More compact models have lasted longer because they follow classical lines, employing standard procedures based on minimal assumptions. A notable example in agricultural science is the equation for estimating the water use of arable crops, published by H.L. Penman of Rothamsted Experimental Station in 1948.

Howard Latimer Penman was born in 1909 in Dunston-on-Tyne, a small town in the north-east corner of England where his father worked as a master carpenter in a shipyard. At Blaydon County Secondary School, Howard passed the Oxford Higher School Certificate in 1927 and was accepted by the University of Durham for a Joint Honours course in mathematics and physics. Years later, a fellow-student wrote: "He was very much a northerner – a Tynesider – and on a suitable occasion could amuse by lapsing into the vernacular or singing a Tyneside song. His general approach to physics was stimulating; he accepted little on authority and thought things out for himself."

In 1930, Penman was awarded a First Class Honours degree in physics and for a short time taught at a boys' school until he decided to make research his career. At this stage, he was fortunate to encounter E.G. Richardson who offered him a studentship to work on the absorption of sound in porous materials. The work was successful and original enough to be published in 1933 with Richardson as a co-author; it was the first of Penman's 104 scientific papers written over the following 43 years. A Senior Exhibition offered by the County Education Committee then enabled him to embark on a research project managed by Richardson to investigate the dependence on temperature of the dispersion of sound in a gas. When completed, this study gained him a PhD from Durham University. Outside the laboratory, Penman was an active member of the Student Representative Council, played soccer and cricket, and sang in two choirs, an activity that he enjoyed for most of his life.

In 1934, Penman successfully applied for a post in the photochemistry section of the Rayon Department at the Shirley Institute in Manchester, administered by the British Cotton Research Association. The reports he presumably wrote on this work did not provide material for general publication. In 1935, however, a short paper on 'The effect of temperature on supersonic dispersion in gases,' based on his PhD, was published in the *Proceedings of the Physical Society.*

In 1937, Penman took a crucial step in his career when he successfully applied for a post in the Soil Physics Department at Rothamsted Experimental Station in Harpenden, a small town about 30 miles (50 km) north of London. Established by Sir John Lawes in 1843, Rothamsted is one of the world's oldest and most distinguished centers of research on agricultural crops.

Three years later, Penman published two papers on 'Gas and vapour movement in the soil' in the *Journal of Agricultural Science*, followed in the same year and journal by an analysis of 'Meteorological and soil factors affecting evaporation from fallow soil.' The latter paper was Penman's first excursion into what he often referred to as 'muddy-boot physics.' In 1941, he collaborated with his colleague R.K. Schofield to produce a major analysis of many measurements of evaporation from fallow soil that predecessors had installed in tanks surrounding Rothamsted's 'Bear Pit.' This was a deep, circular brick-lined enclosure built many years previously by Rothamsted's founders, Sir John Bennet Lawes and Henry Gilbert. (It survived well into the twentieth century but was eventually filled in to satisfy safety regulations imposed by vandals ignorant of the historical importance of the site!) A formidable archive of rainfall and drainage records existed but no previous analysis had been successful because the physics of natural evaporation was not properly understood. To get a better feel for the scale and interaction of the processes involved, Penman conducted a set of laboratory experiments that he described in the *Journal of Agricultural Science*, also in 1941.

In 1942, Penman produced a paper that marked an important extension of his research horizon from soil to the complex ways in which crops respond to climate as well as to soil conditions. However, it was not until 1948 that he published, in the *Proceedings of the*

Royal Society, the classic paper that brought him world renown – 'Natural evaporation from open water, bare soil, and grass.' This was based on a highly original combination of two fundamental equations, one describing the heat balance of a crop stand in terms of micrometeorology and the other describing its water balance in terms of hydrology. The variables involved (as daily averages) were:

1. the net amount of heat available from radiation, both solar and terrestrial
2. air temperature at screen height
3. vapor pressure at screen height
4. windspeed.

One variable was common to both equations – the effective surface temperature of foliage. The core of Penman's contribution to agricultural science was his realization that this unmeasured and, at the time, virtually unmeasurable quantity, could be eliminated by solving the two equations simultaneously to derive a new third equation that achieved world renown as the Penman formula.

To subject his equation to extensive tests in the field, Penman set up parallel irrigation experiments at Rothamsted, which has a clay soil, and at its Woburn outstation, where the soil is sandy. Each spring, he mustered a working party from his staff to install irrigation pipes – hard manual labor but a welcome escape from the laboratory provided the weather was fine. In due course, two major series of papers describing the analysis of Woburn measurements were published in the *Journal of Agricultural Science*. When a working group of the Agricultural Research Council described such a study as 'speculative,' Penman responded in characteristically trenchant language: "The term is unfortunate in its association with gambles and guesses .... Why the Research Council for the country's chief industry should seem to need special pleading for this kind of work is puzzling."

Following successful local tests of his equation, Penman applied it first to the whole of the UK and eventually, when checks against hydrological measurements appeared successful, to the mainland of Europe. His work on crop evaporation is an outstanding example of how a relatively simple but rigorous general model can be applied to many types of mixed vegetation growing in a wide range of climates.

(When Penman's seminal paper was published, he had worked at Rothamsted for 11 years during which he published 14 papers – a fairly leisurely rate by the norms of today. By 1974, however, when he retired, he had published over 100 papers and articles in a variety of journals ranging from the *Proceedings of the Royal Society of London* to the *Transactions of the Hertfordshire Natural History Society Field Club*.)

In due course, the Penman equation was adopted by several government agencies and used both on relatively small scales to estimate the irrigation need of agricultural and horticultural crops and on much larger scales to assess the hydrological efficiency of catchments. As the scientific importance and practical value of Penman's work became recognized internationally, he was increasingly invited to attend conferences abroad and to serve on committees such as the Coordinating Council for the International Hydrological Decade.

In 1954, Penman succeeded R.K. Schofield as Head of the Physics Department at Rothamsted and continued the tradition of allowing his staff the freedom to identify and explore lines of work that challenged them. This treatment followed his own experience when, during his first interview with his head of department he was told to "find something interesting to do and get on with it!" Most, but not all of his staff, made good use of this invitation to tackle challenging problems of their own choice. The benefits were personal while the work was in hand and universal once it was published.

Penman did not live to know that, in 1990, an extended form of his equation was adopted by the Food and Agriculture Organization of the United Nations (FAO) as the international standard for estimating the water need of crops. This would certainly have given him great satisfaction, but he was a modest man and might well have concealed this!

Although the Bear Pit site was not ideal, Penman was confident that records, carefully preserved for many years, could be used to test formulae relating to evaporation to weather.

There are at least two ways in which such testing can be done: by empiricism based on the correlation of estimates with rates of evaporation measured at one or more sites over long periods; and by deriving appropriate formulae to describe the mechanisms involved. The first route was taken by an American, Warren Thornthwaite, who explored the correlation of evaporation rates with temperature as reported from standard weather stations. This statistical approach to the problem did not appeal to Penman, nor did Thornthwaite's suggestion that the total amount of water lost by evaporation from plants and directly from the soil on which they grew, should be referred to as 'evapotranspiration' – a clumsy hybrid banned from Rothamsted publications! Penman coined the term 'potential transpiration' to describe the rate at which water was lost from a stand of vegetation with an abundant water supply and he provided an unambiguous definition: "The loss of water from short, green vegetation, completely covering the ground and never short of water."

Penman's mechanistic formula for evaporation was founded on two major physical principles: the conservation of mass and the conservation of energy. Conservation of mass implied that the rate of evaporation from a uniform area of vegetation should be proportional to the change of vapor pressure with height and to a function of windspeed. Conservation of energy implied that the net input of heat from radiation must be balanced by losses of energy in the form of convection and evaporation.

The two equations describing these processes contain one common term: the surface temperature of the source for evaporation, but this could not be accurately measured in Penman's time, let alone recorded over long periods. Penman overcame this obstacle in an ingenious but essentially simple way: he solved the mass and energy balance equations simultaneously by eliminating surface temperature, the term common to both.

The success of this exercise led to the publication in the *Proceedings of the Royal Society of London* of 'Natural evaporation from open water, bare soil, and grass.' This paper rapidly achieved recognition as a major step advance with great potential benefits for both agronomists and for hydrologists. By a curious coincidence, the American geographer C.W. Thornthwaite, also in 1948, published, in the *Geographical Review*, a paper titled 'A rational approach to the classification of climate.' This included the proposal that rates of evaporation from both vegetation and water could be assessed from empirical correlations with air temperature. Once, at a meeting of meteorologists in the USA, Thornthwaite was asked to say what he thought of the Penman formula. He thought for a moment before replying, with the faint vestige of a smile: "What I really dislike about Penman's formula is that it's so empirical!" The non-American members of the audience were convulsed in laughter, leaving their American friends somewhat baffled!

The soil at Rothamsted is classified as 'clay with flints' in marked contrast to the light sandy soil at an outstation on sandy soil at Woburn. Penman was anxious to establish the extent to which crop growth and yield could be increased by irrigation but recognized that soil type would determine optimal schedules. Every spring, the younger members of his department were deployed to install irrigation spray-lines at both sites and every autumn they were housed for the winter. Practical conclusions from this work were brought together in a UK Ministry of Agriculture, Fisheries and Food Technical Bulletin (No. 4) which had several external co-authors, including L.P. Smith from the Meteorological Office, with whom Penman enjoyed a very fruitful working relationship. Details of measurements and their scientific implications were discussed in a major series of papers, published in the *Journal of Agricultural Science* in 1962.

Building on the success of local trials, Penman began to extend his expertise to the hydrology of catchments, particularly those that were forested, both in the UK and elsewhere in Europe. At the outset, he was convinced that because evaporation from vegetation was mainly limited by the supply of radiant energy, there should be little difference between annual totals for farmland and for forests. However, some of the early field work by staff at the Institute of Hydrology at Wallingford, Berkshire (whose Director, James McCulloch, had worked as a postgraduate with Penman) demonstrated unequivocally that forests lose significantly more water than crops exposed to the same climate, partly because they intercept more water and partly because they are aerodynamically much rougher. It was therefore inappropriate to use the same wind function for both types of vegetation, as Penman initially assumed.

Penman was very fortunate to have Ian Long among his staff, an experimental officer with unique skills in designing, building, and maintaining equipment. One of his most impressive achievements was the construction of a set of neutron probes for measuring the water content of soil as a function of depth; shortly after, this device became available commercially. In 1973, a report on extensive tests of this device occupied about 80 pages of the Rothamsted Annual Report for 1972. Under Penman's direction, Long acquired thermistors soon after they came on the market and used them for many years to provide long-term records of dry- and wet-bulb temperature.

Penman's success in estimating evaporation on a field scale encouraged him to move up to the catchment scale and eventually to the national scale by integrating catchment estimates. In 1950, a major paper on 'Evaporation over the British Isles' was published in the *Quarterly Journal of the Royal Meteorological Society*. This was followed in 1954 by 'Evaporation over parts of Europe,' presented to the General Assembly of the International Association for Scientific Hydrology.

Also in 1954, Penman collaborated with staff at the Ministry of Agriculture, Fisheries and Food and at the Meteorological Office to produce a Technical Bulletin on 'The calculation of irrigation need,' applicable to both agriculture and horticulture. Further afield, he contributed to a government publication on evaporation from Lake Volta.

In 1963, Penman initiated irrigation trials on the Rothamsted farm after getting permission for the drilling of a borehole. Using a neutron probe, changes of water content were monitored at regular intervals as

a function of depth and records for 13 seasons were eventually analysed. One major conclusion was that the soil water deficit at which growth became inhibited by drought was about 2.5 times larger than for the same crops grown on sandy soil at the Woburn farm.

The field study at Woburn, referred to above, ran for many years and major conclusions from this work were eventually published in a series of papers. The first three were published in the *Journal of Agricultural Science* in 1962, followed by a further group in 1970. Major sets of measurements made with the neutron probe were presented in Annual Reports of Rothamsted Experimental Station between 1969 and 1972 and a set of three major papers describing this work was published in the 1973 Report. Unfortunately, this valuable material did not find its way into the open literature.

Also in the 1960s, Penman began to use his formula to explore the hydrology of forested catchments in the UK and attended an International Symposium on Forest Hydrology at Pennsylvania State University to read a paper on the subject. This was followed by a review of the literature on evaporation from forests comparing field measurements with predictions from theory. On a much smaller scale, he became interested in the role that the stomata play in controlling the loss of water from leaves and collaborated with F.L. Milthorpe at the University of Nottingham to publish a paper on the diffusive conductivity of stomata on wheat leaves.

By this stage in his career Penman was much in demand as a speaker, partly because his work was of widespread interest to agronomists, ecologists, and meteorologists, but also because he lectured with admirable clarity and with occasional flashes of north-country humour. He also became involved in the management of scientific societies as a Councillor and Editorial Board member of the British Society of Soil Science, as Secretary of the London Branch of the Institute of Physics, as Secretary and eventually as President of the Royal Meteorological Society which elected him to Honorary Fellowship.

His help was sought by many national bodies: the Ministry of Agriculture for whom he helped advise the group that prepared a major report on 'The calculation of irrigation need'; the Institute of Water Engineers, the Meteorological Office, the Institute of Hydrology as it grew from a small unit to a major international centre. Further afield, he led the British delegation to meetings of the International Hydrological Decade and, in 1972, was host at the World Water Balance Symposium in Reading.

Away from his office, Penman's main interest was in music. During most of his time at Rothamsted, he was a member of the BBC Choral Society; but because this involved a fair amount of travelling and occasional nights away from home, he eventually joined the Bach Choir in nearby St Albans. However, he finally withdrew from this too because, as he explained "I almost sang a wrong note one day!" His repertoire included popular music, particularly folksongs in the strong Geordie accent that he enjoyed reverting to long after leaving Newcastle. Over the years, he accumulated an impressive collection of classical records, played on an early hi-fi system. This was a rare extravagance, for the habit of thrift acquired early in life remained with him even after he became a relatively prosperous Head of Department. He never owned a car, for example, and, twice a day, walked back and forth across Harpenden Common on the route between his very modest home in Rowan Way to his office at Rothamsted, which looked eastward over Harpenden Common. The fine view was sometimes partly obscured by smoke from Penman's pipe that became particularly dense when a new manuscript was on the stocks!

Penman's international reputation ensured that he had many opportunities to travel abroad, to lecture, and to discuss with colleagues a wide range of hydrological problems. These visits included Australia, Canada, Kenya, Lebanon, the Netherlands, the USA, and West Africa. These and many other countries have benefited immeasurably from his work. Throughout the world, water is an essential commodity but there are many regions where it is scarce so that prudent management and use are vital. Penman's formula made it possible to explore and provide answers to a wide range of major environmental problems such as the optimal application of water to crops in rain-scarce areas; the rate of loss of surface water from reservoirs; and, most recently, the hydrological implications of global warming. The economic value of the Penman formula for evaporation is therefore immeasurable.

PENMAN–MONTEITH EQUATION

R Allen, University of Idaho, Kimberly, ID, USA

© 2005, Elsevier Ltd. All Rights Reserved.

The Penman–Monteith (PM) evapotranspiration (ET) equation predicts the rate of total evaporation and transpiration from the earth's surface using commonly measured weather data (solar radiation, air temperature, vapor content, and wind speed). The PM equation follows a single-layer or 'big leaf' approach, where single-surface resistance and single aerodynamic resistance terms represent the transport properties of the cropped surface. The PM procedure provides scientists, engineers, and managers with the ability to evaluate effects of modifications to cultural practices and crop variety improvements on ET such as increased plant height, increased or reduced leaf size or density, reduced row spacing, and reduced stomatal conductance etc., by varying these parameters in the calculation algorithms. The PM method is useful in providing direction in determining changes in crop coefficients under new cropping conditions. Determination of crop coefficients is an expensive and time-consuming process, as it requires additional lysimeter or micrometeorological studies.

The PM equation has the form:

$$E \text{ or } \mathrm{ET} = \frac{\Delta(R_\mathrm{n} - G) + \rho_\mathrm{a} c_\mathrm{p}(e_\mathrm{s} - e_\mathrm{a})/r_\mathrm{a}}{\left(\Delta + \gamma\left(1 + \frac{r_\mathrm{s}}{r_\mathrm{a}}\right)\right)\lambda\rho_\mathrm{w}} \qquad [1]$$

where: Δ is the slope of the saturation vapor pressure vs. temperature curve; R_n is the net radiation flux at the surface; G is the sensible heat exchange from the surface to the soil (positive if the soil is warming); ρ_a is air density; c_p is specific heat of dry air; e_s is the saturation vapor pressure of the air at some height above the surface; e_a is the actual vapor pressure of the air; r_a is aerodynamic resistance to turbulent heat and/or vapor transfer from the surface to some height z above the surface; γ is the psychrometric constant (defined later); r_s is a bulk surface resistance that describes the resistance to flow of water vapor from inside the leaf, vegetation canopy, or soil to outside the surface; λ is the latent heat of vaporization, defined as the energy required to convert a mass of liquid water into vapor (having typical units of joules per kilogram); ρ_w is density of liquid water. All parameter units in eqn [1] must cancel so that the remaining units for evaporation (E) or ET (depending on application to evaporation from soil or ET from soil and vegetation) are presented as L T^{-1}, for example, in millimeters per hour or millimeters per day.

Surface resistance r_s may represent the resistance to vapor flow through plant leaf stomates and/or resistance to vapor flow within soil to the soil surface. For a wet (saturated) surface, r_s is by definition zero. When r_s is zero, eqn [1] reverts to the original Penman equation.

Derivation of the Penman–Monteith Equation

It is useful to review the derivation of the PM equation in order to understand how and why it functions. There are two fundamental approaches to predict E (or ET). These are the surface energy balance equation and the aerodynamic equation. Each equation uses a different approach and each has difficulties for solution when using typical weather data comprised of solar radiation, air temperature, vapor pressure, and wind speed. Penman combined these two approaches into the so-called combination or Penman equation that could be solved using standard weather data only. Monteith later improved on the Penman equation by including a surface resistance term and a more rigorous term for aerodynamic transfer. It is useful to review the combination of the two approaches.

The surface energy balance equation relates to the various ways in which net radiation energy from the sun and atmosphere is balanced at the surface by inputs or outputs of energy from nonradiative parameters. The vertical energy balance at the surface is the sum of sensible heat flux to or from the air and to or from the soil, along with latent heat flux, net radiation, and other miscellaneous fluxes. The major components of the vertical energy balance are expressed as:

$$R_\mathrm{n} = G + \lambda E + H \qquad [2]$$

where λE is the latent heat flux (positive during evaporation) and H is the sensible heat exchange from the surface to air (positive if the air is warming). In eqn [2], E (or ET) is expressed in terms of the energy required to convert the amount of liquid evaporated into vapor by multipling by λ. The miscellaneous terms involved in the surface energy balance, such as heat storage within foliage, photosynthesis, and respiration, are generally insignificant relative to magnitudes of R_n, λE, H, and G, and are commonly

neglected. Under some conditions, change in heat storage in a canopy may need attention, especially in forest canopies. If R_n and sensible heat flux densities H and G can be measured or estimated reliably, then the latent heat flux density, λE, can be computed from eqn [2].

$$\lambda E = R_n - G - H \quad [3]$$

The challenge to the solution of eqn [3] using standard weather data is in solving for H. The traditional aerodynamic expression H is:

$$H = \frac{\rho c_p (T_o - T_a)}{r_{ah}} \quad [4]$$

where T_o is surface temperature, T_a is air temperature, and r_{ah} is the aerodynamic resistance to heat transfer between some mean height within the surface to some height a few meters above the surface. Generally, r_{ah} is assumed equal to r_a of eqn [1].

Equation [4] is analogous to Ohm's law for electrical current flow, where T_o and T_a are equivalent to voltages or potentials, r_{ah} is equivalent to an electrical resistor, and H is analogous to current. Thus, eqn [4] behaves as a linear electrical circuit, so that if the difference between T_o and T_a is doubled, H will double. If resistance r_{ah} is halved (through a doubling of wind speed), then H will double.

The challenge of eqn [4] and thus eqn [3] is in the parameter T_o. T_o can be measured using infrared thermometers, if surface emissivity is known, or it can be measured using a fine thermocouple or other temperature sensor placed just beneath the surface skin. However, these measurements are not common due to the high operational and maintenance requirements of the instruments and difficulty in transfer of measured values to other locations and surface conditions, even those nearby.

The traditional equation for r_{ah} (and r_a) is:

$$r_{ah} = \frac{\left(\ln\left(\frac{z_u - d}{z_{om}}\right) - \psi_m\right)\left(\ln\left(\frac{z_T - d}{z_{oh}}\right) - \psi_h\right)}{k^2 u_z} \quad [5]$$

where: z_u is the height above the ground surface for the wind speed measurement, d is the zero plane displacement of the logarithmic wind profile, z_{om} is a roughness length governing the transfer of momentum from the surface, ψ_m is a correction factor for momentum transfer to account for buoyant instability or stability of the boundary layer, z_T is the height of the air temperature measurement above the ground surface, z_{oh} is an assumed roughness length governing the transfer of sensible heat from the surface, ψ_h is a correction factor for sensible heat transfer to account for buoyant instability or stability of the boundary layer, k is the von-Karman constant (0.41), and u_z is the wind speed measured at the z_u height. Equation [5] is sometimes criticized for its use of z_{oh}, commonly expressed as some constant fraction of z_{om}, whereas in reality the ratio of $z_{oh}:z_{om}$ can vary substantially, especially for dry, sparse vegetation. Other forms of eqn [5] can be written that rely on differences in T_a and wind speed at two different heights above the surface. These forms eliminate the need for z_{oh}; however, measurement of T_a and wind speed at two heights is not common and it is challenging to produce an unbiased pair of measurements. A variety of studies have investigated the effects of foliage density and geometry on apparent bulk roughness of vegetation.

The aerodynamic-based expression for λE is:

$$\lambda E = \frac{\rho c_p (e_o - e_a)}{\gamma (r_{av} + r_s)} \quad [6]$$

where e_o is vapor pressure 'inside' the surface, for example inside a leaf stomatal cavity or beneath the soil skin, e_a is vapor pressure of the air at some height z above the ground surface, γ is the pyschrometric constant, r_{av} is aerodynamic resistance to turbulent vapor transfer from the surface to some height z above the surface, and r_s represents any surface resistance to flow of vapor (defined after eqn [1]).

Aerodynamic resistance r_{av} is computed exactly as for r_{ah}, i.e., using eqn [5], except that z_T becomes z_v (height of vapor pressure measurement above the ground), z_{oh} becomes z_{ov}, which is an assumed roughness length governing the transfer of vapor from the surface, and ψ_h becomes ψ_v, a correction factor to account for the effect of instability or stability of the boundary layer on vapor flow. Generally, $z_T = z_v$ (air temperature and humidity sensors are usually collocated at the same height), and z_{ov} is assumed equal to z_{oh}, and ψ_v is assumed equal to ψ_h. Brutsaert and Allen have shown that the stability parameters ψ_v, ψ_h, and ψ_m can generally be set to zero when predicting ET from well-watered (moist) surfaces because of nearly neutral stability (buoyancy) for those conditions.

Again, the aerodynamic vapor transfer equation is analogous to Ohm's law, where e_o and e_a are equivalent to voltages or potentials, r_{av} and r_s are equivalent to electrical resistors in series, and λE (vapor flux) is analogous to electrical current.

Vapor pressure of air can be determined from paired measurements of relative humidity and air temperature, which are commonly available, or from measurement of dew-point temperature, also commonly available. Vapor pressure inside the soil

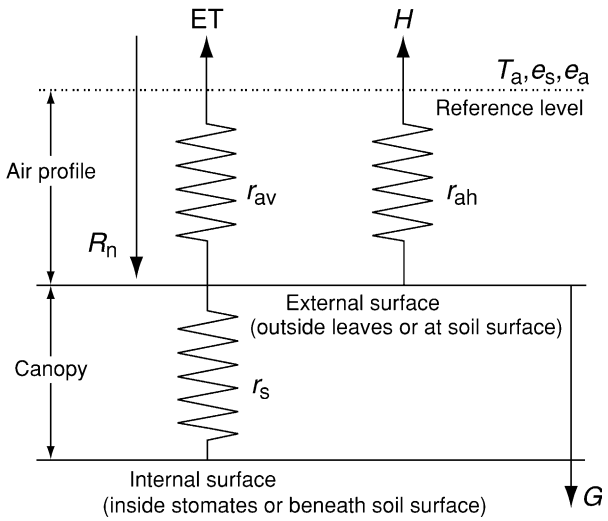

Figure 1 Schematic showing linkage between resistance terms in the Penman–Monteith equation relative to the surface and elevation of temperature and humidity measurements. ET, evapotranspiration; e_s, saturation vapor pressure at mean air temperature; e_a, actual vapor pressure of the air; G, heat exchange from surface to soil; H, heat exchange from surface to air; r_a, aerodynamic resistance; r_s, bulk surface resistance; R_n, net radiation flux at the surface; T_a, air temperature; r_{av}, aerodynamic resistance to vapor transfer; r_{ah}, aerodynamic resistance to heat transfer.

or plant surface is rarely measured, however, so that, as with eqn [3], eqn [6] is challenging to apply in routine practice. Hence the need for the Penman or PM combination equation.

Figure 1 is a schematic showing the relative locations of resistances r_a (or r_{ah} and r_{av}) and r_s, where r_s represents the internal resistance of the soil (if no vegetation) or of the soil, leaves, and canopy in parallel.

To create the PM equation, one needs to define what is known as the Bowen ratio, which is simply the ratio between H and λE. Expanded into the equations for H and λE and written for transfer from inside the surface to the air above:

$$\beta = \frac{H}{\lambda E} = \frac{\rho c_p (T_o - T_a)\gamma (r_{av} + r_s)}{\rho c_p (e_o - e_a)(r_{ah})} \quad [7]$$

Cancelling similar terms:

$$\beta = \frac{H}{\lambda E} = \gamma \frac{(T_o - T_a)(r_{av} + r_s)}{(e_o - e_a)(r_{ah})} \quad [8]$$

The energy balance equation can be rearranged and written as:

$$\lambda E = \frac{R_n - G}{1 + \beta} = \frac{R_n - G}{1 + \gamma \frac{(T_o - T_a)(r_{av} + r_s)}{(e_o - e_a)(r_{ah})}} \quad [9]$$

The next step in the derivation of the PM equation is to define the term Δ, which is defined as the slope of the saturation vapor pressure vs. temperature relation. Saturation vapor pressure $e^o(T)$ is a singular function of T and describes the ability of air to hold more vapor as temperature increases. The slope Δ of the $e^o(T)$ vs. T curve can be expressed as a linear approximation for a segment of the saturation curve between two temperatures T_o and T_a:

$$\Delta = \frac{e_o - e_s}{T_o - T_a} \quad [10]$$

where e_o, e_s, T_o and T_a were defined previously. Vapor pressure inside the surface, e_o, is assumed to be saturated and is therefore equivalent to e^o (T_o). e_s is the saturation vapor pressure associated with T_a, so that $e_s = e^o$ (T_a). In practice, Δ is often calculated as the slope of e^o (T) vs. T at T_a only, since T_o is usually not known.

Using the relationship from eqn [10] to define $(e_o - e_s)/\Delta = T_o - T_a$ and parsing $(e_o - e_s)$ into an equivalent expression of $(e_o - e_s) = (e_o - e_a) - (e_s - e_a)$ so that $T_o - T_a = [(e_o - e_a) - (e_s - e_a)]/\Delta$, this expression is substituted into eqn [9] so that:

$$\begin{aligned}\lambda E &= \frac{R_n - G}{1 + \beta} \\ &= \frac{R_n - G}{1 + \frac{\gamma}{\Delta}\frac{[(e_o - e_a) - (e_s - e_a)](r_{av} + r_s)}{(e_o - e_a)(r_{ah})}} \\ &= \frac{R_n - G}{1 + \frac{\gamma}{\Delta}\left[1 - \frac{(e_s - e_a)}{(e_o - e_a)}\right]\frac{(r_{av} + r_s)}{r_{ah}}}\end{aligned} \quad [11]$$

We define one more temporary term, λE_a, after Penman:

$$\lambda E_a = \frac{\rho c_p (e_s - e_a)}{\gamma r_{ah}} \quad [12]$$

where λE_a is similar to eqn [6], the aerodynamic expression for λE, except that r_s is omitted and $(e_o - e_a)$ is replaced with $(e_s - e_a)$. E_a is a fictitious term that allows the elimination of surface parameters T_o and e_s in the final PM equation. Term $(e_s - e_a)$ is known as the vapor pressure deficit (VPD) of the air, because it represents the difference between the saturation vapor pressure at air temperature $(e_s = e^o$ $(T_a))$ and actual vapor pressure of the air (e_a). Both e_s and e_a can be determined from commonly available humidity and air temperature data measured at some height above the surface, generally 1.5–2 m. Because:

$$\frac{e_s - e_a}{e_o - e_a} = \frac{\lambda E_a}{\lambda E}\frac{r_{ah}}{r_{av} + r_s} \quad [13]$$

Then eqn [11] becomes:

$$\lambda E = \frac{R_n - G}{1 + \frac{\gamma}{\Delta}\left[1 - \frac{\lambda E_a}{\lambda E}\frac{r_{ah}}{r_{av} + r_s}\right]\frac{r_{av} + r_s}{r_{ah}}} \quad [14]$$

Rearranging eqn [14] and setting $r_{av} = r_{ah}$ results in the PM equation:

$$\lambda E = \frac{\Delta(R_n - G) + \gamma\lambda E_a}{\Delta + \gamma\left(1 + \frac{r_s}{r_{ah}}\right)} = \frac{\Delta(R_n - G) + \rho c_p(e_s - e_a)/r_{ah}}{\Delta + \gamma\left(1 + \frac{r_s}{r_{ah}}\right)} \quad [15]$$

where, in eqn [15], E is expressed in terms of energy, rather than in terms of depth of liquid water as in eqn [1]. The PM equation has the extremely valuable advantage of requiring only commonly available weather data, namely solar radiation (used to calculate R_n), air temperature (used to calculate ρ, e_s and Δ), air humidity (used to calculate e_a and assist with R_n), and wind speed (for r_{ah}). Parameter G is generally estimated as a function of R_n or by direct measurement, and r_s is generally estimated as a function of amount of vegetation or amount of surface wetness if soil. The PM (and Penman equation where r_s is assumed zero and $1/r_{ah}$ is replaced by a more simple empirical 'wind function') are widely used around the world as a standard means to predict E and ET.

Other Parameters in the Penman–Monteith Equation

The psychrometric constant γ is computed as:

$$\gamma = \frac{c_p P}{\lambda\epsilon} \quad [16]$$

where $c_p = 1.013\,\mathrm{kJ\,kg^{-1}\,K^{-1}}$ for moist air, P is atmospheric air pressure, λ is the latent heat of vaporization in kilojoules per kilogram, and $\epsilon = 0.622$ is the ratio of molecular weights of water vapor to air. For P in kilopascals, γ will have units of kilopascals per degrees celsius. Mean atmospheric air pressure, P, can be computed routinely as a function of surface elevation using the ideal gas law as:

$$P = P_{os}\left(\frac{T_{os} - \alpha(\mathrm{elev} - \mathrm{elev}_{os})}{T_{os}}\right)^{g/(\alpha_a R)} \quad [17]$$

where: P_{os} and T_{os} are standard atmospheric pressure in kilopascals and absolute temperature in degrees Kelvin at elevation elev_{os}, and elev is elevation of the ground surface above mean sea level; α_a is the assumed constant adiabatic lapse rate, normally taken as $0.0065\,\mathrm{K\,m^{-1}}$ for saturated air or sometimes as $0.01\,\mathrm{K\,m^{-1}}$ for nonsaturated air; g is gravitational acceleration, $9.807\,\mathrm{m\,s^{-2}}$, and R is the specific gas constant for dry air, $287.0\,\mathrm{J\,kg^{-1}\,K^{-1}}$. Values for P_{os}, T_{os}, and elev_{os} are commonly taken for the standard atmosphere at sea level, which are 101.3 kPa, 288 K, and 0 m, respectively. Equation [17] is relatively insensitive to the value of α_a for elevations up to 3000 m.

Air density, ρ, can be computed as:

$$\rho = \frac{1000\,P}{T_v\,R} \quad [18]$$

where P is in kilopascals, R is $287.0\,\mathrm{J\,kg^{-1}\,K^{-1}}$, and T_v is virtual temperature, in degrees Kelvin. T_v can be computed as:

$$T_v = \frac{T}{1 - 0.378\frac{e_a}{P}} \quad [19]$$

where T is air temperature in Kelvin and e_a is mean vapor pressure of the air (kilopascals). Latent heat of vaporization, λ, in megajoules per kilogram can be computed as:

$$\lambda = 2.501 - 2.361 \times 10^{-3}\,T \quad [20]$$

where T is mean air temperature in degrees Celsius. If available, mean surface temperature or wet bulb temperature can be used to compute the value of λ, which better represents conditions at the evaporating surface.

The PM equation can be applied for short periods of 1 h or less, and is intended to represent nearly instantaneous fluxes of ET. However, the equation has traditionally been applied for daily and longer (up to 1 month) calculation time-steps owing to paucity of weather data. For daily and longer time-steps, e_s in the PM equation should be computed as:

$$e_s = \frac{e^o(T_{max}) + e^o(T_{min})}{2} \quad [21]$$

where T_{max} and T_{min} are maximum and minimum daily air temperature for the period and e^o is the saturation vapor pressure function. Actual vapor pressure of the air, e_a, can be computed from relative humidity data, from wet-bulb/dry-bulb pyschrometer data, or from dew-point temperature measurements:

$$e_a = e^o(T_d) \quad [22]$$

where T_d is mean daily or early morning dew-point temperature.

Aerodynamic and Surface Parameters

When used to predict ET from dense vegetation, aerodynamic resistance in the PM equation can

be calculated using parameters for d, z_{om}, and z_{oh} determined as a function of vegetation height:

$$d = 0.67H \quad [23]$$

$$z_{om} = 0.12H \quad [24]$$

$$z_{oh} \approx 0.1 z_{om} \quad [25]$$

where z_{om}, z_{oh}, d, and mean plant height, H, are in meters. For bare soils, common values for z_{om} range from 0.00 001 m for mud flats to 0.005 m for smooth soil to 0.01 m or more for very roughly ploughed soil.

Parameterization of Surface Resistance

The bulk surface resistance r_s for a crop is an integration of effects of transpiration from various locations within the vegetation and contributions from soil evaporation, along with transfers of radiation and sensible heat within the canopy. Simple approaches determine soil evaporation indirectly by estimating the distribution of net radiation below and between a plant canopy having partial ground cover. For crops that completely shade the ground, total surface resistance can be computed, where surface resistances from soil and vegetation are added in parallel according to leaf area and radiation extinction coefficients. For an immature row crop having exposed bare soil between plant rows and incomplete wetting of the soil surface during irrigation, r_s can be expressed through a combination of various surface resistances acting in parallel. The combination is made according to the fractions of surface C represented by each parallel resistance component (Figure 2):

$$\frac{1}{r_s} = \frac{C(1 - K_r^{LAI/C})}{r_{sc}} + K_r^{LAI/C}\left(\frac{C_{sW}}{r_{sssW}} + \frac{C_{sD}}{r_{sssD}}\right) + \frac{C_{eW}}{r_{sseW}} + \frac{C_{eD}}{r_{sseD}} \quad [26]$$

where C is the effective fraction of ground shaded by vegetation and is computed as a function of sun angle, row height and width, leaf density, and row orientation; and C_{sW}, C_{sD}, C_{eW}, and C_{eD} are the fractions of the soil surface that are shaded and wet, shaded and dry, sunlit and wet, and sunlit and dry ($C_{sW} + C_{sD} + C_{eW} + C_{eD} = 1$ and $C_{sW} + C_{sD} = C$). Resistance r_{sc} is the surface resistance of the canopy, r_{sssW} is the surface resistance of wet, shaded soil; r_{sssD} is the surface resistance of dry, shaded soil; r_{sseW} is the surface resistance of wet, sunlit soil; and r_{sseD} is the surface resistance of dry, sunlit soil. Parameter K_r is a radiation extinction coefficient for the vegetation canopy, having a value of approximately 0.7; and LAI is leaf area index.

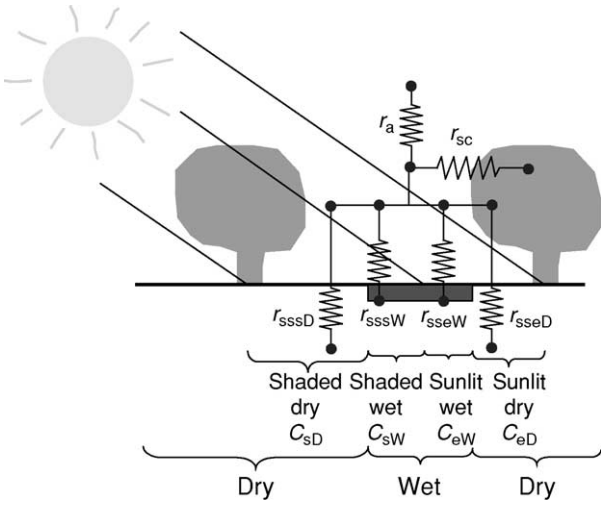

Figure 2 Schematic showing breakdown and definition of surface resistances for soil when vegetation is at partial cover. r_a, aerodynamic resistance; r_{sc}, surface resistance for the vegetation cover; r_{sssW}, surface resistance of wet, shaded soil; r_{sssD}, surface resistance of dry, shaded soil; r_{sseW}, surface resistance of wet, sunlit soil; r_{sseD}, surface resistance of dry, sunlit soil; C_{sD}, fraction of the soil surface that is shaded and dry; C_{sW}, fraction of the soil surface that is shaded and wet; C_{eW}, fraction of the soil surface that is sunlit and wet; C_{eD}, fraction of the soil surface that is sunlit and dry.

C has also been computed as LAI/4. Separate PM equations have been applied for evaporation and transpiration and then recoupled, similar to the procedure for multilayer ET models. For sun angles other than directly overhead, C can be estimated for a row crop as:

$$C = \frac{W + H\,|\sin(\eta + \beta)|\tan\theta_z}{S} \quad [27]$$

where H is mean plant height, θ_z is the solar zenith angle (zero = nadir (overhead)), η is the sun azimuth angle ($\eta = 0$ when sun is due south, η is negative when sun is east of south, and η is positive when sun is west of south), and β is the row orientation relative to north ($\beta = 0$ for north–south orientation, $\beta = 90°$ for east–west row orientation), W is row width, and S is row spacing. Equation [27] presumes a nearly rectangular row shape of height H and width W and has an upper limit of $C = 1$. In some situations, W may not be measured or available, but an estimate of LAI may be available. In this case, C may be approximated during incomplete row closure as:

$$C = \frac{\text{LAI}}{\text{LAI}_C} + \frac{H}{S}\,|\sin(\eta + \beta)|\tan\theta_z \quad [28]$$

where LAI_C is the LAI at complete row closure and shading of the ground. The value for C and, subsequently, for r_s changes with time of day and interacts with R_n, G, wind speed, and temperature. For 24-h computation time-steps, an average daily value for C is determined for computing soil moisture balances for shaded and unshaded soil. An average daily value for C for east–west rows can be determined by weighting eqn [26] for sunlight intensity and integrating between the limits of sunrise and sunset. For north–south row orientation, all soil is sunlit and shaded at various times of the day.

Surface resistance, r_{sc}, for densely growing vegetation is often computed in the 'single-layer' PM as a function of leaf area by assuming all leaves function as resistors in parallel:

$$r_{sc} = \frac{r_l}{LAI_{eff}} \qquad [29]$$

where r_l is the bulk stomatal (or surface) resistance of the vegetation per unit LAI (seconds per meter) and LAI_{eff} is the effective LAI contributing to ET. Parameter r_l is the inverse of g_l, the stomatal conductance per unit leaf area. The value of r_l has been taken as $100\,s\,m^{-1}$ for many well-watered agricultural crops when calculations are made on a 24-h basis. When ET calculations are made on an hourly or shorter basis, r_l for agricultural crops has a value of approximately $70–80\,s\,m^{-1}$, assuming that stability corrections are made or that buoyancy conditions are nearly neutral. The value for r_l increases with environmental stresses, including soil moisture deficit.

Surface resistance, r_{sc}, plays an important role in controlling the flux of transpiration from plants into the atmosphere and must be accurately predicted for routine application of the PM and multilayer ET models. r_{sc} represents the ET-averaged daily resistance for 24-h calculation time steps or the mean canopy resistance for hourly time steps for a fully developed canopy. Algorithms are used to modify r_{sc} as leaf area (LAI) and environmental parameters change. General, simple environmental stomatal regulation algorithms have been proposed, where bulk surface resistance is expressed in terms of multiplicative products of linear functions of solar radiation, air temperature, vapor pressure deficit, and soil water deficit.

Soil resistance is generally assumed to increase with drying of soil. Exponential functions describe the process relatively well. A moisture-based soil resistance function describes experimental data from a Portneuf silt loam soil near Kimberly, Idaho:

$$r_{ss} = 2000e^{-5x_s} \qquad [30]$$

where x_s is the remaining proportion of water in the evaporating layer of the soil surface and e is the natural number. x_s is computed as $x_s = W_{ei}/W_{emax}$, where W_{ei} is the total evaporable moisture near the soil surface on day i and W_{emax} represents the upper limit of evaporable water. A daily or more frequent water balance of the C_{sW}, C_{sD}, C_{eW}, and C_{eD} fractions of the soil surface layer need to be conducted to predict x_s, and thus r_{ss}, for each surface fraction. The evaporation from each fraction is predicted in some proportion to ratio of the inverse of r_{ss} for that fraction to the total bulk r_s for the soil–canopy complex. The soil surface layer is typically presumed to be 0.1–0.15 m thick. Equation [30] predicts values for r_{ss} ranging from approximately $50\,s\,m^{-1}$ directly after wetting to approximately $2000\,s\,m^{-1}$ for a relatively dry surface soil layer.

Multilayer ET Models

The PM equation is basically a single-layer model where the resistances for vegetation and soil are assumed to reside in parallel, i.e., there are no intermediate aerodynamic or convective resistances separating them or within them. More complicated, multilayer ET models have been employed that contain sophisticated parameter algorithms, intermediate resistances, and relatively complex calculation mechanisms than the PM. Multilayer models decompose the computation of r_s, r_{sc}, and r_a for discrete layers within the vegetation canopy. These models are generally capable of making more accurate predictions of ET than the PM, especially for short time-steps (hourly). Because of their increased complexity, multilayer models can provide more capability and flexibility in predicting ET under variable cropping and weather conditions without the need for calibration, depending on the physical basis of internal mechanisms. On the other hand, these models sometimes require substantial calibration of empirical coefficients internal to the model.

Net Radiation

Net radiation, R_n, can be measured using a net radiometer that measures downward and upward fluxes of shortwave and longwave radiation. The surface beneath the net radiometer must be very similar in wetness and vegetation type and amount to that being predicted in the PM equation. In many situations, R_n data are not available for a specific surface or condition, and therefore must be estimated from solar radiation data, air temperature, and possibly vapor pressure. R_n for row crops is often calculated by separately considering the reflectances (albedo) for

soil and vegetation. When calculated, the general formula for R_n is:

$$R_n = (1 - \alpha)R_s + R_{nl} \quad [31]$$

where α is the albedo of the surface, representing the crop-soil mixture, R_s is incoming shortwave radiation (measured by a pyranometer), and R_{nl} is net (incoming − outgoing) longwave radiation. R_{nl} is commonly predicted from air temperature and humidity data from a local weather station.

A general formula for α of a crop-soil mixture is:

$$\alpha = C\alpha_c + (1 - C)\alpha_s \quad [32]$$

where α_c is plant albedo, α_s is soil albedo, and C is the relative fraction of vegetation cover (defined previously) that considers effects of sun angle. Plant albedo can be computed by choosing typical values at the key growth stages. For example, values of α_c have been found to be 0.25, 0.23, 0.23, and 0.30 for beans at Kimberly, Idaho, at emergence, effective cover, ripening, and harvest. Values are 0.25, 0.15, 0.15, and 0.35 for wheat for the same stages. For overcast conditions the value for α_c increases, often to approximately 0.35.

Soil albedo in eqn [32] can be computed as a composite of wet soil and dry soil albedo:

$$\alpha_s = \frac{\alpha_{sM} C_{eW} + \alpha_{sD} C_{eD}}{C_{eW} + C_{eD}} \quad [33]$$

where α_{sM} is albedo of moist soil and α_{sD} is albedo of dry soil. The albedo of a moist, drying soil can be assumed to vary linearly with water content between the value for a fully wet soil and a fully dry soil over a given drying period:

$$\alpha_{sM} = \alpha_{sW} + (\alpha_{sD} - \alpha_{sW})(1 - x_{skin}) \quad [34]$$

where α_{sW} is albedo of wet soil and x_{skin} is the fraction of remaining water in the soil skin (top approx. 1 cm). Example values for α_{sW} and α_{sD} for the Portneuf silt loam near Kimberly are $\alpha_{sW} = 0.10$–0.20 and $\alpha_{sD} = 0.35$.

Soil Heat Flux

The magnitude of soil heat storage or release can be significant over a few hours, but is usually small from day to day because heat stored early in the day as soil warms is lost late in the day and at night as the soil cools. For application of PM to short periods, e.g., using hourly data, measurements or estimates for G are required.

