We call $t_n^i = (\rho(E)y^i(x_n) - h\sigma(E)y^{i(p+1)}(x_n))/\sigma(1)$ the **local truncation error**. For a consistent and stable method determined by (ρ, σ) there exist a real constant $C_{p+1} (\neq 0)$ and an integer $p (\geq 1)$ such that $t_n^i = h^{p+1} C_{p+1} y^{i(p+1)}(x_n)/\sigma(1) + O(h^{p+2})$; p is called the **order** of the method and $C \equiv C_{p+1}/\sigma(1)$ the **error constant**. For a given ρ satisfying (ii), σ is chosen to make the order as small as possible and then to make the error constant as small as possible. However, p cannot exceed $k+1$ if k is odd or $k+2$ if k is even; moreover, p can be equal to $k+2$ only if all the roots of $\rho(\zeta) = 0$ lie on the unit circle.

The following are examples of multistep methods.

(1) Explicit Methods.

(a) Adams-Bashforth methods.

$$k=1, \quad \rho(\zeta) = \zeta - 1, \quad \sigma(\zeta) = 1, \quad p=1,$$

$$C = 1/2 \quad (\text{Euler method});$$

$$k=2, \quad \rho(\zeta) = \zeta(\zeta - 1), \quad \sigma(\zeta) = (3\zeta - 1)/2,$$

$$p=2, \quad C = 5/12;$$

$$k=3, \quad \rho(\zeta) = \zeta^2(\zeta - 1),$$

$$\sigma(\zeta) = (23\zeta^2 - 16\zeta + 5)/12, \quad p=3,$$

$$C = 3/8;$$

etc.

(b) Midpoint rule.

$$k=2, \quad \rho(\zeta) = \zeta^2 - 1, \quad \sigma(\zeta) = 2\zeta,$$

$$p=2, \quad C = 1/6.$$

(c) Milne's predictor.

$$k=4, \quad \rho(\zeta) = \zeta^4 - 1,$$

$$\sigma(\zeta) = (8\zeta^3 - 4\zeta^2 + 8\zeta)/3,$$

$$p=4, \quad C = 7/90.$$

(2) Implicit Methods.

(a) Adams-Moulton methods.

$$k=1, \quad \rho(\zeta) = \zeta - 1, \quad \sigma(\zeta) = (\zeta + 1)/2,$$

$$p=2, \quad C = -1/12 \quad (\text{trapezoidal rule});$$

$$k=2, \quad \rho(\zeta) = \zeta(\zeta - 1),$$

$$\sigma(\zeta) = (5\zeta^2 + 8\zeta - 1)/12,$$

$$p=3, \quad C = -1/24;$$

etc.

(b) Milne's corrector (or the Milne-Simpson formula).

$$k=2, \quad \rho(\zeta) = \zeta^2 - 1, \quad \sigma(\zeta) = (\zeta^2 + 4\zeta + 1)/3,$$

$$p=4, \quad C = -1/90.$$

When an implicit formula (ρ, σ) is used to obtain y_{n+k}^i , the 0th approximation y_{n+k}^{i*} for y_{n+k}^i is usually determined by an explicit formula (ρ^*, σ^*) of the same order as (ρ, σ) (where (ρ^*, σ^*) itself may not necessarily be stable). This kind of combination of implicit and explicit methods is called a **predictor-corrector method** (or **PC method**), where the formula (ρ^*, σ^*) is called the **predictor** and (ρ, σ) the **corrector**. Typical combinations are the midpoint rule and the trapezoidal rule, Milne's predictor and Milne's corrector (this combination is called **Milne's method**), and an Adams-Bashforth method and an Adams-Moulton method of the same order. A predictor-corrector method has the advantage that the local truncation error (of the corrector) can be estimated in the course of calculation without extra computation. In fact, if the orders of the predictor (ρ^*, σ^*) and the corrector (ρ, σ) are equal to p and their error constants to C^* and C , respectively, then the local truncation error t_n^i can be estimated by $t_n^i = KD_n^i + O(h^{p+2})$ ($n = 0, 1, \dots$), where $D_n^i \equiv y_{n+k}^{i*} - y_{n+k}^i$ is the difference between the value y_{n+k}^{i*} at x_{n+k} obtained by the predictor and the y_{n+k}^i obtained by the corrector, and $K = \alpha_k^* C / [(C - C^*)\sigma^*(1)]$ [16].

The term **multistep methods** originates from the fact that these use the values of the dependent variables at more than two different mesh points in order to proceed one step. These are also called **multivalued methods** since they use more than one value of the dependent variable. The multivalued method is, however, a more general concept than the multistep method.

Linear multistep methods are not only examples of the PC method; they are also examples of the **variable-step variable-order algorithms (VSVO algorithms)**, where the order of the formula as well as the step size are automatically chosen according to the behavior of the solution. In practical VSVO algorithms, the Adams-Bashforth-Moulton family of PC pairs of order 1 to 13 are usually used, and for solving stiff systems (\rightarrow Section G) those correctors with large regions of absolute stability are used. In these algorithms we use the multivalued method, which saves the information at different steps in a form convenient for the change of order and of step size. The multivalued method also facilitates error estimation and stability, and results in an efficient use of memory and reduction of the computational cost. For example, in Gear's algorithm the information required for computing y_{n+1} is saved in the following form: $\mathbf{y}_n = (y_n, hy_n', \dots, (h^k/k!)y_n^{(k)})$, where $y'(x)$ is the polynomial $P_{k,n}(x)$ interpolating $f_n, f_{n-1}, \dots, f_{n-k+1}$, where $y_n^{(0)} = d^{i-1}P_{k,n}(x)/dx^{i-1}|_{x=x_n}$ hold. All the local truncation error estimators are based essentially

on Milne's device. In the VSVO algorithms heuristics play an important role [2, 17, 18].

F. Extrapolation Methods

Let us assume that the numerical solution with the step size h at some fixed point x has the form

$$y(x, h) = y(x) + \sum_{i=1}^m \tau_i h^r + O(h^{r(m+1)}),$$

where r is a positive integer. Then we can approximate $y(x, h)$ by a function $R_m(x, h)$ with $(m + 1)$ unknowns determined by the requirement that $R_m(x, h_j) = y(x, h_j)$, $j = 0, 1, 2, \dots, m$, $h_i > h_j$ ($i < j$) in order to approximate $y(x)$ by $R_m(x, 0)$. If $R_m(x, h)$ is a polynomial of degree mr in h , we call the foregoing method a **polynomial extrapolation method**, where $R_m(x, h) = y(x) + o(h^{r(m+1)})$ as h tends to 0. Defining $R_0^i = y(x, h_j)$ and $R_m(x, 0) = R_m^i$ for $j = i, i + 1, \dots, i + m$, we can calculate the R_m^i by the recursion relation $R_m^i = R_{m-1}^{i+1} + (R_m^{i+1} - R_{m-1}^i) / ((h_i/h_{i+m})^r - 1)$, $m \geq 1$. It is well known that, for the following method (Gragg's method), there exists an asymptotic expansion with $r = 2$ [19]: $x_n = nh$, $\eta(0, h) = y(0)$, $\eta(x_1, h) = y_0 + hf(y_0, 0)$, $\eta(x_{n+1}, h) = \eta(x_{n-1}, h) + 2hf(\eta(x_n, h), x_n)$, $n = 1, 2, \dots, N - 1$, where $x_N = x$, $y(x, h) = 1/2[\eta(x_{N-1}, h) + \eta(x_N, h) + hf(\eta(x_N, h), x_N)]$. If $R_m(x, h)$ is a rational function

$$R_m(x, h_j) = (p_0 + p_1 h + p_2 h^2 + \dots + p_v h^v) / (q_0 + q_1 h + q_2 h^2 + \dots + q_v h^v),$$

where $\mu = [m/2]$, $v = m - \mu = [(m + 1)/2]$, $j = i, i + 1, \dots, i + m$, we call this method a **rational extrapolation method**. For $r = 2$, the following formulas were derived by Bulirsch and Stoer [20]:

$$R_m^i = R_{m-1}^{i+1} + (R_{m-1}^{i+1} - R_{m-1}^i) / ((h_i/h_{i+m})^2 \times [1 - (R_{m-1}^{i+1} - R_{m-1}^i) / (R_{m-1}^{i+1} - R_{m-2}^i)] - 1),$$

$$m \geq 1, R_{-1}^i = 0, R_0^i = y(t, h_i).$$

G. Stability

Consider the application of the general k -step method at the n th point (which is consistent and 0-stable)

$$\sum_{j=0}^k \alpha_j y_{n+j} = h \sum_{j=0}^k \beta_j f_{n+j}$$

to $y' = f(x, y)$, $y(x_0) = y_0$. Let \tilde{y}_n be the numerical solution at $x = x_n$. Let $\tilde{e}_n = y(x_n) - \tilde{y}_n$ be the global error, and let φ_n be the total error at the n th application. Then we find

$$\sum_{j=0}^k \alpha_j \tilde{e}_{n+j} = h \sum_{j=0}^k \frac{\partial f}{\partial y}(x_{n+j}, \zeta_{n+j}) \beta_j \tilde{e}_{n+j} + \varphi_{n+k},$$

where ξ_{n+j} lies in the open interval whose endpoints are y_{n+j} and $y(x_{n+j})$. If we make two assumptions, $\partial f/\partial y = \lambda$ (const), $\varphi_n = \varphi$ (const), the above equation reduces to $\sum_{j=0}^k (\alpha_j - h\lambda\beta_j)\tilde{e}_{n+j} = \varphi$, whose general solution is given by

$$\tilde{e}_n = \sum_{s=0}^k d_s r_s^n - \varphi/h\lambda \sum_{j=0}^k \beta_j,$$

where the d_s are arbitrary constants and the r_s are the roots, assumed distinct, of the polynomial equation

$$\sum_{j=0}^k (\alpha_j - h\lambda\beta_j)r^j = 0.$$

We call the linear k -step method **absolutely stable** for a given $h\lambda$ if $|r_s| < 1$, $s = 1, 2, \dots, k$. On the other hand, we call the linear k -step method **relatively stable** for a given $h\lambda$ if $|r_s| < |r_1|$ (or $|r_s| < e^{\lambda h}$), $s = 2, 3, \dots, k$, where r_1 is the root corresponding to the theoretical solution. We call the region $S_a = \{h\lambda \mid |r_s| < 1, s = 1, 2, \dots, k\}$ (or $S_r = \{h\lambda \mid |r_s| < e^{\lambda h}$ (or $|r_1|$), $s = 2, 3, \dots, k\}$) in the complex plane the **region of absolute stability** (or the **region of relative stability**) of the linear k -step method. Also we call $S_a \cap R$ (or $S_r \cap R$) the **interval of absolute stability** (or the **interval of relative stability**) of the linear multistep method, where R is the real line. The explicit methods and the PC methods have a finite interval of absolute stability. The implicit methods usually have larger intervals of absolute stability than the corresponding explicit methods. The higher-order PC methods have smaller intervals, while Runge-Kutta methods do not. The PECE methods usually have larger intervals of stability than the corresponding PEC or P(EC)² methods, where P indicates an application of predictor, C an application of corrector, and E an evaluation of f [21, 22].

Let us consider the linear system $y' = Ay + \varphi(x)$, where A is an $m \times m$ constant matrix and $y(x)$, $y'(x)$, $\varphi(x) \in \mathbf{R}^m$. If A possesses m distinct eigenvalues $\lambda_t = \mu_t + iv_t$, $t = 1, 2, \dots, m$, the theoretical solution of this system is given by

$$y(x) = \sum_{t=1}^m K_t \exp((\mu_t + iv_t)x) C_t + \psi(x),$$

where K_t and C_t , $t = 1, 2, \dots, m$, are, respectively, arbitrary constants and the eigenvectors corresponding to λ_t and $\psi(x)$ is a particular solution. We call the linear system **stiff** if (i) $\mu_t < 0$, $t = 1, 2, \dots, m$, (ii) $s \gg 1$, where $s = \max_{1 \leq t \leq m} |\mu_t| / \min_{1 \leq t \leq m} |\mu_t|$. We call the nonlinear system $y' = f(x, y)$, $y(x)$, $y''(x)$, $f(x, y) \in \mathbf{R}^m$ **stiff in an interval I of x** if, for every $x \in I$, the eigenvalues $\lambda_t(x)$ of the Jacobian matrix of f satisfy (i) and (ii). The ratio s is called the **stiffness ratio**. To solve stiff systems effectively a variety of methods with infinite stability

regions have been proposed. Some of them are:

- (1) **A-stability** (Dahlquist): $S_a \supseteq \{h\lambda \mid \text{Re}(h\lambda) < 0\}$
- (2) **Stiff-stability** (Gear): $S_a \supseteq S_1 \cup S_2$, $S_1 = \{h\lambda \mid \text{Re}(h\lambda) < -a < 0\}$, $S_2 = \{h\lambda \mid -a \leq \text{Re}(h\lambda) \leq b, -c \leq \text{Im}(h\lambda) \leq c, b \geq 0, c > 0\}$
- (3) **A(α)-stability** (Widlund): $S_a \supseteq \{h\lambda \mid -\alpha < \pi - \arg(h\lambda) < \alpha, \alpha \in (0, \pi/2)\}$
- (4) **A₀-stability** (Cryer): $S_a \supseteq \{h\lambda \mid \text{Re}(h\lambda) < 0, \text{Im}(h\lambda) = 0\}$.

The order p and the step number k of linear multistep methods are restricted by the following stability requirements:

- (i) **A-stability**: implicit, $p \leq 2$; trapezoidal rule is the most accurate method.
- (ii) **Stiff-stability**: implicit, $p \leq k$; backward differentiation formulas $\sum_{j=0}^k \alpha_j y_{n+j} = h f_{n+k}$ are stiffly stable for $p = k = 1, 2, \dots, 6$, 0-unstable for $k = 6$.
- (iii) **A(α)-stability**: implicit; there exist high-order **A(0)-stable** linear multistep methods. (A method is said to be **A(0)-stable** if it is **A(α)-stable** for some sufficiently small $\alpha \in (0, \pi/2)$.)

For the Runge-Kutta (P, p) methods, we can write

$$\tilde{e}_{n+1} = \left\{ 1 + h\lambda + (h\lambda)^2/2! + \dots + (h\lambda)^p/p! + \sum_{q=p+1}^{P+1} \gamma_q (h\lambda)^q \right\} \tilde{e}_n + \varphi_{n+1},$$

where $\partial f/\partial y = \lambda$ (const) and γ_q are functions of the coefficients of the method in use. We call a region $R = \{h\lambda \mid |1 + h\lambda + (h\lambda)^2/2! + \dots + (h\lambda)^p/p! + \sum_{q=p+1}^{P+1} \gamma_q (h\lambda)^q| < 1\}$ a **region of absolute stability of the Runge-Kutta (P, p) method**.

The implicit Runge-Kutta methods have a larger region of absolute stability than the corresponding explicit Runge-Kutta methods. Therefore the implicit Runge-Kutta methods are suitable for stiff equations, and the explicit Runge-Kutta methods are suitable for nonstiff or mildly stiff equations.

Recently, Yamaguti and others have pointed out that the instabilities occurring in the numerical solution of ordinary differential equations are closely connected to the phenomena of **chaos** studied by Li, Yorke, and others [23, 24].

H. Boundary Value Problems

A boundary value problem is generally formulated as the problem of obtaining functions $y^i(x)$ that satisfy the differential equations $y^i(x) = f^i(x, y^1(x), \dots, y^m(x))$ and boundary conditions $B_k(y^1(x_{n_1}), \dots, y^m(x_{n_1}); y^1(x_{n_2}), \dots, y^m(x_{n_2}); \dots; y^1(x_{n_m}), \dots, y^m(x_{n_m})) = 0$ ($i, k = 1, \dots, m$), where the f^i and B_k are given functions. If the f^i and B_k are linear in the y^i , we can

first calculate the solutions $y_0^i(x)$ of the differential equations under an appropriate initial condition, as well as a set of m independent solutions $y_j^i(x)$ ($l = 1, \dots, m$) of the homogeneous differential equations (say, under the initial conditions $y_j^i(a) = \delta_j^i$ at some point $x = a$), and then substitute the expression for the desired solution $y^i(x) = y_0^i(x) + \sum_{j=1}^m \alpha_j y_j^i(x)$ in the boundary conditions to obtain simultaneous linear equations for the unknowns α_l (\rightarrow 302 Numerical Solution of Linear Equations). No universally powerful method is known for the case where the f^i or the B_k or both are nonlinear. Ordinarily, we resort to the trial-and-error method of solving the differential equations iteratively under different initial conditions until the solution fully satisfies the boundary conditions, or to approximating the differential operators by suitable difference operators to obtain a set of (generally nonlinear) simultaneous equations approximating at the same time the differential equations and the boundary conditions. For related topics \rightarrow 298 Numerical Computation of Eigenvalues; 315 Ordinary Differential Equations (Boundary Value Problems); [25–27].

I. Methods Other than Difference Methods

Besides difference methods there are frequently used methods for finding in a given finite-dimensional function space a function that best satisfies the differential equations as well as the initial or boundary conditions. Denote the equations by $L[y(x)] = 0$ and assume the conditions to be linear. We choose a function $y_0(x)$ that satisfies the conditions and that is considered to approximate the exact solution, and also functions $y_l(x)$ ($l = 1, \dots, q$) that are considered to represent the typical deviations of $y_0(x)$ from the exact solution and each of which satisfies the homogeneous conditions. We then determine the α_l in such a way that $y(x) = y_0(x) + \sum_{l=1}^q \alpha_l y_l(x)$ best satisfies the differential equations. Corresponding to different interpretations of the words “best satisfy” there are different methods. The **collocation method** determines the α_l so as to nullify the values of $L[y(x)]$ at some prescribed points x_i ; the **method of least squares** minimizes the integral of $[L[y(x)]]^2$ over the considered region; the **Galerkin method** makes $L[y(x)]$ orthogonal to every $y_l(x)$ ($l = 1, \dots, q$); and the **Ritz method** considers the variational problem $\delta J[y(x)] = 0$ whose Euler equation is $L[y(x)] = 0$ (\rightarrow 46 Calculus of Variations F), if such a problem exists, and determines the α_l so as to have $J[y(x)]$ take an extremum value with $y(x) = y_0(x) + \sum_{l=1}^q \alpha_l y_l(x)$.

304 (XV.9) Numerical Solution of Partial Differential Equations

A. General Remarks

The numerical solution of partial differential equations became practical in the 1950s with the advent of automatic digital computers. Nowadays, by means of modern high-performance computers, the numerical solution of partial differential equations is carried out extensively and often on a very large scale for problems in physics, engineering, and other fields of applied analysis, in order to obtain approximate solutions of rigorous equations or to simulate real phenomena by means of numerical experiments. Various numerical-solution schemes have been proposed, applied, and studied, and programming techniques required to implement numerical solutions are being invented regularly; some are of a general nature, and others are devised for particular problems. The variational method, which includes the Ritz-Galerkin method and the finite element method, and

the difference method deserve special mention here because of their generality and scope of application.

B. The Ritz-Galerkin Method

Having been applied mainly to boundary value problems for elliptic partial differential equations, the **Ritz method** is a classical method, which has been used since the old era of mechanical calculators, and is mathematically nothing other than the †direct method in the calculus of variations (→ 46 Calculus of Variations F) applied to †variational problems that are equivalent to the original boundary value problems. In order to exemplify the method, let Ω be a bounded domain in \mathbf{R}^N with piecewise smooth boundary S , and consider the Dirichlet boundary value problem comprised of the Poisson equation

$$\Delta u = -f \quad (1)$$

and the boundary condition

$$u|_S = \beta. \quad (2)$$

Here f and β are given functions on Ω and S , respectively. (In the following, given functions are assumed to be sufficiently smooth.) The boundary value problem (1), (2) is equivalent to the variational problem of minimizing the †functional

$$J[u] = \frac{1}{2}a(u, u) - (u, f) \quad (3)$$

within the set $D(J)$ of **admissible functions** u subject to (2). In (3) the following notation is used:

$$a(u, v) = (\nabla u, \nabla v)_{L_2(\Omega)} = \int_{\Omega} \nabla u \cdot \nabla v \, dx$$

and

$$(u, v) = (u, v)_{L_2(\Omega)} = \int_{\Omega} uv \, dx,$$

while

$$D(J) = \{u \in L_2(\Omega) \mid \nabla u \in L_2(\Omega), \quad u|_S = \beta\}.$$

This variational problem is further reduced to the condition:

$$u \in D(J), \quad a(u, \varphi) = (f, \varphi) \quad (\forall \varphi \in V), \quad (4)$$

where V stands for the †Sobolev space $H_0^1(\Omega)$ (→ 168 Function Spaces B), that is,

$$V = H_0^1(\Omega) = \{u \in L_2(\Omega) \mid \nabla u \in L_2(\Omega), \quad u|_S = 0\}.$$

Note that V is equal to $D(J)$ with $\beta \equiv 0$. The condition (4) is often called a **weak form of the boundary value problem**. In applying the Ritz

method to this problem, we introduce unknown parameters $\alpha_1, \alpha_2, \dots, \alpha_n$ and set the approximate solution u_n in the form

$$u_n = F(x; \alpha_1, \alpha_2, \dots, \alpha_n) \in D(J)$$

and minimize $J[u_n]$ as a function of the n variables $\alpha_1, \alpha_2, \dots, \alpha_n$. A standard way to form u_n is to choose first a $b \in D(J)$ subject to the inhomogeneous boundary condition and $\varphi_1, \varphi_2, \dots, \varphi_n \in V$ subject to homogeneous boundary condition, and then to set

$$u_n = b + \alpha_1 \varphi_1 + \alpha_2 \varphi_2 + \dots + \alpha_n \varphi_n. \quad (5)$$

The functions φ_j ($j = 1, 2, \dots, n$) are called **basis functions** or **coordinate functions** in the Ritz method. Denoting by D_n the set of all possible functions appearing on the right-hand side of (5) and by V_n the linear space generated by $\varphi_1, \varphi_2, \dots, \varphi_n$, we can state the condition to determine the approximate solution u_n as:

$$u_n \in D_n$$

$$a(u_n, \varphi) = (f, \varphi) \quad (\forall \varphi \in V_n). \quad (6)$$

Thus the Ritz method is a kind of **projective approximation method** which approximates the weak equation (4) by its projection on a finite-dimensional space V_n . The condition (6) is equivalent to the equations

$$a(u_n, \varphi_j) = (f, \varphi_j) \quad (j = 1, 2, \dots, n). \quad (7)$$

Particularly when $\beta \equiv 0$ in (2), D_n coincides with V_n , and the equations (7) that determine the coefficients α_j are reduced to a linear equation

$$K\alpha = \gamma \quad (8)$$

for $\alpha = (\alpha_1, \alpha_2, \dots, \alpha_n)$, where the matrix $K = (K_{ij})$ and the vector $\gamma = (\gamma_1, \gamma_2, \dots, \gamma_n)$ are given respectively by $K_{ij} = a(\varphi_i, \varphi_j)$ and $\gamma_j = (f, \varphi_j)$. Solving (8) numerically by the †Gauss elimination method or by †iteration, one eventually obtains the approximate solution u_n by the Ritz method. The Ritz method is also applicable, for instance, to the eigenvalue problem $\Delta u = \lambda u, u|_s = 0$, since this eigenvalue problem is equivalent to the variational problem of finding a stationary **Rayleigh's quotient** $R[u] = a(u, u)/(u, u)$ with V as the set of admissible functions. In the approximation to restrict the admissible functions to V_n , the approximate eigenvalue $\lambda^{(n)}$ is determined through the matrix eigenvalue problem

$$K\alpha = \lambda^{(n)} M\alpha, \quad (9)$$

where the matrix K is as above and the matrix $M = (M_{ij})$ is given by $M_{ij} = (\varphi_i, \varphi_j)$. Sometimes, optimization of $J[u_n]$ or $R[u_n]$ is carried out more directly, e.g., by the †gradient method, particularly when u_n contains free parameters α_j in some nonlinear way.

Many studies have been made of convergence and error estimation for the Ritz method in general (\rightarrow e.g., [1–4]). For instance, it is known that, if $\beta = 0, f \in L^2(\Omega)$, and $\{\varphi_1, \varphi_2, \dots, \varphi_n, \dots\}$ spans a linear subspace dense in $V = H_0^1(\Omega)$, then the approximate solution u_n obtained through (6) (or through (12) below) converges to the rigorous solution in the H^1 -topology (and hence in the L^2 -topology). Nevertheless, success in using the method in practical applications can be gained only by a clever choice of trial functions. A typical but systematic example of such a choice is made by the finite element method (\rightarrow Section C).

We proceed to the **Galerkin method** [1]. Suppose that we are to solve the equation

$$L[u] = \Delta u + (b \cdot \nabla)u = -f, \quad (10)$$

which is the equation in (1) perturbed by a lower-order term (the convection term). Here $b = (b_1(x), \dots, b_n(x))$ and $(b \cdot \nabla)u = \sum_j b_j(x)(\partial u / \partial x_j)$. For simplicity, the boundary condition (2) is assumed to be homogeneous (i.e., $\beta \equiv 0$). Although the boundary value problem (10), (2) cannot be reduced to a variational problem since (10) is not symmetric, it is equivalent to its weaker form

$$a(u, \varphi) - ((b \cdot \nabla)u, \varphi) = (f, \varphi) \quad (\forall \varphi \in V), \quad (11)$$

provided that $u \in V$. Note that (11) is obtained from $(L[u] + f, \varphi)_{L_2} = 0$ by transforming $(L[u], \varphi)$ through integration by parts. Actually, this boundary value problem has a unique solution u for any $f \in L_2(\Omega)$ if $|\operatorname{div} b|$ is sufficiently small. According to the Galerkin method as applied to the present problem, one replaces V by V_n in (11) and determines the approximate solution $u_n = \alpha_1 \varphi_1 + \dots + \alpha_n \varphi_n \in V_n$ by the condition

$$a(u_n, \varphi) - ((b \cdot \nabla)u_n, \varphi) = (f, \varphi) \quad (\forall \varphi \in V_n), \quad (12)$$

which is equivalent to the equations

$$a(u_n, \varphi_j) - ((b \cdot \nabla)u_n, \varphi_j) = (f, \varphi_j) \quad (j = 1, 2, \dots, n). \quad (13)$$

Sometimes it is convenient to project $(L[u] + f, \varphi) = 0$ onto the finite-dimensional space and to deal directly with $(L[u_n] + f, \varphi_j) = 0$ ($j = 1, 2, \dots, n$). When the coefficients of the equation and the given function f are periodic in space variables and when sine or cosine functions are chosen as basis functions, the Galerkin method turns out to be the same as the so-called Fourier approximation method and can be efficiently implemented with the aid of a †fast Fourier transform (FFT) to yield the required Fourier coefficients numerically [5].

The Galerkin method can be applied to the numerical solution of evolution equations, namely, in order to approximate time-

Numerical Solution of PDEs

dependent solutions. This is exemplified through the following initial-boundary value problem for the diffusion equation (heat equation):

$$\frac{\partial u}{\partial t} = \Delta u \quad (t \geq 0, x \in \Omega) \tag{14}$$

with the homogeneous boundary condition

$$u|_s = 0 \tag{15}$$

and the initial condition

$$u|_{t=0} = a(x) \quad (x \in \Omega). \tag{16}$$

We first set the required approximate solution $u_n = u_n(t, x)$ in terms of the basis functions $\varphi_1, \varphi_2, \dots, \varphi_n$ of V_n as

$$u_n = \alpha_1(t)\varphi_1 + \alpha_2(t)\varphi_2 + \dots + \alpha_n(t)\varphi_n, \tag{17}$$

and then determine the coefficients $\alpha_1(t), \alpha_2(t), \dots, \alpha_n(t)$ from the conditions

$$\frac{d}{dt}(u_n, \varphi) = -a(u_n, \varphi) \quad (t \geq 0, \forall \varphi \in V_n) \tag{18}$$

and

$$(u_n(0), \varphi) = (a, \varphi) \quad (\forall \varphi \in V_n). \tag{19}$$

Since (18) is equivalent to the equations

$$\frac{d}{dt}(u_n, \varphi_j) = -a(u_n, \varphi_j) \quad (j = 1, 2, \dots, n),$$

the vector function $\alpha(t) = (\alpha_1(t), \alpha_2(t), \dots, \alpha_n(t))$ is obtained by solving the ordinary differential equation

$$M \frac{d}{dt} \alpha = -K \alpha, \tag{20}$$

where the matrices M and K are those in (8) and (9). The initial value $\alpha(0)$ of α should be given in accordance with (19). Sometimes the procedure above is called a **semidiscrete approximation** based on the Galerkin method. Obviously, this method can be applied to more general evolution equations, for instance, to the **diffusion-convection equation**

$$\frac{\partial u}{\partial t} = L[u] = \Delta u + (b \cdot \nabla)u, \tag{21}$$

which governs time-dependent states corresponding to stationary states subject to (10). As a concrete example, we can refer to the finite element approximation for evolution equations described in Section D. If the geometry of Ω is simple enough, e.g., for 1-dimensional Ω , one can adopt eigenfunctions of $L[\]$ as the basis functions; the resulting version of the semidiscrete Galerkin method is called a **spectral method**.

In order to obtain $u_n(t)$ one has to carry out numerical integration for (20), discretizing the time variable. The Galerkin approxima-

tion with discretization of the space and time variables is called a **full discrete approximation**. Finally, an advantage of the Ritz-Galerkin method is that if the boundary condition imposed on rigorous solutions is a natural boundary condition, then the admissible functions and particularly the basis functions need not satisfy it [4].

C. Finite Element Methods for Boundary Value Problems

In recent years the method of numerical solution of partial differential equations most extensively employed in structural mechanics and many other fields of engineering has been the **finite element method**. In its standard form, the finite element method can be regarded, at least mathematically, as a type of Ritz-Galerkin method that adopts as its basis functions piecewise polynomials of low degree and with narrow supports. Although the idea leading to the finite element method can be traced back to a paper by R. Courant in 1943 (*Bull. Amer. Math. Soc.*), the method acquired its popularity in the late 1950s when it was rediscovered by engineers on the basis of mechanical considerations [6]. Here we apply the method to the boundary value problem (1), (2), assuming that $\beta = 0$ and Ω a polygonal domain in \mathbf{R}^2 [7-9]. First, $\bar{\Omega} = \Omega \cup S$ is divided into small triangles of which the length of any side does not exceed $h > 0$. Each triangle T appearing in this decomposition of $\bar{\Omega}$ is called a **triangular element**, or simply an **element** (following the terminology in structural mechanics), and we denote the set of all triangular elements by \mathcal{T}_h , h being equal to $\max_{T \in \mathcal{T}_h}$ {the longest side of T }. The set of all **nodal points**, i.e., the vertices of the triangular elements, is denoted by N , and we put

$$N_i = \{P \in N \mid P \in \Omega\} = \{P_1, P_2, \dots, P_n\}. \tag{22}$$

Then a standard choice of admissible functions is to adopt as V_n in (6) the following $V_h \subset C = H_0^1(\Omega)$:

$$V_h = \{v_h \in C(\bar{\Omega}) \mid v_h \text{ is linear on each element and } v_h|_s = 0\}, \tag{23}$$

namely, V_h is the set of all elementwise linear continuous functions satisfying the boundary condition. Now the approximate solution $u_h \in V_h$ is determined by the condition

$$a(u_h, \varphi_h) = (f, \varphi_h) \quad (\forall \varphi_h \in V_h). \tag{24}$$

A basis of V_h is formed by pyramidal functions φ_j ($j = 1, 2, \dots, n$) $\in V_h$ such that

$$\varphi_j(P_j) = 1 \quad \text{and} \quad \varphi_j(Q) = 0 \quad (Q \in N \setminus \{P_j\}). \tag{25}$$

In order to obtain u_h , one has to solve (8) numerically for α . Since the support of φ_j is confined to elements adjacent to P_j , the matrix K turns out to be a sparse matrix of **multi-diagonal type**, and hence particular elimination procedures can be applied with high efficiency. In the finite element method, the matrix K is often called the **stiffness matrix**. The convergence of u_h to u as $h \rightarrow 0$ is guaranteed if \mathcal{T}_h ($0 < h \leq h_0$) satisfies a certain regularity condition. For instance, if any angle of a triangle T is not smaller than $\theta_0 > 0$, then u_h converges in the $H^1(\Omega)$ -topology. Moreover, when Ω is convex, it holds that

$$\begin{aligned} \|u - u_h\|_{H^1} &\leq Ch \|f\|_{L_2}, \\ \|u - u_h\|_{L_2} &\leq Ch^2 \|f\|_{L_2} \end{aligned} \quad (26)$$

[7, 9]. Uniform convergence of u_h to u and L_∞ -estimation of the error have also been established (e.g., [7, chap. 3]). u_h is subject to the maximum principle, provided that the triangulation \mathcal{T}_h is of acute type. Here, \mathcal{T}_h is said to be of **acute type** (or of **strongly acute type**) if any angle θ of $T \in \mathcal{T}_h$ is in $0 < \theta \leq (\pi/2)$ ($0 < \theta \leq \theta_1 < (\pi/2)$). To acquire higher accuracy, more sophisticated admissible functions that are piecewise polynomials of higher degree are used. To take account of curved boundaries, several devices, including the **isoparametric method**, have been proposed.

In dealing with biharmonic equations or other equations of higher order, one can conveniently apply a modified version of the finite element method of **mixed type** or of **nonconforming type**; in the latter the approximate solution is sought within a class of functions which are of less regularity at the interface of elements and hence do not belong to the domain of the original variational problem. i.e., which are not admissible in the classical sense [10, 11].

D. Finite Element Methods for Initial Value Problems

The most basic type of finite element method applicable to evolution problems is described here, and concerns the initial boundary value problem (14)–(16), assuming that Ω is the same as in Section B [8, 9]. In the semidiscrete finite element approximation one uses the functions φ_j of the preceding section as the basis for the approximate solution, now denoted by u_h , and then determines u_h through (17)–(19) with V_n replaced by V_h . Then u_h converges to u as $h \rightarrow 0$, provided that the triangulation \mathcal{T}_h is regular. Furthermore, under the same condition that makes (26) hold, the error is given by the fol-

lowing estimate [12]:

$$\|u - u_h\|_{L_2} \leq Ch^2 \|a\|_{L_2} / t \quad (t > 0), \quad (27)$$

which reflects the smoothing property of the diffusion equation. In the terminology of the finite element method, the matrix M in (20) is called the **mass matrix**. In order to gain a fully discrete finite element approximation $u_{\tau,h}$ for u , one discretizes the time variable with the mesh length τ and solves the difference analog of (20), i.e., either

$$M(\alpha(t + \tau) - \alpha(t)) / \tau = -K\alpha(t) \quad (28)$$

or

$$M(\alpha(t + \tau) - \alpha(t)) / \tau = -K\alpha(t + \tau), \quad (29)$$

where t is restricted to $t = k\tau$ ($k = 0, 1, 2, \dots$).

The difference schemes (28) and (29) are of **forward type** and of **backward type**, respectively. From (29) follows $\|\alpha(k\tau)\| \leq \|\alpha(0)\|$, and consequently $\|u_{\tau,h}(t)\|_{L_2} \leq C\|a\|_{L_2}$. In the generally accepted terminology, the approximation is **stable** if for each $T > 0$ there exists a positive constant C_T depending on T such that

$$\|u_{\tau,h}(t)\| \leq C_T \|a\| \quad (0 \leq t = k\tau \leq T). \quad (30)$$

Thus the approximation through (29) is unconditionally stable, while the one through (28) is stable only under certain conditions on the triangulation \mathcal{T}_h and on the time mesh τ . For instance, the forward scheme (28) is stable if \mathcal{T}_h is regular and satisfies the **inverse assumption**

$$\sup_{0 < h \leq h_0} \max_{T \in \mathcal{T}_h} \frac{h}{(\text{longest side of } T)} < +\infty,$$

and if the ratio τ/h^2 is sufficiently small [13, 14].

Sometimes, the mass matrix M in (28) and (29) is modified by the following procedure, called **mass lumping**: For each P_j , one joins alternately the center of gravity of the elements with P_j as one of their vertices and the middle point of the sides with P_j as one of their endpoints, thus forming a closed broken line Γ_j surrounding P_j . We denote by $\bar{\varphi}_j$ the characteristic function of the polygonal domain B_j bounded by Γ_j . When mass lumping is applied, the matrix M is replaced by the matrix $\bar{M} = ((\bar{\varphi}_i, \bar{\varphi}_j))$. Generally, mass lumping relaxes the conditions for the stability and the maximum principle to hold, although it may lower the accuracy to some extent (H. Fujii, *Proc. US-Japan Seminar*, Univ. Tokyo Press, 1973). Usually, schemes without mass lumping are called **consistent mass schemes**.

In principle, there is no difficulty in applying the finite element method to the diffusion-convection equation (21). However, when $\|b\|$ is large, the stability condition becomes strin-

gent. To meet these difficulties, M. Tabata, T. Ikeda [15], and others have devised some schemes that enjoy better stability, the maximum principle, and even the law of conservation of mass by improving mass lumping and introducing the idea of an upstream approximation or an artificial viscosity for discretizing the convection term. Moreover, finite element methods are currently being applied to wave equations, the Navier-Stokes equations, and various other evolution equations.

E. Difference Methods for Boundary Value Problems

In difference methods for solving partial differential equations we reduce the original equation to its **difference analog**, replacing differential quotients of the unknown function by the corresponding difference quotients. The difference analog, usually a system of algebraic equations, is then solved numerically, yielding the desired approximate solution. Since the last part of the method, i.e., the numerical solution of the difference analog, requires a large amount of computation, difference methods were not feasible until the development of automatic computers.

In terms of the variable x , difference approximations for the derivative df/dx are the **forward difference**

$$(D_x^h f)(x) = (f(x+h) - f(x))/h,$$

the **backward difference**

$$(D_x^h f)(x) = (f(x) - f(x-h))/h,$$

and the **central difference (symmetric difference)**

$$(\delta_x^h f)(x) = (f(x+h) - f(x-h))/2h.$$

In order to exemplify the difference method applied to boundary value problems, we return to equations (1) and (2), supposing that Ω is a 2-dimensional square $Q = \{(x, y) | 0 < x < 1, 0 < y < 1\}$ [1, 16-18]. Then we cover $Q \cup S$ by a **square net** (lattice, grid) with mesh length $h = 1/N$, for N a large integer. The set of net points $P_{m,n} = (mh, nh)$ lying in Q is denoted by Ω_h , and S_h is the set of net points on S . We want to have a net function u_h on $R_h = \Omega_h \cup S_h$ that approximates the solution u of (1) and (2), where u_h is determined by the difference equation

$$\Delta_h u_h(x, y) = -f(x, y) \quad ((x, y) \in \Omega_h), \tag{31}$$

and the boundary condition

$$u_h(x, y) = \beta(x, y) \quad ((x, y) \in S_h). \tag{32}$$

Here Δ_h is a difference operator, the 5-point

difference analog of Δ , which is defined by

$$\begin{aligned} \Delta_h \varphi &= D_x^h D_x^h \varphi + D_y^h D_y^h \varphi \\ &= (\varphi(x+h, y) + \varphi(x-h, y) + \varphi(x, y+h) \\ &\quad + \varphi(x, y-h) - 4\varphi(x, y))/h^2. \end{aligned}$$

In view of the maximum principle for net functions on R_h , it is seen that (31) and (32) admit only $u_h = 0$ as a solution if $f = \beta = 0$, which implies that the solution u_h of (31) and (32) exists uniquely for all f and β . When we are concerned with the convergence of u_h to u as $h \rightarrow 0$, we have to consider (31) and (32) for all small $h > 0$. Such a family of difference equations is called a **difference scheme**. Actually, u_h obtained through (31) and (32) converges to u as $h \rightarrow 0$, and we can say that the difference scheme (31) and (32) is convergent. In general, the order of the error $u - u_h$ depends on the smoothness of u . For instance, if $u \in C^4(\Omega)$, then $|u - u_h| \leq Ch^2$ holds uniformly on R_h . When the asymptotic behavior of the error is known to satisfy $u - u_h = wh^2 + o(h^2)$ for some $w = w(x, y)$, it is possible to attain a higher accuracy by eliminating the h^2 -order term if we compute u_h for two different values of h and form an appropriate linear combination of the u_h thus obtained (Richardson's extrapolation; \rightarrow e.g., [17]). The convergence of difference schemes applied to boundary value problems is not affected if rectangular nets are used instead of square nets. Many techniques have been devised to treat curved boundaries. There have been attempts recently to map Ω into a domain Q of simpler geometry, say, a rectangular one, and then discretize the arising partial differential equations with variable coefficients in Q (e.g., J. F. Thompson et al., *J. Comput. Phys.*, 1982.) Moreover, when information regarding the location and nature of singularities of solutions is available, one can refine the net near these points.

The difference analog of elliptic equations described above is a system of linear equations with the values of the u_h as its unknowns. Since the coefficient matrix of this system is of multidagonal type, direct elimination methods can be efficiently applied to solve it. Particularly, some elimination algorithms employing vector computations have been invented [19]. Iteration methods of the Gauss-Seidel type can also be applied, where acceleration of convergence by SOR is effective (\rightarrow 302 Numerical Solution of Linear Equations C).

F. Difference Methods for Initial Value Problems

To demonstrate characteristics of the difference method applied to evolution equa-

tions [17, 20, 21], we first consider the initial boundary value problem (14)–(16) for the diffusion equation supposing that $\Omega = (0, 1)$, a 1-dimensional interval. Then we cover $Q = [0, \infty) \times \bar{\Omega}$ by a rectangular net $t = n\tau$ ($n = 0, 1, 2, \dots$) and $x = jh$ ($j = 0, 1, \dots$) with mesh lengths $\Delta t = \tau$ and $\Delta x = h$. The value of the approximate function $u_{\tau,h}$ at the net point $(n\tau, jh)$ is denoted by U_j^n . Then the simplest **difference scheme of forward type** for (14) is written as

$$\frac{U_j^{n+1} - U_j^n}{\tau} = \frac{U_{j+1}^n + U_{j-1}^n - 2U_j^n}{h^2} \tag{33}$$

Namely, we adopt the difference operator $L_{\tau,h}[\] = D_t - D_x^h D_x^h$ as the difference analog of $(\partial/\partial t) - (\partial^2/\partial x^2)$. Equation (33) is **consistent** in the sense that $L_{\tau,h}[u] = \text{“the residual of } u\text{”} \rightarrow 0$ ($\tau, h \rightarrow 0$) for any smooth solution u of (14). This is the case also with the **difference scheme of backward type**

$$\frac{U_j^{n+1} - U_j^n}{\tau} = \frac{U_{j+1}^{n+1} + U_{j-1}^{n+1} - 2U_j^{n+1}}{h^2} \tag{34}$$

To compute the approximate solution $U^n = \{U_j^n | 0 \leq j \leq N\}$, (33) or (34) must be combined with the approximate initial condition corresponding to (16), say $U_j^0 = a(jh)$, and with the boundary condition $U_0^n = U_N^n = 0$. Then one can proceed from U^0 to U^1 , from U^1 to U^2 , and so on. Actually, (33) is rewritten in the form

$$U_j^{n+1} = \lambda U_{j+1}^n + \lambda U_{j-1}^n + (1 - 2\lambda)U_j^n, \tag{35}$$

with $\lambda = \tau/h^2$, which gives U^{n+1} explicitly in terms of U^n . Hence (33) is an **explicit scheme**. On the other hand, in order to acquire U^{n+1} from U^n according to (34), it is necessary to solve a system of linear equation with U^{n+1} as its unknown. Hence (34) is an **implicit scheme**. Since the coefficient matrix of the system of linear equations to determine U^{n+1} according to (34) is tridiagonal, one can employ a particularly efficient elimination algorithm.

We introduce the maximum norm $\|\varphi_h\|_h = \max_{R_h} |\varphi(jh)|$ for net functions φ_h on $R_h = \Omega_h \cup S_h = \{x = jh | 0 \leq j \leq N\}$. Then, as is obvious from (35), the approximate solution $U^n = u_{\tau,h}(n\tau)$ obtained through (33) satisfies $\|U^n\|_h \leq \|U^0\|_h$ ($n = 0, 1, \dots$), provided that

$$0 < \lambda = \frac{\tau}{h^2} \leq \frac{1}{2} \tag{36}$$

Generally, a difference scheme approximating an initial value problem is said to be **stable** if the approximate solution $u_{\tau,h}$ for the initial value $a_h = u_{\tau,h}(0)$ satisfies, for small τ and h ,

$$\|u_{\tau,h}(t)\|_h \leq M_T \|a_h\|_h \quad (0 \leq t = n\tau \leq T) \tag{37}$$

for any $T > 0$, M_T being a constant depending

on T . **Lax’s equivalence theorem** asserts that if the original initial value problem is well-posed and if the approximating difference scheme is consistent, then the stability of the difference scheme is necessary and sufficient for the convergence of the approximate solution $u_{\tau,h}$ to the rigorous solution u as $\tau, h \rightarrow 0$. For instance the explicit difference scheme (33) for the 1-dimensional diffusion equation is convergent under the mesh condition (36). On the other hand, the implicit scheme (34) is unconditionally stable and hence is convergent. Many difference schemes more sophisticated than (33) and (34), of higher accuracy or with other favorable properties, have been proposed and studied. All these difference schemes can be generalized to the case of many-dimensional Ω . For instance, if $\Omega \subset \mathbf{R}^2$, then by means of the difference operator Δ_h in (31), the forward scheme and the backward scheme are given by $D_t U^n = \Delta_h U^n$ and $D_t U^n = \Delta_h U^{n+1}$, respectively. The former is stable if $0 < \lambda = \tau/h^2 \leq 1/4$, while the latter is unconditionally stable. Moreover, in a method called the **ADI method** (alternating direction implicit method) one introduces $U^{n+1/2}$ on **fractional steps** $t = n\tau + \tau/2$ and discretizes (14) as

$$\begin{aligned} \frac{U^{n+1/2} - U^n}{\tau/2} &= D_x^h D_x^h U^n + D_y^h D_y^h U^{n+1/2}, \\ \frac{U^{n+1} - U^{n+1/2}}{\tau/2} &= D_x^h D_x^h U^{n+1/2} + D_y^h D_y^h U^{n+1/2}. \end{aligned} \tag{38}$$

Then, starting from U^0 , the computation goes as $U^0 \rightarrow U^{1/2} \rightarrow U^1 \rightarrow \dots \rightarrow U^n \rightarrow U^{n+1/2} \dots$ by solving at each step alternatively a difference equation implicit with respect to x and y , for which a particular elimination method can be used with good efficiency. Furthermore, the ADI method is unconditionally stable. Various types of fractional-step method that generalize the ADI method have been proposed [12, 17].

We now proceed to hyperbolic equations. First consider the Cauchy problem where the spatial domain is the whole \mathbf{R}^1 . Noting that the wave equation $v_{tt} = v_{xx}$, for instance, can be rewritten as

$$\frac{\partial u}{\partial t} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \frac{\partial u}{\partial x}$$

by putting $u = {}^t(v_t, v_x)$, we here deal with a hyperbolic system of the form

$$\frac{\partial u}{\partial t} = A \frac{\partial u}{\partial x}, \tag{39}$$

where the unknown u is an m -vector $u = {}^t(u_1, u_2, \dots, u_m)$, and A is a constant $m \times m$ matrix that is supposed to be real and symmetric. For hyperbolic equations, explicit schemes are generally preferred, and as a typ-

ical one we mention the **Friedrichs scheme**. In the Friedrichs scheme applied to (39), the approximate solution $U = {}^t(U_1, U_2, \dots, U_m)$ is determined by

$$\frac{U(t + \tau, x) - \frac{1}{2}(U(t, x + h) + U(t, x - h))}{\tau} = A \delta_x^h U(t, x). \quad (40)$$

Here t is restricted to $t = n\tau$ ($n = 0, 1, \dots$), while x is regarded as a variable ranging over \mathbf{R}^1 . Introducing translation operators T_h and T_{-h} by

$$T_h: \varphi(x) \rightarrow \varphi(x + h) \quad \text{and} \quad T_{-h}: \varphi(x) \rightarrow \varphi(x - h),$$

we obtain from (40)

$$U(t + \tau, \cdot) = S_h U(t, \cdot), \quad (41)$$

where, with the mesh ratio $\lambda = \tau/h$, S_h is given by

$$S_h = \left(\frac{1}{2} + \frac{\lambda}{2} A\right) T_h + \left(\frac{1}{2} - \frac{\lambda}{2} A\right) T_{-h}. \quad (42)$$

Generally, if a difference scheme is reduced to the form of (41), then the operator S_h , which yields evolution of the solution of the difference equation for one time step, is called the **amplification operator** of the scheme. The stability of the difference scheme is implied by the uniform boundedness of the operator norm $\|S_h^n\|$ of S^n acting in the Hilbert space $(L_2(\mathbf{R}^1))^m$ for $0 \leq n \leq T/\tau$. Consequently, the scheme is stable if $\|S_h\| \leq 1 + C\tau$, C being a constant. The symbol $\tilde{S}_h(\xi)$ of S_h with respect to the Fourier transform is called the **amplification matrix** of the scheme. The L_2 -stability of the scheme mentioned above is equivalent to the uniform boundedness of the matrix norm $\|\tilde{S}_h^n(\xi)\|$ for $0 \leq n\tau \leq T$ and $\xi \in \mathbf{R}^1$. Therefore, denoting by $r_h(\xi)$ the spectral radius of $\tilde{S}_h(\xi)$, one can give a necessary condition for the stability by $|r_h(\xi)| \leq 1 + C\tau$, which is called the **von Neumann condition**. Concerning general criteria for the uniform boundedness of powers of $\tilde{S}_h(\xi)$ when $\tilde{S}_h(\xi)$ is not necessarily normal, a fundamental theorem was given by H. O. Kreiss in 1962 [21].

If the largest-modulus eigenvalue of A is denoted by μ_0 , then the Friedrichs scheme is stable and hence is convergent under the condition on the mesh ratio $\lambda = \tau/h$ given by

$$\lambda \leq 1/|\mu_0|. \quad (43)$$

In particular, (43) implies that for the stable Friedrichs scheme

$$\text{propagation speed of the difference scheme} \geq \text{propagation speed of the original equation.} \quad (44)$$

Condition (44) is a necessary condition for general difference schemes approximating

hyperbolic equations to be stable, and is known as the **CFL condition** (Courant-Friedrichs-Lewy condition) [22]. For a scheme more accurate than the Friedrichs scheme we refer to the Lax-Wendroff scheme, which proceeds by way of the following amplification operator S_h :

$$S_h = I + \tau A \delta_x^h + \frac{\tau^2}{2} A^2 D_x^h D_x^h \\ = I + \frac{\lambda}{2} A (T_h + T_{-h}) + \frac{\lambda^2}{2} (T_h - 2I + T_{-h}).$$

The Lax-Wendroff scheme is stable under (43).

There are many other difference schemes to approximate (39), most of which are applicable to higher-dimensional spaces. Some of these schemes can be conveniently employed to solve nonlinear hyperbolic equations, for instance, those arising in the gas dynamics of compressible fluids, for which the Friedrichs scheme and the Lax-Wendroff scheme were originally intended [23]. Concerning difference schemes with variable coefficients which approximate a regularly hyperbolic system with an x -dependent principal part, criteria for the stability of the scheme in terms of the symbol $\tilde{S}_h(x, \xi)$ of S_h have been obtained, making use of the theory of pseudodifferential operators, by P. D. Lax and L. Nirenberg (*Comm. Pure Appl. Math.*, 1966), M. Yamaguti and T. Nogi (*Publ. Res. Inst. Math. Sci.*, 1967), R. Vaillancourt (*Math. Comput.*, 1970), Z. Koshiba (*J. Math. Anal. Appl.*, 1981), and others.

O

305 (IX.11) Obstructions

A. History

The theory of **obstructions** aims at measuring the extensibility of mappings by means of algebraic tools. Such classical results as the †Brouwer mapping theorem and Hopf's extension and †classification theorems in homotopy theory might be regarded as the origins of this theory. A systematic study of the theory was initiated by S. Eilenberg [1] in connection with the notions of †homotopy and †cohomology groups, which were introduced at the same time. A. Komatu and P. Olum [2] extended the theory to mappings into spaces not necessarily † n -simple. For mappings of polyhedra into certain special spaces, the †homotopy classification problem, closely related to the theory of obstructions, was solved in the following cases (K^m denotes an m -dimensional polyhedron): $K^{n+1} \rightarrow S^n$ (N. Steenrod [5]), $K^{n+2} \rightarrow S^n$ (J. Adem), $K^{n+k} \rightarrow Y$, where $\pi_i(Y) = 0$ for $i < n$ and $n < i < n+k$ (M. Nakaoka). There are similar results by L. S. Pontryagin, M. Postnikov, and S. Eilenberg and S. MacLane. Except for the special cases already noted, it is extremely difficult to discuss higher obstructions in general since they involve many complexities. Nevertheless, it is significant that the idea of obstructions has given rise to various important notions in modern algebraic topology, including cohomology operations (\rightarrow 64 Cohomology Operations) and characteristic classes (\rightarrow 56 Characteristic Classes).

The notion of obstruction is also very useful in the treatment of cross sections of fiber bundles (\rightarrow 147 Fiber Bundles), †diffeomorphisms of differentiable manifolds, etc.

B. General Theory for an n -Simple Space Y

The question of whether two (continuous) mappings of a topological space X into another space Y are †homotopic to each other can be reduced to the extensibility of the given mapping: $(X \times \{0\}) \cup (X \times \{1\}) \rightarrow Y$ to a mapping of the product $X \times I$ of X and the unit interval $I = [0, 1]$ into Y . Therefore the problem of classifying mappings can be treated in the same way as that of the extension of mappings.

Let K be a †polyhedron, L a subpolyhedron of K , and $\hat{K}^n = L \cup K^n$ the union of L and the † n -skeleton K^n of K . Let Y be an †arcwise connected n -simple space, and f' be a mapping of L into Y . Denote by $\Phi^n(f')$ the set of mappings of \hat{K}^n into Y that are extensions of f' ,

and by $\Phi^n(f')$ the set of †homotopy classes of mappings in $\Phi^n(f')$ relative to L . The set $\bar{\Phi}^0(f')$ consists of a single element because of the arcwise connectedness of Y , $\bar{\Phi}^1(f')$ is non-empty, and $\bar{\Phi}^n(f')$ ($n \geq 2$) may be empty. Let f^n be an element of $\Phi^n(f')$. If we consider the restriction of f^n to the boundary ∂^{n+1} of an oriented $(n+1)$ -cell σ^{n+1} of K , then $f^n: \partial^{n+1} \rightarrow Y$ determines an element $c(f^n, \sigma^{n+1})$ of the †homotopy group $\pi_n(Y)$ (\rightarrow 202 Homotopy Theory). This element gives a measure of obstruction for extending f^n to the interior of σ^{n+1} . We obtain an $(n+1)$ -cocycle $c^{n+1}(f^n)$ of the †simplicial pair (K, L) with coefficients in $\pi_n(Y)$, called the **obstruction cocycle** of f^n , by assigning $c(f^n, \sigma^{n+1})$ to each $(n+1)$ -cell σ^{n+1} . This obstruction cocycle $c^{n+1}(f^n)$ is the measure of obstruction for extending f^n to \hat{K}^{n+1} . A necessary and sufficient condition for the extensibility is given by $c^{n+1}(f^n) = 0$. Clearly, $c^{n+1}(f^n)$ is uniquely determined for each element f of $\bar{\Phi}^n(f')$. The set of all $c^{n+1}(f^n)$ with $f^n \in \Phi^n(f')$ forms a subset $\mathfrak{o}^{n+1}(f')$ of the group of cocycles $Z^{n+1}(K, L; \pi_n(Y))$. $\Phi^{n+1}(f')$ is non-empty if and only if $\mathfrak{o}^{n+1}(f')$ contains the zero element 0.