One method commonly used in research is the use of heat flux plates installed at shallow depths below the soil surface (e.g., at 0.01 m). Measurements by soil heat flux plates, G_{zs} at some depth z_s are adjusted to represent G at the soil surface by incorporating the change in heat storage between the soil surface and heat flux plate:

$$G = G_{z_s} + C_s \int_0^{z_s} \frac{\partial T_s}{\partial t} dz \quad [35]$$

where $\partial T_s/\partial t$ is the change in temperature with time within the z_s thick layer above the heat flux plate. Temperature is usually measured with thermocouples or buriable thermistors.

Soil heat flux density for dense, short vegetation such as for grass, wheat, or alfalfa can be approximated during daylight periods as:

$$G = 0.4e^{-0.5\,LAI} R_n \quad [36]$$

where e is the natural number and G has the same units as R_n. Equation [36] predicts $G = 0.1\,R_n$ for an LAI = 2.8, which is typical for clipped grass. A low fraction of G/R_n (0.036) has been used during daylight for a deciduous forest. The American Society of Civil Engineers (ASCE) recommends $G/R_n = 0.04$ for full-cover alfalfa during daytime. For LAI = 0 (i.e., bare soil), eqn [36] predicts $G/R_n = 0.4$.

For nighttime under grass forage, the recommendation is $G = 0.5\,R_n$ for grass and 0.2 for full-cover alfalfa. In these reported ratios, the effects of seasonal variations are not addressed. The seasonal lag of soil temperature behind solar radiation can be expected to produce higher ratios.

Application of the Penman–Monteith Equation

Besides direct application of the PM equation to a complex surface of soil and vegetation or to soil only, the equation has been widely used to represent ET from a reference vegetation crop for use in irrigation management. The reference crop ET (ET_o) represents ET from either a cool-season clipped grass or a tall, full-cover alfalfa crop, depending on the parameters specified for aerodynamic and surface resistances.

When the PM equation is used as an ET reference, actual ET for a soil or soil–vegetation surface is computed by multiplying ET_o by a crop coefficient, K_c, where K_c represents the ratio of actual ET to ET_o. The value for K_c of soil is varied according to the moisture level of the soil. Figure 3 shows a comparison of hourly ET predicted by the ASCE version of the PM equation and ET measured by a precision-weighing lysimeter (essentially a huge flowerpot suspended

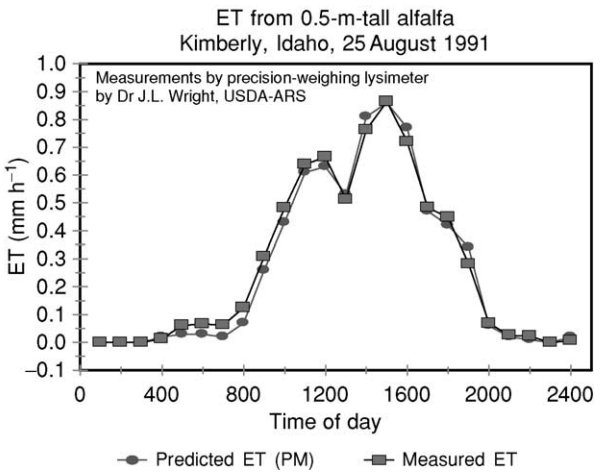

Figure 3 Comparison between evapotranspiration (ET) during hourly periods predicted by the Penman–Monteith (PM) equation (using parameters from the American Society of Civil Engineers) and ET measured by a precision-weighing lysimeter.

below ground via mechanical balances). The PM estimates, based on measured solar radiation, air temperature, humidity, and wind speed, agree very well with field measurements. Results are not always this good, however, and depend on the representativeness of values for roughness and for surface resistance.

PESTICIDES

R H Bromilow, Rothamsted Research, Harpenden, UK

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Pesticides are used worldwide and increase crop yield on average by 30% as well as improving crop quality. Modern organic (i.e., carbon-containing) pesticides have been used widely since the late 1940s, and so there is over 50 years of experience of their behavior in the environment and their impact upon it. The spectrum of compounds applied over this time has changed substantially, with, for example, the older organochlorine insecticides being phased out and with completely new types of chemical structures being regularly introduced. Though increasingly strict registration criteria, coupled with market forces, are leading to the discontinuation of the use of many older compounds, it is likely that several hundred active ingredients will remain available. In the European Union, for example, perhaps 300 of approximately 850 formerly approved compounds will still be marketed after the current review process.

The soil is the ultimate sink for much of the pesticide that is applied to crops or indeed to uncropped land such as railway tracks. Compounds such as nematicides (for control of plant-parasitic nematode worms) are usually incorporated into the topsoil. Many herbicides used in arable crops are applied either to bare soil prior to emergence of the sown crop or to the seed bed immediately postgermination, and so most of the compounds directly reach the soil surface. In contrast, insecticides and fungicides are

usually applied later in the season when the crop may have closed its canopy, and so most compound will be intercepted by the crop foliage; even so, some spray will drift down, and wash-off by rain may subsequently move more compound to the soil. The rates at which pesticides are applied vary widely: a typical arable field in the UK in 2003 received approximately $4\,kg\,ha^{-1}$ of pesticide active ingredients in total per annum, though an intensively sprayed crop such as potatoes averages $15\,kg\,ha^{-1}$.

To understand the behavior of so many diverse compounds, it is necessary to develop an overarching framework of understanding based on the physicochemical properties and degradative behavior of each compound. The behavior of new pesticides can then be assessed by comparison or benchmarking with current compounds of similar properties. Important aspects of pesticide behavior in soil to be considered are persistence, sorption, movement with its potential for contamination of water, uptake by plants, and possible impacts on soil biota and microbial processes.

Physicochemical Properties of Pesticides

The distribution of pesticides amongst the different environmental compartments, including the soil phases and the organisms living both in and on soil, is largely determined by the physicochemical properties of the compound. For example, vapor pressure determines the propensity of a pesticide to be lost by volatilization from a soil surface. If the soil is wet, then the Henry Law constant (the distribution coefficient between water and air) gives a better predictor:

$$H' = \frac{T}{273} \cdot \frac{\mathrm{VP}\,10^{-5}}{22.4\mathrm{WS}} \qquad [1]$$

where H' is the dimensionless Henry Law constant, VP is the vapor pressure (in pascals), and WS is the water solubility (in moles per liter) measured at temperature T (Kelvin). Organic compounds with high H' will have high concentrations in the vapor phase compared with the soil water. As diffusion in air is approximately 10^4 times faster than in water, then this region defines the boundary between movement predominantly via the air and via the water phase in soil (Figure 1).

Water solubility is an easily understood and oft-quoted property. However, lipophilicity, essentially a measure of the partitioning between water and lipid-like organic phases, is a better predictor of many processes, such as accumulation by organisms. To have comparable measurements, lipophilicity is

normally assessed as the 1-octanol/water partition coefficient, K_{ow} (usually expressed as $\log_{10} K_{ow}$). Some pesticide classes span quite a narrow range of lipophilicity, whereas others span up to 7 orders of magnitude of K_{ow} (Figure 2). For compounds that are acids or bases, lipophilicity will depend on the balance of nonionized and ionized forms present; this is determined by the pH and the compound pK_a (the pK_a is the pH at which a particular acid or base function is 50% ionized). Ionized compounds are much less lipophilic (i.e., much more polar) than their undissociated forms.

Rates of degradation influence the depth of penetration into soil and degree of accumulation by biota; these rates generally need to be measured, for only approximate and often uncertain estimates can be made knowing the chemical structure.

Persistence in Soil

Loss Processes and Factors of Influence

Degradation is the main loss process for most pesticides in soil. Initial breakdown may be by biotic or abiotic processes, the latter including photolysis as well as chemical reactions such as hydrolysis and oxidation. However, the further extensive breakdown of complex fragments such as phenyl rings will be an essentially biotic process, with many species of microfungi, bacteria, and actinomycetes able to participate in the various steps. Thus a pesticide reaching soil will be subject to breakdown, leading to a sequence of metabolites or degradation fragments whose ultimate fate is mostly to be oxidized to CO_2 or incorporated into the polymeric matrix of the soil organic matter. This organic matter is itself constantly undergoing slow degradation, balanced by input of fresh organic matter such as crop residues such that an equilibrium level is reached over a number of years.

In soils, the rate of pesticide breakdown under constant conditions of temperature and moisture usually approximates to first-order kinetics, i.e., the rate of decomposition is proportional to the amount remaining:

$$\frac{dc}{dt} = -kc \qquad [2]$$

where c is pesticide concentration, t is the time, and k the rate constant. This is akin to radioactive decay, and by analogy a half-life can be proposed. The half-life ($t_{1/2}$) is estimated by plotting the logarithm of the amount of compound remaining against time, which should approximate to a straight line (Figure 3a). Integrating eqn [1], the rate constant k (units are per time) can then be calculated from:

$$k = \frac{\ln 2}{t_{1/2}} \qquad [3]$$

In the field, however, soil conditions of temperature and moisture can vary considerably over the lifetime of a pesticide, and this influences loss rates. Within

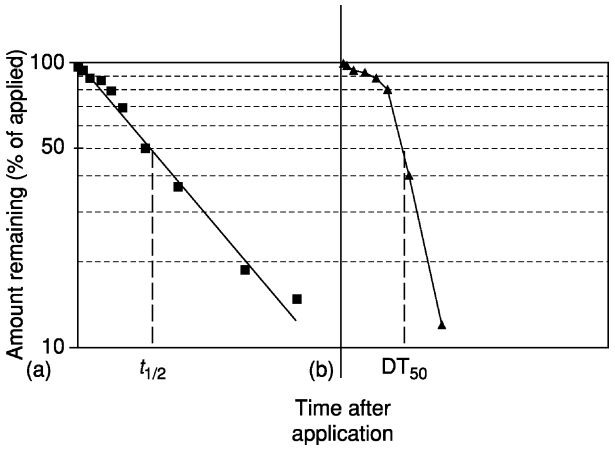

Figure 3 Kinetics of pesticide degradation in soil under constant conditions: (a) first-order kinetics showing the estimation of half-life; (b) microbial adaptation, showing a lag phase followed by rapid breakdown.

the normal range of ambient temperatures, a 10°C rise in temperature increases breakdown rates by two- to threefold both for abiotic and biotic degradation. In frozen soils, breakdown is usually very slow or negligible.

Most of the breakdown of pesticides by microorganisms is incidental to the general breakdown and turnover process of organic matter in soil, and so does not change the microbiota. The quantity of organic material present in the pesticide is normally a minute fraction of that being decomposed naturally in soil. However, occasionally certain pesticides or their metabolites, despite their low concentrations in soil, can be used as a food source by one or more species of microorganisms, and this is known as 'microbial adaptation.' The kinetics of breakdown then follow an initial lag phase, during which the population of the adapted organism increases until it reaches such levels that the pesticide is very rapidly degraded (**Figure 3b**). A second application would be immediately degraded. It should be noted that certain pesticides (e.g., preemergence herbicides and soil insecticides) need to persist in soil for a reasonable length of time if they are to be effective (e.g., several weeks), and such microbial adaptation with its concomitant rapid breakdown has thus limited the efficacy of some compounds, e.g., thiocarbamate herbicides and the carbamate insecticide carbofuran used to treat against corn rootworm (*Diabrotica* spp.).

Soil-moisture content influences both the availability of a pesticide for breakdown and the populations and activities of the microorganisms. It is thought that only compounds in the soil water are freely available to microorganisms for breakdown, and that sorbed compounds only become available as desorption into the soil water occurs to reestablish the sorption equilibrium after such breakdown. Thus, for example, the strongly sorbed herbicide paraquat is very persistent in soil, with a half-life of several years, but in culture medium without soil it can be rapidly degraded by microorganisms. As soils dry, the proportion of compound in the soil water will be decreased and also the activity of microorganisms will be increasingly limited, both of these processes causing a strong slowing of breakdown in drier soils.

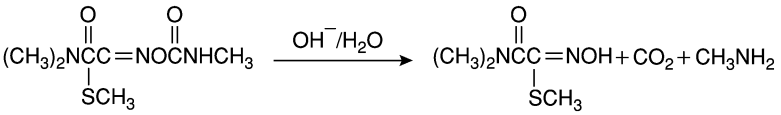
It should be noted that these two factors of temperature and moisture can often serve to cancel each other out in the field, because a sunny spell of weather causes both drying and warming of the surface layer of the soil, which often contains most of the pesticide. Thus breakdown in the field may approximate to first-order kinetics despite the changing environmental conditions caused by weather. However, losses of pesticide in the field can be biphasic, with a more rapid loss in the first few days of application than subsequently; this initial loss is usually attributed to surface processes such as volatilization or photolysis, and the first major rainfall event will move the compound sufficiently into the soil to block photolysis and reduce volatilization. Given the differing processes and variable conditions in the field, it is usual to describe pesticide persistence here by the DT_{50} or DT_{90} values, the disappearance time for 50% or 90%, respectively, of the parent compound; these are measured values with no implications as to the processes or kinetics involved.

Other factors can also influence breakdown rates of pesticides in soil. Increasing organic matter content encourages microbial activity but reduces pesticide availability in the soil water due to stronger sorption. Again these two factors are working in opposite directions, though, in poor sandy soils with little organic matter, degradation can be much slower than in more fertile soils.

Soil pH can also influence breakdown. For example, carbamoyloxime nematicides such as aldicarb and oxamyl are sensitive to hydrolysis at alkaline pH, and so these compounds are not very persistent in soils of pH >7.5 (**Figure 4a**). Conversely, the first generation of sulfonylurea herbicides such as chlorsulfuron (**Figure 4b**) are subject to acid hydrolysis and so do not persist in soils of low pH.

Microbial activity also usually diminishes with soil depth, resulting in breakdown in subsoil usually being slower than in topsoil. Nevertheless, microorganisms can survive to tens of meters depth, in numbers sufficient to cause slow degradation of pesticides in aquifers. Where aquifers are deep and the recharge takes decades, such degradation may remove pesticide traces before the water is abstracted. However,

(a) Oxamyl



(b) Chlorsulfuron

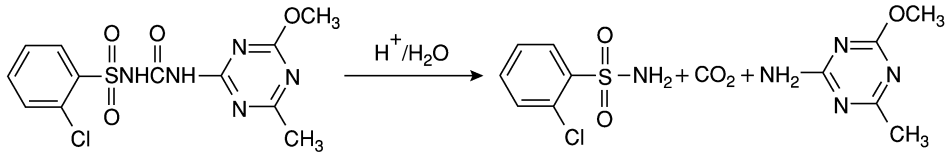


Figure 4 Hydrolysis of pesticides in soil: (a) alkali-catalyzed hydrolysis of oxamyl; (b) acid-catalyzed hydrolysis of chlorsulfuron.

shallow aquifers are inevitably more susceptible to contamination, and much monitoring is done to ensure that widespread contamination of groundwater does not occur.

Another factor in the breakdown process is whether soils are aerobic or anaerobic (i.e., lacking in oxygen). Anaerobic conditions are brought about by prolonged flooding, in which breakdown of soil organic matter uses up the oxygen. An example occurs in the cultivation of rice in paddy fields. This leads to strong reducing conditions, which can cause new degradation pathways to become predominant. Examples are the reduction of aromatic nitro compounds to anilines and of ketones to secondary alcohols. A further aspect is that ferric ions are reduced to ferrous ions under such conditions, and the latter can catalyze the breakdown of some pesticides such as the carbamoyloxime nematicides.

Methods for Studying Pesticide Breakdown

The breakdown pathways of pesticides are identified by incubating radiolabeled pesticide in soil under controlled laboratory conditions. The most usual radiolabel is ^{14}C, the pesticide being synthesized from an appropriate ^{14}C-labeled precursor such that the ^{14}C is in the portion of the molecule likely to be the most recalcitrant to degradation. Such core labeling ensures that most of the metabolites will contain the ^{14}C atom and so can be traced and isolated by thin-layer chromatography or high-pressure liquid chromatography. They can then be identified by techniques such as nuclear magnetic resonance spectroscopy and mass spectrometry. Usually such incubations are done in contained systems such that $^{14}CO_2$ or other volatile radiolabeled compounds produced can be trapped and estimated by liquid scintillation counting. After exhaustive extraction of the soil, typically with a succession of organic solvents increasing in polarity, ^{14}C incorporated in the soil organic matter can be estimated by combustion of the extracted soil with trapping of the evolved $^{14}CO_2$. Adding up the ^{14}C found in these various fractions at each time gives the mass balance which, if the experiments have been done satisfactorily, should be close to the dose applied to the soil at the beginning of the incubation.

Subsequent field studies are usually done with nonradiolabeled compound, with measurement of the parent compound and any major metabolites of interest by high-pressure liquid or gas-liquid chromatography. These techniques need to be very sensitive as some modern pesticides are applied at rates of only $10\,g\,ha^{-1}$ or even less.

Sorption of Pesticides by Soil

The sorption of pesticides to soil is a very important process in determining pesticide behavior in the environment. For example, strong sorption limits movement by leaching, and so such compounds would be unlikely to contaminate groundwater. It is not usually possible to distinguish between adsorption (a surface phenomenon) and absorption (whereby the pesticide penetrates the sorbing matrix such as soil organic matter), and hence use of the term 'sorption,' which covers both processes.

Sorption is typically measured by equilibrating sieved soil with an aqueous solution of the pesticide over a period of 4–24 h. The sorption coefficient ($K_d\,ml\,g^{-1}$) is then calculated from:

$$K_d = \frac{\text{concentration in soil } (g\,g^{-1})}{\text{concentration in water } (g\,ml^{-1})} \qquad [4]$$

Sorption of nonionized and acidic pesticides is largely by partitioning into the soil organic matter. This

process is viewed as essentially a reversible equilibrium, though detailed measurements usually reveal that desorption is somewhat slower than sorption. To allow for comparisons in sorption behavior over soils ranging in organic matter content, K_d can be converted into K_{om} (sorption coefficient on to soil organic matter; $ml\,g^{-1}$) or K_{oc} (sorption coefficient on to soil organic carbon; $ml\,g^{-1}$) by:

$$K_d = \frac{\%\ \text{organic matter}}{100} K_{om} = \frac{\%\ \text{organic carbon}}{100} K_{oc} \quad [5]$$

Such partitioning is largely controlled by the lipophilicity of a pesticide, and various relationships have been proposed to predict sorption from lipophilicity as assessed by the 1-octanol/water partition coefficient (K_{ow}) discussed above. Briggs proposed:

$$\log K_{om} = 0.52 \log K_{ow} + 0.62 \quad [6]$$

Though simplistic, this approach works reasonably well for most pesticides. However, certain compounds have functional groups that confer additional sorption by specific interactions. For example, compounds carrying a positive charge can be sorbed by displacing metal ions in the soil matrix, a process known as cation exchange. A particularly striking example occurs with the bipyridinium herbicides such as paraquat, which is a planar molecular carrying two positive charges (Figure 5a). This is strongly sorbed by both organic matter and clay particles; in soils containing the expanding-lattice clay montmorillonite, paraquat can be intercalated between the layers comprising the crystal lattice and is then very tightly bound. A further mechanism of binding is chelation to metal ions such as iron and aluminum, which is observed with oxalic acid, a simple dicarboxylic acid that is dissociated to the oxalate salt at soil pH (Figure 5b). Another example is the herbicide glyphosate, which carries both negative and positive charges (Figure 5c). Though very polar and water-soluble, it is sorbed quite strongly by soil, owing to chelation by the charged groups.

Movement of Pesticides in Soil

In soil, a pesticide is distributed between the soil solids, soil water, and air phases. Most pesticides, with the notable exception of fumigants, are not very volatile, and so movement of most compounds will be via the soil water rather than via the air phase. Movement can be vertically down the soil profile or laterally. Vertical movement, usually referred to as leaching, can lead to contamination of groundwater if the pesticide is weakly sorbed and persistent. Such leaching can be through the bulk of the soil if the soil is not structured as in many sandy soils; in strongly structured clay soils, movement of pesticides in soil water can occur through cracks or pores such as worm or root channels (often termed 'macropore flow' or 'bypass flow'). As such structured soils are often drained, macropore flow can lead to rapid movement of small amounts of pesticide to drainage, which then contaminates surface waters such as streams and rivers. Lateral movement to surface waters can also occur by surface runoff in regions subject to intense rainfall events. Several general classifications of pesticide mobility in soil based on sorption K_{oc} values have been proposed (and which can be related to K_{om}, K_d, and K_{ow}); one such example is given in Table 1. This is primarily of use for non-ionized pesticides, because sorption of ionizable pesticides may depend on soil pH, and shows that increasing lipophilicity decreases mobility.

In: Walker A (ed.) *Pesticides in Soils and Water*. BCPC monograph 47: 165–174. Silsoe, UK: National Soil Resources Institute, Cranfield University.)

Leaching of pesticides is often studied using lysimeter systems. These are undisturbed blocks of soil, typically 1 m deep and 0.5–1.0 m^2 in area, contained within a casing usually made of stainless steel or fiberglass. Such lysimeters can be taken from different soil types and then brought back to a central location for study. Radiolabeled pesticide is applied, and leachate from the lysimeters is monitored over a 2-year period. Any detected radioactivity is subjected to chromatography to identify it as parent compound or metabolite. In assessing the risk of pesticide leaching to groundwater, in the European Union, for example, the mean concentration of pesticide leached from such lysimeters would not be allowed to exceed 0.1 $\mu g\,l^{-1}$, the drinking-water limit for every pesticide. This is a strict criterion that precludes the registration of many uses of pesticides. At the end of the experiment, soil cores can be taken to measure remaining amounts of pesticide and metabolites, as well as to assess the amount of pesticide incorporated into the soil organic matter.

The behavior of pesticides in soil can be simulated by modeling techniques, and a number of such computer programs are now available. These vary in their complexity, and it can be difficult to parameterize the more detailed models. At a minimum, simulation of pesticide behavior in soil requires as input a sorption coefficient, degradation constant, climate data (temperature, rainfall), and soil properties to allow description of water flow through the soil. Such models can simulate well the behavior of the bulk of pesticide in soil, but it has proved difficult to obtain reliable estimates of variable processes such as losses to drainage via macropore flow.

Uptake of Pesticides from Soil by Plants

Plant roots and stem bases are in contact with the air and water in soil, and so can acquire pesticide present in these phases. Furthermore, crop plants typically transpire water amounting to several times their own weight each day, and so there is substantial mass flow to the roots of soil water and with it a potential burden of pesticide. In practice, the proportion of soil-applied pesticide found in plants is usually small, due in part to the pesticide being degraded and sorbed in soil and also often to it being in the uppermost layers of the soil above the main rooting zone. Nevertheless, pesticide uptake by plants can be important, examples being the carryover of herbicides from one crop to the next so causing phytotoxicity, and secondly the occurrence of pesticide residue in the edible portion of crops at harvest.

Only a few compounds move predominantly via soil air rather than via the water phase, these more volatile compounds being characterized as having the (dimensionless) Henry Law constant greater than 10^{-4}. This discussion will thus focus on uptake into plants via the soil water, the predominant pathway for most pesticides. Uptake can be divided into two processes: (1) uptake into roots, and (2) transport to shoots via the transpiration stream flowing up the xylem vessels. Entry into roots for nonionized pesticides is primarily an equilibration from the soil water into the aqueous phase of the root cells, with partitioning on to the lipid-like constituents of roots. This latter process is determined by pesticide lipophilicity and is the main uptake process for compounds of log $K_{ow} > 2$. Compounds of $\log K_{ow} > 4.5$ can be accumulated at concentrations greater than 100-fold (on a wet weight basis) compared with those of a bathing solution akin to soil water. As soils increase in organic matter content, stronger sorption reduces pesticide concentrations in the soil water and so uptake by plants is less. Translocation of such nonionized chemicals to shoots is, however, in no way related to uptake by roots. Such transport is a passive process, limited by the rate at which compounds can cross the root endodermis, which is a cylindrical sheath of cells surrounding the vascular tissues. Translocation efficiency is related to pesticide lipophilicity, being optimal at $\log K_{ow} \sim 1.8$, at which compounds move with approximately 80% of the efficiency of water, with more polar and more lipophilic compounds becoming increasingly less well transported.

Uptake behavior of ionized compounds is more complex. The most important group is composed of the weak acid herbicides; for these, uptake by roots and transport to shoots are proportional, increasing strongly in more acidic soils because the undissociated forms are much better taken up than their respective anions.

Effects on Soil Processes

The possible impact of pesticides on soil processes mediated by microorganisms, together with that on larger biota such as earthworms, has to be extensively studied before a pesticide is registered. Compounds that are applied to sterilize soil, known as 'soil sterilants' or 'fumigants,' are generally applied at a high rate and are volatile compounds such as methyl bromide (whose use will be phased out) or methyl isothiocyanate that are able to move in the soil air spaces throughout the top soil. These, as their name implies, kill most organisms in the treated zone, though recolonization can occur subsequently from the deeper soil layers that would be less affected.

Other pesticides, however, seem to have relatively little effect on microbially mediated soil

processes such as nitrification or respiration. Although microfungi are an important constituent of the soil microorganisms, fungicides at normal rates seem to have little effect on soil processes, even when thoroughly mixed into soil; and, in the field, only a shallow layer of topsoil would normally contain most of the fungicide reaching the soil surface following foliar sprays. Larger organisms such as earthworms and ground-dwelling beetles can be affected by some insecticides and nematicides, but such effects at the population level are usually short-lived.

Long-term trials over 20 years or more with repeated applications of single or combinations of pesticides applied at normal agronomic rates have found no deleterious effects on soil fertility, as assessed by crop yield, or on soil processes such as respiration and levels of microbial biomass carbon. These findings reinforce the more general observation that problems of soil fertility in worldwide agriculture have not occurred despite several decades of use of pesticides. This shows that the soil is quite robust, no doubt because its biota have been decomposing large amounts of complex organic compounds from plants for millions of years. These residues, and those from organic pesticides, are so degraded by the time that they are incorporated into soil organic matter that any original biological activity has been lost. There is thus no reason to believe that use of pesticides is incompatible with sustainable agricultural systems.

List of Technical Nomenclature

c	Concentration
DT_{50}, DT_{90}	Disappearance time (50%, 90%)
H'	Henry Law constant (dimensionless)
k	First-order rate constant (per time)
K_d	Sorption coefficient to soil (milliliters per gram)
K_{oc}	Sorption coefficient to soil organic carbon (milliliters per gram)
K_{om}	Sorption coefficient to soil organic matter (milliliters per gram)
K_{ow}	1-Octanol/water partition coefficient (dimensionless)
T	Temperature (Kelvin)
t	Time
$t_{1/2}$	Half-life
VP	Vapor pressure (pascal)
WS	Water solubility (moles per liter)

No other single chemical soil characteristic is more important in determining the chemical environment of higher plants and soil microbes than the pH. There are few reactions involving any component of the soil or of its biological inhabitants that are not sensitive to soil pH. This sensitivity must be recognised in any soil-management system (Brady NC and Weil RR (1999) *Nature and Properties of Soils*. Englewood Cliffs, NJ: Prentice-Hall).

Introduction

The acidity–alkalinity status of a soil is referred to as 'soil reaction,' which is often quantified by measuring soil pH. pH is considered to be the 'master variable' of a soil, which determines many of the physical (e.g., flocculation or deflocculation), chemical (e.g., adsorption or desorption), and biological (e.g., mineralization or immobilization) properties of soils. In this chapter, the fundamentals of soil pH will be discussed in relation to its measurement and practical implications.

Theoretical Basis of pH

Pure water dissociates into the hydronium ion $(H_3O)^+$, which is associated with acidity, and hydroxyl $(OH)^-$, which is connected with alkalinity:

$$H_2O + H_2O \rightarrow (H_3O)^+ + (OH)^- \qquad [1]$$

In aqueous media, the free acid cation is mostly present as the hydrated proton $(H_3O)^+$ but for convenience it is often referred to as a hydrogen ion or proton (H^+), and thus the dissociation of water is often represented simply as:

$$H_2O \rightarrow H^+ + OH^- \qquad [2]$$

This is a reversible reaction which obeys the law of mass action:

$$[H^+] \times [OH^-]/[H_2O] = K \qquad [3]$$

where K is a constant. Because the degree of dissociation of pure water is so small, the concentration of undissociated H_2O molecules always remains constant, so that the product $[H^+] \times [OH^-]$ gives a constant value (K_w), known as the dissociation constant or ionization constant of water. The K_w value for pure water at 21°C is 1×10^{-14}, with equal concentration of H^+ and OH^- ions $(1 \times 10^{-7}$ gEq):

$$K_w = [H^+][OH^-] = 1.0 \times 10^{-14} \qquad [4]$$

If a chemical substance is added to water, which either donates or consumes H^+ or OH^- ions, then the concentration balance between H^+ and OH^- ions is disturbed. The numerical product of the concentrations must, however, remain constant, so that if $[H^+]$ increases, $[OH^-]$ must decrease accordingly, and vice versa.

To simplify the arithmetical representation of eqn [4], Sörensen suggested that the equilibrium state could be defined simply by reference to the $[H^+]$ and, to avoid the use of cumbersome decimal fractions, he proposed the use of a term designated 'pH' (French *pouvoir hydrogène* or *puissance d'hydrogene*, or 'hydrogen power') which is defined as the $\log_{10}$ of the reciprocal of the $[H^+]$ measured in gEq:

$$pH = \log_{10}\frac{1}{H^+} \text{ or } -\log_{10}(H^+) \qquad [5]$$

Expressing eqn [4] as a negative logarithm yields:

$$pH + pOH = 14 \qquad [6]$$

where pH and pOH are the negative logarithms of the H^+ and OH^- ion activities, respectively.

Thus, the pH of an aqueous solution is defined as the negative logarithm of the H^+ ion activity in the solution, which is the same as the $[H^+]$ when the salt concentration in the solution is very low. This concept can be applied to a system in which the individual molecules and ions are uniformly dispersed throughout the solution within the limits set by variations due to molecular and ionic thermal movements.

The pH scale ranges from 0 to 14, with pH 7 as the neutral point. At pH 7, $[H^+]$ equals the $[OH^-]$. From pH 7 to 0, the solution is increasingly more acidic; from pH 7 to 14, the solution is increasingly more alkaline (basic; **Figure 1**). The $[H^+]$, which is the ion measured when determining pH, has a 10-fold change between each whole pH number. Thus, a solution with pH 5 will have 10 times more $[H^+]$ than a solution with pH 6.

Measurement of pH

pH is commonly measured either electrometrically using potentiometers or calorimetrically using pH-sensitive dyes.

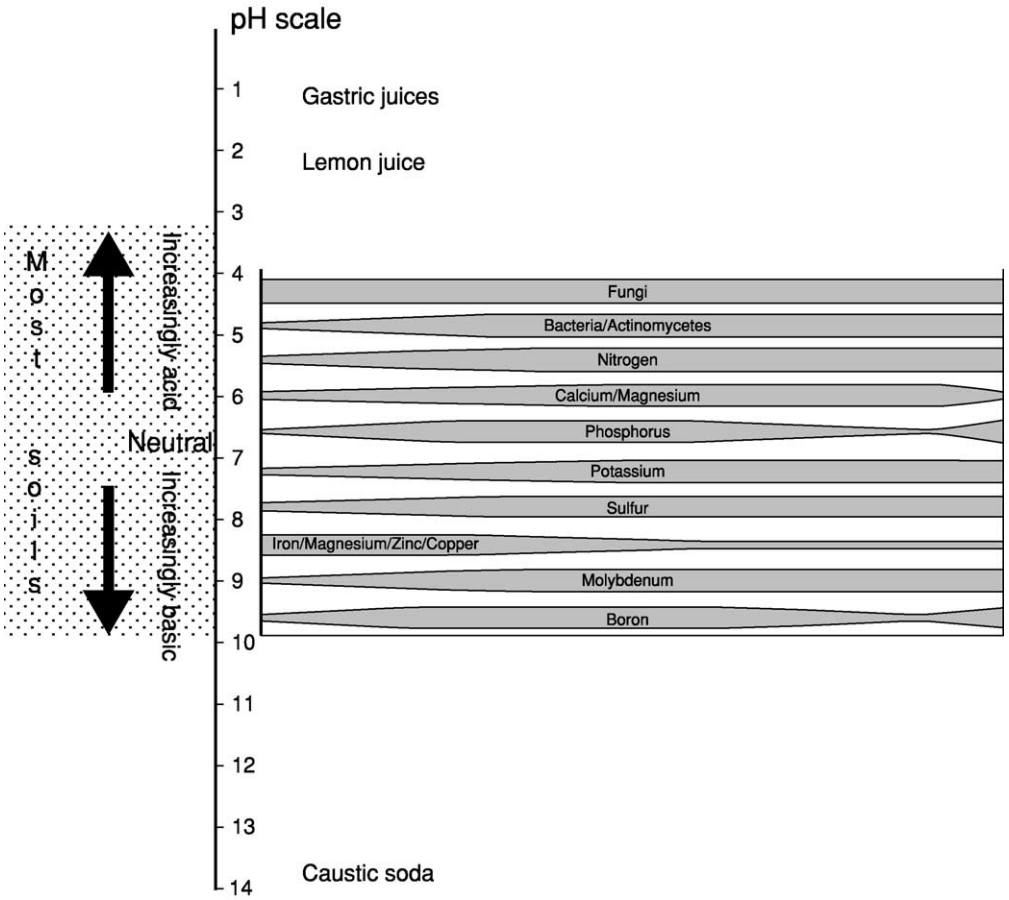

Figure 1 pH scale and the effect of pH on nutrient availability and microbial activity.

Potentiometric Method

This method involves the measurement of potential difference between an electrode whose potential is determined by the $[H^+]$ of the solution and a reference electrode whose potential is independent of $[H^+]$. The normal hydrogen electrode is the glass electrode, and the reference electrode is a calomel electrode in which calomel ($HgCl_2$) is bathed in a solution of potassium chloride (Figure 2).

The glass electrode consists of a thin glass bulb containing dilute HCl, into which is inserted an Ag–AgCl wire, serving as the electrode with a fixed voltage. The HCl solution is separated from the test solution by a membrane of special glass, usually a lithium silicate of particular composition. Differences in H^+ activity across this membrane cause a difference in electrical potential, which can be measured by a potentiometer.

When the glass bulb is immersed in a solution, a potential difference develops between the solution in the bulb and the solution outside the bulb. The electrical potentials developed by this electrode are the membrane potential, plus the potential of the Ag–AgCl–HCl reaction inside the electrode:

$$AgCl + e^- \leftrightarrow Ag + Cl^- \qquad [7]$$

This reaction is reversible and the Ag–AgCl potential ($E^0 = 0.222$ V at 25°C) is likely to remain constant. This potential is cancelled out when the electrode is standardized against a standard pH buffer solution.

The glass electrode develops a second potential at the membrane separating the standard HCl and the test solutions. The minute current flow required by the pH meter develops a double layer in the solutions, causes ion exchange at the inner and outer surfaces, and causes diffusion of ions across the glass membrane. The potentials across the glass membrane can be closely calibrated to the approximate value of the H^+ activity.

A typical reference electrode consists for a wire dipped into the liquid mercury, which makes electrical contact with the pH meter. Current flows from the electrode to the solution phase through the reversible reaction ($E = 0.268$ V at 25°C):

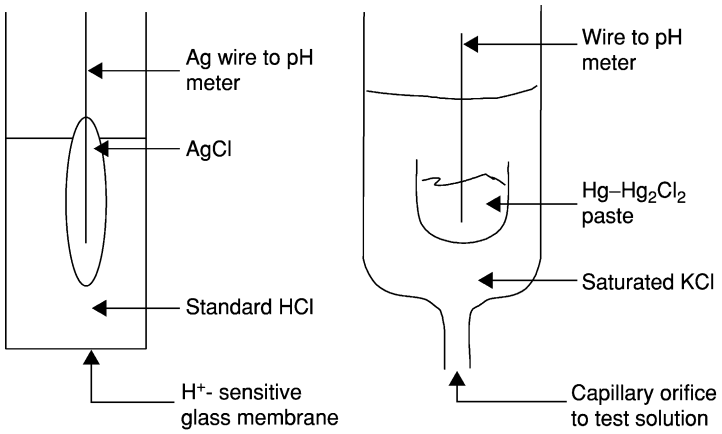

Figure 2 Hydrogen (glass) and reference (calomel) electrodes. Reproduced from Tan KH (1998) *Principles of Soil Chemistry*. New York: Marcel Dekker.

$$Hg_2Cl_2 + 2e^- \leftrightarrow 2Hg + 2Cl^- \quad [8]$$

The Cl^- activity is fixed by the KCl concentration (usually saturated KCl). As a result this potential also cancels out when the pH electrode system is standardized in a standard pH buffer. KCl diffusion through the orifice makes the electrical contact between the reference cell and the test solution. This KCl connection forms a 'salt bridge' between the test solution and the reference electrode. The reference electrode is often built in the same body as the glass electrode to form a combination electrode.

When measuring pH, the potential (E) in the glass electrode is formulated by the Nernst equation:

$$E = (RT/nF)\log(K/H^+) \quad [9]$$

where R is the gas constant, T the absolute temperature, n the valence, F the Faraday constant, K a constant, and H^+ the activity of H^+ ions. E is called the 'half-cell potential' and cannot be measured alone. If the glass electrode is placed against a reference calomel electrode, the potential difference between the two ($E - E_{ref}$) is measurable.

Before any pH measurement, the two electrodes have to be laced first in a solution of known pH. This is called 'standardizing' the electrodes and the pH meter. The overall potential of the total cell E_0 equals $E - E_{ref}$:

$$E_0 = [(RT/F)\log(K/H^+_{std})] - E_{ref} \quad [10]$$

If the two electrodes are now placed in the solution with the unknown $[H^+]$, the potential E_c is:

$$E_c = [(RT/F)\log(K/H^+_{test})] - E_{ref} \quad [11]$$

Subtracting eqn [10] from eqn [11] gives:

$$E_c - E_0 = (RT/F)[\log H^+_{test} - \log H^+_{std}] \quad [12]$$

$$E_c - E_0 = (RT/F)\log(H^+_{test}/H^+_{std}) \quad [13]$$

or

$$E_c - E_0 = (RT/F)(pH_{std}/pH_{test}) \quad [14]$$

where E is the measured potential and is converted to pH units by the scale of the pH meter. E_{ref} includes all other potentials, which are nullified by standardizing the systems with a standard pH buffer solution.

Since $RT/F = 0.0591$ at 25°C:

$$pH = (E_c - E_0)/0.0591 \quad [15]$$

This means that for a change of 1 pH unit, the potential will change by 0.0591 V.

The glass electrode has a uniform response to a wide range of H^+ activities and is less sensitive to interfering ions. The extent of interference is denoted by the selectivity ratio, the concentration ratio of the test ion to interfering ion at which the interfering ion exerts a significant potential at the membrane. The selectivity ratio of the pH glass membrane for H^+ over Li^+, the most serious interfering ion, is approximately 10^9. That is, Li^+ would cause a significant pH error in a pH 9 solution containing 1 mol l^{-1} Li^+ or in a pH 10 solution containing 0.1 mol l^{-1} Li^+. The selectivity ratio for Na^+, the next most serious interference, is approximately 10^{13}.

Determination of pH Using pH-Sensitive Dyes

Rapid measurement of pH can also be achieved colorimetrically with pH indicator dyes. Colorimetric methods are based on the change in color that takes place upon dissociation of a weak acid, or weak base organic dye; thus for a weak acid dye:

$$HI = H^+ + I^- \quad [16]$$

where raising the pH will cause a change in color as the undissociated dye (HI) changes to the dissociated form (I^-). Typically a mixture of dyes is used to yield color changes that take place over a wide range of pH. However, the color can only be measured accurately in a solution from which the solid particles are removed, and the color also depends on the concentration of various salts present in the solution. A dye solution is mixed with the solid to make a slurry, the dye is decanted and the color is visually compared with a color chart. The pH measured in this manner is not precise and can vary from the results obtained using the glass electrode.

Measurement of Soil pH

Because 'pH' is a term that is only defined for solution, in a strict sense, it cannot be applied to a solid-phase material such as soil. However, the chemical properties of the solid-phase components in soil define the pH of the soil solution (i.e., the solution in the soil pores). Further the pH of a soil dispersed in water is not a simple concept like that of a solution. When soil particles, which carry ions attached to them, are dispersed in solution, the ions are not uniformly distributed throughout the solution. The concept of the pH of a soil (or soil suspension) can therefore only be discussed in relation to the properties of the ionic atmosphere around the soil particles (i.e., soil–solution interface).

When a negatively charged soil particle is dispersed in water, the negative charge is neutralized by cations, some of which sit firmly on the clay surface, forming the Stern layer, and some dissociate into the dispersion medium to form the Gouy diffuse double layer. The thickness of this double layer depends in part on the ions dissolved in the dispersion medium, and the thickness increases with a decrease in the concentration of the ions, a decrease in the valency of the cations, and an increase in the size of the cation. The $[H^+]$ in the solution surrounding the soil particles is less than that close to the soil particles, due to the $[H^+]$ gradient in the double layer. As the double layer is made more compact by adding an electrolyte to the soil-water system, the $[H^+]$ gradient across the double layer is reduced, and the pH in the solution becomes almost equal to that close to the surface of the soil particle. Thus the pH of the bulk solution is greater than the pH just outside the Stern layer unless the salt concentration in the solution is high.

The pH of most soils ranges from 3 to 8.5. Soils do not normally have a pH below 3–4 unless they contain free acids (e.g., acid sulfate soils and acid mine drainage). Similarly soils normally only have a pH >8.45 if they contain enough exchangeable sodium (i.e., alkali soils). Further, in calcareous and alkali soils, the effective pH around plant roots can be determined by the concentration of carbon dioxide (CO_2) produced during respiration by roots and microorganisms.

Strictly speaking the pH of a soil should refer to the $[H^+]$ in the soil solution. This is very difficult to measure, and hence soil pH is often referred to measurements made in the soil suspension. Three common, standard methods for determining pH in soils involve the suspension in distilled water, $0.01\,mol\,l^{-1}$ $CaCl_2$, or $1\,mol\,l^{-1}$ KCl solutions at a soil-to-solution (weight-to-volume) ratio of 1:1 (in USA) or 1:2.5 (in New Zealand and Australia).

The pH of a solution in equilibrium with a soil varies with the composition and concentration of the salts in the solution. This is because cations in solution displace H^+ and Al^{3+} ions from soil surfaces. The measure of soil pH in water extract is expected to give a higher value than the pH of the soil solution at natural soil water contents. The excess quantity of water added to prepare the suspension results in a dilution of the salts in the soil solution. Since soils always contain some soluble salts, such as nitrates and chlorides, the apparent pH of the soil will depend on the amount of water added to the soil to make the suspension. Further, the amount of soluble salts in a soil varies continuously throughout the season, depending on factors such as the amount of drainage water percolating through the soil.

Soil pH values measured in $0.01\,mol\,l^{-1}$ $CaCl_2$ or $1\,mol\,l^{-1}$ KCl salt solutions are generally less than the values obtained using water, because the cations in these salts tend to displace H^+ and Al^{3+} from soil materials to soil solution. These salt solutions are sufficiently concentrated to overwhelm variations in salt concentration in soil solution, thereby minimizing the effect of salt concentration on pH in most soils. These solutions also eliminate the junction potential effect. Calcium is used in the determination of pH because it is the predominant soil solution cation in soils of temperate regions. The $0.01\,mol\,l^{-1}$ concentration, however, is somewhat higher than that found in most soil solutions, and thus the pH values obtained by this method are usually lower than the values of soil solutions.

For some subsurface horizons of highly weathered soils of the tropics, pH in salt solution can actually be greater than pH in water, especially in subsoils that are low in permanent-charge silicate clays and low in organic matter. Ion exchange in these soils is dominated by oxides and hydroxides of Fe and Al, and at acid pH values they are net positively charged, creating an effective sink for anion adsorption. Thus, on salt addition (i.e., $CaCl_2$ or KCl) more OH^- is

displaced by Cl^- than H^+ by cations, resulting in an increase in pH.

Factors Affecting Soil pH

The pH of a soil is affected by the concentration of CO_2 in the soil air, salt concentration (salt effect), and the presence of colloidal particles (suspension effect).

Carbon Dioxide

The higher the CO_2 concentration in the soil solution, the lower the pH, and the pH of a neutral or calcareous soil is very sensitive to small changes in CO_2 concentration. In calcareous soils, its magnitude can be calculated from the solubility of calcium carbonate and CO_2 in water, because in such soils the pH is basically determined by the system, calcium carbonate–carbon dioxide–water, which is given approximately by:

$$2\text{pH} = K + \text{pCa} + \text{pCO}_2 \qquad [18]$$

where pCO_2 is the negative logarithm of the partial pressure of CO_2 in equilibrium with the solution, pCa the negative logarithm of the activity of the calcium ions, and K is a constant whose value lies between 10 and 10.5, depending on the value used for the solubility constant of calcium carbonate. The decrease in pH is therefore approximately proportional to the logarithm of the partial pressure of CO_2.

Thus, the pH of a well-aerated calcareous soil containing exchangeable sodium or magnesium ions cannot exceed approximately 8.5 when in equilibrium with the atmosphere; but if the CO_2 concentration rises to 0.1% (i.e., a low value for most soils) the pH drops to 8, and if it rises to 1% (a common value for pasture soils) the pH will be less than 7.5. Many plants suffer from phosphate and minor element deficiencies if the pH rises much above 8, and hence they can only thrive on calcareous soils if they can maintain an adequate concentration of CO_2 around their roots. This is more easily achieved in soils of low porosity, such as clays, than in soils of high porosity, such as well-drained sands, and in organic matter-rich pasture soils than in organic matter-depleted arable soils.