Let $K^\square = K \times I$, $L^\square = (K \times 0) \cup (L \times I) \cup (K \times 1)$. Given two mappings $f_0, f_1: K \rightarrow Y$ satisfying $f_0|L = f_1|L$, we can define a natural mapping $F': L^\square \rightarrow Y$ such that an element F^n of $\Phi^n(F')$ corresponds to a †homotopy h^{n-1} relative to L connecting $f_0|K^{n-1}$ with $f_1|K^{n-1}$. Given an element $F^n \in \Phi^n(F')$, we have the element $c^{n+1}(F^n)$ of $Z^{n+1}(K^\square, L^\square; \pi_n(Y))$, which we identify with $Z^n(K, L; \pi_n(Y))$ through the natural isomorphism of chain groups of the pair (K^\square, L^\square) to those of the pair (K, L) . Thus we can regard $c^{n+1}(F^n)$ as an element of $Z^n(K, L; \pi_n(Y))$, which is denoted by $d^n(f_0, h^{n-1}, f_1)$, and call it the **separation (or difference) cocycle**. If $f_0|K^{n-1} = f_1|K^{n-1}$, we have the canonical mapping $F^n: L^\square \cup (K^\square)^n \rightarrow Y$, and the separation cocycle is denoted simply by $d^n(f_0, f_1)$. The set of separation cocycles corresponding to elements of $\Phi^n(F')$ is considered to be a subset of $Z^n(K, L; \pi_n(Y))$ and is denoted by $\mathfrak{o}^n(f_0, f_1)$. A necessary and sufficient condition for h^{n-1} to be extensible to a homotopy on \hat{K}^n is $d^n(f_0, h^{n-1}, f_1) = 0$. Therefore a necessary and sufficient condition for $f_0|K^n \simeq f_1|K^n$ (rel L) (i.e., relative to L) is $0 \in \mathfrak{o}^n(f_0, f_1)$. Given $f_0^n, f_1^n: \hat{K}^n \rightarrow Y$ with $f_0^n|L = f_1^n|L$, then $d^n(f_0^n, h^{n-1}, f_1^n) \in \mathfrak{o}^n(f_0^n, f_1^n)$ is an element of $Z^n(\hat{K}^n, L; \pi_n(Y))$, which is also considered to be a cochain of the pair (K, L) . In this sense, we call $d^n(f_0^n, h^{n-1}, f_1^n)$ the **separation (or deformation) cochain** over (K, L) . The coboundary of the separation cochain $d^n(f_0^n, h^{n-1}, f_1^n)$ coincides (except possibly for sign) with $c^{n+1}(f_0^n) - c^{n+1}(f_1^n)$.

For a fixed $f_0^n \in \Phi^n(f')$, any n -cochain d^n

of the pair (K, L) with coefficients in $\pi_n(Y)$ is expressible as a separation cochain $d^n = d^n(f_0^n, f_1^n)$ where $f_1^n \in \Phi^n(f')$ is a suitable mapping such that $f_0^n|_{\hat{K}^{n-1}} = f_1^n|_{\hat{K}^{n-1}}$ (existence theorem).

Therefore if we take an element f^{n-1} of $\bar{\Phi}^{n-1}(f')$ whose obstruction cocycle $c^n(f^{n-1})$ is zero, the set of all obstruction cocycles $c^{n+1}(f^n)$ of all such $f^n \in \Phi^n(f')$ that are extensions of f^{n-1} forms a subset of $\mathfrak{o}^{n+1}(f')$ and coincides with a coset of $Z^{n+1}(K, L; \pi_n(Y))$ factored by $B^{n+1}(K, L; \pi_n(Y))$. Thus a cohomology class $\bar{c}^{n+1}(f^{n-1}) \in H^{n+1}(K, L; \pi_n(Y))$ corresponds to an $f^{n-1} \in \Phi^{n-1}(f')$ such that $c^n(f^{n-1})=0$, and $\bar{c}^{n+1}(f^{n-1})=0$ is a necessary and sufficient condition for f^{n-1} to be extensible to \hat{K}^{n+1} (**first extension theorem**).

For the separation cocycle, $\bar{d}^n(f_0, h^{n-2}, f_1) \in H^n(K, L; \pi_n(Y))$ corresponds to each homotopy h^{n-2} on \hat{K}^{n-2} such that $d^{n-1}(f_0, h^{n-2}, f_1)=0$, and $\bar{d}^n(f_0, h^{n-2}, f_1)=0$ is a necessary and sufficient condition for h^{n-2} to be extensible to a homotopy on \hat{K}^n (**first homotopy theorem**).

The subset of $H^{n+1}(K, L; \pi_n(Y))$ corresponding to $\mathfrak{o}^{n+1}(f')$ is denoted by $\mathbf{O}^{n+1}(f')$ and is called the **obstruction to an $(n+1)$ -dimensional extension** of f' . Similarly, the subset $\mathbf{O}^n(f_0, f_1)$ of $H^n(K, L; \pi_n(Y))$ corresponding to $\mathfrak{o}^n(f_0, f_1)$ is called the **obstruction to an n -dimensional homotopy** connecting f_0 with f_1 . Clearly, a condition for f' to be extensible to \hat{K}^{n+1} is given by $0 \in \mathbf{O}^{n+1}(f')$, and a necessary and sufficient condition for $f_0|_{K^n} \simeq f_1|_{K^n} \pmod{L}$ is given by $0 \in \mathbf{O}^n(f_0, f_1)$.

A continuous mapping $\varphi: (K', L') \rightarrow (K, L)$ induces homomorphisms of cohomology groups $\varphi^*: H^{n+1}(K, L; \pi_n(Y)) \rightarrow H^{n+1}(K', L'; \pi_n(Y))$, $H^n(K, L; \pi_n(Y)) \rightarrow H^n(K', L'; \pi_n(Y))$. Then for $f': L \leftarrow Y$, $\mathbf{O}^{n+1}(f' \circ \varphi) \supset \varphi^* \mathbf{O}^{n+1}(f')$, and for $f_0, f_1: K \rightarrow Y$ such that $f_0|_L = f_1|_L$, $\mathbf{O}^n(f_0 \circ \varphi, f_1 \circ \varphi) \supset \varphi^* \mathbf{O}^n(f_0, f_1)$. Therefore we also find that the obstruction to an extension and the obstruction to a homotopy are independent of the choice of subdivisions of K, L , and consequently are topological invariants.

Let f_0, f_1 , and f_2 be mappings $K \rightarrow Y$ such that $f_0|_L = f_1|_L = f_2|_L$. Given homotopies $h_{01}^{n-1}: f_0|_{\hat{K}^{n-1}} \simeq f_1|_{\hat{K}^{n-1}} \pmod{L}$, $h_{12}^{n-1}: f_1|_{\hat{K}^{n-1}} \simeq f_2|_{\hat{K}^{n-1}} \pmod{L}$, then for the composite $h_{02}^{n-1} = h_{12}^{n-1} \circ h_{01}^{n-1}$, we have

$$\begin{aligned} d^n(f_0, h_{01}^{n-1}, f_1) + d^n(f_1, h_{12}^{n-1}, f_2) \\ = d^n(f_0, h_{02}^{n-1}, f_2), \end{aligned}$$

and for the inverse homotopy $h_{10}^{n-1}: f_1|_{\hat{K}^{n-1}} \simeq f_0|_{\hat{K}^{n-1}} \pmod{L}$, clearly

$$d^n(f_1, h_{10}^{n-1}, f_0) = -d^n(f_0, h_{01}^{n-1}, f_1).$$

Therefore $\mathbf{O}^n(f_0, f_0)$ forms a subgroup of $H^n(K, L; \pi_n(Y))$ that is determined by the homotopy class of $f_0|_{\hat{K}^{n-1}}$ relative to L . In

general, if $\mathbf{O}^n(f_0, f_1)$ is nonempty, it is a coset of $H^n(K, L; \pi_n(Y))$ factored by the subgroup $\mathbf{O}^n(f_0, f_0)$. Combined with the existence theorem on separation cochains, this can be utilized to show the following theorem.

Assume that $\Phi^n(f')$ is nonempty. The set of all elements $\bar{\Phi}^n(f')$ that are extensions of an element of $\bar{\Phi}^{n-1}(f')$ is put in one-to-one correspondence with the quotient group of $H^n(\hat{K}^n, L; \pi_n(Y))$ modulo $\mathbf{O}^n(f_0^n, f_0^n)$ by pairing the obstruction $\mathbf{O}^n(f_0^n, f^n)$ with each f^n for a fixed f_0^n . Among such elements of $\bar{\Phi}^n(f')$, the set of f^n that are extensible to \hat{K}^{n+1} is in one-to-one correspondence with the quotient group of $H^n(\hat{K}^{n+1}, L; \pi_n(Y)) = H^n(K, L; \pi_n(Y))$ modulo the subgroup $\mathbf{O}^n(f_0^{n+1}, f_0^{n+1})$, assuming that f_0^n is extended to f_0^{n+1} (**first classification theorem**).

C. Primary Obstructions

Assume that $H^{i+1}(K, L; \pi_i(Y)) = H^i(K, L; \pi_i(Y)) = 0$, where $0 < i < p$ (e.g., $\pi_i(Y) = 0, 0 < i < p$). In this case, by consecutive use of the first extension theorem and the first homotopy theorem, we can show that each $\bar{\Phi}^i(f')$ ($i < p$) consists of a single element and $\mathbf{O}^{p+1}(f')$ also consists of a single element $\bar{c}^{p+1}(f') \in H^{p+1}(K, L; \pi_p(Y))$. The element $\bar{c}^{p+1}(f')$, called the **primary obstruction** of f' , vanishes if and only if f' can be extended to \hat{K}^{p+1} (**second extension theorem**). When $H^{i+1}(K, L; \pi_i(Y)) = 0$ for $i > p$ (for example, when $\pi_i(Y) = 0$ for $p < i < \dim(K-L)$), f' is extendable to K if and only if the first obstruction of f' vanishes (**third extension theorem**).

Correspondingly, if $H^i(K, L; \pi_i(Y)) = H^{i-1}(K, L; \pi_i(Y)) = 0$ ($0 < i < p$), then for any two mappings $f_0, f_1: K \rightarrow Y, f_0|_L = f_1|_L$, $\mathbf{O}^p(f_0, f_1)$ consists of a single element $\bar{d}^p(f_0, f_1) \in H^p(K, L; \pi_p(Y))$, which we call the **primary difference** of f_0 and f_1 . This element vanishes if and only if $f_0|_{\hat{K}^p} \simeq f_1|_{\hat{K}^p} \pmod{L}$ (**second homotopy theorem**). Moreover, when $H^i(K, L; \pi_i(Y)) = 0$ ($i > p$), the primary difference is zero if and only if $f_0 \simeq f_1 \pmod{L}$ (**third homotopy theorem**).

Assume that the hypotheses of the second extension theorem and second homotopy theorem are satisfied. If we assign to each element f^p of $\bar{\Phi}^p(f')$ the primary difference of f^p and the fixed element f_0^p , then $\bar{\Phi}^p(f')$ is in one-to-one correspondence with $H^p(\hat{K}^p, L; \pi_p(Y))$ by the first classification theorem (**second classification theorem**). Similarly, assume that the hypotheses of the third extension theorem and third homotopy theorem are satisfied. If $f_0: K \rightarrow Y, f' = f_0|_L$, then homotopy classes relative to L of extensions f of f' are put in one-to-one correspondence with the

Obstructions

elements of $H^p(K, L; \pi_p(Y))$ by pairing $d^p(f, f_0)$ with f (**third classification theorem**).

D. Secondary Obstructions

For simplicity, assume that $\pi_i(Y) = 0$ ($i < p$ and $p < i < q$). If the primary obstruction $\bar{c}^{p+1}(f') \in H^{p+1}(K, L; \pi_p(Y))$ of $f': L \rightarrow Y$ vanishes, we can define $O^{q+1}(f') \subset H^{q+1}(K, L; \pi_q(Y))$, which we call the **secondary obstruction** of f' . When $Y = S^p$, $q = p + 1$, $p > 2$, the secondary obstruction $O^{p+2}(f')$ coincides with a coset of $H^{p+2}(K, L; Z_2)$ modulo the subgroup $Sq^2(H^p(K, L; Z_2))$, where Sq^2 denotes the Steenrod square operation [5]. In this case, if $L = K^p$, then $O^{p+2}(f')$ reduces to a cohomology class, $Sq^2(i^*)^{-1}f'^*(\sigma)$ with $i: L \rightarrow K$, where σ is a generator of $H^p(S^p, Z)$ (in this case $(i^*)^{-1}f'^*(\sigma) \neq \emptyset$ is equivalent to $\bar{c}^{p+1}(f') = 0$) [5]. Moreover, if $Sq^2f'^*(\sigma) = 0$, then there exists a suitable extension $f^{p+2}: \tilde{K}^{p+2} \rightarrow Y = S^p$ of f' . The set of obstruction cocycles of all such f^{p+2} defines the **tertiary obstruction** $O^{p+3}(f')$, which coincides with a coset of $H^{p+3}(K, L; Z_2)$ modulo the subgroup $Sq^2(H^{p+1}(K, L; Z_2))$. By using the †secondary cohomology operation Φ of J. Adem, it can be expressed as $\Phi((i^*)^{-1}f'^*(\sigma))$ (\rightarrow 64 Cohomology Operations).

All the propositions in this article remain true if we take †CW complexes instead of polyhedra K .

306 (XII.20) Operational Calculus

A. General Remarks

The term “operational calculus” in the usual sense means a method for solving †linear dif-

ferential equations by reducing the operations of differentiation and integration into algebraic ones in a symbolic manner. The idea was initiated by P. S. Laplace in his *Théorie analytique des probabilités* (1812), but the method has acquired popularity since O. Heaviside used it systematically in the late 19th century to solve electric-circuit problems. The method is therefore also called **Heaviside calculus**, but Heaviside gave only a formal method of calculus without bothering with rigorous arguments. The mathematical foundations were given in later years, first in terms of †Laplace transforms, then by applying the theory of †distributions. One of the motivations behind L. Schwartz's creation of this latter theory in the 1940s was to give a sound foundation for the formal method, but the theory obtained has had a much larger range of applications. Schwartz's theory was based on the newly developed theory of †topological linear spaces. On the other hand, J. Mikusiński gave another foundation, based only on elementary algebraic notions and on Titchmarsh's theorem, whose proof has recently been much simplified.

In this article, we first explain the simple theory established by Mikusiński [2] and later discuss its relation to the classical Laplace transform method.

B. The Operational Calculus of Mikusiński

The set \mathcal{C} of all continuous complex-valued functions $a = \{a(t)\}$ defined on $t \geq 0$ is a †linear space with the usual addition and scalar multiplication. \mathcal{C} is a †commutative algebra with multiplication $a \cdot b$ defined by the †convolution $\{\int_0^t a(t-s)b(s)ds\}$. The ring \mathcal{C} has no †zero divisors (**Titchmarsh's theorem**). (There have been several interesting proofs of Titchmarsh's theorem since the first demonstration given by Titchmarsh himself [3]. For example, a simple proof has been published by C. Ryll-Nardzewski (1952).) Hence we can construct the †quotient field \mathcal{Q} of the ring \mathcal{C} . An element of \mathcal{Q} is called a **Mikusiński operator**, or simply an **operator**. If we define $a(t) = 0$ for $t < 0$ for the elements $\{a(t)\}$ in \mathcal{C} , then \mathcal{C} is a subalgebra of \mathcal{M} , which is the set of all locally integrable (locally L_1) functions in $(-\infty, \infty)$ whose †support is bounded below. Here we identify two functions that coincide almost everywhere. The algebra \mathcal{M} has no zero divisor, and its quotient field is also \mathcal{Q} .

The unity element for multiplication in \mathcal{Q} , denoted by $\delta = b/b$ ($b \neq 0$), plays the role of the †Dirac δ -function. It is sometimes called the **impulse function**. The operator $l = \{1\} \in \mathcal{C}$ is the

function that takes the values 0 and 1 according as $t < 0$ or $t > 0$. This operator is **Heaviside's function** and is sometimes called the **unit function**. Usually it is denoted by $\mathbf{1}(t)$ or simply $\mathbf{1}$. The value $\mathbf{1}(0)$ may be arbitrary, but usually it is defined as $1/2$, the mean of the limit values from both sides. The operator l is an **integral operator**, because, as an operator carrying a into $l \cdot a$, it yields

$$l \cdot a = \left\{ \int_0^t a(s) ds \right\} = \text{the integral of } a \text{ over } [0, t].$$

More generally, the operator $\{t^{\lambda-1}/\Gamma(\lambda)\}$ ($\text{Re } \lambda > 0$) gives the λ th-order integral. The operator $s = \delta/l$, which is the inverse operator of l , is a **differential operator**. If $a \in \mathcal{C}$ is of class C^1 , then we have

$$s \cdot a = a' + a(+0)\delta = a' + \{a(+0)\}/\{1\}. \tag{1}$$

Similarly, if $a \in \mathcal{C}$ is of class C^n , we have

$$s^n \cdot a = a^{(n)} + a^{(n-1)}(0)\delta + a^{(n-2)}(0)s + \dots + a(0)s^{n-1}. \tag{2}$$

The operator $a \rightarrow s \cdot a$ can be applied to functions a that are not differentiable in the ordinary sense, and considering the application of s to be the operation of differentiation, we can treat the differential operator algebraically in the field \mathcal{Q} . In particular, we have $s \cdot \mathbf{1} = \delta$, and this relation is frequently represented by the formula

$$d\mathbf{1}(t)/dt = \delta(t). \tag{3}$$

A rational function of s whose numerator is of lower degree than its denominator is an elementary function of t . For example, we have the relations

$$\begin{aligned} 1/(s - \alpha)^n &= \{t^{n-1} e^{\alpha t}/(n-1)!\}, \\ 1/(s^2 + \beta^2) &= \{\beta^{-1} \sin \beta t\}, \\ s/(s^2 + \beta^2) &= \{\cos \beta t\}. \end{aligned} \tag{4}$$

The solution of an ordinary linear differential equation with constant coefficients $\sum_{r=0}^n \alpha_r \varphi^{(r)}(t) = f(t)$ under the initial condition $\varphi^{(i)}(0) = \gamma_i$ ($0 \leq i \leq n-1$) is thus reduced to an equation in s by using formulas (1) and (2), and is computed by decomposing the following operator into partial fractions:

$$\{\varphi(t)\} = \frac{\beta_{n-1}s^{n-1} + \dots + \beta_0 + f}{\alpha_n s^n + \dots + \alpha_1 s + \alpha_0}, \tag{5}$$

where $\beta_r = \alpha_{r+1}\gamma_0 + \alpha_{r+2}\gamma_1 + \dots + \alpha_n\gamma_{n-r-1}$, $0 \leq r \leq n-1$. The general solution is represented by (5) if we consider the constants $\gamma_0, \dots, \gamma_{n-1}$ or $\beta_0, \dots, \beta_{n-1}$ as arbitrary parameters. If the rational function in the right-hand side of (5) is $M(s)/D(s)$ and the degree of the numerator is less than that of the denominator, then the right-hand side of (5) is explicitly repre-

sented by

$$\begin{aligned} &\sum_{r=0}^{l-1} \frac{t^{l-r-1}}{(l-r-1)!r!} \left[\frac{d^r}{d\lambda^r} \left(\frac{M(\lambda)}{D(\lambda)/(\lambda - \lambda_0)^l} \right) \right]_{\lambda=\lambda_0} e^{\lambda_0 t} \\ &+ \sum_{i=1}^m \frac{M(\lambda_i)}{D(\lambda_i)} e^{\lambda_i t}, \end{aligned}$$

where we assume that $\lambda_0, \lambda_1, \dots, \lambda_m$ exhaust the roots of the equation $D(\lambda) = 0$, λ_0 is a multiple root of degree l , and all other roots are simple ($m = n - l$). The above formula is called the **expansion theorem**.

C. Limits of Operators

A sequence a_n of operators is said to **converge** to the **limit** $a = b/q$ if there exists an operator $q (\neq 0)$ such that $q \cdot a_n \in \mathcal{C}$ and the sequence of functions $q \cdot a_n$ converges uniformly to b on compact sets. The limit a is determined uniquely without depending on the operator q . Based on this notion of limits of operators, we can construct the theory of series of operators and differential and integral calculus of functions of an independent variable λ whose values are operators. They are completely parallel to the usual theories of elementary calculus (\rightarrow 106 Differential Calculus; 216 Integral Calculus; 379 Series). A linear partial differential equation in the function $\varphi(x, t)$ of two variables, in particular its initial value problem, reduces to a linear ordinary differential equation of an operational-valued function of an independent variable x .

For a given operator w , the solution (if it exists) of the differential equation $\varphi'(\lambda) = w \cdot \varphi(\lambda)$ with the initial condition $\varphi(0) = \delta$ is unique, is called the **exponential function of an operator** w , and is denoted by $\varphi(\lambda) = e^{\lambda w}$. If the power series

$$\sum_{n=0}^{\infty} \lambda^n w^n / n! \tag{6}$$

converges, the limit is identical to the exponential function $e^{\lambda w}$. However, there are several cases in which $e^{\lambda w}$ exists even when the series (6) of operators does not converge.

For example, for $w = -\sqrt{s}$, we have

$$e^{-\lambda\sqrt{s}} = \{(\lambda/2\sqrt{\pi t^3}) \exp(-\lambda^2/4t)\}, \tag{7}$$

and for $w = -s$, we have

$$e^{-\lambda s} = h^\lambda = s \cdot H_\lambda(t), \tag{8}$$

where the function $H_\lambda(t)$ takes the values 0 and 1 according as $t < \lambda$ or $t > \lambda$. $H_\lambda(t)$ belongs to the ring \mathcal{U} and is called the **jump function** at λ . For $f(t) \in \mathcal{U}$, we have

$$h^\lambda \cdot \{f(t)\} = \{f(t - \lambda)\},$$

and hence we call (8) the **translation operator**

(or **shift operator**). For $w = -s$, the series (6) does not converge, but if we apply the formal relation $e^{-\lambda s} = \sum_{n=0}^{\infty} (-\lambda s)^n/n!$ to $f(t)$, we have a formal Taylor expansion

$$f(t - \lambda) = \sum_{n=0}^{\infty} f^{(n)}(t)(-\lambda)^n/n!$$

The solution of linear \dagger difference equations are represented by rational functions of h^λ . The power series $\sum \alpha_n h^n$ of operators always converges. This fact gives an explicit example of a representation by formal power series. Note that the operators $e^{-\lambda s}$ and $e^{-\lambda\sqrt{s}}$ play an essential role in the solution of the \dagger wave equation

$$\frac{\partial^2 \varphi}{\partial x^2} = \frac{\alpha^2 \partial^2 \varphi}{\partial t^2}$$

and the \dagger heat equation

$$\frac{\partial^2 \varphi}{\partial x^2} = \frac{\alpha^2 \partial \varphi}{\partial t}$$

The operator (7) converges to δ for $\lambda \rightarrow 0$, and this gives a \dagger regularization of the Dirac δ -function.

D. Laplace Transform

For every function $\{f(t)\} \in \mathcal{C}$, the limit

$$\lim_{\beta \rightarrow +\infty} \int_0^\beta e^{-\lambda s} f(\lambda) d\lambda = \int_0^\infty e^{-\lambda s} f(\lambda) d\lambda \quad (9)$$

always exists (in the sense of the limit of operators), and as an operator coincides with the original function $\{f(t)\}$. Therefore, if the usual Laplace transform (\rightarrow 240 Laplace Transform) of the function $f(\lambda)$ exists and (9) is a function $g(s)$, then as a function of the differential operator s , $g(s)$ is the operator that is given by the inverse Laplace transform $f(t)$ of $g(s)$. Formulas (4) and (7) are indeed typical examples of this relation, where the left-hand side is the usual Laplace transform of the right-hand side. In the practical computation of (5), we can compute the Laplace inverse transform of the right-hand side. However, if we took the Laplace transform as the foundation of the theory, it would not only be complicated but also be subject to the artificial restriction caused by the convergence condition on Laplace transforms.

In the theory of operational calculus, the transform

$$g(p) = p \int_0^\infty e^{-pt} f(t) dt \quad (10)$$

is sometimes used instead of the Laplace transform itself. But the difference is not essential; we obtain the latter transform merely by

changing the variable from s to p and multiplying the former transform by p .

E. Relation to Distributions

For $f \in \mathcal{C}$, an operator of the form $h^\lambda \cdot s^k \cdot f$ is identified with a distribution of L. Schwartz with support bounded from below. We can identify with a Schwartz distribution the limit of a sequence f_n (or a suitable equivalence class of sequences) of operators of the form $h^\lambda \cdot s^k \cdot f$ such that f_n, f_{n+1}, \dots are identical in the interval $(-n, n)$. The notions of Schwartz distributions and of Mikusiński operators do not include each other, but both are generalizations of the notions of functions and their derivatives. For formulas and examples \rightarrow Appendix A, Table 12.

307 (XIX.13) Operations Research

A. General Remarks

Operations research in the most general sense can be characterized as the application of scientific methods, techniques, and tools to the operations of systems so as to provide those in control with optimum solutions to problems. This definition is due to Churchman, Ackoff, and Arnoff [1]. Operational research began in a military context in the United Kingdom during World War II, and it was quickly taken up under the name operations research (OR) in the United States. After the war it evolved in connection with industrial organization, and its many techniques have found expanding areas of application in the United States, the United Kingdom, and in other industrial countries. Nowadays OR is used widely in industry for solving practical problems, such as planning, scheduling, inventory, transportation, and marketing. It also has various important applications in the fields of agricul-

ture, commerce, economics, education, public service, etc., and some techniques developed in OR have influenced other fields of science and technology.

B. Applications

Applications of OR to practical problems are often carried out by project teams because knowledge of disparate aspects of the problems are required, and interdisciplinary cooperation is indispensable. The following are the major phases of an OR project: (i) formulating the problem, (ii) constructing a mathematical model to represent the system under study, (iii) deriving a solution from the model, (iv) testing the model and the solution derived from it, (v) establishing controls over the solution and putting it to work (implementation).

When the mathematical model that has been constructed in phase (ii) is complicated and/or the amount of data to be handled is large, a digital computer is often utilized in phases (iii) and (iv).

C. Mathematical Models [2]

Typical mathematical models and tools that appear frequently in OR are:

(1) **Optimization model** (→ 264 Mathematical Programming). This model is characterized by one or more real-valued functions, which are called **objective functions**, to be minimized (or maximized) under some constraints. According to the number of objective functions, the types of objective functions, and the types of constraints, this model is classified roughly as follows: (i) **Single-objective model**, which includes linear, quadratic, convex, nonlinear and integer programming models (→ 215 Integer Programming, 255 Linear Programming, 292 Nonlinear Programming, 349 Quadratic Programming); (ii) **multi-objective model**; (iii) **stochastic programming model** (→ 408 Stochastic Programming); (iv) **dynamic programming model** (→ 127 Dynamic Programming); (v) **network flow model** (→ 281 Network Flow Problems).

(2) **Game-theoretic model** (→ 173 Game Theory). Game theory is a powerful tool for deriving a solution to practical problems in which more than one person is involved, with each player having different objectives.

(3) **Inventory model** (→ 227 Inventory Control). It is necessary for most firms to control stocks of resources, products, etc., in order to carry out their activities smoothly; various inventory models have been developed for such problems. Mathematically, optimization techniques (→ 264 Mathematical Program-

ming), Markovian decision processes (→ 127 Dynamic Programming, 261 Markov Processes), and basic probability theory are used to construct models for these problems.

(4) **Queuing model** (→ 260 Markov Chains H). In a telephone system, calls made when all the lines of the system are busy are lost. The problem of computing the **probability of loss** involved was first solved in the pioneering article on queuing theory by A. K. Erlang in 1917. For systems in which calls can be put on hold when all lines are busy, one deals with the waiting time distribution instead of the probability of loss. In the 1930s, F. Pollaczek and A. Ya. Khinchin gave explicit formulas for the characteristic function of the waiting time distribution. In many situations, such as in telephone systems, air and surface traffic, production lines, and computer systems, various congestion phenomena are often observed, and many kinds of queuing models are utilized to analyze the congestion. Mathematically, almost all such models are formulated by using Markov processes. For practical uses, approximation and computational methods are important as well as theoretical results.

(5) **Scheduling model** (→ 376 Scheduling and Production Planning). **Network scheduling** is used to schedule complicated projects (for example, construction of buildings) that consist of a large number of jobs related to each other in some natural order. **PERT** (program evaluation and review technique) and **CPM** (critical path method) are popular computational methods for this model (→ 281 Network Flow Problems). **Job shop scheduling** is used when we have m jobs and n machines and each job requires some of the machines in a given order. The model allows us to find an optimal order (in some certain sense) of jobs to be implemented on each machine.

(6) **Replacement model**. There are two typical cases. One is the **preventive maintenance model**, which is suitable when replacements are done under a routine policy because a replacement or a repair before a failure is more effective than after a failure. Probabilistic treatments are mainly used, and this model resembles those for queues and Markov processes. The other is a model for deciding whether to replace a piece of equipment in use. In this case, we need to compare costs of both used and new equipment, and evaluations of various types of present cost are important.

(7) **Simulation**. This is a numerical experiment in a simulated model of a phenomenon which we want to analyze. Simulation is one of the most popular techniques in OR.

(8) **Other models**. Besides the models listed above, many problems are formulated by way of various other models in OR. In modeling,

†probability theory, and mathematical †statistics, especially, †Markov chain, †multivariate analysis, †design of experiments, †regression analysis, †time series analysis, etc. often play important roles.

308 (XII.19) Operator Algebras

A. Preliminaries

Let \mathfrak{H} be a †Hilbert space. The set of †bounded linear operators on \mathfrak{H} is denoted by $\mathcal{B}(\mathfrak{H}) = \mathcal{B}$. It contains the identity operator I . The notions of operator sum $A + B$, operator product AB , and †adjoint A^* are defined on it. A subalgebra of $\mathcal{B}(\mathfrak{H})$ is called an **operator algebra**. In this article we consider mainly von Neumann algebras. For C^* -algebras → 36 Banach Algebras G–K.

Any †Hermitian operator A (i.e., an operator such that $A = A^*$) has the property that (Ax, x) is always real for any $x \in \mathfrak{H}$. If $(Ax, x) \geq 0$ for any x , A is called **positive**, and we write $A \geq 0$. When Hermitian operators A and B satisfy $A - B \geq 0$, we write $A \geq B$. Thus we introduce an ordering $A \geq B$ between Hermitian operators. A set $\{A_\alpha\}$ of positive Hermitian operators is said to be an **increasing directed set** if any two of them A_α, A_β always have a common majorant A_γ , that is, $A_\alpha \leq A_\gamma$ and $A_\beta \leq A_\gamma$. If a Hermitian operator A satisfies $(Ax, x) = \sup(A_\alpha x, x)$ for such a set, it is called the **supremum** and is denoted by $\sup A_\alpha$. The supremum $\sup A_\alpha$ exists if and only if the $\sup(A_\alpha x, x)$ is finite for any x , and then A_α converges to A with respect to the weak and strong operator topologies.

B. Topologies in \mathcal{B}

Various topologies are introduced in $\mathcal{B} = \mathcal{B}(\mathfrak{H})$: the †uniform operator topology, the †strong operator topology, and the †weak operator topology (→ 251 Linear Operators). These topologies are listed above in order of decreasing fineness. The operation in \mathcal{B} of taking the adjoint, $A \rightarrow A^*$, is continuous with respect to the uniform operator topology and

weak operator topology, but not with respect to the strong operator topology. The operation from $\mathcal{B} \times \mathcal{B}$ to \mathcal{B} of taking the product, $(A, B) \rightarrow AB$, is continuous with respect to the uniform operator topology, is continuous with respect to the strong operator topology when the first factor is restricted to a set bounded in the operator norm, but is not continuous on $\mathcal{B} \times \mathcal{B}$. It is continuous with respect to the weak operator topology when one of the factors is fixed (i.e., it is separately continuous). The set \mathcal{B} is a †Banach space with respect to the operator norm, or, more precisely, a † C^* -algebra. It is a †locally convex topological linear space with respect to the strong or weak operator topology.

The Banach space \mathcal{B} is the †dual of the Banach space \mathcal{B}_* of all †nuclear operators in \mathfrak{H} (→ 68 Compact and Nuclear Operators I). The weak* topology in \mathcal{B} as the dual of \mathcal{B}_* is called the **σ -weak topology**.

C. Von Neumann Algebras

A subset \mathcal{M} of \mathcal{B} is called a **$*$ -subalgebra** if it is a subalgebra (i.e., $A, B \in \mathcal{M}$ implies $\lambda A + \mu B, AB \in \mathcal{M}$) and contains the adjoint A^* of any $A \in \mathcal{M}$. The **commutant** \mathcal{A}' of a subset \mathcal{A} of \mathcal{B} is the set of operators that commute with both A and A^* for $A \in \mathcal{A}$. The commutant is a **$*$ -subalgebra**, and $\mathcal{A}' = \mathcal{A}''$.

A **von Neumann algebra** \mathcal{M} is a **$*$ -subalgebra** of \mathcal{B} that is defined by one of the following four equivalent conditions: (i) \mathcal{M} is a **$*$ -subalgebra** of \mathcal{B} containing I , closed under the weak operator topology; (ii) \mathcal{M} is a **$*$ -subalgebra** of \mathcal{B} containing I , closed under the strong operator topology; (iii) \mathcal{M} is the commutant of a subset of \mathcal{B} (or, equivalently, $\mathcal{M} = \mathcal{M}''$); (iv) \mathcal{M} is a **$*$ -subalgebra** of \mathcal{B} containing I , closed under the uniform operator topology, and, as a Banach space, coinciding with the conjugate space of some Banach space. Note that a **$*$ -subalgebra** of \mathcal{B} , closed under the uniform operator topology, is a C^* -algebra. Von Neumann algebras are also called **rings of operators** or **W^* -algebras**. The latter term is usually used for a C^* -algebra **$*$ -isomorphic** to a von Neumann algebra in contrast to a concrete von Neumann algebra.

The study of these algebras was started by J. von Neumann in 1929. He showed the equivalence of conditions (i)–(iii) (**von Neumann's density theorem**), and established a foundation for the theory named after him [1]. The notion of von Neumann algebras can be regarded as a natural extension of the notion of matrix algebras in a finite-dimensional space, and therein lies the importance of the theory. The

fourth condition of the definition was given by S. Sakai (*Pacific J. Math.*, 1956).

The following theorem is of use in the theory of von Neumann algebras: Given a *-subalgebra \mathcal{A} of \mathcal{B} containing I , its closure \mathcal{M} with respect to the weak or strong operator topology is von Neumann algebra; and when we denote the set of elements of operator norm ≤ 1 in \mathcal{A} (resp. \mathcal{M}) by \mathcal{A}_1 (resp. \mathcal{M}_1), \mathcal{M}_1 is likewise the closure of \mathcal{A}_1 with respect to the weak or strong operator topology (**Kaplan-sky's density theorem** (*Ann. Math.*, 1951)).

If E is a projection operator in a von Neumann algebra \mathcal{M} , then $E\mathcal{M}E = \{EAE \mid A \in \mathcal{M}\}$ is a *-subalgebra of \mathcal{B} closed with respect to the weak operator topology. It is not a von Neumann algebra because it does not contain I , but since its elements operate exclusively in the closed subspace $E\mathfrak{H}$, we can regard it as an algebra of operators on $E\mathfrak{H}$. In this sense, $E\mathcal{M}E$ can be regarded as a von Neumann algebra on $E\mathfrak{H}$, which we call the **reduced von Neumann algebra** of \mathcal{M} on $E\mathfrak{H}$ and write \mathcal{M}_E . If E is a projection operator in \mathcal{M} , $E\mathcal{M}E = E\mathcal{M}$ restricted to the subspace $E\mathfrak{H}$ is called the **induced von Neumann algebra** of \mathcal{M} on $E\mathfrak{H}$ and is denoted also by \mathcal{M}_E . In the latter case, the mapping $A \in \mathcal{M} \rightarrow EAE \in \mathcal{M}_E$ is a *-homomorphism and is called the **induction** of \mathcal{M} onto \mathcal{M}_E .

The **tensor product** $\mathfrak{H}_1 \otimes \mathfrak{H}_2$ of two Hilbert spaces \mathfrak{H}_i ($i=1, 2$) is the \dagger completion of their \dagger tensor product as a complex linear space equipped with the unique \dagger inner product satisfying $(f_1 \otimes f_2, g_1 \otimes g_2) = (f_1, g_1)_1 (f_2, g_2)_2$ for all $f_i, g_i \in \mathfrak{H}_i$. For any $A_i \in \mathcal{B}(\mathfrak{H}_i)$, there exists a unique operator in $\mathcal{B}(\mathfrak{H}_1 \otimes \mathfrak{H}_2)$ denoted by $A_1 \otimes A_2$ satisfying $(A_1 \otimes A_2)(f_1 \otimes f_2) = A_1 f_1 \otimes A_2 f_2$ for all $f_i \in \mathfrak{H}_i$. For von Neumann algebras $\mathcal{M}_i \subset \mathcal{B}(\mathfrak{H}_i)$, the von Neumann algebra generated by $A_1 \otimes A_2$ with $A_i \in \mathcal{M}_i$ is denoted by $\mathcal{M}_1 \otimes \mathcal{M}_2$ and is called the **tensor product** of \mathcal{M}_1 and \mathcal{M}_2 . The *-isomorphism $A \in \mathcal{M} \rightarrow A \otimes I \in \mathcal{M} \otimes \mathbf{I}$, where \mathbf{I} is the trivial von Neumann algebra consisting solely of complex multiples of the identity operator, is called an **amplification**.

For two von Neumann algebras $\mathcal{M}_i \subset \mathcal{B}(\mathfrak{H}_i)$ ($i=1, 2$), a *-isomorphism π from \mathcal{M}_1 into \mathcal{M}_2 is called **spatial** if there exists a unitary (i.e., a bijective isometric linear) mapping U from \mathfrak{H}_1 to \mathfrak{H}_2 such that $UAU^* = \pi A$ for all $A \in \mathcal{M}_1$, and a *-homomorphism π is called **normal** if $\sup_x \pi A_x = \pi(\sup_x A_x)$ whenever A_x is a bounded increasing net in \mathcal{M} . Any normal *-homomorphism is continuous in the strong and weak operator topologies and is a product of an amplification, a spatial *-isomorphism, and an induction. Its kernel is of the form $E\mathcal{M}$, where E is a projection operator belonging to the **center** $\mathcal{Z} = \mathcal{M} \cap \mathcal{M}'$ of \mathcal{M} . This gives a com-

plete description of all possible **normal representations** (i.e., a normal *-homomorphism into some \mathcal{B}) of a von Neumann algebra.

D. States, Weights, and Traces

A **state** φ of a C^* -algebra \mathcal{A} is a complex-valued function on \mathcal{A} that is (1) complex linear: $\varphi(A+B) = \varphi(A) + \varphi(B)$, $\varphi(cA) = c\varphi(A)$ for $A, B \in \mathcal{A}$, $c \in \mathbb{C}$, (2) **positive**: $\varphi(A^*A) \geq 0$ for $A \in \mathcal{A}$, and (3) **normalized**: $\|\varphi\| = 1$ (equivalent to $\varphi(I) = 1$ if $I \in \mathcal{A}$). For any positive linear functional φ on \mathcal{A} , there exists a triplet $(\mathfrak{H}_\varphi, \pi_\varphi, \xi_\varphi)$ (unique up to the unitary equivalence) of a Hilbert space \mathfrak{H}_φ , a representation π_φ (i.e., a *-homomorphism into $\mathcal{B}(\mathfrak{H}_\varphi)$) of \mathcal{A} , and a vector ξ_φ in \mathfrak{H}_φ such that $\varphi(A) = (\pi_\varphi(A)\xi_\varphi, \xi_\varphi)$ and \mathfrak{H}_φ is the closure of $\pi_\varphi(\mathcal{A})\xi_\varphi$. The space \mathfrak{H}_φ is constructed by defining the inner product $(\eta(A), \eta(B)) = \varphi(B^*A)$ in the quotient of \mathcal{A} by its left ideal $\{A \mid \varphi(A^*A) = 0\}$, where η is the quotient mapping, and by completion. Then π_φ is defined by $\pi_\varphi(A)\eta(B) = \eta(AB)$. This is called the **GNS construction** after its originators I. M. Gel'fand, M. A. Naïmark, and I. E. Siegel.

A **weight** φ on a von Neumann algebra \mathcal{M} is a function defined on the positive elements of \mathcal{M} , with positive real or infinite values, which is additive and homogeneous ($\varphi(A+B) = \varphi(A) + \varphi(B)$ and $\varphi(\lambda A) = \lambda\varphi(A)$ for all $A, B \in \mathcal{M}$ and $\lambda \geq 0$ with the convention $0 \cdot \infty = 0$ and $\infty + a = \infty$). It is said to be **faithful** if it does not vanish except for $\varphi(0) = 0$, **normal** if $\varphi(A) = \sup \varphi(A_x)$ whenever A_x is an increasing net of positive elements of \mathcal{M} and $A = \sup A_x$, and **semifinite** if the left ideal \mathfrak{N}_φ , consisting of all elements $A \in \mathcal{M}$ for which $\varphi(A^*A)$ is finite, has the property that the linear span \mathfrak{M}_φ of $\mathfrak{N}_\varphi^* \mathfrak{N}_\varphi$ is dense in \mathcal{M} . The restriction of φ to positive elements of \mathfrak{M}_φ has a unique extension to a linear functional on \mathfrak{M}_φ , which we denote by the same letter φ . Canonically associated with a normal semifinite weight φ , there exists a Hilbert space \mathfrak{H}_φ , a normal *-representation π_φ of \mathcal{M} , and a complex linear mapping η from \mathfrak{N}_φ into a dense subset of \mathfrak{H}_φ such that $(\eta(B'), \eta(B)) = \varphi(B^*B)$, and $\pi_\varphi(A)\eta(B) = \eta(AB)$, where $B, B' \in \mathfrak{N}_\varphi$ and $A \in \mathcal{M}$. If φ is **finite** (i.e., $\mathfrak{N}_\varphi = \mathcal{M}$), then its extension to \mathcal{M} is a positive linear functional for which the triplet $(\mathfrak{H}_\varphi, \pi_\varphi, \eta(1))$ is given by the GNS construction.

The linear span of all normal states of a von Neumann algebra \mathcal{M} is a norm-closed subspace of its dual \mathcal{M}^* , called its **predual** and denoted by \mathcal{M}_* , because \mathcal{M} turns out to be the dual of \mathcal{M}_* .

A **trace** t on a von Neumann algebra \mathcal{M} is a weight satisfying $t(UAU^*) = t(A)$ for U unitary

in \mathcal{M} and for all positive A in \mathcal{M} (equivalently, $t(A^*A) = t(AA^*)$ for all $A \in \mathcal{M}$).

E. The von Neumann Classification

A von Neumann algebra for which a semi-finite normal trace does not exist is called a **purely infinite** von Neumann algebra or von Neumann algebra of **type III**. In contrast to this, a von Neumann algebra \mathcal{M} is called **semifinite** (resp. **finite**) if for each positive Hermitian operator $A (\neq 0)$ in \mathcal{M} there is a semi-finite (resp. finite) normal trace t such that $t(A) \neq 0$. Every Abelian von Neumann algebra is finite. If there are no central projection operators $E \neq 0$ such that \mathcal{M}_E is finite, \mathcal{M} is called **properly infinite**. Purely infinite \mathcal{M} and $\mathcal{B}(\mathfrak{H})$ for infinite \mathfrak{H} , for example, are properly infinite. A nonzero projection operator E in \mathcal{M} is called **Abelian** when \mathcal{M}_E is Abelian. We call \mathcal{M} a von Neumann algebra of **type I** (or **discrete**) when it contains an Abelian projection E for which I is the only central projection P covering E (i.e., $E \leq P$). A von Neumann algebra is of **type II** if it is semifinite and contains no Abelian projection. A von Neumann algebra of type II is called of **type II₁** if it is finite and of **type II_∞** if it is properly infinite. A finite von Neumann algebra is also characterized as a von Neumann algebra in which the operation of taking the adjoint is continuous with respect to the strong operator topology on bounded spheres (Sakai, *Proc. Japan Acad.*, 1957). A properly infinite von Neumann algebra \mathcal{M} is characterized by the property that \mathcal{M} and $\mathcal{M} \otimes \mathcal{B}(\mathfrak{H})$ for any separable \mathfrak{H} is $*$ -isomorphic.

Given a von Neumann algebra \mathcal{M} , there exist mutually orthogonal projections E_I, E_{II}, E_{III} in the center \mathcal{L} of \mathcal{M} such that $E_I + E_{II} + E_{III} = I$, and $\mathcal{M}_{E_I}, \mathcal{M}_{E_{II}}, \mathcal{M}_{E_{III}}$ are von Neumann algebras of type I, type II, type III, respectively. This decomposition is unique. There also exist unique central projections E_f and E_i such that \mathcal{M}_{E_f} is finite, \mathcal{M}_{E_i} is properly infinite, and $E_f + E_i = 1$. The two decompositions can be combined. (If some of the projections E are 0, the condition on the corresponding \mathcal{M}_E is to be waived.)

F. Factors

A von Neumann algebra whose center consists exclusively of scalar multiples of the identity operator is called a **factor**. Von Neumann's reduction theory (\rightarrow Section G) reduces the study of arbitrary von Neumann algebras on a separable Hilbert space more or less to the study of factors. Factors are classified into **types I_n** ($n = \infty, 1, 2, \dots$), **II₁** (i.e., of type II and

finite), **II_∞** (i.e., of type II and not finite), and **III**. A factor of type I_n is isomorphic to the algebra $\mathcal{B}(\mathfrak{H})$ of all bounded operators on an n -dimensional Hilbert space \mathfrak{H} . Since the discovery of two nonisomorphic examples of factors of type II₁ by F. J. Murray and von Neumann (1943), classification of factors has been a central problem in the theory of von Neumann algebras. After 1967, great progress was made in the investigation of isomorphism classes of factors, and we have uncountably many nonisomorphic examples of factors of types II₁, II_∞, and III. After the discovery of the third to ninth nonisomorphic examples of factors of type II₁ by J. Schwartz (1963) (the third example, 1963), W. Ching (the fourth), Sakai (the fifth), J. Dixmier and E. C. Lance (the sixth and seventh), and G. Zeller-Meier (the eighth and ninth), D. McDuff showed that there exist countably many nonisomorphic examples of factors of type II₁, and finally McDuff (*Ann. Math.*, 1969) and Sakai (*J. Functional Anal.*, 1970) showed the existence of uncountably many nonisomorphic examples of factors of type II₁. For type III factors \rightarrow Section I.

G. The Integral Direct Sum and Decomposition into Factors

The Hilbert spaces considered in this section are all \dagger separable. Let $(\mathfrak{M}, \mathcal{E}, \mu)$ be a \dagger measure space; with each $\zeta \in \mathfrak{M}$ we associate a Hilbert space $\mathfrak{H}(\zeta)$. We consider functions $x(\zeta)$ on \mathfrak{M} whose values are in $\mathfrak{H}(\zeta)$ for each ζ . Let \mathbf{K} be a set of these functions having the following properties: (i) $\|x(\zeta)\|$ is measurable for $x(\zeta) \in \mathbf{K}$; (ii) if for a function $y(\zeta)$, the numerical function $(x(\zeta), y(\zeta))$ is measurable any $x(\zeta) \in \mathbf{K}$, then $y(\zeta) \in \mathbf{K}$; (iii) there is a countable family $\{x_1(\zeta), x_2(\zeta), \dots\}$ of functions in \mathbf{K} such that for each fixed $\zeta \in \mathfrak{M}$, the set $\{x_1(\zeta), x_2(\zeta), \dots\}$ is dense in $\mathfrak{H}(\zeta)$. Then \mathbf{K} is a linear space. We call each function in \mathbf{K} a **measurable vector function**. We introduce in the set of measurable vector functions $x(\zeta)$ with

$$\int \|x(\zeta)\|^2 d\mu(\zeta) < \infty$$

an equivalence relation by defining $x(\zeta)$ and $y(\zeta)$ as equivalent when

$$\int \|x(\zeta) - y(\zeta)\|^2 d\mu(\zeta) = 0.$$

Thus we obtain a space of equivalence classes which we denote by \mathfrak{F} . \mathfrak{F} is a Hilbert space with the inner product

$$(x, y) = \int (x(\zeta), y(\zeta)) d\mu(\zeta),$$

which is called the **integral direct sum** (or **direct integral**) of $\mathfrak{H}(\zeta)$. An operator function $A(\zeta)$ that associates with each $\zeta \in \mathfrak{M}$ a bounded linear operator $A(\zeta)$ on $\mathfrak{H}(\zeta)$ is called **measurable** if for any measurable $x(\zeta)$, $A(\zeta)x(\zeta)$ is also measurable. If, moreover, $\|A(\zeta)\|$ is bounded, $A(\zeta)$ transforms a function in \mathfrak{H} to a function in \mathfrak{H} and thus defines a bounded linear operator on \mathfrak{H} . This operator is called the **integral direct sum** (or **direct integral**) of $A(\zeta)$, and an operator on \mathfrak{H} that can be reduced to this form is called **decomposable**.

Generally, let \mathfrak{H} be a Hilbert space, and consider an Abelian von Neumann algebra \mathcal{A} on \mathfrak{H} . Then we construct a measure space $(\mathfrak{M}, \mathcal{E}, \mu)$ and represent \mathcal{A} as the set of bounded measurable functions on \mathfrak{M} . (This is possible in different ways. The Gelfand representation is an example.) Then a Hilbert space $\mathfrak{H}(\zeta)$ can be constructed so that \mathfrak{H} is represented as the integral direct sum of $\mathfrak{H}(\zeta)$. Operators in \mathcal{A} are all decomposable and are called **diagonalizable**. A von Neumann algebra \mathcal{M} on \mathfrak{H} whose elements are all decomposable is characterized by $\mathcal{M} \subset \mathcal{A}$. The $A(\zeta)$ yielded by the decomposition of operators A in \mathcal{M} generate a von Neumann algebra $\mathcal{M}(\zeta)$ on $\mathfrak{H}(\zeta)$. If we take as \mathcal{A} the center \mathcal{Z} of \mathcal{M} , then almost all the $\mathcal{M}(\zeta)$ are factors (**von Neumann's reduction theory**), and if we take as \mathcal{A} a maximal Abelian von Neumann algebra contained in \mathcal{M} , then almost all the $\mathcal{M}(\zeta)$ are type I factors (F. I. Mautner, *Ann. Math.*, 1950).

H. Tomita-Takesaki Theory

Motivated by the problem of proving the commutant theorem for tensor products (i.e., $(\mathcal{M}_1 \otimes \mathcal{M}_2)' = \mathcal{M}_1' \otimes \mathcal{M}_2'$), which remained unsolved for algebras of type III up until that time, Tomita succeeded in 1967, after years of effort, in generalizing the theory of Hilbert algebras, previously developed only for semifinite von Neumann algebras. The most important ingredient of this theory lies in certain one-parameter groups of $*$ -automorphisms of a von Neumann algebra, called modular automorphisms (see below), each one-parameter group of modular automorphisms being intrinsically associated with a faithful semifinite normal weight of the algebra. Tomita's theory was perfected by Takesaki [13], who also showed that modular automorphisms satisfy (and are characterized by) a condition originally introduced in statistical mechanics by the physicists R. Kubo, P. C. Martin, and J. Schwinger and accordingly known as the KMS condition. In the mathematical foundations of statistical mechanics, this condition characterizes equilibrium states of a physical

system for a given one-parameter group of automorphisms (of a C^* -algebra) describing the time-development of the system. It was a fortunate coincidence that this condition was formulated in a so-called C^* -algebra approach to statistical mechanics by R. Haag, N. M. Hugenholtz, and M. Winnink [14] at about the same time that Tomita's work appeared in 1967. The original proofs of the Tomita-Takesaki theory have been simplified considerably by the work of M. Rieffel [16] and A. Van Daele [15]. Deeper insight into the significance of modular automorphisms is also provided by the work of A. Connes [19], showing that the group of modular automorphisms (up to inner automorphisms) is intrinsic to the von Neumann algebra (i.e., independent of the weight) and belongs to the center of $\text{Out } \mathcal{M}$ (the group $\text{Aut } \mathcal{M}$ of all $*$ -automorphisms of the von Neumann algebra \mathcal{M} modulo the subgroup $\text{Int } \mathcal{M}$ of all inner $*$ -automorphisms).

Some of the basic definitions and results of the **Tomita-Takesaki theory** are as follows. If φ is a normal semifinite faithful weight on \mathcal{M} , the antilinear operator S_φ , defined on a dense subset $\eta(\mathfrak{N}_\varphi \cap \mathfrak{N}_\varphi^*)$ of \mathfrak{H}_φ (\rightarrow Section D) by the relation $S_\varphi \eta(A) = \eta(A^*)$, is \dagger closable and the polar decomposition $\overline{S_\varphi} = J_\varphi \Delta_\varphi^{1/2}$ of its closure defines a positive self-adjoint operator Δ_φ , called a **modular operator**, and an antiunitary involution J_φ . The principal results of the Tomita-Takesaki theory are (1) if $x \in \mathcal{M}$, then $\sigma_t^\varphi(A) \equiv \Delta_\varphi^{it} A \Delta_\varphi^{-it} \in \mathcal{M}$ for all real t , and this defines a continuous one-parameter group of $*$ -automorphisms σ_t^φ of \mathcal{M} , called **modular automorphisms**, and (2) if $A \in \mathcal{M}$, then $j_\varphi(A) \equiv J_\varphi A J_\varphi \in \mathcal{M}'$, and j_φ is a conjugate-linear isomorphism of \mathcal{M} onto \mathcal{M}' . A weight φ on \mathcal{M} is said to satisfy the **KMS condition** at β (a real number) relative to a one-parameter group of $*$ -automorphisms σ_t of \mathcal{M} if, for every pair $A, B \in \mathfrak{N}_\varphi \cap \mathfrak{N}_\varphi^*$, there exists a bounded continuous function $F(z)$ (depending on A, B), on $0 \leq \text{Im } z \leq \beta$ holomorphic in $0 < \text{Im } z < \beta$ and such that $F(t) = \varphi(A \sigma_t(B))$ and $F(t + i\beta) = \varphi(\sigma_t(B)A)$. A given one-parameter group σ_t coincides with a group of modular automorphisms σ_t^φ if and only if φ satisfies the KMS condition at $\beta = -1$ relative to σ_t . (In statistical mechanics, $\beta = (kT)^{-1}$, where k is the Boltzmann constant and T the absolute temperature of the system.)

I. Structure and Classification of Factors of Type III

At the Baton Rouge Conference in 1967, R. T. Powers reported his results [17] on non-isomorphism of the one-parameter family

of factors of type III (now called **Powers's factors**), which had been constructed by von Neumann in 1938 in terms of an infinite tensor product of factors of type I (abbreviated as **ITPFI**). Prior to Powers's work only three different kinds of factors of type III, along with the same number of factors of type II₁, had been distinguished. A systematic classification of ITPFIs was subsequently given by H. Araki and E. J. Woods [18] in terms of two invariants, i.e., the **asymptotic ratio set** $r_\infty(\mathcal{M})$ and the **ρ -set** $\rho(\mathcal{M})$ of the von Neumann algebra \mathcal{M} . Using the Tomita-Takesaki theory, Connes [19] introduced two invariants, namely the **S-set** $S(\mathcal{M})$ (the intersection of the spectra of all modular operators) and the **T-set** $T(\mathcal{M})$ (the set of all real t for which the modular automorphism σ_t^ρ is inner), and, when \mathcal{M} is an ITPFI, proved the equality $S(\mathcal{M}) = r_\infty(\mathcal{M})$ and the relation $T(\mathcal{M}) = 2\pi |\log \rho(\mathcal{M})|^{-1}$. The S-set $S(\mathcal{M})$ of a factor of type III on a separable Hilbert space is either the set of all non-negative reals (**type III₁**), the set of all integral powers of λ (where $0 < \lambda < 1$) and 0 (**type III_λ**), or the set $\{0, 1\}$ (**type III₀**). The work of Araki and Woods shows that there exists only one ITPFI of type III_λ for each $\lambda \in (0, 1)$ (the examples of Powers) as well as for $\lambda = 1$, while there exist continuously many ITPFIs of type III₀. Woods [20] has shown that the classification of ITPFIs of type III₀ is not smooth.

A structural analysis of factors of type III, given independently by Connes [19], Takesaki (*Acta Math.*, 1973), and Araki (*Publ. Res. Inst. Math. Sci.*, 1973) expressed independently a certain class of factors of type III as a kind of crossed product of semifinite von Neumann algebras with their injective endomorphisms (automorphism in the case of Connes). These analyses led Takesaki [21] to the discovery of a duality theorem for crossed products of von Neumann algebras with locally compact groups of their *-automorphisms (→ Section J) and its application to the following **structure theorem for von Neumann algebras of type III**. The crossed product of a von Neumann algebra \mathcal{M} with the group of modular automorphisms σ_t^ρ is a von Neumann algebra \mathcal{N} of type II_∞, with a canonical action θ_t of the dual group as a one-parameter group of *-automorphisms which is trace-scaling, i.e., $\tau \circ \theta_t = e^{-t} \tau$ for some faithful normal trace τ . If \mathcal{M} is properly infinite, the crossed product of \mathcal{N} with θ_t is isomorphic to the original von Neumann algebra \mathcal{M} . In particular, any von Neumann algebra \mathcal{M} of type III can be written as the crossed product of a von Neumann algebra \mathcal{N} of type II_∞ with a one-parameter group of trace-scaling *-automorphisms θ_t . The isomorphism class of \mathcal{M} is determined by the isomorphism class of \mathcal{N} together with the

conjugacy class of θ_t modulo inner automorphisms. The restriction $\tilde{\theta}_t$ of θ_t to the center \mathcal{Z} of \mathcal{N} is of special importance. \mathcal{M} is a factor if and only if $\tilde{\theta}_t$ is ergodic. In that case, \mathcal{M} is of type III₁ if \mathcal{N} is a factor, \mathcal{M} is of type III_λ, $0 < \lambda < 1$, if $\tilde{\theta}_t$ is periodic with period $-\log \lambda$, and \mathcal{M} is of type III₀ if $\tilde{\theta}_t$ is aperiodic and not isomorphic to the one-parameter group of *-automorphisms of $L_\infty(\mathbf{R})$ induced by the translations of the real line \mathbf{R} . (The excluded case does not occur for \mathcal{M} of type III.)