Salt Effect

As discussed above, the pH of a soil depends on the salt concentration in the soil solution. This dependence of measured soil pH on salt concentration can be reduced by making all the measurements in a salt solution that is sufficiently strong to swamp the effects of the changes that occur naturally. But adding a salt solution to the soil will cause cation exchange to take place and, in particular, exchange of H^+ ions from clay surface with the cation of the added salt, which will give a pH that is lower than the soil pH under normal conditions. The added salt solution should therefore cause as little exchange as possible, and the use of $0.01\,\text{mol}\,l^{-1}$ $CaCl_2$ or $1\,\text{mol}\,l^{-1}$ KCl solution has been proposed for most arable soils on the grounds that they approximate to the salt concentration in the soil solution and do not give appreciable junction potential with the calomel electrode. The pH of a soil measured in these solutions is more constant and is much less dependent on the soil-to-solution ratio than the pH measured in a water suspension, and it is also presumably closer to the pH of the solution around the plant roots.

Suspension Effect

The difference in pH values between the suspension and its equilibrium solution is referred to as the 'suspension effect,' and this effect is identical to the Donnan e.m.f.

The electrode portion of a pH measurement circuit is presented in Figure 3, where each vertical bar represents a phase boundary and the double bar represents the liquid–liquid junction. Thus, very appreciable junction potentials can be created between a soil suspension and the calomel electrode so that the measured potential difference between the two electrodes cannot be interpreted solely in terms of the $[H^+]$ outside the glass electrode.

A junction or diffusion potential always develops when two dissimilar substances or solutions of different composition come in contact. It is inevitable that a diffusion potential is created at the liquid junction between a salt bridge and a solution of different composition. An example in this case is the saturated KCl of the reference electrode diffusing into the test solution. At liquid junctions, differences in the mobilities of the cation and anion create a diffusion potential which is also influenced by any differences in the ion activities that exist across the junction. The potential is minimal when the rates of K^+ and Cl^- diffusion into the test solution are equal. It is therefore appropriate that an electrolyte in which the mobilities of the cation and anion are almost identical is used in the salt bridge. Indeed, KCl is used as the reference-cell electrolyte because of the similarity of K^+ and Cl^- diffusion rates in water. Because the current at the liquid junction is mainly carried by K^+ and Cl^- ions, which have similar diffusion coefficients, the liquid

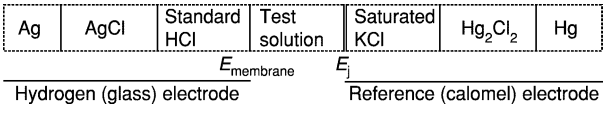

Figure 3 The electrode portion of a pH measurement circuit.

junction potential should be small. As long as the ionic strengths of the standard and unknown solutions are small compared with the concentrated KCl salt bridge solution, any liquid junction potential should, as well as being small, tend to be rather constant in magnitude and hence can usually be ignored.

Because factors involved in the liquid junction potential during pH calibration and subsequent pH measurement are likely to be different, the liquid junction potential contribution to the total e.m.f. of a cell will also be different. In a colloidal suspension, however, the colloid may cause K^+ and Cl^- to diffuse at different rates. Because of attraction and repulsion by the charged colloid, one ion moves ahead of the other. When a salt bridge makes contact through a suspension instead of clear solution, the situation is complicated by a reduced mobility of counter ions which arises from retarding effects created by the oppositely charged colloidal particles. This means that liquid junction potentials (E_j) are likely to be much greater in suspensions than in supernatant liquids. Accurate pH measurements require a negligible E_j, because such potentials are virtually unpredictable. The potentiometer measures all the potentials of the circuit and cannot distinguish between the H^+ ion potential at the glass membrane and the spurious E_j. The value of E_j at the interface between saturated KCl and a colloidal suspension of very low salt concentration can be as high as 240 mV, equivalent to more than 4 pH units (1 pH unit = 59 mV). However, values of E_j greater than 30 mV are uncommon in soils, because salt concentrations in even highly leached soils are high enough to suppress E_j. Therefore measuring pH in salt solutions of 0.01 mol l^{-1} or more virtually eliminates E_j.

Suspension effects can be reduced by introducing the liquid junction of the reference electrode into clear supernatant liquid and not into the suspension. The rates of K^+ and Cl^- diffusion are then unaffected by soil colloid particles. The pH glass electrode, on the other hand, can be placed either in the supernatant solution or in the colloidal suspension. The H^+ activity is the same in both phases, and the glass electrode is unaffected by the presence of the colloid. However, it has been suggested that when measuring soil pH the glass electrode should be in the suspension on the basis that the suspension is better buffered than the supernatant liquid.

Importance of Soil pH

The soil pH is considered as the 'master variable' which controls many other soil properties (Figure 1). pH greatly affects the solubility of minerals in soils. Most minerals are more soluble in acid soils than in neutral or slightly basic solutions. A low pH may indicate the deficiency of basic cations such as Ca^{2+} and Mg^{2+} in soils. Under acid soil conditions, the concentration of most heavy metals, such as lead, cadmium, and mercury, reach phytotoxic levels. Strongly acidic soils usually have high and toxic concentrations of soluble aluminum and manganese. Azaleas, tea, rhododendrons, cranberries, pineapple, blueberries, and several conifer timber species tolerate acidity and grow well in acid soils. In contrast, alfalfa, beans, barley, and sugarbeets grow well only in slightly acidic to moderately basic soils because of a high calcium demand or inability to tolerate soluble aluminum.

Soil pH can also influence plant growth through its effect of beneficial microorganisms. For example, most nitrogen-fixing legume bacteria are not very active in strongly acidic soils. Bacteria that decompose soil organic matter and thus release nitrogen and other nutrients for plant use are also hindered by strong acidity. Similarly earthworms are not active in acid soils, whereas fungi usually tolerate acidity better than do other microbes.

Soil basicity, although more difficult to manage than soil acidity, may also be undesirable for plants. Alkaline soils may reach pH values of more than 10 with increasing levels of exchangeable sodium. Plants on soils with pH >9 usually have reduced growth or even die. Some plants (halophytes) are tolerant of high salt concentration or pH. Soluble $Al(OH)_4^-$ may exist at these high pH values and is also toxic to plants. The major effect of basic pH is to reduce the solubility of all micronutrients (except chlorine, boron, and molybdenum), especially those of iron, zinc, copper, and manganese. Also, phosphate is often not readily available to some plants because of its precipitation in the soil solution by calcium or precipitation on solid calcium carbonate. Iron deficiency, associated with soils high in carbonates, has long been known, and is referred to as 'lime-induced iron chlorosis.'

Summary

Soil pH is one of the most important chemical properties which control many other soil physical, chemical, and biological properties. The pH of a soil depends on the CO_2 concentration in the soil air and the salt concentration in the soil solution, and these are constantly changing.

Introduction

Phosphorus (P) is essential for growth and development of living organisms. In agricultural systems, P inputs to soils are often required to replenish P removed by harvested crops or lost by soil erosion or runoff. Because soils bind P strongly, historically P inputs have been made more to maintain adequate or high levels of soil fertility and less from a concern that excessive P inputs promote P loss in runoff and erosion. However, all soils have a finite capacity to bind P. When this capacity is diminished through repeated P applications in excess of plant needs, soil P mobility and loss to the environment increase. Even when soil P fertility is relatively low, P loss by excessive erosion can be an environmental concern. The concern for P loss is its delivery to surface waters, where P inputs can increase the growth of algae and aquatic plants to undesirable levels. The result is often eutrophication, whose negative ecological and economic effects include anaerobic conditions during decomposition of algal biomass and subsequent deleterious effects on aquatic organisms, increased cost and complexity of water treatment for drinking quality, and impaired recreational water use. Thus, the challenge for soil P management is to maintain adequate soil P fertility for economical crop production and minimize P loss to the environment.

The Soil Phosphorus Cycle

Major Forms of Phosphorus in Soils

Total soil P ranges from 0.01 to 0.30% and occurs in three forms: P dissolved in the soil solution (solution P), organic P, and inorganic P (Figure 1). Solution P exists largely as orthophosphate ions (HPO_4^{-2}, $H_2PO_4^{-1}$), and can vary from 0.01 to 3.0 mg l^{-1}. Some organic P compounds are also present in solution. Organic P comprises between 30 and 65% of total soil P, depending on soil type, and includes phosphate esters, nucleic acids, phospholipids, and other esters. Inorganic P occurs as primary minerals (those derived directly from weathered parent material) and secondary minerals (those formed by precipitation of P with Al, Ca, and Fe), P adsorbed on to the surface of clay minerals, Fe, and Al oxyhydroxides, or Ca carbonates, and P physically occluded within secondary minerals.

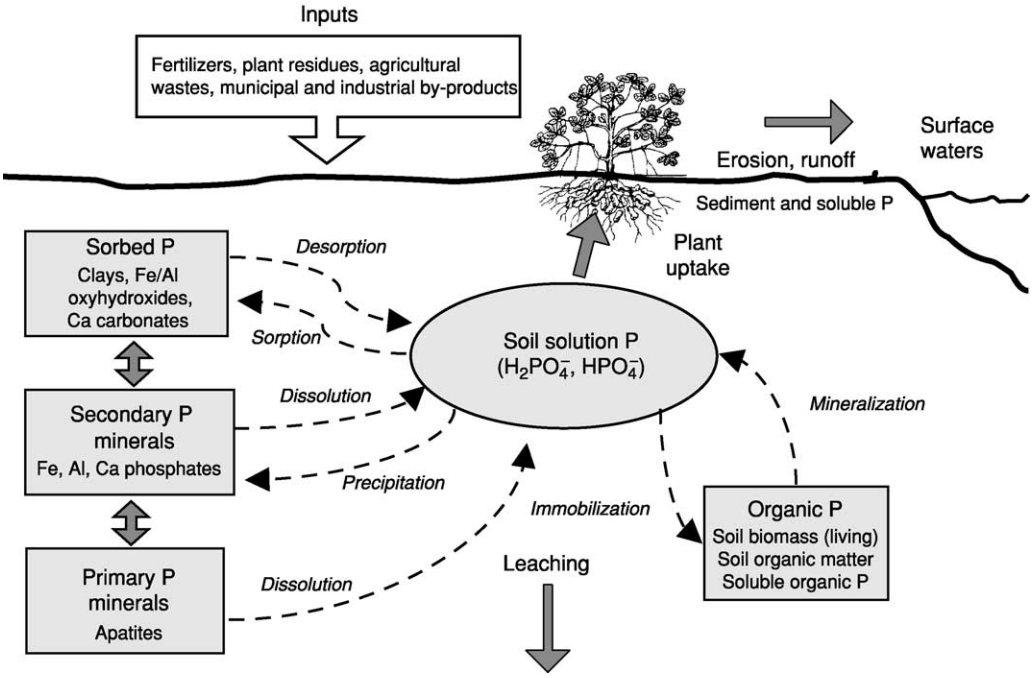

Figure 1 The soil P cycle. Reproduced with permission from Pierzynski GM (2000) Soils and Environmental Quality. Lewis Publications. CRC imprint.

Overview of Soil Phosphorus Cycling and Transformations

Solution P concentrations are largely controlled by mineralization and immobilization of organic P and adsorption and/or desorption and precipitation and/or dissolution of inorganic P. Mineralization is the release of organic P to solution, and immobilization is the conversion of solution P to organic P. Soil microbes require P for activity and growth. If organic materials that they oxidize for energy contain less P than required, microbes immobilize P from solution. If organic materials contain more than enough P, microbes mineralize P to solution. Factors that influence P mineralization and immobilization include the quantity of organic P, the C-to-P (C:P) and N-to-P (N:P) ratios of organic materials, temperature, moisture, aeration, pH, cultivation intensity, and P fertilization.

Adsorption is the chemical bonding of P to mineral surfaces, and desorption is release of P from these surfaces. Positively charged surfaces of clays and Fe, Al, and Ca minerals attract orthophosphate ions (e.g., $H_2PO_4^-$, HPO_4^{-2}) from solution, which adsorb to the surface by exchanging with OH^- and OH_2 groups. When P is bonded through one metal–O–P bond, it is considered labile and can be readily desorbed from the surface to solution. With two metal–O–P bonds, a stable six-member ring forms, desorption is more difficult, and P is considered nonlabile.

Precipitation and dissolution reactions are controlled by the solubility of secondary P minerals, the most common of which are Al–P, Fe–P, and Ca–P. A mineral's solubility represents the concentrations of its constituent ions that can be maintained in solution at equilibrium. When the concentration of solution P is greater than that supported by a mineral's chemical solubility, solution P will precipitate with metal cations (e.g., Al, Ca, Fe) and form P minerals. When the solution P concentration is less than a mineral's chemical solubility, P minerals dissolve into solution. Soil physical and chemical properties influencing P adsorption and/or desorption and precipitation and/or dissolution reactions include the nature and amount of soil minerals, soil pH, cation and anion effects, extent of soil P saturation, organic matter, reaction time and temperature, soil oxidation–reduction status, and P fertilization practices.

Phosphorus Additions to Soils

Because plants absorb P from the soil solution, solution P must be maintained at adequate concentrations, commonly reported as $0.2\,mg\,P\,l^{-1}$ but which may be as low as $0.03\,mg\,P\,l^{-1}$. Soils with relatively high concentrations of labile P can provide all P required by plants. Conversely, soils with little labile P require P additions to achieve optimum crop yields. When fertilizer P (inorganic or organic) is added to soil, solution P increases due to dissolution of inorganic P or mineralization of organic P. This increase disturbs the equilibrium between the solid and solution phases, and P moves from solution to

the solid phase, mostly through precipitation and adsorption. These initial reactions are rapid and leave the P in labile forms that are easily converted back to solution through dissolution and desorption. Over time, some P in the solid phase stabilizes and becomes nonlabile, so that movement back to solution is more difficult or even impossible. As plants absorb P from the soil solution or soluble P is lost in runoff, labile P dissolves or desorbs from the solid phase to solution.

If P additions consistently exceed plant uptake over time, concentrations of soil P increase. Eventually, labile P concentrations may be great enough to meet plant needs without P fertilization. The greater the concentration of labile P, the longer the soil will be able to maintain plant growth. When such soils are left unfertilized, P fertility levels will progressively decrease, through crop production or P loss, to the point when they no longer adequately supply plant P needs. New additions of P are then necessary.

Phosphorus Losses from Soils

Phosphorus transfer from soils to aquatic environments is a major nonpoint-source pollution concern. The major pathway for P loss is surface runoff and soil erosion, although P can also be transported by subsurface water flow to nearby streams, especially if artificial drainage is present (e.g., tiles, drainage ditches). As rainfall or irrigation water interacts with the surface soil, P desorbs or dissolves from soil particles, crop residues, fertilizers, or manure. Dissolved P can leave a field in surface runoff or be resorbed by soil or runoff sediment and then move as particulate P. The eroded sediment load in surface runoff determines particulate P loss. In areas where soils are vulnerable to wind erosion, soil P can also be transported with fine, wind-blown sediments and deposited in nearby waters. Years of extensive research show that P loss is minimal when management practices prevent surface accumulation of P and minimize surface runoff and erosion.

Because soil P is relatively immobile, most fertilizer P remains near the soil surface. However, leaching of P from the surface soil into the subsoil may occur in sandy soils and organic soils, and may be greater in soils where organic fertilizer is added than where inorganic fertilizer is added (Figure 2). Leaching usually occurs in soils where P additions have increased soil P to excessive concentrations. In such soils, P is more mobile because sorption sites have become increasingly saturated and solution P concentrations have increased. Leaching of P can be exacerbated by preferential water flow where soil water containing relatively high concentrations of P from surface layers flows rapidly through soils in cracks, fissures, biopores, or finger flow. Phosphorus that has leached from surface soils may be retained in subsoils, gradually leach further into groundwaters, or move by subsurface flow to nearby streams.

Soil Phosphorus Management

Soil Testing for Phosphorus

Quantifying the ability of a soil to provide plant-available P is usually the first step in P fertility management. Beginning in the 1940s, agronomic soil tests using chemical extractants were developed to estimate rapidly and economically the ability of a soil to supply P to plants over a growing season. Use of the four most common tests, Bray and Kurtz P-1, Mehlich 1, Mehlich 3, and Olsen P, is a well-established practice in the USA. The Bray and Kurtz P-1 test is an acid extractant used in the midwestern and north central USA for acid and neutral soils. The Mehlich 1 and Mehlich 3 tests are acid extractants, with Mehlich 1 used in southeastern and mid-Atlantic states for acid soils and Mehlich 3 used throughout the USA and Canada for both acid and basic soils. The Olsen P test is a basic extractant used in the north central and western USA for calcareous soils. Some other soil P tests used in the USA and Europe include ammonium bicarbonate-DTPA, Morgan and modified Morgan, ammonium lactate–acetic acid, the P_i soil test, and water and dilute salt tests. Soil testing is a reliable method to determine soil P fertility levels and fertilizer P requirements, and can identify soils where P has accumulated to environmentally unacceptable levels.

Characteristics of Phosphorus Fertilizer Sources

An effective P fertilizer must contain an adequate amount of available P so P will be released quickly and sufficiently enough to replenish soil P reserves (Table 1). Mined rock phosphate minerals, or apatites, are the only important raw material for inorganic P fertilizers. Although they contain 12–18% total P, very little of the P is water-soluble, which limits their fertilizer value in certain settings, such as highly acid soils. More common P fertilizers are produced when rock phosphate is acid-treated or heat-treated to break apatite bonds and increase the water-soluble P content. Phosphorus can also be applied to soils in organic fertilizers, including animal wastes, municipal wastes, composts, plant residues, and occasionally industrial by-products (Table 1). Organic fertilizers generally contain relatively low concentrations of P, ranging from 0.1 to 3.0%.

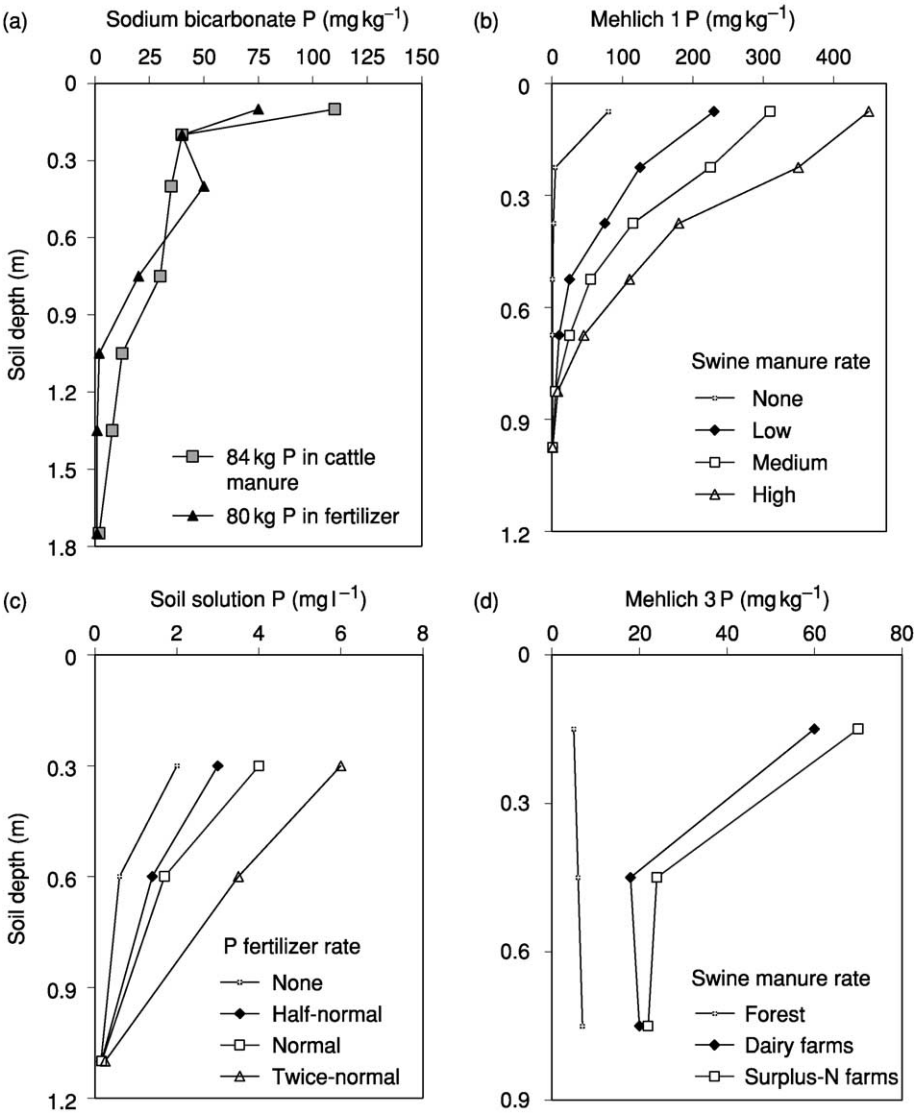

Figure 2 Examples of P-leaching for (a) soils where organic fertilizers and inorganic fertilizers are applied, (b) sandy soils, (c) organic soils, and (d) soils that have excessive concentrations of P. Nutrient Management Practices for Phosphorus

The fundamental goal of agricultural P management is to identify the most profitable and environmentally sound approach to provide crops with P, to prevent P accumulation in soil, and minimize P loss from soil. Effective P management begins with a nutrient budget that calculates P inputs to and P outputs from a farm. When P inputs exceed outputs over time, the usual result is an accumulation of soil P and an increased risk of P loss to water. If P outputs exceed inputs, soil P fertility declines. A positive imbalance (P surplus) is economically undesirable and represents a waste of a limited natural resource in phosphate ores. A P deficit indicates that soil productivity is being slowly degraded and crop production will probably decline. Therefore, balancing farm-scale P inputs and outputs is critical to long-term P fertility management.

On farms where commercial fertilizers are the only P inputs, soil tests and realistic yield goals will assess soil P fertility, crop P needs, and P fertilizer requirements. Analyzing harvested crops will quantify P leaving the farm. In this situation, a P surplus

indicates unnecessary fertilization and a P deficit suggests farmers face economic or logistical limitations to maintaining soil P fertility. In animal-based operations where P inputs also include animal feed, soil testing and yield goals will still identify soil P fertility, crop P needs, and P fertilizer requirements; and a manure analysis will identify available P that can be used as fertilizer. Manure application rates should be based on crop nutrient requirements and manure nutrient concentrations. Crop and animal product nutrient analyses or estimations will quantify farm P outputs. Because animal-based agriculture can produce large quantities of manure and often relies exclusively on land application as the end use for manure, it is especially important that P inputs do not exceed P outputs to prevent the buildup of soil P to concentrations of environmental concern (Table 2). If P inputs significantly exceed P outputs, then management options that reduce P inputs, use on-farm P resources without promoting P losses, and increase P outputs can be investigated. Examples are reducing unnecessary P additions to animal feeds, increasing availability of P in feed with dietary amendments such as phytase, or exporting manures for alternative uses such as compost, fertilizer products, or bioenergy production.

Crop response to P additions in either fertilizers or manures is influenced by the rate, timing, and method of P application. At low rates of P fertilization, the water solubility of fertilizer P should be high to get the full benefit of the limited amount applied. In soils that sorb P strongly and quickly, higher rates of P fertilizer may be necessary to achieve the solution P concentration necessary for crop growth. In such soils, it may be more efficient to have smaller, more frequent P additions closer to the times of high crop P demand. If P fertilizers are broadcast and incorporated, much of the added P interacts with soil particles capable of P sorption. If soils are low in P or have high P sorption capacity, high rates of fertilizer P must be broadcast to increase P availability to desired values. For row crops, placing fertilizer P in concentrated bands immediately adjacent to the crop reduces the contact between soil and fertilizer P, allowing for use of lower fertilizer rates and enhanced P uptake by crops.

Loss of P from soils is also influenced by the rate, timing, and method of fertilizer or manure application. The greatest P loss occurs from fields where high rates of P are applied, where P is broadcast and

Table 1 Major inorganic and organic sources of phosphorus for crop production

Material	*P_2O_5 (%)*	*Total P available (%)*
Inorganic fertilizers		
Rock phosphate	25–40	14–65
Single superphosphate	16–22	97–100
Wet-process phosphoric acid	48–53	100
Triple superphosphate	44–53	97–100
Ammonium phosphates		
Monoammonium phosphate	48–62	100
Diammonium phosphate	46–53	100
Ammonium polyphosphate	35–62	100
Urea–ammonium phosphate	16–42	100
Nitric phosphates	14–28	80–100
Ammoniated normal superphosphate	14–21	97–100
Ammoniated triple superphosphate	44–53	96–100
Potassium phosphates		
Monopotassium phosphate	51	100
Dipotassium phosphate	41	100
Potassium polyphosphate	51	100
Organic fertilizers		
Beef manure	2.1	–
Dairy manure	1.4	–
Poultry manure	4.1	–
Swine manure	3.5	–
Aerobically digested sludge	7.6	–
Anaerobically digested sludge	8.3	–
Composted sludge	3.0	–

unincorporated, and when runoff events occur soon after P application. The least P will be lost from fields where little P is applied, where P is incorporated into soil, where good soil conservation practices reduce erosion, and when runoff events occur well after application. Because these optimum conditions reduce the number of manure application opportunities available throughout the year, manure should be stored in suitable facilities until it can be applied.

Soil and Water Conservation Practices for Phosphorus

An integral component of sound P management is practices that conserve soil and manage water, thus reducing the risk of P loss. To minimize P loss via surface runoff and erosion, it is necessary to reduce rainfall impact on the soil, reduce surface runoff volume and velocity, and increase soil resistance to erosion.

Plant Cover, Crop Rotation, and Strip Cropping

Rainfall breaks up soil aggregates, allowing soil to move with runoff, and compacts and puddles the soil surface, decreasing water infiltration and increasing surface runoff. Crops can intercept up to 45% of rainfall, dissipating raindrop energy and reducing runoff and erosion. After planting, rapid crop canopy helps minimize soil exposure. Adequate soil fertility, optimum seedbed preparation and planting conditions, pest control, and optimum plant spacing all help promote seed germination, plant growth, and canopy closure. Crop rotations where new crops quickly follow preceding harvests minimize the duration of soil exposure. Rotations also help break insect, disease, or weed cycles, which impede plant growth and reduce plant cover. Strip cropping divides fields into long, narrow segments that help control runoff and erosion while growing crops in rotation. More heavily vegetated strips slow runoff and catch soil eroded from more exposed strips. Strips planted on the contour of slopes (contour strip-cropping) are especially effective in controlling runoff and erosion (Figure 3).

Companion Crops, Cover Crops, Green Manures, and Crop Residues

With companion crops such as small-grain and forage crops, the small grain starts first and provides quick plant cover. Harvesting the grain leaves residue and the forage to protect the soil. Cover crops grown during cold or dry seasons can provide soil cover when soils would otherwise be left exposed. Cover crops should germinate easily, grow quickly, provide sufficient plant cover, and be hardy against weather and pests to maximize soil coverage. Green manures act as cover crops and, when plowed under, can add nutrients to soil to increase fertility for succeeding crop growth and build soil organic matter content, which promotes the soil structure, permeability, and aeration needed to maximize rain infiltration and minimize surface runoff and erosion. Crop residues also act as mulch to increase soil coverage. Although plowing residues under may decrease soil coverage, it can promote residue decomposition and erosion-control benefits such as those from green manures.

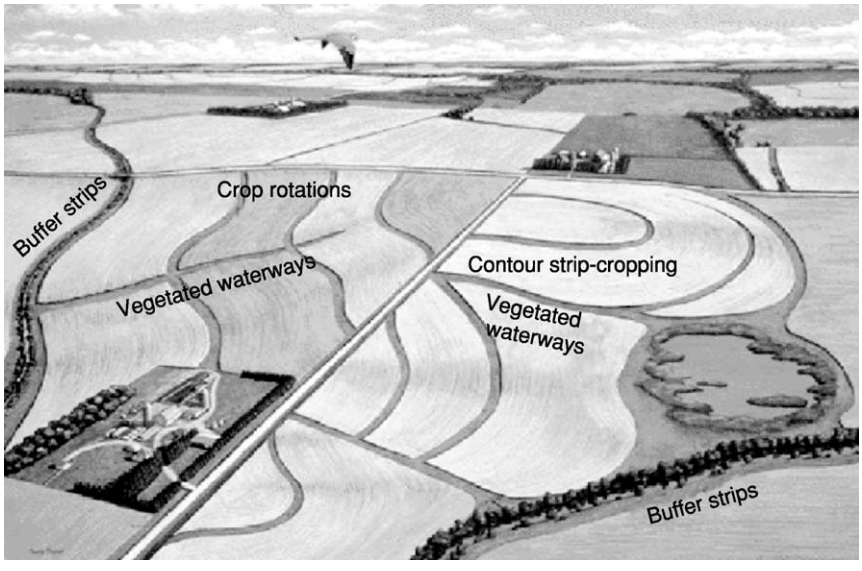

Figure 3 Soil and water conservation practices that can help reduce P export from agricultural fields. Courtesy of USDA Natural Resources Conservation Service.

Conservation Tillage, Contour Cultivation, and Deep Plowing

Conservation tillage, such as stubble mulch tillage, minimum tillage, reduced tillage, and no-tillage, leaves at least 30% of the soil surface covered by plant residue after planting to reduce erosion and surface runoff. Contour cultivation follows the contour lines of sloping fields. Contour ridges produced by tillage and planting form barriers that slow downhill water movement and decrease surface runoff and erosion. In applicable situations, deep plowing can break up pans to increase water infiltration and reduce runoff and erosion. It can also help dilute topsoil layers with high P concentrations into subsoils with less P.

Although reducing tillage will help decrease total P loss in surface runoff by reducing erosion, it may increase dissolved P loss. Because soils are not tilled, P from added fertilizers or manures accumulates at the surface, increasing the concentration of dissolved P in surface runoff. Also, in no-till situations where manures and fertilizers are left unincorporated, dissolved P loss in surface runoff soon after application can increase dramatically.

Terraces, Vegetated Waterways, and Buffer Strips

Terraces divide slopes so that surface runoff is intercepted and carried to a protective outlet. Terraces decrease erosion by shortening slope length, slowing runoff velocity, and trapping sediments. Surface runoff water concentrates in waterways that when bare or unstable are extremely erodible. Vegetated waterways are natural or constructed channels that, when properly established and maintained, transport surface runoff water at a nonerosive velocity from fields, prevent gully formation, and greatly decrease erosion. Vegetated buffer strips act primarily to control water pollution by preventing eroded soil from being carried into streams or ditches.

Innovations in Soil Phosphorus Management

The past two decades have seen an increased awareness of the importance of P loss from agricultural soils. Extensive research has been conducted to better understand sources and pathways of P loss, to identify areas or fields where risk of P loss is high, to develop management practices to minimize P loss, and determine the best means by which to implement such practices. A number of innovations in soil P management have evolved from this research.

Animal Feed Formulations

Inorganic P supplements are routinely added to animal feeds to ensure adequate dietary P. Because P is often added in excess of animal needs, significant amounts of P are excreted in manure and applied to soils, where they are a potential source of P loss. Adjusting diets to match P inputs with animal needs, or increasing the availability of native feed P, as with phytase additions to poultry feeds, can potentially reduce the amount of P that is excreted in manure and land applied. This would also help reduce P surpluses that exist in farm-scale nutrient balances (Table 2). However, research must determine whether dietary manipulations will indeed reduce P loss from soils where manure is applied. For example, adding phytase to poultry feeds to increase P availability to birds may increase the solubility of P in manure and thus increase dissolved P loss in surface runoff from fields where manure has been applied.

Soil and Manure Testing

Soils are important sources of P loss. As soil P concentrations increase due to long-term applications of fertilizer and manures, tests are needed to identify soils that pose a significant environmental risk. Good relationships exist between soil P concentrations as measured by traditional agronomic tests and dissolved P loss in surface runoff or subsurface flow. Research has also shown that some new soil tests, such as extractions with water, iron oxide-coated filter paper, and ion-exchange membranes, and a test for the degree of soil P saturation, can also estimate the risk of P loss from soil. Land-applied manures can too be significant sources of P loss. Simple manure tests, such as extractions with water, can estimate the potential for manure P loss. Although soil and manure tests can identify potential sources of P loss, they give no information about the transport of P. For example, manure applications to a given field increase soil P concentrations and thus the potential for P loss in runoff or erosion. However, if runoff from the field is rare, then transport of P from the field is unlikely. Tools such as the Phosphorus Index can help identify fields where the risk of P pollution from both source and transport factors is high.

Soil and Manure Amendments

The loss of P in runoff is related to the P concentration of both soils and manures. Amending soils, manures, or municipal biosolids with materials containing high amounts of Fe, Al, or Ca can transform the soil or manure P into less-available forms and thus reduce P loss in runoff. Such amendment materials include an Fe-rich by-product from paint production, Al-rich drinking water treatment residuals, aluminum sulfate (alum), and coal combustion by-products. While these amendments are effective in reducing P availability in

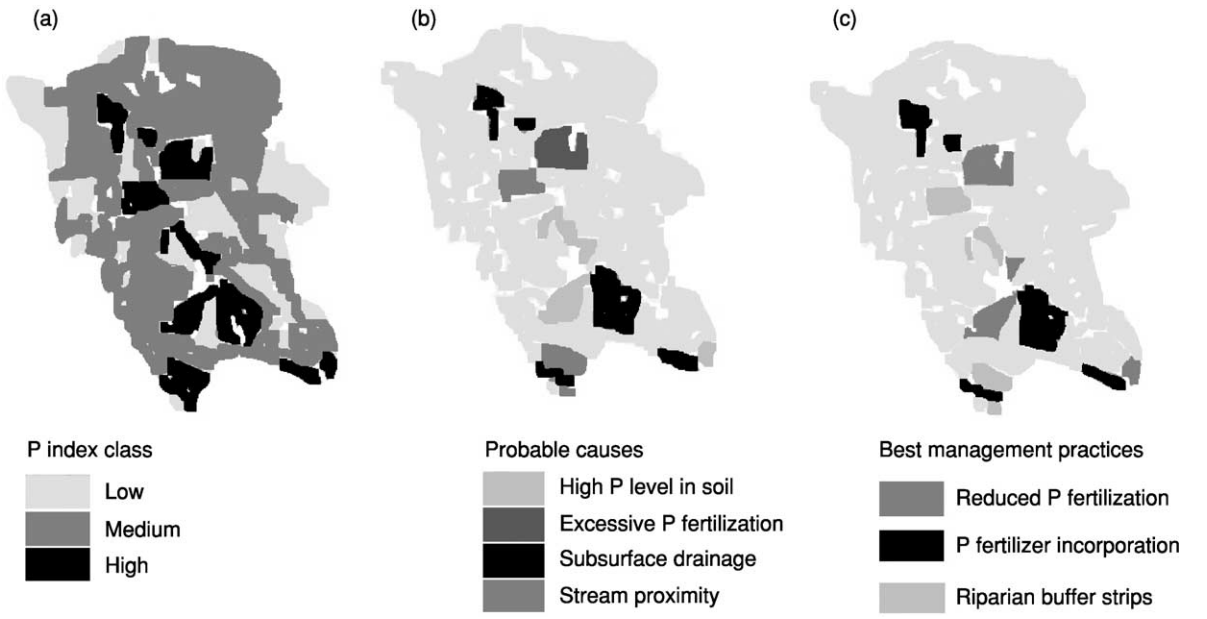

Figure 4 Examples of the P index for a watershed scale, showing (a) P-index ratings, (b) causes of P export, and (c) management practices that can help reduce the P export. soils and manures, they may also contain high concentrations of salts or heavy metals that could have adverse agronomic or environmental effects.

Water-Quality Modeling and the Phosphorus Index

Water-quality simulation models such as EPIC, FHANTM, GLEAMS, AGNPS, SWAT, or ANSWERS are designed to predict P loss from agricultural areas for a variety of soil, hydrologic, or management conditions and are seen as relatively fast, cost-effective tools. Continued research with these models has led to their improvement to simulate P loss better. However, such models are often complex and require large amounts of input data that may be unknown or difficult to measure. They may also be limited in the number of soil, hydrologic, or management conditions they simulate. The Phosphorus Index (P Index) is a much simpler screening tool, developed by the Natural Resources Conservation Service (NRCS) and recently modified; it accounts for source and transport factors controlling P loss and ranks sites according to the risk of P movement (Figure 4). The P Index is designed to allow field personnel easily to identify agricultural areas or practices that are most vulnerable to P loss, thus allowing producers more flexibility in developing P-control strategies.

Introduction

Phosphorus (P) is essential to life; it is a primary component of many important biomolecules such as adenosine triphosphate (ATP), deoxyribonucleic acid (DNA), phospholipids, the phosphopyridine nucleotides ($NADP^+$), and phytin (P storage molecule – inositol hexaphosphate). Plant requirements for P are, on average, between 0.2 and 0.4% of plant dry weight. While this is relatively modest relative to nitrogen (N) requirements, the challenge with P lies in maintaining enough soluble phosphate to prevent deficiencies of P in agricultural crops. Therefore the management of P in agriculture is of major interest.

Phosphorus enters the soil environment in a number of ways. It is present, in varying concentrations, as the primary mineral apatite from which the plant-available phosphate ion is weathered. Phosphorus is applied as inorganic fertilizers or organic materials such as animal manures and other biosolids, or is simply recycled from plant and animal materials in undisturbed soil ecosystems.

The P cycle in soils has both abiotic and biological components. The abiotic component is primarily concerned with the dissolution of P-containing minerals, the formation of phosphates of Al, Fe, Ca, and Mg, and the sorption of phosphates to clays and Al- and Fe-oxides in soil. The biological component is comprised primarily of mineralization of organic P sources and immobilization of soil solution orthophosphate during microbial metabolism. Soil organisms also produce a variety of acids and chelating agents which facilitate the solubilization of phosphate from the inorganic P in the soil. The organisms involved include bacteria and fungi living in the bulk soil and the rhizosphere, as well as mycorrhizal fungi which supply P to the plant. The biological transformations of P in the soil are very important in the availability of P to plants. However, mismanagement or overapplication of P-containing materials can result in excessive amounts of inorganic P, which can have negative environmental impacts. The introduction of excessive P into surface waters can result in eutrophication, or excessive algal productivity, which can ultimately reduce oxygen content in the water, degrading the quality of the habitat for aquatic organisms.

Forms of Soil Phosphorus

The original source of most soil P is from the primary mineral apatite, or rock phosphate (RP). Apatite is a highly insoluble Ca-phosphate compound with the general formula of $Ca_{10}(PO_4)_6X_2$, where X is F^- (fluoroapatite), OH^- (hydroxyapatite), or Cl^- (chloroapatite). In highly weathered, acidic soils, little or none of these apatite minerals remain in the soil. The P in these minerals is released, either chemically or by microorganisms and plant roots, then used by plants and microorganisms. Over time, this P is incorporated into organic matter or other relatively insoluble inorganic P minerals with Al and Fe in acidic soils, and with Ca in neutral to alkaline soils. In highly weathered soils, P is tied up by Al- and Fe-oxides. These compounds are only sparingly soluble (**Figure 1**). Generally, solubility of phosphorus from Al and Fe sources increases with pH levels in the range of about pH 6.5. As pH continues to increase, though, Ca-phosphate minerals are formed and these control soluble P concentrations. Therefore as pH increases above neutrality, soluble P concentrations decrease significantly. The low solubility of inorganic soil P makes the use of P fertilizer materials necessary in many high-yield agricultural systems. Additionally, the practice of liming acid soils to increase pH to about 6.5–7.0 has the practical effect of enhancing P availability for plant growth.

Total amounts of P in soils vary widely, depending on parent material and the extent of weathering. In sandy soils with low organic matter, there may be as little as 100 mg kg^{-1}, while soils high in primary

P minerals (e.g., high-phosphate limestone parent materials), clay content, or organic matter may contain well over 2000 mg kg^{-1} soil. In most soils, inorganic P is the dominant form, although organic P increases with increasing soil organic matter.

The plant-available form of P in soils is orthophosphate, $H_2PO_4^-$ (dominant form at pH 2.2–7.2) or HPO_4^{2-} (dominant form at pH 7.2–12.4). Orthophosphate from soluble phosphate fertilizer materials or mineralized from organic sources rapidly forms precipitates as Al-, Fe-, or Ca-phosphates or is sorbed by Al- and Fe-oxides. Due to these reactions, soluble P is present at very low concentrations in soil solution, typically in the range of less than 0.1 to 1 mg l^{-1}. In nonfertilized soils the solution orthophosphate must be continuously replenished by chemical or biological dissolution of inorganic P compounds or by microbial mineralization of organic P.

Organic P can account for 3–90% of the total soil P, with 30–50% common in most soils. The P content of soil organic matter ranges from about 1 to over 3%. Total organic P in a soil is a function of organic matter content, so that as organic matter increases, so does organic P. Organic P also decreases with soil depth, as does organic C. The chemical structure of organic P in soil is not well known. The major types of organic P compounds which are added to soil by recycling plant, animal, and microbial remains in the soil environment are shown in Figure 2. Of the compounds shown, phytins, or inositol phosphates, are usually found in the greatest quantities, making up 10 to 50% of the total organic P content. The inositol phosphates are typically in a polymeric state, making these compounds relatively resistant to decomposition. The phospholipids and nucleic acids may account for up to 5% of the organic P fraction, while other identifiable forms of organic P are present in trace amounts only.

The microbial biomass represents an important part of the organic P pool in soil. This pool represents actively cycling P in the soil, and is part of the labile or readily available organic P. The microbial biomass is responsible for mineralization and immobilization reactions which convert organic P to inorganic P and inorganic P to organically bound P. The microbial biomass is also active in solubilization of relatively insoluble forms of Al-, Fe-, and Ca-phosphates. The biomass P fraction accounts for up to 5% of the total organic P pool in arable soils, while in undisturbed grassland and forest soils, the fraction may be as high as 20% of the total. Studies have shown that soil disturbance, e.g., tillage, reduces organic matter and total organic P content, and that the microbial biomass P fraction decreases more rapidly than the total organic P pool in general. Therefore, the labile organic P fraction is more susceptible to disturbance than the more stable, complex organic P forms. This indicates the importance of the microbial biomass to making P available for plant use in stable terrestrial ecosystems.

The Phosphorus Cycle

In some ways, the phosphorus cycle is not as complex as the nitrogen or sulfur cycles because P does not typically undergo oxidation–reduction reactions or exist in gaseous forms. However, as in the N and S cycles, the biological processes of mineralization and immobilization as well as plant uptake are present. Additionally, the microbial fraction is active in the solubilization of relatively insoluble inorganic P materials, making P available for plant or microbial uptake or other transformations.

Figure 3 shows the P cycle, illustrating the various compartments of P in the soil environment. The P cycle is divided into a geochemical subcycle and a biological subcycle, with the inorganic solution P pool serving as the central point in the overall cycle. This pool of inorganic solution P serves as the source of orthophosphate for plants and soil microorganisms. The remainder of this article will deal with the biological subcycle of P.

In the biological subcycle, soluble orthophosphate is either taken up by plants or immobilized into the microbial biomass. When organic sources of P, such as crop residues, manures, and municipal biosolids, are land-applied, three possible fates of the P can occur. The organic P, especially inositol phosphates, may be incorporated directly into stable humus, becoming relatively unavailable for plant and microbial use. If the residue has a relatively high P content, relative to C and N, a portion of the P will

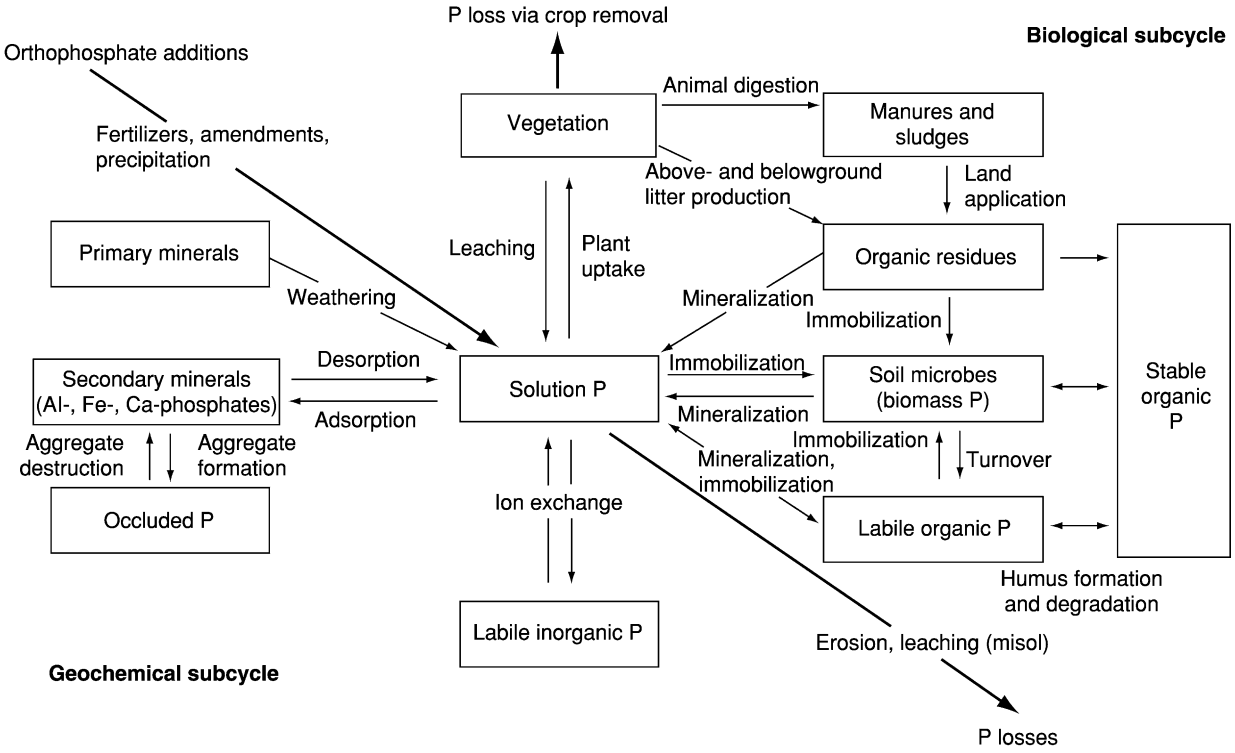

Figure 3 The phosphorus cycle showing inputs, losses, and transformations. This model illustrates the relationship of the chemical and biological P subcycles through the solution orthophosphate pool. Adapted with permission from Walbridge MR (1991) Phosphorus availability in acid organic soils of the lower North Carolina coastal plain. *Ecology* 72: 2083–2100.

be mineralized as orthophosphate during microbial decomposition of the residue. Finally, part of the P in the residue will be incorporated into the microbial biomass during decomposition. This immobilized P may become available as soluble P when the microbial biomass fraction dies back and is itself mineralized by other microorganisms.

While this model of the P cycle segregates biological activity from geochemical activity, it should be noted that the dissolution of apatite and other secondary P minerals can be enhanced by the activities of microorganisms and plants. Dissolution or solubilization of these minerals releases orthophosphate to solution P, where it can then be utilized by plants or microorganisms. Of course, a portion of this P will again precipitate as secondary P minerals, or be adsorbed by Al- and Fe-oxides and clay surfaces.

Mineralization and Immobilization of P

As briefly discussed above, key components of the biological cycling of P in soil are mineralization, the transformation of organic P into inorganic orthophosphate P, and immobilization, the transformation of inorganic P back into organic forms. These reactions are catalyzed by the active microbial biomass fraction in the soil, and are largely a consequence of heterotrophic microbial catabolic and anabolic processes. In order to acquire energy, electron-rich organic compounds are oxidized and degraded in order to produce energy. As these compounds are dismantled, inorganic nutrients are released. In order to build new cells, the biomass must acquire inorganic P and other nutrients. The extent to which P is either mineralized or immobilized during these reactions depends on the carbon-to-phosphorus (C:P) ratio of the compound being degraded. If the C:P ratio is 200:1 or less, then the residue is rich in P and the excess will be mineralized. Conversely, if the residue C:P is greater than about 300:1 there will not be enough P available in the residue to facilitate complete degradation. Therefore immobilization of orthophosphate from the soil by the microbial biomass will occur if decomposition of the residue and biomass growth is to continue. While immobilization decreases the amount of orthophosphate immediately available to plants, this is typically a very short-lived phenomenon and may indeed protect orthophosphate from being tied up in relatively insoluble inorganic compounds. After the added organic materials are mineralized, the microbial biomass will begin to die back to previous levels, resulting in the subsequent mineralization of the microbial P pool.

Mineralization is simply the enzymatic release of orthophosphate during the decomposition of organic materials that contain P. The phosphatase enzyme group is responsible for the hydrolysis of esters and anhydrides of orthophosphate-P. A number of different phosphatase enzymes are observed in the soil environment. The most commonly measured soil phosphatases are the phosphomonoesterases, which hydrolyze phosphomonoester bonds. Two phosphomonoesterases have been widely studied: acid phosphatase and alkaline phosphatase. Acid phosphatase is produced by microorganisms and plants and predominates in acid soils, while alkaline phosphatase is only produced by soil microorganisms and is dominant in alkaline soils (although it is present in acid soils as well). The phytase enzyme is also important. Phytins or inositol phosphates (Figure 1) can make up as much as 50% of the organic P in a soil. Therefore, hydrolysis of orthophosphate from this source can be important to plant nutrition. These extracellular enzymes are actively excreted into the soil by organisms, and also accumulate in soil, protected by sorption to organo-clay complexes in the soil. These enzymes are important not only for the degradation of freshly added organic residues, but also for the release of inorganic P from soil organic matter.

Microbial Solubilization of Inorganic P

Microorganisms are also important in the solubilization of P from mineral sources. Orthophosphate is typically present in soil solution at very low concentrations. This solution P is replenished either from mineralization of organic P sources, as discussed above, or from the dissolution of P from phosphate minerals. The primary P-containing mineral in soils is apatite or rock phosphate. In weathered, acidic soils, little apatite typically remains. In these soils, secondary inorganic P minerals in the form of aluminum and iron phosphates, such as variscite ($AlPO_4 \cdot 2H_2O$) and strengite ($FePO_4 \cdot 2H_2O$), dominate. In alkaline soils, the calcium phosphates dominate (e.g., $Ca_3(PO_4)_2$).

Most forms of inorganic P in soil have limited solubility (Figure 1). It is generally agreed that microorganisms can facilitate the enhanced dissolution of these compounds by at least two mechanisms: production of organic acids and excretion of protons during NH_4^+ assimilation. These mechanisms are performed by soil fungi and bacteria and appear to be potentially important, especially in soils receiving little or no phosphate fertilizer materials.

Phosphate solubilization has been observed for many different species of bacteria, fungi, and actinomycetes in laboratory studies. Bacterial species reported include those in the genera *Bacillus*, *Micrococcus*, and *Pseudomonas*. The most commonly observed P-solubilizing fungi are *Aspergillus* and *Penicillium* species, although a number of other

species have been reported to show P-solubilizing activity. In soil, P-solubilization activities are greatest in the rhizosphere. The plant root system provides ample quantities of readily utilized carbon which results in high microbial activity. The activity of P-solubilizing organisms in the rhizosphere can be potentially important in the P nutrition of plants. While not a direct topic of this chapter, it should be noted that mycorrhizal fungi are also active in solubilization and uptake of P which benefits the host plant. (For more detail) on mycorrhizal activities, see **Mycorrhizal Fungi**. In general, it appears that fungi may be more effective in soil than bacteria. Fungal hyphae can grow across distance in soil microenvironments, allowing for exploitation of P resources not available to relatively immobile bacteria.

Organic acids produced by bacteria and fungi have been shown to solubilize various forms of inorganic phosphates (Figure 4). Citrate, and other organic acids, can be quite effective in solubilizing only minimally soluble forms of P, such as $AlPO_4$. Organic acids are effective as P-solubilizing agents in liquid medium because they cause a reduction in pH in the medium, facilitating acid hydrolysis of the $AlPO_4$, and the released Al^{3+} is then complexed by the organic anion. This chelation or complexation of the released Al helps to minimize reprecipitation of Al-phosphates and the potential for Al-toxicity. While organic acids appear to be effective in solubilizing Al-phosphates, solubilization is typically more effective in the presence of microbial cells than that observed with organic acids alone. Also, some organisms solubilize Al-phosphates with no appreciable production of organic acids. Proton production during the assimilation of NH_4^+ or through respiratory activities appears to be a primary mechanism when organic acids are not produced.

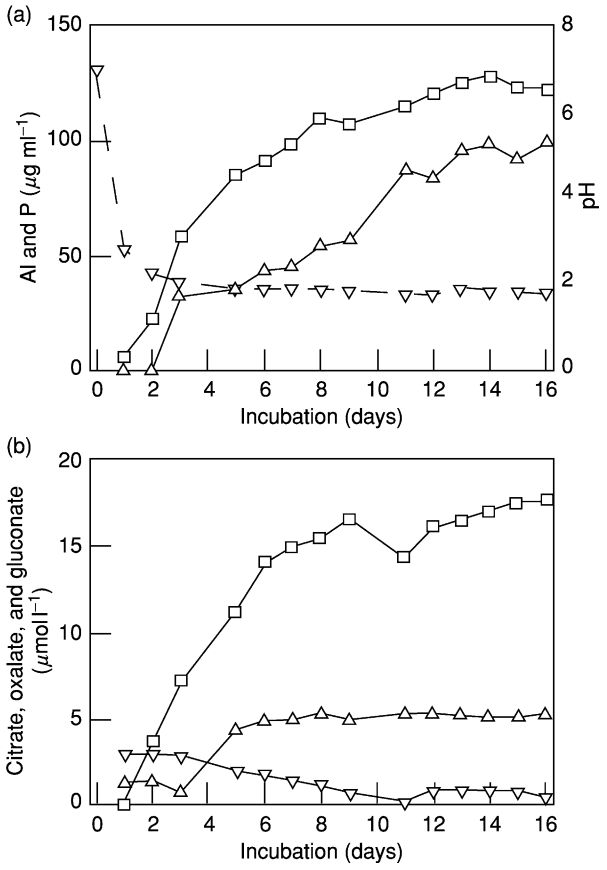

Figure 4 (a) Al (squares) and P (triangles) concentration and pH (inverted triangles) and (b) production of organic acids (squares, citrate; triangles, oxalate; and inverted triangles, gluconate) during the solubilization of $AlPO_4$ by the fungus *Aspergillus niger*. Reproduced with permission from Illmer P, Barbato A, and Schinner F (1995) Solubilization of hardly-soluble $AlPO_4$ with P-solubilizing microorganisms. *Soil Biology and Biochemistry* 27: 265–270.

Dissolution of Ca-phosphates, such as rock phosphate or $Ca_3(PO_4)_2$, also occurs by organic acid production and/or the production of protons during ammonium assimilation or respiration. Typically, a decrease in medium pH occurs during solubilization of P from these minerals. The pH decrease is most pronounced, and solubilization is usually highest, in the presence of ammonium N sources. While organic acids can be effective in solubilization of Ca-phosphates, they are not always produced by all organisms capable of the process. Again, production of protons by physiological processes is important in this regard.

P-Solubilizing Microorganisms and Plant Growth

Inoculation of crops with P-solubilizing microorganisms has met with mixed results. In the 1950s in the Soviet Union, researchers reported excellent results when *Bacillus megatherium* var. *phosphaticum* (also referred to as phosphobacterin) spores were applied to soils that were neutral to alkaline in pH and with high organic matter. The mode of action was thought to be the mineralization of organic P. Research in the USA was not able to verify the claims of significant crop yields and the practice was never adopted. However, other P-solubilizing microorganisms have been used with varying degrees of success in greenhouse and field situations.

Many greenhouse studies have shown positive effects of inoculation on yield and P uptake for several crops, including beans, peas, wheat, soybean, and sorghum. Numerous field studies have also been conducted. In some cases, there is little or no effect, while other research has shown positive effects of inoculation on yields and P uptake. Crops reported to respond

positively to inoculation with P-solubilizing fungi and bacteria include wheat, canola, soybean, and others. An example of the impact of *Penicillium bilaji* on wheat growth and P uptake when used with rock phosphate is shown in Table 1. It should be noted that inoculation of soil or growth media with microorganisms can positively impact plant growth due to production of plant growth-promoting compounds or through suppression of deleterious microorganisms. However, any organism that positively impacts root growth and soil exploration will likely lead to better P availability for the plant.

Phosphorus and the Environment

Interest in the impact of P on the environment has greatly increased over the past decade. Overapplication of P-containing materials, whether inorganic fertilizers or organic sources such as manures and biosolids, can result in high levels of extractable soil inorganic phosphate. If these soils are close to surface waters, then this P can be exported to those waters either as soluble P in runoff water or as P adsorbed to eroding soil particles. In both cases, this can result in the elevation of the bioavailable P in these waters. This can potentially lead to eutrophication of the waters. Eutrophication occurs when excess nutrients, typically N or P, accumulate in the water, resulting in accelerated growth of algae. These algae can cloud the water, decreasing light penetration, and resulting in decreased growth of aquatic plants. Increased algal biomass production stimulates higher rates of degradation in the water column by bacteria. This accelerated decomposition then decreases available oxygen, often making the habitat unfit for many forms of aquatic life.

Many soils that have received regular applications of manure over time have become quite high in total and available P. If manure is applied to a crop to satisfy N requirements, too much P is typically applied, resulting in a P buildup. Although much of the P in these manures is added in the organic form, the result is typically a significant increase in the total amount of inorganic phosphate due to mineralization by soil microorganisms. Table 2 shows the impact of long-term manuring on total P, organic P, and inorganic P content of nine soils in Tennessee. Note that the inorganic P content is on average 2.4 times higher in the manured soils, and the proportion of inorganic P increased by 10.3%. Microbial mineralization of the manure P releases the phosphate and more of it tends to remain relatively labile. This may be due to increased soluble soil C which may then bind to P-sorption sites or with soil Al and Ca, reducing complexation. Microbial mineralization of these organic P sources over long periods of time can therefore result in potential offsite degradation of water quality.

Table 2 Inorganic (Pi) and organic (Po) P content in the 0–15-cm depth of nine Tennessee soils treated with animal manures. Soil textures range from sandy loams to silt loams. Four soils received swine manure, three received dairy manure, and two received poultry litter

	Total P ($mg\,kg^{-1}$)	Po ($mg\,kg^{-1}$)	Pi ($mg\,kg^{-1}$)	% Pi
Inorganic fertilizers	975	793	182	18.7%
Manured soils	1478	1049	429	29.0%

Introduction

Plants are continuously exposed to their ambient soil environment during the whole span of their life-cycle. Sometimes the presence, application, and/or formation of certain substances in soils reach to the extent that they become phytotoxic – the property of a substance at a specified concentration that restricts or constrains the plant growth. With a wide range of characteristics and impacts, phytotoxic substances have long been accumulating in the terrestrial ecosystem, including soils. Once these substances enter the soil, they become part of a cycle that affects all forms of life. Soils act as a sink and a filter, protecting the groundwater from inputs of phytotoxic substances during initial stages of their addition. With continued uncontrolled applications, the concentrations of potentially harmful substances may increase to levels that become toxic to a wide range of plants, and in certain cases toxicity can occur in soil faunas and floras, higher animals, and humans.

The contribution of several different human activities to accumulation of phytotoxic substances has been several times greater than natural sources. Although the use of chemicals expanded in the nineteenth century, it was not until the middle of the twentieth century that the use of chemicals became widespread. In recent years, the quantities of many products in which phytotoxic substances are used have increased notably, enhancing the opportunity for contamination and phytotoxicity in soils. Although there are several forms of phytotoxic substances in soils, they can be grouped into five broad categories: (1) pesticides, (2) metals and metalloids, (3) soil acidity and aluminum and manganese toxicity, (4) soil flooding and manganese and iron toxicity, and (5) soluble salts and sodium toxicity.

Pesticides

Pesticides are substances or mixtures thereof intended to prevent, destroy, repell, or mitigate any pest, which may be an insect, rodent, nematode, fungus, weed, or other form of terrestrial or aquatic plant or animal

Table 1 Class, chemical group, and persistence time of some pesticides

Pesticide class	*Chemical group*	*Pesticide name*	*Persistence time*
Insecticide	Chlorinated hydrocarbons	DDT	3–15 years
Insecticide	Chlorinated hydrocarbons	Chlordane	2–5 years
Insecticide	Chlorinated hydrocarbons	Dieldrin	2–5 years
Herbicide	Triazines	Atrazine	1–2 years
Herbicide	Triazines	Simazine	1–2 years
Herbicide	Benzolics	Dicamba	2–12 months
Herbicide	Phenoxyalkyl acids	2,4-D	1–5 months
Insecticide	Organophosphates	Diazinon	1–12 weeks
Insecticide	Organophosphates	Malathion	1–12 weeks
Insecticide	Carbamates	Carbaryl	1–8 weeks

life that is injurious to growing plants, animal or human health, or the environment. The chemical revolution in agriculture was initiated when the insecticidal properties of dichlorodiphenyltrichloroethane (DDT) were discovered in 1939 along with the herbicidal effects of 2,4-dichlorophenoxyacetic acid (2,4-D) in 1941. Since their discovery, tens of thousands of such chemicals and multichemical formulations have been developed, tested, and put to use. In the past 60 years, synthetic organic pesticides have become a major element in modern agricultural production practices. The advent of pesticide use has coincided with the tremendous increases in agricultural productivity. Although the use of pesticides has provided many benefits to society by protecting crops, animals, and humans, it has also created several problems, including widespread accumulation of residues, with damage to plants, wildlife, fisheries, beneficial insects, and even humans.

The impact of pesticides on plants may be as dramatic and devastating as the impact on insects and animals. Exposure of a sensitive plant may produce remarkable growth distortions and yield loss. During the process of application, pesticides may move from the treatment area to deposit a residue affecting a nontarget species. In the case of some pesticides, the amount remaining after a prior treatment can be a limiting factor for the subsequent crop(s). Even though the quantity of pesticide would be small, it could be sufficient to limit the growth of a sensitive species.

Pesticides are commonly classified according to the target group used to control, deter, or destroy pest organisms: (1) insecticides, (2) fungicides, (3) herbicides, (4) rodenticides, and (5) nematocides. The first three are used in much larger quantities and therefore contaminate soils to a greater extent than rodenticides and nematocides. Whatever the mode of application of pesticides, a high proportion of such chemicals eventually moves into the soil. After finding their way into soils, these chemicals then meet with one or a combination of the following fates as they may: (1) vaporize into the atmosphere without a chemical change, (2) adsorb on soil colloidal complex that consists of humus and clay particles, (3) move with the percolating water to the deeper soil layers or to the groundwater, (4) undergo chemical reactions with other chemicals, (5) be broken down by soil microorganisms, and/or (6) be subjected to absorption by plants. The specific fate of different pesticides in soils is determined by their chemical structures and properties, various processes occurring in soils (retention, transformation, and transport processes and their interactions), climatic conditions, and different forms of anthropogenic activities dealing with the management of pesticides in soils. Some pesticides are not readily biodegradable and persist in soils for many years. Thus there is a large variation in the persistence time of different pesticides in soils (Table 1).

Metals and Metalloids

Metals are a group of chemical elements that exhibit all or most of the following physical qualities: (1) solid at ordinary temperatures, (2) opaque except in extremely thin films, (3) good electrical and thermal conductors, (4) lustrous when polished, and (5) crystalline when in the solid state. Metalloids such as arsenic (As) and selenium (Se) are elements with properties intermediate between those of metals and nonmetals. Some metals and metalloids such as zinc (Zn), copper (Cu), manganese (Mn), nickel (Ni), cobalt (Co), chromium (Cr), molybdenum (Mo), iron (Fe), and Se are essential for living organisms. However, these metals and those that are thought to be nonessential such as lead (Pb), mercury (Hg), cadmium (Cd), and As can pose risks when they build up in soils due to many forms of anthropogenic influences (Table 2). When their bioavailability is high, toxicity can result, with negative effects on plants.

Although metals and metalloids are usually present in soil parent materials, they have several different

Table 2 List of anthropogenic sources of some selected metals and metalloids

Chemical	*Symbol*	*Major uses and sources*[a]
Arsenic	As	Pesticides, animal feed additives, and manures from intensive animal production, desiccants, fossil fuel combustion, electronics, pigments and paints, medical uses
Cadmium	Cd	Electroplating, pigments for plastics and paints, batteries, sewage sludge, fossil fuel combustion, polymer stabilizers, waste disposal, impurities in fertilizers
Chromium	Cr	Chrome-plated metals, pigments, electronics, fossil fuel combustion, impurities in fertilizers, wood preservatives, stainless steel
Copper	Cu	Fly ash, wind-blown copper containing dust, impurities in fertilizers, warfare and military training, waste disposal, medical uses, electronics, sewage sludge, wood preservatives, pesticides
Lead	Pb	Fossil fuel combustion, batteries, pigments and paints, polymer stabilizers, printing, sports shooting, warfare, and military training, waste disposal, impurities in fertilizers, pesticides
Mercury	Hg	Pesticides, chlorine manufacture, medical uses, batteries, electronics
Nickel	Ni	Alloy manufacture, electroplating, sewage sludge, batteries, catalyst
Selenium	Se	Pigments and paints, printing, medical uses
Zinc	Zn	Metallurgical industries, electronics, pesticides, impurities in fertilizers, sewage sludge, pigments and paints, polymer stabilizers, printing, medical uses

[a]In addition to mining of ore bodies in the Earth's crust and smelting of scrap material, and weathering of soil minerals.

anthropogenic sources, including: (1) mining of ore bodies in the earth's crust and smelting of scrap material; (2) sewage sludge produced from the treatment of domestic and industrial waste waters; (3) combustion of fossil fuel consisting of coal and petroleum; (4) manufacture, use, and disposal of metal commodities in metallurgical industries; (5) manufacture, use, and disposal of semiconductors, cables, contacts, and other electrical components of electronic industries; (6) chemical and other industrial sources such as chlorine manufacture, batteries, pigments and paints, catalysts, polymer stabilizers, printing, medical uses, and additives in fuels and lubricants; (7) disposal of household, municipal, and industrial wastes; (8) flood or seepage waters; and (9) sports shooting, warfare, and military training. As an important anthropogenic source of metals and metalloids in soils, the disposal of domestic, municipal, and industrial wastes also contributes to significant quantities of certain substances that can produce harmful environmental effects. In some cases, such wastes may contain less decomposable organic substances. In addition to the nonagricultural sources, agricultural practices constitute important sources of metals which make a significant contribution to their total concentrations in soils in many parts of the world, especially in regions of intensive farming. The main sources are impurities in fertilizers, application of sewage sludge as a source of plant nutrients and organic matter, manures from intensive animal production, use of pesticides, irrigation with metal-rich waters, and corrosion of metal objects.

Atmosphere and water are important transport media for metals from different sources. Soils are often contaminated for up to hundreds of kilometers away from the site of emission. The metals are usually present in air as aerosol particles with a size range of 5–20 μm, but most are between 0.1 and 10 μm in diameter and have a mean residence time of 10–30 days. A high proportion of the metals in more-recent dust deposits are of anthropogenic origin. Water, on the other hand, is an integral component of the weathering processes relating to the release of metals from soil parent material. In addition, contamination of either surface water or groundwater impacts the quality of each other and subsequently the soils irrigated with such waters.

The total metal content of a soil is the result of inputs of metals from the abovementioned sources minus losses in metals removed in crop material, leaching, and volatilization. However, it is not the total amounts but the bioavailable concentrations that are crucial and depend on a number of soil and environmental factors, which also control the speciation of metals in soils. Thus the effect of any metal on plant growth depends not only on its chemical properties but also on its bioavailable concentration. The physiological age and species of the plant concerned are also important.

Soil Acidity and Aluminum and Manganese Toxicity

Soil acidity is usually expressed in terms of pH scale, which quantifies the activity of protons (H^+) present in a solution. Soil acidification can develop naturally when a soil profile is leached, but can be accelerated by certain farming practices and acid precipitation, which is commonly known as acid rain. Various amounts of sulfuric and nitric acids (H_2SO_4 and HNO_3) form in precipitation from certain sulfur (S) and nitrogen (N) gases produced by a number of

sources such as lightning, volcanic eruptions, forest fires, and the combustion of fossil fuels. Since N_2-fixing legumes release H^+ in the root zone, farming practices dealing with continuous cultivation of such legumes may increase the acidity of acid soils. This contribution is crucial when all or a major part of the harvested shoot is not added back to the soil as a measure to control soil acidity. On the other hand, the effects of acid rain are more pronounced on the acidity of water than on soil acidity. Soils generally are sufficiently buffered to accommodate acid rain with little increase in acidity on an annual basis. However, continued inputs of acid rain would have significant effects on the pH of acid soils, especially those that are weakly buffered. Acid rain is also a serious problem for soils that are already highly acidic, since a small increase in acidity could make them even less fertile. Other acidifying processes in soils include: (1) formation of carbonic acid (H_2CO_3) from carbon dioxide (CO_2) in the root zone; (2) dissociation of acids; (3) oxidation of N, S, and Fe compounds; (4) accumulation of organic matter; and (5) deprotonation of pH-dependent charges. The growth of sensitive plants may be adversely affected by high free-H^+ concentration in soils.

Soils become extremely acidic ($pH < 4$) when large amounts of reduced forms of S are oxidized to H_2SO_4 if the soils are exposed to oxygen when they are drained or excavated. With a $\geq$0.15-m-thick sulfuric horizon that is often present, such soils are commonly referred to as acid sulfate soils. These soils could be categorized into potential acid sulfate soils (H_2SO_4 may be produced), active acid sulfate soils (H_2SO_4 is being produced), or postactive acid sulfate soils (H_2SO_4 has been produced). The amounts of S present in these soils provide the basis for estimating the amount of liming material ($CaCO_3$) required to neutralize the H_2SO_4 that could be produced. In many cases, the volume of soil that needs to be treated and the amounts of $CaCO_3$ required are huge enough to make such neutralization an impractical solution to the problem.

Aluminum (Al) is the most abundant metal in the Earth's crust, comprising about 7% of its mass, and is found in soils primarily in the form of insoluble aluminum silicates and oxides. Although Al is a nonessential element, its toxicity occurs in acid soils, which is considered as the most common and severe problem associated with such soils. When soils become more acidic, phytotoxic species of Al such as Al^{3+}, $Al(OH)^{2+}$, and $Al(OH)_2^+$ are released into soil solution. Since most plant species are sensitive to micromolar concentrations of Al, toxicity of this metal may become a major limiting factor for plant productivity on acid soils. Aluminum toxicity has been recognized as a major constraint for the production of several crops in acid soils for the past 80 years. When plants grow and develop under acid soils in natural conditions, they are continuously exposed to Al and the damage is cumulative. As a general phenomenon, Al toxicity primarily restricts root growth, with an effect on plant metabolism through interference with the uptake, transport, and use of several nutrients by plants. However, it is not known whether these observed effects are the primary cause of Al toxicity or they are only indirect or secondary effects. In addition to plants, many bacteria such as those that are involved in certain transformations in N cycle are also adversely affected by high Al levels associated with low soil pH. In contrast to Al, Mn is an essential plant nutrient, which is readily transported from roots to shoots and, therefore, symptoms of Mn toxicity first appear on shoots. Excessive levels of Mn in soils also interfere with the uptake of other mineral nutrients such as calcium (Ca^{2+}) and magnesium (Mg^{2+}). Plant species and genotypes within a species vary greatly with regard to their susceptibility to Mn toxicity. Manganese toxicity is not as widespread as Al toxicity.

Soil Flooding and Manganese and Iron Toxicity

With the exception of rice (*Oryza sativa* L.) and Kallar grass (*Leptochloa fusca* (L.) Kunth.), periodic flooding during the growing season adversely affects growth and productivity of crops. Soil-flooded conditions are also expressed through terms such as 'soil saturation,' 'waterlogging,' 'anoxia,' and 'hypoxia.' Lack of oxygen has been found to be the major problem associated with soil flooding that impacts plant growth. A great deal of information during recent decades has accumulated from research on the molecular, biochemical, and physiological responses of a number of plant species to flooding of the growth medium. The use of molecular plant-breeding and genomic transformations to improve flooding tolerance in crops has been rated as a promising solution to this problem.

In addition to oxygen stress, reduced forms of certain elements can also cause phytotoxicity in flooded soils. For instance, the reduced forms of Mn and Fe are far more soluble than their oxidized forms. Therefore, the toxicity of Mn and Fe is greatly increased by low-oxygen conditions, particularly in acid paddy soils. Other growth-reducing and yield-loss factors in flooded soils could arise from root rot disease, N deficiency, nutrient imbalance, and/or accumulation of high levels of CO_2 in the root zone. Such levels of CO_2 in flooded soils could cause severe leaf chlorosis and reduction in plant biomass in flood-sensitive crops such as soybeans (*Glycine max* L.).

Soil Salinity and Sodium Toxicity

Accumulation of soluble salts can occur in soils to levels that can adversely affect crop growth and yield. Salt-affected soils mostly exist under arid and semiarid regions. Major cations in salt-affected soils are Na^+, Ca^{2+}, Mg^{2+}, and, to a lesser extent, potassium (K^+). The major anions are chloride (Cl^-), sulfate (SO_4^{2-}), bicarbonate (HCO_3^-), carbonate (CO_3^{2-}), and nitrate (NO_3^-). Salt-affected soils are generally classified into two main categories, saline and sodic. Soil salinity is generally characterized by measuring electrical conductivity of the saturated soil paste extract (EC_e) and expressed in units of deci-siemens per meter. In some parts of the world, saline soils are also known as white alkali soils. Soil sodicity is evaluated in terms of the relative amounts of Na^+ on the cation exchange sites (exchangeable sodium percentage, ESP) or in the soil solution (sodium adsorption ratio, SAR), given the accompanying levels of salinity. Other names for sodic soils include 'black alkali soils,' 'solonetz,' and 'slick-spots.'

The presence of voluminous data indicates that there are no single values of EC_e and ESP (or SAR) for saline and sodic soils, respectively. In general, an EC_e of $4\,dS\,m^{-1}$ is used as the boundary between saline and nonsaline soils; the soils of higher EC_e are called 'saline.' Actually, salt-sensitive plants are affected at half of this salinity ($2\,dS\,m^{-1}$) and highly tolerant plants at about twice of this salinity ($8\,dS\,m^{-1}$) or at an even greater value. Similarly, an ESP of 15 (an ESP of 6 in Australia) is considered as the critical limit for soil sodicity; the soils of higher ESP show dispersive behavior in most cases and suffer from serious physical problems when wetted. Different terminology for alkali soils is used in some parts of the world to express sodicity hazard. Alkali soils are characterized by high sodicity (ESP of more than 15) and pH (pH >8.3), and contain soluble CO_3^{2-} and HCO_3^- of Na^+, i.e., C_{Na}: $(C_{Cl} + C_{SO_4})$ ratio greater than 1. These soils contain Na^+ and $CO_3^{2-} + HCO_3^-$ as the dominant ions and tend to have low salinities and high pH values, which cause an increase in swelling and dispersion. On the other hand, the pH of sodic soils can be either more than or less than 7, and such soils can be either saline or nonsaline. Therefore, use of the term 'alkali' provides a practical distinction in terms of soil management.

Deterioration of salt-affected soils occurs through changes in the proportions of soil solution and exchangeable ions and soil reaction (pH) that lead to osmotic and specific ion effects together with imbalances in the availability of plant-available nutrients. Excess Na^+ in soils accelerates the development of structural problems created by certain physical processes (slaking, swelling, and dispersion of clay minerals) and specific conditions (surface crusting and hard-setting) that may affect water and air movement, plant-available water-holding capacity, root penetration, seedling emergence, runoff, erosion, as well as tillage and sowing. These chemical and physical changes have a bearing on the activity of plant roots and soil microbes, and ultimately on crop growth and yield.

Excess soluble salts in salt-affected soils originate either through the weathering of parent minerals (causing fossil or primary salinity and sodicity) or from man-made activities involving improper use and management of land and water resources (contributing to secondary salinity and sodicity). Secondary salinity and sodicity of arable land resources are as old as the history of human settlement and irrigation. A well-documented case occurred in Mesopotamia where, between 4000 and 2000 BC, secondary salinization affected the land in the valleys of the Euphrates and Tigris as a result of improper irrigation practices. History repeated itself in the twentieth century in many countries and regions. Although the vast river systems in arid and semiarid regions with extensive irrigated agriculture supply water for irrigation, they also contain appreciable quantities of salts. The inappropriate use of such irrigation systems accelerates the development of secondary salinity and sodicity, which plague these regions. Dryland (or nonirrigated) salinization is commonly due to rising water tables over essentially saline subsoils caused by clearance of trees or other deep-rooted crops, usually to make land available for rain-fed agriculture. The area under human-induced salinity and sodicity has increased substantially, particularly in the twentieth century.

Remediation Strategies for Phytotoxic Substances

There is a long history of accumulation and control of phytotoxic substances in soils. The concentrations of such substances in soils are increasing because the inputs are not balanced by the output in terms of removal from the plough layer. Although the accumulation of phytotoxic substances in soils provides a direct stimulus for cleanup, mostly public and political pressure to reduce these substances in soils only occurs when critical levels are reached. The past focus to remove phytotoxic substances from soils was on the use of traditional physical and chemical methods. Physical remediation is the process of correcting the problem by a number of physical means. For example, containment of pollutants could be done by covering the polluted site with a layer impermeable to rain

water. Clay or cement has been used in the past to provide an impermeable cap preventing water from reaching the pollutants and leaching them away. Chemical remediation involves the use of a variety of chemicals for different phytotoxic substances. For example, $CaCO_3$ is used to neutralize H_2SO_4 in acid sulfate soils, while gypsum ($CaSO_4 \cdot 2H_2O$) has been a commonly used amendment to ameliorate excess Na^+ in sodic soils. The enormous cost associated with the physical and chemical means is one of the major reasons for slow progress in the removal of phytotoxic substances from the soils. Therefore, efforts have been made to minimize the cost of amelioration of such soils. In recent decades, strategies assisted by certain microorganisms and higher plants have shown the potential to remediate the soils at relatively low costs. These strategies are gaining an increasing interest among policy makers and scientists. Biological remediation, commonly known as bioremediation, deals with cleaning soils with the assistance of certain microorganisms that have the capability of breaking down some specific phytotoxic substances. Persistent pesticides such as DDT and dioxin have been reported to succumb to the attack of a white rot fungi species, *Phanerochaete chrysosporium*. Phytoremediation is a plant-based approach, which involves the use of suitable crops, grasses, shrubs, and trees that have the potential to grow on contaminated soils with the ability to improve such soils in several different ways.

Phytoremediation of metals and metalloids can be done through phytoextraction, which involves the use of pollutant-scavenging plants to transport and concentrate metals and metalloids from the soil into the aboveground shoot. The efficiency of phytoextraction for a given metal ($Phyto_{Metal}$) is the product of the dry-matter yield of shoot (S_{DM}) and concentration of the metal in shoot (S_{CM}), as given in the following equation:

$$Phyto_{Metal} = S_{DM} \times S_{CM} \quad [1]$$

The plants able to accumulate high concentrations of metals are known as hyperaccumulators (Table 3). The concentrations of metals accumulated in such plants may be 100 times greater than those occurring in nonaccumulator plants growing on the same substrates. Following the harvest of the metal-enriched plants, the weight and volume can be reduced by ashing. Metal-enriched plants can be disposed of as hazardous material or, if economically feasible, used for metal recovery. Phytoremediation can be done through reduction in the bioavailability of metals in the soil (phytostabilization) and volatilization of pollutants such as Hg and Se from the foliage (phytovolatilization).

Table 3 Some important metal hyperaccumulators

Element	*Metal-accumulator plant species*
Cadmium	*Thlaspi caerulescens*
Cobalt	*Haumaniastrum robertii*
Copper	*Haumaniastrum katangense*
Lead	*Thlaspi rotundifolium* subsp.
Manganese	*Macadamia neurophylla*
Nickel	*Berkheya coddii*
Selenium	*Astragalus pattersoni*
Thallium	*Iberis intermedia*
Uranium	*Atriplex confertifolia*
Zinc	*Thlaspi calaminare*

In contrast to the phytoremediation of metal-contaminated soils, phytoremediation of salt-affected soils works through plant roots to enhance leaching of soluble salts and Na^+ from the root zone to the deeper soil layers. The enhanced partial pressure of carbon dioxide (P_{CO_2}) in the root zone during cropping is considered as a major factor contributing to the amelioration of calcareous sodic soils. Aqueous CO_2 helps in the dissolution of native soil calcite ($CaCO_3$) to provide Ca^{2+} for the Na^+–Ca^{2+} exchange at the cation exchange sites. In addition, H^+ released by the roots of certain phytoremediation crops such as N_2-fixing legumes may react with soil $CaCO_3$ to provide Ca^{2+}. Phytoremediation of sodic soils ($Phyto_{Sodic}$) is considered as a function of the following factors:

$$Phyto_{Sodic} = \sum R_{P_{CO_2}} + R_{H^+} + R_{Phy} \quad [2]$$

where $R_{P_{CO_2}}$ refers to P_{CO_2} within the root zone, R_{H^+} is H^+ release in the root zone of N_2-fixing crops, and R_{Phy} refers to physical effects of roots in improving soil aggregation and hydraulic properties of the root zone. The collective effects of these factors ultimately lead to soil improvement, provided drainage is adequate and leaching occurs. The salinity–sodicity combination in soil solution during phytoremediation remains suitable to maintain adequate soil structure and aggregate stability, which prevent reduction in soil permeability to air and water.

Phytoremediation of sodic soils has been shown to be advantageous in several economic, environmental, and agronomic aspects: (1) no financial outlay to purchase chemical amendments, (2) financial and other benefits from plant species grown during phytoremediation, (3) promotion of soil aggregate stability and creation of macropores that improve soil hydraulic properties, (4) better plant nutrient availability in soil during and after phytoremedition, and (5) more uniform and greater zone of amelioration in terms of soil depth. In general, phytoremediation

Table 4 Some plant species used for phytoremediation of salt-affected soils

Common name	*Botanical name*
Alfalfa	*Medicago sativa* L.
Barley	*Hordeum vulgare* L.
Bermuda grass	*Cynodon dactylon* (L.) Pers.
Kallar grass	*Leptochloa fusca* (L.) Kunth
Millet rice	*Echinochloa colona* (L.) Link
Para grass	*Urochloa mutica* (Forssk.) T. Q. Nguyen
Rhodes grass	*Chloris gayana* Kunth
Rice	*Oryza sativa* L.
Sesbania	*Sesbania bispinosa* (Jacq.) W. Wight
Sordan	*Sorghum* × *drummondii* (Steud.) Millsp. & Chase
Sorghum	*Sorghum bicolor* (L.) Moench

works well on coarse- to medium-textured and moderately salt-affected soils. On such soils, its performance has been found to be comparable with soil application of chemical amendments such as gypsum. Several plant species of agricultural significance have been successfully grown as a phytoremediation tool on a variety of salt-affected soils (Table 4). Phytoremediation may face certain limitations under conditions of very high levels of salinity and/or sodicity, where the growth of phytoremediation crops is likely to be variable and patchy. Under these conditions, the use of chemical amendments is probably necessary.

PLANT–SOIL–WATER RELATIONS

Introduction

Water for evapotranspiration from land surfaces is supplied mainly by the soil. The soil water reservoir balances the episodic excesses of water supply from rainfall against the more smoothly varying atmospheric demand for evapotranspiration. The role of soil moisture within the soil–plant–atmosphere system depends on the soil moisture reservoir size and the availability of water in that reservoir, which, in turn depends on the texture and structure of the soil and the characteristics of the root system.

One key function of plant roots is their ability to link the soil, where water and nutrients reside, to the organs and tissues of the plant, where these resources are used by the canopy. Hence roots serve to connect the soil environment to the atmosphere by providing a first link in the pathway for fluxes of water and solutes through the plant to the atmosphere. Fluxes along

the soil–plant–atmospheric continuum are regulated by aboveground plant properties such as the regulation of plant transpiration by the leaf stomata, which interact with the atmosphere, and plant root properties such as depth, distribution, and activity of roots, as well as soil properties such as water potential, water content, and hydraulic conductivity.

Plant root systems show a remarkable ability to adapt to soil depth and to changes in availability of water and nutrients and the chemical properties (e.g., salinity) in soils. Root response to soil properties in turn affects the uptake of soil water and nutrients and the storage of carbon belowground. Root distribution may change when ecosystems respond to greenhouse warming and carbon dioxide fertilization.

Liquid Water Flow Inside the Plant

Water is absorbed in the *liquid state* by the roots from the soil. The general flow pattern is shown in Figure 1: soil → root cells → endodermis → xylem → leaf cells → stomata → air (the latter as vapor flow). Most of the transport (±80%) through the root and leaf cells takes place along the microcapillaries situated in the cell wall. However, the roots contain endodermis cells in which the continuous system of microcapillaries in the cell walls is interrupted by the so-called Casparian strips. Consequently most of the water has to pass through the cells itself. This means that the permeability of the endodermis cell and the semipermeable membrane (plasmalemma) can be an important determinant in controlling the water flow. Hence a low soil temperature and/or poor soil aeration will induce a low metabolic activity of the endodermis cell, which may cause a high resistance of the semipermeable membrane against water uptake. The resistance of the xylem vessels is quite low compared with the large resistances encountered in transport from cell to cell.

Figure 2 shows a daily cycle of transpiration and water uptake which is regularly observed in summer. Before sunrise a plant is usually at full turgor, there is no transpiration, and stomata are fully closed. After sunrise, radiation increases and stomata open. During midday hours the transpiration demand increases, the water head in the leaves drops, because plant roots cannot take up water quickly enough, turgidity declines, and stomata will partially or completely close. This leads to a decrease in transpiration and an increase in leaf temperature. After closing the stomata, water head and turgidity will be restored, which may lead to opening of the stomata again in the afternoon. During nighttime there is complete recovery of water head and turgidity under nonevaporation conditions.

Accurate mathematical description of water uptake by crops with a nonuniform root system is complicated. Therefore it has been customary to describe water flow through the entire soil–plant–atmosphere system with an electrical analog. This model assumes that the water flux density v_z (cubic centimeters per square centimeters per second) through the rooted soil zone and the root–stem–leaf-stomata path is proportional to the total water potential/head difference Δh_{total} (centimeters) and inversely proportional to the total resistance R (seconds) of the system. Thus,

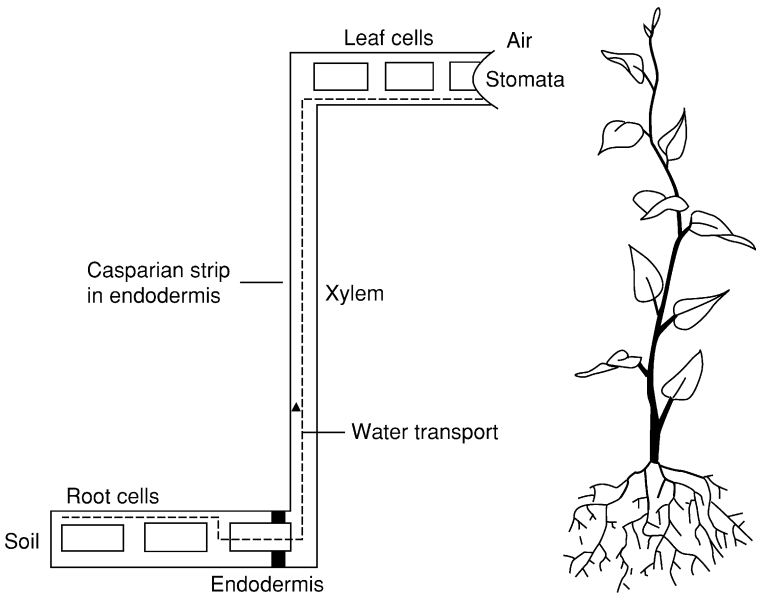

Figure 1 Liquid transport through the plant tissues.

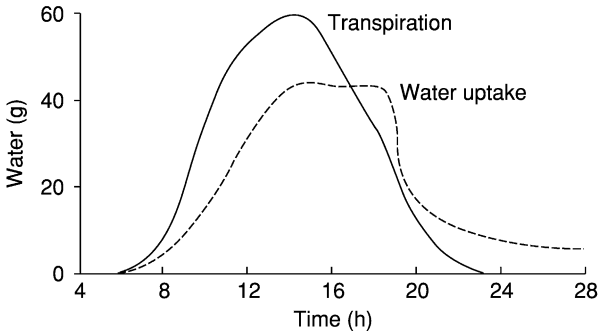

Figure 2 Daily cycle of plant transpiration and root water uptake.

considering a one-dimensional, steady-state flow in a series network, the liquid flow equation is:

$$T = -\frac{\Delta h_{\text{total}}}{R_{\text{total}}} = -\frac{(h_{\text{root}} - h_{\text{soil}})}{R_{\text{soil}}} = -\frac{(h_{\text{leaf}} - h_{\text{root}})}{R_{\text{plant}}} = \frac{h_{\text{leaf}} - h_{\text{soil}}}{R_{\text{soil}} + R_{\text{plant}}} \quad [1]$$

where T (centimeters per second) is the transpiration rate, h_{soil}, h_{root}, and h_{leaf} (centimeters) are pressure heads in the soil, at the root surface and in the leaves, respectively, and R_{soil} and R_{plant} (seconds) are liquid flow resistances of the soil and the plant, which are assumed to be constant; hence R_{plant} does not include stomatal resistance. When the transpiration demand of the atmosphere on the plant system is too high or when the soil is rather dry, R_{soil} and R_{plant} influence h_{leaf} in such a way that transpiration is reduced by closure of the stomata.

Equation [1] can be applied to the root system as a whole by measuring T, h_{soil}, and h_{leaf} during two periods, thus obtaining two equations with two unknowns, from which R_{soil} and R_{plant} can be computed. The relative importance of R_{soil} and R_{plant} is an important object of study. Under wet conditions R_{soil} is close to zero. Generally one can state, except for very dry soil, that $R_{\text{plant}} > R_{\text{soil}}$. Most of the plant resistance is concentrated in the roots, to a lesser extent in the leaves, and a minor part in the xylem vessels. Some researchers have concluded that R_{plant} increases with progressive drying of the soil and decreases when the transpiration rate is higher (**Figure 3**). It must be emphasized that this is a controversial issue, as other researchers think that R_{plant} depends neither on soil water content nor on transpiration rate.