A von Neumann algebra on a separable Hilbert space is called **approximately finite-dimensional** (or **approximately finite** or **hyperfinite**) if it is generated by an increasing sequence of finite-dimensional *-subalgebras. This class of von Neumann algebras includes many important examples, such as ITPFI and the von Neumann algebra generated by any representation of canonical commutation (or anticommutation) relations on a separable Hilbert space. The classification of approximately finite-dimensional factors is almost complete. In fact the uniqueness of an approximately finite-dimensional factor of type II₁ has been known since the work of von Neumann. It is called the **hyperfinite factor**. The uniqueness of approximately finite-dimensional factors of type II_∞ (which is then the tensor product of the hyperfinite factor with $\mathcal{B}(\mathfrak{H})$) and of type III_λ, $0 < \lambda < 1$, (which are then Powers's factors) has been demonstrated by Connes [22]. Approximately finite-dimensional factors of type III₀ are classified exactly by the isomorphism classes of the ergodic groups $\tilde{\theta}_t$ of *-automorphisms of commutative von Neumann algebras \mathcal{Z} . Any such factor is a **Krieger's factor**, i.e., a crossed product of a commutative von Neumann algebra with a single *-automorphism. Examples of such factors have been extensively studied by Krieger, who has also shown [23] that isomorphism of a Krieger's factor is equivalent to weak equivalence of the associated nonsingular transformation of the standard measure space.

A von Neumann algebra on a separable Hilbert space is approximately finite-dimensional if and only if it is injective (→ 36 Banach Algebras H).

J. Crossed Products

The **crossed product** $\mathcal{M} \otimes_\alpha G$ of a von Neumann algebra \mathcal{M} (acting on a Hilbert space \mathfrak{H}) and a locally compact Abelian group G relative to a continuous action α of G on \mathcal{M} (by *-automorphisms α_g , $g \in G$) is the von Neumann algebra \mathcal{N} generated by the operators $\pi(A)$, $A \in \mathcal{M}$ and $\lambda(h)$, $h \in G$, defined on the Hilbert space $L_2(G, \mathfrak{H})$ of all \mathfrak{H} -valued L_2 -

functions on G (relative to the Haar measure) by

$$[\pi(A)\xi](g) = \alpha_g^{-1}(A)\xi(g),$$

$$[\lambda(h)\xi](g) = \xi(h^{-1}g),$$

where $\xi \in L_2(G, \mathfrak{H})$. The canonical action $\hat{\alpha}$ of the dual \hat{G} on \mathcal{N} is defined by $\hat{\alpha}_p(B) = \mu(p)B\mu(p)^*$ for $B \in \mathcal{N}$ and $p \in \hat{G}$, where $\mu(p)$ is defined by $[\mu(p)\xi](g) = \langle g, p \rangle \xi(g)$. The **duality theorem of Takesaki** [21] asserts that $[\mathcal{M} \otimes_\alpha G] \otimes_\alpha \hat{G}$ is isomorphic to $\mathcal{M} \otimes \mathcal{B}(L_2(G))$, where the second factor $\mathcal{B}(L_2(G))$ is the algebra of all bounded linear operators on $L_2(G)$.

K. Natural Positive Cone

The closure V^α of the set of vectors $\Delta_\phi^\alpha \eta(A)$ for all positive A in $\mathfrak{N}_\phi \cap \mathfrak{N}_\phi^*$ reflects certain properties of the von Neumann algebra \mathcal{M} for $0 \leq \alpha \leq 1/2$ [24, 25]. In particular, $V^{1/4}$ is called the **natural positive cone**. It is a self-dual closed convex cone, and is intrinsic to the von Neumann algebra \mathcal{M} (i.e., independent of the weight ϕ). Every normal positive linear functional ψ on \mathcal{M} has a unique representative $\xi(\psi)$ in this cone (i.e., $\psi(A) = (\pi_\phi(A)\xi(\psi), \xi(\psi))$), and the mapping ξ is a concave, monotone, bijective homeomorphism, homogeneous of degree $1/2$. The group of all $*$ -automorphisms of \mathcal{M} has a natural unitary representation $U(g)$, $g \in \text{Aut } \mathcal{M}$, satisfying the relations $U(g)AU(g)^* = g(A)$, $U(g)\xi(\phi) = \xi(\phi \circ g^{-1})$.

L. C^* -Algebras and von Neumann Algebras

Let a C^* -algebra \mathcal{A} be given. A $*$ -representation $x \rightarrow T_x$ gives rise to a von Neumann algebra \mathcal{M} , generated by T_x , $x \in \mathcal{A}$. The type of this representation is defined according to the type of \mathcal{M} . A C^* -algebra is called a **C^* -algebra of type I** if its $*$ -representations are always of type I. It is known that this class is exactly the class of GCR algebras (\rightarrow 36 Banach Algebras H). It is also known that a separable non-type I C^* -algebra has a representation of type II and a general non-type I C^* -algebra has a representation of type III (J. Glimm, *Ann. Math.*, 1961; Sakai [8]).

For a C^* -algebra \mathcal{A} , all its representations generate \dagger injective von Neumann algebras if and only if \mathcal{A} is \dagger nuclear [26, 27].

M. Topological Groups and von Neumann Algebras

Consider a unitary representation $g \rightarrow U_g$ of a locally compact Hausdorff group G (\rightarrow 423

308 Ref. Operator Algebras

Topological Groups). If this representation is a \dagger factor representation, the type of this representation is defined according to the type of the von Neumann algebra \mathcal{M} generated by U_g , $g \in G$. A \dagger group of type I is a group whose factor representations are all of type I. For example, connected semisimple Lie groups and connected nilpotent Lie groups are of type I (Harish-Chandra, *Trans. Amer. Math. Soc.*, 1953; J. M. G. Fell, *Proc. Amer. Math. Soc.*, 1962). Examples of groups that are not of type I are known (\rightarrow 437 Unitary Representation E).

309 (XX.7) Orbit Determination

A. General Remarks

The purposes of the theory of **orbit determination** are (1) to study properties of orbits of celestial bodies, (2) to determine orbital elements from observed positions of the celestial bodies, and (3) to compute their predicted positions utilizing the orbital elements. Celestial bodies to which the theory is applied are mainly planets, asteroids, comets, satellites, and artificial satellites in the solar system, although orbits of meteors and visual, photo-

metric, and eclipsing binaries can be determined by similar methods.

B. Kepler's Orbital Elements

Consider, for example, an asteroid moving on an ellipse with one focus at the sun. The elliptic orbit is fixed by the initial conditions of the motion or the integration constants of the †Hamilton-Jacobi equation (→ 55 *Celestial Mechanics*) and is described by **Kepler's orbital elements** a, e, ω, i, Ω , and t_0 (Fig. 1).

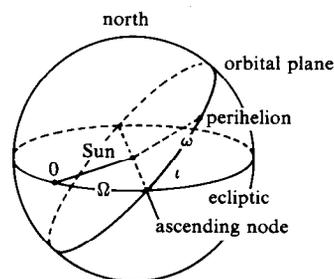

Fig. 1
Orbital elements

The size and shape of the ellipse are determined by the semimajor axis (half the †major axis) a and the †eccentricity e , while the argument ω of perihelion, measured from the ascending node to the perihelion, shows the direction of the major axis. (Sometimes, we adopt as one of the main parameters the **perihelion distance** $q = a(1 - e)$ instead of the semimajor axis a .) The position of the orbital plane is determined by the inclination angle i to the ecliptic and the longitude Ω of the ascending node, and then the position of the asteroid on the orbit is determined by the time t_0 of the perihelion passage. The period T of one revolution, or **mean motion** $n = 2\pi/T$, which is the mean angular velocity, is computed by Kepler's third law $n^2 a^3 = \mu$, with μ a constant depending on the mass of the asteroid. The mean motion is a fundamental frequency in the solution of the Hamilton-Jacobi equation and is obtained by differentiating the energy constant $-\mu/2a$ with respect to an action variable $\sqrt{\mu a}$.

To express the position of the asteroid on the ellipse as a function of time, we use the **true anomaly** v , which is the angular distance of the asteroid from the perihelion, the **eccentric anomaly** E , and the **mean anomaly** $M = n(t - t_0)$. Of these three anomalies the mean anomaly can be derived directly from Kepler's elements, although it must be transformed to the true anomaly or to the eccentric anomaly when we compute the coordinates of the aster-

oid. Kepler's equation

$$E - e \sin E = M \quad (1)$$

holds between E and M . Solving this equation, we obtain an expression for E as a function of M :

$$E = M + \sum_{n=1}^{\infty} \frac{2}{n} J_n(ne) \sin nM, \quad (2)$$

where J_n is the †Bessel function of order n . However, in practical computations, we often solve equation (1) directly by numerical methods or by using tables.

C. Orbit Determination

An astrometric observation of a celestial body usually consists of measurements of two coordinates (right ascension and declination) on the celestial sphere. Therefore, to derive six orbital elements, three sets of observations should be made at three moments separated by appropriate time intervals. If the topocentric distance of the celestial body is known, the orbital elements can be computed directly from observations. However, since the distance is not usually known, special methods have had to be developed. A method for orbit determination was worked out by C. F. †Gauss at the beginning of the 19th century to find the orbit of Ceres, the first asteroid to be discovered. Although the topocentric distances are not known, we know that orbits of asteroids are planar, and Kepler's second law, the law of conservation of areal velocity, holds approximately. Therefore we can assume that the area of the triangle made by the sun and the two positions of the asteroid observed at different moments is proportional to the corresponding time interval. Using this property of the orbit we can derive the topocentric distance and then the orbital elements. This method is called the indirect method, and similar methods can be developed for parabolic and hyperbolic orbits.

D. Osculating Elements and Orbit Improvement

For the †two-body problem the orbit is a fixed and invariable ellipse, and therefore Kepler's orbital elements are constants. On the other hand, when gravitational interactions from other bodies cannot be disregarded, the orbital elements are found to be variable by computing the †perturbations by the †method of variation of constants. The perturbations are expressed as sums of periodic, †secular, and long-periodic terms.

Orbit Determination

Because of the perturbations, the orbit deviates from the fixed ellipse, although at every moment the instantaneous velocity and position of the asteroid determines an ellipse. The orbital elements of the ellipse thus defined at each moment, called **osculating elements**, are variable with time. To compute perturbations that cause this change of osculating elements, it is necessary to observe the initial conditions of motion, i.e., the osculating elements at the initial moment. During a time interval shorter than the period of one revolution, the variations of the osculating elements are usually very small. Therefore, by three sets of observations made at three moments at short intervals, it is possible to determine the orbital elements that can be identified with the osculating elements observed at the mean moment. However, if the intervals are very short, errors in the determined values often are very large, and it becomes necessary to carry out observations at distant moments also. When such additional observations are made, those data are compared with the respective values that follow from the initial observations, and the perturbations computed from them; then the method of least squares is used to improve the estimation of the orbital elements.

E. Artificial Satellites

Since the periods of revolution of asteroids are of the order of a few years, the osculating elements change very little in a few weeks. On the other hand, for artificial satellites moving around the earth, the periodic as well as secular perturbations become very large after a few hours because the period of revolution may be as short as two hours. Therefore, to determine orbital elements for artificial satellites, observed positions should be corrected by subtracting the effects of periodic perturbations computed from approximate orbital elements already known. By using the observations thus corrected, mean orbital elements are derived by the method of orbit improvement. The approximate orbital elements can be computed if the launching conditions of the satellites are known. In this manner, mean orbital elements can be derived every day, and variations of the mean orbital elements, or amounts of secular perturbations, for a certain period (say, for 100 days) are found. From them, information on atmospheric density and the gravitational potential of the earth are derived. It should be remarked that for artificial satellites distance measurements have been made by radar, and velocity determinations have been made by measuring the Doppler effect.

For satellites of other planets, measurements of two coordinates with respect to the centers of the planets are made. Masses of planets can be computed by Kepler's third law when the orbital elements of satellites are known, and gravitational potentials of the planets can be determined from their secular perturbations.

F. Binaries

In the study of visual binaries, methods similar to those for satellites can be applied, although the exact estimation of the distances to binaries is often impossible. For photometric binaries radial components of velocities are derived by measuring the Doppler effect; and for eclipsing binaries important information, such as their masses, densities, and sizes, as well as data regarding their internal constitutions, can be derived from the observed orbital elements.

Ordered Linear Spaces

A. History

Many spaces used in functional analysis, such as [†]Hilbert spaces, [†]Banach spaces, and [†]topological linear spaces, are generalizations of Euclidean spaces, where the leading idea has been to generalize the distance in Euclidean spaces in various ways. On the other hand, generalizing the order concept for real numbers has led to spaces of another kind: ordered linear spaces and vector lattices. The theory of vector lattices was presented in a lecture by F. Riesz at the International Congress of Mathematicians in 1928 [1] and has been developed by many authors. Among them we cite H. Freudenthal, L. V. Kantorovitch (*Mat. Sb.*, 2 (44) (1937)), Riesz (*Ann. Math.*, (2) 41 (1940)), S. Kakutani, F. Bohnenblust, G. Birkhoff [2], H. Nakano [3], B. C. Vulikh [5], and H. H. Schaefer [8]. Vector lattices have been used in lattice-theoretic treatments of integration (→

Section I), [†]spectral resolution, and [†]ergodic theory. The central notion is Banach lattices (→ Section F), but the theory has been extended to the case where *E* is a [†]locally convex topological linear space with the structure of a vector lattice [6–8].

B. Definitions

A real [†]linear space *E* is said to be an **ordered linear space** if *E* is supplied with an [†]order relation \geq with the following two properties: (i) $x \geq y \Rightarrow x + z \geq y + z$; (ii) $x \geq y$ and $\lambda \geq 0$ (λ is a real number) $\Rightarrow \lambda x \geq \lambda y$.

If, in addition, *E* forms a [†]lattice under this order \geq , we call *E* a **vector lattice (Riesz space or lattice ordered linear space)**.

For Sections B through E, we assume *E* to be a vector lattice. For any $x, y \in E$, the [†]join and [†]meet of x, y are denoted by $x \vee y$ and $x \wedge y$ respectively. The following relations are obvious:

$$(x + z) \vee (y + z) = (x \vee y) + z,$$

$$(x + z) \wedge (y + z) = (x \wedge y) + z,$$

$$\lambda x \vee \lambda y = \lambda(x \vee y), \quad \lambda x \wedge \lambda y = \lambda(x \wedge y) \quad (\lambda \geq 0),$$

$$\lambda x \vee \lambda y = \lambda(x \wedge y), \quad \lambda x \wedge \lambda y = \lambda(x \vee y) \quad (\lambda \leq 0)$$

and

$$(x \vee y) \wedge z = (x \wedge z) \vee (y \wedge z),$$

$$(x \wedge y) \vee z = (x \vee z) \wedge (y \vee z).$$

The last relation means that *E* is a [†]distributive lattice.

For $x \in E$, the elements $x \vee 0, (-x) \vee 0$, and $x \vee (-x)$ are called respectively the **positive part, negative part, and absolute value** of the element x , and are denoted respectively by $x^+, x^-,$ and $|x|$. The following identities hold: $x = x^+ - x^-$ (**Jordan decomposition**), $|x| = x^+ + x^-, x^+ \wedge x^- = 0, x \vee y + x \wedge y = x + y, |\lambda x| = |\lambda| |x|$, and $|x - y| = x \vee y - x \wedge y$.

For $a, b \in E$ with $a \leq b$, the set $\{x | a \leq x \leq b\}$ is called an **interval** and is denoted by $[a, b]$. A subset of *E* is called (**order**) **bounded** if it is included in an interval. An element e of *E* is said to be a **unit** or an **Archimedean unit** if for any $x \in E$ there exists a natural number n such that $x \leq ne$. A linear subspace *I* of *E* is called an **ideal (or order ideal)** of *E* if $x \in I$ and $|y| \leq |x|$ imply $y \in I$.

C. Order Limits

Given a subset $\{x_\alpha\}$ of *E*, if an element x of *E* is an upper bound of $\{x_\alpha\}$ and any upper bound y of $\{x_\alpha\}$ satisfies the relation $y \geq x$, then it is called the **least upper bound (or su-**

premmum) of $\{x_\alpha\}$ and is denoted by $\sup_\alpha x_\alpha$ or $\bigvee_\alpha x_\alpha$. The **greatest lower bound** (or **infimum**) of $\{x_\alpha\}$, denoted by $\inf_\alpha x_\alpha$ or $\bigwedge_\alpha x_\alpha$, is defined dually.

A sequence $\{x_n\}$ ($x_n \in E$) is said to be **order convergent** to x if there exists a nonincreasing sequence $\{u_n\}$ ($u_n \in E$) such that $\bigwedge_n u_n = 0$ and $|x_n - x| \leq u_n$. In this case x is called the **order limit** of $\{x_n\}$ and is denoted by $x = o\text{-lim } x_n$. For order convergent sequences $\{x_n\}$ and $\{y_n\}$, we can show the following relations: $o\text{-lim}(\lambda x_n + \mu y_n) = \lambda(o\text{-lim } x_n) + \mu(o\text{-lim } y_n)$ and $o\text{-lim}(x_n \times y_n) = (o\text{-lim } x_n) \times (o\text{-lim } y_n)$. We say that E is **Archimedean** if the relations $0 \leq nx \leq y$ ($n = 1, 2, 3, \dots$) imply $x = 0$. If E is Archimedean, then the relations $x = o\text{-lim } x_n$ and $\lambda = \lim \lambda_n$ imply $\lambda x = o\text{-lim } \lambda_n x_n$. We say that E is **complete** (**σ -complete**) if any (countable) subset of E that is bounded above has a least upper bound. A σ -complete vector lattice is always Archimedean. If E is σ -complete, for any sequence $\{x_n\}$ bounded above, $o\text{-lim sup } x_n$ is defined to be $\bigwedge_n \bigvee_{m \geq n} x_m$; we define $o\text{-lim inf } x_n$ similarly. With these definitions, $x = o\text{-lim } x_n$ is equivalent to $x = o\text{-lim sup } x_n = o\text{-lim inf } x_n$. Any Archimedean vector lattice can be extended to a complete vector lattice in the same way as the real numbers are constructed from the rational numbers by Dedekind cuts (\rightarrow 294 Numbers).

D. Examples of Vector Lattices

†Sequence spaces, such as c , m , and l_p , and †function spaces, such as C , M , and L_p , form vector lattices under pointwise ordering (\rightarrow 168 Function Spaces). Among these spaces c and C are not σ -complete, but the others are complete. We give two examples. First, let Σ be a σ -algebra of subsets of a space Ω , and let $A(\Omega, \Sigma)$ be the set of all finite σ -additive †set functions defined on Σ . Then $A(\Omega, \Sigma)$ is a complete vector lattice if we define $\mu_1 \geq \mu_2$ to mean $\mu_1(S) \geq \mu_2(S)$ for any $S \in \Sigma$. The second example is an ordered space consisting of all †bounded symmetric operators T on a Hilbert space H , where we define $T_1 \geq T_2$ to mean $(T_1 x, x) \geq (T_2 x, x)$ for any $x \in H$. In general, this space is not a vector lattice. However, if A is a commutative † W^* -algebra of operators on H and S is the set of †symmetric operators belonging to A , then S is a complete vector lattice under the ordering just defined. We can replace the conditions of finiteness in $A(\Omega, \Sigma)$ and boundedness in S with weaker ones and still obtain the same situation. The †Radon-Nikodym theorem in $A(\Omega, \Sigma)$ and the †spectral resolution theorem of symmetric operators in S can be extended to theorems of †spectral representations in general vector lattices.

Let E_1 be a linear space of functions defined on a set Ω ordered pointwise. If there exists a bijective mapping defined on a vector lattice E onto E_1 that is linear and order isomorphic, we call E_1 a **representation** of E . If E has an Archimedean unit and is simple (which means that E and $\{0\}$ are the only ideals of E), then E can be represented as the set of real numbers such that the Archimedean unit of E is represented by the number 1 (H. Freudenthal, *Proc. Akad. Amsterdam*, 39 (1936)).

E. Dual Spaces

Let $\mathfrak{Q}(E, F)$ be the set of **order bounded** linear mappings of a vector lattice E into a vector lattice F , where order boundedness means that any bounded (in the sense of the order) subset of E is mapped into a bounded set of F . For any $\varphi_1, \varphi_2 \in \mathfrak{Q}(E, F)$, define $\varphi_1 \geq \varphi_2$ to mean $\varphi_1(x) \geq \varphi_2(x)$ ($x \geq 0, x \in E$). If F is complete, then $\mathfrak{Q}(E, F)$ is a complete vector lattice. An element $\varphi \in \mathfrak{Q}(E, F)$ is called a **positive operator** if $\varphi \geq 0$. If F is the set of real numbers \mathbf{R} , then $\mathfrak{Q}(E, F)$ is the set of all (order) bounded †linear functionals on E . This space, called the **dual lattice** of the vector lattice E and denoted by E^b , is a complete vector lattice. For $f \in E^b$ and $x \geq 0, x \in E$, we have

$$f^+(x) = \sup_{0 \leq y \leq x} f(y), \quad f^-(x) = - \inf_{0 \leq y \leq x} f(y),$$

$$|f|(x) = \sup_{|y| \leq x} f(y).$$

F. Banach Lattices

A linear space E is called a **normed vector lattice** if E is a vector lattice having the structure of a †normed space satisfying $|x| \leq |y| \Rightarrow \|x\| \leq \|y\|$. Furthermore if a normed vector lattice E is complete relative to the norm, we call E a **Banach lattice**. The examples in Section D are Banach lattices (for $\mu \in A(\Omega, \Sigma)$ we define $\|\mu\| = |\mu|(\Omega)$).

In Banach lattices, $\|x_n - x\| \rightarrow 0$ and $\|y_n - y\| \rightarrow 0$ imply $\|x_n \times y_n - x \times y\| \rightarrow 0$. Among relations between order convergence and norm convergence in Banach lattices, the following is one of the most fundamental: In a Banach lattice E , norm convergence of a sequence $\{x_n\}$ to x is equivalent to **relative uniform star convergence** of $\{x_n\}$ to x , i.e., for any subsequence $\{x_{n(m)}\}$ of $\{x_n\}$, there exists a subsequence $\{x_{n(m(l))}\}$ of $\{x_{n(m)}\}$ and an element y of E satisfying the relations $\|x_{n(m(l))} - x\| \leq y/l$ ($l = 1, 2, \dots$).

Any set bounded relative to the order is bounded relative to the norm, but the converse does not hold in general. For a linear functional, however, these two concepts of boundedness coincide, and the order dual of

E is the same as the norm dual of E . Moreover, the dual (in any sense) of a Banach lattice is also a Banach lattice.

G. Abstract M Spaces and Abstract L Spaces

For a Banach lattice E , we consider the following three conditions: (M) $x, y \geq 0 \Rightarrow \|x \vee y\| = \max(\|x\|, \|y\|)$. (L) $x, y \geq 0 \Rightarrow \|x + y\| = \|x\| + \|y\|$. (L_p) $x \wedge y = 0 \Rightarrow \|x + y\|^p = \|x\|^p + \|y\|^p$ ($1 < p < \infty$). If E satisfies one of the conditions (M), (L), or (L_p), we say that E is an **abstract M space**, and **abstract L space**, or an **abstract L_p space**, written AM, AL, and AL_p , respectively. If the unit ball of an AM space has a †greatest element, it is called the **Kakutani unit** of E . The duals of AM spaces, AL spaces, and AL_p spaces are AL spaces, AM spaces with the Kakutani units, and AL_q spaces ($1/p + 1/q = 1$), respectively. An AM space with a Kakutani unit is represented by $C(\Omega)$, i.e., the set of all real-valued continuous functions defined on a compact Hausdorff space Ω . The AL spaces and AL_p spaces are represented by L_1 and L_p , respectively, on a †measure space. Here the representation of a Banach lattice means a representation of a vector lattice preserving the norm (Kakutani, *Ann. Math.*, (2) 42 (1941); Bohnenblust, *Duke Math. J.*, 6 (1940)).

H. Spectral Properties of Positive Operators

The n -dimensional real vector space E_n is a vector lattice under pointwise order (\rightarrow Section D). An element x in E_n is called **strictly positive** if $x_i > 0$ for all i . A square matrix $A = (a_{i,j})$ of order n is called **positive** if $a_{i,j} \geq 0$ for all i and j . It corresponds to a positive operator in E_n (\rightarrow Section E). A is called **irreducible** if there exists no permutation matrix P such that $P^{-1}AP = \begin{pmatrix} A_1 & A_2 \\ 0 & A_3 \end{pmatrix}$, where A_1 and A_3 are square matrices of order n_i ($1 \leq n_i < n$). We denote by $\sigma(A)$ the †spectrum of A and by $r(A)$ the †spectral radius of A , i.e., $\sup\{|\alpha| \mid \alpha \in \sigma(A)\}$. The spectral circle of A is the circle of radius $r(A)$ having the origin as its center. O. Perron (*Math. Ann.*, 64 (1907)) and G. Frobenius (*S. B. Preuss. Akad. Wiss.*, 1908 and 1912) established the following remarkable result on the spectral properties of positive matrices.

Theorem (Perron-Frobenius). Let A be a positive square matrix. Then its spectral radius $r(A)$ belongs to $\sigma(A)$, and for this spectrum $r(A)$ there exists an eigenvector $x \geq 0$. Assume further that A is irreducible and the order of A is greater than 1. Then $r(A) > 0$ and the eigenspace of A for $r(A)$ is a 1-dimensional subspace

spanned by a strictly positive element. In this case the eigenvalues of A on the spectral circle are the k th roots of unity for some k multiplied by $r(A)$, each of which is a simple root of the eigenequation of A .

Since a positive matrix of order n corresponds to a positive operator in E_n , extensions of this theorem to positive operators in ordered linear spaces have been studied by many mathematicians. For these extensions, see the following articles: M. G. Kreĭn and M. A. Rutman (*Amer. Math. Soc. Transl.*, 26 (1950); original in Russian, 1948), F. F. Bonsall (*J. London Math. Soc.*, 30 (1955)), S. Karlin (*J. Math. Mech.*, 8 (1959)), T. Ando (*J. Fac. Sci. Hokkaido Univ.*, ser. 1, 13 (1957)), H. H. Schaefer [8], H. P. Lotz (*Math. Z.*, 108 (1968)), F. Niĭro and I. Sawashima (*Sci. Pap. Coll. Gen. Educ., Univ. Tokyo*, 1966), I. Sawashima and F. Niĭro (*Nat. Rep. Ochanomizu Univ.*, 30 (1979)), and S. Miyajima (*J. Fac. Sci. Univ. Tokyo*, 27 (1980)).

I. Integrals Based on Ordering

As applications of ordered linear space theory, we state the integrals of Daniel-Stone and of Banach. Let us begin with a set \mathfrak{E} of real-valued functions defined on an abstract space S and assume that \mathfrak{E} is a vector lattice with respect to the usual order relation, addition, and scalar multiplication. Assume further that a functional $E(f)$ defined on \mathfrak{E} satisfies the following conditions: (i) additivity, i.e., $E(f + g) = E(f) + E(g)$; (ii) positivity, i.e., $f \geq 0$ implies $E(f) \geq 0$; (iii) $f, f_n \in \mathfrak{E}$ ($n = 1, 2, \dots$) and $|f| \leq \sum_{n=1}^{\infty} |f_n|$ imply $E(|f|) \leq \sum_{n=1}^{\infty} E(|f_n|)$, where $|f|$ means $f \vee (-f)$. A functional on \mathfrak{E} satisfying both conditions (i) and (ii) is called a positive linear functional. A positive linear functional on \mathfrak{E} satisfies M. H. Stone's condition (iii) if and only if it satisfies P. J. Daniell's condition (iii)': $f_1 \geq f_2 \geq \dots$ and $\lim_{n \rightarrow \infty} f_n = 0$ imply $\lim_{n \rightarrow \infty} E(f_n) = 0$. Next, we define, for every function φ on S admitting $\pm\infty$ as values, a functional $N(\varphi)$ as follows:

$$N(\varphi) = \inf \left\{ \sum_{n=1}^{\infty} E(|f_n|) \mid f_n \in \mathfrak{E}, |\varphi| \leq \sum_{n=1}^{\infty} |f_n| \right\}.$$

Here we put $N(\varphi) = +\infty$ when for a function φ there are no functions $\{f_n\}$ such that $|\varphi| \leq \sum_{n=1}^{\infty} |f_n|$. A function φ is, by definition, a **null function** if $N(\varphi) = 0$ holds, and a set A is a **null set** if its †characteristic function is a null function. Since each function of $\mathfrak{F}_0 = \{\varphi \mid N(\varphi) < +\infty\}$ takes finite values except on a null set, we can define addition and the scalar multiplication for such functions except on a null set. Let \mathfrak{F} be the set of equivalence classes of \mathfrak{F}_0

with respect to the relation $\varphi \sim \psi$ defined as $N(\varphi - \psi) = 0$. Then \mathfrak{F} is a Banach lattice with the norm N , and \mathfrak{E} is included in \mathfrak{F} (by identifying f and g of \mathfrak{E} when $E(|f - g|) = 0$). Let us denote now by \mathfrak{L} the closure of \mathfrak{E} in \mathfrak{F} . Then any function φ belonging to \mathfrak{L} is said to be **Daniell-Stone integrable**, and $L(\varphi) = N(\varphi^+) - N(\varphi^-)$ ($\varphi^+ = \frac{1}{2}(|\varphi| + \varphi)$, $\varphi^- = \frac{1}{2}(|\varphi| - \varphi)$) is called the **Daniell-Stone integral** of φ . The integral L thus defined is, as a functional on \mathfrak{L} , an extension of the functional E on \mathfrak{E} . For this integral, Lebesgue's convergence theorem is easily proved, and a result corresponding to Fubini's theorem has been obtained [9]. Furthermore, the concepts of measurable functions, measurable sets, and measure can be defined by using L and \mathfrak{L} . Also, the relation between L and the Lebesgue integral with respect to this measure is known [9]. Since \mathfrak{L} is an abstract L -space, the Daniell-Stone integral $L(\varphi)$ is represented by the Lebesgue integral of φ on a certain measure space. The Daniell-Stone integral introduced above is due to M. H. Stone [9]. Daniell (*Ann. Math.*, (2) 19 (1917-1918)) originally defined the upper integral $\bar{I}(\varphi)$ by using $E(f)$ on \mathfrak{E} satisfying conditions (i), (ii), and (iii'). Also, he defined the set \mathfrak{L} of Daniell-Stone integrable functions by $L = \{\varphi \mid \bar{I}(\varphi) = -\bar{I}(-\varphi)\}$. S. Banach defined an integral by using methods similar to Daniell's, replacing condition (iii') for a positive linear functional $E(f)$ on \mathfrak{E} by condition (iii''): $\lim_{n \rightarrow \infty} f_n = 0$, $|f_n| \leq g$, and $f_n, g \in \mathfrak{E}$ imply $\lim_{n \rightarrow \infty} E(f_n) = 0$ [10]. Furthermore, N. Bourbaki [11] and E. J. McShane (*Proc. Nat. Acad. Sci. US*, 1946) have defined a more general integral than the Daniell-Stone with a condition analogous to (iii'), replacing the sequence in it by a directed family of functions $\{f_\alpha\}$.

Specifically if, in the Daniell-Stone integral, S is a locally compact Hausdorff space and \mathfrak{E} is the set of continuous functions with compact supports, then a functional $E(f)$ on \mathfrak{E} satisfying conditions (i) and (ii) is proved to satisfy the condition (iii'), and the Daniell-Stone integral $L(\varphi)$ can be constructed from $E(f)$ [11].

Banach also defined another integral for all real-valued bounded functions on $[0, 1)$ by using the Hahn-Banach extension theorem [12]. His definition is as follows: Let \mathfrak{F} be the set of all real-valued bounded functions on $[0, 1)$ and \mathfrak{A} be the family of all finite sets of real numbers $\alpha = (\alpha_1, \alpha_2, \dots, \alpha_n)$. Furthermore, we define, for $x(s) \in \mathfrak{F}$ and $\alpha \in \mathfrak{A}$,

$$M(x, \alpha) = \sup_{-\infty < s < +\infty} \frac{1}{n} \sum_{k=1}^n x(s + \alpha_k),$$

where $x(s)$ is considered as the periodic extension to $(-\infty, +\infty)$ of the function defined

310 Ref.
Ordered Linear Spaces

originally on $[0, 1)$ and

$$p(x) = \inf_{\alpha \in \mathfrak{A}} M(x, \alpha).$$

Then, by the Hahn-Banach extension theorem, there exists a linear functional F on \mathfrak{F} satisfying $F(x) \leq p(x)$. If we write $\int x(s) ds$ for $F(x)$, then we can prove immediately that $\int x(s) ds$ has the following properties: (1) $\int \{ax(s) + by(s)\} ds = a \int x(s) ds + b \int y(s) ds$, where a and b are real constants. (2) $x(s) \geq 0$ implies $\int x(s) ds \geq 0$. (3) $\int x(s + s_0) ds = \int x(s) ds$, where s_0 is an arbitrary real number. (4) $\int 1 ds = 1$. If necessary, we can add the property (5) $\int x(1 - s) ds = \int x(s) ds$ by defining

$$\int x(s) ds = \frac{1}{2} \{F(x(s)) + F(x(1 - s))\}.$$

Then

$$F(x) = \int x(s) ds$$

or

$$\frac{1}{2} \{F(x(s)) + F(x(1 - s))\} = \int x(s) ds$$

is called the **Banach integral** of $x(s)$.

The construction of the Daniell-Stone integral and the Banach integral opened avenues to several other abstract integrals based on the order relation, such as an integral for more general functions with values in a vector lattice, or an integral considered as a mapping from a vector lattice into another vector lattice (or from an ordered set into another ordered set). Indeed, if the function takes values in a complete vector lattice, then almost all results in this section (e.g., the Hahn-Banach extension theorem) hold trivially. For discussions of these and other abstract integrals → [13-15].

311 (II.12) Ordering

A. Ordering

The concept of ordering is abstracted from various relations, such as the inequality relation between real numbers and the inclusion relation between sets. Suppose that we are given a set $X = \{x, y, z, \dots\}$; the relation between the elements of X , denoted by \leq or other symbols, is called an **ordering** (**partial ordering**, **semiordeering**, **order relation**, or simply **order**) if the following three laws hold: (i) the **reflexive law**, $x \leq x$; (ii) the **antisymmetric law**, $x \leq y$ and $y \leq x$ imply $x = y$; and (iii) the **transitive law**, $x \leq y$ and $y \leq z$ imply $x \leq z$.

A set X with an ordering between its elements is called an **ordered set** (**partially ordered set** or **semiordeered set**). A subset of an ordered set X is also an ordered set with respect to the same ordering as in X . If for an arbitrary pair of elements x, y of an ordered set A either $x \leq y$ or $y \leq x$ must hold, then the ordering \leq

is called a **total** (or **linear**) **ordering**, and A is called a **totally ordered** (or **linearly ordered**) **set**.

We sometimes write $x \leq y$ as $y \geq x$. The binary relation \geq is called the **dual ordering** of \leq ; it is also an ordering. More generally, the duals of concepts, conditions, and propositions concerning an ordering are defined by replacing the ordering with its dual. For example, $x < y$ means that $x \leq y$ and $x \neq y$, while $x > y$ means that $x \geq y$ and $x \neq y$; and $>$ is the dual of $<$. If a universal proposition concerning the ordering is true, then its dual is also true; this principle is called the **duality principle for ordering**. Incidentally, $x \leq y$ is equivalent to the statement $x < y$ or $x = y$, according to the definition of $<$.

B. Definitions

A subset of an ordered set X of the form $\{x \mid a < x < b\}$ is denoted by (a, b) , and a set of the form (a, b) , $\{x \mid x < a\}$, or $\{x \mid x > a\}$ is called an **interval**. In particular, $S(c) = \{x \mid x < c\}$ is called the **segment** of X determined by c . A pair of elements a, b satisfying $a \leq b$ is called a **quotient** of X and is denoted by b/a .

When $a < c < b$ or $b < c < a$, c is said to lie **between** a and b . A totally ordered set A is said to be **dense** if for any pair of distinct elements a and b in A there exists a third element c lying between a and b . When $a < b$ and there is no element lying between a and b , then a is called a **predecessor** of b , and b a **successor** of a . In this manner, most of the terminology associated with the inequality of numbers is carried over to general ordering.

In an ordered set A , an element a is called an **upper bound** of a subset X if $x \leq a$ for every element x of X . When an upper bound exists, X is said to be **bounded from above** (or **bounded above**). The dual concept of an upper bound is a **lower bound** of the subset; and if the subset has a lower bound, it is said to be **bounded from below** (or **bounded below**). A set bounded both from above and from below is simply said to be **bounded**. When a is an upper bound of X and $a \in X$, then a is called the **greatest element** (or **maximum element**) of X . Such an element a (if it exists) is unique and is denoted by $\max X$; its dual is the **least element** (or **minimum element**) and is denoted by $\min X$. If there is a least element in the set of upper bounds of X , it is called the **least upper bound** (or **supremum**) of X and is denoted by **l.u.b.** X or **sup** X . Its dual is the **greatest lower bound** (or **infimum**) and is denoted by **g.l.b.** X or **inf** X .

If the ordered set X is the image $\varphi(\Lambda)$ of a set Λ under a \dagger mapping φ , where Λ is of the form $\{\lambda \mid C(\lambda)\}$, then $\sup X$ is also written

$\sup_{C(\lambda)} \varphi(\lambda)$ and is called the supremum of $\varphi(\lambda)$ for all λ that satisfy $C(\lambda)$. When there is no danger of misunderstanding, it may be written as $\sup_{\lambda} \varphi(\lambda)$ or $\sup \varphi(\lambda)$ and called simply the supremum of $\varphi(\lambda)$; similar conventions hold for inf, max, min, etc.

An element a of a set X is called a **maximal element** if $a < x$ never holds for any element x of X ; its dual is a **minimal element**. If the greatest (least) element exists, it is the only maximal (minimal) element. But in general, a maximal (minimal) element is not necessarily unique.

C. Chain Conditions

An ordered set X is said to satisfy the **minimal condition** if every nonempty subset of X has a minimal element. The dual condition is called the **maximal condition**. An infinite sequence $\{a_1, a_2, \dots, a_n, \dots\}$ of elements of an ordered set X such that $a_1 < a_2 < \dots < a_n < \dots$ is called an **ascending chain**, and the condition that X has no ascending chain is called the **ascending chain condition**. The notions dual to those of ascending chain and ascending chain condition are **descending chain** and **descending chain condition**, respectively. By the **chain condition**, we mean either the ascending or the descending chain condition. Under the axiom of choice, the maximal condition is equivalent to the ascending chain condition, and the minimal condition to the descending chain condition.

If a totally ordered set X satisfies the minimal condition or, equivalently, if every nonempty subset of X has a least element, then the set X is called a **well-ordered set**, and its ordering is called a **well-ordering**.

The following theorem is called the principle of **transfinite induction**: Let $P(x)$ be a proposition concerning an element x of a well-ordered set X such that (i) $P(x_0)$ is true for the least element x_0 of X , and (ii) $P(x)$ is true if $P(y)$ is true for all y satisfying $y < x$. Then $P(x)$ is true for all x in X . Mathematical induction is a special case of this principle, where X is the set of all natural numbers. To define a mapping F from a well-ordered set X into a set Y , we may use the following principle: Suppose that $F(x_0)$ is defined for the least element x_0 of X , and for each element x of X there is given a method to associate an element $G(f)$ of Y uniquely with each mapping $f: S(x) \rightarrow Y$ with domain $S(x)$, where $S(x)$ is the segment of X determined by x . Then there exists a unique mapping $F: X \rightarrow Y$ satisfying $F(x) = G(F|S(x))$ for all x . The definition of the mapping F by this principle is called a **definition by transfinite induction**. The prin-

311 G Ordering

ciples of induction are often used for proving propositions or giving definitions concerning ordinal numbers (\rightarrow 312 Ordinal Numbers).

D. Directed Sets

An ordered set (or in general a preordered set (\rightarrow Section H)) in which every finite subset is bounded from above is called a **directed set**. Let B be a subset of a directed set A . If $\{b | b \geq a\} \cap B \neq \emptyset$ for every element a of A , then B is said to be **cofinal** in A ; such a subset B is itself a directed set. If $\{b | b \geq a\} \subset B$ for some element a of A , then B is said to be **residual** in A ; such a subset B is also cofinal in A . The condition that B is cofinal in A is equivalent to the condition that $A - B$ is not residual in A .

E. Order-Preserving Mappings

A mapping $\varphi: A \rightarrow A'$ of an ordered set A into an ordered set A' is called an **order-preserving mapping** (**monotone mapping** or **order homomorphism**) if $a \leq b$ always implies $\varphi(a) \leq \varphi(b)$. Moreover, if φ is bijective and φ^{-1} is also an order-preserving mapping from A' onto A , then φ is called an **order isomorphism**. A' is said to be **order homomorphic** (**order isomorphic**) to A when there exists an order homomorphism (order isomorphism) φ such that $A' = \varphi(A)$. If a mapping $\varphi: A \rightarrow A'$ gives an order isomorphism of A to the dual of A' , φ is called a **dual isomorphism** (or **anti-isomorphism**).

F. Direct Sum and Direct Product

Let S be a set that is the disjoint union of a family $\{A_{\lambda}\}_{\lambda \in \Lambda}$ of its subsets, and suppose that each A_{λ} is an ordered set. For $a, b \in S$, define $a \leq b$ to mean that $a, b \in A_{\lambda}$ for some $\lambda \in \Lambda$ and $a \leq b$ with respect to the ordering in A_{λ} . The ordered set S obtained in this way is called the **direct sum** (or **cardinal sum**) of the family $\{A_{\lambda}\}_{\lambda \in \Lambda}$ of ordered sets. When $(a_{\lambda})_{\lambda \in \Lambda}$ and $(b_{\lambda})_{\lambda \in \Lambda}$ are elements of the Cartesian product $P = \prod_{\lambda \in \Lambda} A_{\lambda}$ of a family $\{A_{\lambda}\}_{\lambda \in \Lambda}$ of ordered sets, we define $(a_{\lambda})_{\lambda \in \Lambda} \leq (b_{\lambda})_{\lambda \in \Lambda}$ to mean that $a_{\lambda} \leq b_{\lambda}$ holds for all $\lambda \in \Lambda$. The ordered set P obtained in this way is called the **direct product** (or **cardinal product**) of the family $\{A_{\lambda}\}_{\lambda \in \Lambda}$ of ordered sets.

G. Ordinal Sum and Ordinal Product

Suppose that $\mathfrak{U} = \{A, B, \dots\}$ is a family of mutually disjoint ordered sets and is itself an

ordered set. Then an ordering \leq can be defined in the disjoint union $S = \bigcup X (X \in \mathfrak{A})$ as follows: $x \leq y$ in S means that either (i) there exists an A satisfying $x, y \in A \in \mathfrak{A}$ and $x \leq y$ holds with respect to the ordering in A ; or (ii) for A and B satisfying $x \in A \in \mathfrak{A}, y \in B \in \mathfrak{A}$, we have $A < B$. The ordered set S obtained in this way is called the **ordinal sum** obtained from \mathfrak{A} and is denoted by $\sum_{\mathfrak{A}} X$. In particular, if $\mathfrak{A} = \{A, B\}$ and $A < B$, the ordinal sum is denoted by $A + B$.

Suppose that X is a subset of the Cartesian product $\prod_{\lambda} X_{\lambda}$ of a family of ordered sets indexed by an ordered set Λ , and the subset $\{\lambda | x_{\lambda} \neq y_{\lambda}\}$ of Λ has a least element whenever $x = (x_{\lambda})_{\lambda \in \Lambda}$ and $y = (y_{\lambda})_{\lambda \in \Lambda}$ are two distinct elements of X . The ordering in X defined by setting $x < y$ when $x_{\mu} < y_{\mu}$ for the least element μ of $\{\lambda | x_{\lambda} \neq y_{\lambda}\}$ is called the **lexicographic ordering** in X . It can be applied to $X = \prod_{\lambda} X_{\lambda}$ if Λ is well-ordered; X is then called the **ordinal product**. When A, B, \dots are ordered sets, $AB \dots$ is often used to denote the ordinal product obtained from $X_1 = A, X_2 = B, \dots$ with the ordering $1 < 2 < \dots$ of indices; the ordering in this ordinal product is called the **lexicographic ordering** in the Cartesian product $A \times B \times \dots$.

H. Preordering

A relation R between elements of a set X is called a **preordering** (or **pseudoordering**) if it satisfies the reflexive law and the transitive law, but not necessarily the antisymmetric law. By defining $(x_1, y_1)R(x_2, y_2) \Leftrightarrow x_1 \leq x_2$, for example, a preordering of pairs (x, y) of real numbers is obtained. From a preordering R an equivalence relation \sim can be defined in X by $x \sim y \Leftrightarrow (xRy \text{ and } yRx)$. Let $[X] = X/\sim$ be the quotient set of set X by this equivalence relation, and let $[x], [y]$ be the equivalence classes determined by $x, y \in X$; then an ordering \leq can be defined in $[X]$ by $[x] \leq [y] \Leftrightarrow xRy$. (For further topics \rightarrow 52 Categories and Functors; 409 Structures.)

312 (II.13) Ordinal Numbers

A. General Remarks

Let $A \cong B$ mean that two ordered sets A, B are order isomorphic; then the relation \cong is an equivalence relation. An equivalence class under this relation is called an **order type**, and the class to which an ordered set A belongs is called the **order type of A** . Historically, an ordinal number was first defined as the order type of a well-ordered set (Cantor [2]). However, it was found that a contradiction occurs if order type defined in this way are considered to form a set. Hence, another definition was given by J. von Neumann [3], which is stated in Section B. A similar situation was found concerning the definition of cardinal numbers, which led to a new definition of cardinal numbers using ordinal numbers, which is given in Section D.

B. Definitions

A set α is called an **ordinal number** if it satisfies the following two conditions: (i) α is a well-ordered set with the binary relation \in as its ordering; and (ii) $\beta \in \alpha$ implies $\beta < \alpha$. According to this definition, the empty set is an ordinal number, which is denoted by 0. Also, $1 = \{0\}, 2 = \{0, 1\}, 3 = \{0, 1, 2\}, \dots$ are ordinal numbers. These ordinal numbers, which are finite sets, are called **finite ordinal numbers**. The finite ordinal numbers are identified with the natural numbers (including 0). The set $\omega = \{0, 1, 2, \dots\}$ of all natural numbers is also an ordinal number. An ordinal number that is an infinite set, like ω , is called a **transfinite ordinal number**.

For every well-ordered set A , there exists one and only one ordinal number order isomorphic to A . This ordinal number is called the **ordinal number of A** . (Throughout this article, lower-case Greek letters denote ordinal numbers.) We also write $\alpha \in \beta$ as $\alpha < \beta$, which defines an ordering of the ordinal numbers. The least ordinal number is 0, and the ordering of the finite ordinal numbers coincides with the usual ordering of the natural numbers. The least transfinite ordinal number is ω . The ordering \leq , introduced by defining $\alpha \leq \beta$ to mean either $\alpha < \beta$ or $\alpha = \beta$, is a linear ordering and, in fact, a well-ordering of the ordinal numbers. Therefore transfinite induction can be applied to ordinal numbers.

For any ordinal number α , the set $\alpha' = \{\xi | \xi \leq \alpha\}$ is also an ordinal number, and is the successor of α . There exists at most one

ordinal number that is the †predecessor of α . A transfinite ordinal number without a predecessor is called a **limit ordinal number**, and all the other ordinal numbers are called **isolated ordinal numbers**. The first limit ordinal number is ω . For any set A of ordinal numbers, $\{\xi \mid \exists \eta (\xi < \eta \in A)\}$ is an ordinal number and is $\sup A$, the †supremum of A .

C. Sum, Product, and Power

The **sum** $\alpha + \beta$, the **product** $\alpha \cdot \beta$ (or $\alpha\beta$), and the **power** α^β of ordinal numbers α, β are defined by transfinite induction on β and have the following properties:

$$\alpha + 0 = \alpha, \quad \alpha + \beta' = (\alpha + \beta)',$$

$$\alpha + \gamma = \sup\{\alpha + \xi \mid \xi < \gamma\};$$

$$\alpha \cdot 0 = 0, \quad \alpha \cdot \beta' = \alpha \cdot \beta + \alpha,$$

$$\alpha \cdot \gamma = \sup\{\alpha \cdot \xi \mid \xi < \gamma\};$$

$$\alpha^0 = 1, \quad \alpha^{\beta'} = \alpha^\beta \cdot \alpha, \quad \alpha^\gamma = \sup\{\alpha^\xi \mid \xi < \gamma\}.$$

Here γ is a limit ordinal number, and for the power we assume that $\alpha > 0$. The sum and product thus defined satisfy the associative laws $(\alpha + \beta) + \gamma = \alpha + (\beta + \gamma)$, $(\alpha \cdot \beta) \cdot \gamma = \alpha \cdot (\beta \cdot \gamma)$ and the left distributive law $\alpha \cdot (\beta + \gamma) = \alpha \cdot \beta + \alpha \cdot \gamma$; the power satisfies the laws $\alpha^{\beta+\gamma} = \alpha^\beta \cdot \alpha^\gamma$, $\alpha^{\beta^\gamma} = (\alpha^\beta)^\gamma$. If α and β are the ordinal numbers of the well-ordered sets A and B , respectively, then $\alpha + \beta$ is the ordinal number of the †ordinal sum $A + B$, and $\alpha \cdot \beta$ is the ordinal number of the †ordinal product BA .

When $\pi > 1$, any ordinal number α can be written uniquely in the form

$$\alpha = \pi^{\beta_1} \cdot \gamma_1 + \pi^{\beta_2} \cdot \gamma_2 + \dots + \pi^{\beta_n} \cdot \gamma_n;$$

$$\beta_1 > \beta_2 > \dots > \beta_n > 0, \quad 0 < \gamma_i < \pi, \quad 1 \leq i \leq n,$$

which is called the π -**adic normal form** for α ; when $\pi = \omega$, it is called **Cantor's normal form**.

Let f be an ordinal number-valued function of ordinal numbers. We say that f is **strictly monotone** when $\alpha < \beta$ implies $f(\alpha) < f(\beta)$. If f is strictly monotone, then $\alpha \leq f(\alpha)$. We say that f is **continuous** when $f(\gamma) = \sup\{f(\xi) \mid \xi < \gamma\}$ for each limit ordinal number γ . A strictly monotone continuous function is called a **normal function**. If f is a normal function, then for any α there exists a β that satisfies $f(\beta) = \beta > \alpha$. In fact, it suffices to define $\beta_n (n < \omega)$ by $\beta_0 = f(\alpha + 1)$, $\beta_{n+1} = f(\beta_n)$ and put $\beta = \sup\{\beta_n \mid n < \omega\}$. Since $f(\alpha) = \omega^\alpha$ is a normal function, there exists an ε that satisfies $\omega^\varepsilon = \varepsilon$. Such an ordinal number ε is called an ε -**number**. We say that β is **cofinal** to α when there exists a monotone function f that satisfies $\alpha = \sup\{f(\xi) \mid \xi < \beta\}$. The first ordinal number that is cofinal to α is

called the **cofinality** of α and is denoted by $\text{cf}(\alpha)$.

D. Cardinal Numbers

Let $M \sim N$ mean that a one-to-one correspondence exists between the two sets M and N . An ordinal number α with the property that $\alpha \sim \xi$ implies $\alpha \leq \xi$ is called an **initial number** or a **cardinal number**.

With the †axiom of choice, it can be shown that for each set M there exists one and only one cardinal number α satisfying $M \sim \alpha$. This unique α is called the **cardinality** (or **cardinal number**) of the set M and is denoted by \overline{M} .

All finite ordinal numbers are cardinal numbers, and ω is the least transfinite cardinal number. There exists one and only one monotone function that maps the class of ordinal numbers onto the class of transfinite cardinal numbers, and it is a normal function. The value of this function corresponding to α is denoted by \aleph_α (**aleph alpha**) or ω_α . In particular, $\aleph_0 = \omega$, and \aleph_1 is both the smallest uncountable cardinal number and the smallest uncountable ordinal number. A finite ordinal number is called an **ordinal number of the first number class**, and an ordinal number α satisfying $\aleph_0 \leq \alpha < \aleph_1$ is called an **ordinal number of the second number class**. The concept of **ordinal number of the third (or higher) number class** is defined similarly.

E. Inaccessible Ordinal Numbers

The cofinality $\text{cf}(\alpha)$ of α always satisfies $\text{cf}(\alpha) \leq \alpha$. An ordinal number is said to be **regular** when $\text{cf}(\alpha) = \alpha$ and **singular** when $\text{cf}(\alpha) < \alpha$. For any ordinal number α , $\text{cf}(\alpha)$ is a regular cardinal number; therefore any regular ordinal number is a cardinal number. When $\alpha = \omega_\beta$ is regular and β is a limit ordinal number, α is said to be **weakly inaccessible**. Let R be the set-valued function of ordinal numbers, defined by $R(0) = \emptyset$ and $R(\alpha) = \bigcup \{\mathfrak{P}(R(\xi)) \mid \xi < \alpha\}$ (by †transfinite induction), where $\mathfrak{P}(M)$ denotes the †power set of M . A regular ordinal number α is said to be **strongly inaccessible** when $\alpha > \omega$ and the following condition is satisfied: If x, y are a pair of sets such that $x \in R(\alpha)$, $y \subset R(\alpha)$, and there exists a mapping of x onto y , then $y \in R(\alpha)$. If a regular ordinal number α is strongly inaccessible, it is weakly inaccessible. A strongly inaccessible ordinal number is usually defined as a regular number $\alpha > \omega$ such that $\beta < \alpha$ implies $\overline{\mathfrak{P}(\beta)} < \alpha$. Under the axiom of choice, this definition is equivalent to the one given here. Moreover, under the †generalized continuum hypothesis, strong

inaccessibility and weak inaccessibility are equivalent.

313 (XIII.2) Ordinary Differential Equations

A. General Remarks

Let x be a real (complex) variable and y a real (complex) function of x . Assume that $y = F(x)$ is a differentiable function of class C^n if x, y are real, and a holomorphic function if x, y are complex. We write $y', y'', \dots, y^{(n)}$ for the first n derivatives of y . A relation among $x, y, y', \dots, y^{(n)}$,

$$f(x, y, y', \dots, y^{(n)}) = 0 \tag{1}$$

(which holds identically with respect to x), is called an **ordinary differential equation** for the function $y = F(x)$. Here we assume that the function f in the left-hand side of (1) is a real (complex) function of the $n + 2$ variables $x, y, y', \dots, y^{(n)}$ and is defined in a given domain of \mathbf{R}^{n+2} (\mathbf{C}^{n+2}). Usually we assume further that f has a certain regularity, such as being of class C^r ($r = 0, 1, \dots, \infty$), †real analytic, or ‡complex analytic. A function $y = F(x)$ that satisfies (1) is called a **solution** of (1). To find a solution of (1) is to **solve** or **integrate** it. Ordinary differential equations may be contrasted to **partial differential equations**, which are equations similar to (1) but in which y is a function of two or more variables x_1, x_2, \dots and which contain the partial derivatives $\partial y / \partial x_1, \partial y / \partial x_2, \dots$ (— 320 Partial Differential Equations). Ordinarily, the term **differential equation** refers to an ordinary or partial differential equation. In this article,

since we are concerned only with ordinary differential equations, we omit the word “ordinary.” If the left-hand side f of (1) contains $y^{(n)}$ explicitly or $\partial f / \partial y^{(n)} \neq 0$, then we say that the **order** of (1) is n , and if further f is a polynomial in $y, y', \dots, y^{(n)}$ that is of degree m with respect to $y^{(n)}$, we say that the **degree** of (1) is m . In particular, if f is a linear form in $y, y', \dots, y^{(n)}$, then (1) is said to be **linear**. A differential equation that is not linear is said to be **nonlinear** (— 252 Linear Ordinary Differential Equations; 291 Nonlinear Problems).