The uptake of water and nutrients by plant roots is not always a passive process, it can be actively regulated by the plant. Water often discharges from the cut surface of active roots even if they are growing in unsaturated soil. If a manometer is attached to such a root, the pressure is usually high (0.1–0.2 MPa

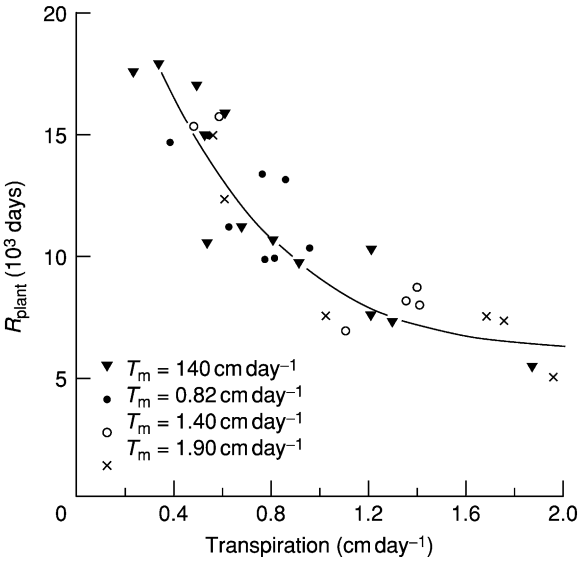

Figure 3 Plant resistance R_{plant} versus transpiration rate T as computed from an Italian ryegrass column experiment, showing the inverse proportionality of R_{plant} with T. (Reproduced from Hansen GK (1974) Resistance to water flow in soil and plants, plant water status, stomatal resistance and transpiration of Italian ryegrass as influenced by transpiration demand and soil water depletion. *Acta Agriculturae Scandinavica* 24: 83–92.)

(1–2 bar)), sometimes even more. This root pressure arises as a result of osmotic effects. The root surface can be considered as a semipermeable membrane: permeable for water in two directions while solutes are held back inside the root. Accumulation of solutes in the root xylem causes a very low osmotic potential. As a result water flows into the roots and a positive root pressure develops in the root xylem, resulting in the discharge from cut surfaces of active roots. Such a root pressure can be high enough to carry water up to a height of 10–20 m. Therefore it has been commonly thought that this active process is the only mechanism that supplies water to the tops of trees. However, if there is a demand for water by the atmosphere, the root pressure is soon unable to satisfy it. The driving force is then no longer the pumping action of the roots, but the sucking action of the leaves, after they have lost water to the atmosphere. This sucking action is more powerful than the force from a mechanical pump could ever produce, as it arises from the chemical potential of water in the presence of solutes. The positive pressure in the xylem vessels of the root then changes to a negative pressure, which may be lower than −1 MPa (−10 bar). The result is that water flows by a passive process from the soil to the xylem vessels in the vascular cylinder. In conclusion: root water uptake due to the osmotic effect plays no essential role in the water economy of plants.

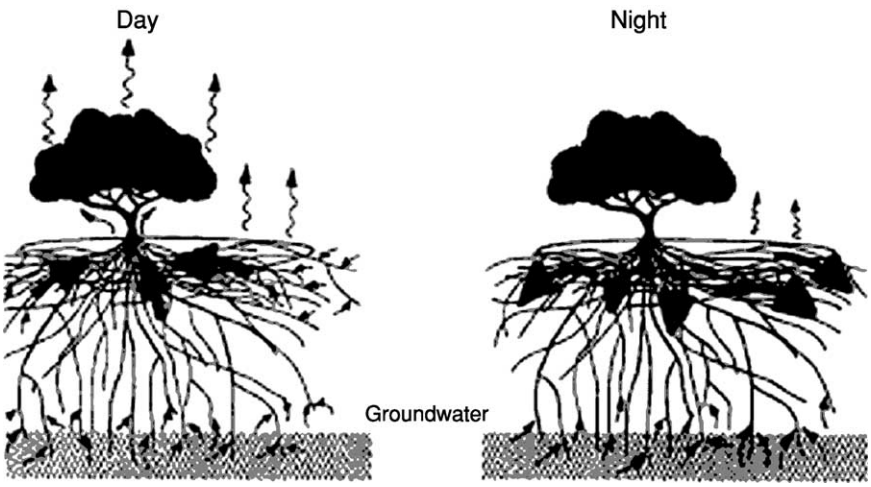

Figure 4 Mechanism of hydraulic lift by plants during night and subsequent uptake during daytime. (Reproduced from Dawson TE (1977) Determining water use by trees and forests from isotopic, energy balance and transpiration analysis: the roles of tree size and hydraulic lift. *Tree Physiology* 16: 263–272.)

In tall trees the xylem vessels are so strong that they do not collapse when the internal equivalent pressure (a potential) is appreciably lower than the external pressure: possibly more than 1.5 MPa (15 bar!) below the atmospheric pressure of 0.1 MPa (1 bar). Water has a high tensile strength, so when the chains of water molecules are drawn toward the leaves, they hold together against the frictional drag imposed by the walls of the conduit. As a result of this cohesion, cavitation does not occur, not even at very low equivalent pressure. In other words, the water is prevented from boiling. The plant exploits this cohesion of water, to transport water through the xylem vessels at very low equivalent pressures. It is this cohesion that enables trees to grow higher than the critical 'pump lift height' of 10 m.

A potentially important effect that happens in the real world but that models overlook is the marked influence plant roots can have on the distribution and redistribution of soil water via the processes of 'hydraulic lift' (Figure 4). During the day, water is absorbed at all depths and passes into the main transpiration stream. During the night, in the case of hydraulic lift, deep-rooted herbs, grasses, shrubs, and trees take in water from deeper, moist soil layers and exude that water during the night into the drier, upper soil layers. For example, sugar maple trees can lift hydraulically 100 l of water through their root systems into the upper soil layer during one night. This water is then absorbed the next day and transpired. But neighboring plants may also utilize this source of water. The result of hydraulic lift is usually a decline in groundwater table depth as well as stream discharge, compared with vegetation systems where hydraulic lift is absent.

Measurement of Root Water Uptake

Root water uptake can generally be derived by applying the water conservation equation to a given volume of soil. Commonly it is assumed that, in an unsaturated soil, water flows only in the vertical direction z. Consider a soil volume of unit cross-sectional area in the horizontal plane, bearing vegetation, with a lower boundary at $z = 0$ (for example, at the groundwater table or a level with constant pressure head) and an upper boundary at the soil surface at $z = z$ (positive upwards). This soil volume is partly explored by roots and partly without roots. The water conservation equation can then be written for every height z and for a short time interval $t_2 - t_1$ as:

$$\int_0^z \bar{S}_z \mathrm{d}z = \bar{v}_0 - \int_0^z \frac{\partial \theta}{\partial t} \mathrm{d}z - \bar{v}_z$$
$$\bar{v}_{\mathrm{root}} = \bar{v}_{\mathrm{total}} - \bar{v}_{\mathrm{soil}} \qquad [2]$$

where $\bar{S}_z$ (cubic centimeter per square centimeter per day) is the time-averaged volume of water taken up by the roots per unit bulk volume of the soil in unit time and considered positive from the soil into the roots, $\bar{v}_0$ (centimeters per day) is the time-averaged volumetric flux density through the lower boundary, θ (cubic centimeters per cubic centimeter) is the volumetric soil water content and $\bar{v}_z$ (centimeters per day) the time-averaged volumetric flux density through the upper boundary. The latter can be calculated from Darcy's law as:

$$\bar{v}_z = -k(h)\left(\frac{\partial h}{\partial z} + 1\right) \qquad [3]$$

where $k(h)$ is the hydraulic conductivity of the soil (centimeters per day) and h is the soil water pressure

head (centimeters). For the calculation of root water uptake patterns, the $k(h)$ curve and the profiles of θ and h have to be known. When the moisture-retention curve is used, it suffices to measure either θ or h and infer the unknown one via the retention curve. The flux at the bottom $\bar{v}_0$ should be derived either from measurements (e.g., using a lysimeter) or by means of eqn [3]. Application of eqn [2] gives the integrated root water uptake over a given depth interval in the root zone. Differentiation of eqn [2] gives the water uptake rate by the roots at depth z.

An example is shown in Figure 5, where a calculation of water extraction by roots at depth z is given for red cabbage on clay for a period of 7 days. The mean pressure head in this period is given in Figure 5a; the time-averaged cumulative withdrawal patterns of both crop and soil, $\bar{v}_{total}$, soil only, $\bar{v}_{soil}$, and crop only, $\bar{v}_{roots}$ are presented in Figure 5b, while the time-averaged extraction rate at depths z, $S(z)$, is given in Figure 5c. From Figure 5b and c it follows that the effective rooting depth can be found at the depth where the cumulative withdrawal function of total flow and soil flow intercept. From Figure 5c it can be seen that for the considered period the maximum extraction rate occurs at a depth of 0.30–0.35 m below surface.

The main conclusions of many reported root water uptake measurements on different vegetation can be elucidated with Figure 6, which shows at various times the root water uptake pattern of a red cabbage crop growing on sticky clay in the presence of a 90-cm-deep groundwater table. The magnitude of the root extraction rate is generally small at the top of the profile (unless the soil is wet just after rainfall or irrigation). Downward the extraction rate increases to a certain maximum and next decreases to zero at the root zone bottom. As the soil dries, the zone of maximum root

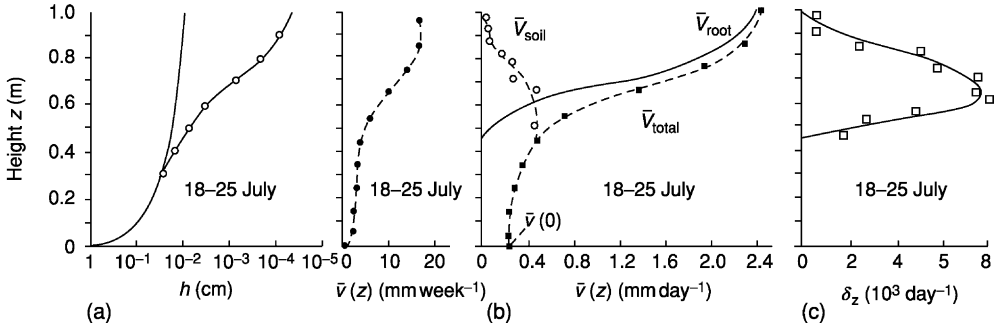

Figure 5 Profiles of: (a), pressure head h; (b), time-averaged cumulative water withdrawal of both a cabbage crop and clay soil, $\bar{v}_{total}$, of soil only, $\bar{v}_{soil}$, and of roots only, $\bar{v}_{root}$; and (c) time-averaged extraction rate S for red cabbage on clay for the period 18–25 July 1967. water uptake moves from shallow to larger depths in dynamic correspondence with the downward progression of roots into deeper, moist soil. The maximum extraction rate appears to depend on the demand the atmosphere exerts on the plant system, on the depths to which the roots penetrate, and on the soil moisture pressure-head distribution. Later in the season, water uptake from the upper layers becomes relatively less important. Most of the water is absorbed from the zone of low tension near the water table. Thus, a relatively small part of the root system can be responsible for most of the plant water uptake.

We may conclude that root water uptake depends on a number of factors such as soil hydraulic conductivity, rooting depth, root density distribution, soil moisture pressure head, demand set by the atmosphere ('potential' transpiration) on the plant system, and the presence of a water table. This list indicates that it is not simple to model water uptake by roots, nor to generalize on the effect of a single modification at the root zone.

Modeling Root Water Uptake in Ecologic, Hydrologic, and Atmospheric Communities

Ecologic Communities: Detailed Radial Root Model

A detailed, plant-based approach is to consider the convergent radial flow of soil water toward and into a representative individual root, taken to be a line or narrow-tube sink. Uniform thickness and absorptive properties along its length are assumed. The root system as a whole can then be described as a set of such individual roots, assumed to be regularly spaced in the soil at definable distances that may vary within the soil profile. The flow equation is cast in cylindrical coordinates and is solved for the distribution of soil-water pressure heads, water contents, and fluxes from the root outward.

In the single-root radial model, the root is viewed as a hollow cylinder of uniform radius and infinite length, having uniform water-absorbing properties. The governing Darcy flow equation can be written in radial coordinates as:

$$\frac{\partial\theta}{\partial t} = \frac{1}{r}\frac{\partial}{\partial r}\left[rk(h)\frac{\partial h}{\partial r}\right] \qquad [4]$$

where r is radial distance from the center of the root (centimeters). For steady-state conditions ($\partial\theta/\partial t = 0$) with water flowing from a distance, r_2, to a root with radius r_1, the solution under the assumption of constant k is:

$$q_{root} = \frac{2\pi k(h_{soil} - h_{root})}{\ln(r_2/r_1)} \qquad [5]$$

where q_{root} (cubic centimeters per centimeter per day) is the rate of water uptake per unit length of root, h_{soil} (centimeters) is the soil-water pressure head and h_{root} is the pressure head in the soil at the root surface (centimeters). Equation [5] is in hydrology known as the steady-state flux toward a well per unit length of well. For a discrete soil layer of thickness Δz and a rooting length per unit volume of soil of L_{root} (centimeters per cubic centimeter), the water uptake rate Δv_{root} (centimeters per day) can be written as

$$\Delta v_{root} = L_{root}\Delta z q_{root} \qquad [6]$$

Within this soil layer located at depth z, eqn [6] can be written as:

$$\Delta v_{root} = \frac{2\pi}{\ln(r_2/r_1)} L_{root} k(h_{soil} - h_{root} + z)\Delta z \qquad [7]$$

or similarly:

$$\Delta v_{root} = BL_{root} k(h_{soil} - h_{root} + z)\Delta z \qquad [8]$$

where $B = 2\pi/\ln(r_2/r_1)$ and represents a dimensionless geometry and root distribution factor.

Due to root shrinkage in a drying soil, the surface area of roots in contact with soil decreases and the root membrane resistance increases, and thus a kind of 'contact' resistance may develop. This resistance can be taken into account by assuming that root water uptake is proportional to the relative saturation, θ/θ_{sat}, of the soil. Hence:

$$\Delta v_{root} = BL_{root} k\frac{\theta}{\theta_{sat}}(h_{soil} - h_{root} + z)\Delta z \qquad [9]$$

Does the concept of contact resistance also hold for heavier-textured soils? **Figure 7** shows computed hydraulic conductivities of a soil root system according to eqn [9] and conductivities of the bulk soil. At low soil-moisture contents, both conductivities are comparable, but at higher moisture contents the hydraulic conductivity of the soil root system becomes not higher than 10^{-6} cm per day, far less than the hydraulic conductivity of the bulk soil. Hence, the use of soil hydraulic conductivity is not very realistic to describe root water uptake. It seems better to take an 'effective conductivity,' which represents the conductivity of the soil–root interface and the root tissue. Moreover, in modeling studies, h_{root} is often taken to be constant over the root zone, while water uptake is assumed to be potential until $h_{root} = -16\,000$ cm (wilting point).

In addition to an expression such as eqn [9], a second, similar type of equation can describe the flux over the root surface into the root using the difference between h_{root} and the pressure head inside the root,

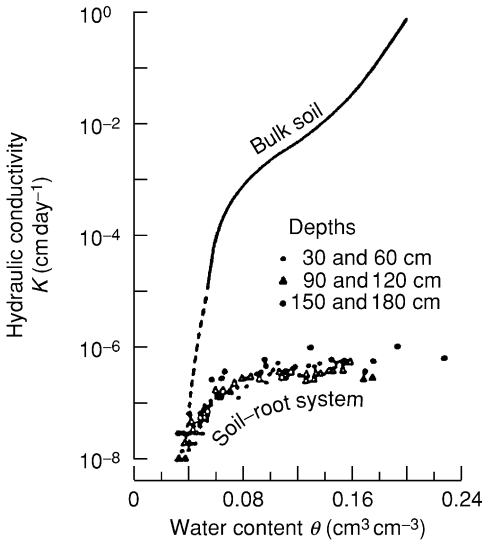

Figure 7 A comparison of the hydraulic conductivity of a soil–cotton root system obtained at various depths with the soil hydraulic conductivity (K) for various soil moisture contents. (Reproduced from Taylor HM and Klepper B (1975) Water uptake by cotton root systems: an examination of assumptions in the single root model. *Soil Science* 120: 57–67.)

h_{plant} (assumed to be uniform over the whole root system), and the hydraulic conductivity of the root. By equating the flux densities toward and into the root, h_{root} and h_{plant} can be derived by a number of iterations.

Hydrologic Communities: General Root System Model

The second, more hydrologically oriented approach is to regard the root system as a diffuse sink that penetrates each layer of soil uniformly, though not necessarily with a constant strength throughout the root zone. Root water uptake can then be represented as a sink term that is added to the vertical water flow equation through the soil. This macroscopic way of solving the root water uptake problem is to combine the continuity equation of water flow with a sink term representing water extraction by plant roots:

$$\frac{\partial\theta}{\partial t} = -\frac{\partial v}{\partial z} - S \qquad [10]$$

where θ (cubic centimeters per cubic centimeter) is the soil water content, t (days) is time, v_z (centimeters per day) is the Darcian soil water flux density (eqn [3]) taken positively upward, and S (cubic centimeters per cubic centimeter per day) is the root water uptake rate, which depends on depth, time, soil-water pressure head, and root density.

Combination of eqns [3] and [10] results in the physics-based soil water flow equation, known as the Richard equation:

$$\frac{\partial\theta}{\partial t} = C(h)\frac{\partial h}{\partial t} = \frac{\partial\left[k(h)\left(\frac{\partial h}{\partial z}+1\right)\right]}{\partial z} - S(z) \qquad [11]$$

where C is the differential water capacity ($d\theta/dh$) (per centimeter).

Under optimal moisture conditions, the maximum possible root water extraction rate $S_p(z)$, integrated over the rooting depth, is equal to the potential transpiration rate, T_p (centimeters per day), which is governed by atmospheric conditions. In many applications a homogeneous root distribution over the rooting depth is assumed, which gives:

$$S_p = \frac{T_p}{|z_{root}|} \qquad [12]$$

where T_p is the potential transpiration rate (centimeters per day) and $|z_{root}|$ is the root zone depth (centimeters). The potential root water extraction rate at a certain depth, $S_p(z)$ (per day), may for nonhomogeneous root distributions be determined by the root length density $L_{root}(z)$ (centimeters per cubic centimeter) as fraction of the total root length density over the rooting depth $|z_{root}|$ (centimeters), according to:

$$S_p(z) = \frac{L_{root}(z)}{\int_{-z_{root}}^{0} L_{root}(z)\partial z} T_p \qquad [13]$$

So far root water uptake under optimal soil-water conditions, S_p, has been considered. Under nonoptimal conditions, i.e., too dry, too wet, or too saline, a reduction is applied. A much-used reduction function for water stress is shown in Figure 8. Water uptake greater than h_1 (oxygen deficiency) and less than h_4 (wilting point) is set equal to zero; between h_2 and h_3 (reduction point), water uptake is maximal. Between h_1 and h_2, a linear variation is assumed, and between h_3 and h_4 either a linear (Figure 8) or hyperbolic variation is assumed. The value of h_3 depends on the demand of the atmosphere and thus varies with T_p.

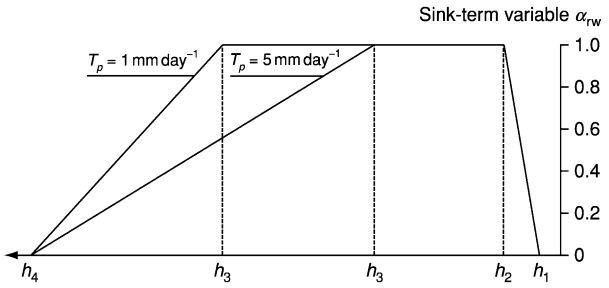

Figure 8 Dimensionless sink term variable α as a function of the soil-water pressure head h. (Source: Feddes RA, Kowalik PJ, and Zaradny H (1978) *Simulation of Field Water Use and Crop Yield*. Simulation Monographs. Wageningen, The Netherlands: Pudoc.)

For an indication of these h_1–h_4 values for five crops, see Table 1.

For many crops the reduction in crop yield due to salinity can be linearly related to the electrical conductivity of the soil solution. Crops tolerate an increase in the soil salinity up to a threshold value above which relative yields Y/Y_m and thus relative transpiration T/T_m show an approximately linear decrease with increasing salt concentration or electrical conductivity EC_e (Figure 9).

In order to simplify parameter calibration and take advantage of existing experimental data, we may assume the water and salinity stress to be multiplicative. This means that the actual root water flux density, $S(z)$ (per day), is calculated from:

$$S(z) = \alpha_{rw}(z)\alpha_{rs}(z)S_p(z) \qquad [14]$$

where α_{rw} (−) and α_{rs} (−) are the reduction factors due to water and salinity stresses respectively. Integration of $S_a(z)$ over the rooting depth then yields the actual transpiration rate T_a.

Numerical solution of eqn [11] requires knowledge of the soil hydraulic functions of which various databanks exist in literature for all kind of soil textures. Also data are needed for the initial moisture profile and during the simulation period of the top and bottom boundary conditions of the flow system. At the top the vegetation plays a dominant role in the partitioning of the various fluxes. Hence one needs in principle a coupling of the soil water balance model with a daily vegetation growth model. Only in this way can a proper prediction of vegetation development and growth in dependency of the actual prevailing soil water conditions be obtained, thus assuring proper feedback.

Table 1 Critical pressure head values of the sink-term function depicted in Figure 8 for some main crops

Crop	h_1	h_2	$h_{3,high}$	$h_{3,low}$	h_4
Potatoes	−10	−25	−320	−600	−16 000
Sugar beet	−10	−25	−320	−600	−16 000

Atmospheric Communities: Large-Scale Root System Model

In global circulation models (GCM), land surface parameterizations are often based on the concept of one big leaf per grid element. However, at the resolvable scale of GCM models, land surfaces are very heterogeneous. On the other hand, various soil–vegetation–atmosphere-transfer (SVAT) schemes have been developed for use in GCM and numerical weather-prediction models. Their weakest component, however, remains their link with the lower boundary. SVAT models, which sometimes may be overparameterized, use a variety of different methods to represent the relationship between roots, soil moisture, and transpiration. Moreover SVAT parameters are generally highly variable in space and difficult to measure. Different SVAT models driven by the same meteorological forcing of air temperature, humidity, wind speed, incoming solar radiation, long-wave radiation, and rainfall can produce remarkably different surface energy and water balances. The question in this context is therefore: What is the role of roots?

With agrohydrologic models, the effect of root distribution on the course of actual transpiration in time can be evaluated. Take, for example, a grass vegetation (covering the soil completely), with a rooting depth of 80 cm growing on a loamy sand containing 10% clay (less than 2 μm). At the bottom, free drainage prevails; and initially throughout the profile the soil-water pressure head $h = -200$ cm, implying a rather wet soil. If at the soil surface a potential transpiration rate $T_p = 4$ mm day^{-1} is applied for two different relative root density distributions: root 1, where most of the roots are located in the topsoil, and root 2, with a uniform root distribution (Figure 10a), the results of this simulation are as shown in Figure 10b. The moisture content of the top soil layer decreases more rapidly than the moisture content of deeper soil layers. Hence root 1 produces an earlier onset of moisture stress than root 2, after 30 days showing an actual transpiration rate that is about half that of root 2. This clearly demonstrates that roots influence the behavior of a land surface model, the role of

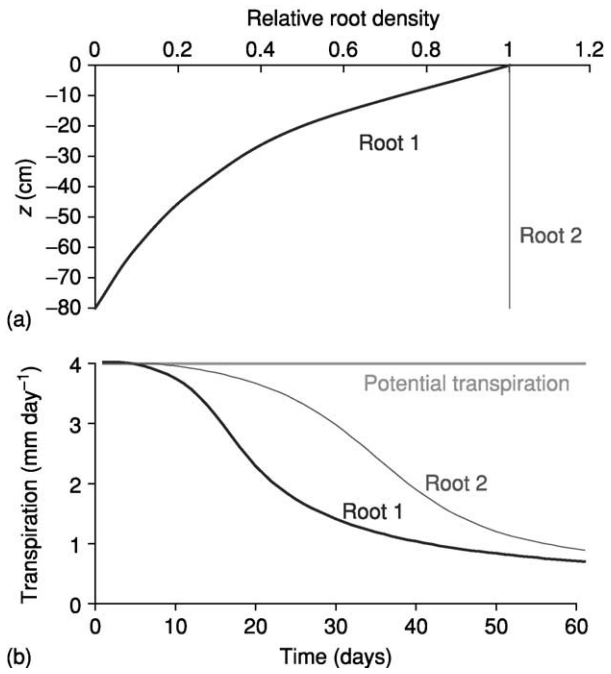

Figure 10 (a) Two different relative root density distribution functions adopted for grass, with a rooting depth of 80 cm, growing on loamy sand; (b) simulated actual transpiration rate in time for the two root-distribution functions, taking $T_p = 4$ mm per day as the upper boundary condition.

roots being particularly important when soil moisture limits evapotranspiration.

Introduction

Water constitutes the largest single chemical component of plants, yet the volume within the plant is very small in relation to the total volume transpired. Adequate plant water status requires that root uptake of soil water satisfies the atmospheric demand (i.e., transpiration requirements). When water uptake is insufficient, a plant water deficit can develop. Various parameters are used to measure plant water status, the most common being water potential. Numerous plant processes are affected by declining plant water status, the most sensitive being cell expansion, which affects new growth. Stomatal closure is another sensitive process. Plants' responses to declining soil water content are mediated by lowered leaf water potential and/or by chemical agents produced in roots. Some parameters of plant water status can be used for irrigation-scheduling purposes.

Water in Plants

In herbaceous plants, water normally constitutes more than 90% of fresh weight, although in rare cases it can be less than 70%. In woody plants, over 50% of fresh weight consists of water. Of the total water content of plants, 60–90% is located within cells, the rest (10–40% of total water) is mainly in cell walls. The water in cell walls forms a continuum with specialized transport cells throughout the plant.

The total volume of water within a plant is very small in relation to the total volume of water transpired during its lifetime. Even on a daily basis, the volume of water within plants is insufficient to buffer appreciably daily transpiration requirements on a warm, sunny day. The very large amounts of water transpired by plants, in relation to that retained within plant tissue, can be viewed as the 'cost' that plants incur as a consequence of stomatal opening to allow CO_2 absorption for photosynthesis.

A primary function of water contained in cells is the maintenance of cell and tissue turgor. Cell turgor is essential for cell enlargement and therefore for optimal plant growth. Other primary functions are the transport of solutes and participation in metabolic activities. Because of its high dielectric constant, water acts as a solvent for many mineral and organic solutes, enabling their transport within cells and throughout the plant. Also, water is directly involved in chemical reactions in cells such as CO_2 reduction in photosynthesis. Cooling is another primary function of water in plants. Because of the high energy requirement for water vaporization (10.5 kJ mol^{-1} at 25°C), water evaporating from leaf surfaces (during transpiration) cools the leaf, thereby avoiding excessive daytime heating from incoming solar radiation.

The water status of plants is a primary determinant of plant growth and development, and therefore of crop productivity in agricultural systems, and of plant survival in natural systems. Almost every plant physiological process is directly or indirectly affected by plant water content. For example, cell enlargement is dependent on the level of cell turgor, photosynthesis is directly inhibited by insufficient water, and stomatal control of transpiration and CO_2 absorption is dependent on the water status of stomatal guard cells.

The water status of plants is the sum of the interaction of various atmospheric, plant, and soil factors. The availability of soil water, the atmospheric demand (determined by radiation, humidity, temperature, wind), the capacities of the root system to absorb water and of the plant to transport absorbed water to transpiring leaves, and stomatal responses for regulating transpiration, can all appreciably influence plant water status.

Plant water status is commonly characterized by its water potential (Ψ). Water potential is a measure of the free energy status of water, which, because of its applicability to each component of the soil–plant–atmosphere system, enables water movement between these components to be considered. It theoretically represents the work involved in moving one mole of water from a selected point within the plant (or soil) to a reference point of pure water at the same temperature and at atmospheric pressure. Ψ varies from zero at the reference point to negative values within the plant and soil. It is normally measured in units of pressure, with megapascals (MPa) being most commonly used.

Leaves are the plant organs where most of the exchange of CO_2 and H_2O between the plant and the atmosphere occurs. The pathway for the inward diffusion of CO_2 is much the same as that for the outward diffusion of H_2O vapor. The outward diffusion of H_2O vapor from the saturated surfaces within the

plant to the drier atmosphere follows a gradient of the partial pressure of H_2O vapor. To maximize CO_2 fixation by photosynthesis, stomata must remain open for as long as possible during daylight periods. This also maximizes the period of water loss by transpiration.

The water status of leaves (considered as Ψ) is the balance between the water lost to the atmosphere by transpiration (T) and the water absorbed by the plant from soil, which is a function of soil water potential (ψ_{soil}) and the combined resistance to water movement within the roots and shoots (r). These relationships are described by the equation:

$$\Psi = \psi_{soil} - T\ r \qquad [1]$$

Even in saturated soils (where $\psi_{soil} = 0$), Ψ is negative when transpiration occurs. During daylight periods, absorption of water lags behind transpiration owing mainly to the high resistance to water flow from soil into root xylem tissue. As atmospheric evaporative demand increases during the morning, transpiration increases, which lowers the water potential of cells from which water is evaporating. Within the plant, water then moves from nonevaporating parenchyma cells of leaves, which have a higher Ψ, toward the evaporating cells, establishing a Ψ gradient. This gradient is transmitted throughout the plant–soil system, enabling continuous water movement. In the afternoon, transpiration decreases on account of reduced atmospheric evaporative demand. However, water uptake by roots continues until parenchyma cells fully rehydrate, and their Ψ equals soil Ψ, which usually occurs during the night. At this stage, plant and soil water are in equilibrium, and absorption by roots ceases. (*See* **Soil–Plant–Atmosphere Continuum**.) In some species under certain climatic conditions (high nighttime vapor pressure deficit, wind), transpiration can occur at night; when it does, it is generally relatively small compared to daytime transpiration. However, it can be sufficient to prevent nighttime equilibration of plant and soil water potentials.

Plant Water Status Indicators

Direct Indicators of Plant Water Status

Relative water content The water content of plant tissue is the fraction of the total fresh tissue weight that is water. It can be considered either on a fresh- or dry-weight basis. As there can be considerable variation between different plant tissues and organs in the maximum water content, the normalized parameter relative water content (RWC) is used. RWC is the water content of plant tissue or a plant organ relative to its maximum water content when it is fully hydrated (i.e., saturated). RWC provides a measure of the degree of hydration of tissue, which is considered to have an important controlling role on numerous plant functions.

Relative water content is expressed as:

$$\mathrm{RWC} = (\mathrm{FW} - \mathrm{DW})/(\mathrm{SFW} - \mathrm{DW}) \qquad [2]$$

where FW is the fresh weight (grams), DW the dry weight (grams), and SFW is the saturated fresh weight (grams).

Water potential and components The most commonly used parameter to characterize plant water status is water potential (Ψ). Total water potential (Ψ) has four components: the osmotic potential (ψ_s), pressure potential (ψ_p), matric potential (ψ_m), and gravitational potential (ψ_g):

$$\Psi = \psi_s + \psi_p + \psi_m + \psi_g \qquad [3]$$

Osmotic potential (ψ_s) results from dissolved solutes in cell sap and is proportional to solute concentration and inversely proportional to cell water volume. ψ_s in plants is always negative and decreases as solutes concentrate during plant dehydration. Pressure potential is a measure of tissue turgor produced by the diffusion of water into the protoplast of cells enclosed by largely inelastic cell walls. Matric potential (ψ_m) arises from the action, on water, of electrostatic forces of attraction associated with cell wall and colloidal surfaces, and of capillary forces associated with narrow transport vessels. In plants it is considered to be negligible. Gravitational potential (ψ_g) results from gravitational forces acting on the water within plants. On account of the gradient of ψ_g with height of 0.01 MPa m^{-1}, ψ_g is normally negligible compared with the other components of plant Ψ; it is only considered to be significant in very tall trees. In most situations, total plant water potential is considered to be the sum of the pressure potential (ψ_p) and osmotic potential (ψ_s).

As both pressure and osmotic potential are dependent on tissue water content, there are relationships between RWC and ψ_s and ψ_p, and consequently between RWC and Ψ. These relationships are schematically represented in Figure 1. In a fully hydrated plant, RWC equals 1, ψ_p is positive, ψ_s is negative, and Ψ (the sum of ψ_p and ψ_s) equals zero. As RWC progressively declines, both ψ_p and ψ_s decline, and consequently Ψ becomes more negative. When RWC has declined sufficiently for ψ_p to equal zero, the plant loses turgor and wilts.

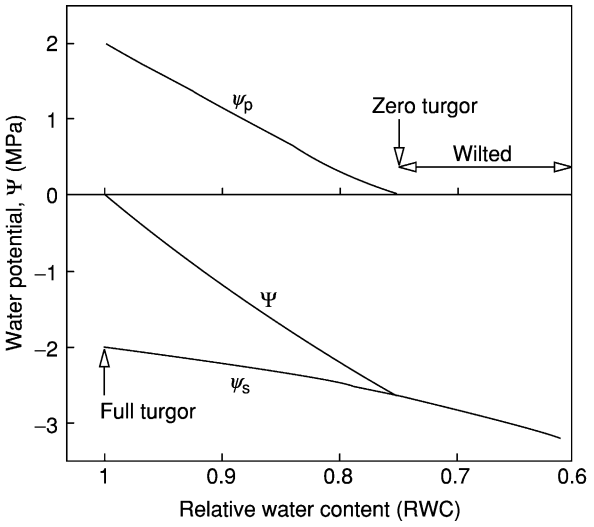

Figure 1 Höffler–Thoday diagram illustrating the relationships between total water potential (Ψ), pressure potential (ψ_p), osmotic potential (ψ_s), and relative water content (RWC) as a cell or tissue loses water from a fully turgid state. Full and zero turgor, and wilting are indicated by arrows. (Adapted from Jones HG (1992) *Plants and Microclimate*. Cambridge, UK: Cambridge University Press, with permission.)

Several methods are used to measure the total water potential of plant tissue. Thermocouple psychrometry and hygrometry are the most accurate methods, but both require very stable environmental conditions. Consequently, whilst they can be used under controlled conditions, they are very difficult to use in field studies. The pressure-chamber method is suitable for routine and rapid field measurement.

Pressure potential (ψ_p) can only be measured directly by the pressure microprobe, which is inserted into cell protoplasm. This technique is limited to relatively large cells and is generally restricted to laboratory measurement. In practice, the most commonly used procedure is to measure both Ψ and ψ_s, and then to calculate ψ_p as the difference between Ψ and ψ_s. Osmotic potential (ψ_s) is commonly measured by either thermocouple psychrometry or hygrometry after previously freezing and thawing the sample to break cell membranes and reduce ψ_p to zero; normally a correction is made for the dilution by apoplastic water. Another method for measuring ψ_s is by determining a moisture-release curve (also called pressure–volume curve) with a pressure chamber.

Indirect Indicators of Plant Water Status

Stomatal conductance Stomatal conductance (g_l) is a measure of the degree of stomatal opening and can be used as an indicator of plant water status. Stomatal conductance is related to leaf Ψ by feedback processes. Reductions in g_l prevent further decreases in Ψ by reducing transpiration; also, reductions in Ψ can induce stomatal closure, resulting in lowered g_l. Stomatal responses are discussed more fully in the section Stomatal Responses, below. Stomatal conductance can be measured with both dynamic and steady-state diffusion porometers.

Stem diameter variations Transpiring plants and trees undergo diurnal variation in stem or trunk diameter. During the morning, when plants are most vigorously transpiring, some water from stem tissue, mostly from phloem tissue, is incorporated into the transpiration stream, producing a measurable reduction in stem diameter. During the afternoon, as transpiration slows, this tissue begins to rehydrate, with a corresponding increase in stem diameter. Rehydration continues throughout the night as some water uptake continues from soil, when transpiration has usually completely ceased. Commonly, stem diameter has a maximum daily value just before dawn, and a minimum daily value in the early afternoon. The magnitude of the diurnal contraction is dependent on atmospheric evaporative demand and plant water status. Under given atmospheric conditions, the magnitude of daily stem contraction increases with increasing plant water deficit. Consequently, stem contraction can be used as an indicator of plant water status. In some fruit-tree and vegetable species, variations in stem diameter have been shown to be very sensitive measures of plant water status.

In young herbaceous plants and young trees, well-watered healthy plants show a trend of increasing daily maximum stem-diameter values, which is an indication of growth. In such plants, a reduction in the rate of growth is apparent in a change in the slope of daily maximum stem-diameter values, which may be due to a lack of water or also to inadequate crop management or changed environmental conditions. In more mature plants, daily maximum stem-diameter values tend to be more constant. Sensors incorporating sensitive pressure transducers, known as linear variable differential transducers (LVDT), connected to data loggers enable continuous monitoring of stem diameter.

Sap flow Sap-flow sensors measure transpiration flow as the ascent of sap within xylem tissue; measurements can be made in stems, trunks, branches, or tillers. Given that transpiration is sensitive to plant water status, with the effect being mediated by stomatal opening (see Stomatal Responses, below), sap flow can be used as an indicator of plant water status.

Sap flow rates can be out of phase with transpiration because of capacitance effects in stems or branches arising from the storage of water. Continuous data recording enables the time course of transpiration to be followed.

Two different techniques are used to measure sap flow; both use heat as a tracer. One is the stem (or trunk) sector heat-balance method, in which a section of the entire stem circumference is electrically heated, and the axial and radial heat-loss measured. The mass flow rate of sap is calculated as a function of the heat dissipated by the ascending sap. The other method is the heat-pulse method in which the heater and temperature sensor probes are placed inside the trunk in a radial direction. The sap velocity is calculated as a function of the time required by the flowing sap to transport heat to a particular location.

Leaf or canopy temperature When plant water status is adequate, canopy temperature (i.e., average temperature of total leaf surface) is appreciably less than the air temperature, through the cooling effect of evaporation. As stomata partially close in response to increasing plant water stress, the energy balance of the plant is altered; less heat is dissipated through the evaporation of water, and consequently canopy temperature increases. With increasing plant water stress, the difference between canopy and air temperature lessens and, under conditions of severe water stress, may become positive. Canopy temperature is most commonly measured with infrared thermometers.

Other Methods

As plant water status affects overall plant growth, measurable parameters such as fruit growth and expansive growth of leaves or stems have been used as indicators of plant water status. Visual characters such as leaf rolling, color change, and visible wilting have also been used. However, visual characteristics are normally an indication that the water stress is severe.

Water Deficits in Plants

Traditionally, 'plant water deficit' or 'plant water stress' has been defined as being when plant water status is reduced sufficiently to affect normal plant functioning (e.g., plant growth, stomatal conductance, rate of photosynthesis). It is not possible to define water deficit in terms of absolute values on account of the complex interaction of atmospheric, plant, and soil factors involved. Also, preconditioning effects from the prior history of the plant can modify plant response at a given water potential. Consequently, a commonly used approach is to express the measured values of the stressed plants in relation to those of well-irrigated plants which have experienced the same environmental conditions and previous general history.

Plant water deficits occur when any plant process is affected by:

1. Limited water absorption by roots because of dry, cool, or poorly aerated soil;
2. High evaporative demand, on account of low relative humidity, high air temperature, high wind speed, high radiation, or combinations of the four;
3. A combination of limited water absorption and high evaporative demand.

Generally, plant water deficits can be considered as being induced by either insufficient available soil water, or a high atmospheric evaporative demand. Plant water deficits induced by lack of soil water may continue for days, possibly weeks, until they are either alleviated by rain or irrigation or the plant dies. Those that are solely due to high atmospheric evaporative demand ('midday' water deficits) are much more transient, occurring for no more than several hours in the middle part of the day.

When not alleviated, water deficits induced by lack of soil water become progressively more intense. The time course of leaf and soil Ψ during a theoretical drying cycle of several days is shown in Figure 2. As soil continues to dry and soil Ψ to decrease, there is increasingly less available soil water for root uptake.

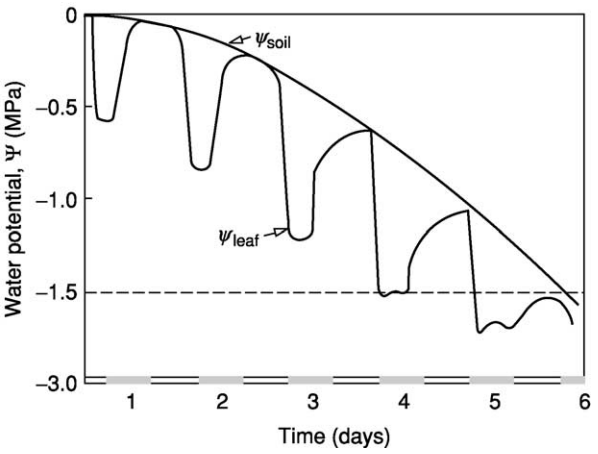

Figure 2 Time course of soil water potential (ψ_{soil}) and leaf water potential (ψ_{leaf}) during a drying cycle. Dashed line represents soil water potential at which permanent wilting of the plant occurs. (Adapted from Kramer PJ (1983) *Water Relations of Plants*. New York: Academic Press, with permission.)

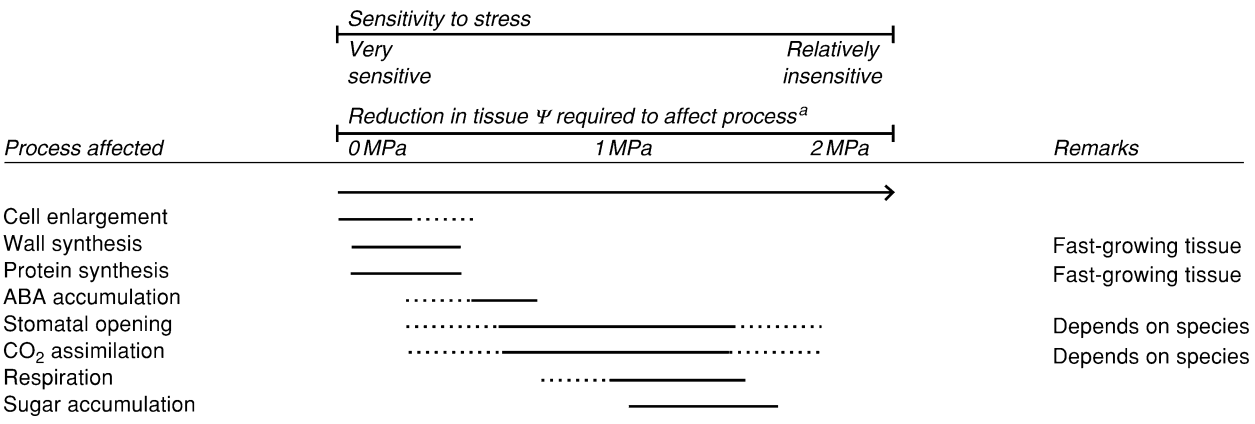
Table 1 Plant process affected by water stress and their sensitivity. Length of the horizontal lines represent the range of stress levels within which a process becomes first affected. Dashed lines signify deductions based on more tenuous data



[a]With Ψ of well-watered plants under mild evaporative demand as the reference point.
Source: Hsaio TC (1973) Plant responses to water stress. *Annual Review of Plant Physiology* 24: 519–570.

This results in a general tendency for plant Ψ to decrease over time. Eventually, the plant is unable to absorb sufficient water for plant Ψ to equilibrate with soil Ψ at night. When plants are unable to recover cell and tissue turgor, which occurs at a threshold soil-water potential value (usually approximately −1.5 MPa), permanent wilting of the plant occurs.

Midday water deficits can even occur in plants growing in moist soil or nutrient solutions. They occur when high atmospheric evaporative demand causes high midday transpiration rates that exceed the rate of water uptake by roots. Where these situations are recurrent, daytime growth is inhibited by these water deficits, and most growth occurs at night, as long as nighttime temperatures are not limiting. Midday water deficits are not restricted to hot and dry environments; they have also been observed in the humid tropics and in greenhouses. Recurrent midday water deficits can reduce yield in cropping situations. In intensive greenhouse crop-production systems, fog systems are commonly used to prevent midday water deficits.

Plant processes affected by water deficits, and an indication of their sensitivity, are shown in Table 1. Processes such as cell enlargement, cell wall synthesis, and protein synthesis are very sensitive, being affected by relatively small reductions in Ψ. Other processes, such as stomatal opening and CO_2 assimilation, generally require larger reductions in Ψ. As plant water deficits intensify, an increasing number of plant processes are affected (Table 1), and there can be complex interactions between them. Two of these processes, expansive growth and stomatal responses, are discussed more fully below.

Expansive Growth

The plant process most sensitive to water deficit is cell enlargement, which affects expansive growth. The effects of plant water deficits on expansive growth are very important, because they result in reduced expansion of the plant assimilation surface (i.e., leaf area). The main factor controlling cell enlargement and therefore leaf expansion is turgor pressure (ψ_p). The relationship between ψ_p and cell expansion can be represented by the Lockhart equation:

$$dV/V\,dt = E_g(\psi_p - \psi_{p,th}) \qquad [4]$$

where the relative change in cell volume (V), with time, is dependent on ψ_p above a threshold value ($\psi_{p,th}$) below which no cell expansion occurs. E_g is the gross extensibility of the cell wall (i.e., its capacity to expand). Increases in cell wall extension during growth are irreversible. Values of $\psi_{p,th}$ are normally only slightly less than ψ_p values of nonstressed plants, so even small reductions in ψ_p can result in reduced growth. Neither E_g nor $\psi_{p,th}$ is constant: they can be influenced by previous exposure to water stress and by growing conditions. With the progressive imposition of water stress, plants can adapt by either reducing $\psi_{p,th}$, increasing E_g, or doing both in order to maintain growth at lower ψ_p.