Let $\varphi(x, y, c_1, \dots, c_n)$ be a function of the $n + 2$ variables x, y, c_1, \dots, c_n of class C^r in a domain D , and let $(x_0, y_0, c_1^0, \dots, c_n^0) \in D$, $\varphi(x_0, y_0, c_1^0, \dots, c_n^0) = 0$, and $\varphi_y(x_0, y_0, c_1^0, \dots, c_n^0) \neq 0$. Then the equation $\varphi(x, y, c_1^0, \dots, c_n^0) = 0$ defines an implicit function $y(x)$ of class C^r satisfying the condition $y(x_0) = y_0$. Consider c_1, \dots, c_n to be constants in $\varphi(x, y, c_1, \dots, c_n) = 0$ and differentiate φ n times with respect to x . Then we obtain a system of n equations in the variables $x, y, y', \dots, y^{(n)}, c_1, \dots, c_n$. If we can eliminate c_1, \dots, c_n from these n equations and $\varphi = 0$, then we obtain an n th-order differential equation of the form (1). Conversely, a solution of an n th-order differential equation can usually be written in the form

$$\varphi(x, y, c_1, \dots, c_n) = 0, \tag{2}$$

which contains n **arbitrary constants** c_1, \dots, c_n (sometimes called **integration constants**). A solution containing n arbitrary constants of the form (2) of an n th-order differential equation is called a **general solution**, and a solution $\varphi(x, y, c_1^0, \dots, c_n^0) = 0$ obtained from a general solution $\varphi = 0$ by giving particular values c_1^0, \dots, c_n^0 to the arbitrary constants is called a **particular solution**. Some equations admit solutions that are not particular solutions. They are called **singular solutions** (for example, †Clairaut differential equations; — Appendix A, Table 14.I).

B. Systems of Differential Equations

A set of n differential equations containing n unknown functions y_1, \dots, y_n of a variable x is called a **system of ordinary differential equations**. Here each equation of the system has a form similar to (1), but each left-hand side contains y_1, \dots, y_n and their derivatives. A set of n functions y_1, \dots, y_n of x is called a **solution** if the functions satisfy the given system of differential equations. The highest order of derivatives in the left-hand sides is called the **order** of the system of differential equations.

We consider most frequently a first-order system of the form

$$y'_i = f_i(x, y_1, \dots, y_n), \quad i = 1, 2, \dots, n. \tag{3}$$

If we put $y = y_1$, $y' = y_2$, ..., $y^{(n-1)} = y_n$ and solve (1) with respect to $y^{(n)}$ to get $y^{(n)} = f_n(x, y_1, \dots, y_n)$, then (1) is equivalent to a system of equations of the form (3), where $f_1 = y_2$, $f_2 = y_3$, ..., $f_n = f$. In an analogous way, a general system of equations can be transformed to a system of the form (3). Therefore (3) is called the **normal form** of differential equations.

C. The Geometric Interpretation

When x, y_1, \dots, y_n are real, (3) can be interpreted as follows: Let $I = (a, b)$ be an open interval and D a domain of \mathbf{R}^n . Let

$$y_i = \varphi_i(x, c_1, \dots, c_n), \quad i = 1, 2, \dots, n, \quad (4)$$

be functions of class C^1 defined for $(x, c_1, \dots, c_n) \in I \times D$, and let $\mathfrak{D}(x_0)$ be the image in the y_1, \dots, y_n -space of D under the mapping $y_i = \varphi_i(x_0, c_1, \dots, c_n)$ ($i = 1, 2, \dots, n$) for a fixed $x_0 \in I$. We assume that for each fixed $x_0 \in I$ we have $\partial(\varphi_1, \dots, \varphi_n)/\partial(c_1, \dots, c_n) \neq 0$ in D . Then for every $x = x_0 \in I$, c_1, \dots, c_n are considered to be functions of (y_1, \dots, y_n) defined in a neighborhood of every point (y_1^0, \dots, y_n^0) of $\mathfrak{D}(x_0)$, and we have $y_i' = \varphi_i'(x, c_1, \dots, c_n) = f_i(x, y_1, \dots, y_n)$ ($i = 1, 2, \dots, n$), i.e., y_1, \dots, y_n satisfy a system of differential equations of the form (3). On the other hand, (4) represents a family of curves of class C^1 in the x, y_1, \dots, y_n -space \mathbf{R}^{n+1} containing n parameters c_1, \dots, c_n , for which (y_1', \dots, y_n') is the tangent vector (in the terminology of physics, (y_1', \dots, y_n') gives the speed and the direction of a stationary flow in \mathbf{R}^{n+1} at each point). By solving (3) we find the family of curves of class C^1 in \mathbf{R}^{n+1} (in the terminology of physics, we find a stationary flow of which the speed and the direction are given at each point). A solution containing n parameters analogous to (4) is called a **general solution** of (3), and a solution obtained from a general solution by giving particular values to the n parameters is called a **particular solution**.

As may be imagined by the interpretation in this section, there exists in general one and only one particular solution passing through the point $(x_0, y_1^0, \dots, y_n^0)$ for $x_0 \in I$, $(y_1^0, \dots, y_n^0) \in \mathfrak{D}(x_0)$. The problem of finding this solution, i.e., the solution of (3) for which $y_i(x_0) = y_i^0$ for $x = x_0$, is called the **initial value problem** (\rightarrow 316 Ordinary Differential Equations (Initial Value Problems)).

D. Methods of Integration

We have different methods of solving differential equations. To solve differential equations by a finite number of integrations is called the **method of quadrature**. This method is useful

for some special types of differential equations (\rightarrow Appendix A, Table 14.I). S. Lie gave theoretical foundations for this method by using Lie transformation groups (\rightarrow 431 Transformation Groups; Appendix A, Table 14.III). There are many other methods, for example, power series methods (assuming that the solution can be expanded in a power series $\sum a_n(x-a)^n$, substituting the series for y in (1), and finding its coefficients); methods of successive approximation; methods using \dagger Laplace transforms or \dagger Fourier transforms; \dagger perturbation methods; numerical methods; etc. (\rightarrow 303 Numerical Solution of Ordinary Differential Equations).

Historically, finding explicit solutions of various kinds of differential equations has been the main object of the theory. Recently, however, the importance of qualitative studies, in particular theorems on the existence and uniqueness of solutions, has been recognized. For example, if a solution with a property A is given, and if the uniqueness of the solution having the property A and the existence of solutions having the properties A and B can be shown, then the given solution necessarily has the property B . In this way, topological and analytic studies of differential equations are applied to find their solutions (\rightarrow 314 Ordinary Differential Equations (Asymptotic Behavior of Solutions); 315 (Boundary Value Problems); 316 (Initial Value Problems); 126 Dynamical Systems).

314 (XIII.5) Ordinary Differential Equations (Asymptotic Behavior of Solutions)

A. Linear Differential Equations

A system of linear ordinary differential equations can be written as

$$x' = A(t)x, \quad (1)$$

where t is a real independent variable, $\mathbf{x} = (x_1, \dots, x_n)$ is an n -dimensional complex vector function of t , and $A(t)$ is an $n \times n$ matrix whose elements are complex-valued functions of t . If $A(t)$ is a continuous function of t defined on an open interval I , any solution of (1) is continuously differentiable for $t \in I$. The question naturally arises as to how the solutions behave as t approaches either one of the endpoints of I ; that is, the question of the **asymptotic properties** of the solutions. The interval I can always be taken to be $0 \leq t < \infty$, by applying a suitable transformation of the independent variable if necessary.

The study of the asymptotic expansions of solutions when the coefficient $A(t)$ is an analytic function of t was initiated by H. Poincaré in 1880. This work was continued by J. Horn, J. C. C. A. Kneser, and others in the direction of removing assumptions on the structure of $A(t)$ and extending the domain where the expansions are valid. The theory has been almost completed by W. J. Trjitzinsky, J. Malmquist, and M. Hukuhara (\rightarrow 254 Linear Ordinary Differential Equations (Local Theory)). On the other hand, O. Perron initiated a new direction of research by weakening the regularity conditions on the coefficients. His work was continued by F. Lettenmeyer, R. A. Späth, Hukuhara, and others. The methods used in these two lines of investigation were originally distinct, but Hukuhara established a unified method of treating the problems arising in these two different types of investigations. Furthermore, he succeeded in sharpening those results previously obtained.

Here we assume that $A(t)$ need not be analytic. The following asymptotic properties of a solution $\mathbf{x}(t)$ as $t \rightarrow \infty$ are considered: (i) boundedness of $\limsup t^{-1} \log |\mathbf{x}(t)|$; (ii) boundedness of solution: $\limsup |\mathbf{x}(t)| < \infty$; (iii) convergence of solution: $\lim \mathbf{x}(t)$; (iv) integrability: $\int_0^\infty |\mathbf{x}(s)|^p ds < \infty$, etc. We call $\chi(\mathbf{x}) = \limsup t^{-1} \log |\mathbf{x}(t)|$ the **type number** (or **Lyapunov characteristic number**) of the solution $\mathbf{x}(t)$. The fact that all solutions of (1) are bounded is equivalent to the stability of the solution $\mathbf{x} = 0$, and the fact that all solutions of (1) tend to zero as $t \rightarrow \infty$ is equivalent to the asymptotic stability of the solution $\mathbf{x} = 0$.

B. Constant Coefficients and Periodic Coefficients

We begin with the particular case of (1), where $A(t)$ is a constant matrix:

$$\mathbf{x}' = A\mathbf{x}. \tag{2}$$

To study the asymptotic properties of the

solutions of (2), it suffices to transform the matrix A into a Jordan canonical form, since the structure of the solution space of (2) is completely determined by the Jordan canonical form of A . Thus all solutions of (2) are bounded if and only if every eigenvalue of A has a real part not greater than zero, and those with zero real parts are of simple type, that is, the corresponding blocks in the Jordan canonical form are all 1×1 matrices; all solutions of (2) tend to zero as $t \rightarrow \infty$ if and only if every eigenvalue of A has negative real part.

Consider the linear system

$$\mathbf{x}' = A_0(t)\mathbf{x}, \tag{3}$$

where $A_0(t)$ is a periodic matrix function of period ω . According to Floquet's theorem, (3) is transformed into a system with constant coefficients by means of a suitable transformation $\mathbf{x} = P(t)\mathbf{y}$, where $P(t)$ is a nonsingular periodic matrix of period ω . Thus, at least theoretically, the information on the asymptotic behavior of the solutions of the periodic system (3) can be derived from the corresponding theory for the system with constant coefficients (2).

C. Asymptotic Integration

Suppose that $A(t)$ is bounded. Then the type number $\chi(\mathbf{x})$ is finite for any nontrivial solution $\mathbf{x}(t)$ of (1), and the number of distinct type numbers does not exceed n .

Consider the linear system

$$\mathbf{x}' = [A + B(t)]\mathbf{x}, \tag{4}$$

where A is a constant matrix and $B(t)$ is a matrix function such that $\int_t^{t+1} \|B(s)\| ds \rightarrow 0$ as $t \rightarrow \infty$. For any nontrivial solution $\mathbf{x}(t)$ of (4), the limit $\mu = \lim t^{-1} \log |\mathbf{x}(t)|$ exists and is equal to the real part of one of the eigenvalues of A . Conversely, if at least one eigenvalue of A has real part μ , then there exists a nontrivial solution $\mathbf{x}(t)$ of (4) satisfying $\lim t^{-1} \log |\mathbf{x}(t)| = \mu$. Suppose in addition that $B(t) \rightarrow 0$ as $t \rightarrow \infty$. Let $\mu_1 \leq \mu_2 \leq \dots \leq \mu_n$ be the real parts of the eigenvalues of A . Then there exists a fundamental system of solutions of (4), $\{\mathbf{x}_1(t), \dots, \mathbf{x}_n(t)\}$, such that for any $c_i, c_k \neq 0$,

$$\log |c_1 \mathbf{x}_1(t) + \dots + c_k \mathbf{x}_k(t)| = \mu_k t + o(t).$$

A sharp estimate of the term $o(t)$ was given by Hukuhara.

Next consider the linear system

$$\mathbf{x}' = [A(t) + B(t)]\mathbf{x}, \tag{5}$$

where the matrices $A(t)$ and $B(t)$ satisfy $\int_0^\infty \|A'(s)\| ds < \infty$ and $\int_0^\infty \|B(s)\| ds < \infty$.

Let $\lambda_1(t), \dots, \lambda_n(t)$ and $\lambda_1, \dots, \lambda_n, \lambda_k = \lim \lambda_k(t)$,

be the eigenvalues of $A(t)$ and $A = \lim A(t)$, respectively. N. Levinson proved the following theorem: Assume that $\lambda_1, \dots, \lambda_n$ are mutually distinct and $M_{jk}(t) = \text{Re} \int_0^t [\lambda_j(s) - \lambda_k(s)] ds$ satisfy either $M_{jk}(t) \rightarrow \infty$ as $t \rightarrow \infty$ and for each pair (j, k) , $M_{jk}(t_2) - M_{jk}(t_1) \geq -K$ for $t_1 < t_2$, or $M_{jk}(t) \rightarrow -\infty$ as $t \rightarrow \infty$ and $M_{jk}(t_2) - M_{jk}(t_1) \leq K$ for $t_1 < t_2$, or $|M_{jk}(t_2) - M_{jk}(t_1)| \leq K$ for all t_1, t_2 , where K is a positive constant. Then (5) has a fundamental system of solutions $\{x_1(t), \dots, x_n(t)\}$ such that

$$x_j(t) = \exp\left(\int_0^t \lambda_j(s) ds\right) [\xi_j + o(1)], \quad j = 1, \dots, n,$$

where ξ_j is an eigenvector of A corresponding to λ_j .

D. Boundedness and Convergence of Solutions

Consider again the linear system (5) satisfying $\int^\infty \|A'(s)\| ds < \infty$ and $\int^\infty \|B(s)\| ds < \infty$. Suppose that all eigenvalues of $A(t)$ have nonpositive real parts and that the eigenvalues of $A = \lim A(t)$ whose real parts vanish are simple. Then all solutions of (5) are bounded. This result is a generalization, due to L. Cesari, of the so-called **Dini-Hukuhara theorem**.

In the case of general $A(t)$, it is known that not all solutions of (5) are bounded even if all solutions of (1) tend to zero as $t \rightarrow \infty$ and if the matrix $B(t)$ is such that $\int^\infty \|B(s)\| ds < \infty$ and $B(t) \rightarrow 0$ as $t \rightarrow \infty$. However, if $A(t)$ is periodic or satisfies $\liminf \text{Re} \int^t \text{tr} A(s) ds > -\infty$, then under the assumption that $\int^\infty \|B(s)\| ds < \infty$, the boundedness of all solutions of (1) implies the boundedness of all solutions of (5).

The following inequalities often provide useful information about the asymptotic behavior of solutions of (1):

$$|x(0)| \exp\left(-\int_0^t \mu[-A(s)] ds\right) \leq |x(t)|$$

$$\leq |x(0)| \exp\left(\int_0^t \mu[A(s)] ds\right), \quad t \geq 0,$$

where $\mu[A(t)] = \lim_{h \rightarrow +0} [\|I + hA(t)\| - 1]/h$. ($\mu[A(t)]$ was introduced by Lozinskii.) If $\limsup \int^t \mu[A(s)] ds < \infty$, then all solutions of (1) are bounded; if $\lim \int^t \mu[A(s)] ds$ exists, then for every solution $x(t)$ of (1), $|x(t)|$ tends to a finite limit as $t \rightarrow \infty$; and if $\lim \int^t \mu[A(s)] ds = -\infty$, then all solutions of (1) tend to zero as $t \rightarrow \infty$. It can be shown that every solution of (1) tends to a finite limit as $t \rightarrow \infty$, provided that $\int^\infty \|A(s)\| ds < \infty$.

If all solutions of (1) are bounded, then $\limsup \text{Re} \int^t \text{tr} A(s) ds < \infty$. If $\liminf \text{Re} \int^t \text{tr} A(s) ds > -\infty$, then (1) has a solution $x(t)$ with the property that $\limsup |x(t)| > 0$. When $\lim |x(t)|$

exists for every solution $x(t)$ of (1), if there exists a nontrivial solution $x(t)$ of (1) such that $\lim x(t) = 0$, then $\lim \text{Re} \int^t \text{tr} A(s) ds = -\infty$, but if there is no such solution, then $\text{Re} \int^t \text{tr} A(s) ds$ is bounded.

E. Nonlinear Differential Equations

Consider a system of nonlinear differential equations of the form

$$x' = Ax + f(t, x), \tag{6}$$

where A is an $n \times n$ constant matrix and $f(t, x)$ is an n -vector function that is continuous for $t \geq 0, |x| < \Delta$, and that satisfies $f(t, 0) = 0$. Suppose that $f(t, x)/|x| \rightarrow 0$ as $|x| \rightarrow 0$ and $t \rightarrow \infty$. Then for every eventually nontrivial solution $x(t)$ of (6) that tends to zero as $t \rightarrow \infty$, $\mu = \lim t^{-1} \log|x(t)|$ exists and equals the real part of one of the eigenvalues of A . Conversely, if at least one eigenvalue of A has real part $\mu < 0$, then there exists a solution $x(t)$ of (6) such that $\lim t^{-1} \log|x(t)| = \mu$. Suppose that $f(t, x)/|x| \rightarrow 0$ as $|x| \rightarrow 0$ uniformly with respect to t . Then if all eigenvalues of A have negative real parts, the zero solution $x(t) = 0$ of (6) is asymptotically stable, and if A has an eigenvalue whose real part is positive, then the zero solution of (6) is †unstable. Suppose that $f_x(t, x) = (\partial f_j(t, x)/\partial x_k) \rightarrow 0$ as $|x| \rightarrow 0$ uniformly with respect to t . In this case, if A is a matrix such that its k eigenvalues have negative real parts and the other $n - k$ eigenvalues have positive real parts, then there exists a k -dimensional manifold S containing the origin with the following property: For t_0 sufficiently large, any solution $x(t)$ of (6) tends to zero as $t \rightarrow \infty$, provided that $x(t_0) \in S$, and if $x(t_0) \notin S$, $x(t)$ cannot remain in the vicinity of the origin no matter how close $x(t_0)$ is to the origin.

In the nonlinear system

$$x' = F(t, x), \tag{7}$$

suppose that $F(t, x)$ is of period ω with respect to t and has continuous partial derivatives with respect to x . Suppose, moreover, that (7) has a solution $p(t)$ of period ω . If all the †characteristic exponents of the †variational system of (7) with respect to $p(t)$, $y' = F_x(t, p(t))y$ with $F_x(t, x) = (\partial F_j(t, x)/\partial x_k)$, have negative real parts, then the periodic solution $p(t)$ is asymptotically stable. If an autonomous system $x' = F(x)$ has a periodic solution $p(t)$ and the corresponding variational system $y' = F_x(p(t))y$ has $n - 1$ characteristic exponents with negative eigenvalues, then there exists an $\varepsilon > 0$ such that for any solution $x(t)$ satisfying $|x(t_1) - p(t_0)| < \varepsilon$ for some t_0 and t_1 , we have $|x(t) - p(t + c)| \rightarrow 0$ as $t \rightarrow \infty$ for a suitable choice of c (asymptotic phase).

F. Scalar Differential Equations

The aforementioned results can be specialized to the case of higher-order scalar (or single) ordinary differential equations. Much sharper results can often be derived through direct analysis of scalar equations themselves. In particular, detailed and deep results have been obtained for second-order linear differential equations of the form

$$x'' + q(t)x = 0, \tag{8}$$

e.g., †Mathieu's equation.

If $\int^\infty s|q(s)| ds < \infty$, then (8) has a fundamental system of solutions $\{x_1(t), x_2(t)\}$ satisfying, for $t \rightarrow \infty$,

$$x_1(t) = 1 + o(1), \quad x_2(t) = t[1 + o(1)],$$

$$x'_1(t) = t^{-1}o(1), \quad x'_2(t) = 1 + o(1);$$

if $\int^\infty |q(s) + 1| ds < \infty$, then (8) has a fundamental system of solutions satisfying

$$x_1(t) = e^t[1 + o(1)], \quad x_2(t) = e^{-t}[1 + o(1)],$$

$$x'_1(t) = e^t[1 + o(1)], \quad x'_2(t) = -e^{-t}[1 + o(1)];$$

and if $\int^\infty |q(s) - 1| ds < \infty$, then (8) has a fundamental system of solutions

$$x_1(t) = e^{it}[1 + o(1)], \quad x_2(t) = e^{-it}[1 + o(1)],$$

$$x'_1(t) = ie^{it}[1 + o(1)], \quad x'_2(t) = -ie^{-it}[1 + o(1)].$$

Suppose that $q(t) \rightarrow c > 0$ as $t \rightarrow \infty$ and $\int^\infty |q'(s)| ds < \infty$. Then $x(t)$ and $x'(t)$ are bounded for every solution $x(t)$ of (8). The same is true if $q(t)$ is a positive periodic function of period ω such that $\omega \int_0^\omega q(s) ds \leq 4$. If $q(t)$ is negative, then (8) always has both bounded and unbounded monotone solutions.

The number of linearly independent solutions $x(t)$ of (8) satisfying $\int^\infty |x(s)|^2 ds < \infty$ plays an important role in †eigenvalue problems. It is known that the ordinary differential operator $l[x] = x'' + q(t)x$ is of †limit point type at infinity if there exist a positive function $M(t)$ and positive constants k_1, k_2 such that $q(t) \leq k_1 M(t)$, $|M'(t)M^{-3/2}(t)| \leq k_2$, and $\int^\infty M^{-1/2}(s) ds = \infty$, and that $l[x]$ is of †limit circle type at infinity if $q(t) > 0$, $\int^\infty q^{-1/2}(s) ds = \infty$, and $\int^\infty [q^{-3/2}(s)q'(s)]' + (1/4)q^{-5/2}(s)q'^2(s) ds < \infty$.

Finally consider the nonlinear equation

$$x'' + q(t)|x|^\gamma \operatorname{sgn} x = 0, \tag{9}$$

where γ is a positive constant and $q(t)$ is a positive function. If $q'(t) \geq 0$, then all solutions of (9) are bounded; if either $q'(t) \geq 0$ and $\lim q(t) < \infty$ or $q'(t) \leq 0$ and $\lim q(t) > 0$, then all solutions $x(t)$ of (9) are bounded together with their derivatives $x'(t)$; and if $q'(t) \geq 0$, $\lim q(t) = \infty$ and either $q''(t) \geq 0$ or $q''(t) \leq 0$, then all solutions of (9) converge to zero as $t \rightarrow \infty$.

Equation (9) is said to be **oscillatory** if every solution of (9) that is continuable to $t = \infty$ has arbitrarily large zeros. If (9) is oscillatory and if $q_1(t) \geq q(t)$, then the equation $x'' + q_1(t)|x|^\gamma \operatorname{sgn} x = 0$ is also oscillatory. When $\gamma = 1$, (9) is oscillatory if $q(t) \geq (1 + \epsilon)/4t^2$ for some $\epsilon > 0$, and is not oscillatory if $q(t) \leq 1/4t^2$. A necessary and sufficient condition for equation (9) with $\gamma \neq 1$ to be oscillatory is as follows: $\int^\infty sq(s) ds = \infty$ if $\gamma > 1$; $\int^\infty s^\gamma q(s) ds = \infty$ if $0 < \gamma < 1$.

315 (XIII.4)
Ordinary Differential Equations (Boundary Value Problems)

A. General Remarks

Consider the differential equation in the real variable x

$$f(x, y, y', \dots, y^{(n)}) = 0. \tag{1}$$

Let a_1, \dots, a_k be points in an interval $I \subset \mathbf{R}$ and consider several relations between nk values $y(a_i), y'(a_i), \dots, y^{(n-1)}(a_i), i = 1, \dots, k$. The problem of finding solutions of (1) satisfying these relations is called a **boundary value problem** of (1), and the relations considered are called **boundary conditions**. When $k = 2$ and a_1, a_2 are the endpoints of I , the problem, called a **two-point boundary value problem**, has been a main subject of study. We can consider boundary value problems in the same way for systems of differential equations.

B. Linear Differential Equations

Consider a linear ordinary differential operator L defined by

$$L[y] = p_0(x)y^{(n)} + p_1(x)y^{(n-1)} + \dots + p_n(x)y,$$

where $p_k(x)$ is a complex-valued function of class C^{n-k} defined on a compact interval $a \leq x \leq b$ and $p_0(x) \neq 0$ for any $x \in [a, b]$. We define a system of **linear boundary operators** U_1, \dots, U_m by

$$U_i[y] = \sum_{j=1}^n M_{ij}y^{(j-1)}(a) + \sum_{j=1}^n N_{ij}y^{(j-1)}(b).$$

Given a function $f(x)$ and complex constants $\gamma_1, \dots, \gamma_m$, the linear boundary value problem defined by

$$L[y] = f(x), \quad U_i[y] = \gamma_i, \quad i = 1, \dots, m, \quad (2)$$

is a two-point boundary value problem. When $f(x) \equiv 0$, $\gamma_i = 0$, $i = 1, \dots, m$, the problem is called **homogeneous**; otherwise it is called **inhomogeneous**. Let $L^*[y]$ be a formally adjoint differential operator of $L[y]$. A set of m^* linear boundary conditions $U_i^*[y] = 0$, $i = 1, \dots, m^*$, is said to be an **adjoint boundary condition** of $U_i[y] = 0$, $i = 1, \dots, m$, if for any function y of class C^n satisfying $U_i[y] = 0$, $i = 1, \dots, m$, and any function y^* of class C^n satisfying $U_i^*[y^*] = 0$, $i = 1, \dots, m^*$, we have $\int_a^b L[y]y^* dx = \int_a^b yL^*[y^*] dx$. The boundary value problem

$$L^*[y] = 0, \quad U_i^*[y] = 0, \quad i = 1, \dots, m^*, \quad (3)$$

is said to be an **adjoint boundary value problem** of

$$L[y] = 0, \quad U_i[y] = 0, \quad i = 1, \dots, m. \quad (4)$$

We say that the problem (4) is **self-adjoint** if $L[y] = L^*[y]$ and the conditions $U_i[y] = 0$, $i = 1, \dots, m$, are equivalent to the conditions $U_i^*[y] = 0$, $i = 1, \dots, m^*$.

The boundary value problem containing a parameter λ

$$L[y] = \lambda y, \quad U_i[y] = 0, \quad i = 1, \dots, m, \quad (5)$$

admits nontrivial solutions only for special values of λ . Such values of λ are called the **eigenvalues** (or **proper values**) of (5), and the corresponding solutions $\neq 0$ are called the **eigenfunctions** (or **proper functions**) of (5). For any value of λ that is not an eigenvalue, there exists a unique function $G(x, \xi, \lambda)$ such that the conditions $L[y] = \lambda y + f$, $U_i[y] = 0$ are equivalent to $y = \int_a^b G(x, \xi, \lambda)f(\xi)d\xi$. The function $G(x, \xi, \lambda)$ is called the **Green's function** of (5). If $\lambda = 0$ is not an eigenvalue, then (5) is equivalent to

$$y(x) = \lambda \int_a^b G(x, \xi)y(\xi)d\xi,$$

where $G(x, \xi) = G(x, \xi, 0)$. For a function $G(x, \xi, \lambda)$ of (5) and the function $G^*(x, \xi, \lambda)$ of $L^*[y] = \lambda y$, have the relation $G(x, \xi, \lambda) = \bar{G}(x, \xi, \lambda)$ the assumption that (5) is self-adjoint has only real eigenvalues which or countably infinite discrete eigenvalues are orthogonal to each other is an orthonormal set of eigenfunctions that no eigenfunction is linearly dependent on the set $\{\varphi_n\}$, then the system $\{\varphi_n\}$ is an orthonormal set in the Hilbert space consisting of functions that are square integrable on (a, b) , and hence for any function f expansion $f = a_1\varphi_1 + a_2\varphi_2 + \dots$ $L_2(a, b)$ the Parseval equality $\int_a^b |f|^2 dx = \sum |a_n|^2$ if f is a function of class C^n satisfying $U_i[f] = 0$, then the Fourier expansion converges uniformly to f on $[a, b]$.

The boundary value problem of order n

$$(p(x)y')' + (q(x) + \lambda r(x))y = 0,$$

$$\alpha y(a) + \beta y'(a) = 0, \quad \gamma y(b) + \delta y'(b) = 0,$$

is called a **Sturm-Liouville problem** if p, q, r are real-valued functions defined on $[a, b]$ and $\alpha, \beta, \gamma, \delta$ are real constants. p, q, r are continuous and $p(x) > 0$ on $[a, b]$. Then (i) the eigenvalues λ_n form a sequence tending to $+\infty$; (ii) the eigenfunctions $\varphi_n(x)$ associated with λ_n have no zeros in $a < x < b$, and there exist adjacent zeros of $\varphi_n(x)$ at a zero of $p(x)$; (iii) the set of eigenfunctions is complete on $[a, b]$ with weight function $r(x)$.

$$\int_a^b r(x)\varphi_m(x)\varphi_n(x)dx = 0, \quad m \neq n.$$

When the coefficients p_0, \dots, p_n are defined in an open interval $a < x < b$, $b \leq \infty$ and p_k is of class C^{n-k} , L is a natural way operator in the Hilbert space consisting of functions that are square integrable in $a < x < b$, and the general theory is based on operator theory in Hilbert space (\rightarrow 390 Spectral Analysis of Operators).

C. Nonlinear Differential Equations

Boundary value problems for nonlinear differential equations are very difficult to solve. Results are obtained only for equations of the form

Consider, for example, the boundary value problem

$$y'' = f(x, y, y')$$

and boundary conditions $y(a) = A$, $y(b) = B$. The following theorem has been proved: Suppose that $f(x, y, y')$ is continuous for $a \leq x \leq b$, $\underline{\omega}(x) \leq y \leq \bar{\omega}(x)$, $-\infty < y' < +\infty$, and $|f(x, y, y')| \leq M(1 + y'^2)$; $\underline{\omega}''(x) > f(x, \underline{\omega}(x), \underline{\omega}'(x))$ and $\bar{\omega}''(x) < f(x, \bar{\omega}(x), \bar{\omega}'(x))$ for $a \leq x \leq b$; and $\underline{\omega}(a) \leq A \leq \bar{\omega}(a)$ and $\underline{\omega}(b) \leq B \leq \bar{\omega}(b)$. Then (6) admits a solution $y(x)$ such that $y(a) = A$, $y(b) = B$, and $\underline{\omega}(x) \leq y(x) \leq \bar{\omega}(x)$ for $a \leq x \leq b$. If in addition f is an increasing function with respect to y , the solution is unique. Moreover, under suitable conditions, the solution is obtainable by the method of successive approximations.

The boundary value problem

$$y''' + 2yy'' + 2\lambda(k^2 - y^2) = 0,$$

$$y(0) = y'(0) = 0, \quad y'(x) \rightarrow k \quad (x \rightarrow \infty),$$

where λ and k are constants, appears in the theory of fluid dynamics. It is known that if $\lambda \geq 0$, the problem has a solution, and that if $0 \leq \lambda \leq 1$, the solution is unique.

Consider the system of differential equations

$$y_j' = f_j(x, y_1, \dots, y_n), \quad j = 1, \dots, n.$$

The problem of finding a solution such that $y_j(a_j) = b_j$, $j = 1, \dots, n$, called **Hukuhara's problem**, reduces to the initial value problem when the a_j coincide. The problem of solving

$$y^{(n)} = f(x, y, y', \dots, y^{(n-1)}),$$

$$y(a_j) = b_j, \quad j = 1, \dots, n,$$

is reduced to Hukuhara's problem by a suitable change of variables. The following result is a generalization of Perron's theorem: Let $\underline{\omega}_j(x)$, $\bar{\omega}_j(x)$, $j = 1, \dots, n$, be continuous and right and left differentiable functions and $\underline{\omega}_j(x) \leq \bar{\omega}_j(x)$ for $a \leq x \leq b$. Suppose that the $f_j(x, y_1, \dots, y_n)$ are continuous for $a \leq x \leq \beta$ and $\underline{\omega}_k(x) \leq y_k \leq \bar{\omega}_k(x)$, $k = 1, \dots, n$; satisfy $(x - a_j)(D^\pm \bar{\omega}_j(x) - f_j(x, y_1, \dots, y_n)) \geq 0$ for $y_j = \bar{\omega}_j(x)$ and $\underline{\omega}_k(x) \leq y_k \leq \bar{\omega}_k(x)$, $k \neq j$; satisfy $(x - a_j)(D^\pm \underline{\omega}_j(x) - f_j(x, y_1, \dots, y_n)) \leq 0$ for $y_j = \underline{\omega}_j(x)$ and $\underline{\omega}_k(x) \leq y_k \leq \bar{\omega}_k(x)$, $k \neq j$; and satisfy $\underline{\omega}_j(a_j) \leq b_j \leq \bar{\omega}_j(a_j)$. Then there exists a solution $y(x)$ such that $y_j(a_j) = b_j$ and $\underline{\omega}_j(x) \leq y(x) \leq \bar{\omega}_j(x)$. This theory was applied by M. Hukuhara to the study of singular points of ordinary differential equations.

316 (XIII.3) Ordinary Differential Equations (Initial Value Problems)

A. General Remarks

Consider a system of ordinary differential equations

$$dy_i/dx = f_i(x, y_1, \dots, y_n), \quad i = 1, \dots, n. \quad (1)$$

A. L. Cauchy first gave a rigorous proof for the existence and uniqueness of solutions: If f_i , $i = 1, \dots, n$, and their derivatives $\partial f_i / \partial y_k$ are continuous in a neighborhood of a point (a, b_1, \dots, b_n) , then there exists a unique solution of (1) satisfying the conditions $y_i(a) = b_i$, $i = 1, \dots, n$. These conditions are called **initial conditions**, and the values a, b_1, \dots, b_n **initial values**. The problem of finding solutions that satisfy initial conditions is called an **initial value problem** (or **Cauchy problem**). If we consider (x, y_1, \dots, y_n) as the coordinates of a point in the $(n + 1)$ -dimensional space \mathbf{R}^{n+1} , then a solution of (1) represents a curve in this space called a **solution curve** (or **integral curve**). The statement that a solution satisfies initial conditions $y_i(a) = b_i$, $i = 1, \dots, n$, means that the integral curve represented by it passes through the point (a, b_1, \dots, b_n) .

Since, in general, we can transform a differential equation of higher order into a system of differential equations of the form (1) by introducing new dependent variables, all definitions and theorems concerning the system (1) can be interpreted as applying to a higher-order equation. For example, for the equation $y^{(n)} = f(x, y, y', \dots, y^{(n-1)})$ the conditions $y(a) = b$, $y'(a) = b', \dots, y^{(n-1)}(a) = b^{(n-1)}$ constitute initial conditions, and the values $a, b, b', \dots, b^{(n-1)}$ are initial values. If f and its derivatives $\partial f / \partial y^{(i)}$ are continuous, then there exists a unique solution satisfying given initial conditions.

Suppose that the f_i are continuous. Then a system of functions $(y_1(x), \dots, y_n(x))$ is a solu-

tion of (1) if and only if

$$y_i(x) = b_i + \int_a^x f_i(x, y_1(x), \dots, y_n(x)) dx, \quad i = 1, \dots, n.$$

When the f_i are not continuous, we define $(y_1(x), \dots, y_n(x))$ to be a solution of (1) for the initial value problem $y_i(a) = b_i$ if $(y_1(x), \dots, y_n(x))$ satisfied the integral equation just given.

We use the vectorial notation: $\mathbf{y} = (y_1, \dots, y_n)$, $\mathbf{f} = (f_1, \dots, f_n)$ together with $\|\mathbf{y}\|^2 = y_1^2 + \dots + y_n^2$. The equations (1) are then written as the single equation

$$\mathbf{y}' = \mathbf{f}(x, \mathbf{y}).$$

B. Equations in the Real and Complex Domains

We state main theorems for differential equations in the real domain in Sections C–F and in the complex domain in Section G.

C. Existence Theorems

Suppose that $\mathbf{f}(x, \mathbf{y})$ is continuous for $|x - a| \leq r$ and $\|\mathbf{y} - \mathbf{b}\| \leq \rho$, and that $\|\mathbf{f}(x, \mathbf{y})\| \leq M$ there. Then equation (1) admits a solution satisfying $\mathbf{y}(a) = \mathbf{b}$ and defined in an interval $|x - a| \leq \min(r, \rho/M)$ (**existence theorem**). There are two methods of proving this theorem, one using **Cauchy polygons** and one using **fixed-point theorems** for function spaces. From this theorem we deduce that if $\mathbf{f}(x, \mathbf{y})$ is continuous in a domain D of \mathbf{R}^{n+1} , then there exists a solution curve passing through any point of D . Let $\mathbf{y} = \varphi_1(x)$ and $\mathbf{y} = \varphi_2(x)$ be solutions of (1) defined in the intervals I_1 and I_2 , respectively. If $I_1 \subset I_2$ and $\varphi_1(x) = \varphi_2(x)$ for $x \in I_1$, we say that φ_2 is a **prolongation** or **extension** of φ_1 . Given a solution of (1), there exists a nonextendable solution that is an extension of the solution. The solution curve of a nonextendable solution tends to the boundary of D as x tends to any one of the ends of its interval of definition.

D. Uniqueness Theorems

Continuity does not imply uniqueness of the solution. If (1) admits at most one solution satisfying a given condition, we call this condition a **uniqueness condition**. Various kinds of **uniqueness theorems**, which state uniqueness conditions, are known.

The **Lipschitz condition**:

$$\|\mathbf{f}(x, \mathbf{y}) - \mathbf{f}(x, \mathbf{z})\| \leq L \|\mathbf{y} - \mathbf{z}\|, \quad L > 0 \text{ a constant,}$$

is one of the simplest. When \mathbf{f} is continuous and satisfies the Lipschitz condition, the **method of successive approximation**, initiated by C. E. Picard, is often used to prove the existence of solutions. This method is as follows: We choose a suitable function, for example $\mathbf{y}_0(x) \equiv \mathbf{b}$, and then define $\mathbf{y}_k(x)$, $k = 1, 2, \dots$, recursively by $\mathbf{y}_k(x) = \mathbf{b} + \int_a^x \mathbf{f}(x, \mathbf{y}_{k-1}(x)) dx$. Then $\{\mathbf{y}_k(x)\}$ is uniformly convergent, and its limit is a solution of (1) satisfying $\mathbf{y}(a) = \mathbf{b}$.

Assuming the continuity of \mathbf{f} , H. Okamura gave a necessary and sufficient condition for uniqueness: Suppose that \mathbf{f} is continuous in D . Then a necessary and sufficient condition for there to exist a unique solution curve of (1) going from any point of D to the right is that there exist a C^1 -function $\varphi(x, \mathbf{y}, \mathbf{z})$ defined for $(x, \mathbf{y}, \mathbf{z})$ such that (x, \mathbf{y}) and $(x, \mathbf{z}) \in D$ and satisfying the conditions $\varphi(x, \mathbf{y}, \mathbf{z}) = 0$ for $\mathbf{y} = \mathbf{z}$, $\varphi(x, \mathbf{y}, \mathbf{z}) > 0$ for $\mathbf{y} \neq \mathbf{z}$, and

$$\frac{\partial \varphi}{\partial x} + \sum_i \frac{\partial \varphi}{\partial y_i} f_i(x, \mathbf{y}) + \sum_i \frac{\partial \varphi}{\partial z_i} f_i(x, \mathbf{z}) \leq 0.$$

E. Perron's Theorem

Consider the scalar equation $y' = f(x, y)$. We have **Perron's theorem**: Let $\omega(x)$ and $\bar{\omega}(x)$ be continuous functions that are right differentiable in $\alpha \leq x < \beta$ and satisfy $\omega(x) \leq \bar{\omega}(x)$, and let f be a continuous function defined on $D: \alpha \leq x < \beta, \omega(x) \leq y \leq \bar{\omega}(x)$. Suppose that $D^+ \omega(x) \leq f(x, \omega(x))$ and $D^+ \bar{\omega}(x) \geq f(x, \bar{\omega}(x))$. ($D^+ \omega$ denotes the right derivative of ω .) Then for any $(a, b) \in D$ there exists a solution defined on $a \leq x < \beta$ and satisfying $y(a) = b$. The fact that the interval of definition is $a \leq x < \beta$ can be expressed by saying that if we denote the set $\infty < x < \beta, |y| < \infty$ by Ω , then D is closed in Ω and there exists, among solution curves going from a point in D to the right, a curve that reaches the boundary of Ω .

Perron's theorem was generalized by M. Hukuhara and M. Nagumo. Let Ω be an open set in \mathbf{R}^{n+1} , D a closed set in Ω , and \mathbf{f} a continuous function in D . A necessary and sufficient condition for (1) to admit a solution curve going from any point (a, \mathbf{b}) in D to the right is that there exist a sequence of points in D , $\{(a_k, \mathbf{b}_k)\}$, such that $a_k \downarrow a$ and $(\mathbf{b}_k - \mathbf{b}) / (a_k - a) \rightarrow \mathbf{f}(a, \mathbf{b})$. Moreover, every solution curve is prolonged to the right to the boundary of Ω . Let $S(\mathbf{y})$ be a continuous subadditive and positively homogeneous function and $\omega(x)$ a function continuous and right differentiable on $\alpha \leq x < \beta$. A sufficient condition for $D: \alpha \leq x < \beta, S(\mathbf{y}) \leq \omega(x)$ to possess the property in the statement of Perron's theorem is given by $D^+ \omega(x) \geq S(\mathbf{f}(x, \mathbf{y}))$ for $\|\mathbf{y}\| = \omega(x)$.

A continuous function $\omega(x)$ is said to be a

right majorizing function of (1) with respect to $S(\mathbf{y})$ if for any solution $\varphi(x)$, $S(\varphi(a)) \leq \omega(a)$ implies $S(\varphi(x)) \leq \omega(x)$ for $x \geq a$ if both $S(\varphi(x))$ and $\omega(x)$ are defined. In order for $\omega(x)$ to be a right majorizing function, it suffices that $D^+ \omega(x) > S(\mathbf{f}(x, \mathbf{y}))$ for $\|\mathbf{y}\| = \omega(x)$. A function satisfying this inequality is called a **right superior function** of (1) with respect to $S(\mathbf{y})$. If $F(x, S(\mathbf{y})) > S(\mathbf{f}(x, \mathbf{y}))$, then any solution of $y' = F(x, y)$ is a right superior function of (1). Theorems stating such facts are called **comparison theorems**.

If (1) has a unique solution, the condition $D^+ \omega(x) \geq S(\mathbf{f}(x, \mathbf{y}))$ for $S(\mathbf{y}) = \omega(x)$ implies that $\omega(x)$ is a right majorizing function of (1). Conversely, we can derive from comparison theorems general uniqueness theorems, one of which we state. Suppose that $G(x, y)$ is continuous for $\alpha < x < \beta$ and $0 \leq y < r(x)$; $G(x, 0) \equiv 0$; a solution of $y' = G(x, y)$ such that $y = o(r(x))$ as $x \rightarrow \alpha + 0$ vanishes identically; and finally that $S(\mathbf{f}(x, \mathbf{y}_1) - \mathbf{f}(x, \mathbf{y}_2)) \leq G(x, S(\mathbf{y}_1 - \mathbf{y}_2))$. Then for two solutions φ_1, φ_2 of (1) such that $S(\varphi_1 - \varphi_2) = o(r(x))$ as $x \rightarrow \alpha + 0$, we have $\varphi_1 \equiv \varphi_2$. Assuming that \mathbf{f} is continuous at (a, \mathbf{b}) and taking $y/(x - a)$ as G , we obtain Nagumo's condition $(x - a)S(\mathbf{f}(x, \mathbf{y}_1) - \mathbf{f}(x, \mathbf{y}_2)) \leq S(\mathbf{y}_1 - \mathbf{y}_2)$.

G. Peano proved the following theorem: With the same notation and assumption as in Perron's theorem, there exist a **maximum solution** $\bar{\varphi}$ and a **minimum solution** $\underline{\varphi}$ of $y' = f(x, y)$ such that $y(a) = b$ for $\underline{\omega}(a) \leq b \leq \bar{\omega}(a)$, and such that there exists a solution curve passing through any point in $\alpha \leq x < \beta$, $\varphi(x) \leq y \leq \bar{\varphi}(x)$. This theorem was extended by Hukuhara as follows. Suppose that $\mathbf{f}(x, \mathbf{y})$ is continuous and bounded in $D: \alpha \leq x \leq \beta, \|\mathbf{y}\| < \infty$. Let C be a †continuum in D , and let $\mathfrak{F}(C)$ denote the set of solutions intersecting C . Then $\mathfrak{F}(C)$ is a continuum of the †function space $C([\alpha, \beta])$. From this theorem we can deduce the **Kneser-Nagumo theorem**, which says that the intersection of the set of points belonging to the members of $\mathfrak{F}(C)$ and a hyperplane $x = \xi$ is a continuum. It was proved by Hukuhara that if C is in the hyperplane $x = \alpha$, then (1) admits a solution connecting the two hyperplanes $x = \alpha$ and $x = \beta$ and passing through the boundary of the set of points belonging to the members of $\mathfrak{F}(C)$.

F. Equations Containing Parameters

We assume uniqueness of the solution of

$$y' = \mathbf{f}(x, \mathbf{y}, \lambda), \quad \lambda = (\lambda_1, \dots, \lambda_m), \tag{2}$$

where \mathbf{f} is a continuous function of (x, \mathbf{y}, λ) . Let $\varphi(x, a, \mathbf{b}, \lambda)$ denote the solution of (2) satisfying $y(a) = \mathbf{b}$. Then $\varphi(x, a, \mathbf{b}, \lambda)$ is continuous with respect to $(x, a, \mathbf{b}, \lambda)$ in its region of definition.

If the derivatives $\partial \mathbf{f} / \partial y_k$ are also continuous, then $\varphi(x, a, \mathbf{b}, \lambda)$ is a continuously differentiable function of (x, \mathbf{b}) ; $z_{jk} = \partial \varphi_j / \partial b_k, j = 1, \dots, n$, satisfy the system of linear ordinary differential equations and the initial condition

$$\frac{d}{dx} z_{jk} = \sum_{i=1}^n \left(\frac{\partial f_j}{\partial y_i} \right) z_{ik}, \quad z_{jk}(a) = \delta_{jk};$$

and $z_j = \partial \varphi_j / \partial a, j = 1, \dots, n$, satisfy the same system with the initial condition $z_j(a) = -f_j(a, \mathbf{b}, \lambda)$, where $(\partial f_j / \partial y_i)$ means $(\partial^2 f_j / \partial y_i \partial y_j)$ $(x, \varphi(x, a, \mathbf{b}, \lambda), \lambda)$. If \mathbf{f} further admits continuous derivatives $\partial \mathbf{f} / \partial \lambda_i$, then $\varphi(x, a, \mathbf{b}, \lambda)$ is continuously differentiable with respect to λ_i , and moreover, $w_{ji} = \partial \varphi_j / \partial \lambda_i, j = 1, \dots, n$, satisfy the system

$$\frac{d}{dx} w_{ji} = \sum_{k=1}^n \left(\frac{\partial f_j}{\partial y_k} \right) w_{ki} + \left(\frac{\partial f_j}{\partial \lambda_i} \right), \quad w_{ji}(a) = 0.$$

These differential systems are called the **variational equations** of (1).

C. Carathéodory proved the existence of solutions of (1) under the less restrictive assumption that \mathbf{f} is continuous with respect to y for any fixed x and measurable with respect to x for any fixed y .

Suppose that \mathbf{f} is continuous and satisfies a Lipschitz condition. Let $\mathbf{z}(x)$ be a function such that $\mathbf{z}(a) = \mathbf{b}$ and $\|\mathbf{z}'_i(x) - f_i(x, \mathbf{z}(x))\| \leq \varepsilon(x)$, and let $\mathbf{y}(x)$ be a solution of (1) such that $\mathbf{y}(a) = \mathbf{b}$. Then we obtain

$$\|\mathbf{z}_i(x) - \mathbf{y}_i(x)\| \leq e^{L|x-a|} \left| \int_a^x \varepsilon(x) e^{-L|x-a|} dx \right|,$$

which gives approximate solutions of (1).

G. Equations in the Complex Domain

We assume that the variables x, y_1, \dots, y_n all have complex values. We have the following theorem: If \mathbf{f} is holomorphic at (a, \mathbf{b}) , then (1) has a unique solution that is holomorphic at $x = a$ and takes the value \mathbf{b} at $x = a$. This theorem can be proved by utilizing the method of successive approximations and fixed-point theorems. Cauchy proved the theorem by using **majorant series**. This method, called the **method of majorants**, proceeds for the scalar equations as follows: Let $f(x, y) = \sum a_{jk}(x - a)^j (y - b)^k$ and $y = \sum c_n (x - a)^n$. Substituting the latter series into both members, we can successively determine the coefficients c_n by the method of undetermined coefficients. Assuming that $|f| < M$ for $|x - a| < r$ and $|y - b| < \rho$, consider the solution $Y = \sum C_n (x - a)^n$ of

$$\frac{dY}{dx} = \frac{M}{(1 - (x - a)/r)(1 - (Y - b)/\rho)}$$

satisfying $Y(a) = b$. We have $C_n \geq |c_n|$ for any n ,

which shows that $\sum C_n(x-a)^n$ is a majorant series of $\sum c_n(x-a)^n$.

We have the following **uniqueness theorem**: Suppose that $f(x, y)$ is holomorphic at (a, \mathbf{b}) . Let C be a curve having the point a as one of its ends and $\varphi(x)$ be a solution with the following properties: φ is holomorphic on C except possibly at $x=a$, and there exists a sequence of points on C , $\{a_k\}$, such that $a_k \rightarrow a$ and $\varphi(a_k) \rightarrow \mathbf{b}$. Then $\varphi(x)$ is holomorphic at a . By a theorem of identity, the analytic continuation of a solution continues to be a solution if it does not encounter any singularity of f . If a solution $\varphi(x)$ is holomorphic on a smooth curve $x = \chi(t)$, with $0 \leq t \leq t_0$ and $\chi(0) = a$, and $\varphi(a) = \mathbf{b}$, then $y = \varphi(\chi(t))$ is a solution for $0 \leq t \leq t_0$ of

$$y' = \chi'(x)f(\chi(t), y) \quad (3)$$

satisfying $y(0) = \mathbf{b}$. Conversely, if (3) has a solution $y = \psi(t)$ defined in $0 \leq t \leq t_0$ and satisfying $y(0) = \mathbf{b}$, and if $f(x, y)$ is holomorphic at $(\chi(t), \psi(t))$ for $0 \leq t \leq t_0$, then (1) has a solution $\varphi(x)$ holomorphic on C and $\psi(t) = \varphi(\chi(t))$ for $0 \leq t \leq t_0$.

Suppose that $f = f_1/f_2$, where f_1 and f_2 are holomorphic at (a, \mathbf{b}) . If $f_1(a, \mathbf{b}) \neq 0$, $f_2(a, \mathbf{b}) \neq 0$, and $f_2(a, \mathbf{b}) = 0$, then the equation $y' = f(x, y)$ admits a unique solution such that $y \rightarrow \mathbf{b}$ as $x \rightarrow a$, and this solution can be expanded into a Puiseux series:

$$y = \sum_{n=0}^{\infty} c_n(x-a)^{n/r}.$$

If f is holomorphic at (a, \mathbf{b}) , then the solution $y = \varphi(x, x_0, y_0)$ of (1) satisfying $y(x_0) = y_0$ is holomorphic with respect to (x, x_0, y_0) at (a, a, \mathbf{b}) . If $f(x, y, \lambda)$ is holomorphic at $(a, \mathbf{b}, \lambda_0)$, then the solution of (2), $y = \varphi(x, x_0, y_0, \lambda)$, satisfying $y(x_0) = y_0$ is holomorphic at $(a, a, \mathbf{b}, \lambda_0)$. Suppose that x is a real variable and y is a complex vector. If f is continuous with respect to (x, y) and holomorphic with respect to y , then the solution $\varphi(x, x_0, y_0)$ is holomorphic with respect to y_0 . If $f(x, y, \lambda)$ is continuous with respect to (x, y, λ) and holomorphic with respect to (y, λ) , then $\varphi(x, x_0, y_0, \lambda)$ is holomorphic with respect to (y_0, λ) .

317 (X.21) Orthogonal Functions

A. Orthogonal Systems

Let (X, μ) be a measure space. For complex-valued functions f, g on X belonging to the function space $L_2(X)$, we define the inner product $(f, g) = \int_X f(x)\overline{g(x)} d\mu(x)$ and the norm $\|f\| = (f, f)^{1/2}$. If $(f, g) = 0$, then we say that f and g are **orthogonal** on X with respect to the measure μ . If X is a subset of a Euclidean space and μ is the Lebesgue measure m , then we simply say that they are orthogonal. If the measure has a density function $\varphi(x)$ with respect to the Lebesgue measure and $(f, g) = \int_X f(x)\overline{g(x)}\varphi(x) dm(x) = 0$, we say that they are orthogonal with respect to the **weight function** $\varphi(x)$. If $\|f\|^2 = 1$, then f is said to be **normalized**. A set of functions $\{f_n(x)\}$ ($n = 1, 2, \dots$) is said to be an **orthogonal system** (or **orthogonal set**), and we write $\{f_n\} \in O(X)$, if any pair of functions in the set are orthogonal. The orthogonal set $\{f_n(x)\}$ is said to be **orthonormal**, and we write $\{f_n\} \in ON(X)$ if each f_n is normalized.

Let $\{f_n\}$ be a set of linearly independent functions in $L_2(X)$, and let R be a subset of $L_2(X)$. If we can approximate any function $f \in R$ arbitrarily closely by a finite linear combination of the $f_n(x)$ with respect to the norm in $L_2(X)$, we say that $\{f_n\}$ is **total** in R . Let $\{f_n\} \in O(X)$. If $(\varphi, f_n) = 0$ for all n implies $\varphi(x) = 0$ almost everywhere (a.e.), then $\{f_n\}$ is said to be **complete** in $L_2(X)$. An orthogonal system $\{f_n\}$ is complete in $L_2(X)$ if and only if the system is total in $L_2(X)$.

If $\{f_n\} \in O(X)$, then the series $\sum_{n=1}^{\infty} c_n f_n(x)$ is called an **orthogonal series**. If the series converges to $\varphi(x)$ in the mean of order 2, then $c_n = (\varphi, f_n) / \|f_n\|^2$. We call the c_n ($n = 1, 2, \dots$) the

expansion coefficients or **Fourier coefficients** of $\varphi(x)$ with respect to $\{f_n\}$.

If $\{g_n\} \subset L_2(X)$ are linearly independent, we can construct an orthonormal system $\{f_n\}$ by forming suitable linear combinations of the g_n ; $\{f_n\}$ spans the same subspace as $\{g_n\}$. For this purpose we set $f_1(x) = g_1(x)/\|g_1\|$, $f_n(x) = \varphi_n(x)/\|\varphi_n\|$, where $\varphi_n(x) = g_n(x) - \sum_{v=1}^{n-1} (g_n, f_v) f_v(x)$, $n \geq 2$. This procedure is called **Schmidt orthogonalization** or **Gram-Schmidt orthogonalization**.

If the c_n are Fourier coefficients of $\varphi(x) \in L_2(X)$ with respect to $\{f_n(x)\} \in ON(X)$, then we have the \dagger Bessel inequality $\sum_{n=1}^{\infty} |c_n|^2 \leq \|\varphi\|^2$. Equality in the Bessel inequality for all $\varphi \in L_2(X)$ (the \dagger Parseval identity) is equivalent to completeness of $\{f_n\}$ in $L_2(X)$. In this case $\sum_{n=1}^{\infty} c_n f_n(x)$ is called the **orthogonal expansion** of φ with respect to $\{f_n\}$, and conversely, for any sequence $\{c_n\}$ such that $\sum |c_n|^2 < \infty$, there is a function $\varphi \in L_2(X)$ that has the c_n as its Fourier coefficients, and

$$\sum_{n=1}^{\infty} |c_n|^2 = \|\varphi\|^2,$$

$$\varphi(x) = \text{l.i.m.} \left(\sum_{m=1}^n c_m f_m(x) \right).$$

This is called the \dagger **Riesz-Fischer theorem**.

B. Orthogonal Systems on the Real Line

We assume that X is a finite interval (a, b) and that functions on X are real-valued. We write $O(a, b)$ or $ON(a, b)$ instead of $O(X)$, $ON(X)$.

(1) If $\{f_n\} \in ON(a, b)$, $|f_n(x)| \leq M$ (const.), and $\sum c_n f_n(x)$ converges \dagger a.e., then $c_n \rightarrow 0$ as $n \rightarrow \infty$.

(2) We can construct a complete orthonormal system $\{f_n(x)\}$ and a function $\varphi(x) \in L_1(a, b)$ such that its orthogonal expansion $\sum c_n f_n(x)$ diverges everywhere. (3) If $\{f_n(x)\} \in ON(a, b)$ and $\sum c_n^2 \log^2 n < \infty$, then $\sum c_n f_n(x)$ converges a.e. The factor $\log^2 n$ cannot be replaced by any other monotone increasing factor $\omega(n)$ satisfying $0 \leq \omega(n) = o(\log^2 n)$ (**Rademacher-Men'shov theorem**). K. Tandori proved that if $c_n \downarrow 0$ and $\sum c_n \varphi_n$ converges a.e. for any orthonormal system $\{\varphi_n\}$, then $\sum |c_n|^2 \log^2 n < \infty$.