Stomatal Responses

When leaf water status is adequate (i.e., well-watered plants) and atmospheric evaporative demand is low, stomatal opening is determined primarily by light conditions and the low CO_2 partial pressure of substomatal cavities. Under these conditions, the

stomata are fully open during daylight periods, maximizing assimilation of CO_2, thereby ensuring optimal rates of photosynthesis.

When plant water deficits develop and leaf Ψ decreases, partial stomatal closure occurs to reduce water loss from the plant, with a consequent reduction in photosynthesis. In many species, Ψ must decline to a threshold value before stomatal closure commences. Threshold Ψ values for stomatal closure vary with species, leaf age, previous exposure to radiation, the stress history of the plant, and environmental conditions. If the plant has previously been subjected to a progressive, mild water stress, it can be preconditioned so that the threshold Ψ value is lowered, thereby enabling assimilation to proceed at lower Ψ. Stomata can also close in response to low air humidity, even when leaf water status is adequate.

When recovering from water stress, stomata respond relatively slowly. Unlike Ψ, which rapidly recovers to nonstressed values once water stress is alleviated, stomatal conductance can take several hours, even days, to recover to nonstressed values.

Stomatal closure in response to plant water deficits is not solely controlled by turgor pressure of leaf cells. The process is complex, with the additional involvement of solute movement. When water deficits develop, stomatal guard cells simultaneously lose both water and cell solutes, particularly K^+ ions. It seems that water stress promotes the efflux of K^+ ions from guard cells, resulting in the loss of cell turgor, which induces stomatal closure. In the contrary situation, when water stress is relieved, synchronized changes in K^+ concentration and water content of guard cells have been detected prior to stomatal opening.

Root Signals

Traditionally it has been accepted that drying soil has a hydraulic effect on plant water relations and consequently on cell expansion and leaf gas exchange. The basic theory is that a reduction in soil water potential causes a reduction in plant pressure potential, inducing reduced cell expansion and stomatal closure. In recent decades, it has become clear that stomatal closure, and also leaf expansion, are controlled by a mechanism or mechanisms additional to changes in pressure potential of leaf cells. Reductions in stomatal conductance (g_l) of plants, in drying soil, have been related more strongly to changes in soil water status than to leaf water status. These observations indicate that plants can 'sense' that soil in the root zone is drying and can communicate this information to the leaves by a means other than reduced leaf water status. The evidence to date suggests that a chemical signal, abscisic acid (ABA), is produced in roots in drying soil and is transported to leaves in the xylem sap, where it induces stomatal closure before reductions in leaf water potential occur. Although ABA is produced in both roots and leaves, it is accepted that root tips are the major source of ABA produced in response to drying soil. The sensitivity of stomata to ABA is mediated by the nutritional and water status of the plant and can be genetically determined. The triggering of stomatal closure by chemical root signals has been observed in many agricultural species.

Much of the research work to date on chemical root signals has been conducted on the effects of ABA on stomatal responses. However, other plant growth processes sensitive to water stress, such as leaf expansion and leaf initiation, are also influenced by chemical root signals. For example, in some species, even when leaf water potential is artificially maintained, soil drying induces reductions in leaf elongation.

The relative degree of control of hydraulic and chemical root signals over stomatal conductance and leaf expansion, in field-grown plants, is the subject of considerable research and debate. In some studies, changes in ABA concentration in xylem sap do not correlate well with changes in stomatal conductance, suggesting that there may be chemical agents other than ABA that induce stomatal closure. As yet, no other such agents have been identified. Additionally, there is controversy associated with some data from studies conducted under controlled conditions, such as the induction of ABA production by mechanical impedance to root growth in potted plants, where the nature of the experimental conditions may contribute to ABA production.

It is now accepted that plant processes such as stomatal conductance and leaf expansion that are sensitive to water stress are affected by both chemical root signals and changes in leaf water status. Currently, research is being conducted to investigate possible interactions between hydraulic and chemical signals.

Applications of Plant–Water Relations to Irrigation Scheduling

The most common practical application of plant–water relations is to assist in irrigation management. Different plant water status indicators have been proposed for use in irrigation scheduling (IS). The

advantage of plant-based measurements over alternative IS methods based on soil-moisture monitoring or estimation of evapotranspiration (ET) requirements is that the actual unit of production (the plant) is being assessed, rather than using an environmental parameter (e.g., the soil) or a mathematical estimate (e.g., of ET).

Generally, indicators of plant water status are suitable for determining the timing of irrigation (i.e., when to irrigate), but not the amount of water to apply. An additional method, for example that of the Food and Agriculture Organization of the UN (FAO) for estimating crop evapotranspiration requirements (*See* **Crop Water Requirements**), can be used to estimate the amounts to apply. Interpretation of data of plant water status indicators requires comparison with previously established threshold values that define the need for irrigation (e.g., a maximum allowable daily stem-diameter contraction). Plant water status data are normalized to take into account variations in water status due to evaporative demand, i.e., to distinguish effects mostly due to insufficient soil water from those mostly due to atmospheric demand. Ideally, measurements of plant water status are considered in relation to those obtained from fully irrigated plants.

In some crops such as cotton, the timing of irrigation has been determined by predawn or midday measurements of leaf water potential. To use leaf Ψ for this purpose, the relationship between leaf Ψ and growth is established previously, for the individual species. In some fruit-tree species, stem Ψ has been used in preference to leaf Ψ, because variations in leaf Ψ, due to rapid changes in evaporative demand, are avoided. Stem Ψ is measured in leaves that have been previously covered to prevent transpiration.

Until recently, plant water status measurements were generally based on discrete manual measurements (e.g., leaf water potential, stomatal conductance), which limited the amount of data that could be obtained on account of the time and labor required for each measurement. Recent developments in sensor and data technology have enabled continuous monitoring of plant water status. Data from infrared thermometers, LVDT (stem-diameter) sensors and sap-flow gauges can be recorded every few minutes, providing detailed information on the dynamics of plant water status. Automatic programmers for irrigation management are being increasingly used; these systems can be integrated with continuously measured parameters of plant water status so that crops can be automatically irrigated when the selected indicator of plant water status reaches a defined limit. Discrete measurements of plant water status cannot be used in this way.

Different methods based on temperature difference between air and canopy have been developed to schedule irrigation. The most widely used is the crop water stress index, which relates canopy (T_c) and air (T_a) temperature to the vapor pressure deficit (VPD),

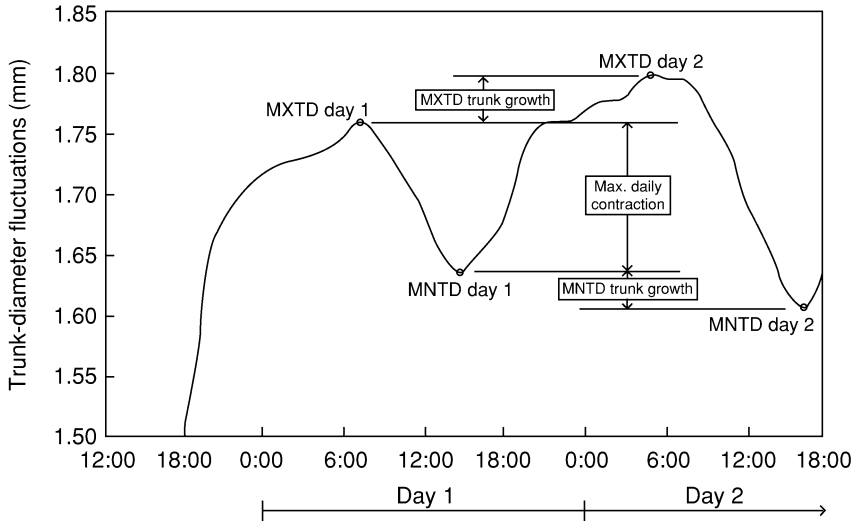


Figure 3 Parameters that can be derived from trunk-diameter measurements, including maximum daily trunk contraction, and trunk growth expressed as daily differences in maximum and minimum daily trunk diameters (MXTD and MNTD, respectively). (Adapted from Goldhamer DA and Fereres E (2001) Irrigation scheduling protocols using continuously recorded trunk diameter measurements. *Irrigation Science* 20: 115–125, with permission.)

and compares this with $T_c - T_a$ for a well-watered crop at the same VPD.

Trunk-diameter measurements with LVDT sensors have been proposed for IS in a number of fruit-tree species. Good correlations between variations in trunk diameter and changes in tree water status were observed in these species. Applying trunk- or stem-diameter measurements for IS requires firstly the definition of parameters derived from the data, and then the development of criteria for applying the derived parameters, as discussed previously. Maximum daily contraction, the difference between daily maximum values, and difference between daily minimum values (Figure 3) have been proposed as the most sensitive parameters to detect water stress in some fruit trees. As of 2004, irrigation protocols are being developed for fruit trees and vegetable species that involve: (1) selecting the derived parameter most suitable for an individual species and particular growth stage, and (2) relating the derived parameters to reference values of well-watered crops and normalizing them for VPD. A consideration when using this method is the number of replicates required to account for between-plant variability.

Sap-flow sensors have also been used for irrigation scheduling in fruit trees. A method for the automatic control of irrigation has been developed, in which sap-flow sensors determine the amount of water consumed by the plant, at short time intervals. An irrigation system can be programmed to replenish this water at specified times or time intervals. Variability between plants is an issue when scaling from single plants to crops.

POLAR SOILS

J C F Tedrow, Formerly with Rutgers University, New Brunswick, NJ, USA

Introduction

Soil science, traditionally allied with food and fiber production, has been viewed primarily through the eyes of the farmer. It is therefore understandable why soils of the polar regions, with negligible agricultural potential, were the last to receive serious scientific attention. Early investigators of polar soils showed all land in northern Siberia as being mantled with Tundra soil. The tundra is described as developed on a treeless plain of the north where conditions are swampy and the land is underlain by permanently frozen ground (permafrost). Investigators tend to use the 50°F July isotherm as the approximate southern limit of the arctic, a term used somewhat interchangeably with the word 'tundra.' Subsequent investigators of the arctic lands have convincingly shown that not only are there a variety of soils present locally, depending upon relief, substrate, and physiographic setting, but also there are major regional differences.

Climate

Climate of the northern polar regions is characterized by long, cold winters and short, cool summers. Mean monthly temperature for the warmest month in the vicinity of the tree line ranges from approximately 50 to 54°F but, in the northern extremities of ice-free land such as northern Greenland, Svalbard, and Franz Josef Land, the temperatures of warmest month decrease to 32–34°F. Precipitation values approximate 25 cm annually in the main polar belt but decrease somewhat northward.

Vital activity in polar soils is limited to 2–4 months per year, depending upon region, site, relief, vegetation, snow cover, and related factors. Annual snowfall in the polar regions generally is 30–60 cm, with much redistribution by wind action.

In the far north, the ice-free sectors have a desert-like aspect. Naturalists have long had a variety of names for these northern sectors, such as 'high polar,' 'cold steppe,' 'arctic wastes,' 'rock desert,' 'polar tundra,' 'barren-ground tundra,' 'fell field' (desert-like), 'desert glacial,' 'nival zone,' and 'dry periglacial zone.' The far north (polar desert) has a number of desert affinities such as saline soil conditions, and the presence of desert pavement and wind-abraded rocks.

Biotic Factors

One of the distinctive characteristics of the polar landscapes is the absence of trees. The northern edge of forested land marks one of the most striking vegetative changes anywhere on earth. There are, however, a number of problems associated with plotting a circumpolar tree line in detail, because there are interruptions by high mountains, glaciers, and open bodies of water. Further, over long periods the tree line may shift as evidenced by the presence of tree stumps well north of the present tree line. Also, there are differences between the physiognomic forest line and the tree species line.

The tundra zone is characterized mainly by wet cotton-grass meadows and wet sedge meadows, commonly referred to as 'typical tundra' (**Figure 1**). There are also extensive bogs present. The uplands and mountain sectors, however, have drier, upland and barren plant communities.

The polar desert zone supports a discontinuous, sparse vegetative cover (**Figure 2**). Here the vascular plants do not compete for "open space" as they do within the tundra zone. The plant cover consists mainly of lichens, mosses, liverworts, and a scattering of arctic-alpine herbaceous plants.

The subpolar desert zone, also known as midarctic or arctic tundra, is a blend of high arctic and tundra vegetative elements. **Figure 3** shows the location of the three soil zones of the arctic: tundra, polar desert, and subpolar desert. This is a generalized depiction and does not take into account factors such as littoral climates, high mountains, and special geologic conditions.

Permafrost

Permafrost, also known as perennially frozen ground, is generally considered to be a thickness of soil, surficial deposits, or bedrock at a variable depth below the surface of the earth in which the temperature of the matrix has existed below the freezing point of water for a period of at least several years. Permafrost therefore may consist of frozen soil, frozen bedrock, and clear ice. Permafrost underlies nearly all of the polar lands, including adjacent offshore sectors. The thickness of permafrost varies greatly, with a few locations in Siberia having a depth of more than 1200 m. In Siberia permafrost extends hundreds of miles south of the tree line (**Figure 4**) and still much further into high mountain areas of the world.

Of special interest to soil scientists is the rate and depth of thaw in polar soils. Seasonal thaw usually begins in snow-free sectors in early June, but by late July or early August seasonal thaw has largely reached its maximum. Depth of seasonal thaw may be less than 30 cm in the far north, but within the northern fringes of the forested land it may extend to a depth of 150–250 cm or more.

Permafrost generally exists as massive ice or as frozen soil with the pore spaces in the soil filled with ice. There are, however, many locations in mountainous areas and elsewhere where ice is present only at the contact points of the soil particles, a condition referred to as dry permafrost.

Soil Development and Classification

Systems of Classification

Up until the mid-1900s, there was very little attention given to detailed classification of polar soils. Tundra soil was recognized, but descriptions were vague and incomplete. The most reliable information was from Russian sources, but even these

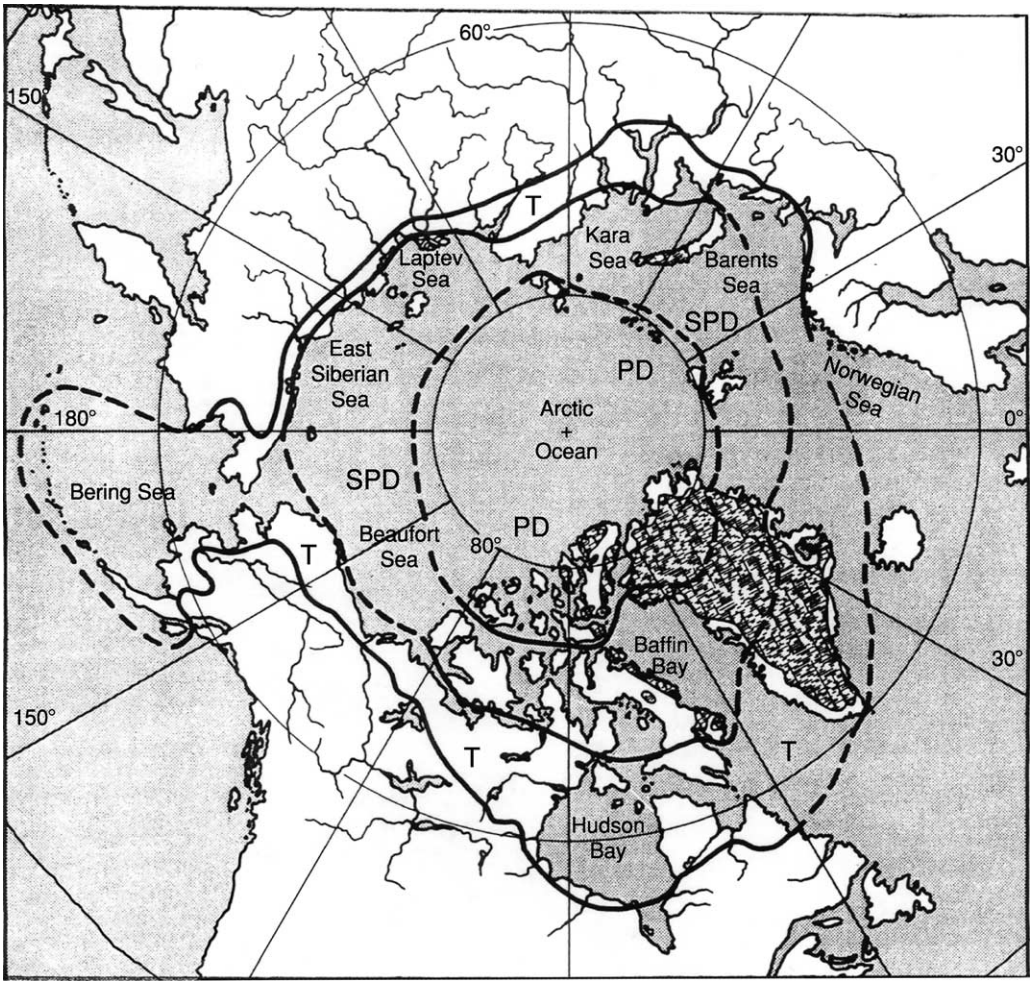

Figure 3 Delineation of soil zones of the northern polar lands. PD, Polar Desert zone; SPD, Subpolar Desert zone; T, Tundra zone. © J Tedrow.

were preliminary and generally carried out just north of the forested land. During more recent years there have been several proposals advanced for classifying polar soils. Table 1 shows four systems that have been proposed. Other schemes of classification have also been proposed by Russian, French, and New Zealand (for Antarctica) investigators. In *Soil Taxonomy* (US), soils of the polar regions are collectively referred to as Gelisols (soil order). Gelisols are divided into Histels, Turbels, and Orthels. The Canadian system is similar in principle to that of *Soil Taxonomy* but there are differences in nomenclature. Soils are first described under the Cryosol order followed by Organic Cryosols, Turbic Cryosols, and Static Cryosols. The Food and Agriculture Organization of the UN (FAO) system is similar to that of *Soil Taxonomy* and also of Canada. The Tedrow system uses a somewhat different approach in that the polar regions are first divided into soil zones, then genetic soil divisions. There have been a number of systems proposed by Russian investigators, most of which follow similar lines in that the polar regions are first divided into bioclimatic zones, then genetic soil characterization.

Tundra Zone

The tundra zone is characterized by a preponderance of hydric mineral soils. These were, for years, the benchmark soils of the northern polar regions. A variety of soils are now recognized within the tundra zone, including the mineral soils that have impeded drainage. The soils are generally silty, but there are wide ranges in texture, from sandy loams and sands to heavy bentonitic clays. Earlier writings have indicated that, with frequent freezing and thawing, individual mineral particles become reduced to silt size, but such a phenomenon has been discounted largely.

Figure 5 shows an idealized Upland Tundra (Molliturbel) soil. The buried organic-rich layer, as shown at the 24- to 26-inch depth, usually has an age of 8000–11 000 years BP, which puts the time of burial within the Hypsithermal Interval. Pollen from these buried layers is generally rich in Ericaceae, Cyperaceae, *Betula*, and *Salix*.

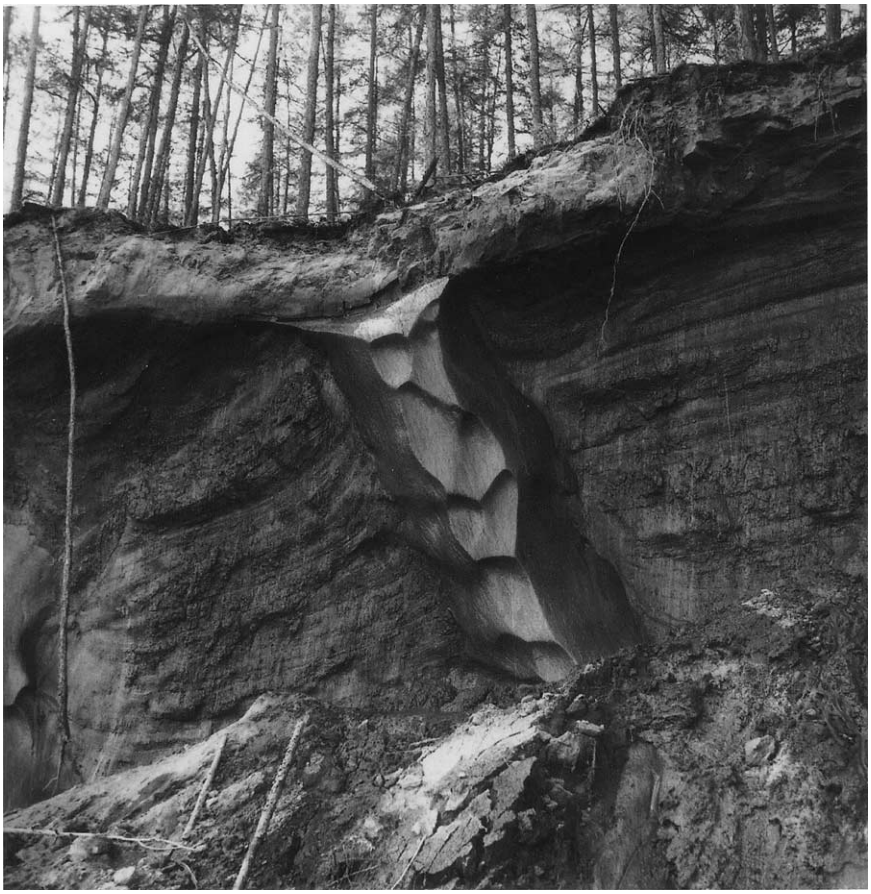

Figure 4 Ice wedge in permafrost along the Aldan River, Siberia. The top 150 cm active layer above the ice wedge is composed of well-drained silt and fine sand. © J Tedrow.

Clay minerals in Tundra (Molliturbel) soil generally consist of illite and kaolinite. The pH values of wet mineral soils in the tundra zone generally are within the 4.5–6.5 range, but, where there is a dusting of carbonate-bearing minerals from sources such as vegetation-free floodplains, the soils are alkaline.

Within the tundra zone there are extensive sectors of Bog soils (Histels). Organic deposits having a thickness of greater than 10 m have been recorded. The bogs are generally acidic.

There are many small, isolated areas of well-drained soils within the tundra zone. These soils, designated as Arctic Brown (Haplorthels), develop on sites where there is free drainage to a depth of at least 60 cm. The soils develop a brownish color in the solum, much as they do within the northern forested zone. These soils are usually acid, but on wind-swept spurs the soil may be alkaline.

Also, within the tundra zone there are a few Rendzina (Umbrothels) soils formed on limestone bedrock. On the other hand, where the soils from on acid bedrock such as a granite, a Podzol-like (Spodic Psammoturbel) soil may develop. In mountainous sectors of northern lands, the soils may be shallow and rocky, corresponding to a Lithosol (Orthels).

Polar Desert Zone

Polar Desert soils (Haploturbels) generally form on positive relief elements and on sandy/gravelly plains. Desert pavement is usually present where there is an abundance of gravel in the substrate. Maximum Polar Desert soil development is usually confined to open-textured material underlain by a dry permafrost. A browning effect may be present within a solum with up to 3% of easily reducible iron. Mud coatings and travertine formation may be evident in some locations.

The organic matter content of Polar Desert soil is generally less than 1%, but, where a vascular plant cover is present, the organic matter content increases accordingly. It is believed that most of the organic matter in Polar Desert soil is contributed by algae, including diatoms. The organic matter in Polar Desert soil is quite stable. In northern

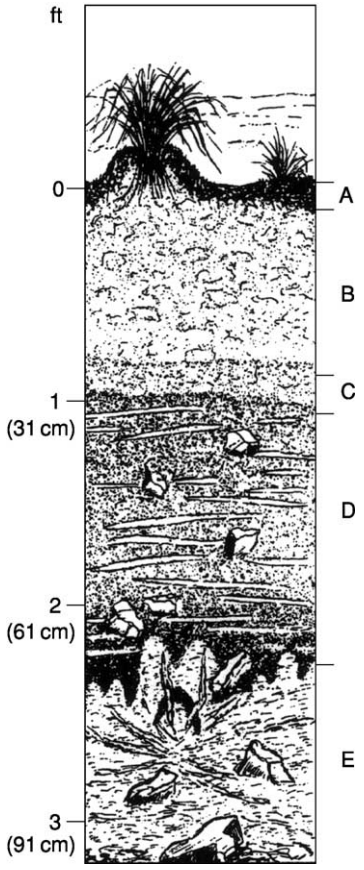

Figure 5 Idealized profile of Tundra (Molliturbel) soil. A, dark brown to black organic matter, consisting of partially decomposed sedges, sphagnum, and heaths. This horizon may vary from a thin, discontinuous one to an organic mat some 15 cm thick. Usually very loose, fibrous, wet, and strongly acid. B, light olive-brown (2.5Y 5/4) silt loam. Usually very wet, but loose and friable when dried. Nearly always mottled but in varying degrees. Strongly acid. C, dark gray (2.5Y 4/0) silt loam, mottled, very wet. The bottom of this layer approximates the permafrost table. D, very dark gray (2.5Y 3/0) silt loam, permanently frozen. Considerable organic staining in the ice; shreds of organic matter intermixed throughout the horizon. The bottom of the layer is very uneven and is much darker in color than the central portion of the horizon. The upper part of the horizon is also darker than the central portion. The horizon varies from frozen mineral soil to ground ice. Pieces of peaty material are commonly present. E, frozen gray mineral matter interspersed with ground ice. No evidence of organic staining. In many instances the material is nearly clear ice. Weakly acid to calcareous, depending upon parent material. © J Tedrow.

Greenland a sample of topsoil yielded an age of 3300 years BP.

The pH of Polar Desert soils varies widely from approximately 4.4 to as high as 7.9. Likewise electrical conductivity ranges from less than 10 to 66 $m\Omega\ cm^{-1}$. Salt crusts of thenardite (Na_2SO_4) and other minerals form on some of the well-drained to xeric sites. Figure 6 shows an idealized profile of Polar Desert soil. It is common to have only minor differentiation of the soil horizons other than that induced by the distribution of iron coatings on soil particles.

Within the polar desert zone, Tundra, Bog, Rendzina, and other soils are also present. These soils have similar characteristics to those found in the tundra zone (Table 1).

Subpolar Desert Zone

At one time many polar investigators included the subpolar desert zone as a part of the polar desert zone, but for specialist purposes it is appropriate to recognize a separate zone. The subpolar desert zone has been well recognized by naturalists, particularly plant geographers, who have used a number of climate and phytographic criteria to delineate the zone. Terms such as 'arctic tundra,' 'stony-sedge-moss-lichen tundra,' 'arctic desert,' and 'semipolar desert,' among others have been proposed. The subpolar desert zone is transitional and has few, if any, unique properties of its own. Conditions are somewhat analogous to those in parkland lying between the forest and prairies. There is no single criterion for delineating the subpolar desert zone, instead separation is based on a combination of factors, including soil, plants, and climate. The occasional Polar Desert soils within the subpolar desert zone usually contain little brunification and horizon differentiation, as is the case within the polar desert soil zone. In the subpolar soil zone, Tundra, Bog, Rendzina, and other soils are present (Table 1).

Patterned Ground

In the polar environment, there are at least two opposing forces operating. One involves pedogenic forces – those resulting in the development of genetic soil horizons. A second set of processes is frost-related and, in effect, consists of destructive forces. 'Patterned

ground' is a group term for symmetrical forms such as circles, polygons, nets, steps, and stripes. Various terms have been used to describe the frost structures, such as 'rutmark,' 'råmark,' 'frost polygon,' 'strukturboden,' 'polygonboden,' 'ice-wedge polygon,' 'stone polygon,' 'soil circle,' 'mud circle,' 'stone ring,' 'stone stripe,' 'hummocky ground,' 'frost boil,' 'ice mound,' 'palsa,' 'pingo,' and many others.

One of the more common forms of patterned ground is the ice-wedge polygon. The ground develops a series of ice wedges that result from annual soil temperature amplitudes. Year after year the ice wedges tend to increase in size, exerting exceptionally strong lateral forces that result in a buckling of both the edges and centers of the polygons (Figure 7). Changes of elevation of the soil surfaces may result in the center of the polygon being either raised or depressed. Change in elevation induced by frost action will result in some parts of the polygon being better drained, but other parts will become more poorly drained. This complex phenomenon of changes in drainage induced by frost action has received very little attention from pedologists. In addition to hydric changes in the soil induced by polygon formation, another set of cryogenic processes ruptures and deforms the soil horizons.

Apart from polygonal ground formation, another set of processes involves frost stirring, resulting in the development of stone rings (sorted circles). Figure 8 shows a form of stone rings in which the pattern of deformation has resulted from an upwelling of the mineral material in the form of a core of raw, earthy material and an outward displacement of the coarser rock fragments. Figure 8 shows lichen crusts on the outer rock fragments, whereas the central part of the stone ring is free of lichens, indicating a less stable condition.

Nonsorted circles are common throughout the polar regions, especially where the soils are of medium to clayey texture. Figure 9 shows a slight dome-shaped pattern with small, secondary desiccation cracks (zellenboden).

On sloping land, there are many elongated forms of patterned ground that result from at least two processes: frost sorting and solifluction (the slow gravity driven downhill movement of saturated soil). Patterns consist of stone garlands, stone stripes, soil stripes, and others. Where solifluction processes are intense, the genetic soil horizons become highly deformed and, in some locations, completely obliterated.

Cold Desert Zone

The antarctic continent, also referred to as the cold desert zone, was the last sector of the globe to receive the attention of pedologists. Only since World War II has there been significant pedologic information forthcoming from Antarctica. Soil maps of the globe traditionally provide information only to about 60° S, which excludes all of Antarctica (Figure 10). One of the interesting aspects of cold desert zone pedology is that there is virtually no effective organic component in the soils except for a few special conditions such as

Figure 7 Ice-wedge (nonsorted) polygons in Prince Patrick Island. © J Tedrow.

Figure 8 Stone rings (sorted circles) in Prince Patrick Island. © J Tedrow.

occur at the penguin rookeries, where there are local accumulations of guano. Late in the nineteenth century, pedology was recognized as an independent scientific discipline, and it was agreed that organic matter was an essential component of the soil system. While virtually all pedologists who have worked in Antarctica speak of soils in the traditional sense, plenary bodies have largely ignored the question of antarctic soils. The position of plenary bodies was understandable when, in earlier times, very little information was available concerning Antarctica, but considerable pedologic information is now available.

Of the 2–3% of Antarctica that is free of ice and snow, only a small percentage has surficial deposits adequate for any semblance of soil formation. The remainder of the ice-free land consists of bedrock and boulder fields. Permafrost is believed to be present throughout the cold desert zone, but most

Figure 9 Nonsorted circles in northern Alaska. © J Tedrow.

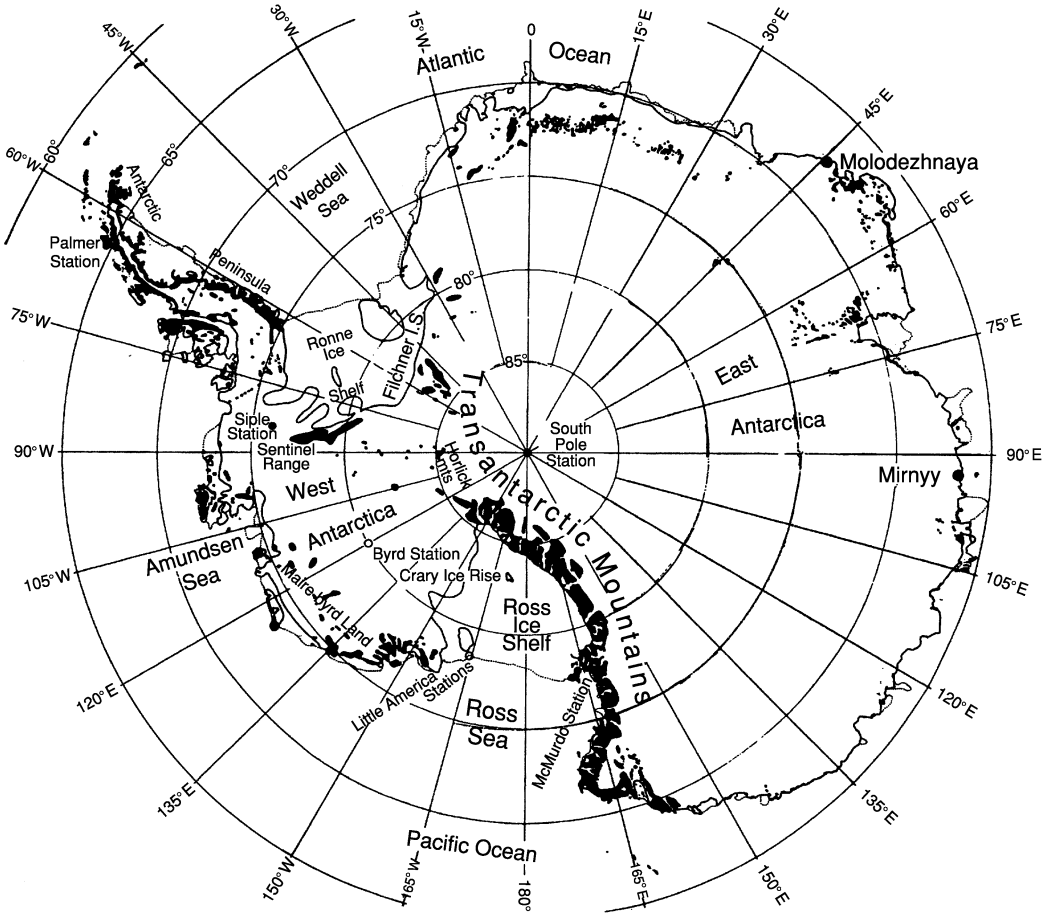

Figure 10 Map of Antarctica. The dark areas are largely without a snow-ice cover. © J Tedrow.

of the surface deposits are subject to dry frost conditions.

Physical and chemical weathering in the cold desert zone is intense. Boulders exhibit cavernous weathering forms in which shells of exfoliation can be pried off. Wind polishing of rocks is intense with the abrasion caused by the blowing of ice particles. Ice in the cold desert at very low temperatures may have a hardness like that of quartz. Desert varnish is also evident in many places, especially on older land surfaces.

Although air temperatures in the cold desert zone may be well below freezing, solar radiation causes the rock surfaces to attain elevated temperatures on wind-free, sunny days. The temperature gradient in rocks during sunny days results in both physical and chemical weathering. Garnets split, feldspars weather, and clay substances accumulate in the fractured areas. Accumulation of calcite, gypsum, magnesium sulfate, and other minerals is widespread. Also, highly soluble forms of calcium, magnesium, sodium, potassium, chloride, sulfate, and nitrate have been reported. There are a number of forms of patterned ground present in antarctic deserts, with the most common form being of a polygonal nature.

Table 2 shows two classification schemes proposed for the cold desert zone, both of which follow the same pathways in principle. Figure 11 shows an idealized soil of the cold desert (Subxerous-Xerous). This depiction is one of maximum soil development on till composed mostly of sandstone, conglomerate, and dolerite. Horizonation is somewhat blurred, with no structural aggregates being present. The 'active' layer is approximately 51 cm thick but, because of the ultra dry, loose condition, depth to the frost table can only be approximated. Cold desert soils, for all practical purposes, are without terrestrial life. Algae including lichens are occasionally present and, in rare

situations, protozoa, rotifers, and nematodes can be found.

There is evidence that there is ionic migration in the soil, even when it is in a dry, frozen state. Buildup of salts is common in the soil as well as in bedrock and boulders. Nearly all soils of the cold desert are alkaline, with pH values being in the 7–10 range. In special situations, however, acid soils have been reported.

Closed basins, depressions, and other sites commonly have saline soils and accumulations of salt encrustations. Saline lakes have been reported in the dry valleys of Victoria Land and in the Mirnyy area. Salt content of water in a closed lake basin in Wright Valley is 34%. The salt consists mainly of calcium and chloride. Clay minerals in cold desert soils consist primarily of micas, kaolinite, vermiculite, montmorillonite, and chlorite. Some of the clay-size fraction also contains quartz, feldspar, and amorphous material.

The cold desert soils can be divided into Ultraxerous, Xerous, and Subxerous varieties (**Table 2**). In the Molodezhnaya sector of Antarctica, some of the soils show advanced weathering and have been designated as Ahumisol. There are also a very few, extremely small locations, where there are clumps of vascular plants, in which the soils have been designated as Protoranker. Along the margins of some saline lakes, there are shallow accumulations of algae. Also, in the penguin (and skua) nesting areas, the soils, rich in bird droppings, feathers, and bones, have been designated as Ornithogenic or Avian. In the area of volcanic vents such as at the top of Mt. Erebus, the soils have been designated as Hydrothermal.

Introduction

Industrialized societies annually release large quantities of synthetic chemicals into Earth's natural environments, both intentionally, in the case of pesticides, and inadvertently, through the production, transport, refining, and combustion of fossil fuels, waste streams from manufacturing, chemical spills, disposal of products by consumers, and discharges from a wide variety of other sources. Currently, there are more than 75 000 chemicals registered in the US Environmental Protection Agency (US EPA) inventory of chemical substances manufactured or processed in, or imported into, the USA. The number of potential chemical contaminants is substantially higher, as the EPA inventory does not include pesticides, radioactive materials, food additives, drugs, or cosmetics. Many of these compounds ultimately end up as contaminants in the atmosphere, water, sediment, or soil. To add to the complexity of the problem, the compounds of concern vary widely in their characteristics. A contaminant can belong to any of a number of disparate classes of compounds that differ in important properties such as charge, polarity, water solubility, pK_a, molecular weight, and aromaticity. These chemical characteristics subsequently determine a contaminant's fate in the environment and its hazard to humans and other organisms.

One of the most important processes determining the fate of a given chemical is its susceptibility to biological degradation. There have been more than five decades of research into chemical biodegradation, including microbial mechanisms and the chemical and environmental factors that govern its rate and extent in soils.

Biodegradation

Biodegradation is the partial or complete breakdown of a chemical pollutant resulting from the physiological reactions of microorganisms. In general, microorganisms carry out such processes to obtain necessary carbon, nutrients, and energy for their survival and growth. Through the millennia, bacteria have experienced extreme competition (primarily from each other) for limiting resources. As a result, they have evolved unrivaled metabolic capabilities, utilizing nearly every thermodynamically favorable reaction for energy and nearly every organic molecule for carbon. For example, whereas humans gain energy only through the oxidation of specific organic substrates using oxygen as an electron acceptor (i.e., through aerobic respiration), bacteria utilize virtually all natural and many man-made organics, numerous inorganic molecules (e.g., Fe(0); Fe(II), H_2S, S(0) H_2, NH_4), and light for energy. Moreover, besides oxygen, specific microorganisms can utilize a variety of chemicals, including an assortment of synthetic pollutants and pesticides, as terminal electron acceptors. Specific examples of microbial biodegradation processes under aerobic and anaerobic conditions are provided in subsequent sections.

The microbial degradation of pollutants can yield many different products. Generally, the biodegradation of a large organic molecule results in smaller, less complex organic molecules that may be more or less toxic than the parent compound. In some cases, an organic contaminant is completely converted to an inorganic product such as CO_2. A transformation of this type is referred to as 'mineralization' and is associated with the elimination of toxicity of the parent compound. Although plants, animals, and microorganisms can all metabolize some pollutants, the mineralization of organic contaminants is generally carried out by bacteria and fungi only. These microorganisms are responsible for nearly all of the relevant biotransformations of environmental pollutants.

Whereas biodegradation occurs naturally in soils and other environments without any intervention, bioremediation involves the application of natural processes to remove pollutants from contaminated sites. In short, bioremediation is the use of microorganisms to clean up unwanted compounds, although the specific technology employed will depend on the

nature of the site and the pollutant of concern. Contaminants may be treated *in situ* through the addition of nutrients to stimulate indigenous microorganisms (biostimulation) or by the inoculation of specific microorganisms capable of degrading the compound (bioaugmentation). Alternatively, contaminated soils can be excavated and treated *ex situ* using biological reactors, composting, or other approaches.

The biodegradation of soil pollutants is critical because of the impact the resultant transformations can have on human and environmental health. For example, in the absence of appreciable degradation, compounds released into soil may leach to groundwater. Contamination of groundwater poses a potentially serious threat to drinking-water supplies and public health. Moreover, compounds present in groundwater have a tendency to persist much longer than those in soils due to the limited supplies of oxygen and inorganic nutrients and low microbial numbers generally found in subsurface aquifers. Soil pollutants and pesticides can also pose a threat to human and nonhuman health if they are bioconcentrated by soil organisms. Biological uptake directly from soil can adversely affect both individual organisms and food webs. A contaminant may be sufficiently concentrated in soil to harm the organism that contacts it initially. However, certain compounds, even if initially present at low concentration, can be accumulated and magnified through herbivory and predation. A biomagnified compound has the potential to damage organisms at higher trophic levels, despite their very limited contact with the contaminated soil. Alternatively, some compounds are so potent that they are a threat at very low concentrations. Microbial transformations can lower the risk associated with a particular pollutant because they reduce or eliminate the toxicity of the compound.

Aerobic Transformation Processes

Many different synthetic pollutants and pesticides have been shown to serve as growth substrates for specific bacteria and fungi under aerobic conditions, providing both carbon and energy to these organisms. Often, these compounds are completely mineralized by one organism or by a series of different organisms to CO_2 and cell constituents. During this process, the novel pollutant is generally modified by specific enzymes to one or more metabolites that are common in cellular metabolism (e.g., pyruvic acid, acetyl-CoA). Those metabolites are then converted to energy and biomass through the common metabolic pathways. Aerobic mineralization is generally a growth-linked process whereby microbial numbers increase as the chemical concentration decreases. Growth-linked biodegradation is desirable in that it can bring about a rapid loss of a contaminant from soil. Many different organic contaminants are subject to mineralization in soils, including most components of crude oil and gasoline, and numerous pesticides.

A variety of organic chemicals are biotransformed through a nongrowth-linked process termed 'cometabolism.' Cometabolism is the fortuitous transformation of a molecule by an enzyme synthesized within a cell for another purpose. By this process, the cell modifies the chemical structure, but gains no energy, carbon, or inorganic nutrients from the reaction. Several groups of aerobic bacteria present in soils, including methanotrophic bacteria (which oxidize methane for energy), nitrifying bacteria (which oxidize ammonia for energy), and propane-, phenol-, and toluene-oxidizing bacteria, have been observed to transform a variety of different compounds through cometabolic reactions. Each of the above groups of bacteria produces nonselective monooxygenase or dioxygenase enzymes that are responsible for these reactions. For example, methanotrophic bacteria produce methane monooxygenase (MMO), an enzyme that normally functions to oxidize methane for energy (Figure 1). However, MMO has a broad substrate specificity and has been observed to catalyze the initial oxidation of numerous alkanes, alkenes, and aromatics as well as the degradation of an array of chlorinated aliphatics, such as *cis*- and *trans*-1,2-dichloroethylene (*cis*- and *trans*-1,2-DCE), trichloroethylene (TCE), and 1,2-dichloropropane. As previously noted, bacteria do not gain carbon or energy from the cometabolic oxidation of most compounds; thus, an additional cosubstrate is often required for bacterial growth (e.g., toluene for toluene

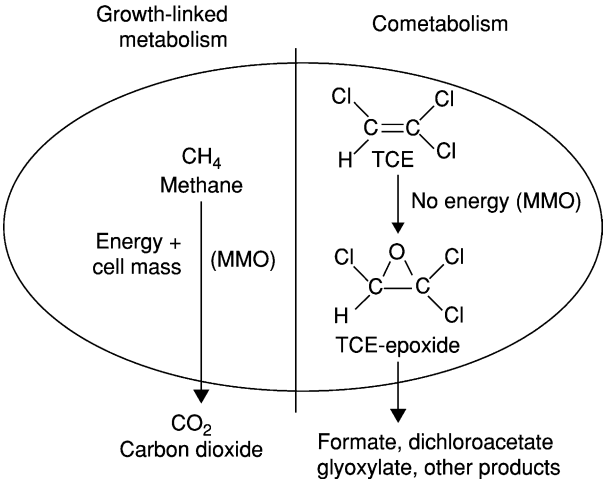

Figure 1 Representation of an individual methanotrophic bacterium degrading methane to carbon dioxide through growth-linked metabolism and degrading trichloroethylene (TCE) to TCE epoxide via cometabolism. MMO, methane monooxygenase.

oxidizers, methane for methanotrophs, etc.). Although cometabolic reactions sometimes result in the accumulation of persistent intermediates, in many instances, the initial oxidative reaction produces readily degradable compounds that are then mineralized. For example, as shown in Figure 1, the initial cometabolic attack of MMO on TCE creates an unstable TCE epoxide, which further degrades to a variety of growth substrates, such as glyoxylate, formate, and dichloroacetate.

Anaerobic Transformation Processes

A wide variety of pollutants and pesticides are subject to biodegradation under anaerobic conditions. As described for aerobic degradation, both mineralization and cometabolic reactions also occur in anaerobic environments. For some compounds, biodegradation will only occur under such conditions, since the organisms capable of carrying out the process are obligate anaerobes (i.e., they die in the presence of oxygen). Under anaerobic conditions, the degradation of specific pollutants and pesticides can be coupled to the reduction of terminal electron acceptors other than O_2, such as NO_3, Mn(IV), Fe(III), SO_4, or CO_2. This process is termed 'anaerobic respiration.' The gasoline constituent toluene, for example, has been reported to be biologically degraded with each of these different electron acceptors. For a given substrate, the energy yield during anaerobic respiration with the aforementioned compounds is less than for the same reactions using oxygen ($O_2 > NO_3 > Mn(IV) > Fe(III) > SO_4 > CO_2$) as an electron acceptor. Therefore, the anaerobic reactions tend to occur more slowly, and microbial growth yields are lower than for aerobic reactions.

If a large quantity of a readily biodegradable pollutant is added to a soil, it is not uncommon for the dominant, terminal electron-accepting reaction to progress from aerobic respiration (with O_2 as the primary electron acceptor) all the way to methanogenesis (with CO_2 as the primary acceptor), passing through each dominant electron acceptor in the order shown in Figure 2. Some microorganisms (e.g., facultative anaerobes) can utilize more than one electron acceptor, although rarely are these reactions performed simultaneously by a given organism. For example, many denitrifying bacteria grow aerobically in the presence of oxygen, then anaerobically on nitrate when oxygen levels are reduced. Other microorganisms, including many sulfate-reducing bacteria, are obligate anaerobes and are capable of using only one of the common electron acceptors (i.e., sulfate) for growth. As electron acceptors are depleted in sequence, the dominant metabolic reactions (and in many instances, the dominant microorganisms) accounting for the chemical losses shift. The reduction

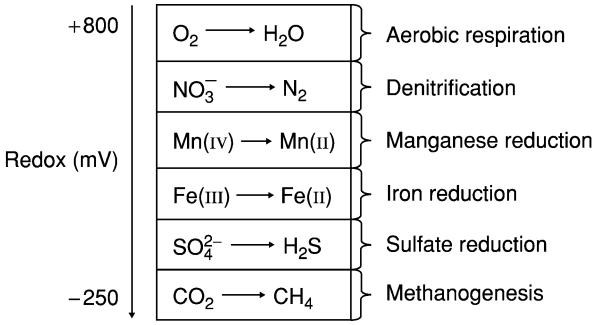

Figure 2 Sequence of common electron-accepting reactions. Reactions are given in general order of occurrence from top to bottom, with the reactions at the top taking place at the highest redox potential and providing the highest energy yield to microorganisms during degradation of a given organic compound.

potential declines accordingly as the sequence of terminal electron acceptors progresses from oxygen to carbon dioxide. In the absence of available external electron acceptors, some organic molecules are also subject to fermentation, whereby small amounts of energy are gained by an organism through internal oxidation–reduction reactions. However, when all common electron acceptors are consumed in a contaminated soil, the biodegradation reaction is likely to cease, even though biodegradable compounds are still present. It is for this reason that oxygen is frequently added via sparging or other means to enhance biodegradation in environments that have experienced heavy contamination with organic pollutants. It may also be necessary to add inorganic fertilizers in such instances, as the supply of macro- and micronutrients in the soil may be inadequate to sustain microbial degradative activity.

Some groups of chlorinated contaminants, including polychlorinated biphenyls (PCBs), chlorophenols, chlorinated solvents, and certain organochlorine pesticides can serve as alternate electron acceptors, by a process known as reductive dechlorination (also called halorespiration). This process, which occurs only in the absence of oxygen, is a critical step in the degradation of these persistent pollutants. During reductive dechlorination, bacteria transfer electrons from a growth substrate (primarily hydrogen) to the chlorinated compounds, causing the release of chloride ion and the production of various organic daughter products. For example, during reductive dechlorination of perchloroethylene (PCE), the daughter products are TCE, *cis*-1,2-DCE, vinyl chloride (VC), and ethylene, respectively (Figure 3). The occurrence of these degradation products (particularly *cis*-1,2-DCE and VC) suggests that reductive dechlorination of PCE or TCE is occurring in an environment. A similar reaction has been noted for PCBs and several organochlorine pesticides (e.g., 1,1,1-trichloro-2,2-bis

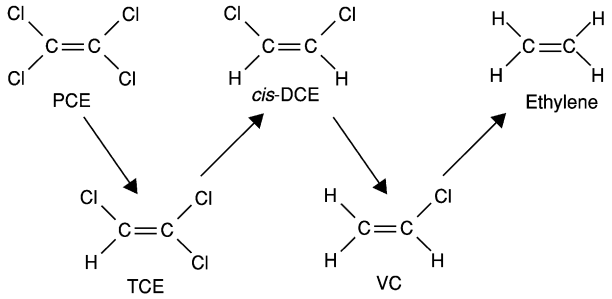

Figure 3 Biodegradation pathway of perchloroethylene (PCE) during reductive dechlorination. *cis*-DCE, *cis*-1,2-dichloroethylene; VC, vinyl chloride.

(4-chlorophenyl)ethane (DDT); pentachlorophenol (PCP); and 3,5,6-trichloro-4-amino-2-pyridinecarboxylic acid (picloram)) under strongly reducing conditions. In soils, reductive dechlorination of PCBs is observed as a shift in the representative PCB congeners found within an environment (there are 209 PCB congeners based on possible positions and numbers of chlorine atoms on the biphenyl molecule) from more chlorinated to less chlorinated congeners. Other chemical pollutants such as perchlorate (ClO_4; an oxidant used in solid rocket fuel) and hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX; an explosive), have also been observed to serve as terminal electron acceptors in soils.

Chemical Properties Affecting Biodegradation

All natural organic compounds are biodegradable. The occurrence and rates of biodegradation of these compounds vary widely depending on environmental conditions and chemical complexity (e.g., lignin biodegradation is extremely slow, even under ideal conditions), but it is generally believed that no natural organic materials are completely resistant to microbial destruction. Given hundreds of millions of years of evolution and the constant competition among microorganisms for limiting nutrients and energy, it is not surprising that microbial enzymes have coevolved in nature in step with new organic compounds. In contrast to nature, however, rapid advances in organic chemistry have allowed mankind to develop and produce an overwhelming array of new organic compounds in a short time period. A majority of these thousands of new compounds have been introduced to the Earth's environment for the first time since the mid-1940s. Many of these chemicals, particularly those that are similar in structure to naturally occurring organics, have proven to be readily biodegradable. Other, more novel synthetics, however, are highly resistant to microbial attack.

Some of the key factors that influence the degradability of a molecule include the type, number, and location of molecular substituents, the type of bonds, the degree of branching, and the molecular weight of the compound (Figure 4). The addition of new organic or inorganic substituents to a common molecular structure is one means of creating novel synthetic compounds. Small differences in the type and location of these substituents can determine whether a molecule is readily biodegradable or highly persistent. Pollutants that are resistant to biodegradation owing to their chemical structure are termed 'recalcitrant' molecules. A number of synthetic organic compounds and pesticides have been developed by adding halogens (particularly chlorine, fluorine, and bromine) to organic compounds. Because the halogen–carbon bond is very stable and resistant to microbial attack, this type of substitution tends to make a molecule recalcitrant, with increasing halogenation leading to increasing persistence. For example, organochlorine pesticides, such as DDT, toxaphene, 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), pentachlorophenol, chlordane, aldrin, hexachlor, and metoxychlor, were once widely used. Many of these pesticides have now been banned from use in the USA and most European countries due to their long-term persistence and negative impacts in various ecosystems. These molecules proved to be highly resistant to aerobic biodegradation and persistent or very slowly degraded under anaerobic conditions. Halogenated pollutants such as PCBs, polybrominated biphenyls (PBBs), freon propellants and refrigerants (e.g., CCl_3F, CCl_2F_2), and chlorinated solvents (e.g., PCE, carbon tetrachloride) have also proven to be persistent contaminants.

Other molecular traits that may decrease a chemical's biodegradability include high molecular weight, low water solubility, and extensive branching. As molecular weight increases to more than approximately 500–600, chemical biodegradability tends to decrease markedly. This reflects, in part, the inability of large molecules to enter the microbial cell. In some instances, extracellular enzymes produced by bacteria or fungi can initiate an attack on a large molecule, breaking it into smaller pieces that can then be metabolized further. For example, it is large size that prevents the biodegradation of many organic polymers that constitute plastics, such as polyethylene and polystyrene. If reduced to a molecular weight of less than 500 from their typical molecular weights of a few thousand to more than 100 000, many of these polymer structures are biodegradable. Molecular branching also tends to reduce chemical biodegradability. The molecular branches tend to sterically interfere with the common degradative enzymes used by microorganisms. For example, many alkanes

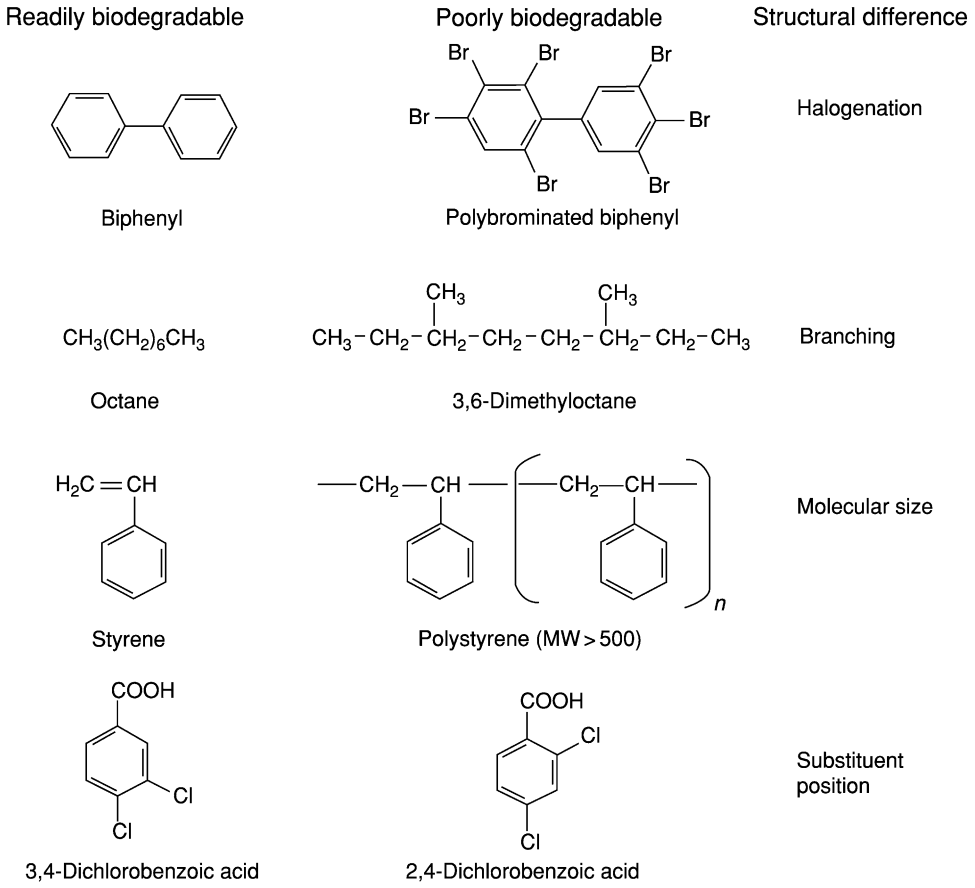

Figure 4 Influence of molecular structure on contaminant biodegradability.

are transformed by bacteria through the sequential oxidation and cleavage of two carbon molecules at a time, in a process known as beta-oxidation. During this process, the alkane is sequentially oxidized (usually at the terminal carbon) to an alcohol, an aldehyde, and then an aliphatic acid. The acid is then cleaved to form acetyl-CoA, which the cell can utilize for energy. This beta-oxidation process continues until the alkane is completely degraded to acetyl-CoA. Branching of the alkane, particularly branching with one or more methyl groups, can block the two-carbon cleavage of beta-oxidation, causing an otherwise biodegradable molecule to become recalcitrant. For this reason, branched alkanes, such as pristaine and phytane, tend to be among the slowest molecules to biodegrade during a crude oil spill. These molecules are frequently employed as internal standards to assess the biodegradation of other, more labile, components of crude oil after an environmental release.

Environmental Factors Affecting Biodegradation

A compound that is readily metabolized in a laboratory may escape breakdown and persist unexpectedly in the field, even if an organism capable of causing its degradation is present. Unless pollutants are accessible to microorganisms and environmental conditions are conducive to microbial growth, contaminants will not undergo biotransformations and may remain in soil for extended periods. Thus, the extent of chemical biodegradation will depend in large part upon the physical, chemical, and biological properties of a contaminated site. A number of important factors influencing the growth of microorganisms and therefore biodegradation are described below.

Bioavailability

Pollutants released into soil will not be biodegraded if they are biologically unavailable. Even the most labile compound may persist if it does not come into contact with microorganisms. Bioavailability of a compound can be reduced if the compound is sorbed to soil particles, entrapped within the soil matrix, or dissolved in a nonaqueous solvent (Figure 5).

Sorption Chemical compounds can bind to solid surfaces through the actions of a variety of attractive forces. In some instances, a compound will adhere to the outer surfaces of soil particles in a process known

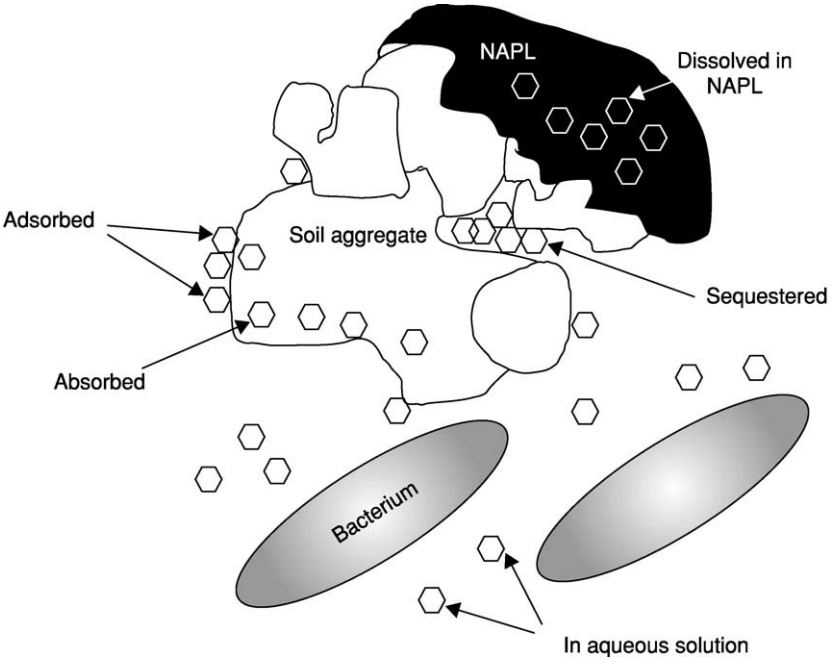

Figure 5 Representation of different potential states of an organic pollutant (cyclohexane) in a soil environment. (Not drawn to scale.) NAPL, nonaqueous-phase liquid.

as adsorption. Absorption refers to retention within the interior matrix of a solid particle. In either case, a compound partitions from a liquid phase (usually from water) onto or into a solid phase. Typically, the nonspecific term 'sorption' is used to describe this phenomenon. Since compounds must generally be in an aqueous phase and enter the microbial cell to be subject to biodegradation, sorption often increases a pollutant's resistance to biological attack. After a given period of time in a soil, a pollutant establishes equilibrium between the sorbed and the aqueous phase. The extent of sorption at equilibrium, as quantified by the pollutant's sorption coefficient (K_d), reflects the characteristics of both the pollutant and the soil matrix. When comparing pollutants of a single structural class (e.g., polycyclic aromatic hydrocarbons, PAHs), those molecules with higher K_d values, which tend to be primarily present in soils in the sorbed phase, generally biodegrade more slowly than those with lower K_d values. In order to enhance pollutant desorption, some bacteria and fungi have been observed to produce extracellular biosurfactants. The release of these surfactant molecules can increase the rate and extent of pollutant desorption and, subsequently, accelerate contaminant biodegradation.

Clay minerals and soil organic matter contain the principle sites to which pollutants can sorb. Charged compounds such as cationic pesticides (e.g., diquat) are often retained by clay minerals. Nonpolar organic molecules, on the other hand, tend to associate with soil organic matter through both adsorption and absorption. For example, PAHs such as phenanthrene, anthracene, and pyrene are subject to sorption and diminished availability as a result of their interactions with humic materials.

Entrapment within the soil matrix After their release into soil, some compounds can slowly move from positions within the soil that are accessible to organisms into positions that are inaccessible. These compounds can experience a time-dependent decline in bioavailability termed 'aging.' Nonpolar organic pollutants, for example, can diffuse deeply into hydrophobic regions of soil organic matter and, as a result, evade microbial cells that might otherwise degrade them. Other compounds may diffuse into soil nanopores, thus becoming physically protected from metabolism by microorganisms. Although the details of the mechanisms involved vary, a compound that has moved into remote sites is said to be sequestered in soil.

The degree to which sequestration occurs depends upon a number of variables, including the properties of the soil and the contaminant involved. Although much work needs to be done to isolate the soil components most responsible for the entrapment of pollutants, soil organic matter content appears to be positively correlated with the extent of chemical sequestration. Soil structure also probably plays a key role in the sequestration of some contaminants. Pollutants may be more protected from biodegradation

in soils possessing highly developed aggregates than in less structured soils. The chemistry of a contaminant is clearly critical also. Preliminary work has suggested an inverse relationship between a compound's water solubility and its potential for sequestration, but the relative importance of this and other properties remains largely unknown. Pollutants for which sequestration has been observed include the PAHs phenanthrene and anthracene, and various pesticides, such as 1,2-dibromoethane, DDT, and chlordane.

Nonaqueous-phase liquid A number of relevant environmental contaminants can be present in soils dissolved in non-aqueous solvents. For example, crude oil is a nonaqueous-phase liquid (NAPL) composed of a number of compounds, many of which have very low water solubility. Since microorganisms are typically active in the aqueous phase only, pollutants in NAPLs can escape biodegradation. The extent to which an individual compound dissolved in a NAPL will be degraded depends upon a number of factors, including the rate of partitioning between the nonaqueous and aqueous phases, the equilibrium concentration of the pollutants in the aqueous phase, the nature of the interface between the two phases, and the toxicity of the NAPL to the microorganisms responsible for degradation. Although individual compounds within a NAPL tend to be degraded at different rates, in general, pollutants in a nonaqueous phase can be extremely persistent.

Nutrient Availability

Heterotrophic microorganisms in soil require a number of macro- and micronutrients, an energy source, and an electron acceptor to grow. Often, a pollutant provides a carbon or energy source, but all other requirements must be fulfilled if biodegradation is to occur. A biodegradable compound released into a nutrient-poor soil (i.e., low available nitrogen or phosphorus) can persist for an extended period of time, because microorganisms that possess the capacity to metabolize the contaminant cannot appreciably grow. In some instances, as during the biodegradation of the explosives 2,4,6-trinitrotoluene (TNT) and RDX under nitrogen-limiting conditions, specific organisms can degrade an organic compound to obtain a scarce noncarbon nutrient (in this case, nitrogen). Some organic phosphorus-containing compounds, such as triethylphosphate (TEP), can also be utilized by microorganisms to obtain phosphorus under conditions in which the compound is unavailable for microbial growth. During bioremediation of soil contaminants, the addition of nitrogen, phosphorus, or other limiting nutrients is often conducted to stimulate the growth of indigenous or added microorganisms.

pH

Some bacteria and fungi can survive and grow under very acidic or alkaline conditions, but the optimum pH for most soil microorganisms is near neutrality. Unless organisms have evolved to live under extreme pH conditions, both high and low pH can lead to the denaturing of microbial enzymes and the hydrolysis of other crucial cell components. It is therefore not surprising that biodegradation tends to be fastest near pH 7 and slows considerably as the pH becomes appreciably more alkaline or acidic. In addition to its direct effect on cells, pH will also influence the chemistry of ionizable pollutants in soil. The sorption and subsequent bioavailability of cationic pesticides (e.g., paraquat, diquat), basic pesticides (e.g., atrazine), and acidic pesticides (e.g., 2,4-D, dicamba) will depend in part on the pH of the soil solution in which they are present. To enhance microbial growth and biodegradation, bioremediation protocols sometimes include chemical treatment of the contaminated soil (e.g., by lime addition) to adjust pH to the optimum for the biodegradative organisms.

Temperature

The growth of microorganisms is highly dependent on temperature, and the prevailing temperature in soil is an important factor controlling the rate and extent to which a pollutant is biodegraded. Most microorganisms in soil are mesophilic, with temperature optima ranging from approximately 25 to 35°C, and growth possible from 15 to 45°C. Therefore, optimal temperatures for biodegradation in soils tend to be within the best growth range for these organisms, with rates increasing as temperatures increase within this range. However, it should not be implied that biodegradation processes cease below 15°C or above 45°C. There are many bacterial species that are psychrophilic, with growth optima less than 15°C, and those that are thermophilic, with growth optima exceeding 40°C and sometimes with extremes as high as 65°C. These organisms can be responsible for contaminant biodegradation in extreme environments such as in polar climates (for psychrophiles) or in compost (for thermophiles). In fact, thermophiles have been applied in numerous *ex situ* bioremediation applications due to their ability to rapidly degrade some contaminants.

Water Content

The moisture content of soil influences the growth and metabolism of microorganisms. As with the other abiotic factors discussed above, tolerance to desiccation varies among organisms. Environments characterized by low water content tend to support only

limited microbial activity. The optimal activity of most microorganisms occurs at soil moistures ranging from 60 to 80% of the soil's water-holding capacity (WHC). Biodegradation can be very limited in dry soils, and pollutants may persist in arid or drought-affected regions longer than in wet areas. Conversely, excessive moisture can limit oxygen diffusion in soil and cause a shift from aerobic to anaerobic conditions. As previously noted, the absence of available oxygen can severely inhibit the disappearance of some pollutants and pesticides, although such conditions may be necessary to promote the degradation of other compounds (e.g., by reductive dechlorination).

Presence of Appropriate Microorganisms

Microorganisms capable of performing a given biodegradation reaction are frequently indigenous in soil. For example, bacteria that aerobically degrade the common gasoline components benzene, toluene, ethylbenzene, and xylenes (BTEX) are ubiquitous in most surface soils. If these contaminants persist for long times in a given soil, it is likely that environmental factors such as nutrient availability, oxygen levels, contaminant availability, or the presence of toxic cocontaminants are impeding the biodegradation process. For some contaminants, however, biodegradative populations are less universally distributed and/or are present only at very low densities. For example, the gasoline oxygenate methyl *tert*-butyl ether (MTBE) has been observed to biodegrade readily in some aerobic soils and aquifers but to be highly persistent in others. In environments where the contaminant persists, the absence of a biodegrading population has been cited as a key factor limiting its destruction. Bioaugmentation has been used at some sites to promote MTBE biodegradation. Similarly, the absence of a specific dehalorespiring microorganism (*Dehalococcoides ethenogenes*) has recently been cited as the key factor determining the extent of biodegradation of PCE and TCE in some anaerobic environments (see **Figure 3**). If this organism is absent, dechlorination of PCE (or TCE) appears to stall at *cis*-DCE or VC, rather than progressing all the way to ethylene. As with MTBE, bioaugmentation has been used to add this organism to specific sites in order to enhance contaminant biodegradation.

Predation

Bacteria are subject to predation by protozoa. Such grazing can influence the biodegradation of soil pollutants, with both inhibition and stimulation possible. Predation by soil protozoa can reduce the number of cells metabolizing a contaminant and cause a decline in the rate at which the compound disappears. Alternatively, due to the positive effect predation has on nutrient availability, grazing may stimulate the growth of microorganisms. Through their metabolism of microbial cells, protozoa release available nitrogen, phosphorus, and other nutrients back into soil and, consequently, stimulate the surviving microbial cells to grow faster. The dynamics of predator–prey relationships in soil are complicated and are not completely understood. Whether predation decreases or increases biodegradation rates depends upon a number of factors, including the starting density of the bacterial prey and predator organisms, the size of the cells, and the properties of the soil in which the organisms live.

Presence of Other Compounds

Microorganisms metabolizing a pollutant can be affected by the presence of other soil contaminants. In particular, it is not uncommon for a cocontaminant (such as a heavy metal or low molecular weight hydrocarbon) to be present in toxic concentrations in a heavily polluted soil, thereby inhibiting the biodegradation of a target compound by killing the biodegradative population. An organism may also preferentially use a compound other than the pollutant as a carbon or energy source and, as a result, biodegradation of the selected contaminant can be slowed. Alternatively, the presence of a second compound can stimulate microbial activity and accelerate biodegradation. For example, bioremediation of a compound that is cometabolized can be enhanced by the addition of a substrate on which the cometabolizing microorganism can grow. The addition of biphenyl to soils has been observed to enhance the rate of degradation of some of the less-chlorinated PCBs. In some instances, however, the growth substrate will actually inhibit degradation of the cometabolized compound owing to competitive enzyme inhibition. The presence of toluene above a given concentration, for instance, can reduce the rates of TCE cometabolism by specific toluene-oxidizing strains. For bioremediation applications, intermittent addition of the growth substrate may be necessary to promote degradation of a cometabolized substrate.

Summary

Biodegradation is an important process by which chemical pollutants may be removed from soil. Microorganisms have a remarkable ability to metabolize an extremely diverse range of synthetic compounds and can be invaluable in the remediation of contaminated environments. The rate and extent of biodegradation of a given contaminant in soil depends on a number of variables, including chemical structure, contaminant bioavailability, and an array

of environmental factors, such as nutrient availability, pH, temperature, soil moisture, predation, and the presence of cocontaminants.

Introduction

Many human activities have resulted in the intentional or unintentional release of pollutants into the soil environment. Some of these compounds are natural or derived from natural sources (i.e., petroleum hydrocarbons, metals), and would hence not be considered pollutants *per se* in their native environment. Their presence in soil is considered to be polluting because they are not native to soil or their quantities are much higher than normally occurs in soils. In contrast, many pollutant compounds are partially or totally man-made (i.e., pesticides, explosives), possessing no naturally occurring analogs.

While many of the pollutants that have been introduced into the soil environment have been shown to be biologically degraded by soil microorganisms, some pollutants have also proven to be toxic to various members of the soil microbial community. The adverse affects of toxic pollutants can be manifested as changes in the structure (composition) of the microbial community, alterations in the functions (activity) of the microbial community, or quite often both.

The effect of pollutants in terms of overall soil 'health' or ecosystem functioning has undergone considerable theoretical and empirical expansion since 1979. A conceptual framework for assessing pollutant effects is presented in **Figure 1**. This framework was developed based on side-effects testing of agricultural pesticides but is widely applicable to all classes of pollutants. The main aspects shown in **Figure 1** are that pollutant effects can range from negligible to critical (compared with a no- or preexposure control) depending on both the magnitude and the duration of the observed deficit in a given soil parameter. The soil parameter can be an aspect of either the microbial community structure (i.e., specific microbial populations) or function (i.e., nitrogen-cycling activities). Under this conceptual framework, large parameter deficits can be acceptable if they are short in duration, and small, long-term parameter deficits can also be acceptable.

Types of Effects

Microbial Community Composition

The introduction of a pollutant into the soil ecosystem can result in several types of general and specific changes in the microbial community composition. These effects are summarized in **Figure 2** and are a function of the concentration of the pollutant, the duration of the exposure, and the ability of the compound to be biodegraded.

General If the pollutant is very toxic or is present at very high concentrations, it can reduce the abundance of all microorganisms present in the soil due to cell lysis or death. In contrast, if the pollutant is introduced at a moderate concentration and can also serve as a carbon and/or energy source for soil microbes, an

overall increase in the abundance of microorganisms (bacteria, fungi, and protists) may be observed.

The general effects of pollutants on microbial community composition can be assessed using a variety of methods. Systematic laboratory experiments are designed to determine the abundance of total microorganisms before and after exposure to the test pollutant, which is usually introduced into the soil at several concentrations. Field samples collected from inside a contaminated area and from an adjacent uncontaminated area (matched as closely as possible in terms of soil type, vegetation, etc.) also allow the general effects of pollutants to be evaluated.

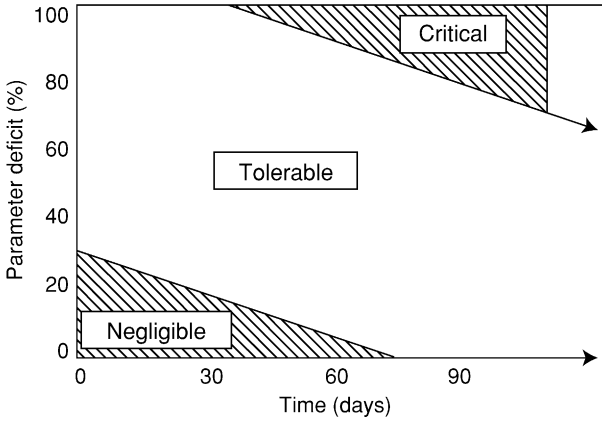

Figure 1 A conceptual framework for assessing the severity of pollutant effects based on the magnitude and duration of the observed effects. Adapted from Domsch K-H, Jagnow G, and Anderson T (1983) An ecological concept for the assessment of side effects of agrochemicals on soil microorganisms. *Residue Reviews* 86: 65–105, Figure 10, with permission. © 1983, Springer-Verlag, New York, Inc.

Microbial numbers or microbial biomass can be determined by a number of methods, including, but not limited to: spread or pour plate and/or most probable number (MPN) methods, using general microbiological media to enumerate total culturable heterotrophs; epifluorescent direct microscopic counts of total acridine orange- or 4′,6′-diamidino-2-phenylindole (DAPI)-stained cells; chloroform fumigation/extraction procedures to quantify microbial biomass carbon (converted to number of cells based on a factor); extraction and analysis of the total phospholipid fatty acid (PLFA) concentration (converted to number of cells based on a factor); and extraction of nucleic acids combined with quantitative polymerase chain reaction (PCR) techniques using Bacteria-, Fungi-, and Protista-specific primers.

Specific Some pollutants exert toxic effects on specific classes of soil microbes. The pollutants may kill or reduce the number of active (vegetative) cells, while spores and other resistant microbes may be relatively unaffected. In many cases, reductions in the abundance of a specific microbial population are due not to direct killing of specific cells, but to inhibition of specific cellular activities and functions to the extent that the cell cannot remain viable or reproduce. Similar to general effects, if the pollutant is present at moderate levels, the abundance of specific

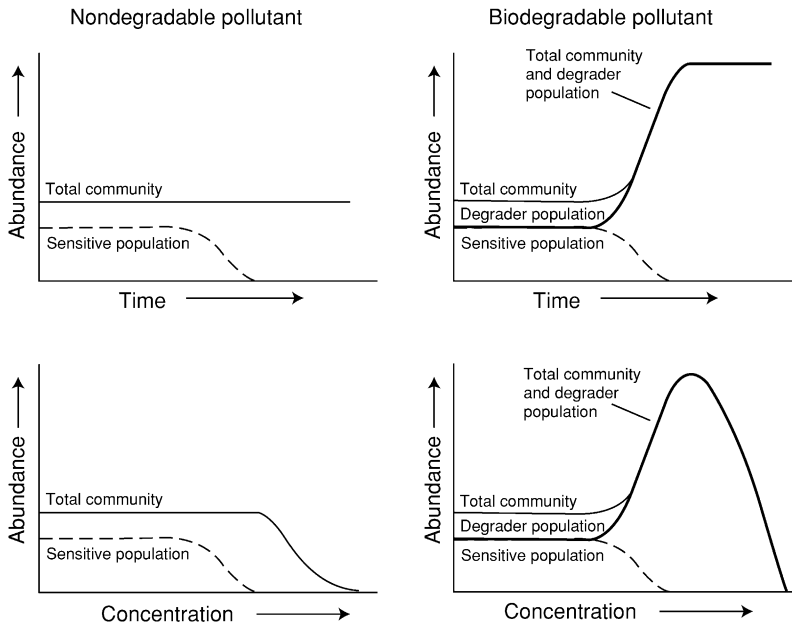

Figure 2 Expected changes in soil microbial community structure in response to biodegradable and nonbiodegradable pollutants with respect to duration and magnitude of exposure.

microorganisms able to use the pollutant as a carbon and/or energy source may increase substantially compared with their preexposure level.

Effects of pollutants on specific microbial populations are assessed in a manner similar to that described above. Most of the enumeration methods have variants to allow the concentration of specific types of microorganisms to be determined. Plate counts and MPN techniques can be performed using media tailored to certain types of organisms (i.e., purified agar incubated in the presence of hydrocarbon vapors to enumerate hydrocarbon degraders; anaerobic liquid media with nitrate or sulfate as the sole terminal electron acceptor to enumerate nitrate- or sulfate-reducing organisms, etc.). Epifluoresecence microscopy can be done using fluorescently labeled deoxyribonucleic acid (DNA) probes directly to count specific cells of a given microbial strain in contrast to total cells. The profile of different fatty acids that is generated using most PLFA methods can be interpreted to determine the proportion of different microbial populations (Gram-positive versus Gram-negative; sulfate reducers; methanogens; anaerobes, etc.) in a given sample. Lastly, the PCR methods can be adapted for use with genus- and even strain-specific primers/probes, allowing very small subsets of the overall microbial community to be enumerated.

Microbial Community Function

Pollutants have the ability to decrease (or increase) different activities or functions of the soil microbial community. Some of these changes are in direct response to the pollutant itself, while others may be the indirect result of changes brought about by the pollutant (i.e., changes in pH). In addition, the changes may be in general activities common to almost all microbial cells, or they may be activities that only a small subpopulation of the microbial community is capable of performing. Redundancy in the microbial community (i.e., more than one microbial strain able to perform the same activity) can be a major determining factor for whether the pollutant causes short- or long-term changes in the overall function of the soil microbial community. However, the heterogeneous nature of microbial distribution does limit the potential for redundancy to mitigate the adverse effects of pollutants at the microscale, and is most likely to be observed at the meso- and macro-scale (i.e., soil ecosystem *in toto*).

General Carbon mineralization (conversion of carbonaceous material to carbon dioxide) is the most general function of soil microbial communities that can be affected by exposure to pollutants. The majority of microorganisms in most soils are chemoheterotrophic, metabolizing available organic material as their carbon and energy source for growth and cell maintenance. Pollutants can interfere with carbon mineralization by direct interaction with specific degradative enzymes, but often act by disrupting or decoupling the cellular systems needed for energy generation and flow (i.e., production of adenosine triphosphate (ATP), regeneration of nicotinamide adenine dinucleotide (phosphate) (NAD(P)), and flavine adenine dinucleotide (FAD), etc.). Biodegradable pollutants will generally increase the net carbon mineralization (respiration) of a soil because of overall increases in microbial activity and microbial cell densities. However, nonbiodegradable pollutants can also cause increased respiration by triggering stress responses in the microbial community whereby more energy (and hence, carbon throughput) is needed to cope with the pollutant stressor.

Changes in carbon mineralization are usually determined by measuring the basal respiration of soil in the presence of the pollutant and comparing it with the same soil without the pollutant present. In many cases, substrate-induced respiration is also measured by adding a labile carbon source such as glucose and measuring the resulting respiratory production of carbon dioxide by soil in the presence and absence of the pollutant. Any pollutants (or pollutant concentrations) that cause significant decreases in carbon metabolism are also likely to affect adversely the input of fresh carbon (i.e., plant root exudates, plant biomass), reducing overall carbon cycling and raising concerns about long-term soil health. Finally, if the pollutant is biodegradable, its effects will probably decrease over time as its concentration is reduced.

Specific The cycling of nitrogen in the soil is by far the most studied microbial activity with respect to pollutant effects. The nitrogen cycle is shown in Figure 3. The consensus that has emerged from decades of research is that ammonification and denitrification activity is widely distributed throughout the soil microbial community, while ammonium oxidation, nitrate oxidation, and nitrogen fixation activity is concentrated in only a few microbial genera. This underlies the observation that nitrification, and especially ammonium oxidation, is very sensitive to many types of pollutants. Two bacterial genera, *Nitrosomonas* and *Nitrobacter*, are believed to be the predominant autotrophic nitrifying populations in soil, although some heterotrophic nitrifiers also exist. These two strains are highly sensitive not only to pollutants, but also to a range of environmental conditions, especially pH. Nitrification, therefore,

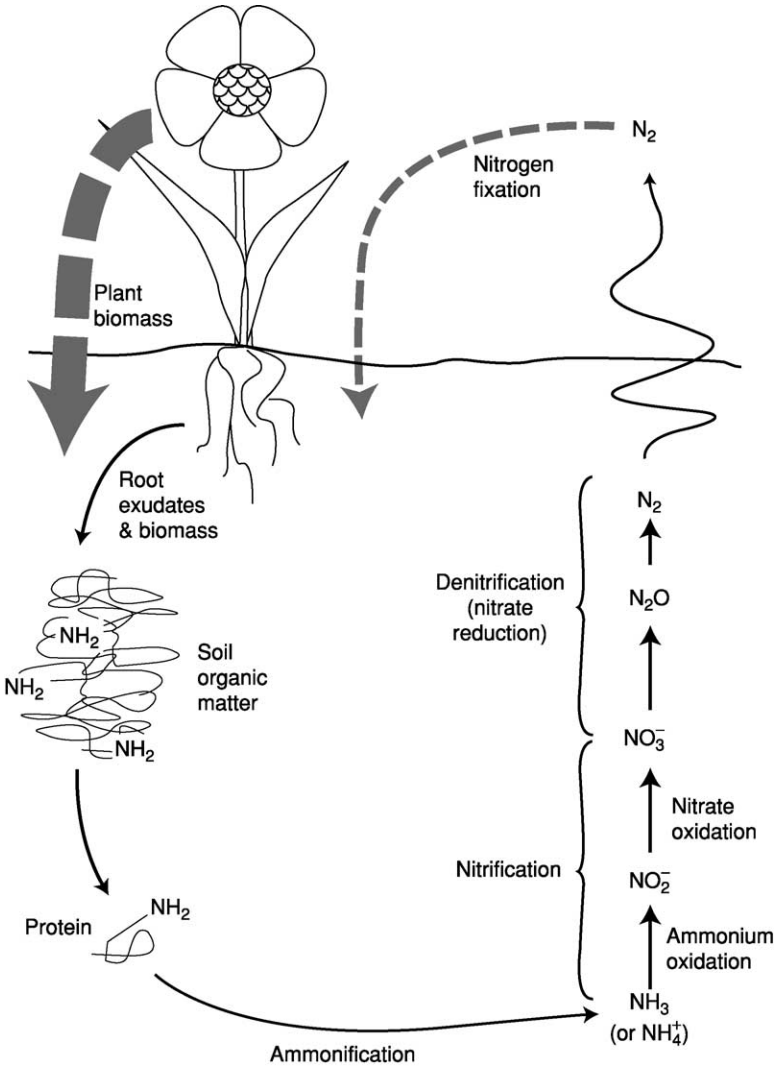

Figure 3 Soil nitrogen cycle.

may be thought of as a 'sentinel' soil activity, serving as the first indicator of soil ecosystem disturbance by pollutants. Although nitrogen-fixation ability is limited to a few symbiotic and free-living bacterial genera, nitrogen-fixing activity *per se* seems to be less sensitive to most pollutants than nitrification.

The effects of pollutants on the microbial activities associated with the cycling of other nutrients such as sulfur, phosphorus, etc., have not been extensively studied. This is probably due to the perceived lesser importance of these elements compared with carbon and nitrogen to the overall health of the soil microbial community. It has been assumed that these elements are present in excess what is needed by the soil biota, while carbon, and more so nitrogen, are the limiting nutrients. Because the activities involved in the cycling of phosphorus, sulfur, etc., appear to be widely distributed within the microbial community, only in extreme cases would dramatic pollutant effects be expected to be observed (i.e., massive decimation of total microbial biomass).

A final category of specific effects of pollutants relates to changes in the activities of soil enzymes. Some of the more generic enzymes include: dehydrogenase, acid and alkaline phosphatase, phosphodiesterase, arylsulfatase, amidases, urease, and protease. Many soil enzymes are released from microbial cells into the open soil environment, with the goal of liberating the soil nutrients associated with soil organic matter (SOM). Whereas disruption of carbon mineralization (respiration) is a general effect of pollutants on soil microbial community function, the effects of pollutants on soil enzymes disrupt other necessary aspects of carbon cycling in soils (i.e., conversion of large, extracellular organic molecules to smaller molecules available for cellular uptake and metabolism).

Several reports have focused on the effects of pollutants on soil enzymes, but the exact nature of the effects have been less-rigorously investigated (i.e., are the pollutants directly interacting with the enzymes, or with the organisms that are producing and releasing the enzymes?). Again, due to the relatively widespread and generic activities of these enzymes, pollutant effects seem to be relatively small except in cases of excessive and/or prolonged contamination. Generally, dehydrogenase and urease have been shown to be more inhibited by pollutants, while phosphatase has often been observed to be stimulated.

Effects of Different Classes of Pollutants

The effects that have been observed to be caused by different types of soil pollutants are presented in Table 1. This table, and the discussion in this section, reflects the general consensus of the current literature and hence should be considered as a guide regarding potential pollutant effects, in contrast to a comprehensive summary of all the available data. Indeed, in many cases the published literature presents contrasting results, pointing to the need for continued research with more standardized (and environmentally relevant) experimental procedures. Many of the effects are highly dependent on other physiochemical soil parameters (i.e., pH, redox, cation exchange capacity, organic matter, or clay content) which modulate the bioavailability of the pollutants. Information on the effects of a specific compound should be sought out in the peer-reviewed literature.

Petroleum Products

The effects of petroleum-based products, ranging from short, straight-chain hydrocarbons to highly condensed polynuclear aromatic hydrocarbons (PAH), have been studied largely in response to the reality of widespread pollution by these compounds due to accidental releases at gas stations and oil refineries. However, there are considerable 'natural' releases of these compounds into the environment from seeps (e.g., the La Brea tar pits in California, USA; undersea seeps in the Gulf of Mexico; etc.).

The most general effect of petroleum products is an increase in microbial biomass and changes in the community structure due to utilization of the compounds as carbon and energy sources (Table 1). Respiration is also usually increased, but effects on other activities are minimal.

Halogenated Compounds

The compounds in this class include compounds used in chlorinated degreasing and dry-cleaning such as perchloroethylene (PCE) and trichloroethylene (TCE), polychlorinated biphenyls (PCBs), and other halogenated industrial chemicals. Compounds containing chlorine and bromine have been more closely studied than fluorinated and/or iodinated chemicals.

Halogenated compounds enter the environment through accidental releases from industry, leaking waste drums, and landfill leachate. Very high levels of contamination usually coalesce into the groundwater below the soil as dense, nonaqueous-phase liquids (DNAPL), but vapors from these areas may still rise up through the subsurface and affect the soil community. In general, very few effects are observed from contamination with moderate levels of halogenated aliphatic compounds (Table 1). However, chlorinated aromatic compounds have been observed to affect some aspects of the microbial community structure (biomass and diversity) and function (especially nitrification).

Pesticides

Pesticides (including fungicides, nematocides, insecticides, and herbicides) are the only class of compounds that are intentionally introduced into the environment on a regular basis. The use (and misuse) of pesticides, the development of new pesticides, and the registration of new pesticides (particularly in Europe), has been one of the primary driving forces behind the study of the effects of pollutant on soil microorganisms. The major focus for pesticides has been on 'side-effects testing,' during which the effects of the compound(s) on soil organisms other than the target 'pest' organism are examined. Initially, broad measurements of general effects on soil functions that were deemed important indicators of overall soil health (especially from an agricultural perspective) were studied. More recent work, however, has employed molecular methods to examine effects down to the level of single microbial species and how pesticides may influence long-term soil health.

In a broad study of more than 50 pesticides, the recommended agricultural doses caused no long-term effects on the structure or function of the soil microbial community. Interestingly, when effects are observed, it is often attributed to the pesticide breakdown products rather than the parent compounds.

Explosives

These compounds have only recently been recognized as potentially significant pollutants. The major compounds in this class include: the nitroaromatics 2,4,6-trinitrotoluene (TNT), 1,3,5-trinitrobenzene (TNB), 2,4,6-trinitrophenol (picric acid), and *N*-methyl-*N*,2,4,6-tetranitroaniline (tetryl); the nitramines hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX),

and octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine (HMX); and the nitroesters nitroglycerin (NG), nitrocellulose (NC), and pentaerythritol tetranitrate (PETN). Gross pollution with explosives is most often associated with manufacturing and training activities, and historical soil contamination for 50 years or longer has been reported at many military installations where these activities have occurred.

The toxic effects of these compounds in the environment have only recently been initiated, and reports of effects on soil (micro)organisms are sparse. Most of the explosives are sparingly soluble and, when mixed with the binders or waxes used in actual explosives formulations, their bioavailability is quite limited. The summary in Table 1 indicates that some effects have been observed, but more research is clearly needed.

Metals

Metals enter the soil environment primarily through atmospheric deposition downwind of smelting operations or via leaching from mine spoils. Some metals are essential for microbial cells, some are needed in trace quantities, and others are nonessential and/or toxic. The most toxic metals are the heavy metals cadmium, lead, and mercury, but high concentrations of copper, zinc, chromium, iron, manganese, nickel, cobalt, arsenic, and silver can also exert adverse affects on microorganisms.

The toxicity can be manifest by replacement of essential metal reaction centers of enzymes, reaction of metal ions with the sulfhydryl and phosphate groups of proteins, or displacement of key structural elements. Metal toxicity is highly dependent on the pH and redox state of the soil, as these strongly influence the oxidation state and solubility of metals and hence their bioavailability to soil microbes. Microorganisms themselves have also developed a broad range of resistance mechanisms to counteract the effects of metals. These include facilitated transport of the metal ions out of the cell, or complexation of the metal with reactive molecules (glutathione, etc.) that render it less bioavailable.