(4) If the orthogonal expansion of a function $\varphi \in L_2(a, b)$ is \dagger summable by Abel's method on a set E , then it is $\dagger(C, 1)$ -summable a.e. on E . $(C, 1)$ -summability a.e. of the orthogonal expansion of a function $\varphi \in L_2(a, b)$ is equivalent to convergence a.e. of the partial sums $s_{2^n}(x)$ ($n = 1, 2, \dots$) of its expansion. (5) Suppose that $\{f_n(x)\} \in ON(a, b)$, $|f_n(x)| \leq M$. Then: (i) If the a_n are the Fourier coefficients of $\varphi(x)$ with respect to $\{f_n(x)\}$, then

$$\left(\sum_{n=1}^{\infty} |a_n|^{p'} \right)^{1/p'} \leq M^{(2-p)/p} \left(\int_a^b |\varphi(x)|^p dx \right)^{1/p},$$

where $1 < p \leq 2$, $1/p + 1/p' = 1$. Conversely, if $(\sum |a_n|^p)^{1/p} < \infty$ ($1 < p \leq 2$), there exists a function $\varphi(x)$ which has the a_n as its Fourier coefficients and such that

$$\left(\int_a^b |\varphi(x)|^{p'} dx \right)^{1/p'} \leq M^{(2-p)/p} \left(\sum_{n=1}^{\infty} |a_n|^p \right)^{1/p}$$

(**F. Riesz's theorem**). When the orthonormal system is the trigonometric system, this is called the **Hausdorff-Young theorem**. (ii) Let $\{a_n^*\}$ be the decreasing rearrangement of $\{|a_n|\}$; then

$$\sum_{n=1}^{\infty} a_n^{*p} n^{p-2} \leq A_p \int_a^b |\varphi(x)|^p dx \quad (1 < p \leq 2).$$

If $q \geq 2$ and $\sum a_n^{*q} n^{q-2} < \infty$, then there exists a function $\varphi(x)$ which has the a_n as its Fourier coefficients and such that

$$\int_a^b |\varphi(x)|^q dx \leq A_q \sum_{n=1}^{\infty} a_n^{*q} n^{q-2}$$

(**Paley's theorem**). When the system is trigonometric, this is called the **Hardy-Littlewood theorem**. (6) If for some positive ε we have $\sum |c_n|^{2-\varepsilon} < \infty$, then $\sum c_n f_n(x)$ converges a.e.

(7) If we set $s^*(x) = \sup_n |\sum_{v=1}^n c_v f_v(x)|$, then $\|s^*\|_q \leq A_q (\sum c_v^{*q} v^{q-2})^{1/q}$ ($q > 2$), where $\{c_n^*\}$ is the decreasing rearrangement of $\{|c_n|\}$.

C. Examples of Orthogonal Systems

(1) $\{\cos nx\} \in O(0, \pi)$, $\{\sin nx\} \in O(0, \pi)$. (2) $\{1, \cos nx, \sin nx\} \in O(0, 2\pi)$ (\rightarrow 159 Fourier Series). (3) Suppose that $A(x)$ is positive and continuous, and let $y_n(x)$ be solutions of $y''(x) + \lambda_n A(x)y(x) = 0$ satisfying the condition $y_n(a) = y_n(b) = 0$, where λ_n is any \dagger eigenvalue. Then $\{\sqrt{A(x)}y_n(x)\} \in O(a, b)$ (for orthogonality of eigenfunctions \rightarrow 315 Ordinary Differential Equations (Boundary Value Problems) B). (4) Set $r_n(x) = -1$ or 1 according as the n th digit of the binary expansion of x ($0 < x \leq 1$) is 1 or 0 , and $r_n(x) = 0$ if x is expandable in two ways. Then $\{r_n(x)\} \in O(0, 1)$. This is called **Rademacher's system of orthogonal functions**. The system is not complete, but it is interpreted as a \dagger sample space of coin tossing. Rademacher's system is useful for constructing various counter-examples. (5) Let the binary expansion of n be $n = 2^{v_1} + 2^{v_2} + \dots + 2^{v_p}$ ($v_1 < v_2 < \dots < v_p$), and set $w_n(x) = r_{v_1+1}(x)r_{v_2+1}(x) \dots r_{v_p+1}(x)$. Then $\{w_n(x)\}$ is a complete orthonormal system called **Walsh's system of orthogonal functions**. This system is interpreted as a system of characters of the group of binary numbers, and there are many theorems for this system analogous to those for the trigono-

metric system. (6) In the interval $[0, 1]$, set

$$\begin{aligned} \chi_m^k(x) &= \sqrt{2^m}, & x \in ((k-1)/2^m, (k-1/2)/2^m) \\ &= -\sqrt{2^m}, & x \in ((k-1/2)/2^m, k/2^m) \\ &= 0, & x \in ((l-1)/2^m, l/2^m), \\ & & l \neq k, 1 \leq l \leq 2^m. \end{aligned}$$

The orthonormal system $\chi_m^k(x)$ ($1 \leq k \leq 2^m$, $1 \leq m$) is called **Haar's system of orthogonal functions**. The Haar expansion of the continuous function $f(x)$ converges to $f(x)$ uniformly.

D. Orthogonal Polynomials (→ Appendix A, Table 20)

Suppose that we are given a weight function $\varphi(x) \geq 0$ ($\varphi(x) > 0$ a.e.) defined on (a, b) and that the inner product of functions f, g on (a, b) is defined by $(f, g) = \int_a^b f(x)g(x)\varphi(x)dx$. We orthogonalize $\{x^n\}$ by Schmidt orthogonalization and obtain polynomials $p_n(x)$ of degree n . Here the sign of $p_n(x)$ can be determined so that the sign of the coefficient of the highest power of x is positive. We call $\{p_n(x)\}$ the **system of orthogonal polynomials** belonging to the weight function $\varphi(x)$. This system is complete in $L_2^{(\varphi)}(a, b)$, which is defined to be the space of functions f such that $\int_a^b |f(x)|^2 \varphi(x)dx < \infty$. In other words, the system $\{\sqrt{\varphi(x)}p_n(x)\}$ is a complete orthonormal system in the ordinary $L_2(a, b)$ space. Concerning the convergence problem of the orthogonal expansion by $\{p_n(x)\}$, the **Christoffel-Darboux formula**

$$\sum_{k=0}^n p_k(t)p_k(x) = \frac{\alpha_n}{\alpha_{n+1}} \frac{p_n(x)p_{n+1}(t) - p_n(t)p_{n+1}(x)}{t-x}$$

plays an important role.

Several important special functions in classical mathematical physics are given by orthogonal polynomials:

(1) Setting $\varphi(x) = (1-x)^\alpha(1+x)^\beta$ ($\alpha > -1, \beta > -1$) in $[-1, 1]$, we get the **Jacobi polynomials**, although they are sometimes defined in $[0, 1]$ with respect to $\varphi(x) = x^\alpha(1-x)^\beta$ (→ Appendix A, Table 20.V). If we set $\alpha = \beta$ in the Jacobi polynomials, we get the **ultraspherical polynomials** (or **Gegenbauer polynomials**) (→ Appendix A, Table 20.I). Furthermore, if $\alpha = \beta = 0$, then we get the †**Legendre polynomials**, and if $\alpha = \beta = -1/2$, we get the **Chebyshev polynomials** $T_n(x) = \cos(n \arccos x)$. The $T_n(x)$ also appear in the best approximation problem (→ Appendix A, Table 20.II; 336 Polynomial Approximation).

(2) If we set $\varphi(x) = x^\alpha e^{-x}$ in $(0, \infty)$, we get the **Sonine polynomials** (or **associated Laguerre polynomials**) with appropriate constant factors.

If α is a positive integer m , we get

$$S_n^{(m)}(x) = x^{-m} e^x \left(\frac{d^n}{dx^n} (x^{n+m} e^{-x}) \right).$$

The particular case $m=0$ gives the **Laguerre polynomials**. In this case, however, it is customary to normalize them as $L_n(x) = (e^x/n!)(d^n/dx^n)(x^n e^{-x})$ (→ Appendix A, Table 20.VI). Laguerre polynomials are used in numerical integrations of a Gaussian type in $(0, \infty)$. Furthermore, associated Laguerre polynomials appear in the solutions of the Schrödinger equation for the behavior of hydrogen atoms. This system of orthogonal polynomials is useful in the expansions of approximate eigenfunctions of atoms analogous to hydrogen, velocity distribution functions of molecules in gas theory, and so on.

(3) Setting $\varphi(x) = e^{-x^2}$ (or $e^{-x^2/2}$) in $(-\infty, \infty)$, we get **Hermite polynomials** $H_n(x) = (-1)^n e^{x^2} (d^n e^{-x^2}/dx^n)$, modulo constant factors (→ Appendix A, Table 20.VI). Hermite polynomials are special cases of parabolic cylinder functions (→ 167 Functions of Confluent Type). These polynomials appear as eigenfunctions of the Schrödinger equation for harmonic oscillators. They are also connected with probability integrals and are used in mathematical statistics.

(4) Replacing the integral by a finite sum $\sum_{m=0}^n f(m)g(m)$ in the definition of inner product, we get so-called **orthogonality for a finite sum**. (Regarding orthogonal polynomials with respect to a finite sum (→ Appendix A, Table 20.VII) and their application to the mean square approximation → 19 Analog Computation F.) Since orthogonal polynomials with respect to a finite sum are often called simply orthogonal polynomials by engineers, one must be careful not to confuse these with the ordinary ones.

318 (XX.14) Oscillations

A. General Remarks

A **vibration** or **oscillation** is a phenomenon that repeats periodically, either exactly or approximately. Exactly periodic oscillations are studied in the theory of †periodic solutions of differential equations. The †period of a solution $f(t)$ is called the **period** of the oscillation, and its reciprocal the **frequency**. The difference between the greatest and least values of $f(t)$ (globally or in an interval) is the **amplitude**. The theory of vibrations has its origin in the study of mechanical vibrations, but its nomenclature has been used also for electric circuits. As examples of practical applications of the theory of oscillations, we mention, in engineering, the prevention of vibrations and the generation of stable sustained oscillations, and in geophysics, investigations concerning the free oscillation of the earth, the existence of which has recently been confirmed.

B. Linear Oscillation

Periodic solutions of †linear differential equations have been studied in detail for a long time. Perhaps the simplest case of such an oscillation is represented by the differential equation

$$d^2x/dt^2 + n^2x = 0, \quad (1)$$

where the **restitutive force** is proportional to the displacement from the equilibrium position. Typical examples are the free vibration of a simple pendulum with small amplitude and an electric circuit composed of a self-inductance and capacity (without resistance). The solution is given by $x = A \cos(nt + \alpha)$. This is called **harmonic oscillation** or **simple harmonic motion**. Here the amplitude is A , the period is $2\pi/n$, n is the **circular frequency**, and α is the **initial phase**.

A system of m †degrees of freedom (x_1, \dots, x_m) is said to be in free harmonic oscillation if the coordinates can be expressed as

$$x_i = \sum_{k=1}^m A_{ik} \cos(n_k t + \alpha_k), \quad i = 1, 2, \dots, m.$$

Each of these simple harmonic oscillations is called a **normal vibration**. As a limiting case, where the number of degrees of freedom is infinite, we have the vibration of a string:

$$\frac{\partial^2 u(x, t)}{\partial t^2} = n^2 \frac{\partial^2 u(x, t)}{\partial x^2},$$

$$u(0, t) = u(l, t) = 0.$$

The solution is given by a series

$$\sum_k A_k \sin(k\pi x/l) \cos(k\pi n t/l),$$

which is just the superposition of the fundamental vibration (corresponding to $k=1$) and simply harmonic motions of frequencies equal to multiples of the fundamental frequency.

If a resisting force proportional to the velocity is acting, the equation becomes

$$d^2x/dt^2 + 2\epsilon dx/dt + n^2x = 0, \quad n > \epsilon, \quad (2)$$

whose solution

$$x = Ae^{-\epsilon t} \cos(\sigma t + \alpha), \quad \sigma = \sqrt{n^2 - \epsilon^2} \quad (3)$$

is not periodic. However, x becomes zero at a fixed interval π/σ , and the extremal values in the intervals decrease to zero in a geometrical progression with the common ratio $v = \exp(-\pi\epsilon/\sigma)$. This phenomenon is called **damped oscillation** with **damping ratio** v and **logarithmic decrement** $\log v = -\pi\epsilon/\sigma$. In this case, too, $2\pi/\sigma$ is called the period.

When a driving force term $\varphi(t)$ is present in the right-hand side of (2), the solution takes on the additional term

$$\frac{e^{-\epsilon t}}{\sigma} \left(\sin \sigma t \int \varphi(t) e^{\epsilon t} \cos \sigma t dt - \cos \sigma t \int \varphi(t) e^{\epsilon t} \sin \sigma t dt \right),$$

which represents the **forced oscillation** due to $\varphi(t)$.

If $\epsilon < 0$ in (2) (**negative resistance**), the solution (3) increases in amplitude, so that a small disturbance is amplified, resulting in an automatic generation of oscillation. This phenomenon is called **self-excited vibration**. Besides being caused by some special kinds of circuit elements (e.g., tunnel diodes), such a situation often occurs when the vibrating system has time delay characteristics (\rightarrow 163 Functional-Differential Equations).

Among sustained vibrations, other than forced oscillations and self-excited vibrations, are the **parametrically sustained vibrations** caused by periodic variation of a parameter of the vibrating system. Electric wires and pantographs for use in high-speed electric railways must be designed to prevent unwanted parametrically sustained vibrations. On the other hand, a parametron is an electric element utilizing parametrically sustained vibration.

C. Nonlinear Oscillation

Actual vibrating systems contain more or less nonlinear elements, which give rise to various kinds of oscillations different from those described by the linear theory (\rightarrow 290 Non-

linear Oscillation). For example, $d^2x/dt^2 - \varepsilon(1-x^2)dx/dt + x = 0$ ($\varepsilon > 0$) represents a stable sustained oscillation such that for large values of ε , two nearly stationary states occur alternately, the transition from one to the other taking place abruptly. This is called **relaxation oscillation**.

P

319 (I.3) Paradoxes

A. General Remarks

A statement that is apparently absurd but not easily disproved is called a **paradox**. A contradiction between a proposition and its negation is called an **antinomy** if both statements can be supported by logically equivalent reasoning. In practical use, however, "paradox" and "antinomy" often mean the same thing.

B. Paradoxes in Set Theory

(1) **The Russell Paradox (1903)**. We classify sets into two kinds as follows: Any set that does not contain itself as an element is called a **set of the first kind**, and any set that contains itself as an element is called a **set of the second kind**. Every set is either a set of the first kind or of the second kind. Denote the set of all sets of the first kind by M . If M is a set of the first kind, M cannot be an element of M . But if M is of the first kind, then M must be an element of M , by definition. This is contradictory. On the other hand, if M is a set of the second kind, M must be an element of M ; but since M is an element of M , M is a set of the first kind, so M cannot be an element of M , by definition. This is contradictory.

Since the kind of reasoning employed in this paradox is very simple and is often utilized in mathematics, it became popular in set theory. To remove this paradox from set theory, Russell suggested **ramified type theory**. If we adopt this theory, however, it becomes very hard to develop even an ordinary theory of real numbers (\rightarrow 156 Foundations of Mathematics). On the other hand, this paradox, together with the Burali-Forti paradox, indicates that the definition of a set should be restrictive. This realization led to the development of **axiomatic set theory**.

(2) **The Burali-Forti Paradox (1897)**. Let $W = \{0, 1, 2, \dots, \omega, \dots\}$ be the **well-ordered set** (\rightarrow 312 Ordinal Numbers A) of all **ordinal numbers**. Let Ω be the ordinal number of W . Then every ordinal number, being an element of W , is less than Ω . But Ω is an ordinal number. Hence, $\Omega < \Omega$. This is contradictory.

(3) **The Richard Paradox (1905)**. The expressions in the English language can be enumerated by the device that is applied to the usual enumeration of the algebraic equations

with integral coefficients. From the specified enumeration of all expressions in the English language, by striking out those which do not define a real number in the interval $(0, 1]$, we obtain an enumeration of those which do. Consider the following expression: "The greatest real number represented by a proper nonterminating decimal fraction whose n th digit, for any natural number n , is not equal to the n th digit of the nonterminating decimal fraction representing the real number defined by the n th expression in the last-described enumeration." Then we have before us a definition of a real number in the interval $(0, 1]$ by means of an expression in the English language. This real number, by its definition, must differ from every real number definable by an expression in the English language. This is contradictory.

The following paradox was given by Berry (1906): "The least natural number not nameable in fewer than twenty-two syllables" is actually named by this expression, which has twenty-one syllables. The Epimenides paradox is a traditional ancient Greek paradox of this kind: Epimenides (a Cretan) said, "Cretans are always liars. . . ."

C. Paradoxes of the Continuum

The problem of the continuum is important in both mathematics and philosophy. There are several **paradoxes of Zeno** concerning the continuum, among which the following two are best known:

(1) Assume that Achilles and a tortoise start simultaneously from the points A and B , respectively, Achilles running after the tortoise. When Achilles reaches the point B , the tortoise advances to a point B_1 . When Achilles reaches the point B_1 , the tortoise advances further to a point B_2 . Thus Achilles can never overtake the tortoise.

(2) A flying arrow occupies a certain point at each moment. In other words, at each moment the arrow stands still. Therefore the arrow can never move.

320 (XIII.19) Partial Differential Equations

A. General Remarks

A partial differential equation is a functional equation

$$F\left(x_1, \dots, x_n, z, \frac{\partial z}{\partial x_1}, \dots, \frac{\partial^2 z}{\partial x_1^2}, \frac{\partial^2 z}{\partial x_1 \partial x_2}, \dots\right) = 0$$

that involves a function z of independent variables x_1, x_2, \dots, x_n , its partial derivatives, and the independent variables x_1, \dots, x_n . The definition of a system of partial differential equations is similar to that of a system of ordinary differential equations. (The partial differential equation becomes an ordinary differential equation if the number of independent variables is one.)

The order of the highest derivative appearing in a partial differential equation is called the **order** of the partial differential equation.

Usually we write p_i for $\partial z / \partial x_i$, x for x_1 , and y for x_2 when $n = 2$, and $p = \partial z / \partial x$, $q = \partial z / \partial y$, $r = \partial^2 z / \partial x^2$, $s = \partial^2 z / \partial x \partial y$, $t = \partial^2 z / \partial y^2$ when z is a function of x and y .

A partial differential equation is called **linear** if it is a linear relation with respect to z and its partial derivatives. For example, the equation

$$A(x, y)r + B(x, y)s + C(x, y)t + D(x, y)p + E(x, y)q + F(x, y)z = G(x, y)$$

is a linear partial differential equation. A partial differential equation is **quasilinear** if it is a linear relation with respect to the highest-order partial derivatives. A partial differential equation is called **nonlinear** if it is not linear (→ 291 Nonlinear Problems). A function $z = \varphi(x_1, x_2, \dots, x_n)$ that satisfies the given partial differential equation is called a **solution** of the partial differential equation. Obtaining such a solution for a given partial differential equation is called **solving** this equation, and by analogy to the case $n = 2$, the **integral hypersurface** of the equation is

$$z - \varphi(x_1, x_2, \dots, x_n) = 0.$$

For a system of partial differential equations, we define solutions in the same manner.

Example 1. X_1, X_2, \dots, X_n are functions of n independent variables x_1, x_2, \dots, x_n . Then solving the partial differential equation

$$X_1 \frac{\partial z}{\partial x_1} + X_2 \frac{\partial z}{\partial x_2} + \dots + X_n \frac{\partial z}{\partial x_n} = 0 \tag{1}$$

is equivalent to solving the system of ordinary differential equations

$$\frac{dx_1}{X_1} = \frac{dx_2}{X_2} = \dots = \frac{dx_n}{X_n} \tag{2}$$

In other words, if f_1, f_2, \dots, f_{n-1} are $n - 1$ independent integrals of (2), then for an arbitrary function Φ , $z = \Phi(f_1, \dots, f_{n-1})$ is a general solution of (1) (→ Section C).

Example 2. If P_1, P_2, \dots, P_n, R are functions of independent variables x_1, \dots, x_n and the dependent variable z , and if the quasilinear partial differential equation (**Lagrange's differential equation**)

$$P_1 \frac{\partial z}{\partial x_1} + P_2 \frac{\partial z}{\partial x_2} + \dots + P_n \frac{\partial z}{\partial x_n} = R \tag{3}$$

has an integral hypersurface $V(z, x_1, \dots, x_n) = 0$, then we have

$$P_1 \frac{\partial V}{\partial x_1} + P_2 \frac{\partial V}{\partial x_2} + \dots + P_n \frac{\partial V}{\partial x_n} + R \frac{\partial V}{\partial z} = 0, \tag{4}$$

which is an equation of type (1). From this we can obtain a general solution by the method of example 1. The same procedure is applicable to solving other systems of partial differential equations.

B. Characteristic Manifolds

We consider a partial differential equation of the n th order of two independent variables x, y :

$$F(x, y, z, p_{10}, p_{01}, \dots, p_{n0}, \dots, p_{0n}) = 0,$$

$$\text{where } p_{jk} = \frac{\partial^{j+k} z}{\partial x^j \partial y^k} \tag{5}$$

With this equation, we associate a manifold defined by a real parameter λ ,

$$x = x(\lambda), \quad y = y(\lambda), \quad p_{jk} = p_{jk}(\lambda), \tag{6}$$

$$j, k = 0, 1, \dots, n - 1; \quad j + k \leq n - 1,$$

and consider the following problem: Find a solution $\varphi(x, y)$ of (5) that satisfies

$$\frac{\partial^{j+k} \varphi(x, y)}{\partial x^j \partial y^k} = p_{jk}(\lambda), \tag{7}$$

$$j, k = 0, 1, 2, \dots, n - 1; \quad j + k \leq n - 1$$

on the curve $x = x(\lambda), y = y(\lambda)$. We call this problem the **Cauchy problem** for equation (5).

If F vanishes for a system of values x^0, y^0, p_{jk}^0 ($j, k = 0, 1, 2, \dots, n; p_{00}^0 = z^0; j + k \leq n$) and is holomorphic in a neighborhood of this system of values, if x, y, p_{jk} are holomorphic functions of λ in a neighborhood of $\lambda = 0$ and take the respective values x^0, y^0, p_{jk}^0 at $\lambda = 0$, and if

$$P_{n0} dy^n - P_{n-1,1} dx dy^{n-1} + \dots + (-1)^n P_{0n} dx^n \neq 0 \tag{7}$$

for (x^0, y^0, p_{jk}^0) , then we have a unique holomorphic solution of this Cauchy problem in a neighborhood of (x^0, y^0, p_{jk}^0) . (Here we use the notation $p_{jk} = \partial F / \partial p_{jk}$.) This is **Cauchy's existence theorem**. We cannot apply this theorem when the left-hand side of (7) vanishes at (x^0, y^0, p_{jk}^0) . At such a point, uniqueness of the solution fails, and there may be several solutions through the point (x^0, y^0, p_{jk}^0) . There are n curves on which the left-hand side of (7) vanishes on the integral surface $z = \varphi(x, y)$. These curves are called **characteristic curves** of (5). We associate the values

$$p_{jk}(\lambda) = \left. \frac{\partial^{j+k} \varphi(x, y)}{\partial x^j \partial y^k} \right|_{x=x(\lambda), y=y(\lambda)},$$

$$j, k = 0, 1, \dots, n; \quad j + k \leq n,$$

with each point (x, y) on these curves. The manifold $\{x(\lambda), y(\lambda), p(\lambda)\}$ ($p(\lambda) = \{p_{jk}(\lambda)\}$) of the parameter λ is called a **characteristic manifold** of equation (5). Cauchy's existence theorem cannot be applied on the characteristic manifold.

The foregoing considerations can be extended, to some extent, to the space of higher dimensions \mathbf{R}^n or \mathbf{C}^n . Let P be a linear partial differential operator of order m :

$$P(x, D) = \sum_{|\alpha| \leq m} a_\alpha(x) D^\alpha,$$

$$D^\alpha = \left(\frac{\partial}{\partial x_1} \right)^{\alpha_1} \dots \left(\frac{\partial}{\partial x_n} \right)^{\alpha_n}, \quad |\alpha| = \alpha_1 + \dots + \alpha_n.$$

The coefficients are assumed smooth and real in \mathbf{R}^n or holomorphic in \mathbf{C}^n . Its homogeneous part of order m , denoted by $P_m(x, D)$, is called the **principal part** of P . Let S be a hypersurface defined by $\varphi(x) = 0$ with $\text{grad } \varphi(x) \neq 0$. S is called a **characteristic surface** if $P_m(x, \text{grad } \varphi(x)) = 0$ holds for x in a neighborhood of S or merely for $x \in S$, and $\varphi(x)$ is called a phase function. A real vector $\xi^0 (\neq 0)$, or a complex vector $\xi^0 \neq 0$ is called a characteristic direction at the point x_0 if $P_m(x_0, \xi^0) = 0$. The zeros (x, ξ) ($\xi \neq 0$) of $P_m(x, \xi)$ are called the **characteristic set**. Furthermore (x_0, ξ^0) is called simple if $\text{grad}_\xi P_m(x_0, \xi^0) \neq 0$. Suppose that (x_0, ξ^0) is simple. The integral curve $(x(t), \xi(t))$ that satisfies

$$\dot{x} = \text{grad}_\xi P_m(x, \xi),$$

$$\dot{\xi} = -\text{grad}_x P_m(x, \xi)$$

is called the **bicharacteristic strip** of P_m . Evidently $P_m(x, \xi)$ is constant along the bicharacteristic strip. In particular, if this constant is zero, it is said to be **null-bicharacteristic**. The phase function $\varphi(x)$ can be obtained at least locally by using the bicharacteristic strip.

C. Classification of Solutions

First, we consider a partial differential equation of the first order of two independent variables:

$$F(x, y, z, p, q) = 0. \tag{8}$$

A solution of (8) that contains two arbitrary constants is called a **complete solution**. If we get one complete solution of (8), then we can obtain all the solutions by differentiations and eliminations. Let (9) be a complete solution:

$$V(x, y, z, a, b) = 0. \tag{9}$$

Differentiating this, we get

$$\frac{\partial V}{\partial x} + p \frac{\partial V}{\partial z} = 0, \quad \frac{\partial V}{\partial y} + q \frac{\partial V}{\partial z} = 0. \tag{10}$$

Eliminating a and b from (9) and (10), we get the original equation (8). Furthermore, solving equation (8) is equivalent to getting three functions a, b, z of x, y from (8), (9), and (10). If we regard a, b as functions of x, y , in (9), we get

$$\frac{\partial V}{\partial a} \frac{\partial a}{\partial x} + \frac{\partial V}{\partial b} \frac{\partial b}{\partial x} = 0, \quad \frac{\partial V}{\partial a} \frac{\partial a}{\partial y} + \frac{\partial V}{\partial b} \frac{\partial b}{\partial y} = 0. \tag{11}$$

Therefore we can replace (9) and (10) by (9) and (11). Hence we have the following three cases: (i) When a, b are constants, we get a complete solution. (ii) When $V = 0, \partial V / \partial a = 0$, and $\partial V / \partial b = 0$, we get a solution that does not contain arbitrary constants, because z, a, b are all functions of x and y . We call this solution a **singular solution** of (8). (iii) When $\partial V / \partial a, \partial V / \partial b$ do not vanish simultaneously, the Jacobian $D(a, b) / D(x, y)$ vanishes because of (11). This means that there exists a functional relation between a and b . If there are two such relations, a and b are constants and the solution z becomes a complete solution. Therefore we assume that there is only one such relation between a and b , whose form is assumed to be $b = \varphi(a)$. Then we get

$$V(x, y, z, a, \varphi(a)) = 0, \quad \frac{\partial V}{\partial a} + \frac{\partial V}{\partial b} \varphi'(a) = 0. \tag{12}$$

If we solve (12) for the unknowns a and z , we get a solution z of (8) that contains an arbitrary function φ instead of arbitrary constants. Such a solution is called a **general solution** of the partial differential equation (8) of the first order. By specializing this function φ , we obtain a **particular solution** of (8). Thus (i)–(iii) exhaust all the cases, and by obtaining a complete solution of (8) we can get all the solutions of (8). The number of complete solutions may be more than 1, or it may be infinite. These complete solutions can be transformed into each other by contact transformations.

Moreover, they are contained in the general solutions.

Now we consider the case where the number of independent variables is n . Take an equation that contains $n - r + 1$ arbitrary constants $a_1, a_2, \dots, a_{n-r+1}$:

$$V(x_1, x_2, \dots, x_n; a_1, a_2, \dots, a_{n-r+1}) = 0. \tag{13}$$

Differentiate this equation assuming that a_1, \dots, a_{n-r+1} take fixed values. Then we get

$$\frac{\partial V}{\partial x_i} + p_i \frac{\partial V}{\partial z} = 0, \quad p_i = \frac{\partial z}{\partial x_i}, \quad i = 1, 2, \dots, n. \tag{14}$$

If we eliminate $a_1, a_2, \dots, a_{n-r+1}$ from (13) and (14), we obtain r partial differential equations of the first order:

$$F_j(x_1, x_2, \dots, x_n, z, p_1, p_2, \dots, p_n) = 0, \quad j = 1, 2, \dots, r. \tag{15}$$

We call (13) a **complete solution** of (15). In this case, as in the case when $n = 2$, we get all the solutions of (15) from a complete solution (13) of (15). We have the same classification as in the case $n = 2$: (i) When we regard a_1, \dots, a_{n-r+1} as constants, then we have a complete solution of (15). (ii) When we can eliminate the constants a_1, \dots, a_{n-r+1} from equations

$$V = 0, \quad \frac{\partial V}{\partial a_1} = 0, \dots, \frac{\partial V}{\partial a_{n-r+1}} = 0,$$

we get a solution that does not contain an arbitrary constant. Such a solution is called a **singular solution** of (15). (iii) If not all of the $\partial V/\partial a_i$ vanish, there exists at least one functional relation among $a_1, a_2, \dots, a_{n-r+1}$. We assume that there exist exactly k ($\leq n - r$) relations among $a_1, a_2, \dots, a_{n-r+1}$:

$$f_j(a_1, a_2, \dots, a_{n-r+1}) = 0, \quad j = 1, \dots, k. \tag{16}$$

Then there exist numbers $\lambda_1, \lambda_2, \dots, \lambda_k$ such that

$$\frac{\partial V}{\partial a_i} = \lambda_1 \frac{\partial f_1}{\partial a_i} + \dots + \lambda_k \frac{\partial f_k}{\partial a_i}, \quad i = 1, \dots, n - r + 1. \tag{17}$$

Hence, by eliminating $a_1, a_2, \dots, a_{n-r+1}, \lambda_1, \lambda_2, \dots, \lambda_k$ from (13), (16), and (17), we generally obtain exactly one relation between x_1, \dots, x_n and z . This is a solution of (15) that contains exactly k arbitrary functions f_1, f_2, \dots, f_k . Such a solution is called a **general solution** of (15). In particular, if $k = n - r + 1$, then it is a complete solution. We might think that there are $n - r$ general solutions corresponding to $k = 1, \dots, n - r$. But these general solutions are not essentially different. For the partial equation of the second order $F(x, y, z, p, q, r, s, t) = 0$, this defi-

inition of a general solution is not applicable since we cannot successfully define a general solution by using the number of arbitrary functions contained in a solution.

Instead, we now use the following definition, due to J. G. Darboux: A solution of a general partial differential equation is called a **general solution** if by specializing its arbitrary functions and constants appropriately we obtain a solution whose existence is established by Cauchy's existence theorem. A solution $z = \varphi(x, y)$ of a general partial differential equation is called a **singular solution** if Cauchy's existence theorem cannot be applied on any curves on the manifold formed by $z = \varphi(x, y)$, $p = \partial\varphi/\partial x$, $q = \partial\varphi/\partial y$.

D. Cauchy's Method

We can regard equation (8) as a relation between the point (x, y, z) on the integral surface S and the direction cosines of a tangent plane at that point. Therefore the tangent planes at all points of the surface form a one-parameter family. They envelop a cone (T) whose vertex is (x, y, z) on S . The tangent plane at a point M on the integral surface S is tangent to this cone (T) along one generating line G of (T) .

A curve on S whose tangents are all generating lines of (T) is a characteristic curve. If we write

$$X = \frac{\partial F}{\partial x}, \quad Y = \frac{\partial F}{\partial y}, \quad Z = \frac{\partial F}{\partial z}, \quad P = \frac{\partial F}{\partial p}, \quad Q = \frac{\partial F}{\partial q},$$

then the characteristic curve is given by the system of ordinary differential equations:

$$\frac{dx}{P} = \frac{dy}{Q} = \frac{dz}{Pp + Qq} = \frac{-dp}{X + pZ} = \frac{-dq}{Y + qZ}. \tag{18}$$

We call this system the **characteristic differential equation** or **Charpit subsidiary (auxiliary) equation** of the partial differential equation (8) of the first order. System (18) determines not only x, y, z but also p and q . The set of these surface elements (x, y, z, p, q) is the characteristic manifold. This characteristic manifold is considered as a part of the integral surface with infinitesimal width, and in this case we call it the **characteristic strip**. The characteristic strip is represented by the equations $x = x(\lambda), y = y(\lambda), z = z(\lambda), p = p(\lambda), q = q(\lambda)$ containing a parameter. On the integral surface $z = z(x, y)$, we have

$$\frac{dz}{d\lambda} = \frac{\partial z}{\partial x} \frac{dx}{d\lambda} + \frac{\partial z}{\partial y} \frac{dy}{d\lambda}$$

and

$$dz = p dx + q dy. \tag{19}$$

Equation (19) is called the **strip condition**. The equations (18) evidently satisfy this condition.

The solution $u(t, x) = u(t, x_1, \dots, x_n)$ of

$$u_t + f(t, x_1, \dots, x_n, u_{x_1}, \dots, u_{x_n}) = 0,$$

$$u(0, x) = \varphi(x)$$

is obtained (at least locally) as follows. Let the solution of the differential equations

$$\frac{dx_i}{dt} = f_{x_i}(t, x_1, \dots, x_n, \xi_1, \dots, \xi_n),$$

$$\frac{d\xi_i}{dt} = -f_{\xi_i}(t, x_1, \dots, x_n, \xi_1, \dots, \xi_n), \quad 1 \leq i \leq n,$$

issuing from (x_0, ξ^0) at $t = 0$ be $(x(t; x_0, \xi^0), \xi(t; x_0, \xi^0))$. Then specializing $\xi_j^0 = \varphi_{x_j}(x_0)$ ($1 \leq j \leq n$), the solution $u(t, x)$ is obtained by quadrature along these curves (characteristic strips) from the relation

$$\frac{du}{dt} = -f(t, x, \xi) + \sum_{j=1}^n \xi_j f_{\xi_j}(t, x, \xi).$$

In particular, when $f(t, x, \xi)$ is homogeneous of degree 1 in ξ , by Euler's identity the right-hand side is identically zero. This means that u is constant along the characteristic strip.

E. Homogeneous Partial Differential Equations

Assume that $f(\xi_1, \xi_2, \dots, \xi_m)$ is a homogeneous polynomial of m independent variables $\xi_1, \xi_2, \dots, \xi_m$. We denote the differential operator $\partial/\partial x_s$ by D_s . Then consider a homogeneous partial differential equation

$$f(D_1, D_2, \dots, D_m)u = 0. \tag{20}$$

We can obtain a homogeneous equation from an inhomogeneous partial differential equation by transformation of the dependent variable. For example, $D_1^2 w = D_2 w$ becomes the homogeneous partial differential equation $(D_1^2 - D_2 D_3)u = 0$ by the transformation of the dependent variable $u = e^{x_3} w$. The equation $(D_1^2 - D_2 D_3)u = 0$ corresponds to the homogeneous polynomial $f(\xi_1, \xi_2, \xi_3) = \xi_1^2 - \xi_2 \xi_3$. Generally, for equation (20), we consider the solution

$$u = F(\theta_1, \theta_2, \dots, \theta_s), \tag{21}$$

where $\theta_1, \theta_2, \dots, \theta_s$ are functions of x_1, \dots, x_m and F is an arbitrary function of θ_i . Such a solution is called a **primary solution** of (20). For example, for the equation $(D_1^2 - D_2^2)u = 0$, there are two primary solutions, $u = F(x_1 + x_2)$ and $u = F(x_1 - x_2)$. For \dagger Laplace's equation

$$\Delta u = \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} = 0,$$

we have a primary solution $u = F(z + ix \cos \alpha + iy \sin \alpha)$, where α is a parameter.

Second, for the \dagger wave equation

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} - \frac{1}{c^2} \frac{\partial^2 u}{\partial t^2} = 0, \tag{22}$$

we have a solution

$$u = \gamma f(\alpha, \beta), \quad \gamma = \frac{1}{r}, \quad \alpha = t - \frac{r}{c}, \quad \beta = \frac{z-r}{x+iy}, \tag{23}$$

where $r^2 = x^2 + y^2 + z^2$, f is an arbitrary function, and γ is a particular solution of (22).

Furthermore, $v = f(\alpha, \beta)$ satisfies the equation of a characteristic curve of (22):

$$\left(\frac{\partial v}{\partial x}\right)^2 + \left(\frac{\partial v}{\partial y}\right)^2 + \left(\frac{\partial v}{\partial z}\right)^2 = \frac{1}{c^2} \left(\frac{\partial v}{\partial t}\right)^2.$$

Such a solution, which is the product of particular solutions and some function that contains an arbitrary function, is called a **primitive solution** of the original equation. Equation (22) has another primitive solution of the type

$$u = \frac{1}{r} g\left(t + \frac{r}{c}, \frac{z-r}{x+iy}\right),$$

where g is an arbitrary function.

Laplace's equation has a primitive solution

$$u = \frac{1}{r} f\left(\frac{z-r}{x+iy}\right).$$

A **basic equation** is an equation, such as Laplace's equation, that has a primary solution and a primitive solution. A solution of an equation that has the same characteristic curves as a basic equation can be obtained from a particular solution of the basic equation by integrations and additions. For example, if we choose a particular solution $u = r^{-1}$ of Laplace's equation, which is a specialization of the primitive solution $u = r^{-1} f((z-r)/(x+iy))$, then

$$u = \iiint [(x-\xi)^2 + (y-\eta)^2 + (z-\zeta)^2]^{-1/2} \times F(\xi, \eta, \zeta) d\xi d\eta d\zeta$$

is a solution of

$$\Delta u + 4\pi F(x, y, z) = 0$$

in the interior of the domain of integration.

F. Determined Systems

The general form of a system of partial differential equations in two independent variables is

$$F_i(x, y, u^{(1)}, u^{(2)}, \dots, u^{(m)}, u_x^{(1)}, u_y^{(1)}, \dots, u_x^{(m)}, u_y^{(m)}, u_{xx}^{(1)}, \dots) = 0, \quad i = 1, 2, \dots, h, \tag{24}$$

i.e., a system of h equations for m functions

$u^{(1)}, u^{(2)}, \dots, u^{(m)}$ of the independent variables x and y . The system is called a **determined system** if $h = m$, an **overdetermined system** if $h > m$, and an **underdetermined system** if $h < m$.

An example of a determined system is the †Cauchy-Riemann equation

$$u_x - v_y = 0, \quad u_y + v_x = 0,$$

for $u(x, y), v(x, y)$, which can be further reduced to two determined equations $\Delta u = 0$ and $\Delta v = 0$.

A simple example of an overdetermined system is

$$u_x = f(x, y), \quad u_y = f(x, y).$$

A necessary and sufficient condition for the existence of a solution of this system is $f_y = f_x$. The **Cauchy-Riemann differential equations** for a holomorphic function $f(z_1, z_2) = u + iv$ of two complex variables $z_1 = x_1 + iy_1, z_2 = x_2 + iy_2$ are

$$u_{x_1} = v_{y_1}, \quad u_{x_2} = v_{y_2}, \quad u_{y_1} = -v_{x_1},$$

$$u_{y_2} = -v_{x_2},$$

which can be reduced to

$$u_{x_1 x_1} + u_{y_1 y_1} = 0, \quad u_{x_1 x_2} + u_{y_1 y_2} = 0,$$

$$u_{x_2 x_2} + u_{y_2 y_2} = 0, \quad u_{x_1 y_2} - u_{x_2 y_1} = 0,$$

which is also an overdetermined system.

An example of an underdetermined system is

$$\frac{\partial(u, v)}{\partial(x, y)} = u_x v_y - u_y v_x = 0.$$

If this equation holds, there exists a functional relation $w(u, v) = 0$ that can be regarded as a solution of this underdetermined system.

G. General Theory of Differential Operators

In recent developments of the theory of partial differential equations, there is a trend to construct a general theory for †differential operators regardless of the classical types of differential equations (\rightarrow 112 Differential Operators). For example, we take a property that is satisfied by some equation of classical type (e.g., an †elliptic differential equation) and proceed to characterize all equations that have this property. (For example, †hypoellipticity is a property of classical †parabolic and elliptic equations.) There are several basic problems in this general theory: the existence of a fundamental solution, the existence of a local solution, unique continuation of solutions, the differentiability and analyticity of solutions, and the propagation of smoothness. We explain here only two of them: the fundamental solution and the local existence of solutions.

H. Fundamental Solutions

L is assumed to be a linear partial differential operator with constant coefficients. If a †distribution E satisfies the equation

$$LE(x) = \delta(x),$$

where $\delta(x)$ is the †Dirac δ -function, then we call $E(x)$ a **fundamental solution** (or **elementary solution**) of L . Also, if L is a linear differential operator and E satisfies the equation

$$L_x E(x, y) = \delta(x - y),$$

then we call this distribution $E(x, y)$ a **fundamental kernel** (or **elementary kernel**) of L .

Let L be a differential operator with constant coefficients and $E(x)$ be a fundamental solution of L . Then $E(x, y)$ is a fundamental kernel of L . Sometimes $E(x, y)$ itself is called a fundamental solution. L. Ehrenpreis and B. Malgrange proved that any linear differential operator with constant coefficients has a fundamental solution [4].

If we take a fundamental solution (fundamental kernel) E and add to it an arbitrary solution of the equation $Lu = 0$, then we get another fundamental solution (fundamental kernel) of L . This freedom of the fundamental solution (fundamental kernel) can be used to construct †Green's functions of the boundary value problem of elliptic equations and of the mixed initial-boundary value problem for parabolic equations. A Green's function is a fundamental solution (fundamental kernel) that satisfies given boundary conditions (\rightarrow 188 Green's Functions; 189 Green's Operator). The fundamental solutions (fundamental kernels) relative to the Cauchy problem are also defined as in this section. For example, consider a fundamental solution of the Cauchy problem concerning the future behavior of a differential operator $L = \partial/\partial t - P(\partial/\partial x)$, namely, a distribution $E(t, x)$ that satisfies $LE = 0$ ($t > 0$) and $E(t, x)|_{t=0} = \delta(x)$. If we put $\tilde{E}(t, x) = E(t, x)$ ($t \geq 0$) and $\tilde{E}(t, x) = 0$ ($t < 0$), then $\tilde{E}(t, x)$ is a fundamental solution (or kernel) of the differential operator L , that is, $L\tilde{E} = \delta(t, x)$. Sometimes a fundamental solution of the Cauchy problem for a parabolic equation is called a Green's function. On the other hand, a fundamental solution (or kernel) of the Cauchy problem for a hyperbolic equation is called a †Riemann function. A Riemann function actually is not always a function; in general it is a distribution.

Example 1. A fundamental solution of the 3-dimensional Laplacian

$$\Delta = \frac{\partial^2}{\partial x_1^2} + \frac{\partial^2}{\partial x_2^2} + \frac{\partial^2}{\partial x_3^2}$$

is $E(x) = -1/4\pi r$, where $r = \sqrt{x_1^2 + x_2^2 + x_3^2}$.

Example 2. A fundamental solution of the Cauchy problem for the future of the 3-dimensional wave operator

$$L = \frac{\partial^2}{\partial t^2} - \sum_{i=1}^3 \frac{\partial^2}{\partial x_i^2},$$

i.e., a distribution $E(t, x)$ ($t \geq 0$) that satisfies $LE = 0$ ($t > 0$), $E(0, x) = 0$, and $(\partial/\partial t)E(0, x) = \delta(x)$, is given by $E(t, x) = (1/4\pi t)\delta(r-t)$ ($t > 0$), $r = \sqrt{x_1^2 + x_2^2 + x_3^2}$. A fundamental solution for L is given by $\tilde{E}(t, x) = E(t, x)$ ($t \geq 0$); $= 0$ ($t < 0$) (\rightarrow Appendix A, Table 15.V).

I. Existence of Local Solutions

Given a linear differential operator L and the equation $Lu = f$, we have the problem of determining whether this equation always has a solution in some neighborhood of a given point. If the coefficients of L and f are holomorphic in a neighborhood of this point and if the homogeneous part of highest order does not vanish, then there exists a solution that is holomorphic in a neighborhood of the given point (\dagger Cauchy-Kovalevskaya existence theorem).

If L is a linear differential operator with constant coefficients, E is a fundamental solution of L , and f is a function (or distribution) that is zero outside of a compact set, then we have a solution u that is the \dagger convolution of E and f : $u = E * f$. On the other hand, H. Lewy proposed the following example [3]:

$$Lu \equiv \frac{\partial u}{\partial x_1} + i \frac{\partial u}{\partial x_2} + 2i(x_1 + ix_2) \frac{\partial u}{\partial x_3} = f(x_3),$$

where f is a real function of x_3 . He showed that if this equation has a solution that is of class C^1 , then f must be real analytic. Therefore, if f is of class C^∞ but not real analytic, then this equation has no C^1 -solution. Actually, no solution exists even in the distribution sense. (Note that, since the coefficients of L are now complex-valued, the results mentioned at the beginning of this section are no longer applicable.)

For linear differential operators L , a study by L. Hörmander gives some necessary conditions and also some sufficient conditions for the local existence of a solution of the equation $Lu = f$ for sufficiently general f [4]. This result has been developed and completed by L. Nirenberg and F. Trèves [18] and by R. Beals and C. Fefferman [19]. The operator considered by S. Mizohata (*J. Math. Kyoto Univ.*, 1 (1962)),

$$L \equiv \frac{\partial}{\partial x_i} + ix_1^k \frac{\partial}{\partial x_2},$$

serves as a standard model in this problem. In

the neighborhood of the origin, if k is even, L is locally solvable, and if k is odd, it is not locally solvable. However, for linear partial differential operators with multiple characteristics, the problem of local solvability becomes extremely difficult.

321 (XIII.21) Partial Differential Equations (Initial Value Problems)

A. General Remarks

First, we give two examples of initial value problems for partial differential equations.

(I) Consider the partial differential equation $u_x - u_y = 0$ of two independent variables x and y . If the function $\varphi(y)$ is of class C^1 , then $u = \varphi(x + y)$ is a solution of this equation that satisfies $u(0, y) = \varphi(y)$.

(II) We denote a point of \mathbf{R}^{n+1} (or \mathbf{C}^{n+1}) by (t, x) , $x = (x_1, \dots, x_n)$. Let L be a linear partial differential operator of order m :

$$L = \frac{\partial^m}{\partial t^m} + \sum_{|\alpha| \leq m} a_{v_0, v_1, \dots, v_n}(t, x) \frac{\partial^{|\alpha|}}{\partial t^{v_0} \partial x_1^{v_1} \dots \partial x_n^{v_n}},$$

$$|\alpha| = v_0 + v_1 + \dots + v_n, \quad v_0 < m,$$

where the coefficients $a_{v_0, v_1, \dots, v_n}(t, x)$ are functions of class C^ω (i.e., real analytic functions or holomorphic functions) in a neighborhood of $(t, x) = (0, 0)$. If the functions $v(t, x)$ and $w_k(x)$ ($0 \leq k \leq m - 1$) are of class C^ω in a neighborhood of $(t, x) = (0, 0)$, then there exists a unique solution $u(t, x)$ of class C^ω in a neighborhood of $(t, x) = (0, 0)$ that satisfies

$$L[u] = v(t, x),$$

$$\frac{\partial^k u}{\partial t^k}(0, x) = w_k(x), \quad 0 \leq k \leq m - 1. \quad (1)$$

This is called the **Cauchy-Kovalevskaya existence theorem** (for linear partial differential equations).

As in (II) we choose one of the independent variables as the principal variable and regard the others as parameters. When we assign a value a to the principal variable t , the values of the dependent variables (unknown functions) and their derivatives are called **initial values**, **initial data**, or **Cauchy data**. Conditions to determine initial values are called **initial conditions**. The problem of finding a solution of (1) under given initial conditions is called an **initial value problem** or **Cauchy problem**. We may consider initial value problems not only for initial conditions on a hyperplane $t = a$, but

321 B PDEs (Initial Value Problems)

also for initial conditions on a hypersurface, called an **initial surface** (\rightarrow Section C).

Let $a(x, D)$ be a linear partial differential operator of order m :

$$a(x, D) = \sum_{|\alpha| \leq m} a_\alpha(x) D^\alpha, \quad D^\alpha = \frac{\partial^{|\alpha|}}{\partial x_1^{\alpha_1} \dots \partial x_n^{\alpha_n}},$$

$$|\alpha| = \alpha_1 + \dots + \alpha_n,$$

where the coefficients $a_\alpha(x)$ are of class C^ω in a neighborhood of $x = 0$. Its **characteristic polynomial** is

$$h(x, \xi) = \sum_{|\alpha| = m} a_\alpha(x) \xi^\alpha, \quad \xi^\alpha = \xi_1^{\alpha_1} \dots \xi_n^{\alpha_n}.$$

Let $S: s(x) = 0$ be a regular surface (i.e., $s_x = (\partial s / \partial x_1, \dots, \partial s / \partial x_n) \neq (0)$) of codimension 1. We suppose that S is a noncharacteristic surface, that is, $h(x, s_x) \neq 0$ on S . Let $v(x)$ and $w_k(x)$ ($0 \leq k \leq m - 1$) be the functions of class C^ω in a neighborhood of $x = 0$ and on S , respectively. We consider the Cauchy problem

$$a(x, D)u(x) = v(x), \quad \frac{\partial^k u}{\partial n^k(x)} = w_k(x) \quad \text{on } S,$$

$$0 \leq k \leq m - 1, \quad (1)$$

where n is the outward normal direction of S . S is thus the initial surface. Then there exists a unique solution $u(x)$ of class C^ω in a neighborhood of $x = 0$. In fact, by the change of variables $X_1 = s(x)$, $X_i = x_i$ ($2 \leq i \leq n$) if $\partial s / \partial x_1 \neq 0$ on S , this problem can be reduced to the Cauchy problem (1) by taking account of the fact that $h(x, s_x) \neq 0$ on S .

The Cauchy-Kovalevskaya theorem asserts the local existence of solution when the initial values are of class C^ω . Indeed, J. Hadamard noted that if the initial values are not of class C^ω , the initial value problem does not always have a solution. For example, consider the initial value problem

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} = 0$$

with the initial values

$$u(0, y, z) = w(y, z), \quad \frac{\partial u}{\partial x(0, y, z)} = 0.$$

If the function $w(y, z)$ is not of class C^ω in any neighborhood of $y = z = 0$, the solution of this problem can never exist in (or even on one side $x \geq 0$ of) any neighborhood of $x = y = z = 0$.

B. The Cauchy-Kovalevskaya Existence Theorem for a System of Partial Differential Equations in the Normal Form

The Cauchy-Kovalevskaya existence theorem (1) is extended for more general systems of

partial differential equations in the normal form studied by Kovalevskaya. Consider

$$\frac{\partial^{p_i} u_i}{\partial t^{p_i}} = F_i \left(t, x, u_1, \dots, u_m, \dots, \frac{\partial^{|\nu|} u_j}{\partial t^{\nu_0} \partial x_1^{\nu_1} \dots \partial x_n^{\nu_n}}, \dots \right),$$

where $1 \leq i, j \leq m$, $|\nu| = \nu_0 + \nu_1 + \dots + \nu_n \leq p_j$, $\nu_0 < p_j$, and $x = (x_1, \dots, x_n)$. We assume that F_i ($1 \leq i \leq m$) are functions of class C^ω with respect to arguments $t, x, u_1, \dots, u_m, \dots, \partial^{|\nu|} u_j / \partial t^{\nu_0} \partial x_1^{\nu_1} \dots \partial x_n^{\nu_n}, \dots$, in a neighborhood of $(0, 0, \dots, 0)$. If the functions $w_{ik}(x)$ ($1 \leq i \leq m, 0 \leq k \leq p_i - 1$) are of class C^ω in a neighborhood of $x = 0$, then there exists a unique solution $u_1(t, x), \dots, u_m(t, x)$ of class C^ω in a neighborhood of $(t, x) = (0, 0)$ that satisfies the equations and the initial values

$$\frac{\partial^k u_i}{\partial t^k}(0, x) = w_{ik}(x), \quad 1 \leq i \leq m, \quad 0 \leq k \leq p_i - 1$$

[2, 4].

C. Single Equations of the First Order

For a single partial differential equation given in the normal form

$$\frac{\partial u}{\partial x} = F \left(x, y_1, \dots, y_k, u, \frac{\partial u}{\partial y_1}, \dots, \frac{\partial u}{\partial y_k} \right), \quad (2)$$

we assume that $F(x, y_1, \dots, y_k, u, q_1, \dots, q_k)$ is a real-valued function of class C^2 in a neighborhood of $x = a, y_i = b_i, u = c, q_i = d_i$, and that $\varphi(y_1, \dots, y_k)$ is also a function of class C^2 such that $\varphi = c, \partial\varphi/\partial y_i = d_i$ at $y_i = b_i$. Then there is a solution u of (2) in a neighborhood of $x = a$ and $y_i = b_i$ that satisfies $u(a, y_1, \dots, y_k) = \varphi(y_1, \dots, y_k)$ and is of class C^2 .

For the uniqueness of solutions of this Cauchy problem, A. Haar (*Atti del Congresso Internazionale dei Matematici*, 1928, Bologna, vol. 3) showed that if F satisfies the \dagger Lipschitz condition

$$\begin{aligned} &|F(x, y, u', q') - F(x, y, u, q)| \\ &\leq A \sum_{i=1}^k |q'_i - q_i| + B|u' - u|, \end{aligned}$$

then the solution of the initial value problem for (2) is unique. To obtain this result he studied the partial differential inequality

$$\left| \frac{\partial u}{\partial x} \right| \leq A \sum_{i=1}^k \left| \frac{\partial u}{\partial y_i} \right| + B|u| + C. \quad (3)$$

Next, we consider more general equations of the first order

$$F \left(x_1, \dots, x_k, u, \frac{\partial u}{\partial x_1}, \dots, \frac{\partial u}{\partial x_k} \right) = 0. \quad (4)$$

Suppose that $F(x_1, \dots, x_k, u, p_1, \dots, p_k)$ is a real-valued function of class C^2 in a neighborhood of $x_i = a_i, u = b, p_i = c_i$; $\varphi(x_1, \dots, x_k), S(x_1, \dots, x_k)$ are functions of class C^2 in a neighborhood of $x_i = a_i$ that satisfy $b = \varphi(a_1, \dots, a_k), c_i = (\partial\varphi/\partial x_i)_{x=a}, S(a_1, \dots, a_k) = 0$; and

$$\left[\sum_{v=1}^k \frac{\partial F}{\partial p_v} \frac{\partial S}{\partial x_v} \right]_{x=a, u=b, p=c} \neq 0. \quad (5)$$

Then there exists a solution u of (4) of class C^2 in a neighborhood of $x = a$ that satisfies $u = \varphi(x)$ on the hypersurface $S(x) = 0$.

Furthermore, if F, φ, S are of class C^1 and satisfy (5), then there is at most one solution u of (4) of class C^1 in a neighborhood of a that satisfies $u = \varphi(x)$ on the hypersurface $S(x) = 0$. These facts can be proved in the following way. By choosing $S_1(x), \dots, S_{k-1}(x)$ and then $S(x)$ so that the \dagger Jacobian $\partial(S, S_1, \dots, S_{k-1})/\partial(x_1, \dots, x_k)$ does not vanish and by changing variables from x to S, S_1, \dots, S_{k-1} , we obtain a normal form solved for $\partial u/\partial S$ by condition (5) (this condition means that the hypersurface $S(x) = 0$ is not tangent to the \dagger characteristic curves).