Persistent Organic (POPs)

D Johnson, Rothamsted Research, Harpenden, UK

Introduction

Organic pollutants are ubiquitous environmental contaminants and, for many of the compounds, the environmental burden has risen, largely as a result of anthropogenic activity in the nineteenth and twentieth centuries. Soil can be a major environmental sink for many of the organic pollutants released into the atmosphere. Once in a soil, nonionic organic pollutants can often be highly persistent. The primary rate-limiting factors determining the long-term persistence of persistent organic pollutants (POPs) in soil are thought to be fundamental sorption/desorption mechanisms that control the distribution of chemical between the solid and aqueous phases of the soil. Soil POPs are potentially available to many organisms, including soil microflora, macrofauna

(earthworms are particularly important), and grazing animals. However, the availability of soil POPs tends to decline with time. The bioavailability of POPs to soil organisms is important in determining the potential hazard presented by a contaminated soil and may also influence the efficiency of bioremediation of contaminated soils.

Persistent Organic Pollutants

During the nineteenth and twentieth centuries humans have produced and released vast quantities of organic compounds into the biosphere. These are widely distributed throughout the environment and many are thought to be carcinogenic and mutagenic. This has led to the prioritization of organic pollutants by the United States Environmental Protection Agency (USEPA) and the European Community (EC). These lists include polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), polychlorinated dibenzo-*p*-dioxins and furans (PCDD/Fs), chlorobenzenes (CBs), phthalate acid esters, and other miscellaneous compounds. These compounds enter the environment through a wide variety of processes including inefficient combustion, dry and wet deposition from the atmosphere, widespread pesticide use, and wastewater drainage from industrial and domestic sources into sewers. Hence, the soil is a major sink for POPs. Once in a soil, high-molecular-weight non-ionic organic compounds may persist for long periods.

POPs are characterized by their relatively high octanol/water partition coefficient (log Kow) and low water solubility. Thus, once in a soil they tend be resistant to microbial degradation and prone to bioaccumulation. Atmospheric transport processes such as 'global distillation' result in an almost ubiquitous contamination of soils, often thousands of kilometers from major POP sources. The highest soil concentrations of POPs are usually found near industrial point sources, urban areas, and in organic-rich soils such as those that have received sludge amendment. The recent decline in the manufacturing industry in many western economies has left large areas of soil contaminated by POPs and requiring remediation before they can be redeveloped.

Legislation relating to organic compounds in soil is largely based on toxicological criteria with the ultimate aim of protecting wildlife and human health. Thus, it is important that the 'availability' of compounds to transfers from the soil to the organisms is accurately understood in a quantitative manner. Recent research on the fate and behavior of organic chemicals in soils suggests that the availability of an organic compound from the soil into the food chain may be highly dependent upon the form in which a compound is present in a soil. This is influenced by a number of factors, including its residence time within the soil, physicochemical properties of the compound and soil, and how it entered the soil. Desorption of sorbed compounds into the soil solution enhances biodegradation, leaching, volatilization, plant uptake and other chemical/photochemical transformations. Whilst these processes are generally enhanced by the chemical being present in the bulk soil solution, chemical degradation, photochemical transformations and biodegradation of soil-sorbed compounds are also possible. Furthermore, soil-sorbed compounds may also be lost from areas of soils by the erosive action of wind or running water, uptake by invertebrates or direct ingestion of soil by grazing livestock.

The persistence and relative significance of each loss pathway in a given soil depends on the physicochemical properties of the organic chemical and environmental conditions. However, regardless of the main loss pathway, the overall loss of organic chemicals from soils is often biphasic. This means that a short period of rapid initial loss is most often followed by a longer period of slow dissipation. Loss processes in soils exhibit similar patterns. The primary rate-limiting factors governing this biphasic behavior are thought to be fundamental sorption/desorption mechanisms that control the distribution of chemical between the solid and aqueous/gaseous phases of soil and hence, the supply of chemicals available to the various loss pathways. The availability of organic compounds in a soil will affect both the toxicological threat and the potential to remediate a contaminated site. Further details relating to specific technologies available for contaminated soils can be found in the article Remediation of polluted soils (*See* **Remediation of Polluted Soils**).

Physicochemical Properties of Persistent Organic Pollutants in Soils

The principal persistent organic pollutants found in soils are PAHs, PCBs, CBs, and PCDD/Fs. Table 1 displays comparative physicochemical data for a number of selected organic chemicals that occur in contaminated soils.

Persistence and Aging Behavior of Organic Chemicals in Soils

Figure 1 illustrates the decay curves of three model nonionic organic compounds after they enter a soil. The persistence and overall loss of organic chemicals from soils following their entry into a soil are dependent on the physicochemical properties of the soil and the chemicals themselves, environmental

factors, including temperature and precipitation, and anthropogenic factors such as cultivation and drainage.

Curve A (Figure 1) is typical of organic contaminants with short half-lives that exhibit relatively rapid dissipation with most of the residues ultimately being removed from the soil. Such decay curves are typical of compounds that are volatile, water-soluble, or easily degraded (or a combination of these). Examples of this chemical type are the lighter chlorinated benzenes and volatile aromatic hydrocarbons. At the other extreme, chemicals that are nonvolatile, relatively water-insoluble and recalcitrant are characterized by persistence profile C (Figure 1). Such chemicals are strongly sorbed and persist in soils over often extremely long periods. Examples include PCDDs and PCDFs. Most organic compounds fall within these two extremes, exhibiting persistence profiles similar to curve B. Curves A and B are essentially similar in shape with an initial period of rapid loss followed by a much slower dissipation of the chemical. This leads to a 'persistent residual fraction' of the compound forming in the soil, the size of which will be determined largely by the physicochemical properties of the compound and soil. As commented earlier, a loss profile of this shape is often referred to as 'biphasic' and is typical of organic chemicals with intermediate sorption potentials.

The 'Aging' of Persistent Organic Pollutants Within Soils

As can be seen in Figure 2, when a nonionic organic compound enters a soil it undergoes a number of loss processes including leaching, volatilization, chemical and biological degradation, and plant uptake. In addition, sorption- and transport-related processes mean that an increasing component of the soil-borne compound becomes 'irreversibly bound' within the soil matrix, i.e., they cannot be extracted by conventional analytical techniques. The result is that, as the residence times of organic compounds increase within a soil, they become increasingly difficult to extract. This phenomenon has become known as the 'aging effect.' There is also an assumption that there is an analogous decline in a compound's bioavailability as soil residence time increases and extraction efficiency declines, but this may be erroneous (see later).

Figure 2 demonstrates that this process of declining extractability of soil-bound compounds is, in part, due to the formation of irreversibly bound residues within the soil matrix. The development of irreversibly bound residues is a major contributing factor in the formation of persistent residual fractions of organic chemicals in soils. Addressing this issue is complicated by the fact that the experimental data are highly dependent on the extraction method used and the knowledge that the efficiency of extraction of an organic chemical from a soil will decline with an increase in contact time between a chemical and the soil, i.e., the 'aging effect.'

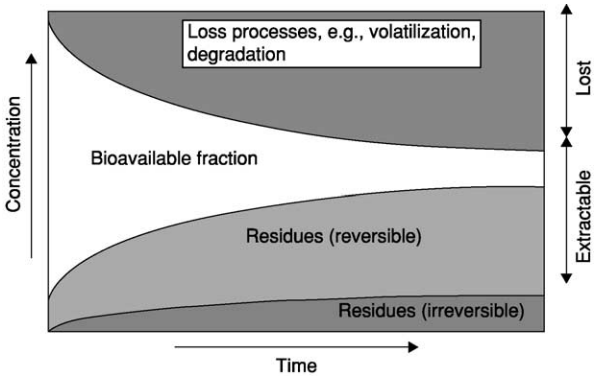

Figure 2 Dynamics of organic chemical persistence, bioavailability and loss in soils.

Mechanisms Contributing to the Persistence of Organic Chemicals in Soils

Several groups of mechanisms are thought to be involved in the 'aging effect'. The processes involved can be split into transport-related and sorption-related mechanisms. Transport-related mechanisms are those where sorption/desorption of organic chemicals is controlled by water flow in soils. Due to their particle size, distribution, and management, soils may develop distinct structural arrangements ranging from simple homogeneous granular sands to pronounced columnar and prismatic clay structures. In the latter soil type, swelling and shrinkage may create a network of cracks that rapidly conduct most water while the remainder of the water moves relatively slowly through the soil matrix. Water flow in sandy soils is more uniform, but it is important to recognize that preferential flow may also occur in such soils. Comprehensive reviews of water movement in structured soils and the implications of this for solute transport and fate will not be discussed in detail here but readers requiring more information can find further reading at the end of this article.

Sorption-Related Mechanisms

The nature and significance of sorption-related mechanisms are less well understood than transport-related mechanisms and much research is still required in this field. The literature still contains many contradictions as to what are the dominant sorption-related mechanisms controlling the persistence of nonionic organic chemicals in soils. Sorption mechanisms can be divided into two distinct classes: diffusive mass transfer and chemisorption. Diffusive mass transfer mechanisms include film diffusion, pore diffusion, retarded intraparticle diffusion, and intraorganic matter diffusion. Film diffusion relates to the resistance encountered by an organic chemical when crossing a thin film of water surrounding soil solids/aggregates, or when moving from the solid phase into the bulk solution or gaseous phases. Film diffusion is generally regarded as insignificant in comparison to other processes discussed here. Pore diffusion is the molecular diffusion of organic chemicals within pores between soil particles inside soil aggregates. The current literature suggests that, similar to film diffusion, pore diffusion rarely contributes to the formation of persistent chemical residual fractions.

Chemisorption occurs when a functional group of an organic chemical interacts with reactive moieties on soil solids through the formation of strong chemical bonds, principally covalent bonds. Such interactions give rise to the formation of a fraction that is irreversibly sorbed, despite exhaustive extraction procedures, and has become known as 'bound residues' in the pesticide science field. However, pesticides are often ionic, in contrast to nonionic compounds such as nonionic persistent organic pollutants, which are less likely to form chemical bonds with soil solids. Thus chemisorption is unlikely to be a major rate-limiting factor governing the persistence and loss of hydrophobic organic chemicals in soils. Where a contaminant has a tendency to ionize or contains polar functional groups, then chemisorption may be important. In addition, biologically mediated degradation processes may alter the structure of nonionic organic chemicals so they are more susceptible to chemisorption. A 1996 study demonstrated that once partial oxidation of a PAH occurs by biologically mediated degradation, the irreversible chemisorption of metabolites can occur and in some cases can be so significant that the process becomes competitive with biodegradation. The significance of chemisorption in the formation of persistent residual fractions has yet to be fully elucidated. Further investigation is clearly necessary because the exact processes involved in persistent residual fraction formation may be important in determining whether the compounds remain chemically and, more importantly, biologically unavailable.

Sorption Retarded Intraparticle Diffusion

Of the mass transfer mechanisms involved in the formation of persistent residual fractions it is generally agreed that sorption retarded intraparticle diffusion (SRPD) and sorption retarded intraorganic matter diffusion (SROMD) are the two primary rate-limiting factors. SRPD has been defined as 'aqueous-phase diffusion of solute within pores of microporous particles (e.g., sand grains) mediated by retardation resulting from instantaneous sorption to pore walls.' However, SRPD is often used as an umbrella term for a number of similar processes that occur by diffusion of organic compounds through pores. The above definition of SRPD refers to the molecular diffusion of chemicals in pore water that is retarded, chromatographic-like, by local sorption on pore walls. This process is more marked in larger mesopores (diameter $>2\,\mu$m), and the sorption may or may not be aided by sorption to and within organic matter lining these pores (see later for description of SROMD). As the pore's diameter decreases, the tortuosity of the pore tends to increase, further hindering diffusion processes.

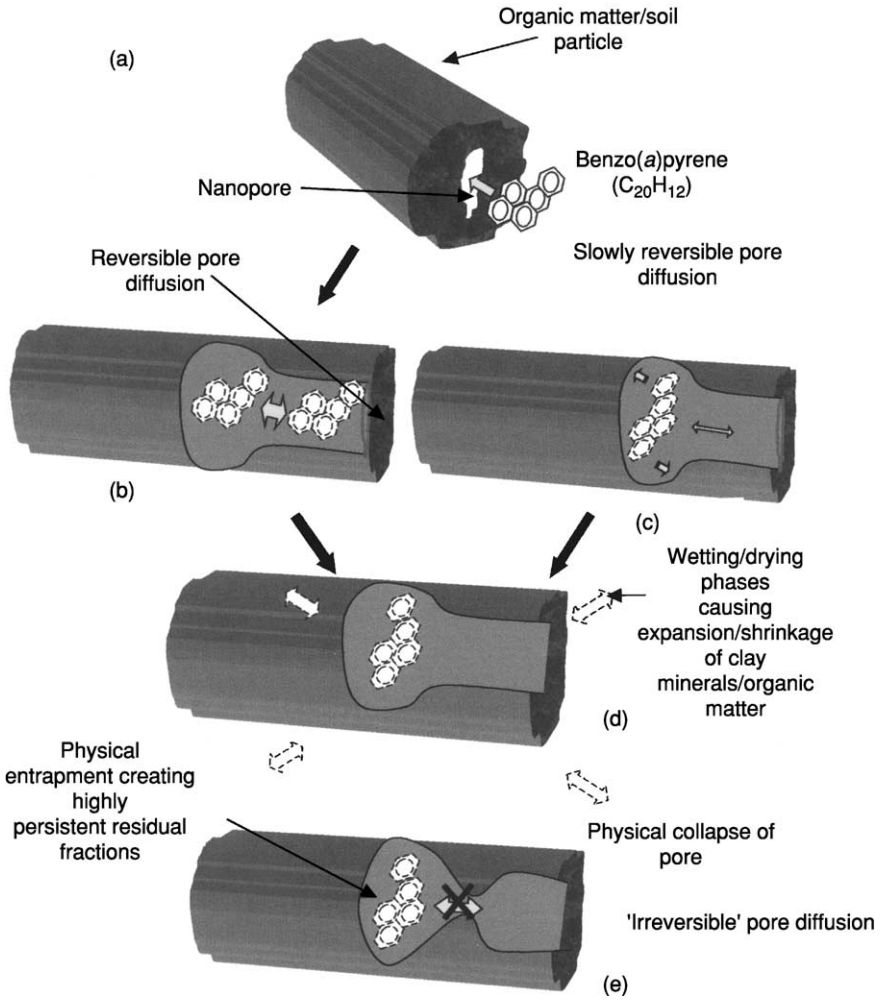

Figure 3 A conceptual diagram showing the mass-transfer limited processes leading to sorption-retarded pore diffusion. (a)–(e) are discussed in the text.

Figure 3 graphically illustrates the various stages of diffusion that occur in exceptionally narrow nanopores traversed by a model PAH, benzo(*a*)pyrene. Compounds tend to enter nanopores as they diffuse along gradually narrowing mesopores (>2 μm) followed by micropores (<2 μm) and eventually end up in nanopores whose diameter may be only a few Angstroms larger than the molecule itself (Figure 3a). In extremely narrow pores, diffusion is often exceptionally slow due to the high viscosity of pore water. Polar minerals have one or more layers of water strongly sorbed on their surfaces. This ordered layering of molecules increases the viscosity of the water and greatly slows molecular diffusion within nanopores (Figure 3b). The water contained in very narrow pores of a few Angstroms may be 'ice-like' and thereby greatly restrict solute diffusion. The tortuosity of pores becomes an increasingly important factor in the retardation of pore diffusion and tortuosity may only influence desorption when the pore diameter is less than 6 nm. In extremely narrow and tortuous pores, steric hindrance may further retard desorption (Figure 3c). When this occurs sorption is only very slowly reversible, contributing to the persistent residual fractions discussed earlier. Natural wetting/drying phases of a field soil will lead to expansion and contraction of clay mineral lattices (Figure 3d), which can induce physical collapse of pores and physical entrapment of solute molecules within 'blind alleys' (Figure 3e).

Figure 3 therefore represents a series of steps that progressively restrict solute diffusion and retard desorption leading to persistent residual fractions of organic compounds in soils. These compounds, although chemically unaltered, are usually unavailable to traditional chemical extraction techniques and the assumption is that they are also not bioavailable. However, it is important to remember that, although such compounds are often referred to as irreversibly bound, this may not always be the case. Physical

destruction of the soil aggregates they are associated with may release the compounds or at least increase their biological and chemical availability. Acidification dissolves the inorganic oxide cements that hold soil aggregates together and hence may similarly increase rates of pore diffusion and sorption.

Intraorganic Matter Diffusion

Intraorganic matter diffusion (IOMD) is the other important rate-limiting process involved in the desorption of persistent organic compounds from soils. Soil organic matter can exist as surface coatings, lining pores, or as discrete particles. Organic matter diffusion may be the primary rate-limiting process in soils with high-organic-matter contents but, since slow sorption also occurs in soils with low to zero organic matter, it clearly is not the only rate-limiting process. IOMD is considered to be diffusion solely within the matrix of organic matter (OM), which is thought to resemble a polyelectrolyte polymer mesh, with retardation resulting from reversible sorption on the internal surfaces of organic matter. OM polymers are said to have glassy (condensed, rigid) or rubbery (expanded, flexible) structures (Figure 4). Diffusion in polymers occurs by either a place change mechanism, in which movement is accomplished by cooperative interchange of position in polymer segments and the penetrating molecule, or by a defect mechanism where the penetrant may jump between lattice defects, voids, and pores. OM polymers consist of condensed, rigid 'glassy' phases through which diffusion is slow (Figure 4b) or more expanded and flexible 'rubbery' structures through which diffusion is faster (Figure 4a).

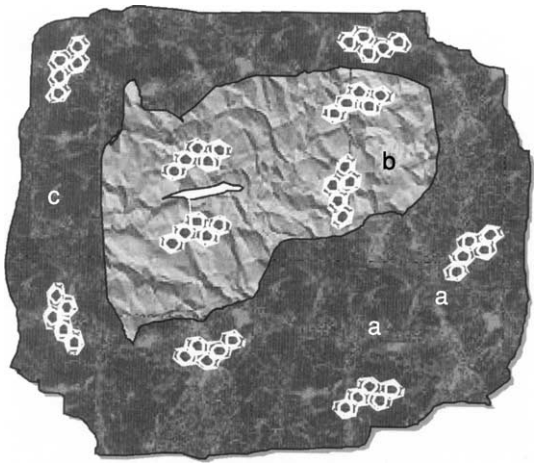

Figure 4 A conceptual diagram describing the slow sorption processes involved in organic matter diffusion (OMD). (a) Diffusion through a rubbery phase; (b) diffusion through a more condensed glassy phase b; and (c) adsorption in a 'Langmuir site' (see text for further details).

In addition, some organic compounds may undergo 'Langmuir-like' adsorption (Figure 4c) in internal voids in the OM matrix, which has been likened to a hole-filling mechanism. These slow diffusion processes lead to the formation of physically protected compounds which, as in the case of SRPD, are often mistakenly labelled as irreversibly bound residues. The OM diffusion and binding processes are in fact transitory since environmental variables may swell or soften the OM matrix, converting it from a glassy to a more rubbery state and accelerating diffusion processes. Increasing temperatures, change in pH, and the presence of cosolvents can all act to increase the diffusivity of tightly bound compounds.

In summary, it is probable that a number of mass transfer mechanisms are responsible for retarded diffusion leading to the formation of persistent residual fractions within most soils. Of these, the two most important are usually SROMD and SRPD. Although much work is needed to determine the exact contribution of each mechanism, it is likely that in most soils it is a synergy of both OMD and SRPD that is primarily responsible for the formation of persistent residual fractions. Residual fractions are often considered both biologically and chemically unavailable. However, as the preceding passages have shown, the mechanisms that lead to their formation are often transitory. This is particularly important when considering biological availability since the very conditions which are known to enhance diffusion rates often occur in the intestines of biological organisms (low pH, mechanical manipulation, and elevated temperatures). Hence, soil ingestion by an organism may have an impact upon a compound's availability and traditional extraction techniques used to determine the risk presented by a persistent residual fraction may be inaccurate.

The (Bio)availability of Organic Chemicals in Soils

The term 'bioavailability' is often discussed in the literature but rarely defined. For the purposes of this article, it may be defined as 'the fraction of a chemical that is absorbed by an organism.' This is a broad definition and encompasses bioavailability to plants and microorganisms via a variety of potential routes. The amount of compound present in an organism will be a function of the rate of absorption versus the rate of excretion.

POPs in soils are potentially bioavailable to many different organisms. In this article, a very brief overview is provided of the bioavailability of POPs to those organisms that are thought to be most important. These are plants, bacteria, and fungi, and

grazing animals. Macroinvertebrates and particularly earthworms are dealt with in more depth as they may represent important routes for POPs to enter the food chain. Organisms such as earthworms that are in constant physical contact with the soil may accumulate significantly higher body burdens of POPs than the surrounding soil. These concentrations may not be great enough to cause either acute or chronic toxicity in the earthworms. However, many species feed on earthworms and will concentrate the lipophilic compounds in the body fat. The result is an increase in POP body burdens as you rise up the trophic level of the food chain. This phenomenon has become known as biomagnification and may lead to symptoms of toxicity in organisms that have little contact with soil POPs.

Availability to Plants

Generally, translocation of nonionic organic compounds from the roots to shoots is negligible due to the low water solubility, high n-octanol/water partition coefficients and strong associations of many compounds to soil particles/organic matter. Plant uptake of nonionic organic chemicals from soils is usually dominated by vegetative uptake of contaminated vapor from the surrounding air. Although high concentrations of soil-borne nonionic contaminants are rarely available for translocation by plant roots, heavily contaminated soils can influence the concentrations of organics in above-ground vegetation by the soil–air–plant route. In a review of crop plant uptake of organic compounds from soils it was concluded that the vast majority of organic compounds in soil are so strongly sorbed by the soil matrix that they exhibit low bioavailability to crop plants and so are accumulated at very low concentrations in the edible portion of food crops.

Availability to Soil Microflora

The 'availability' of organic compounds in soils to microorganisms is critical if they are to be broken down and removed from the environment via either natural attenuation or bioremediation. Microbial biodegradation is a major process affecting the persistence of POPs in soils. The extent of POP bioavailability to bacteria in different soils may differ significantly, even under the same optimum growth conditions. Sorption has an important influence on the bioavailability of hydrophobic organic compounds in soils. A reduction in the degradation rates with increasing soil sorption capacity is apparent. Furthermore, a persistent residual fraction of POPs may remain unavailable to soil bacteria after remediation. This can be attributed to the slow migration of an increasingly large fraction of the POPs into the soil organic matter and mineral matrix with time.

As discussed earlier, POP chemical availability falls with increasing residence time in a soil. This reduced chemical availability is often mirrored by an analogous decline in bioavailability. This 'aging effect' may reduce the efficiency of bioremediation of a contaminated soil as a function of time. However, the reduced bioavailability may also reduce the potential toxicological threat of organic compounds in a soil. There is currently a great deal of research devoted to developing an accurate assessment of the bioavailability of organic compounds in soils. When developed, such an assessment of bioavailability will be able to identify both the suitability of a soil for bioremediation and the potential toxicological threat presented by that soil.

Grazing Animals

Soil ingestion by grazing farm animals has been estimated to be in the range of 1–18% of the dry-matter intake, depending on forage conditions. Thus, ingested soil may represent a potentially major route of uptake for soil-borne organic contaminants by ruminants. It follows that consumption of meat and/or dairy products may be an important exposure pathway to humans. However, the total intake of organic compounds by grazing livestock is relatively low, even when a worst-case scenario is taken into consideration. Furthermore, due to the effect of slow diffusion, discussed earlier, the fraction of a compound 'available' to grazing livestock is likely to be less than that taken up on a weight compound/weight soil basis. It follows that any contemporary risk assessments may overestimate exposure of grazing livestock to soil-borne organic compounds.

Availability to Earthworms

Earthworms are extremely numerous, especially in pasture land where their biomass can be up to $272\,g\,m^{-2}$. Add to that the fact that an individual earthworm can consume up to 400 times its own weight in soil over a 12-month period, and their importance in the dynamics and persistence of organic compounds in soils becomes apparent. This high density and activity mean that up to 25% of the surface layers of soil is turned over annually. A relatively high body lipid content means that earthworms accumulate POPs. Earthworms may facilitate faster release of certain sorbed residues, since a large quantity of soil passes through the gut, and is consequently exposed to digestive enzymes that act on soil organic matter. Hence, the assumption that there is an analogous decline in chemical and biological

availability of organic compounds may break down when an active (in this case gastrointestinal) uptake mechanism is involved as opposed to a more passive mechanism, such as contact between skin and soil.

Introduction

Groundwater contamination presently comprises one of the major global concerns. In developing countries, groundwater is subject to contamination mainly due to poor sanitation associated with high rates of population growth. In rural areas of developed countries, groundwater contamination is mainly attributed to fertilization, use of pesticides and herbicides, and inappropriate habits of irrigation from the point of view of amounts of groundwater pumping and water quantities used for irrigation. In urban areas of developed countries, groundwater contamination is attributed to a variety of species (both chemical pollutants and microorganisms), originating from urban development, and domestic and industrial wastes.

Aquifers are formations of comparatively high permeability capable of storing significant quantities of groundwater. Due to these two properties, groundwater aquifers comprise the major source of fresh

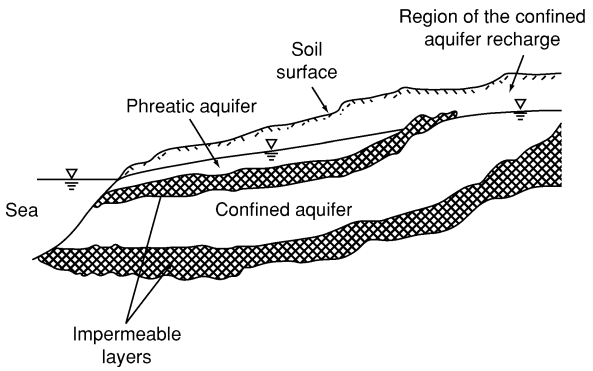

Figure 1 Schematics of phreatic and confined aquifers.

water for humans. Figure 1 provides a schematic of the major two types of aquifer: (1) phreatic aquifers, and (2) confined aquifers. The bottom of the phreatic aquifer, which is also called the 'free surface aquifer,' comprises impermeable formations, whereas the top is unprotected against the penetration of pollutants through the vadose (unsaturated) zone. Such pollutants usually arrive at the phreatic aquifer with infiltrating runoff water (which provides the aquifer recharge) or water from other sources. A confined aquifer is bounded top and bottom by impermeable formations. However, in some areas, where the confined aquifer is subject to recharge, it is basically a phreatic aquifer.

There are several avenues for groundwater contamination. One common avenue of groundwater contamination is associated with direct contact between surface water and groundwater. An example of this type of groundwater contamination is represented by the role of the Arkansas River in the contamination of the aquifers in western Kansas. The Arkansas River is a draining river of surface water contaminated by pollutants of the big farms in Colorado. This type of water flows downstream through Kansas. In western Kansas, due to excessive pumping of groundwater, the Arkansas River supplies water into the aquifer, and thereby pollutes the groundwater with pollutants diverted from Colorado. In the Tel-Aviv area, Israel, the Ayalon River diverts pollutants from its upstream portion into the aquifer of Tel-Aviv, where the groundwater table is often significantly lower than the water level of the Ayalon River.

However, in most cases, groundwater is subject to contamination due to the arrival of seeping contaminants through the vadose zone of the soil that overlies the aquifer. Sometimes groundwater pollution is transferred by various types of mechanisms into the vadose zone, and generally groundwater contamination is intimately connected with the state of the vadose zone.

Association of Pollutant Transport with the Water Cycle

Almost every textbook, guidebook, and manual of hydrology incorporates some descriptions and discussions which refer to the global cycle of water and emphasize its importance for properly maintaining the environment. The global water cycle demonstrates how quantities of water in the global scale are almost unchanged, while water is subject to transfer between different parts of the environment. The dielectric coefficient represents the ratio of the potential (and also the field strength) surrounding an electrostatic charge in a specific environment (medium) to the potential surrounding an identical charge in a vacuum. Due to its large dielectric coefficient, water has an extremely high capability to dissolve salts. Therefore, all chemical processes characterizing the different types of organisms take place in a water environment. By employing soaps and detergents, human society has increased the dissolving capability of water even to materials considered 'immiscible in water.' Society also utilizes water to transport solids as suspended and bed load; where suspended load is the flux of suspended solids and bed load is the flux of solids subject to movement (due to momentum transfer from the flowing water) at the bottom of the conduit. In contemporary urban society, water is mainly used as an agent to dissolve and transport solid material. Therefore, nowadays the involvement of the water cycle stages in pollutant transport in and between different parts of the environment is crucial for the preservation of human health and a balanced environment. It is extremely important to calculate budgets and mass flux balances of contaminants in different areas of the environment. In the bible, in the book of Ecclesiastes, the author expressed his astonishment that all rivers go to the sea, but the sea is never full. However, observations indicate that the salinity of the sea increases, and throughout the history of geology scientists have tried (unsuccessfully) to calculate the age of the earth according to the accumulation of salt in seas and oceans. It is not the appropriate place to evaluate why this calculation has not been successful, but simple mass flux balance shows that fresh water flowing into the sea incorporates small concentrations of various salts, and water leaving the sea in the vapor phase is almost free of salts. Therefore, the salinity of the sea must increase, as it does in lakes such as the Dead Sea (which is saturated with sodium chloride) that are not drained into other big water bodies.

Figure 2 provides a general schematic description showing how water and pollutants are transferred

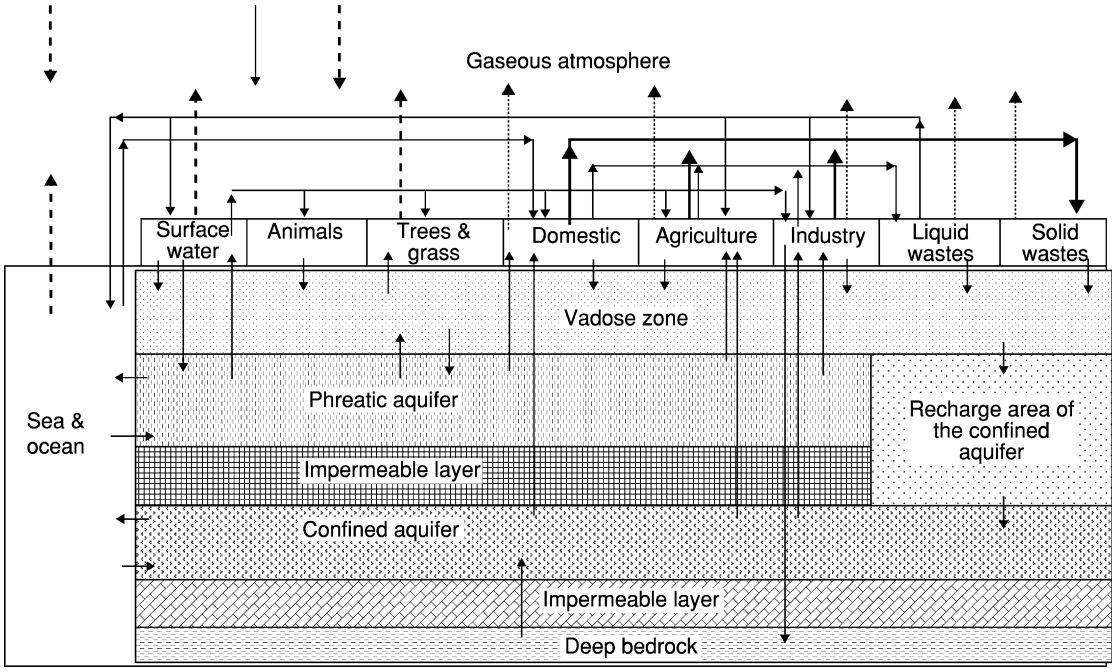

Figure 2 The water cycle associated with pollutant transport.

between different parts of the environment and different water consumers. This figure shows several parts of the environment that can be considered as storage locations for water: (1) seas and oceans, (2) the gaseous atmosphere, and (3) the various geologic formations. Figure 2 also shows some consumers of water. Note that it refers to surface water as one of the consumers, though some professionals may prefer to use another definition for surface water. There are about eight major water consumers (again the exact number of consumers is not as important as is their role in pollution production and transport). Thin solid arrows refer to the direction of transport of water with solutes and pollutants; thick solid arrows refer to solid wastes. Dotted arrows refer to transfer of air pollutants; and thick dashed arrows refer to transfer of pure water (vapors and/or precipitation). Therefore, according to Figure 2, pure water, as precipitation, is transferred from the atmosphere into the sea and the terrestrial part of the environment, but contaminated water is also transferred, e.g., acid rain.

Regarding consumers, domestic consumption also includes municipal uses, transportation, and all activities of an urban society. The major global water reservoir of seas and oceans provides a source of pure water in the atmosphere through evaporation. Through desalination, the atmosphere provides water for domestic use. On the other hand, salinity transport into groundwater might take place due to sea water intrusion into phreatic and confined aquifers, which is not a rare phenomenon, and may be enhanced in locations of excessive groundwater pumping. Phreatic and confined aquifers comprise the major terrestrial water storage of the environment. This storage is connected with the surface water and supplies water to society (domestic, agricultural, and industrial needs). All water consumers discharge water with higher solute concentrations than they originally obtained. Some consumers produce wastewater that should be transferred into liquid-waste collection sites, treated, and then delivered to seas, surface water storage, or agricultural and industrial uses. Some water used by consumers may directly enter the vadose zone, e.g., agricultural irrigation waters. This water may be subject to evapotranspiration (and thereby solutes of this water are accumulated in vegetation and the vadose zone) and/or infiltration through the vadose zone into the phreatic aquifer. (*See* **Evapotranspiration**.) Such infiltration is associated with the accumulation of some additional quantities of solutes. The phreatic aquifer may supply water with contaminants into the vadose zone by capillary movement, induced by water consumption of trees. Volatile contaminants dissolved in groundwater may be transferred as vapors into the vadose zone gaseous phase. The transfer of pollutant between the phreatic aquifer and the vadose zone is greatly enhanced by temporal, seasonal, and annual fluctuations of the groundwater table elevation.

Various industries apply techniques of deep well injection to get rid of their wastes. As an example, pumping of crude oil is associated with pumping of

brines. The latter, in many cases is directly injected into the deep bedrock. In parts of south Florida, practices of deep well injection were used for disposal of industrial wastes.

With regard to the two types of aquifers, the confined aquifer is subject to recharge in restricted areas and discharges water into the sea. Excessive groundwater pumping from the confined aquifer may lead to saltwater intrusion from the sea, as well as brine intrusion from the deep bedrock. The phreatic aquifer is intimately connected with the surface water and through the vadose zone it obtains infiltrating runoff water with solutes accumulated during the infiltration process. The vadose zone is the 'membrane' that separates the phreatic aquifer from the water consumers. The vadose zone changes the solute content (including a variety of solutes, pollutants, suspended and colloidal materials, microbes, parasites, etc.) of the infiltrating water owing to its different soil components, clay minerals, and residual water saturation. During the runoff water infiltration, solutes adsorbed to clay minerals may be released and transferred into the infiltrating water. On the other hand, suspended materials transported with the surface runoff usually cannot penetrate the vadose zone, and they do not arrive at the aquifer. In some cases, the infiltrating water quality may be improved by the adsorption of solutes by clay minerals. However, some of the positive phenomena of water-quality improvement are time-dependent, and therefore they should be carefully evaluated from a quantitative viewpoint.

It is appropriate to assume that every solute whose concentration in water is above its threshold concentration should be considered as a pollutant whose presence is involved in some risks to human health and the environment.

Any part of the environment involved in the water cycle and associated pollutant transport should be preserved in an appropriate risk-free mass budget and flux balance. Figure 2 indicates that special attention should be given to mass balances in the vadose zone and the phreatic aquifer due to the intimate relationships between these two types of strata.

Simplified Mass Budget and Flux Balances in Phreatic Aquifers

This section applies simplified mass budget and flux balance calculations to a variety of environmental development stages typical of different global locations. Figure 3 refers to four different scenarios or stages relevant to groundwater contamination within phreatic aquifers. The first stage, which is not emphasized by Figure 3, considers the natural environment

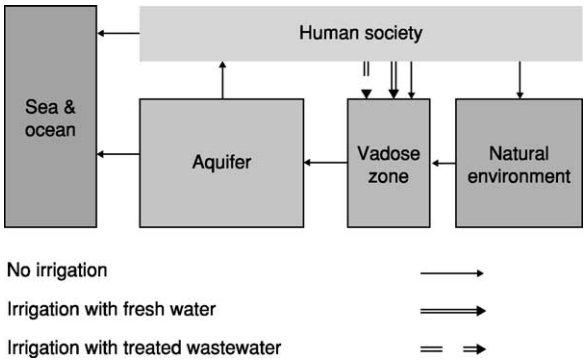

Figure 3 Different stages (scenarios) of pollutant flux development.

with very few effects from society. The second stage refers to involvement of human society with no (or very limited) irrigation practices. The third stage is associated with freshwater irrigation; and the fourth stage is associated with all types of irrigation by fresh water and treated wastewater. The calculations refer to a single contaminant, which is considered as the limiting pollutant of the environment; but similar calculations can be done with regard to any relevant pollutant.

Figure 4 describes the involvement of water and pollutant fluxes with the simplified water cycle. The following types of water fluxes and their relevance to pollutant transport are described by Figure 4:

1. Q_{nr} is the natural recharge of the phreatic aquifer, namely the net recharge (precipitation minus evapotranspiration). Even in the natural environment, the recharging flow rate accumulates some contaminants, ΔC_0 aboveground and ΔC_1 during its infiltration through the vadose zone;
2. Q_{so} is the groundwater flow rate that is emitted into seas and oceans;
3. Q_{hs} is the flow rate consumed by society. Society always supplies some contaminants into the natural recharge and increases its pollutant concentration by ΔC_1. Human society also increases the pollutant concentration by the amount ΔC_4 before delivering the water into seas and oceans;
4. Q_{ir} represents the irrigation flow rate. It is assumed that people apply groundwater for irrigation purposes. The irrigation flow rate comprises a certain portion of Q_{hs}. However, irrigation is associated with evaporation flow rate, Q_{ev1}. Evaporation decreases the flux of irrigation water that infiltrates into the aquifer. However, it is assumed that all pollutants present with Q_{ir} arrive at the phreatic aquifer. Furthermore, the reduced infiltrating discharge ($Q_{ir} - Q_{ev1}$) accumulates additional pollutant concentration ΔC_1 during its infiltration through the vadose zone;

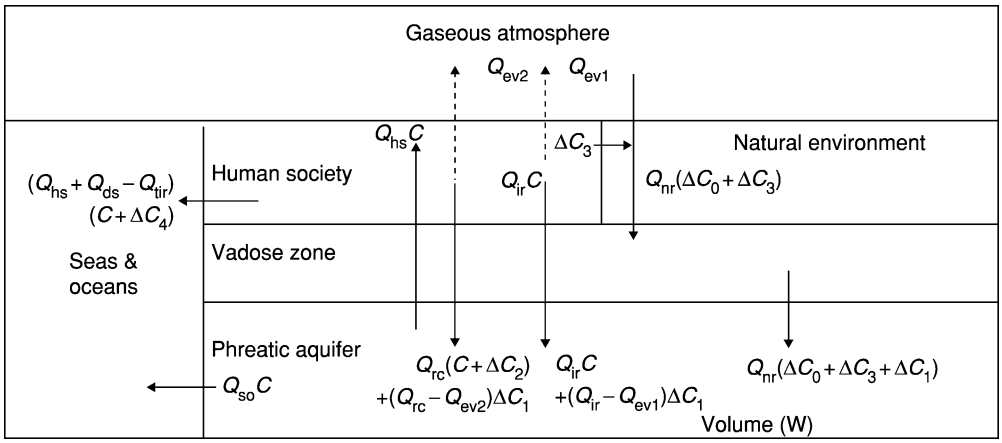

Figure 4 Considered fluxes of water and pollutants in various scenarios.

5. Q_{rc} is the flow rate of recycled wastewater. Wastewater-recycling decreases the discharge from populations that is delivered into seas and oceans. It is assumed that all recycled wastewater is used for irrigation. Probably the pollutant concentration within this type of water is greater by ΔC_2 than pollutant concentration in groundwater. However, again this type of irrigation is associated with evaporation flow rate, Q_{ev2}. Again considerations should be made with regard to the additional pollutant mass flux originating from experiencing wastewater-recycling.

We assume that measures are taken to keep the aquifer total volume W unchanged, and we also assume that initially the pollutant concentration is C_0. Then all pollutant mass budget and flux balance calculations for the different stages, described by Figures 3 and 4, indicate that the pollutant concentration increases exponentially as:

$$C = C_\infty - \Delta C\left[1 - \exp\left(-\frac{Q_{nr} - Q_{ev}}{W}t\right)\right] \qquad [1]$$

where

$$\Delta C = C_\infty - C_0$$

The values of C_∞ and ΔC are given in Table 1, Q_{ev} is the total rate of evaporation. Therefore the time required to obtain steady state conditions, namely when C is smaller than C_∞ by one percent of ΔC is:

$$(t)_{C=C_\infty-0.01\Delta C} = \frac{4.61(Q_{nr} - Q_{ev})}{W} \qquad [2]$$

Table 1 summarizes the results of water flux balance calculations and pollutant mass budget and flux balance calculations. In Table 1, expressions of the two bottom cells of the fourth column have been obtained by assuming that evapotranspiration associated with irrigation is significantly smaller than the natural recharge of the aquifer. Otherwise, these expressions should be replaced by simple deduction of relevant expressions of the third column. However, it should be noted that only the last term of the bottom cell expression in the fourth column represents the real contribution of wastewater recycling to pollutant concentration in the groundwater, provided that irrigation with treated wastewater replaces irrigation with water pumped from the aquifer. Q_{tir} and Q_{ev} in Table 1 are values of total irrigation $(Q_{ir}+Q_{rc})$ and total evaporation $(Q_{ev1}+Q_{ev2})$ respectively.

Table 1 can be useful for initial evaluation of long-term implementation of water resources management practices. This table indicates that irrigation, even with water of drinking quality, increases the pollutant concentration in the aquifer. On the other hand, though the marginal increase in aquifer pollution by wastewater-recycling is greater than irrigation with drinking water, this effect is mitigated if wastewater-recycling is implemented as a substitute for irrigation with drinking water.

Study of Figure 4 and Table 1 may lead to some useful ideas about the preservation of groundwater quality in phreatic aquifers. First of all, such an objective should be achieved by adequate considerations based on the control of all pollutant inputs, which should be minimized, and pollutant outputs, which should be maximized. Figure 4 and the results of calculations in Table 1 indicate that irrigation of all types poses a major threat to groundwater quality, as it circulates pollutants between the groundwater and the human population. Of course, advanced treatment of wastewater to drinking-water quality is appropriate, as it reduces the pollutant input, but such an approach does not necessarily provide sufficient guarantee against the accumulation

Table 1 Water and pollutant mass budget and flux balance results for typical cases of aquifer exploitation scenarios

Stage (scenario)	*Water balance*	*Pollutant concentration at $t\to\infty$*	*Increase of C_∞ (value of ΔC)*
Natural environment	$Q_{so} - Q_{nr} = 0$	$C_\infty = \Delta C_0 + \Delta C_1$	0
No irrigation	$Q_{so} + Q_{hs} - Q_{nr} = 0$	$C_\infty = \Delta C_0 + \Delta C_3 + \Delta C_1$	ΔC_3
Freshwater irrigation	$Q_{so} + Q_{hs} + Q_{ev1} - Q_{nr} - Q_{ir} = 0$	$C_\infty = \dfrac{Q_{nr}(\Delta C_0 + \Delta C_3 + \Delta C_1) + (Q_{ir} - Q_{ev1})\Delta C_1}{Q_{nr} - Q_{ev1}}$	$\dfrac{Q_{ev1}}{Q_{nr}}(\Delta C_0 + \Delta C_3 + \Delta C_1) + \dfrac{Q_{ir} - Q_{ev1}}{Q_{nr} - Q_{ev1}}\Delta C_1$
All types of irrigation	$Q_{so} + Q_{hs} + Q_{ev1} + Q_{ev2} - Q_{nr} - Q_{ir} - Q_{rc} = 0$	$C_\infty = \dfrac{Q_{nr}(\Delta C_0 + \Delta C_3 + \Delta C_1) + (Q_{tir} - Q_{ev})\Delta C_1 + \Delta C_1 + Q_{rc}\Delta C_2}{Q_{nr} - Q_{ev}}$	$\dfrac{Q_{ev2}}{Q_{nr}}(\Delta C_0 + \Delta C_3 + \Delta C_1) + \dfrac{Q_{ev2}}{Q_{nr}}\left(\dfrac{Q_{ir} - Q_{ev1}}{Q_{nr}}\right)\Delta C_1 + \dfrac{Q_{rc} - Q_{ev2}}{Q_{nr} - Q_{ev}}\Delta C_1 + \dfrac{Q_{rc}\Delta C_2}{Q_{nr} - Q_{ev}}$

of high pollutant concentrations in the phreatic aquifers.

As stated, Figure 4 refers to a single pollutant. In an aquifer system subject to a variety of pollutants, whose presence introduces risks to human health and the environment, similar mass budget and flux balance calculations should be made with regard to each one of these pollutants for the evaluation of long-term processes involved with groundwater quality.

Penetration of Solutes into the Phreatic Aquifer

Figure 5 provides a classic description of the distribution of water saturation in the phreatic aquifer and the vadoze zone. This figure does not include the water saturation distribution close to the ground surface, which is subject to significant changes due to precipitation, irrigation, dry seasons, etc.