D. Quasilinear Equations of the Second Order

Consider the equation

$$\sum_{i,j=1}^k a_{ij}(x, u, p) \frac{\partial^2 u}{\partial x_i \partial x_j} + b(x, u, p) = 0,$$

where $x = (x_1, \dots, x_k), p = (p_1, \dots, p_k)$, and $p_i = \partial u/\partial x_i$. We assume that the initial conditions are $u = \varphi(x)$ on $S(x) = 0$ and

$$\sum_{i=1}^k \frac{\partial S}{\partial x_i} \frac{\partial u}{\partial x_i} = \psi(x)$$

on the same hypersurface. Taking the other functions $S_1(x), \dots, S_{k-1}(x)$ and then $S(x)$ so that the Jacobian $\partial(S, S_1, \dots, S_{k-1})/\partial(x_1, \dots, x_k)$ does not vanish, we change the variables x to s_0, s_1, \dots, s_{k-1} ($s_0 = S, s_i = S_i$). Then we get

$$\sum_{\mu, \nu=0}^{k-1} Q(S_\mu, S_\nu) \frac{\partial^2 u}{\partial s_\mu \partial s_\nu} + b^* = 0, \quad (6)$$

where

$$Q(S_\mu, S_\nu) = \sum_{i,j=1}^k a_{ij} \frac{\partial S_\mu}{\partial x_i} \frac{\partial S_\nu}{\partial x_j},$$

$$p_i = \sum_{\mu=0}^{k-1} \frac{\partial S_\mu}{\partial x_i} \frac{\partial u}{\partial s_\mu},$$

$$b^* = b + \sum_{\lambda=0}^{k-1} \sum_{j=1}^k a_{ij} \frac{\partial^2 S_\lambda}{\partial x_i \partial x_j} \frac{\partial u}{\partial s_\lambda}.$$

When $s_0 = 0$, the initial conditions are trans-

formed to

$$u = \varphi^*(s_1, \dots, s_{k-1}) = \varphi(x(0, s_1, \dots, s_{k-1})),$$

$$\frac{\partial u}{\partial s_0} = \psi^*(s_1, \dots, s_{k-1})$$

$$= \left[\sum_{i=1}^{k-1} \left(\frac{\partial S}{\partial x_i} \right)^2 \right]^{-1} \left[\psi(x(0, s_1, \dots, s_{k-1})) - \sum_{\lambda=1}^{k-1} \frac{\partial \psi^*}{\partial s_\lambda} \sum_{i=1}^k \frac{\partial S_\lambda}{\partial x_i} \frac{\partial S}{\partial x_i} \right].$$

Suppose that $Q(S, S) \neq 0$, and set $\partial u / \partial s_i = q_i$. Then equation (6) added to the initial conditions $u = \varphi^*(s_1, \dots, s_{k-1})$, $q_0 = \psi^*(s_1, \dots, s_{k-1})$ at $s_0 = 0$ is equivalent to the system in the normal form of partial differential equations of the first order

$$\begin{aligned} \frac{\partial u}{\partial s_0} &= q_0, & \frac{\partial q_\mu}{\partial s_0} &= \frac{\partial q_0}{\partial s_\mu}, & \mu &= 1, \dots, k-1, \\ \frac{\partial q_0}{\partial s_0} &= -\frac{1}{Q(S, S)} \left[\sum_{\mu=1}^{k-1} \left(\sum_{\nu=1}^{k-1} Q(S_\mu, S_\nu) \frac{\partial q_\mu}{\partial s_\nu} - 2Q(S_\mu, S) \frac{\partial q_0}{\partial s_\mu} \right) - b^* \right] \end{aligned}$$

with initial conditions

$$u = \varphi^*(s_1, \dots, s_{k-1}), \quad q_0 = \psi^*(s_1, \dots, s_{k-1}),$$

$$q_\mu = \partial \varphi^* / \partial s_\mu$$

when $s_0 = 0$. Thus, if the coefficients are of class C^ω , the preceding theory applies to this equation.

E. Continuous Dependence of Solutions on the Initial Values

First, we consider the following simple example of a linear equation. The wave equation

$$\frac{\partial^2 v}{\partial t^2} = c^2 \frac{\partial^2 v}{\partial x^2}$$

for $v(x, t)$ is the simplest hyperbolic equation. Its solution satisfying the initial conditions $v(x, 0) = f(x)$, $(\partial v / \partial t)(x, 0) = g(x)$ is given by

$$v(x, t) = \frac{1}{2}(f(x+ct) + f(x-ct)) + \frac{1}{2} \int_{x-ct}^{x+ct} g(\lambda) d\lambda.$$

It is obvious from this expression that if we regard $f(x)$ and $g(x)$ as elements of the function space $C(\mathbf{R})$ of continuous functions of $x \in \mathbf{R}$ with the topology of uniform convergence on compact sets, then $v(x, t)$ is determined as the value of a linear operator from $C(\mathbf{R}^2)$ to $C(\mathbf{R}^2)$ on xt -space. If such continuous dependence on the initial values is established, or more precisely, if there is a unique solution for sufficiently smooth initial values that depends on the initial values continuously in a

321 E PDEs (Initial Value Problems)

suitable sense, we say that the initial value problem is **well posed (properly posed or correctly posed)**.

Systematic research on the well-posedness of Cauchy problems was initiated by I. G. Petrovskii, who considered the following system of partial differential equations, which is more general than differential equations of the normal form. (The coefficients are all assumed to be functions of t only.)

$$\begin{aligned} \frac{\partial^n u_j}{\partial t^{n_j}} &= \sum_{k=1}^N \sum_{|\nu| \leq m} a_{j k \nu_0 \nu_1 \dots \nu_n}(t) \frac{\partial^{\nu_0 + \nu_1 + \dots + \nu_n} u_k(x, t)}{\partial t^{\nu_0} \partial x_1^{\nu_1} \dots \partial x_n^{\nu_n}} \\ &+ B_j(x_1, \dots, x_n, t), \quad j = 1, \dots, N, \\ |\nu| &= \nu_0 + \nu_1 + \dots + \nu_n, \quad \nu_0 < n_k. \end{aligned} \tag{7}$$

This has a normal form if $n_k = m$ ($k = 1, \dots, N$).

Now, taking the derivatives

$$\left(\frac{\partial}{\partial t} \right)^{n_j-1} u_j(x, t), \quad \left(\frac{\partial}{\partial t} \right)^{n_j-2} u_j(x, t), \dots, \left(\frac{\partial}{\partial t} \right) u_j(x, t)$$

as new unknowns, we get another system:

$$\begin{aligned} \frac{\partial u_j}{\partial t} &= \sum_{k=1}^{N'} \sum_{|\nu| \leq m} a_{j k \nu_1 \dots \nu_n}(t) \frac{\partial^{\nu_1 + \dots + \nu_n} u_k(x, t)}{\partial x_1^{\nu_1} \dots \partial x_n^{\nu_n}} \\ &+ C_j(x, t), \quad j = 1, \dots, N'. \end{aligned} \tag{8}$$

We take as the space of initial values the topological linear space composed of all functions whose derivatives up to a sufficiently large order are bounded on the whole space \mathbf{R}^n and equipped with the topology determined by the seminorms that are the maximums of derivatives up to a given order on the whole space, and we take as the range space a similar space on the xt -space, where $x \in \mathbf{R}^n$ and $0 \leq t \leq T$. Then we can formulate a necessary and sufficient condition for the well-posedness of the initial value problem for the future (the problem is regarded as specifying a mapping that assigns to the initial values on $t = 0$ the values $u(x, t)$ for $t > 0$). To give such a condition we consider the following system of ordinary differential equations, which are given by a Fourier transformation on the x -space of system (8):

$$\begin{aligned} \frac{d \hat{u}_j}{dt} &= \sum_{k=1}^{N'} \sum_{|\nu| \leq m} a_{j k \nu_1 \dots \nu_n}(t) \\ &\times (2\pi i \xi_1)^{\nu_1} \dots (2\pi i \xi_n)^{\nu_n} \hat{u}_k(\xi, t) + C_j(\xi, t), \\ &j = 1, \dots, N'. \end{aligned} \tag{9}$$

If the fundamental system of solutions of (9) is $v_i^{(j)}(\xi, t)$ ($i = 1, \dots, N'$, $j = 1, \dots, N'$), then the condition is that these functions satisfy the inequalities

$$|v_i^{(j)}(\xi, t)| \leq C(1 + |\xi|)^L, \quad 0 \leq t \leq T, \tag{10}$$

where C and L are constants independent of ξ . This is the condition obtained by Petrovskii.

If system (7) is of normal form and is well posed for the future, it is also well posed for the past. In this case, equation (7) is said to be of **hyperbolic type** (\rightarrow 325 Partial Differential Equations of Hyperbolic Type). An example that is not of a normal form and is well posed is a parabolic equation (\rightarrow 327 Partial Differential Equations of Parabolic Type). In Petrovskii's theory it is sufficient to assume that the coefficients in (7) are continuous and bounded, and we can take T arbitrarily large provided that (10) is satisfied. Hence Petrovskii's theory guarantees global existence of solutions.

F. Uniqueness of Solutions

If a linear partial differential equation of the first order of normal form has coefficients of class C^ω , then the solution of class C^1 satisfying the prescribed initial conditions is unique (**Holmgren's uniqueness theorem**, 1901). Every system of partial differential equations of higher order of normal form can be reduced to a system of the first order of normal form. Therefore, if the coefficients are of class C^ω , there is only one solution for the original initial value problem with continuous partial derivatives up to the order of the equation. Moreover, if an analytic manifold S of dimension $n-1$ (n is the number of independent variables) is not characteristic for the given equation of order m , there is at most one solution whose derivatives of order up to $m-1$ coincide with given functions on the manifold S . The proof of this fact relies on the Cauchy-Kovalevskaya existence theorem.

The uniqueness problem for the initial value problem is in general very difficult even for linear equations when the coefficients are not of class C^ω .

In particular, if the number of independent variables is 2 and the coefficients are all real, then we have a result of T. Carleman (1939) about the system:

$$\frac{\partial u_\mu}{\partial x} = \sum_{\nu=1}^m a_{\mu\nu}(x, y) \frac{\partial u_\nu}{\partial y} + \sum_{\nu=1}^m b_{\mu\nu}(x, y) u_\nu, \quad (11)$$

where the $a_{\mu\nu}$ are of class C^2 and the $b_{\mu\nu}$ are continuous. He proved that if the eigenvalues of the matrix $(a_{\mu\nu})$ are all distinct, then even when some of the eigenvalues are complex, there is at most one solution of class C^1 for the initial value problem. If we omit the assumption about the eigenvalues, however, the theorem does not hold in general, because we have a counterexample due to A. Pliš (1954) where all coefficients are of class C^∞ , $m=2$, $b_{\mu\nu} \equiv 0$.

A. P. Calderón showed that Carleman's result can be extended to the case $n > 2$ (*Amer. J. Math.*, 80 (1958)). Consider the following linear partial differential equation of the k th order:

$$\frac{\partial^k u}{\partial x^k} + \sum_{j=1}^k P_j \left(x, y, \frac{\partial}{\partial y} \right) \left[\frac{\partial^{k-j} u}{\partial x^{k-j}} \right] + B[u] = 0, \quad (12)$$

where $P_j(x, y, \xi)$ is a homogeneous polynomial of degree j of $\xi = (\xi_1, \dots, \xi_n)$ with real coefficients and B is a differential operation in (x, y) of order at most $k-1$. We assume that the coefficients of $P_j(x, y, \xi)$ are functions of (x, y) of class C^1 , their derivatives are Hölder continuous, and the coefficients of B are bounded and continuous. If the characteristic equation of (12),

$$\lambda^k + \sum_{j=1}^k P_j(x, y, \xi) \lambda^{k-j} = 0,$$

has only distinct roots for $\xi \neq 0$, then the C^k -solution of the Cauchy problem is unique in a neighborhood of $x = a$. Calderón proved this except for the cases $k \geq 4$, $n = 2$, where a certain topological difficulty arises. S. Mizohata (*J. Math. Soc. Japan*, 11 (1959)) succeeded in obtaining the proof for the exceptional cases.

This result can be extended to systems of equations under similar assumptions. See L. Hörmander [4] for an extension to the complex coefficient case. S. Mizohata, T. Shirota, and H. Kumanogo discuss the uniqueness theorem for equations of double characteristics or of parabolic type.

For nonlinear equations there are, in general, very few results about the global existence of solutions. For example, if the function F in equation (2) in the normal form satisfies the Lipschitz condition with constants A and B that are independent of x , then we get a global existence theorem. The method of proof of this theorem is as follows: First, we prove the existence for $|x| \leq \varepsilon_1$ and sufficiently small ε_1 by Picard's successive iteration method. Then we regard $x = \varepsilon_1$ as the hyperplane on which the initial values are assigned and proved the existence of a solution on $\varepsilon_1 \leq |x_1| \leq \varepsilon_2$, and so on. The same method can be applied to nonlinear systems of the first order if they are special types of quasilinear systems.

G. Construction of Solutions by Asymptotic Expansion

Let $a(x, D) = \sum_{|\alpha| \leq m} a_\alpha(x) D^\alpha$ be a linear partial differential operator of order m , with coefficients of class C^∞ . We write $a(x, \xi) = \sum_{|\alpha| \leq m} a_\alpha(x) \xi^\alpha = h(x, \xi) + h'(x, \xi) + \dots$ with h and h' homogeneous in ξ of degree m and $m-1$, respectively. Let $K: \varphi(x) = 0$ be a regular

surface of codimension 1. We assume that K is a simple characteristic, i.e., $h(x, \varphi_x) = 0$ and $(\partial h / \partial \xi_i(x, \varphi_x)) \neq (0)$ on K . Let $f_j(t)$ ($j = 0, 1, \dots$) be a sequence of functions satisfying $df_j/dt(t) = f_{j-1}(t)$, $j = 1, 2, \dots$. Then the equation $a(x, D)u(x) = 0$ has a formal solution in the form

$$u(x) = \sum_{j=0}^{\infty} f_j(\varphi(x))u_j(x).$$

The coefficients $u_j(x)$ are obtained by solving successively the equations

$$L_1[u_j] = \sum_{k=2}^m L_k[u_{j-k+1}], \tag{13}$$

where

$$L_1 = \sum_{i=1}^n \frac{\partial h}{\partial \xi_i}(x, \varphi_x) D_i + \frac{1}{2} \sum_{i,j=1}^n \frac{\partial^2 h}{\partial \xi_i \partial \xi_j}(x, \varphi_x) \varphi_{x_i x_j} + h'(x, \varphi_x)$$

and L_k ($2 \leq k \leq m$) are differential operators of order k depending only on a and φ . By this method of asymptotic expansion of solution, fundamental solutions and singularities of solutions for hyperbolic equations have been studied (Hadamard [5, 6]; R. Courant and P. Lax, *Proc. Nat. Acad. Sci. US*, 42 (1956); Lax, *Duke Math. J.*, 24 (1957); D. Ludwig, *Comm. Pure Appl. Math.*, 22 (1960); S. Mizohata, *J. Math. Kyoto Univ.*, 1 (1962); → 325 Partial Differential Equation of Hyperbolic Type).

If $a(x, D)$ is an operator with analytic coefficients, this formal solution is convergent. By using this fact, Mizohata constructed null solutions. In fact, put $f_j(t) = t^{p+m+j} / \Gamma(p+m+j)$ ($p \geq 0$), $j = 0, 1, \dots$. Define $u(x)$ by $u(x) = 0$ for $\varphi(x) \leq 0$ and $u(x) = \sum_{j=0}^{\infty} f_j(\varphi(x))u_j(x)$ for $\varphi(x) \geq 0$ obtained by the preceding process. Then $u(x)$ is a null solution of $a(x, D)u(x) = 0$ (Mizohata, *J. Math. Kyoto Univ.*, 1 (1962)).

The Cauchy problem in the case when the initial surface has characteristic points had been studied by J. Leray and by L. Gårding, T. Kotake, and Leray. Let $a(x, D)$ be a differential operator with holomorphic coefficients in a complex domain. Let $S: s(x) = 0$ be a regular surface and T be a subvariety of codimension 1 of S . Suppose that S is noncharacteristic on $S - T$, but characteristic on T . Consider the Cauchy problem (1) of Section A. Then the solution $u(x)$ is ramified around a characteristic surface K that is tangent to S on T , and it can be uniformized (Leray, *Bull. Soc. Math. France*, 85 (1957); Gårding, Kotake, and Leray, *Bull. Soc. Math. France*, 92 (1964)).

Next we consider the Cauchy problem (1) when the initial surface S ($x_1 = 0$) is noncharacteristic, but the initial values $w_k(x)$ ($0 \leq k \leq m - 1$) have singularities on a regular subvariety T ($x_1 = x_2 = 0$) of S . We assume that

321 G
PDEs (Initial Value Problems)

$h(0, \xi_1, 1, 0, \dots, 0) = 0$ has m distinct roots. Then there exist m characteristic surfaces $K_i: \varphi_i(x) = 0$ ($1 \leq i \leq m$) originating from T . $\varphi_i(x)$ is obtained by solving the †Hamilton-Jacobi equation $h(x, \varphi_x) = 0$, $\varphi(0, x_2, \dots, x_n) = x_2$. Now, if $w_k(x)$ ($0 \leq k \leq m - 1$) has a pole along T , the Cauchy problem (1) has a unique solution in the form

$$u(x) = \sum_{i=1}^m \left\{ \frac{F_i(x)}{[\varphi_i(x)]^{p_i}} + G_i(x) \log \varphi_i(x) \right\} + H(x),$$

where $F_i(x)$, $G_i(x)$ ($1 \leq i \leq m$) and $H(x)$ are holomorphic functions in a neighborhood of $x = 0$ and p_i ($1 \leq i \leq m$) are integers > 0 . In order to obtain this solution, we set $u(x)$ in the form $u(x) = \sum_{i=1}^m \sum_{j=0}^{\infty} f_j(\varphi_i(x))u_{i,j}(x)$, where $f_0(t)$ is a function with a pole or a logarithmic singularity at $t = 0$ chosen so that $u(x)$ satisfies the initial conditions. Thus we can determine the coefficients $u_{i,j}(x)$ by solving successively the equations (13) on each K_i ($1 \leq i \leq m$) (Y. Hamada, *Publ. Res. Inst. Math. Sci.*, 5 (1969); C. Wagschal, *J. Math. Pures Appl.*, 51 (1972)). When the multiplicity of characteristic roots is more than 1, the situation is not the same. For example, consider the Cauchy problem

$$D_1^2 u - D_2 u = 0, \quad u(0, x_2) = \frac{1}{x_2^2},$$

$$D_1 u(0, x_2) = 0.$$

The solution is

$$u(x) = \sum_{k=0}^{\infty} (-1)^k n! x_1^{2n} / (2n)! x_2^{n+1}$$

with essential singularities along $x_2 = 0$. This situation occurs quite generally. We factor $h(x, \xi) = h_1(x, \xi)^{r_1} \dots h_s(x, \xi)^{r_s}$, where h_i ($1 \leq i \leq s$) are irreducible polynomials of degree m_i in ξ with holomorphic coefficients. We assume that the equation $\prod_{i=1}^s h_i(0, \xi_1, 1, 0, \dots, 0) = 0$ has p distinct roots ($p = m_1 + \dots + m_s$). Then there exist p characteristic surfaces K_i ($1 \leq i \leq p$) originating from T . We suppose more generally that the initial values $w_k(x)$ are multi-valued functions ramified around T . Then the Cauchy problem (1) has a unique holomorphic solution on the universal covering space of $V - \bigcup_{i=1}^p K_i$, where V is a neighborhood of $x = 0$. In fact, this is solved by transforming this problem into †integrodifferential equations. Such a method of solution is closely related to the method discussed in this section. See Hamada, Leray, and Wagschal (*J. Math. Pures Appl.*, 55 (1976)). In this case, even if the initial values have only poles, the solution in general may have essential singularities along $\bigcup_{i=1}^p K_i$, but if $a(x, D)$ satisfies Levi's condition ($a(x, D)$ is well decomposable), the solution does not yield essential singularities along $\bigcup_{i=1}^p K_i$. See J. De Paris (*J. Math. Pures Appl.*, 51 (1972)).

322 (XIII.20) Partial Differential Equations (Methods of Integration)

A. General Remarks

The methods of integrating partial differential equations are not as simple as those for ordinary differential equations. For ordinary differential equations, we often obtain the desired solution by first finding the general solution containing several arbitrary constants and then specializing those constants to satisfy prescribed additional conditions. The situation is more complicated, however, for partial differential equations. In the formal general solution of a partial differential equation we have arbitrary functions instead of arbitrary constants, and there are cases where it is impossible, or very difficult, to find a suitable specialization of these functions so that the given additional conditions are fulfilled. For this reason, methods of solution are rather specific and are classified according to the types of additional conditions. In many cases, we as-

sume that a problem is mathematically well posed, guess the possible solutions, and verify it directly.

A problem is said to be mathematically **well posed (properly posed or correctly posed)** if, under assigned additional conditions, the solution (i) exists, (ii) is uniquely determined, and (iii) depends continuously on the assigned data. By carefully examining problems in physics and engineering, we usually obtain many well-posed and important problems. In these problems, usually the data are sufficiently smooth functions. In these cases, part (iii) of the above definition (the continuous dependence of the solutions on the data) follows often from assumptions (i) and (ii). For example, elliptic equations like †Laplace's equation $u_{xx} + u_{yy} = 0$ for $u(x, y)$ describe laws of static or stationary phenomena such as the field of universal gravitation, the electrostatic field, the magnetostatic field, the steady flow of incompressible fluids without vortices, and the steady flow of electricity or heat. For this equation, †boundary value problems are well posed, but †initial value problems are not (→ 323 Partial Differential Equations of Elliptic Type). By contrast, for †hyperbolic equations like $u_{tt} - u_{xx} = 0$ for $u(x, t)$ and †parabolic equations like $u_t - u_{xx} = 0$ for $u(x, t)$ which control the change (in reference to time) of the various stationary phenomena, initial value problems or mixed problems with both boundary conditions and initial conditions are well posed (→ 325 Partial Differential Equations of Parabolic Type).

For the rest of this article we explain fundamental and typical methods of integration (→ Appendix A, Table 15).

B. The Lagrange-Charpit Method

For the partial differential equation of the first order

$$F(x, y, u, p, q) = 0, \quad p = \frac{\partial u}{\partial x}, \quad q = \frac{\partial u}{\partial y}, \quad (1)$$

we consider a system of ordinary differential equations called †characteristic differential equations:

$$\frac{dx}{F_p} = \frac{dy}{F_q} = \frac{du}{pF_p + qF_q} = \frac{-dp}{F_x + pF_u} = \frac{-dq}{F_y + qF_u}. \quad (2)$$

If we obtain at least one †integral of this system containing p , q , and an arbitrary constant a in the form

$$G(x, y, u, p, q) = a, \quad (3)$$

and if we find p and q from (1) and (3), then $du = p dx + q dy$ is an †exact differential form, and by integrating it we get a solution $\Phi(x, y, u, a, b)$

$=0$ of (1). A solution of (1) containing two arbitrary constants is called a †complete solution. Here, setting $b=g(a)$ and eliminating a from the two equations $\Phi(x, y, u, a, g(a))=0$ and $\Phi_a + \Phi_b g'(a)=0$, we obtain a solution involving an arbitrary function. Such a solution is called a †general solution of (1). For example, consider $pq=1$. Since the characteristic differential equations are

$$\frac{dx}{q} = \frac{dy}{p} = \frac{du}{2pq} = \frac{-dp}{0} = \frac{-dq}{0},$$

we have $p=a$ (constant), and hence from the original equation we get $q=a^{-1}$. Then $du = adx + a^{-1}dy$ is an exact differential form, and by integrating it a complete solution $u = ax + a^{-1}y + b$ is obtained. A general solution is found by eliminating a from $u = ax + a^{-1}y + g(a)$ and $0 = x - a^{-2}y + g'(a)$.

Likewise, when we have n independent variables x_1, \dots, x_n in the equation

$$F(x_1, \dots, x_n, u, p_1, \dots, p_n) = 0, \quad p_i = \frac{\partial u}{\partial x_i}, \quad (1')$$

we can use the †characteristic differential equations to find a complete solution and a general solution (the **Lagrange-Charpit method**; → 82 Contact Transformations).

C. Separation of Variables and the Principle of Superposition

The simplest and most useful method is the **separation of variables**. Concerning the equation $u_x^2 + u_y^2 = 1$ in $u(x, y)$, for example, by setting $u = \varphi(x) + \psi(y)$ we obtain $\varphi'(x)^2 + \psi'(y)^2 = 1$ or $\varphi'(x)^2 = 1 - \psi'(y)^2$. Since the right-hand side is independent of x and the left-hand side is independent of y , both sides must be equal to the same constant α^2 . From this we get a (complete) solution involving two arbitrary constants α, β :

$$u = \alpha x + \sqrt{1 - \alpha^2} y + \beta.$$

For †linear equations, it is often effective to write the solution as a product $u = \varphi(x)\psi(y)$. From the †heat equation $u_y = u_{xx}$, we obtain by this process a relation $\psi'(y)/\psi(y) = \varphi''(x)/\varphi(x)$, from which we get a particular solution $u = ae^{-v^2y} \sin v(x - \alpha)$ containing a parameter v .

Next, when the equation is linear and homogeneous, by forming a linear combination of particular solutions that correspond to various values of a parameter v , we obtain a new solution (the **principle of superposition**). For example, by integrating the solution $e^{-v^2y} \cos vx$ with respect to the parameter v between the limits $-\infty$ and ∞ (namely, by a superposition consisting of a linear combination and a limiting process), we obtain a new

solution

$$u = \int_{-\infty}^{\infty} e^{-v^2y} \cos vx \, dv = \sqrt{\frac{\pi}{y}} \exp\left(-\frac{x^2}{4y}\right) \quad (y > 0), \quad (4)$$

which is the †fundamental solution of the heat equation. This name refers to the fact that the function (4) can be used to obtain solutions of the heat equation under some initial conditions. More exactly, a solution of $u_y - u_{xx} = 0$ that is a function of class C^2 in $y > 0$, is continuous in $y \geq 0$, and coincides with a bounded continuous function $\varphi(x)$ on $y=0$ can be obtained by a superposition of the solution (4) such as

$$u(x, y) = \frac{1}{2\sqrt{\pi y}} \int_{-\infty}^{\infty} \varphi(\xi) \exp\left(-\frac{(x-\xi)^2}{4y}\right) d\xi.$$

The method of separation of variables applied after a suitable transformation of variables is often successful. In particular, by using orthogonal coordinates, †polar coordinates, or †cylindrical coordinates according to the form of boundary, we often obtain satisfactory results. For example, concerning the boundary value problem for Laplace's equation $\Delta u = u_{xx} + u_{yy} = 0$, which is smooth in the circle $r^2 = x^2 + y^2 < 1$ and takes the value of a given continuous function $g(\theta)$ on the circumference $r=1$, we can use polar coordinates to rewrite the equation in the form

$$\Delta u = u_{rr} + \frac{u_r}{r} + \frac{1}{r^2} u_{\theta\theta} = 0$$

and apply the method of separation of variables to obtain particular solutions $r^n \cos n\theta$, $r^n \sin n\theta$. Hence it is reasonable to suspect that by a superposition of these particular solutions we can obtain the desired solution:

$$u(x, y) = \frac{a_0}{2} + \sum_{n=1}^{\infty} (a_n \cos n\theta + b_n \sin n\theta) r^n.$$

In fact, this series is a desired solution if the coefficients a_n, b_n can be chosen so that the series converges uniformly for $0 \leq r \leq 1$ and can be differentiated term by term for $0 < r < 1$, and if we have

$$g(\theta) = \frac{a_0}{2} + \sum_{n=1}^{\infty} (a_n \cos n\theta + b_n \sin n\theta).$$

By virtue of the uniqueness of the solution of an elliptic equation, this is the unique desired solution. The boundary value problem in the preceding paragraph is well posed.

D. Mixed Problems

For linear homogeneous equations of hyperbolic or parabolic type, **mixed problems** fre-

quently appear, i.e., problems in which both initial and boundary conditions are assigned. These problems are, furthermore, classified into two types.

For the first type, homogeneous boundary conditions are assigned. For example, in vibration problems of a nonhomogeneous string between $0 \leq x \leq l$, we must find the solution of the equation

$$(T(x)u_x)_x = \rho u_{tt}$$

satisfying an initial condition $u = f(x)$, $u_t = g(x)$ for $t = 0$, under homogeneous boundary conditions: (i) $u = 0$ for $x = 0$ and $x = l$ in the case of two fixed ends; (ii) $u_x = 0$ for $x = 0$ and $x = l$ in the case of two free ends; (iii) $-u_x + \sigma_0 u = 0$ for $x = 0$, and $u_x + \sigma_1 u = 0$ for $x = l$ ($\sigma_0 > 0$, $\sigma_1 > 0$), where the two ends are tied elastically to the fixed points; (iv) $T(0)u(0) = T(l)u(l)$, $T(0)u'(0) = T(l)u'(l)$ (periodicity condition); (v) u, u' are finite at $x = 0$ and $x = l$ (regularity condition).

The method of separation of variables is applicable to problems of this type also. For example, suppose that we have two fixed ends. Disregarding the initial condition for a while, we find a particular solution fulfilling only the boundary condition by setting $u(x, t) = y(x)\exp ivt$. Here, $y(x)$ must satisfy

$$(T(x)y')' + v^2 \rho(x)y = 0, \quad y(0) = y(l) = 0. \quad (5)$$

Except when the solution is trivial (i.e., $u(x, t) = 0$), $y(x) \neq 0$ must hold. But in the special case $T(x) \equiv 1$, $\rho(x) \equiv 1$, $l = \pi$, the values of v for which functions of this kind exist are only $1, 2, 3, \dots$ (the corresponding $y(x)$ is $\sin vx$).

Also, in more general cases, nontrivial solutions $y(x)$ exist only for some discrete values of v . These v are called 'eigenvalues of (5), and the corresponding solutions $y(x)$ are called 'eigenfunctions for the eigenvalues v . That is, the desired particular solution can be obtained by solving the 'eigenvalue problem (5). Again, when $T(x) \equiv \rho(x) \equiv 1$, $l = \pi$, particular solutions are $\sin nx \exp int$, $\sin nx \exp(-int)$ ($n = 1, 2, \dots$). We consider

$$u(x, t) = \sum_{n=1}^{\infty} (a_n \cos nt + b_n \sin nt) \sin nx, \quad (6)$$

which is obtained by a superposition of these particular solutions. If we can determine the coefficients a_n, b_n so that this series converges uniformly and is twice differentiable term by term, and

$$f(x) = \sum_{n=1}^{\infty} a_n \sin nx, \quad g(x) = \sum_{n=1}^{\infty} nb_n \sin nx,$$

then the series (6) is a solution of the mixed problem in question. If the uniqueness of the solution of the mixed problem is proved, it is not necessary to look for any solution other

than the one obtained by combining the method of separation of variables and the principle of superposition.

Furthermore, the method described in this section is applicable to solving the following nonhomogeneous equation, which characterizes the motion of a string under the influence of an external force $f(x, t)$:

$$u_{tt} - u_{xx} = f(x, t) \quad (7)$$

under the boundary condition for the first type of mixed problem and the initial condition $u = u_t = 0$ for $t = 0$. In this case, we expand the unknown u and the function $f(x, t)$ in terms of the system of eigenfunctions $\{\sin nx\}$, and by substituting

$$u = \sum_{n=1}^{\infty} a_n(t) \sin nx, \quad f(x, t) = \sum_{n=1}^{\infty} A_n(t) \sin nx$$

into (7), we reduce the problem to determining $a_n(t)$ ($n = 1, 2, \dots$). When the external force varies with a harmonic oscillation over time as in $f(x, t) = -\varphi(x)\exp(-i\omega t)$, a similar method can be applied by setting $u = v(x)\exp(-i\omega t)$.

For mixed problems of the second type, the homogeneous initial condition $u = 0, u_t = 0$ for $t = 0$ is assigned, but the boundary condition is nonhomogeneous. For example, when an oscillating string is at rest until $t = 0$, and for $t > 0$ its right end is fixed and its left end moves subject to an assigned rule, the behavior of the string is described by the solution of $u_{tt} - u_{xx} = 0$ under the boundary condition $u(0, t) = f(t)$, $u(l, t) = 0$ ($t > 0$). This is called a **transient problem**. If we now choose an arbitrary function $B(x, t)$ that fulfills all the boundary and initial conditions, and if we set $u - B(x, t) = v(x, t)$ and $B_{xx} - B_{tt} = f(x, t)$, then v satisfies

$$v_{tt} - v_{xx} = f(x, t) \quad \text{for } t > 0$$

with $v = v_t = 0$ for $t = 0$; $v = 0$ for $x = 0$ and $x = l$. Then $v(x, t)$ describes the oscillation of a string that is at rest until $t = 0$ and moves under the effect of an external force represented by $f(x, t)$ for $t > 0$. Problems of this kind often appear in electrical engineering.

Such problems can be reduced to problems of the first type in the manner described in the previous paragraph, but there are some direct methods that are more effective, the first being **Duhamel's method**. Consider the case where $f(t)$ is the unit impulse function:

$$f(t) = \begin{cases} 1, & t > 0, \\ 0, & t < 0, \end{cases}$$

and let $U(x, t)$ be a solution corresponding to this case and vanishing for $t \leq 0, x > 0$. Then a solution corresponding to the general case is given by

$$u = \int_0^t \frac{\partial}{\partial t} U(x, t - \tau) f(\tau) d\tau.$$

The second method is based on application of the †Laplace transformation. Denoting the Laplace transform of a solution $u(x, t)$ by

$$\int_0^\infty ue^{-pt} dt = \frac{v(x, p)}{p},$$

we multiply both sides of $u_{tt} - u_{xx} = 0$ by e^{-pt} and integrate the result with respect to t from 0 to ∞ . Then, taking account of the initial condition, we have

$$v_{xx} - p^2v = 0$$

with the boundary condition

$$v(0, p) = p \int_0^\infty f(t)e^{-pt} dt, \quad v(l, p) = 0.$$

If for $p = \alpha + i\beta$ ($\alpha > \alpha_0$) we can find a solution $v(x, p)$ of this boundary value problem for the ordinary differential equation, then the desired solution is given by

$$u(x, t) = \frac{1}{2\pi i} \int_L \frac{v(x, p)}{p} e^{pt} dp,$$

where L is a path in $\alpha > \alpha_0$ parallel to the imaginary axis. This is called the **Bromwich integral**.

E. Green's Formula and Application of Fundamental Solutions

Given a linear partial differential operator

$$L[u] \equiv \sum_p a_p(x) D^p u, \quad p = (p_1, \dots, p_n),$$

$$D^p = \partial^{p_1} \dots \partial^{p_n} / \partial x_1^{p_1} \dots \partial x_n^{p_n},$$

we call the operator

$$L^*[v] \equiv \sum_p (-1)^{p_1 + \dots + p_n} D^p (\bar{a}_p(x) v)$$

the **adjoint operator** of L , and the operator

$${}^tL[v] \equiv \sum_p (-1)^{p_1 + \dots + p_n} D^p (a_p(x) v)$$

the **transposed operator** of L . Sometimes tL is also called the adjoint operator of L . In the complex Hilbert space, the adjoint operators are more appropriate than the transposed operators. In this case, the operator L^* defined above is usually called the **formal adjoint operator** to distinguish it from the one defined by

$$(L[u], v) = (u, L^*[v]) \text{ for all } u \in D(L),$$

$D(L)$ being the domain of the definition of L (\rightarrow 251 Linear Operators). These transposed or adjoint operators are often used to represent (at least locally) the solutions u of $L[u] = f$.

We explain in more detail the specific case where the number of independent variables is

2. For the linear partial differential operator

$$L(u) = A(x, y) \frac{\partial^2 u}{\partial x^2} + 2B(x, y) \frac{\partial^2 u}{\partial x \partial y} + C(x, y) \frac{\partial^2 u}{\partial y^2} + D(x, y) \frac{\partial u}{\partial x} + E(x, y) \frac{\partial u}{\partial y} + F(x, y)u$$

and its adjoint partial differential operator

$$M(v) = \frac{\partial^2 (Av)}{\partial x^2} + 2 \frac{\partial^2 (Bv)}{\partial x \partial y} + \frac{\partial^2 (Cv)}{\partial y^2} - \frac{\partial (Dv)}{\partial x} - \frac{\partial (Ev)}{\partial y} + Fv,$$

we have †Green's formula:

$$\iint_D (vL(u) - uM(v)) dx dy = - \int_{\partial D} \left(P \frac{\partial x}{\partial n} + Q \frac{\partial y}{\partial n} \right) ds, \quad (8)$$

where

$$P = v \{ Au_x + Bu_y \} - u \{ (Av)_x + (Bv)_y \} + Duv, \\ Q = v \{ Bu_x + Cv_y \} - u \{ (Bv)_x + (Cv)_y \} + Euv, \quad (9)$$

and ∂D denotes the boundary curve of the domain D , n the internal normal of ∂D at a point of ∂D , and s the arc length.

We can apply this formula for solving a nonhomogeneous equation $L(u) = f$ as follows. Assume that there exists a solution of $L(u) = f$ satisfying the assigned additional condition, and choose a †fundamental solution of $M(v) = 0$ having an adequate singularity at a point (x_0, y_0) of D and fulfilling a suitable boundary condition. Then, if we substitute these solutions u and v into (8), we obtain an explicit representation of $u(x_0, y_0)$. If we can verify that the function $u(x, y)$ thus obtained is a solution of $L(u) = f$ fulfilling the assigned additional conditions, then we see, under the assumption of uniqueness of solutions, that this and only this function $u(x, y)$ is the desired solution. For example, consider a boundary problem for

$$L(u) = \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}, \text{ for which } M(v) = \frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2}.$$

The problem is, for a circle of radius r with center at the origin, to find a function $u(x, y)$ that is continuous in the interior and on the circumference C_r of the circle, and that satisfies $L(u) = f$ in the interior of the circle (f is bounded and continuous in the interior of the circle) and is equal to a given continuous function g on the circumference C_r . In this case, we consider the circumference K_ϵ of sufficiently small radius ϵ with center (x_0, y_0) contained in the interior of the first circle, and set

$$v(x, y) = (1/2\pi) \log 1/\rho + h(x, y), \\ \rho = ((x - x_0)^2 + (y - y_0)^2)^{1/2}. \quad (10)$$

We apply formula (8) to the domain D_ε enclosed by the circumferences K_ε and C_r . If, in (10), h satisfies $M(v)=0$ in the interior of the circle enclosed by C_r and vanishes on C_r , then we get

$$\iint_{D_\varepsilon} v f dx dy = - \int_{K_\varepsilon} (v u_n - u v_n) ds + \int_{C_r} g v ds.$$

By letting ε tend to zero, the first term on the right-hand side yields

$$-u(x_0, y_0) \int_0^{2\pi} \frac{1}{2\pi} \frac{\partial \log \rho}{\partial \rho} \rho d\theta = -u(x_0, y_0),$$

by the logarithmic singularity of v at the point (x_0, y_0) . Therefore we have an explicit representation of u ,

$$u(x_0, y_0) = \int_{C_r} g v_n ds - \iint_{x^2+y^2 \leq r^2} v f ds dy, \quad (11)$$

and it is easily verified that this is the desired solution.

As stated in the previous paragraph, to apply Green's formula it is necessary to find a solution v of $M(v)=0$ possessing a fundamental singularity as the logarithmic singularity, i.e., a so-called fundamental solution. As fundamental singularities for

$$M(v) = \frac{\partial v}{\partial y} - \frac{\partial^2 v}{\partial x^2} \quad \text{and} \quad M(v) = \frac{\partial^2 v}{\partial y^2} - \frac{\partial^2 v}{\partial x^2}$$

of parabolic type and of hyperbolic type, we must take those given respectively by

$$u(x, y) = \begin{cases} \frac{1}{2\sqrt{\pi(y-y_0)}} \exp\left(-\frac{(x-x_0)^2}{4(y-y_0)}\right), & y > y_0, \\ 0, & y \leq y_0, \end{cases}$$

and

$$v(x, y) = \begin{cases} 1/2, & |x-x_0| < y-y_0, \\ 0, & |x-x_0| \geq y-y_0 \end{cases}$$

(→ 323 Partial Differential Equations of Elliptic Type; 325 Partial Differential Equations of Hyperbolic Type; 327 Partial Differential Equations of Parabolic Type).

323 (XIII.24)
Partial Differential Equations of Elliptic Type

A. General Remarks

Suppose that we are given a linear second-order partial differential equation

$$L[u] \equiv \sum_{i,j=1}^n a_{ij}(x) \frac{\partial^2 u}{\partial x_i \partial x_j} + \sum_{i=1}^n b_i(x) \frac{\partial u}{\partial x_i} + c(x)u = f(x), \quad (1)$$

where $x=(x_1, \dots, x_n)$, $a_{ji}=a_{ij}$. If the quadratic form $\sum a_{ij} \xi_i \xi_j$ in ξ is positive definite at every point x of a domain G , this equation (or the operator L) is said to be **elliptic** (or of **elliptic type**) in G . For $n=2$, $a_{11}(x)a_{22}(x)-(a_{12}(x))^2 > 0$ is the condition of ellipticity. In this case, by a change of independent variables, the equation is transformed locally into the canonical form

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + b_1(x, y) \frac{\partial u}{\partial x} + b_2(x, y) \frac{\partial u}{\partial y} + c(x, y)u = f(x, y).$$

The operator $\sum_{i=1}^n \partial^2/\partial x_i^2$, denoted by Δ , is called **Laplace's operator** (or the **Laplacian**). The simplest examples of elliptic equations are $\Delta u=0$ (**Laplace's differential equation**) and $\Delta u=f(x)$ (**Poisson's differential equation**) (→ Appendix A, Table 15).

B. Fundamental Solutions

Let K be the n -dimensional ball with radius R , center x_0 , boundary Ω (an $(n-1)$ -dimensional sphere), and area S_n , and let r be the distance from x_0 to x . Then for any function $u(x)$ of class C^2 we have

$$u(x_0) = \frac{1}{S_n} \int_{\Omega} u dS - \frac{R^{n-1}}{(n-2)S_n} \times \int_K (r^{2-n} - R^{2-n}) \Delta u dx \quad \text{for } n > 2,$$

$$u(x_0) = \frac{1}{2\pi} \int_{\Omega} u dS - \frac{1}{2\pi} \int_K \log \frac{R}{r} \Delta u dx \quad \text{for } n = 2.$$

Thus, if u is a solution of Poisson's equation $\Delta u = f(x)$, we have a representation of $u(x_0)$ by replacing Δu by f in the integrals just given. Next, concerning the solutions of the equation $\Delta u + cu = 0$ ($c > 0$, constant), the following relation holds:

$$\frac{1}{S_n} \int_{\Omega} u dS = \frac{\Gamma(n/2) J_n(R\sqrt{c})}{(R\sqrt{c}/2)^{n'}} u(x_0),$$

where Γ is the \dagger gamma function, $n' = (n-2)/2$, and J_n is the \dagger Bessel function of order v .

Now, if we put

$$V(x, \xi) = \begin{cases} \left(\sum_{i=1}^n (x_i - \xi_i)^2 \right)^{1-n/2} = r^{2-n}, & n \geq 3, \\ \log \left(\sum_{i=1}^2 (x_i - \xi_i)^2 \right)^{-1/2} = \log \frac{1}{r}, & n = 2, \end{cases}$$

then the function $u(x)$ defined by

$$u(x) = -\frac{1}{\omega_n} \int_G V(x, \xi) f(\xi) d\xi,$$

$$\omega_n = 2\pi^{n/2} \frac{n-2}{\Gamma(n/2)}$$

represents a \dagger particular solution of $\Delta u = f(x)$, where $V(x, \xi)$ as a function of the variables x satisfies $\Delta V(x, \xi) = 0$ except at $x = \xi$.

Consider now the more general case (1). A function $E(x, \xi)$ is called a **fundamental solution** (or **elementary solution**) of (1) or of L if

$$u(x) = \int_G E(x, \xi) f(\xi) d\xi$$

provides a solution of (1) for any $f(x) \in C^\infty$ with compact support. A fundamental solution $E(x, \xi)$ is a solution of the equation $L[E] = 0$ having a singularity at $x = \xi$ of the form $-\omega_n^{-1} \sqrt{a(\xi)} r^{2-n}$ ($n \geq 3$) or $\omega_2^{-1} \sqrt{a(\xi)} \log r$ ($n = 2$), where $a(\xi) = \det(a^{ij}(\xi))$ and $r = (\sum a^{ij}(\xi)(x_i - \xi_i)(x_j - \xi_j))^{1/2}$ and (a^{ij}) is the inverse matrix of (a_{ij}) .

Roughly, there are three different methods of constructing fundamental solutions. The first and most general is to use pseudodifferential operators (\rightarrow 345 Pseudodifferential Operators). The second is that of J. Hadamard [1], which uses the geodesic distance between two points x and ξ with respect to the Riemannian metric $\sum a^{ij}(x) dx_i dx_j$. This is important in applications of elliptic equations to geometry. The third method is due to E. E. Levi [2] and is as follows: Let

$$V(x, \xi) = \begin{cases} r^{2-n}, & n \geq 3, \\ -\log r, & n = 2. \end{cases}$$

To obtain a solution of $L[u] = f(x)$ we set

$$u = \int_G V(x, \xi) \varphi(\xi) \sqrt{a(\xi)} d\xi.$$

Writing $L[V(x, \xi)] = \chi(x, \xi)$, we obtain the following \dagger integral equation of Fredholm type in $\varphi(x)$:

$$\varphi(x) - \frac{1}{\omega_n} \int_G \chi(x, \xi) \varphi(\xi) \sqrt{a(\xi)} d\xi = \frac{1}{\omega_n} f(x).$$

If we denote the \dagger resolvent of this equation by $\bar{\chi}(x, \xi)$ and put

$$\gamma(x, \xi) = V(x, \xi) - \omega_n \int_G V(x, \xi') \bar{\chi}(\xi', \xi) \sqrt{a(\xi')} d\xi',$$

then $E(x, \xi) = -\gamma(x, \xi) \sqrt{a(\xi)}/\omega_n$ is seen to be a fundamental solution of L . Thus Levi's method enables us to construct a fundamental solution locally by successive approximation, because the integral equation in φ as above has a unique solution expressible by Neumann series if the domain G is small enough (\rightarrow 189 Green's Operator).

C. The Dirichlet Problem

Let G be a bounded domain with boundary Γ . We call the problem of finding a solution u of the given elliptic equation in G that is continuous on $G \cup \Gamma$ and takes the assigned continuous boundary values on T the **first boundary value problem** (or **Dirichlet problem**). In particular, the Dirichlet problem for $\Delta u = 0$ has been studied in detail (\rightarrow 120 Dirichlet Problem).

If $c(x) < 0$ and $f(x) \leq 0$ or if $c(x) \leq 0$ and $f(x) < 0$ in (1), a solution u does not attain its local negative minimum in G . This is called the **strong maximum principle** (\rightarrow [3, 4] for **Hopf's maximum principle** and **Giraud's theorem**). The maximum principle is one of the most powerful tools available for the treatment of elliptic equations of the second order with real coefficients. From this it follows that the solution of the Dirichlet problem for (1) is unique if $c(x) < 0$. Furthermore, concerning the uniqueness of the solution, we have the following criterion: If there exists a function $\omega(x) > 0$ of class C^2 in G and continuous on $G \cup \Gamma$ such that $L[\omega(x)] < 0$, then the solution of the Dirichlet problem is unique.

Let G be a \dagger regular domain in the plane. If we denote \dagger Green's function of Δ relative to the Dirichlet problem in G by $K(x, y; \xi, \eta)$, then the solution u of $\Delta u = f(x, y)$ vanishing on Γ is given by

$$u(x, y) = -\frac{1}{2\pi} \iint_G K(x, y; \xi, \eta) f(\xi, \eta) d\xi d\eta,$$

where $f(x, y)$ satisfies a \dagger Hölder condition.

The Dirichlet problem for

$$\begin{aligned} L[u] &\equiv \Delta u + a(x, y) \frac{\partial u}{\partial x} + b(x, y) \frac{\partial u}{\partial y} + c(x, y) u \\ &= f(x, y) \end{aligned}$$

with prescribed boundary values reduces to the problem in the previous paragraph. In fact, let $h(x, y)$ be a function that coincides with the prescribed boundary value on Γ . Then if we put $u = h(x, y) + v$, the problem is reduced to finding a solution v satisfying an equation similar to the one for $L[u]$ (replacing f by $f - L[h]$) and vanishing on Γ . Now suppose that Γ consists of a finite number of Jordan curves whose curvatures vary continuously, a and b are continuously differentiable, and c and f satisfy Hölder conditions. Let $K(x, y; \xi, \eta)$ be Green's function for the Dirichlet problem relative to Δ . To find a solution of $L[u] = f$ vanishing on Γ we set

$$u = -\frac{1}{2\pi} \iint_G K(x, y; \xi, \eta) \rho(\xi, \eta) d\xi d\eta.$$

Then ρ is a solution of the integral equation

$$\rho(x, y) + \iint_G H(x, y, \xi, \eta) \rho(\xi, \eta) d\xi d\eta = f(x, y),$$

where $H(x, y, \xi, \eta) = (-1/2\pi) \{a(x, y)K_x(x, y; \xi, \eta) + b(x, y)K_y(x, y; \xi, \eta) + c(x, y)K(x, y; \xi, \eta)\}$. Therefore we have the following alternatives: Either $L[u] = f$ has a unique solution for any f and any given boundary values on Γ , or $L[u] = 0$ has nontrivial solutions vanishing on Γ (in this case the number of linearly independent solutions is finite).

More general equations of type (1) have been studied by J. Schauder and others. Schauder proved, first, that when the $b_i(x)$ and $c(x)$ are zero, $a_{ij}(x)$ and $f(x)$ satisfy Hölder conditions, and the boundary Γ of G is of class C^2 , then there exists a unique solution $u(x)$ vanishing on Γ . Next, when the $b_i(x)$ and $c(x)$ are continuous and a_{ij} and f satisfy Hölder conditions, he showed the following alternatives: Either $L[u] = f$ admits a unique solution vanishing on Γ for every f , or $L[u] = 0$ has nontrivial solutions vanishing on Γ (in this case, the number of linearly independent solutions is finite).

In (1), suppose that a_{ij} , b_i , and c are Hölder continuous of exponent α ($0 < \alpha < 1$) uniformly on \bar{G} and that Γ is of class $C^{2+\alpha}$. Then we have the following inequality (**Schauder's estimate**) for any $u \in C^{2+\alpha}(\bar{G})$:

$$\|u\|_{2+\alpha, \bar{G}} \leq K_1 (\|L[u]\|_{\alpha, \bar{G}} + \|u\|_{2+\alpha, \Gamma}) + K_2 \|u\|_{0, \bar{G}}, \quad (2)$$

where $\|\cdot\|_{k, S}$ stands for the norm in the function space $C^k(S)$ (\rightarrow 168 Function Spaces). K_1 and K_2 are positive constants depending on L , G , and α but independent of u . More precisely, K_1 depends only on the ellipticity constant λ of L defined as the smallest number ≥ 1 such that

$$\lambda^{-1} |\xi|^2 \leq \sum a_{ij}(x) \xi_i \xi_j \leq \lambda |\xi|^2 \quad (3)$$

for any $(x, \xi) \in \bar{G} \times \mathbf{R}^n$. The inequality (2) is one of the most important **a priori estimates** in the theory of elliptic equations [5, 6] (\rightarrow inequality (9) in Section H).

D. Quasilinear Partial Differential Equations

Consider the second-order partial differential equation in $u(x_1, \dots, x_n)$:

$$F(x_1, \dots, x_n, u, p_1, \dots, p_n, p_{11}, \dots, p_{ij}, \dots, p_{nn}) = 0,$$

where $p_i = \partial u / \partial x_i$, $p_{ij} = \partial^2 u / \partial x_i \partial x_j$. If, for a solution $u(x)$, $\sum_{i,j=1}^n (\partial F / \partial p_{ij}) \xi_i \xi_j$ is a positive definite form, we say that the equation is **elliptic** at $u(x)$. Moreover, if for any values of u, p_i, p_{ij} this quadratic form is positive definite, we say simply that the equation is of **elliptic type**. The equation is called **quasilinear** if F is linear in p_{ij} . For example, the equation of minimal surfaces (\rightarrow 334 Plateau's Problem)

$$(1 + p_1^2)p_{11} - 2p_1 p_2 p_{12} + (1 + p_2^2)p_{22} = 0$$

is a quasilinear elliptic equation. Furthermore,

$$\Delta u = f(x, y, u, u_x, u_y)$$

is also elliptic. E. Picard solved this equation by the **method of successive approximation** [7]. Specifically, let $h(x, y)$ be the harmonic function taking the assigned boundary values on Γ . Starting from $u_0(x, y) = h(x, y)$, we define the functions $u_n(x, y)$ successively as the solutions of

$$\Delta u_n = f(x, y, u_{n-1}, \partial u_{n-1} / \partial x, \partial u_{n-1} / \partial y),$$

coinciding with h on Γ . Let $K(x, y; \xi, \eta)$ be Green's function in G and in the region defined by $|u - h(x, y)| \leq A$, $|p - h_x| \leq B$, $|q - h_y| \leq B$, $(x, y) \in G$, and let the supremum of $|f(x, y, u, p, q)|$ be C . Assume now that

$$\frac{C}{2\pi} \iint_G K d\xi d\eta \leq A, \quad \frac{C}{2\pi} \iint_G |K_x| d\xi d\eta \leq B,$$

$$\frac{C}{2\pi} \iint_G |K_y| d\xi d\eta \leq B,$$

and that f satisfies a Hölder condition in (x, y) . Moreover, let

$$\begin{aligned} &|f(x, y, u', p', q') - f(x, y, u, p, q)| \\ &\leq L|u - u'| + L'(|p' - p| + |q' - q|). \end{aligned}$$

Assume finally that

$$\iint_G (LK + L'(|K_x| + |K_y|)) d\xi d\eta \leq \gamma < 1.$$

Under these assumptions, $\{u_n(x, y)\}$ is uniformly convergent, and the limit $u(x, y)$ coinciding with $h(x, y)$ on Γ satisfies

$$\Delta u = f(x, y, u, \partial u / \partial x, \partial u / \partial y).$$

Furthermore, it is known that the solution is unique within the region mentioned above. This method can be applied when G is small and the values of h_x and h_y are limited.

When f does not contain p and q , the following method is known. Let $\omega(x, y)$ and $\bar{\omega}(x, y)$ both be continuous on $G \cup \Gamma$ and of class C^2 in G . Suppose that $f(x, y, u)$ satisfies a Hölder condition in $\omega(x, y) \leq u \leq \bar{\omega}(x, y)$, and that

$$\Delta\omega \geq f(x, y, \omega(x, y)), \quad \Delta\bar{\omega} \leq f(x, y, \bar{\omega}(x, y)).$$

Then, given a continuous function φ on Γ such that $\omega \leq \varphi \leq \bar{\omega}$, there exists a unique solution u of $\Delta u = f(x, y, u)$ such that

$$\omega(x, y) \leq u(x, y) \leq \bar{\omega}(x, y) \text{ in } G,$$

$$u(x, y) = \varphi \text{ on } \Gamma.$$

Finally, consider the equation

$$A \frac{\partial^2 u}{\partial x^2} + 2B \frac{\partial^2 u}{\partial x \partial y} + C \frac{\partial^2 u}{\partial y^2} = 0,$$

where A, B , and C are functions of x, y, u, p, q and $AC - B^2 > 0$. Under the following conditions, there exists a solution of the Dirichlet problem: A, B, C are of class C^2 , and their derivatives of order 2 always satisfy Hölder conditions; G is convex; and the boundary value φ along Γ considered as a curve in xyu -space represented by the parameter of arc length is of class $C^{3+\alpha}$ ($\alpha > 0$). Moreover, any plane having 3 common points with this curve has slope less than a fixed number Λ . The proof of this theorem is carried out in the following way: For any function u satisfying

$$|u(x, y)| \leq \max|\varphi|, \quad |u_x| \leq \Lambda, \quad |u_y| \leq \Lambda,$$

replacing u, p, q by $u(x, y), u_x(x, y), u_y(x, y)$, respectively, in A, B , and C , we have the linear equation in v :

$$A[u] \frac{\partial^2 v}{\partial x^2} + 2B[u] \frac{\partial^2 v}{\partial x \partial y} + C[u] \frac{\partial^2 v}{\partial y^2} = 0.$$

We can obtain the solution v taking the boundary value φ on Γ . Thus we have a mapping $u \rightarrow v$. Applying the 'fixed-point theorem in function space to this mapping, we have the desired solution $v(x, y) = u(x, y)$.

Concerning the Dirichlet problem for the second-order semilinear elliptic partial differential equation

$$\sum_{i,j=1}^n a_{ij}(x) \frac{\partial^2 u}{\partial x_i \partial x_j} = f\left(x, u, \frac{\partial u}{\partial x_1}, \dots, \frac{\partial u}{\partial x_n}\right),$$

a work by M. Nagumo (*Osaka Math. J.*, 6 (1954)) establishes a general existence theorem.

For the general nonlinear equation

$$F(x_1, \dots, x_n, u, p_1, \dots, p_n, p_{11}, \dots, p_{ij}, \dots, p_{nn}) = 0,$$

if $\sum(\partial F/\partial p_{ij}) \xi_i \xi_j > 0, F_u \leq 0$, the solution of the

Dirichlet problem for this equation is unique. Even when $F_u \leq 0$ does not hold, the conclusion remains the same if we can reduce the equation to this case by a suitable change of variables.

Quasilinear equations in divergence form

$$\sum_{i=1}^n \frac{\partial}{\partial x_i} a_i\left(x, u, \frac{\partial u}{\partial x_1}, \dots, \frac{\partial u}{\partial x_n}\right) = f\left(x, u, \frac{\partial u}{\partial x_1}, \dots, \frac{\partial u}{\partial x_n}\right), \tag{4}$$

or more generally, any quasilinear elliptic equation

$$\sum_{i,j=1}^n a_{ij}\left(x, u, \frac{\partial u}{\partial x_1}, \dots, \frac{\partial u}{\partial x_n}\right) \frac{\partial^2 u}{\partial x_i \partial x_j} = f\left(x, u, \frac{\partial u}{\partial x_1}, \dots, \frac{\partial u}{\partial x_n}\right), \tag{5}$$

and even quasilinear elliptic systems have been treated in detail in several recent works [8, 9]. J. Serrin [10] treated the Dirichlet problem and established the existence and the uniqueness of solutions for some classes of equations of type (5) containing the minimal surface equation. His method is to estimate the maximum norms of u and of its first derivatives, to apply a result of O. A. Ladyzhenskaya and N. N. Ural'tseva [9] and the Schauder estimate (2), and finally to use the Leray-Schauder fixed-point theorem [11].

E. Relation to the Calculus of Variations

Consider the bilinear form

$$J = \int_G \left(\sum a_{ij}(x) \frac{\partial u}{\partial x_i} \frac{\partial u}{\partial x_j} + 2 \sum b_i(x) \frac{\partial u}{\partial x_i} u + c(x) u^2 + 2f(x) u \right) dx,$$

where we assume $\sum a_{ij}(x) \xi_i \xi_j > 0$. Under the boundary conditions imposed on u , if there exists a function u that makes J minimum, then assuming some differentiability condition on $a_{ij}(x), b_i(x), c(x)$, we have the Euler-Lagrange equation

$$\sum_j \frac{\partial}{\partial x_j} \left(\sum_i a_{ij}(x) \frac{\partial u}{\partial x_i} \right) - \left(c(x) - \sum_i \frac{\partial}{\partial x_i} b_i(x) \right) u - f(x) = 0,$$

which is a linear second-order self-adjoint elliptic equation.

B. Riemann treated the simplest case, where $a_{ij}(x) = \delta_i^j, b_i(x) = c(x) = 0$, i.e., the case $\Delta u = 0$. He proved, assuming the existence of the minimum of J , the existence of the solution of $\Delta u = 0$ with assigned boundary values. This result,

called **Dirichlet's principle**, was used by D. Hilbert, R. Courant, H. Weyl, O. Nikodym, and others to show the existence of solutions for linear self-adjoint elliptic equations.

If $F(x_1, \dots, x_n, u, p_1, \dots, p_n)$ satisfies $\sum(\partial^2 F/\partial p_i \partial p_j) \xi_i \xi_j > 0$ (and F has some regularity), then the function that minimizes the integral

$$J = \int_G F\left(x_1, \dots, x_n, u, \frac{\partial u}{\partial x_1}, \dots, \frac{\partial u}{\partial x_n}\right) dx_1, \dots, dx_n$$

with the given boundary condition satisfies the Euler-Lagrange equation (of type (4))

$$\sum_{i,j=1}^n F_{p_i p_j} \frac{\partial^2 u}{\partial x_i \partial x_j} + \sum_{i=1}^n F_{u p_i} \frac{\partial u}{\partial x_i} + \sum_{i=1}^n F_{x_i p_i} - F_u = 0$$

($p_i = \partial u/\partial x_i$) and the boundary condition as well. This is also an elliptic partial differential equation in u . The case where F is a function of p alone (in particular, the case of †minimal surfaces) has been studied by A. Haar, T. Radó, J. Serrin, and others, particularly for $F = (1 + p_1^2 + \dots + p_n^2)^{1/2}$ in the case of the minimal surface equation.

F. The Second and Third Boundary Value Problems

Let G be a domain in \mathbf{R}^n with a smooth boundary consisting of a finite number of hypersurfaces. Also, let $B[u]$ be the boundary operator defined by

$$B[u] = a \frac{\partial u}{\partial v} + \beta u, \tag{6}$$

where $a = (\sum_{i=1}^n (\sum_{j=1}^n a_{ij} \cos(v_0 x_j))^2)^{1/2}$, v_0 is the outer normal of unit length at the point $x \in S$, and v is the **conormal** defined by

$$\cos(vx_i) = \sum_{j=1}^n a_{ij} \cos(v_0 x_j) / a, \quad i = 1, \dots, n.$$

The problem of finding the solution $u(x)$ of the equation $L[u] = f$ continuous on the closed domain \bar{G} and satisfying $B[u] = \varphi$ on the boundary S of G is called the **second boundary value problem** (or **Neumann problem**) when $\beta \equiv 0$, and the **third boundary value problem** (or **Robin problem**) when $\beta \neq 0$. In general, in boundary value problems, the condition that the solutions must satisfy at the boundary is called the **boundary condition**. We assume that the boundary S of G is expressed locally by a function with †Hölder continuous first derivatives (G is then called a **domain of class $C^{1,\lambda}$**). Assume that G is such a domain, $c \leq 0$, $\beta \geq 0$, and at least one of c and β is not identically 0. Then the second and third boundary value problems admit one and only one solution. When $c \equiv 0$ and $\beta \equiv 0$, the solutions of the

second boundary value problem are determined uniquely up to additive constants. Furthermore, let M be the †adjoint operator of L , and let

$$B'[v] = a \frac{\partial v}{\partial v} + (\beta - b)v,$$

where

$$b = \sum_{i=1}^n \cos(v_0 x_i) \left[b_i - \sum_{j=1}^n \frac{\partial a_{ij}}{\partial x_j} \right].$$

Then if the boundary S of G is of class C^1 and f, φ are continuous, in order that there exist at least one solution u of the second or third boundary value problem relative to $L[u] = f$, it is necessary and sufficient that

$$\int_G f v dx - \int_S \varphi v dS = 0,$$

where v is any solution of $M[v] = 0$ with the boundary condition $B'[v] = 0$. Here the necessity is easily derived from Green's formula. G. Giraud used the notion of fundamental solution to reduce the second and third boundary value problems relative to $L[u] = f$ to a problem of integral equations, under the assumptions that G is a domain of class C^1 , the coefficients of L and f satisfy Hölder conditions, and φ and β are continuous [3; also 12].

G. Method of Orthogonal Projection

The theory of †Hilbert spaces is applicable to the boundary value problems in Section F. In general, let $H^m(G)$ be the space of functions in $L_2(G)$ whose partial derivatives in the sense of †distributions up to order m belong to $L_2(G)$. For elements f and g in $H^m(G)$, we define the following inner product:

$$(f, g)_m = \sum_{|\alpha| \leq m} \int_G D^\alpha f(x) \overline{D^\alpha g(x)} dx,$$

where

$$D^\alpha = \frac{\partial^{|\alpha|}}{\partial x_1^{\alpha_1} \dots \partial x_n^{\alpha_n}}, \quad |\alpha| = \alpha_1 + \dots + \alpha_n$$

(→ 168 Function Spaces). With respect to this inner product, $H^m(G)$ is a Hilbert space. When u satisfies $L[u] = f$ ($f \in L_2(G)$) and $\varphi(x)$ is an arbitrary element of $H^1(G)$, Green's formula yields

$$-\sum_{i,j=1}^n \left(a_{ij} \frac{\partial u}{\partial x_i} \cdot \frac{\partial \varphi}{\partial x_j} \right) + \sum_{i=1}^n \left(b'_i(x) \frac{\partial u}{\partial x_i} \cdot \varphi \right) + (c(x)u, \varphi) + \int_S a \frac{\partial u}{\partial v} \cdot \bar{\varphi} dS = (f, \varphi).$$

where $b'_i(x) = b_i(x) = -\sum_j (\partial a_{ij} / \partial x_j)$. Taking account of the boundary condition on u :

$a \partial u / \partial v + \beta u = 0$, we get

$$\sum_{i,j} \left(a_{ij} \frac{\partial u}{\partial x_i}, \frac{\partial \varphi}{\partial x_j} \right) - \sum_i \left(b_i \frac{\partial u}{\partial x_i}, \varphi \right) - (cu, \varphi) + \int_S \beta u \bar{\varphi} dS = -(f, \varphi).$$

Thus the problem is reduced to finding $u(x) \in H^1(G)$ satisfying this equation for all $\varphi \in H^1(G)$. This equation can be regarded as an equation in $H^1(G)$. If necessary, by replacing $c(x)$ by $c(x) - t$ for a large t , we can show that for any $f(x) \in L_2(G)$, there exists a unique solution $u(x) \in H^1(G)$ [12, 13]. Now, for a solution of this functional equation, if we take $\varphi(x) \in \mathcal{D}(G)$, we have $(u, L^*[\varphi]) = (f, \varphi)$, where L^* is the †adjoint operator of L . This means that $u(x)$ is a solution of $L[u] = f$ in the sense of distributions, and we call such a $u(x)$ a **weak solution**. Such a treatment may be called the **method of orthogonal projection**, following Weyl. In this case, it can be shown that if we assume smoothness of the coefficients, the boundary S , and β , then the solution $u(x) \in H^1(G)$ belongs to $H^{s+2}(G)$ when $f(x) \in H^s(G)$ ($s=0, 1, \dots$). Thus, if we apply Green's formula, we can see that u satisfies the boundary condition $a \partial u / \partial v + \beta u = 0$. In particular, when $s > n/2$, we see that $u(x) \in C^2(\bar{G})$ by †Sobolev's theorem [12]. In other words, $u(x)$ is a **genuine solution**.

Next, we introduce the complex parameter λ and consider the boundary value problem $(L + \lambda I)[u] = f, f \in L_2(G), a \partial u / \partial v + \beta u = 0$. If t is large, $(L - tI)$ is a one-to-one mapping from the domain $\mathcal{D}(L) = \{u \in H^2(G) | a \partial u / \partial v + \beta u = 0\}$ onto $L_2(G)$. Thus, denoting its inverse, which acts on the equation from the left, by G_t , we have

$$(I + (\lambda + t)G_t)[u] = G_t f.$$

Conversely, since the solution $u(x)$ contained in $L_2(G)$ (hence also contained in $\mathcal{D}(L)$) satisfies the equation and the boundary condition, the problem is reduced to the displayed equation in $L_2(G)$ considered above. Now, since G is bounded and G_t is a continuous mapping from $L_2(G)$ into $H^2(G)$, **Rellich's theorem** yields that G_t is a †compact operator when it is regarded as an operator in $L_2(G)$. So we can apply the †Riesz-Schauder theorem (\rightarrow 189 Green's Operator).

H. Elliptic Equations of Higher Order

The differential operator of order m :

$$L = \sum_{|\alpha| \leq m} a_\alpha(x) D^\alpha, \quad D^\alpha = \frac{\partial^{|\alpha|}}{\partial x_1^{\alpha_1} \dots \partial x_n^{\alpha_n}},$$

$$|\alpha| = \alpha_1 + \dots + \alpha_n,$$

323 H PDEs of Elliptic Type

is called an **elliptic operator** if $\sum_{|\alpha|=m} a_\alpha(x) \xi^\alpha \neq 0$ ($\xi \neq 0$). In particular, if

$$\text{Re} \sum_{|\alpha|=m} a_\alpha(x) \xi^\alpha \geq c |\xi|^m, \quad c > 0,$$

L is called a **strongly elliptic operator**. In this case, m is even. L. Gårding studied the Dirichlet problem for strongly elliptic operators [14]. If we put $m=2b$, the boundary value condition is stated as $\partial^j u / \partial v^j = f_j(x)$ ($j=0, 1, \dots, b-1$), where v is the normal of unit length at the boundary. Using the notion of function space, this boundary condition means that the solutions belong to the closure $\hat{H}^b(G)$ of $\mathcal{D}(G)$ in $H^b(G)$ (\rightarrow 168 Function Spaces). In this treatment, **Gårding's inequality**

$$(-1)^b \text{Re}(L[u], u) \geq \delta \|u\|_b^2 - c \|u\|^2, \quad u \in \hat{H}^b(G), \quad (7)$$

where δ and c are positive constants, plays an important role.

In general, for an elliptic operator L defined in an open set G , if $u(x)$ satisfies $L[u] = f(x)$ and $f(x)$ belongs to H^s on any compact set in G , then $u(x)$ belongs to H^{m+s} on every compact set in G (**Friedrich's theorem** [15]).

General boundary value problems for elliptic equations of higher order have been considered by S. Agmon, A. Douglis, and L. Nirenberg [16], M. Schechter [17], and others. These problems are formulated as follows:

$$L[u] = f(x), \quad B_j(x, D)u(x) = \varphi_j(x), \quad x \in S, \quad j = 1, 2, \dots, b (= m/2), \quad (8)$$

where the $B_j(x, D)$ are differential operators at the boundary and f and $\{\varphi_j\}$ are given functions. Under certain algebraic conditions (**Shapiro-Lopatinskii conditions**) on $(L, \{B_j\})$, the problems are treated also in $H^m(G)$; hence the L^2 **a priori estimates** play a fundamental role: If $u \in H^m(G)$,

$$\|u\|_m \leq K(\|Lu\| + \sum_{j=1}^b \|B_j u\|_{m-m_j-(1/2), S} + \|u\|), \quad (9)$$

where K is a constant determined by (L, B_j, G) , $\|\cdot\|_{k, S}$ is the norm in $H^k(S)$, and m_j are the orders of B_j (compare (9) with (2)). Under these estimates the boundary value problem is said to be **coercive**. In applications, the theory of interpolation of function spaces are also used [18] (\rightarrow 168 Function Spaces). Variational general boundary value problems have been treated by D. Fujiwara and N. Shimakura (*J. Math. Pures Appl.*, 49 (1970)) and others. For systems of such equations, there are works by F. E. Browder (*Ann. math. studies* 33, Princeton Univ. Press, 1954, 15-51) and others.

I. Analyticity of Solutions

In a linear elliptic equation $Lu = f$, suppose that all the coefficients and f are of class C^∞ (resp. real analytic) in an open set G and that u is a distribution solution in G . Then u is also of class C^∞ (resp. real analytic) in G [19]. Hence the linear elliptic operators are **hypocoelliptic** (resp. **analytically hypocoelliptic**) (\rightarrow 112 Differential Operators). In particular, harmonic functions (i.e., solutions of $\Delta u = 0$) are (real) analytic in the domain of existence, whatever the boundary values may be.

Hilbert conjectured that when $F(x, y, u, p, q, r, s, t)$ ($p = p_1, q = p_2, r = p_{11}, s = p_{12}, t = p_{22}$) is analytic in the arguments, then any solution u of the elliptic equation $F = 0$ is analytic on the domain of existence (1900, Hilbert's 19th problem; \rightarrow 196 Hilbert). This conjecture was proved by S. Bernshtein, Radó, and others, and then H. Lewy proposed a method of extending this equation to a complex domain so that it can be regarded as a hyperbolic equation (*Math. Ann.*, 101 (1929)). This result was further extended by I. G. Petrovskii to a general system of nonlinear differential equations of elliptic type (*Mat. Sb.*, 5 (47), (1939)).

J. The Unique Continuation Theorem

Since all the solutions of Laplace's equation $\Delta u = 0$ are analytic, it follows that if $u(x)$ vanishes on an open set in a domain, then $u(x)$ vanishes identically in this domain. This **unique continuation theorem** can be extended to linear elliptic partial differential equations with analytic coefficients in view of the analyticity of solutions. This fact is also proved by applying Holmgren's uniqueness theorem (\rightarrow 321 Partial Differential Equations (Initial Value Problems)). The unique continuation theorem, first established by T. Carleman for second-order elliptic partial differential equations $L[u] = 0$ with C^1 -coefficients in the case of two independent variables, was extended to second-order linear elliptic equations with C^2 -coefficients in the case of any number of independent variables by C. Müller, E. Heinz, and finally by N. Aronszajn [20]. This research was extended by A. P. Calderón [21] and others in the direction of establishing the uniqueness of the Cauchy problem. However, it is to be remarked that even if we assume that the coefficients are of class C^∞ , we cannot affirm the unique continuation property for general elliptic equations. A counterexample was given by A. Plis (*Comm. Pure Appl. Math.*, 14 (1961)). See also the work of K. Watanabe (*Tohoku Math J.*, 23 (1971)).

K. Elliptic Pseudodifferential Operators and the Index

A pseudodifferential operator $P(x, D)$ with symbol $p(x, \xi) \in S_{0,1}^m$ (\rightarrow 345 Pseudodifferential Operators) is said to be **elliptic**, provided there exists a positive constant c such that $|p(x, \xi)| \geq c(1 + |\xi|)^m$ for all $x \in \mathbb{R}^n$ and $|\xi| \geq c^{-1}$. The notion of ellipticity can be extended to operators on a manifold. The theory of elliptic pseudodifferential operators has been widely applied to the study of elliptic differential equations, and is particularly useful in the calculation of the index of elliptic operators. B. R. Vainberg and V. V. Grushin [22] calculated the index i of the coercive boundary value problem for an elliptic operator by showing that i is equal to the index of some elliptic pseudodifferential operator on the boundary.

Example [23]: Given a real vector field (v_1, v_2) on the unit circle $x_1^2 + x_2^2 = 1$, suppose the vector $(v_1(x), v_2(x))$ rotates l times around the origin as the point $x = (x_1, x_2)$ moves once around the unit circle in the positive direction. Then the index of the boundary value problem

$$\left(\frac{\partial^2}{\partial x_1^2} + \frac{\partial^2}{\partial x_2^2} \right) u(x) = f(x), \quad x_1^2 + x_2^2 < 1,$$

$$v_1(x) \frac{\partial u}{\partial x_1} + v_2(x) \frac{\partial u}{\partial x_2} = g(x), \quad x_1^2 + x_2^2 = 1,$$

is equal to $2 - 2l$.

M. F. Atiyah and I. M. Singer determined the index of a general elliptic operator on a manifold in terms of certain topological invariants of the manifold (\rightarrow 237 K-Theory H). The index of noncoercive boundary value problems has also been studied by Vainberg and Grushin, R. Seeley (*Topics in pseudodifferential operators*, C.I.M.E. 1968, 335-375), and others.

L. The Giorgi-Nash-Moser Result

Let us state the following result (J. Moser [24]): Let L be of the form

$$Lu = \sum_{i,j=1}^n \frac{\partial}{\partial x_j} \left\{ a_{ij}(x) \frac{\partial u}{\partial x_i} \right\},$$

where $a_{ij} = a_{ji}$ are real-valued, of class $L^\infty(G)$, and such that the ellipticity condition (3) holds at almost everywhere in G with some $\lambda \geq 1$. Also, let G' be any subdomain of G whose distance from ∂G is not smaller than $\delta > 0$. Then, for any weak solution $u \in H^1(G)$ of the equation $Lu = 0$ and for any two points x and y in G' , we have the inequality

$$|u(x) - u(y)| \leq A|x - y|^\alpha \|u\|_{L^2(G)},$$

where A and α ($A > 0, 0 < \alpha \leq 1$) depend only on (n, λ, δ) and are independent of the particular choice of (L, G, G', u) . Moser proved that the above inequality is a corollary to a Harnack-type inequality (\rightarrow 327 Partial Differential Equations of Parabolic Type G).

M. Asymptotic Distribution of Eigenvalues

Let L be an elliptic operator on \bar{G} of order m with smooth coefficients realized as a self-adjoint operator in $L^2(G)$ under a nice boundary condition, where G is a bounded domain in \mathbf{R}^n with smooth boundary. Let $N(T)$ ($T > 0$) be the number of eigenvalues of L smaller than T . Then, it holds that

$N(T) = CT^{n/m} + \text{an error term, as } T \rightarrow +\infty,$

$$C = (2\pi)^{-n} \int_G dx \int_{S^{n-1}} a(x, \xi)^{-n/m} dS_\xi, \quad (10)$$

where $a(x, \xi)$ is the principal symbol of L and S^{n-1} is the unit sphere on \mathbf{R}^n . C is independent of the boundary condition and, if L is of constant coefficients, of the shape of G .

Formula (10) was at first established by H. Weyl [25] for the case of $L = \text{Laplacian}$, and hence it is often called **Weyl's formula**. Weyl's method is based on the minimax principle [26]. T. Carleman (*Ber. Math.-Phys. Klasse der Sächs. Akad. Wiss. Leipzig*, 88 (1936)) studied the behavior of the trace of the Green's function of $zI - L$ as $|z| \rightarrow \infty$ in the complex plane (\rightarrow [27]). S. Minakshisundaram (*Canad. J. Math.*, 1 (1947)) discussed this formula in connection with the heat equation; see also S. Mizohata and R. Arima (*J. Math. Kyoto Univ.*, 4 (1964)). L. Hörmander (*Acta Math.*, 121 (1968)) treated the case of compact manifolds without boundary and obtained the best possible error estimate. H. P. McKean and I. M. Singer (*J. Differential Geometry*, 1 (1967)) treated the case of manifolds and discussed the geometric meaning of this formula. In general, $N(T)$ is no more than $O(T^{n/m})$ if L is of degenerate elliptic type (C. Nordin, *Ark. Mat.*, 10 (1972)).

N. Equations of Degenerate Elliptic Type

An operator L of the form (1) is said to be degenerate at $x^0 \in \bar{G}$ in the direction $\xi \in \mathbf{R}^n$ if ξ is a null vector of the matrix $(a_{ij}(x^0))$. L is said to be of degenerate elliptic type if $(a_{ij}(x))$ is nonnegative definite at any $x \in \bar{G}$ and if L is degenerate at some point of \bar{G} in some direction.

Suppose that the coefficients of L and the boundary Γ of G are smooth enough. At $x \in \Gamma$, denote by $v(x) = (v_1(x), \dots, v_n(x))$ the unit outer

PDEs of Elliptic Type

normal vector to G . Let Σ_3 be the set of $x \in \Gamma$ at which L is not degenerate in the normal direction. Also, let Σ_1, Σ_2 , and Σ_0 be the sets of $x \in \Gamma \setminus \Sigma_3$ at which $b(x) > 0, < 0$, and $= 0$, respectively, where $b(x)$ is defined by

$$b(x) = - \sum_{i=1}^n v_i(x) \left\{ b_i(x) - \sum_{j=1}^n \frac{\partial a_{ij}(x)}{\partial x_j} \right\}. \quad (11)$$

Then the Dirichlet problem for equation (1) is to find a function $u(x)$ defined on $G \cup \Sigma_2 \cup \Sigma_3$ satisfying

$$L[u] = f \text{ in } G, \quad (1)$$

$$u = g \text{ on } \Sigma_2 \cup \Sigma_3, \quad (12)$$

where f and g are given functions.

Let $1 < p < \infty$. We set $q = p/(p-1)$. We also put

$$c^*(x) = c(x) - \sum_{i=1}^n \frac{\partial b_i(x)}{\partial x_i} + \sum_{i,j=1}^n \frac{\partial^2 a_{ij}(x)}{\partial x_i \partial x_j}. \quad (13)$$

We have the following existence theorem [28]:

If (i) either $c < 0$ on \bar{G} or $c^* < 0$ on \bar{G} and if (ii) $pc + qc^* < 0$ on \bar{G} , the Dirichlet problem (1) and (12) (with $g=0$) has a weak solution $u \in L^p(G)$ for any $f \in L^p(G)$. The regularity of solutions is also discussed in [28]. The value of $b(x)$ is closely related to the regularity near the point $x \in \Gamma$ if L is degenerate at x in the normal direction (\rightarrow also M. S. Baouendi and C. Goulaouic, *Arch. Rational Mech. Anal.*, 34 (1969)).

Degenerate elliptic equations of type (1) have also been investigated from the probabilistic viewpoint (\rightarrow 115 Diffusion Processes). The general boundary value problems for degenerate elliptic equations of higher order have been treated by M. I. Vishik and V. V. Grushin [29], N. Shimakura (*J. Math. Kyoto Univ.*, 9 (1969)), P. Bolley and J. Camus (*Ann. Scuola Norm. Sup. Pisa*, IV-1 (1974)), and others.

324 (XIII.22) Partial Differential Equations of First Order

A. Quasilinear Partial Differential Equations and Their Characteristic Curves

Suppose that we are given a quasilinear partial differential equation

$$\sum_{i=1}^n P_i(x, u) \frac{\partial u}{\partial x_i} = Q(x, u), \quad x = (x_1, \dots, x_n). \quad (1)$$

A curve defined by a solution $x_i = x_i(t)$, $u = u(t)$ of the system of ordinary differential equations

$$\frac{dx_i}{dt} = P_i(x, u), \quad i = 1, \dots, n; \quad \frac{du}{dt} = Q(x, u)$$

is called a **characteristic curve** of (1) (→ 320 Partial Differential Equations; 322 Partial Differential Equations (Methods of Integration)). A necessary and sufficient condition for $u = u(x)$ to be a solution of (1) is that the characteristic curve passing through any point on the hypersurface $u = u(x)$ (in the $(n+1)$ -dimensional xu -space) always be contained in this hypersurface. For example, the characteristic curve of $\sum_{i=1}^n x_i \partial u / \partial x_i = ku$ is $x_i = x_i^0 e^t$, $u = u^0 e^{kt}$ (a solution of $x'_i = x_i$, $u' = ku$). Therefore the solution $u = u(x)$ is a function such that $u(\lambda x_1, \dots, \lambda x_n) = \lambda^k u(x_1, \dots, x_n)$ ($\lambda = e^t > 0$), i.e., a homogeneous function of degree k .

B. Nonlinear Partial Differential Equations and Their Characteristic Strips

We denote the value of $\partial u / \partial x_i$ by p_i and define the **surface element** (or **hypersurface element**)

by the $(2n + 1)$ -dimensional vector $(x, u, p) = (x_1, \dots, x_n, u, p_1, \dots, p_n)$. Consider the partial differential equation

$$F(x_1, \dots, x_n, u, p_1, \dots, p_n) = 0, \quad p_i = \partial u / \partial x_i. \tag{2}$$

A set $(x(t), u(t), p(t))$ of surface elements depending on a parameter t and satisfying the system of ordinary differential equations

$$\frac{dx_i}{dt} = F_{p_i}, \quad \frac{du}{dt} = \sum_{i=1}^n p_i F_{p_i}, \quad \frac{dp_i}{dt} = -(F_{x_i} + p_i F_u)$$

is called a **characteristic strip** of equation (2), and the curve $x = x(t), u = u(t)$ is called a **characteristic curve** of (2). For quasilinear equations, this definition of characteristic curve coincides with the one mentioned in Section A. Furthermore, an r -dimensional differentiable manifold consisting of surface elements satisfying the relation

$$du - \sum_{i=1}^n p_i dx_i = 0$$

is called an r -dimensional **union of surface elements**. A solution of the partial differential equation (2) is, in general, formed by the set of all characteristic strips possessing, as initial values, surface elements belonging to an $(n - 1)$ -dimensional union of surface elements satisfying $F(x, u, p) = 0$.

An example of a nonlinear partial differential equation of first order is $pq - z = 0$ (where $x_1 = x, x_2 = y, u = z, p_1 = p, p_2 = q$). The equations of the characteristic strip are $x' = q, y' = p, z' = 2pq, p' = p, q' = q$, and therefore the characteristic strip is given by $y = y_0 + (p_0/q_0)x, z = z_0 + 2p_0x + (p_0^2/q_0)x^2, p = p_0 + (p_0/q_0)x, q = q_0 + x$ (if we take x as an independent variable and impose an initial condition $y = y_0, z = z_0, p = p_0, q = q_0$ at $x = 0$). Putting $z_0 = W(y_0)$ (an arbitrary function) for $x = 0$, we have, furthermore, $y = y_0 + W(y_0)/(W'(y_0))^2, z = W(y_0) + 2W(y_0)W'(y_0) + W(y_0)x^2/(W'(y_0))^2$. The elimination of y_0 from these expressions yields a general solution $z = z(x, y)$. In this case, a complete solution is $4az = (x + ay + b)^2$ (where a, b are constants), and a singular solution is $z = 0$.

C. Complete Systems of Linear Partial Differential Equations

For functions $P_i(x)$ ($i = 1, \dots, x = (x_1, \dots, x_n)$) of class C^∞ , define a differential operator X by

$$X = \sum_{v=1}^n P_v(x) \frac{\partial}{\partial x_v}$$

We call k differential operators $X_i = \sum_{v=1}^n P_v^i(x) \partial / \partial x_v$ ($i = 1, \dots, k$) mutually inde-

324 D
PDEs of First Order

pendent when the rank of the matrix (P_v^i) is equal to k . If a system of k independent linear partial differential equations involving one unknown function $f(x)$,

$$X_1 f = 0, \dots, X_k f = 0, \tag{3}$$

has the maximum number $n - k$ of independent integrals, then the system (3) is called a **complete system**. A necessary and sufficient condition for the system (3) to be a complete system is that there exist k^3 functions $\lambda_{ij}^v(x)$ of class C^∞ such that

$$[X_j, X_i] \equiv X_j X_i - X_i X_j = \sum_{v=1}^k \lambda_{ij}^v(x) X_v,$$

that is,

$$\sum_{h=1}^n \left(P_h^j \frac{\partial P_h^i}{\partial x_h} - P_h^i \frac{\partial P_h^j}{\partial x_h} \right) = \sum_{v=1}^k \lambda_{ij}^v P_v^v$$

Here, $[X_j, X_i]$ is a differential operator of first order, called the **commutator** of the differential operators X_i, X_j or the **Poisson bracket**.

D. Involutionary Systems

For two functions $F(x, u, p), G(x, u, p)$ of x, u, p of class C^∞ , we define the **Lagrange bracket** $[F, G]$ by

$$[F, G] = \sum_{v=1}^n \left(\frac{\partial F}{\partial p_v} \left(\frac{\partial G}{\partial x_v} + p_v \frac{\partial G}{\partial u} \right) - \frac{\partial G}{\partial p_v} \left(\frac{\partial F}{\partial x_v} + p_v \frac{\partial F}{\partial u} \right) \right)$$

If F, G do not contain u and are homogeneous linear forms with respect to p , then F and G are differential operators $F = X_1 u$ and $G = X_2 u$ with respect to u (for $p_v = \partial u / \partial x_v$), and we see that $[F, G] = [X_1, X_2]_u$. This bracket has the following properties:

$$[F, G] = -[G, F],$$

$$[F, \varphi(G_1, \dots, G_k)] = \sum_{i=1}^k \frac{\partial \varphi}{\partial G_i} [F, G_i],$$

$$[[F, G], H] + [[G, H], F] + [[H, F], G]$$

$$= \frac{\partial F}{\partial u} [G, H] + \frac{\partial G}{\partial u} [H, F] + \frac{\partial H}{\partial u} [F, G].$$

When F, G are functions of x and p only, we usually use the notation (F, G) and call it also the **Poisson bracket**. In this case, the right-hand side of the third relation vanishes.

Consider k partial differential equations involving one unknown function $u(x_1, \dots, x_n)$,

$$F_i(x, u, p) = 0, \quad i = 1, \dots, k; \quad p_v = \frac{\partial u}{\partial x_v}. \tag{4}$$

If a common solution $u(x)$ of these equations exists, it is also a solution of $[F_i, F_j] = 0$ ($i, j =$

1, ..., k). Therefore, from the equations thus obtained, we take independent equations and add them to the original system. If we then have more than $n + 1$ equations, the original system has no solution. Otherwise, we obtain a system $F_j = 0$ ($j = 1, \dots, r$) for which the F_j are independent (i.e., the rank of $(\partial F_i / \partial p_v)$ is equal to r), and all $[F_i, F_j] = 0$ can be derived from $F_j = 0$. A system (4) such that $[F_i, F_j] \equiv 0$ for all i, j is called an **involution** (or **involutory**) **system**. We always treat a system by extending it to an involutory system. When $k = 1$, we regard the equation itself as an involutory system.

When the equations (4) are mutually independent, a necessary and sufficient condition for them to have in common a solution with $n - k$ degrees of freedom (a solution that coincides with an arbitrary function on an adequate manifold of dimension $n - k$) is that the system (4) be a system of equations involving unknowns p and equivalent to an involutory system.

An involutory system (4) can be extended to an involutory system consisting of n independent equations by adding $n - k$ suitable equations

$$F_{k+1}(x, u, p) = a_{k+1}, \dots, F_n(x, u, p) = a_n. \quad (4')$$

That is, we can find successively $f = F_l$ ($l = k + 1, \dots, n$) such that F_l satisfies the system of equations

$$[F_i, f] = 0, \quad i = 1, \dots, l - 1,$$

which is a complete system of linear partial differential equations for f , and the F_i ($i = 1, \dots, n$) are mutually independent. Then, if we find that p_v as functions of (x, u, a) ($a = (a_{k+1}, \dots, a_n)$) from (4) and (4'), the system of \dagger total differential equations

$$\frac{\partial u}{\partial x_v} = \rho_v(x, u, a), \quad v = 1, \dots, n,$$

is \dagger completely integrable, and we can find u as a solution containing essentially $n - k + 1$ parameters c, a_{k+1}, \dots, a_n , that is, a complete solution of (4). Moreover, if we have an involutory system of $n + 1$ independent equations $F_1 = 0, \dots, F_k = 0, F_{k+1} = a_{k+1}, \dots, F_{n+1} = a_{n+1}$, then we find a complete solution by eliminating p_1, \dots, p_n between the equations. This method of integrating an involutory system is called **Jacobi's second method of integration**.

E. Relation to the Calculus of Variations

Consider a partial differential equation of first order $F(x_1, \dots, x_n, u, p_1, \dots, p_n) = 0$. If a solution $u(x)$ of this equation is given as an implicit

function by $\varphi(x_1, \dots, x_n, u) = 0$, we have

$$F\left(x_1, \dots, x_n, u, -\frac{\partial \varphi / \partial x_1}{\partial \varphi / \partial u}, \dots, -\frac{\partial \varphi / \partial x_n}{\partial \varphi / \partial u}\right) = 0.$$

This gives formally a partial differential equation with independent variables u, x_1, \dots, x_n and a dependent variable φ . It does not contain φ explicitly. That is, this equation has the form

$$F(x_1, \dots, x_{n+1}, \partial \varphi / \partial x_1, \dots, \partial \varphi / \partial x_{n+1}) = 0.$$

Then, by finding a partial derivative, say $\partial \varphi / \partial x_{n+1}$, as a function of the remaining ones from the displayed equation, we get a partial differential equation of the form

$$\partial \varphi / \partial t + H(t, x, \partial \varphi / \partial x) = 0,$$

which is called the **normal form** of the partial differential equation of first order. Setting $p_i = \partial \varphi / \partial x_i$, the equations of the characteristic curve of this equation are

$$\frac{dx_i}{dt} = H_{p_i}(t, x, p), \quad \frac{dp_i}{dt} = -H_{x_i}(t, x, p), \quad i = 1, \dots, n,$$

which are called **Hamilton's differential equations**.

Now, consider the \dagger Euler-Lagrange differential equations

$$dF_{x'_i} / dt - F_{x_i} = 0, \quad i = 1, \dots, n,$$

for the integral

$$J = \int_{t_0}^{t_1} F(t, x, x') dt, \quad x' = \frac{dx}{dt}.$$

Under the assumption that $\det(F_{x'_i x'_j}) \neq 0$, we put $F_{x'_i} = p_i$, and solve these relations with respect to x'_i in the form, say, $x'_i = \varphi_i(t, x, p)$. Furthermore, if we put

$$\left(\sum_{v=1}^n x'_v F_{x'_v} - F \right)_{x' = \varphi(t, x, p)} = H(t, x, p),$$

then the Euler-Lagrange equations are equivalent to Hamilton's differential equations

$$dx_i / dt = H_{p_i}, \quad dp_i / dt = -H_{x_i}, \quad i = 1, \dots, n,$$

since $F(t, x, x') = \sum_{i=1}^n p_i H_{p_i} - H$.

A curve represented by a solution of the Euler-Lagrange equations is called a **stationary curve**. Now consider a family of stationary curves in a domain G of the $(n + 1)$ -dimensional tx -space such that passing through every point of G there is one and only one curve in this family, and suppose that the family is \dagger transversal to an r -dimensional manifold \mathfrak{A} ($r \leq n$) (that is, $F \delta t - \sum F_{x'_i} \delta x_i = 0$ for the differentials $\delta t, \delta x_i$ along \mathfrak{A} ; in particular, if \mathfrak{A} consists of only one point ($r = 0$), a stationary curve passing through this point is transversal to \mathfrak{A}). In

this case, if we denote by $V(t, x)$ the value of the integral J along the stationary curve from \mathfrak{A} to any point (t, x) of G , then the equation

$$\partial V/\partial t + H(t, x, \partial V/\partial x) = 0$$

holds. This equation is called the **Hamilton-Jacobi differential equation** or the **canonical or eikonal equation**. Conversely, a solution of this equation is equal to the value of the integral J for a family of stationary curves transversal to an adequate \mathfrak{A} .

F. The Monge Differential Equation

Consider the partial differential equation (2). By eliminating p and t between

$$\frac{dx_i}{dt} = F_{p_i}, \quad \frac{du}{dt} = \sum_{i=1}^n p_i F_{p_i}, \quad \text{and} \quad F(x, u, p) = 0$$

(for example, by eliminating p between $dx_i/dx_1 = F_{p_i}/F_{p_1}$ and $F = 0$ when $F_{p_1} \neq 0$), we obtain

$$M(x_1, \dots, x_n, u, \partial x_2/\partial x_1, \dots, \partial x_n/\partial x_1) = 0.$$

This equation is called the **Monge differential equation**, and the curve represented by its solution is called an **integral curve** of the equation. In the $(n + 1)$ -dimensional tx -space, a curve that is an envelope of a 1-parameter family of characteristic curves of the partial differential equation (2) is a solution of the Monge equation. A characteristic curve is also an integral curve. When $n = 2$, an integral curve that is not a characteristic curve is a \dagger line of regression of the surface generated by the family of characteristic curves tangent to the integral curve under consideration (which is an integral surface of $F(x, u, p) = 0$). If F is linear in p_i , i.e., quasilinear, all integral curves coincide with characteristic curves.

Partial Differential Equations of Hyperbolic Type

A. Second-Order Linear Hyperbolic Equations

A \dagger linear partial differential equation in $n + 1$ variables $t, x = (x_1, \dots, x_n)$ of the second order,

$$L[u] = \frac{\partial^2 u}{\partial t^2} - \sum_{i=1}^n a_{0i} \frac{\partial^2 u}{\partial t \partial x_i} - \sum_{i,j=1}^n a_{ij} \frac{\partial^2 u}{\partial x_i \partial x_j} - a_0 \frac{\partial u}{\partial t} - \sum_{i=1}^n a_i \frac{\partial u}{\partial x_i} - au = 0, \quad (1)$$

with coefficients a_{0i}, \dots, a that are functions in (t, x) is said to be **hyperbolic** (or of **hyperbolic type**) (with respect to the t -direction) in tx -space if the **characteristic equation** of equation (1) considered at each point of tx -space,

$$H(t, x; \lambda, \xi) = \lambda^2 - \sum_{i=1}^n a_{0i} \xi_i \lambda - \sum_{i,j=1}^n a_{ij} \xi_i \xi_j = 0, \quad (2)$$

has two distinct real roots $\lambda = \lambda_1(t, x, \xi), \lambda_2(t, x, \xi)$ for any n -tuple of real numbers $\xi = (\xi_1, \dots, \xi_n) \neq (0, \dots, 0)$. In particular, (1) is called **regularly hyperbolic** if these two roots are separated uniformly, that is,

$$\lim_{(t,x), |\xi|=1} |\lambda_1(t, x, \xi) - \lambda_2(t, x, \xi)| = c > 0.$$

A typical example of hyperbolic equations is the **wave equation**

$$\square u = \frac{\partial^2 u}{\partial t^2} - \frac{\partial^2 u}{\partial x_1^2} - \dots - \frac{\partial^2 u}{\partial x_n^2} = 0. \quad (3)$$

Equation (3) is also called the **equation of a vibrating string**, the **equation of a vibrating membrane**, or the **equation of sound propagation** according as $n = 1, 2$, or 3 . Another example is

$$\frac{\partial^2 u}{\partial t^2} - c^2 \frac{\partial^2 u}{\partial x^2} - 2 \frac{\partial u}{\partial t} = 0,$$

which describes the propagation of electric current in a conducting wire with leakage and is called the **telegraph equation** (\rightarrow Appendix A, Table 15).

A hyperplane $\lambda(t - t^0) + \dots + \xi_n(x_n - x_n^0) = 0$ passing through a point $p^0 = (t^0, x^0)$ in tx -space and having normal direction (λ, ξ) is called a **characteristic hyperplane** of (1) at p^0 if the direction (λ, ξ) satisfies the characteristic equation at $p^0: H(t^0, x^0; \lambda, \xi) = 0$. A hypersurface $S: s(t, x) = 0$ in tx -space is a **characteristic hypersurface** of (1) if at each point of S the tangent hyperplane of S is a characteristic hyperplane of (1), that is, $H(t, x; s_t, s_x) = 0$ everywhere on S . According to the theory of first-order par-

tial differential equations, a characteristic hypersurface of S is generated by so-called **bicharacteristic curves**, i.e., solution curves $t = t(\tau)$, $x(\tau)$ of a system of ordinary differential equations

$$\frac{dt}{d\tau} = H_\lambda, \quad \dots, \quad \frac{dx_n}{d\tau} = H_{\xi_n},$$

$$\frac{d\lambda}{d\tau} = -H_t, \quad \dots, \quad \frac{d\xi_n}{d\tau} = -H_{x_n},$$

$$H(t, x; \lambda, \xi) = 0.$$

Now if (1) is hyperbolic, the set of all characteristic hyperplanes at $p^0: \{\lambda(t-t^0) + \dots + \xi_n(x_n - x_n^0) = 0 \mid H(t^0, x^0; \lambda, \xi) = 0\}$ has as its envelope a cone $C(p^0)$ with the vertex p^0 . Moreover, since the intersection of any hyperplane $t = \text{constant}$ and the cone $C(p^0)$ is an $(n-1)$ -dimensional ellipsoid or two points for $n=1$, a conical body $D_+(p^0)$ ($D_-(p^0)$) is determined, whose boundary consists of the part of $C(p^0)$ with $t \geq t_0$ ($t \leq t_0$) and the interior of the ellipsoid on the hyperplane $t = \text{constant}$. A †smooth curve γ in tx -space is called **timelike** if the tangent vector of γ at each point p on γ belongs to $D_+(p)$ or $D_-(p)$. Consider the set of points that can be connected with the point p^0 by a timelike curve. We call its closure an **emission**, and a subset $\mathcal{D}_+(p^0)$ ($\mathcal{D}_-(p^0)$) of the closure for which $t \geq t_0$ ($t \leq t_0$) a **forward (backward) emission**. An emission is a conical body surrounded by characteristic hyperplanes in some neighborhood of the vertex p^0 . If the coefficients of (1) are bounded functions, the emissions $\mathcal{D}_\pm(p^0)$ are contained in a conical body

$$K = \left\{ (t, x) \mid \lambda_{\max}^2 (t - t^0)^2 \geq \sum_{i=1}^n (x_i - x_i^0)^2 \right\}$$

independently of the situation of p^0 , where $\lambda_{\max} = \max_{(t,x), |\xi|=1} (|\lambda_1(t, x, \xi)|, |\lambda_2(t, x, \xi)|)$.

B. The Cauchy Problem

Important for the hyperbolic equation (1) is the †Cauchy problem, i.e., the problem of finding a function $u = u(t, x)$ that satisfies (1) in $t > 0$ and the initial conditions

$$u(0, x) = u_0(x), \quad \partial u / \partial t(0, x) = u_1(x), \quad (4)$$

where the functions $u_0(x)$ and $u_1(x)$ are given on the initial hyperplane $t = 0$.

Suppose that (1) is regularly hyperbolic and the coefficients are bounded and sufficiently smooth (i.e., of class C^v with v sufficiently large). Then for the Cauchy problem the following theorem holds. Theorem (C): There exists a positive integer $l (= [n/2] + 3)$, depending on the dimension $n + 1$ of the tx -space, such that if the functions $u_0(x)$ and $u_1(x)$ in (4)

are of class C^l , then there exists a unique solution $u = u(t, x)$ of class C^2 in the domain $0 \leq t < \infty$, $-\infty < x_i < \infty$ ($1 \leq i \leq n$). Moreover, this correspondence $\{u_0(x), u_1(x)\} \rightarrow u(t, x)$ is continuous in the following sense: If a sequence of initial functions $\{u_{0k}(x), u_{1k}(x)\}$ ($k = 1, 2, \dots$) and their derivatives up to the l th order tend to 0 uniformly on every compact set in the hyperplane $t = 0$, then the sequence of corresponding solutions $u_k(t, x)$ also tends to 0 uniformly on every compact set in each hyperplane $t = \text{constant}$. In other words, the Cauchy problem for regularly hyperbolic equations is †well posed in the sense of Hadamard [2].

For dependence of the solution on initial data, the following proposition is valid: The values of the solution u at a point $p^0 = (t^0, x^0)$ depend only on the initial data on a domain G_0 (**domain of dependence**) of the initial hyperplane, which is determined as the intersection of the backward emission $\mathcal{D}_-(p^0)$ and the initial hyperplane. We have the following dual proposition: A change in the initial conditions in a neighborhood of a point Q_0 of the initial hyperplane induces a change of values of the solution only in some neighborhood of the forward emission $\mathcal{D}_+(Q_0)$ (**domain of influence**). If the coefficients of the equation are bounded, the intersection of emissions $\mathcal{D}_\pm(p^0)$ and the hyperplane $t = \text{constant}$ is always compact. It follows that the domain of dependence and the domain of influence are bounded. In some special cases, there exists a proper subdomain of G_0 such that the solution depends only on the initial data on the subdomain. For example, for the wave equation (3) with $n=3$, the solution for the Cauchy problem at a point $p^0 = (t^0, x^0)$ (\rightarrow Section D) is determined, as can be seen from the solution formula (12), by the initial data in a neighborhood of the cone with vertex $p^0: (t-t^0)^2 = \sum_{i=1}^3 (x_i - x_i^0)^2$, namely, in a neighborhood of the intersection of bicharacteristic curves (lines, in this case) passing through p^0 and the initial hyperplane. If the solution of the Cauchy problem has such a property, it is said that **Huygens's principle** is valid, or that diffusion of waves does not occur. For the wave equation (3), Huygens's principle is valid only for odd $n > 1$.

C. The Energy Inequality

The energy conservation law for the wave equation (3),

$$\begin{aligned} E(t) &= \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} \left(\left(\frac{\partial u}{\partial t} \right)^2 + \sum_{i=1}^n \left(\frac{\partial u}{\partial x_i} \right)^2 \right) dx_1 \dots dx_n \\ &= \text{constant}, \end{aligned}$$

is generalized to the so-called energy inequality for hyperbolic equations, which plays an essential role in deducing the well-posedness of the Cauchy problem and the properties of the domain of dependence of the solution. Let the coefficients of a hyperbolic equation (1) be bounded functions, and let $G(\tau)$ be the intersection of the conical body $K = \{(t, x) | \lambda_{\max}^2(t - t^1)^2 \geq \sum_{i=1}^n (x_i - x_i^1)^2\}$ with the hyperplane $t = \tau$ ($\tau < t^1$). The $k (\geq 1)$ th-order energy integral of the solution $u(t, x)$ of (1) on $G(\tau)$ is defined by

$$E_{\tau}^{(k)}(u, G(\tau)) = \int_{G(\tau)} \sum_{\alpha_0 + \dots + \alpha_n \leq k} \left| \frac{\partial^{|\alpha|} u}{\partial t^{\alpha_0} \dots \partial x_n^{\alpha_n}}(\tau, x) \right|^2 dx.$$

Then the following inequality holds:

$$E_{\tau}^{(k)}(u, G(\tau)) \leq CE_{t^0}^{(k)}(u, G(t^0)), \quad t^0 \leq \tau < t^1, \quad (5)$$

where the constant C is independent of u . We call (5) the **energy inequality** (J. Schauder [5]). For the wave equation (3), the hypothesis $l = [n/2] + 3$ in theorem (C) can be replaced by a weaker condition $l = [n/2] + 2$, but if we take $l = [n/2] + 1$, there is an example for which no global solution of class C^1 exists. In general, even though the initial functions are of class C^1 , the solution in the Cauchy problem for hyperbolic equations may not be of class C^1 , while if the energy of the initial functions is bounded, the energy of the solution is also bounded.

D. Representation Formulas for Solutions of the Cauchy Problem

We consider solution formulas that represent solutions of the Cauchy problem explicitly as functionals of the initial functions. The problem of solving (1) under the condition (4), or more generally, the problem of solving an equation $L[u] = f(t, x)$ under (4), can be reduced, by transforming the unknown function u and applying †Duhamel’s method, to the Cauchy problem with initial conditions on the hyperplane $t = \tau$:

$$u(\tau, x) = 0, \quad \partial u / \partial t(\tau, x) = \varphi(x) \quad (4')$$

for arbitrary τ . We define a function $\chi_q(s)$ of a real variable s by

$$\begin{aligned} \chi_q(s) &= |s|^q / 4(2\pi i)^{n-1} q! && (n \text{ odd}), \\ &= -s^q \log |s| / (2\pi i)^n q! && (n \text{ even}), \end{aligned} \quad (6)$$

where n is the dimension of the x -space and q is a positive integer such that $q + n$ is even. Then for a function $\varphi(x)$ of class C^v (with v sufficiently large) with compact support, the

following equality holds [7]:

$$\varphi(x) = \int_{-\infty}^{\infty} \Delta_y^{(n+q)/2} \varphi(y) dy \int_{|\omega|=1} \chi_q((x-y)\omega) d\omega, \quad (7)$$

where Δ_y is the †Laplacian with respect to the variables $y = (y_1, \dots, y_n)$ and $d\omega$ is the surface element of the unit sphere $|\omega| = 1$ in x -space. Now, since the †principle of superposition is valid because (1) is linear, we can infer from formula (7) that the Cauchy problem (1) with initial condition (4') can be reduced to the one for initial conditions with parameters y, ω :

$$u(\tau, x) = 0, \quad \partial u / \partial t(\tau, x) = \chi_q((x-y)\omega). \quad (4'')$$

In fact, since $\chi_q(s)$ is $(q-1)$ -times differentiable by definition, the Cauchy problem (1) with initial condition (4'') has a unique solution $R_q(t, x; \tau, y, \omega)$ for q chosen large enough so that theorem (C) can be applied to (1) with initial condition (4''). Moreover, $R_q(t, x; \tau, y, \omega)$ is a function of (t, x, τ, y, ω) of class C^v , and v increases with q . Now, let $\varphi(x)$ be a function of class C^v with sufficiently large v and with compact support. Then, by (7) and the definition of R_q , the integral

$$\int_{-\infty}^{\infty} \Delta_y^{(n+q)/2} \varphi(y) dy \int_{|\omega|=1} R_q(t, x; \tau, y, \omega) d\omega \quad (8)$$

is a solution of the Cauchy problem (1) with initial condition (4'). Therefore, when R_q is found explicitly, (8) yields a solution formula of the Cauchy problem (1) with initial condition (4') as a functional of the initial functions. Since in (8), the integral $\int_{|\omega|=1} R_q d\omega$ is not necessarily of class C^{n+q} as a function of $(t, x; \tau, y)$, $\Delta_y^{(n+q)/2} \int_{|\omega|=1} R_q d\omega$ is in general not a function in the ordinary sense. But we denote it by $R(t, x; \tau, y)$ formally, and understand that a linear operator

$$u(t, x) = \int R(t, x; \tau, y) \varphi(y) dy \quad (9)$$

is defined by (8). The kernel $R(t, x; \tau, y)$ in this sense is called a **fundamental solution** or **Riemann function** of the Cauchy problem. If we extend the function $\int_{|\omega|=1} R_q(t, x; \tau, y, \omega) d\omega$ defined for $t \geq \tau$ to $t < \tau$, assigning it the value 0 there, then $R(t, x; \tau, y) = \Delta_y^{(n+q)/2} \int_{|\omega|=1} R_q(t, x; \tau, y, \omega) d\omega$ can be considered a †distribution on $(t, x; \tau, y)$ -space, and the equality $L(t, x, \partial/\partial t, \partial/\partial x)R(t, x; \tau, y) = L^*(\tau, y, \partial/\partial \tau, \partial/\partial y)R(t, x; \tau, y) = \delta(t - \tau)\delta(x - y)$ is valid, where L^* is the †adjoint operator of L and δ is †Dirac’s δ -function. In other words, $R(t, x; \tau, y)$ is a fundamental solution of L in the sense of distribution theory.

The fundamental solution $R(t, x; \tau, y)$ can be analyzed using the asymptotic expansion with

respect to the sequence of functions $\{\chi_q(s)\}$, and we have the following important result: If the coefficients of (1) are of class C^∞ (resp. real analytic), then the fundamental solution $R(t, x; \tau, y)$ is of class C^∞ (real analytic) in (t, x) except for points that are on bicharacteristic curves of (1) passing through the point (τ, y) . In the language of the Cauchy problem, the smoothness of the solution u at a point $p = (t, x)$ depends only on the smoothness of the initial conditions on a neighborhood of the intersection of the initial hyperplane and all bicharacteristic curves passing through p . This fact is called **Huygens's principle in the wider sense**. Behavior of the fundamental solution $R(t, x; \tau, y)$ near discontinuous points has also been investigated [2].

For the wave equation (3), the fundamental solution can be constructed, and therefore we can write the solution formula explicitly. The solution formula for (3) with initial condition (4') for $n \geq 3$ is

$$u(t, x) = \frac{1}{(n-2)!} \frac{\partial^{n-2}}{\partial t^{n-2}} \int_0^t (t^2 - \tau^2)^{(n-3)/2} \tau Q(x, \tau) d\tau,$$

$$Q(x, \tau) = \frac{1}{\omega_n} \int_{|\omega|=1} \varphi(x + \tau\omega) d\omega,$$

where $\omega_n = 2\sqrt{\pi^n}/\Gamma(n/2)$ is the surface area of the unit sphere of n -dimensional space. Solutions of the Cauchy problem (3) with initial condition (4) for $n = 1, 2,$ and 3 are, respectively,

$$u(t, x) = \frac{u_0(x+t) + u_0(x-t)}{2} + \frac{1}{2} \int_{x-t}^{x+t} u_1(\xi) d\xi \quad (10)$$

(d'Alembert's solution),

$$u(t, x_1, x_2) = \frac{1}{2\pi} \frac{\partial}{\partial t} \int_{C_t} \frac{u_0(\xi_1, \xi_2) d\xi_1 d\xi_2}{\sqrt{t^2 - (x_1 - \xi_1)^2 - (x_2 - \xi_2)^2}} + \frac{1}{2\pi} \int_{C_t} \frac{u_1(\xi_1, \xi_2) d\xi_1 d\xi_2}{\sqrt{t^2 - (x_1 - \xi_1)^2 - (x_2 - \xi_2)^2}} \quad (11)$$

(Poisson's solution), and

$$u(t, x_1, x_2, x_3) = \frac{1}{4\pi} \frac{\partial}{\partial t} \int_{D_t} \frac{u_0(\xi_1, \xi_2, \xi_3)}{t} d\omega_t + \frac{1}{4\pi} \int_{D_t} \frac{u_1(\xi_1, \xi_2, \xi_3)}{t} d\omega_t \quad (12)$$

(Kirchhoff's solution), where C_t is a disk in the $\xi_1 \xi_2$ -plane with center (x_1, x_2) and radius t , D_t is a sphere in the $\xi_1 \xi_2 \xi_3$ -space with center (x_1, x_2, x_3) and radius t , and $d\omega_t$ is the surface element of D_t .

E. Second-Order Nonlinear Hyperbolic Equations

A second-order nonlinear differential equation

$$\frac{\partial^2 u}{\partial t^2} = A\left(t, x, u, \frac{\partial u}{\partial t}, \frac{\partial u}{\partial x_i}, \frac{\partial^2 u}{\partial t \partial x_i}, \frac{\partial^2 u}{\partial x_i \partial x_j}\right), \quad 1 \leq i, j \leq n, \quad (13)$$

is called **hyperbolic** in a neighborhood of a function $U(t, x)$ if the linear equation of the form (1) obtained from (13) is hyperbolic, where $a_{0i}(t, x)$ and $a_{ij}(t, x)$ are determined by substituting u by $U(t, x)$ in the partial derivatives of A with respect to $\partial^2 u / \partial t \partial x_i$ and $\partial^2 u / \partial x_i \partial x_j$, respectively. If the functions A in (13) and $U = x_0(x) + tu_1(x)$ determined by (4) are sufficiently smooth with respect to $t, x, u, \dots, \partial^2 u / \partial x_i \partial x_j$, the Cauchy problem for (13) with initial condition (4) has a unique solution in some neighborhood of the initial hyperplane under the condition that equation (13) is hyperbolic in a neighborhood of U . In general, initial value problems for nonlinear equations have only local solutions.

F. Higher-Order Hyperbolic Equations

An N th-order linear differential equation in $n+1$ variables $t, x = (x_1, \dots, x_n)$ with constant coefficients

$$L\left(\frac{\partial}{\partial t}, \frac{\partial}{\partial x}\right)u = \sum_{\alpha_0 + |\alpha| \leq N} a_{\alpha_0 \alpha} \left(\frac{\partial}{\partial t}\right)^{\alpha_0} \left(\frac{\partial}{\partial x}\right)^\alpha u = 0, \quad (14)$$

where $\alpha = (\alpha_1, \dots, \alpha_n)$, $|\alpha| = \alpha_1 + \dots + \alpha_n$, and

$$\left(\frac{\partial}{\partial x}\right)^\alpha = \frac{\partial^{|\alpha|}}{\partial x_1^{\alpha_1} \dots \partial x_n^{\alpha_n}},$$

is **hyperbolic in the sense of Gårding** if the following two conditions are satisfied: (i) the partial derivative $\partial^N / \partial t^N$ appears in L ; (ii) the real parts of the roots $\lambda = \lambda_1(\xi), \dots, \lambda_N(\xi)$ of the **characteristic equation** $L(\lambda, i\xi) = 0$ are bounded functions of real variables $\xi = (\xi_1, \dots, \xi_n)$.

When L is a homogeneous equation of the N th order, condition (ii) is equivalent to the following condition: (ii') $\lambda_1(\xi), \dots, \lambda_N(\xi)$ are purely imaginary for all real $\xi = (\xi_1, \dots, \xi_n) \neq (0, \dots, 0)$. The principal part (consisting of the highest-order terms) of a hyperbolic equation is also hyperbolic. If (14) is hyperbolic, a theorem analogous to theorem (C) holds for the Cauchy problem for (14) with initial conditions

$$\partial^k u / \partial t^k(0, x) = u_k(x), \quad 0 \leq k \leq n-1; \quad (15)$$

that is, the Cauchy problem for (14) with initial condition (15) is well posed in the sense of Hadamard. Conversely, if the Cauchy problem

for (14) with initial condition (15) is well posed, then (14) must satisfy the hyperbolicity conditions (i) and (ii) in the sense of Gårding. In other words, well-posedness of the Cauchy problem is equivalent to hyperbolicity in the sense of L. Gårding [14]. Gårding's conditions for hyperbolicity cannot be generalized to the case of variable coefficients, since the influence of the lower-order terms in the equation is taken into account in the definition of hyperbolicity. However, in the case of constant coefficients, an N th-order homogeneous equation remains hyperbolic for any addition of lower-order terms if and only if the characteristic equation has N distinct purely imaginary roots for any real $\zeta = (\zeta_1, \dots, \zeta_n) \neq (0, \dots, 0)$. In this case the equation is called **hyperbolic in the strict sense**. Thus a linear equation with variable coefficients

$$L[u] = \frac{\partial^N u}{\partial t^N} + \sum_{\substack{\alpha_0 + |\alpha| \leq N \\ \alpha_0 < N}} a_{\alpha_0 \alpha}(t, x) \left(\frac{\partial}{\partial t}\right)^{\alpha_0} \left(\frac{\partial}{\partial x}\right)^\alpha u = 0 \tag{16}$$

is called **hyperbolic in the sense of Petrovskii** if the characteristic equation

$$\lambda^N + \sum_{\alpha_0 + |\alpha| = N} a_{\alpha_0 \alpha}(t, x) \lambda^{\alpha_0} (i \zeta)^\alpha = 0$$

has N distinct purely imaginary roots (called **characteristic roots**) $\lambda_1(t, x, \zeta), \dots, \lambda_N(t, x, \zeta)$ for each point $p = (t, x)$ and each $\zeta \neq 0$. Moreover, if the characteristic roots $\lambda_1, \dots, \lambda_N$ are separated uniformly, i.e., the inequality

$$\lim_{(t, x), |\zeta|=1, j \neq k} |\lambda_j(t, x, \zeta) - \lambda_k(t, x, \zeta)| = c > 0$$

holds, (16) is said to be **regularly hyperbolic**. In the second-order case, this definition is equivalent to the previous one. Theorem (C) holds for the Cauchy problem for a regularly hyperbolic equation (16) with initial conditions (15). For the domain of dependence of the solution, a result analogous to the case of the second-order equation can be obtained using an energy inequality [9, 10]. If the coefficients are of class C^∞ , Huygens's principle in the wider sense is valid, that is, discontinuity of the solution is carried over only along bicharacteristic curves.

G. Systems of Hyperbolic Equations

For systems of equations

$$\sum_{j=1}^l L_{ij}[u_j] = 0, \quad 1 \leq i \leq l,$$

where the L_{ij} are higher-order linear differential operators of the form (16), several types of hyperbolicity are formulated in connection with the well-posedness of the Cauchy prob-

lem. We take up two important types, hyperbolicity in the sense of Petrovskii and symmetric hyperbolicity due to Friedrichs.

We call a system of linear differential equations

$$\sum_{j=1}^l \sum_{\alpha_0 + |\alpha| \leq n_j} a_{\alpha_0 \alpha}^{ij}(t, x) \left(\frac{\partial}{\partial t}\right)^{\alpha_0} \left(\frac{\partial}{\partial x}\right)^\alpha u_j = 0, \quad 1 \leq i \leq l, \tag{17}$$

a **system of hyperbolic differential equations** (in the sense of Petrovskii) if the determinant

$$\det \left(\sum_{\alpha_0 + |\alpha| \leq n_j} a_{\alpha_0 \alpha}^{ij}(t, x) \left(\frac{\partial}{\partial t}\right)^{\alpha_0} \left(\frac{\partial}{\partial x}\right)^\alpha \right), \tag{18}$$

calculated formally using the matrix of differential operators in the system, is hyperbolic in the sense of Petrovskii as a single equation of $N (= \sum_{j=1}^l n_j)$ th order. Petrovskii showed that the Cauchy problem for a system that is hyperbolic in this sense is well posed [10]. There were some imperfections in his argument, which have been corrected by others (\rightarrow S. Mizohata [12]). In the case of constant coefficients, the Cauchy problem for (17) is well posed if and only if (18) is hyperbolic in the sense of Gårding.

K. O. Friedrichs, observing that the energy inequality played an essential role in Petrovskii's research, studied symmetric hyperbolic systems of equations, since for them the energy inequalities are valid most naturally. A system of first-order linear differential equations

$$A_0(t, x) \frac{\partial u}{\partial t} = \sum_{i=1}^n A_i(t, x) \frac{\partial u}{\partial x_i} + Bu \tag{19}$$

is called **symmetric hyperbolic** (in the sense of Friedrichs) if the matrices $A_i(t, x)$ ($0 \leq i \leq n$) are symmetric and $A_0(t, x)$ is positive definite. A typical example is provided by Maxwell's equations. For this system it has been shown that the Cauchy problem is well posed and the domain of dependence of the solution is bounded [13].

H. Weakly Hyperbolic Operators

We adopt the following definition of hyperbolicity: a linear differential operator of N th order

$$L = \frac{\partial^N}{\partial t^N} + \sum_{\substack{\alpha_0 + |\alpha| \leq N \\ \alpha_0 \leq N-1}} a_{\alpha_0 \alpha}(t, x) \left(\frac{\partial}{\partial t}\right)^{\alpha_0} \left(\frac{\partial}{\partial x}\right)^\alpha$$

is called **hyperbolic** if the Cauchy problem for $L[u] = 0$ with initial condition (15) is well posed in Hadamard's sense. A hyperbolic operator L is called **strongly hyperbolic** if L remains hyperbolic for any addition of lower-order terms, and **weakly hyperbolic** otherwise.

A necessary condition for hyperbolicity is that all characteristic roots of $L_N(t, x, \lambda, \xi) = 0$ be real for any (t, x, ξ) (P. D. Lax [15], Mizohata [16]). In the case of constant coefficients, strongly hyperbolic operators have been characterized by K. Kasahara and M. Yamaguti (*Mem. Coll. Sci. Kyoto Univ.* (1960)).

As for operators with variable coefficients, it is known that not only regularly hyperbolic operators but also some special classes of not regularly hyperbolic operators are strongly hyperbolic (V. Ya. Ivrii, *Moscow Math. Soc.*, 1976). Let us consider the hyperbolicity of an operator L which is not regularly hyperbolic under the assumption that the multiplicities of the characteristic roots are constant and at most 2; namely, the characteristic polynomial

$$L_N(t, x, \lambda, \xi) = \lambda^N + \sum_{\substack{\alpha_0 + |\alpha| = N \\ \alpha_0 \leq N-1}} a_{\alpha_0 \alpha}(t, x) \lambda^{\alpha_0} \xi^\alpha$$

is decomposed in the following way:

$$L_N(t, x, \lambda, \xi) = \prod_{j=1}^s (\lambda - \lambda_j(t, x, \xi))^2 \prod_{j=s+1}^{N-s} (\lambda - \lambda_j(t, x, \xi)),$$

$$\lim_{\substack{(t, x) \\ |\xi|=1, j \neq k}} |\lambda_j(t, x, \xi) - \lambda_k(t, x, \xi)| = c > 0.$$

Assume that the $\lambda_j(t, x, \xi), j = 1, 2, \dots, N-s$, are real. Then L is hyperbolic if and only if it satisfies **E. E. Levi's condition**, i.e.,

$$l_j(t, x, \xi) = \left[L_{N-1} + \frac{1}{2} \left(\frac{\partial^2 L_N}{\partial \lambda^2} \frac{\partial \lambda_j}{\partial t} + \sum_{\alpha=1}^n \frac{\partial^2 L_N}{\partial \lambda \partial \xi_\alpha} \frac{\partial \lambda_j}{\partial x_\alpha} \right) \right]_{\lambda=\lambda_j} = 0$$

for all $(t, x, \xi), j = 1, 2, \dots, s$,

where L_{N-1} denotes the homogeneous part of $(N-1)$ th order among lower-order terms of L (Mizohata and Y. Ohya [17]). Thus, for a **weakly hyperbolic** operator with variable coefficients, even the principal part is not necessarily hyperbolic. J. Chazarain [18] has studied weakly hyperbolic operators with characteristic roots of arbitrary constant multiplicity. O. A. Oleinik [19] studied the Cauchy problem with nonconstant multiplicities for second-order equations. For higher-order equations, if the multiplicity of characteristic roots at (\hat{t}, \hat{x}) is at most p , or more precisely, if there exist positive rational numbers q and r ($q \geq r$) such that

$$\left(\frac{\partial}{\partial \lambda} \right)^p L_N(\hat{t}, \hat{x}, 0, \xi) \neq 0$$

and

$$\left(\frac{\partial}{\partial \lambda} \right)^{\alpha_0} \left(\frac{\partial}{\partial \xi} \right)^\alpha \left(\frac{\partial}{\partial t} \right)^{\beta_0} \left(\frac{\partial}{\partial x} \right)^\beta L_N(\hat{t}, \hat{x}, 0, \xi) = 0$$

($\forall \xi \in \mathbf{R}^n \setminus 0$)

for $\alpha_0 + |\alpha| + q\beta_0 + r|\beta| < p$, then it is necessary for the well posedness of the Cauchy problem that

$$\left(\frac{\partial}{\partial \lambda} \right)^{\alpha_0} \left(\frac{\partial}{\partial \xi} \right)^\alpha \left(\frac{\partial}{\partial t} \right)^{\beta_0} \left(\frac{\partial}{\partial x} \right)^\beta L_{N-s}(\hat{t}, \hat{x}, 0, \xi) = 0$$

($\forall \xi \in \mathbf{R}^n \setminus 0$)

for $\alpha_0 + |\alpha| + q\beta_0 + r|\beta| + s(1+q) < p$ are satisfied, where L_{N-s} ($1 \leq s \leq N$) are the homogeneous lower-order terms of order $N-s$ of L (Ivrii and V. M. Petkov [20]).

On the other hand, the sufficient condition in the case of multiplicity 2 is given by some conditions related to the subprincipal symbol

$$L_{N-1} - \frac{1}{2} \left(\frac{\partial^2 L_N}{\partial \lambda \partial t} + \sum_{\alpha=1}^n \frac{\partial^2 L_N}{\partial \xi_\alpha \partial x_\alpha} \right),$$

which corresponds to Levi's condition in the case of constant multiplicity, and to the †Poisson brackets (A. Menikoff, *Amer. J. Math.*, 1976; Ohya, *Ann. Scuola Norm. Sup. Pisa*, 1977; L. Hörmander, *J. Anal. Math.*, 1977).

The Cauchy problem for a weakly hyperbolic system of equations is more complicated, because of the essential difficulty that the matrix structure

$$\left(\sum_{\alpha_0 + |\alpha| = n_j} a_{\alpha_0 \alpha}^{ij}(t, x) \lambda^{\alpha_0} \xi^\alpha \right)$$

associated with (17) is not clear in general (→ references in [20]).

I. Gevrey Classes

Classically, the functions of †class s ($s \geq 1$) of Gevrey (→ 58 C^∞ -Functions and Quasi-Analytic Functions G; 168 Function Spaces B (14) were introduced into the studies of the fundamental solution for the heat equation:

$$\mathcal{Y}_{loc}^{(s)}(\mathbf{R}^n) = \{ \varphi(x) \in C^\infty(\mathbf{R}^n) \mid \text{for any compact subset } K \text{ of } \mathbf{R}^n \text{ and any multi-indices } \alpha, \text{ there exist constants } C_K \text{ and } A \text{ such that } \sup_K |(\partial/\partial x)^\alpha \varphi(x)| \leq C_K A^{|\alpha|} |\alpha|!^s \}.$$

This class of functions was used efficiently in the studies of the Cauchy problem for †weakly hyperbolic partial differential equations:

$$L \left(t, x, \frac{\partial}{\partial t}, \frac{\partial}{\partial x} \right) u(t, x) = f(t, x)$$

in $[0, T] \times \mathbf{R}^n = \Omega,$

$$\left(\frac{\partial}{\partial t} \right)^j u(0, x) = u_j(x), \quad j = 0, 1, \dots, N-1.$$

We assume that the multiplicities of the characteristic roots are constant, i.e.,

$$L_N(t, x, \lambda, \xi) = \prod_{i=1}^k (\lambda - \lambda_i(t, x, \xi))^{p_i},$$

where v_i is constant for any $(t, x, \xi) \in \Omega \times \mathbf{R}^n$, $\lambda_i(t, x, \xi)$ is real and distinct, and $\sum_{i=1}^k v_i = N$. Let $\max_{1 \leq i \leq k} v_i = p$. If we suppose that $L(t, x, \partial/\partial t, \partial/\partial x) - \tilde{L}(t, x, \partial/\partial t, \partial/\partial x)$ is a (\dagger pseudo) differential operator of order at most q , where

$$\tilde{L} = \prod_{i=1}^p a_i \left(t, x, \frac{\partial}{\partial t}, \frac{\partial}{\partial x} \right)$$

is a (pseudo)differential operator with $a_i(t, x, \partial/\partial t, \partial/\partial x)$ being strictly hyperbolic (pseudo) differential operators associated with L_N , then for any s such that $1 \leq s < p/q$, the Cauchy problem is well posed in $\gamma_{loc}^{(s)}(\Omega)$, provided that all $a_{\alpha\alpha}(t, x)$ of L and $f(t, x)$ belong to $\gamma_{loc}^{(s)}(\Omega)$, and that $\{u_j(x)\}_{0 \leq j \leq N-1}$ are given in $\gamma_{loc}^{(s)}(\mathbf{R}^n)$ (Ohya [21], J. Leray and Ohya [22]). This result was proved even for the case of arbitrary nonconstant multiplicity of characteristic roots by M. D. Bronshtein [23].

J. Lacunas for Hyperbolic Operators

The theory of lacunas of fundamental solutions of hyperbolic operators, initiated by Petrovskii [24], has been developed further in a paper [25] by M. F. Atiyah, R. Bott, and L. Gårding.

Let $L(\xi) = L_N(\xi) + M(\xi)$ be a hyperbolic polynomial with respect to the vector $\theta \in \mathbf{R}^n - 0$, where $L_N(\xi)$ is the principal part of L ; this means that $L_N(\theta) \neq 0$ and $L(\xi + t\theta) \neq 0$ when $|tm|$ is sufficiently large. Then L has a fundamental solution $E = E(L, \theta, x)$ in the form

$$E(L, \theta, x) = (2\pi)^{-n} \int L(\xi - ic\theta)^{-1} e^{ix(\xi - ic\theta)} d\xi,$$

where c is sufficiently large and the integral is taken in the sense of \dagger distribution. The convex hull of the support of E , denoted by $K = K(L, \theta) = K(A, \theta)$, is a cone depending only on the real part $\text{Re } A$ of the complex hypersurface $A: L(\xi) = 0$, and contained in the union of the origin and the half-space $x \cdot \theta > 0$. Let A_ξ be the \dagger tangent conoid of A at ξ , transported to the origin, and define the wavefront surface $W(A, \theta)$ by the union of all $K(A_\xi, \theta)$ for $\xi \neq 0$. Then it can be shown that the singular supports of $E(L, \theta)$ and all the $E(L_N^k, \theta)$ are contained in $W(A, \theta)$ and, moreover, that they are locally holomorphic outside W . In [25], the Herglotz-Petrovskii-Leray formulas are generalized to any nonstrict $L(\xi)$. Thus we have

$$D^\beta E(L_N^k, \theta, x) = \text{const} \int_{x^*} (x \cdot \xi)^q \xi^\beta L_N^k(\xi)^{-k} \omega(\xi), \quad q > 0, \quad (20)$$

$$D^\beta E(L_N^k, \theta, x) = \text{const} \int_{t_x \cdot \partial x^*} (x \cdot \xi)^q \xi^\beta L_N^k(\xi)^{-k} \omega(\xi), \quad q \leq 0 \quad (20')$$

**325 K
PDEs of Hyperbolic Type**

when $x \in K(A, \theta) \setminus W(A, \theta)$. Here, $q = mk - |\beta| - n$ is the degree of homogeneity of the left-hand side, and $\omega = \sum_{j=1}^n (-1)^{j-1} \xi_j d\xi_1 \wedge \dots \wedge \widehat{d\xi_j} \wedge \dots \wedge d\xi_n$. The integrands are closed \dagger rational $(n-1)$ -forms on $(n-1)$ -dimensional complex \dagger projective space and are integrated over certain \dagger homology classes $\alpha^* = \alpha(A, \theta, x)^*$ and $t_x \cdot \partial \alpha^*$. These formulas provide means of obtaining topological criteria for lacunas. Let $\mathcal{L} \subset K^{\mathbb{C}}$ be a maximal connected open set, where $E(L, \theta, x)$ is holomorphic. \mathcal{L} is said to be a **weak (strong) lacuna** of L if $E(L, \theta, x)$ is the restriction of an entire function to \mathcal{L} ($E(L, \theta, x) = 0$ in \mathcal{L}). In [25] it is shown that x belongs to a weak lacuna for all $E(L_N^k, \theta, \cdot)$ if and only if $\partial \alpha^* = 0$. The sufficiency directly follows from (20') and the necessity follows from a theorem of A. Grothendieck (*Publ. Math. Inst. HES*, 1966) which implies that the rational forms which appear in (20') span all the \dagger cohomology classes in question.

K. Mixed Initial-Boundary Value Problems

Let Ω be a domain in \mathbf{R}^n with a sufficiently smooth boundary Γ , let $L(t, x, \partial/\partial t, \partial/\partial x)$ be a linear hyperbolic operator of N th order defined in $[0, \infty) \times \bar{\Omega} = \{(t, x) | t \in [0, \infty), x \in \bar{\Omega}\}$, and let $B_j(t, x, \partial/\partial t, \partial/\partial x)$, $j = 1, 2, \dots, b$, be linear differential operators of N_j th order defined in a neighborhood of $[0, \infty) \times \Gamma$.

The problem of finding a function $u(t, x)$ satisfying the conditions

$$\begin{aligned} L[u] &= 0 \quad \text{in } (0, \infty) \times \Omega, \\ B_j[u] &= 0 \quad \text{on } (0, \infty) \times \Gamma, \quad j = 1, 2, \dots, b, \\ \partial^k u / \partial t^k(0, x) &= u_k(x), \quad 0 \leq k \leq N-1, \end{aligned} \quad (21)$$

is called a **mixed initial-boundary value problem**. A typical example of such a mixed problem is provided by the case $L = \square$ ($n=2$) and $B[u] = u(t, x)$, which describes the vibration of membranes with a fixed boundary.

The mixed problem (21) is said to be well posed if for any initial data $u_k(x) \in C^\infty(\bar{\Omega})$, $0 \leq k \leq N-1$, which are compatible with the boundary conditions, there exists a unique solution $u(t, x) \in C^\infty([0, \infty) \times \bar{\Omega})$.

Mixed problems for second-order hyperbolic equations are considered in [6]. In regard to mixed problems for hyperbolic equations of higher order, we make the following four assumptions: (i) $\Omega = \mathbf{R}_+^n = \{(x', x_n) | x' \in \mathbf{R}^{n-1}, x_n > 0\}$; (ii) $\Gamma = \{x | x_n = 0\}$ is not characteristic for L or B_j ; (iii) L is regularly hyperbolic; (iv) $N_j \leq N-1$ and $N_j \neq N_k$ if $j \neq k$.

We denote the \dagger principal parts of L and B_j by $L_N(t, x', x_n, \partial/\partial t, \partial/\partial x')$ and $B_{j0}(t, x', \partial/\partial t, \partial/\partial x')$, respectively. By the hyper-

bolicity of L , an equation in κ

$$L_N(t, x', 0, \lambda, \xi', \kappa) = 0 \quad \text{for } \text{Im } \lambda < 0, \quad \xi' \in \mathbf{R}^{n-1}$$

has μ roots κ_j^+ with $\text{Im } \kappa_j^+ > 0$, and $N - \mu$ roots κ_j^- with $\text{Im } \kappa_j^- < 0$, and the number μ is independent of (t, x') and (λ, ξ') . A necessary condition for the well-posedness of the mixed problem (21) is that the number of boundary conditions coincide with this integer μ . The function R defined by

$$R(t, x', \lambda, \xi') = \det \left[\bigoplus_C \frac{B_{j0}(t, x', \lambda, \xi', \kappa) \kappa^{l-1}}{L^+(t, x', \lambda, \xi', \kappa)} d\kappa \right]_{j,l=1,2,\dots,\mu},$$

where $L^+ = \prod_{j=1}^{\mu} (\kappa - \kappa_j^+(t, x', \lambda, \xi'))$ and C is a contour enclosing all κ_j^+ , is called a **Lopatinski determinant**.

We say that L and B_j satisfy the uniform Lopatinski condition if

$$\inf_{\substack{(t, x'), \text{Im } \lambda < 0 \\ |\xi'| + |\lambda| = 1}} |R(t, x', \lambda, \xi')| = c > 0.$$

When the uniform Lopatinski condition is satisfied, the mixed problem (21) is well posed, and (21) represents a phenomenon with a finite propagation speed, which is the same as that of the Cauchy problem for $L[u] = 0$ (T. Balaban [26], H. O. Kreiss [27], and R. Sakamoto [28]). An analogous result holds in the case of a domain Ω with a compact boundary Γ , provided that L and B_j satisfy the uniform Lopatinski condition at every point of Γ .

In the treatment of mixed problems for L and B_j not satisfying the uniform Lopatinski condition, the well-posed problems have been characterized for operators with constant coefficients when $\Omega = \mathbf{R}_+^n$ (Sakamoto [29]). For general domains, however, the well-posedness of mixed problems depends not only on the properties of the Lopatinski determinant but also on the shape of the domain (M. Ikawa [30]).

L. Asymptotic Solutions

In order to explain some properties of phenomenon governed by hyperbolic equations, asymptotic solutions play an important role. Consider, for example, the **acoustic problem**

$$\begin{aligned} \square u &= 0 \quad \text{in } (0, \infty) \times \Omega, \\ u &= 0 \quad \text{on } (0, \infty) \times \Gamma. \end{aligned}$$

Let $w(t, x; k)$ be a function defined in $(0, \infty) \times \Omega$ with parameter $k \geq 1$ of the form

$$w(t, x; k) = e^{ik(\varphi(x)-t)} \sum_{j=0}^N v_j(t, x) k^{-j}, \quad (22)$$

where φ is a smooth function satisfying the **eikonal equation** $|\nabla \varphi|^2 = 1$. If $v_j, j = 0, 1, \dots, N$, satisfy the **transport equations**

$$2 \frac{\partial v_j}{\partial t} + 2 \nabla \varphi \cdot \nabla v_j + \Delta \varphi v_j = -i \square v_{j-1}, \quad v_{-1} = 0,$$

we have

$$\square w = O(k^{-N}).$$

Then w of (22) is an approximate solution of $\square u = 0$ for large k , and it represents a wave propagating in the direction $\nabla \varphi$.

When $\text{supp } w \cap (0, \infty) \times \Gamma \neq \emptyset$, if w hits the boundary Γ transversally, we can construct

$$w^+(t, x; k) = e^{ik(\varphi^+(x)-t)} \sum_{j=0}^N v_j^+(t, x) k^{-j}$$

such that

$$|\nabla \varphi^+|^2 = 1 \quad \text{in } \Omega, \quad \varphi^+ = \varphi, \quad \text{and}$$

$$\frac{\partial \varphi}{\partial \nu} > 0 \quad \text{on } \Gamma,$$

and v_j^+ satisfy the transport equations and $v_j^+ = -v_j$ on $(0, \infty) \times \Gamma$, where ν is the unit inner normal of Γ . Then $w + w^+$ is an approximate solution, and w^+ represents a **reflected wave** propagating in the direction

$$\nabla \varphi^+ = \nabla \varphi - 2(\nabla \varphi \cdot \nu) \nu.$$

These asymptotic solutions show that the high-frequency waves propagate approximately according to the laws of geometric optics.

If asymptotic solution (22) has a **caustic**, i.e., $\{x + |\nabla \varphi(x)| l \in R \mid x \in \text{supp } w\}$ has an envelope, w of the form (22) cannot be an asymptotic solution near the caustic. The asymptotic behavior of high-frequency solutions near the caustic was first considered by G. B. Airy (*Trans. Cambridge Philos. Soc.*, 1838). Under the condition that the principal curvatures of the caustic are positive, w in the form (22) can be prolonged to a domain containing the caustic satisfying the asymptotic solution

$$\begin{aligned} w(t, x; k) &= e^{ik(\theta(x)-t)} \{ \text{Ai}(-k^{2/3} \rho(x)) g_0(t, x; k) \\ &\quad + ik^{-1/3} \text{Ai}'(-k^{2/3} \rho(x)) g_1(t, x; k) \}, \end{aligned} \quad (23)$$

where Ai is the Airy function

$$\text{Ai}(z) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{i(zt+t^3/3)} dt$$

and

$$g_l(t, x; k) = \sum_j g_{lj}(t, x) k^{1/6-j}$$

(D. Ludwig [31]).

Concerning the reflection of **grazing rays** by

strictly convex obstacles, the reflected wave can be constructed by the superposition of asymptotic solutions of the type (23).

The methods of construction of asymptotic solutions of the forms (22) and (23) are also applicable to Maxwell equations or more general hyperbolic systems (R. K. Luneberg [32]; Ludwig and Granoff, *J. Math. Anal. Appl.*, 1968; Guillemin and Sternberg, *Amer. Math. Soc. Math. Surveys*, 14 (1977)).

M. Propagation of Singularities

Let L be a hyperbolic operator with C^∞ coefficients and consider the Cauchy problem $L[u] = 0$ with initial condition (15). When the initial data have singularities, the solution also has singularities for $t > 0$, which is a property of hyperbolic equations quite different from the properties of parabolic ones. It should be noted that the propagation of singularities cannot be derived from the Huygens principle in the wider sense, i.e., even for regularly hyperbolic operators of second order we cannot determine the location and the type of singularities of the solutions for initial data with singularities directly from the singularities of the fundamental solution $R(t, x; \tau, y)$.

Suppose that the multiplicities of characteristic roots of L are constant. Assume that u_k , $k = 0, 1, \dots, N-1$, have, on either side of a sufficiently smooth $(n-1)$ -dimensional manifold Γ , continuous derivatives of sufficiently high order to suffer jump discontinuities across Γ . Then the solution u has continuous partial derivatives of sufficiently high order everywhere except on the characteristic surfaces of L issuing from Γ , and across these the partial derivatives of u have jump discontinuities (Courant and Hilbert [1]).

For more general singularities of initial data, it is known that the wavefront propagates along the bicharacteristic strips satisfying $\varphi_l - \lambda_l(t, x, \nabla\varphi) = 0$, $l = 1, 2, \dots, N-s$, that is, $WFu(\cdot, t)$ is contained in $\{(x(t), \xi(t)) \in T^*(\mathbf{R}^n) \mid (dx_j/dt)(s) = (\partial\lambda_l/\partial\xi_j)(s, x, \xi), (d\xi_j/dt)(s) = -(\partial\lambda_l/\partial x_j)(s, x, \xi), (x(0), \xi(0)) \in \bigcup_k WF(u_k)\}$ (J. Chazarain [18]).

The propagation of singularities is more complicated in mixed problems because of the reflections of singularities at the boundary. For the acoustic problem, R. B. Melrose [33] showed the following: Suppose $\mathcal{O} = C\Omega \subset \{x \mid |x| < R\}$ for some $R > 0$, and all the broken rays according to the geometric optics starting from $\Omega_R = \Omega \cap \{|x| < R\}$ go out of Ω_R in a fixed time. Then for initial data with singularities in

325 Ref. PDEs of Hyperbolic Type

Ω_R , the solution becomes smooth in Ω_R for sufficiently large t .

326 (XIII.27) Partial Differential Equations of Mixed Type

A. General Remarks

Let $A[u(x)] = 0$ be a quasilinear second-order partial differential equation. The type (elliptic, hyperbolic, or parabolic) of the equation depends on the location of the point x . If the type varies as the point x moves, the equation is said to be of **mixed type**. An example is the equation

$$\left(1 - \frac{u^2}{c^2}\right) \frac{\partial^2 \varphi}{\partial x^2} - \frac{2uv}{c^2} \frac{\partial^2 \varphi}{\partial x \partial y} + \left(1 - \frac{v^2}{c^2}\right) \frac{\partial^2 \varphi}{\partial y^2} = 0 \quad (1)$$

of 2-dimensional stationary flow without rotation of a compressible fluid without viscosity, where φ is the velocity potential, $u = \partial\varphi/\partial x$ and $v = \partial\varphi/\partial y$ are the velocity components, and c is the local speed of sound, which is a known function of the speed $q = (u^2 + v^2)^{1/2}$ of the flow. Equation (1) is of elliptic type if $q < c$, i.e., the flow is **subsonic**, and of hyperbolic type if $q > c$, i.e., the flow is **supersonic**. If there exist points where the flow is subsonic as well as points where it is supersonic, (1) is of mixed type. The study of equations of mixed type has become important with the development of high-speed jet planes.

B. Chaplygin's Differential Equation

It is difficult to solve equation (1) directly since it is nonlinear. However, we can linearize it by taking q and $\theta = \arctan(v/u)$ as independent variables (the hodograph transformation). The linearized equation takes the form

$$\frac{\partial^2 z}{\partial x^2} - K(x) \frac{\partial^2 z}{\partial y^2} = 0, \quad xK(x) \geq 0, \quad (2)$$

which is called **Chaplygin's differential equation**. Equation (2) is hyperbolic for $x > 0$ and elliptic for $x < 0$. The study of general equations of mixed type, even when they are linear, is much more difficult and less developed than the study of equations of nonmixed type. Almost all research so far has been on equation (2) or slight modifications of it.

C. Tricomi's Differential Equation

The simplest equation of the form (2) is

$$\frac{\partial^2 z}{\partial x^2} - x \frac{\partial^2 z}{\partial y^2} = 0, \quad (3)$$

which is called **Tricomi's differential equation**. F. G. Tricomi considered the following boundary value problem for (3): In Fig. 1, AC and BC are two characteristic curves of (3) and σ is a Jordan curve connecting A and B . We seek a solution of (3) in the domain D bounded by AC , BC , and σ that takes given values on σ and on one of the two characteristic curves, say on AC . This boundary value problem is called the **Tricomi problem**. Tricomi proved the existence and uniqueness of the solution of his problem under some conditions on the shape of σ and the smoothness of the boundary values. After Tricomi, much research has been done on his and similar problems for equations of form (2) [2]. We can also consider problems such as finding a solution of (3) (or of (2)) satisfying the initial conditions

$$z(0, y) = z_1(y), \quad (\partial z / \partial x)(0, y) = z_2(y)$$

on the common boundary $x=0$ of the elliptic domain and the hyperbolic domain of the equation. This is called the **singular initial value problem**. S. Bergman [3] obtained an integral formula for the solution under the condition that $z_1(y)$ and $z_2(y)$ are real analytic.

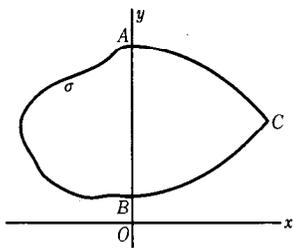

Fig. 1

D. Friedrichs's Theory

For the study of equations of mixed type it would of course be most convenient if there existed a general theory of boundary value problems independent of the type of the equation. However, constructing such a general theory is considered very difficult, because the well-posedness of boundary conditions as well as the analytic properties of solutions are quite different according to the type. The first contributor to the solution of this difficult problem was K. O. Friedrichs [4], who noticed that although the methods of solving the Cauchy problem and the Dirichlet problem are quite different, both methods utilize energy integrals in the proof of the uniqueness of solutions. Using this observation, he succeeded in constructing a unified theory that enables us to treat various types (including the mixed type) of linear equations in a single scheme—an admissible boundary value problem for a **symmetric positive system** of first-order linear

326 Ref. PDEs of Mixed Type

partial differential equations. There is, however, a difficulty in Friedrichs's theory since it does not give a unified procedure for reducing a given boundary value problem for a given equation to an admissible boundary value problem for a symmetric positive system of partial differential equations. The study of equations of mixed type that are of more general form than (2) by means of Friedrichs's theory is an open problem.

E. Further Studies

Work on equations of more general type than (2) or (3) has appeared (not all depending on Friedrichs's theory). For example, the following equations are treated in [5, 6, 7], respectively:

$$\sum_{i=1}^n \frac{\partial^2 z}{\partial x_i^2} + \frac{t}{|t|} \frac{\partial z}{\partial t} = 0,$$

$$\left(\frac{\partial^2}{\partial x^2} + \frac{y}{|y|} \frac{\partial^2}{\partial y^2} \right)^n z = 0,$$

$$G(y) \frac{\partial^2 z}{\partial x^2} + \frac{\partial^2 z}{\partial y^2} - K(y)z = h,$$

where $z = (z_1, \dots, z_n)$ and $G(y)$ and $K(y)$ are symmetric matrices.

327 (XIII.26) Partial Differential Equations of Parabolic Type

A. General Remarks

Consider a second-order linear partial differential equation

$$\sum_{i,j=1}^n \left[a_{ij}(x,t) \frac{\partial^2 u}{\partial x_i \partial x_j} + \sum_{i=1}^n b_i(x,t) \frac{\partial u}{\partial x_i} \right] + c(x,t)u - \frac{\partial u}{\partial t} = f \quad (1)$$

for an unknown function u of $(n+1)$ independent variables $(x,t) = (x_1, \dots, x_n, t)$, where $a_{ij} = a_{ji}$. This equation is said to be **parabolic** (or of **parabolic type**) if and only if the quadratic form $\sum a_{ij} \xi_i \xi_j$ in ξ is positive definite at each point (x,t) of the region under consideration. x and t are sometimes called the variables of space and of time, respectively.

The most widely studied of the parabolic equations is the **equation of heat conduction** (or the **heat equation**):

$$L[u] \equiv \Delta u - \frac{\partial u}{\partial t} = 0, \quad (2)$$

where $\Delta = \sum_{i=1}^n \partial^2 / \partial x_i^2$ is the Laplacian taken over the space variables.

B. The Equation of Heat Conduction

The 1-dimensional case of the heat equation is

$$L[u] \equiv \frac{\partial^2 u}{\partial x^2} - \frac{\partial u}{\partial t} = 0 \quad (3)$$

for the temperature $u(x,t)$ in a rod, considered as a function of the distance x measured along the rod and the time t . Equation (3) was one of the first treated in the theory of partial differential equations. Consider a finite rod with constant temperature 0 at its ends $x=a$ and $x=b$. Thermodynamics suggests that the initial temperature $\varphi(x)$ ($\varphi(a) = \varphi(b) = 0$) prescribed at $t=0$ is sufficient to determine the distribution of heat $u(x,t)$ in the rod at all later times $t > 0$. On such physical grounds, we can expect that a solution to the following problem exists: Find a continuous function $u(x,t)$ that satisfies equation (3) for $a \leq x \leq b$, $t > 0$, and the boundary conditions

$$u(a,t) = u(b,t) = 0, \quad \lim_{t \downarrow 0} u(x,t) = \varphi(x), \quad a \leq x \leq b. \quad (4)$$

According to J. Fourier the answer to this problem is expressed in a series $\sum_{n=1}^{\infty} c_n u_n$ constructed by superposition of the particular

solutions $u_n = \sin \sqrt{\lambda_n} (x-a) \exp(-\lambda_n t)$. Here the λ_n are the roots of $\sin \sqrt{\lambda_n} (b-a) = 0$, and the c_n are chosen so that $\sum_{n=1}^{\infty} c_n u_n(x,0) = \varphi(x)$. In fact, if $\varphi(x)$ is continuously differentiable, then $\sum_{n=1}^{\infty} c_n u_n(x,t)$ is the required solution. Thus we are led to the problem of expanding a given function $\varphi(x)$ in a Fourier series.

The temperature distribution in an infinite rod is given by a continuous function $u(x,t)$ that satisfies equation (3) for $t > 0$ and that, for $t=0$, takes values given by $\varphi(x)$, where

$$\lim_{t \downarrow 0} u(x,t) = \varphi(x). \quad (5)$$

If $\varphi(x)$ is bounded, then it can also be represented by superposition of particular solutions $e^{-(a-x)^2/4t}$ of (3) as

$$u(x,t) = \begin{cases} \frac{1}{2\sqrt{\pi t}} \int_{-\infty}^{\infty} \varphi(\alpha) e^{-(a-x)^2/4t} d\alpha, & t > 0, \\ \varphi(x), & t = 0. \end{cases} \quad (6)$$

Partial differential equations of parabolic type are important because of their connection with various phenomena in the physical world; they include not only equations that govern the flow of heat but also those that describe diffusion processes (\rightarrow 115 Diffusion Processes).

C. Partial Differential Equations of Parabolic Type in Two Variables

We are concerned mainly with the partial differential equation of parabolic type in two variables:

$$a(x,t) \frac{\partial^2 u}{\partial x^2} + 2b(x,t) \frac{\partial^2 u}{\partial x \partial t} + c(x,t) \frac{\partial^2 u}{\partial t^2} + d(x,t) \frac{\partial u}{\partial x} + e(x,t) \frac{\partial u}{\partial t} + f(x,t)u = g, \quad (7)$$

with $ac = b^2$. In the region where $|a| + |c| > 0$, equation (7) can be reduced to the form

$$\frac{\partial^2 \omega}{\partial \xi^2} + d'(\xi, \tau) \frac{\partial \omega}{\partial \xi} + e'(\xi, \tau) \frac{\partial \omega}{\partial \tau} + f'(\xi, \tau) \omega = g' \quad (7')$$

by an appropriate change of variables $\xi = U(x,t)$, $\tau = V(x,t)$. If $e' < 0$ in this region, we can assume without loss of generality that our equation takes the canonical form

$$a(x,t) \frac{\partial^2 u}{\partial x^2} + b(x,t) \frac{\partial u}{\partial x} + c(x,t)u - \frac{\partial u}{\partial t} = g, \quad (8)$$

with $a > 0$, from the outset. It has the single family of characteristics

$$t = \text{constant}. \quad (9)$$

There are four typical problems to be posed with regard to equation (8).

The first consists of determining, in some neighborhood of a given curve C nowhere tangent to a characteristic, a solution u that possesses prescribed values of u and $\partial u/\partial n$, or of a linear combination of u and $\partial u/\partial n$, along C . For instance, the problem of finding a solution $u(x, t)$ such that $u(x_0, t) = g(t)$ and $u_x(x_0, t) = h(t)$ for given functions $g(t)$ and $h(t)$ is a problem of this type. Consider the equation

$$\frac{\partial^2 u}{\partial x^2} - \frac{\partial u}{\partial t} = 0 \tag{10}$$

in the region $a < t < b, x_0 \leq x$. According to E. Holmgren, a solution $u(x, t)$ satisfying the conditions

$$\lim_{x \downarrow x_0} u(x, t) = g(t), \quad \lim_{x \downarrow x_0} u_x(x, t) = h(t), \tag{11}$$

where $g'(t)$ is bounded and continuous, exists if and only if

$$h(t) + \frac{1}{\sqrt{\pi}} \int_a^t \frac{g'(\tau)}{\sqrt{t-\tau}} d\tau = k(t) \tag{12}$$

is of class C^∞ and satisfies

$$|k^{(n)}(t)| \leq M(n!)^2/r^n \tag{13}$$

for positive constants M and r .

In the second type of problem we are required to find in a region of the form

$$\varphi_1(t) \leq x \leq \varphi_2(t), \quad t_1 < t < t_2, \tag{14}$$

a solution of (8) that takes prescribed values on part of the boundary of that region. Here we impose the hypothesis on the curves $x = \varphi_1(t)$ and $x = \varphi_2(t)$ that they are nowhere tangent to a characteristic (9). M. Gevrey [3] showed that if such a solution does exist, the functions $\varphi_1(t)$ and $\varphi_2(t)$ must satisfy the Hölder condition with exponent $\alpha > 1/2$:

$$|\varphi_i(t+h) - \varphi_i(t)| \leq c|h|^\alpha, \quad c = \text{constant}, \tag{15}$$

for sufficiently small h . The problem of heat conduction mentioned in Section B corresponds to the particular case $\varphi_1(t) = \text{constant}, \varphi_2(t) = \text{constant}$, for which condition (15) is automatically fulfilled.

The third type of problem is to find in a region of the form

$$a \leq x \leq b, \quad t > 0, \tag{14'}$$

a solution of (8) that satisfies the conditions

$$\lim_{t \downarrow 0} u(x, t) = \varphi(x);$$

$$\frac{\partial u}{\partial x} - hu = 0 \quad \text{for } x = a, \quad h = \text{constant} > 0;$$

$$\frac{\partial u}{\partial x} + Hu = 0 \quad \text{for } x = b, \quad H = \text{constant} > 0. \tag{16}$$

This problem, posed for equation (10), is also a mathematical formulation of the problem of heat conduction in a rod [4]. If $\varphi(x)$ is of class C^1 , then the solution to this problem can be expanded as

$$u(x, t) = \sum_{n=1}^{\infty} c_n e^{-\lambda_n t} \varphi_n(x),$$

$$c_n = \int_a^b \varphi(x) \varphi_n(x) dx, \tag{17}$$

where $\varphi_n(x)$ is a normalized function ($\int_a^b \varphi_n^2(x) dx = 1$) that satisfies the boundary conditions

$$\varphi_n'(a) - h\varphi_n(a) = 0, \quad \varphi_n'(b) + H\varphi_n(b) = 0 \tag{18}$$

and the equation

$$\frac{d^2 \varphi_n(x)}{dx^2} = -\lambda_n \varphi_n(x). \tag{19}$$

The fourth type of problem is to find a function $u(x, t)$ that satisfies (8) for $t > 0$ and the initial condition $\lim_{t \downarrow 0} u(x, t) = \varphi(x)$. It corresponds to the problem of heat conduction in an infinite rod.

D. Green's Formula

The †adjoint of the differential operator $L[u]$ in (3) is given by

$$M[v] \equiv \frac{\partial^2 v}{\partial x^2} + \frac{\partial v}{\partial t}. \tag{20}$$

Integration by parts yields the identity

$$\iint_G (\psi L[\varphi] - \varphi M[\psi]) dx dt$$

$$= \int_C \varphi \psi dx + \int_C \left(\psi \frac{\partial \varphi}{\partial x} - \varphi \frac{\partial \psi}{\partial x} \right) dt, \tag{21}$$

where G is the region bounded by the closed curve C , and the line integral on the right is evaluated in the counterclockwise direction over C . We call (21) **Green's formula** for the partial differential equation of parabolic type (3). As in the case of partial differential equations of elliptic type (\rightarrow 323 Partial Differential Equations of Elliptic Type), this formula is used to establish the uniqueness of the solution of (3) and to derive an integral representation for it.

For example, the uniqueness of the solution is established in the following way: Let the curve \widehat{AD} and \widehat{BE} in Fig. 1 be such that no characteristic meets either of them in more than one point. If $u(x, t)$ is continuous in the closed region $(ABED)$, vanishes on $\widehat{AD}, \widehat{BE}$, and the segment \widehat{AB} , and satisfies equation (3) in $(ABED)$ except on \widehat{AB} , then it vanishes identically. Green's formula (21), applied to the region $G = (ABQP)$ and the functions $\psi \equiv 1$,

$\varphi \equiv u^2$, yields

$$2 \iint_G \left(\frac{\partial u}{\partial x} \right)^2 dx dt + \int_{P\bar{Q}} u^2 dx = 0.$$

In a similar way, by extending Green's formula suitably, we are able to prove uniqueness theorems for the four problems stated in Section C for more general linear parabolic equations.

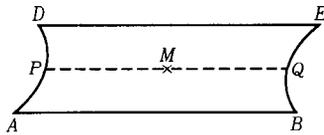

Fig. 1

To obtain a representation for solutions we proceed as follows: Let $u(x, t)$ be a solution of (3) and Let

$$U(\alpha, \beta, x, t) = \frac{1}{\sqrt{4\pi(\beta-t)}} e^{-(\alpha-x)^2/4(\beta-t)} \quad (22)$$

be a particular solution. Applying Green's formula to the region $(PABQMP)$ and the functions $\varphi = u(x, t)$, $\psi = U(x_0, t_0 + h, x, t)$, where h is a positive number and M is a point with coordinates (x_0, t_0) , we obtain

$$\begin{aligned} & \int_{P\bar{Q}} u(x, t_0) e^{-(x_0-x)^2/4h} \frac{dx}{\sqrt{4\pi h}} \\ &= \int_{PAB\bar{Q}} u(x, t) U(x_0, t_0 + h, x, t) dx \\ &+ \left(U \frac{\partial u}{\partial x} - u \frac{\partial U}{\partial x} \right) dt. \end{aligned}$$

Since the integral in the left-hand side of this equality approaches $u(x_0, t_0)$ as $h \downarrow 0$, we can establish the basic representation formula

$$\begin{aligned} u(x_0, t_0) &= \int_{PAB\bar{Q}} u(x, t) U(x_0, t_0, x, t) dx \\ &+ \left(U \frac{\partial u}{\partial x} - u \frac{\partial U}{\partial x} \right) dt \end{aligned} \quad (23)$$

for solutions u of (3). Formula (23) shows that $u(x_0, t_0)$ is determined in terms of the particular solution (22) if we know the values of u and $\partial u/\partial x$ on the part $PAB\bar{Q}$ of the boundary of the region $(ABED)$. The function (22) is called the **fundamental solution** of (3) because it plays the same role as the fundamental solution $\log r$ ($r = ((\alpha - x)^2 + (\beta - y)^2)^{1/2}$) of Laplace's equation $\partial^2 u/\partial x^2 + \partial^2 u/\partial y^2 = 0$.

Similarly, the following function E (called the **Gauss kernel**) is a fundamental solution of equation (2):

$$E(\alpha, \beta, x, t) = (4\pi(\beta-t))^{-n/2} \exp \left\{ -\frac{|\alpha-x|^2}{4(\beta-t)} \right\}, \quad (24)$$

where $(x, \alpha) \in \mathbb{R}^n \times \mathbb{R}^n$ and $t < \beta$. For equation (3), the following **maximum principle** holds: In the region $(ABED)$ of Fig. 1, suppose that $L[u] \geq 0$ and that u takes its maximum value K at an interior point M . Then u is identically equal to K on the segment $\bar{Q\bar{P}}$ and in the region $(ABQP)$. More generally, various versions of the maximum principle are known for equation (1) [5].

E. The Laplace Transform Method

Let $u(x, t)$ be a solution of (3) for $t > 0$ and

$$v(x, \lambda) = \int_0^\infty e^{-\lambda t} u(x, t) dt, \quad \lambda > 0, \quad (25)$$

be its \dagger Laplace transform with respect to t . Utilizing integration by parts, we have

$$\begin{aligned} \int_0^\infty e^{-\lambda t} u_t(x, t) dt &= [e^{-\lambda t} u(x, t)]_{t=0}^{\infty} \\ &+ \lambda \int_0^\infty e^{-\lambda t} u(x, t) dt \\ &= -\varphi(x) + \lambda v(x, \lambda), \end{aligned} \quad (26)$$

provided that $\lim_{t \rightarrow \infty} e^{-\lambda t} u(x, t) = 0$ and $\lim_{t \downarrow 0} u(x, t) = \varphi(x)$. We find in view of (3):

$$\frac{\partial^2 v}{\partial x^2} = \lambda v(x, \lambda) - \varphi(x). \quad (26')$$

Once the solution of (26') has been found, the desired solution of (3) can be derived by inverting the Laplace transform (25). This idea can also be applied to the solution of parabolic equations with constant coefficients in $(n+1)$ variables, such as (1).

F. General Second-Order Equations of Parabolic Type

Consider the equation (1) with $f=0$, which can be written as

$$\frac{\partial u}{\partial t} = A(t)u, \quad (27)$$

where $A(t)$ is a second-order \dagger elliptic operator with parameter t . Let D be a region (bounded or unbounded) of points x whose boundary is a smooth hypersurface S . We pose the following initial boundary value problem for (27): Find a function $u(x, t)$ that satisfies in $D \times (0, \infty)$ equation (27) together with the conditions

$$\lim_{t \downarrow 0} u(x, t) = \varphi(x), \quad x \in D,$$

$$\partial u(x, t)/\partial n + h(x, t)u(x, t) = f(x, t), \quad x \in S, \quad (16')$$

where $\partial/\partial n$ is the directional derivative in the

outward conormal direction at (x, t) ($x \in S$), and $h(x, t) \geq 0$.

The Laplace transform is not suitable for solving problems (27) and (16'). Instead, the theory of 1-parameter semigroups of linear operators (\rightarrow 378 Semigroups of Operators and Evolution Equations) can be applied to establish similar fundamental results. Let m be a large positive integer. For $t > 0$, put $t_k = k\delta$ for $k=0, 1, \dots, m-1$ with $\delta = t/m$. By the Laplace transform method as described above, we can associate with ψ a unique solution v of $A(t_k)v = \lambda v - \psi$ with $\lambda = 1/\delta$. We put $R_k\psi = \lambda v$. By iterating this procedure m times, we have a function $u_m(x, t) = R_{m-1}R_{m-2} \dots R_0\varphi$ starting from the initial value φ at $t=0$. Then we obtain a solution $u(x, t)$ of (27) and (16') as the limit of $u_m(x, t)$ as $m \rightarrow \infty$. The following results are known [6, 7]: (i) There exists a $u = U(\xi, \tau, x, t)$ ($x, \xi \in D, t > \tau \geq 0$) that, as a function of x and t , satisfies equation (27) and the homogeneous boundary conditions (16') with $\varphi=0, f=0$. (ii) The function $u(x, t)$ defined by

$$u(x, t) = \int_D \varphi(\xi)U(\xi, 0, x, t)d\xi + \int_0^t d\tau \int_S f(\xi, \tau) \left(U(\xi, \tau, x, t) - \frac{\partial U(\xi, \tau, x, t)}{\partial n_\xi} \right) dS_\xi \quad (23')$$

is a solution of (27) and satisfies (16'). Thus $U(\xi, \tau, x, t)$ is a generalization of the function (24), called the **fundamental solution** of the linear parabolic equation (27) with boundary conditions (16'). Besides the properties (i) and (ii), the fundamental solution satisfies $U(\xi, \tau, x, t) \geq 0, \int_D U(\xi, \tau, z, w)U(z, w, x, t) dz = U(\xi, \tau, x, t)$ ($\tau < w < t$), and further $\int_D U(\xi, \tau, x, t) dx = 1$ under some additional assumptions. Therefore this theory is of considerable significance from the point of view of the theory of probability (\rightarrow 115 Diffusion Processes).

It can be shown that a weak solution of the parabolic equation (27) is a genuine solution. That is, if $u(x, t)$ is locally summable and

$$\int_0^\infty \int_D u(x, t) \left(\frac{\partial \varphi(x, t)}{\partial t} + A(t)^* \varphi(x, t) \right) dx dt = 0$$

for any function $\varphi(x, t)$ of class C^2 in $D \times (0, \infty)$ and vanishing outside a compact subset of D ($A(t)^*$ is the adjoint of the partial differential operator $A(t)$ and $dx = dx_1 \dots dx_{n-1}$), then $u(x, t)$ satisfies (27) in $D \times (0, \infty)$ in the usual sense. In particular, when the coefficients of $A(t)$ are infinitely differentiable, any solution $u(x, t)$ of (27) in the distribution sense is a genuine solution (\rightarrow 125 Distributions and Hyperfunctions).

If the function h in the boundary conditions (16') and the coefficients of A are independent of t , then the fundamental solution $U(\xi, \tau, x, t)$ depends only on ξ, x , and $t - \tau$ and is written as $U(\xi, x; t - \tau)$ ($t > \tau$). Furthermore, if A is self-adjoint, then there exist a sequence of eigenfunctions $\{\psi_p(x; \lambda) | p=1, 2, \dots\}$ ($A\psi_p + \lambda\psi_p = 0$) and a sequence $\{\rho_p(\lambda)\}$ of measures on the real line for which the following hold: (1) The fundamental solution $U(\xi, x; t)$ is expressed in the form

$$U(\xi, x; t) = \sum_{p=1}^\infty \int_{-\infty}^\infty e^{-\lambda t} \psi_p(\xi; \lambda) \psi_p(x; \lambda) d\rho_p(\lambda).$$

(2) The solution $u(x, t)$ of (27) satisfying (16') with $f(x, t) \equiv 0$ is expanded as

$$u(x, t) = \sum_{p=1}^\infty \int_{-\infty}^\infty e^{-\lambda t} \psi_p(x; \lambda) \varphi_p(\lambda) d\rho_p(\lambda),$$

where

$$\varphi_p(\lambda) = \int_D \psi_p(x; \lambda) \varphi(x) dx$$

($\varphi(x)$ is the function given in (16')).

G. Nash's Results

Let us consider a parabolic equation

$$\frac{\partial u}{\partial t} = \sum_{i,j=1}^n \frac{\partial}{\partial x_j} \left\{ a_{ij}(x, t) \frac{\partial u}{\partial x_i} \right\}, \quad (28)$$

where $a_{ij} = a_{ji}$ are real-valued functions of class C^∞ and equal to constants outside a fixed compact set of \mathbf{R}^n for all $t \geq t_0$ (this regularity assumption can be relaxed). Suppose that there exists a constant $\lambda \geq 1$ such that $\lambda^{-1}|\xi|^2 \leq \sum a_{ij}(x, t) \xi_i \xi_j \leq \lambda|\xi|^2$ for all $(t, x, \xi) \in (t_0, \infty) \times \mathbf{R}^n \times \mathbf{R}^n$. Then, for any bounded solution $u(x, t)$ of (28) in $(t_0, \infty) \times \mathbf{R}^n$ and for any (x, y, t, s) such that $x \in \mathbf{R}^n, y \in \mathbf{R}^n$, and $t_0 < t \leq s$, the inequality

$$|u(x, t) - u(y, s)| \leq AB \left\{ \left(\frac{x-y}{\sqrt{t-t_0}} \right)^\alpha + \left(\frac{s-t}{t-t_0} \right)^\beta \right\}, \quad (29)$$

holds, where $B = \sup\{|u(x, t)| | t \geq t_0, x \in \mathbf{R}^n\}$ and $\beta = \alpha/(2\alpha + 2)$. In this inequality, the constants α and A are positive, depending on (n, λ) but independent of the particular choice of $(a_{ij}), t_0$ and of u [9].

As a corollary to this theorem, J. Nash proved that, if the a_{ij} do not contain t and if $v(x)$ is a bounded solution in \mathbf{R}^n of the elliptic equation obtained by replacing $\partial u/\partial t$ by 0 in (28), the inequality

$$|v(x) - v(y)| \leq A'B'|x-y|^\sigma \quad (30)$$

holds for any $(x, y) \in \mathbf{R}^n \times \mathbf{R}^n$, where $\sigma = \alpha/(\alpha + 1)$ with α in (29) and $B' = \sup|v(x)|$. The constant

A' depends only on (n, λ) (\rightarrow 323 Partial Differential Equations of Elliptic Type L).

H. Partial Differential Equations of p -Parabolic Type

Let p and m be given positive integers. Let us consider an equation for an unknown function u of $(n+1)$ independent variables (x, t) of the type

$$\frac{\partial^m u}{\partial t^m} + \sum_{\alpha, j} a_{\alpha, j}(x, t) \frac{\partial^\alpha}{\partial x^\alpha} \frac{\partial^j u}{\partial t^j} = f, \quad (31)$$

where $\alpha = (\alpha_1, \dots, \alpha_n)$ and $\partial^\alpha / \partial x^\alpha = (\partial / \partial x_1)^{\alpha_1} \dots (\partial / \partial x_n)^{\alpha_n}$. We write also $|\alpha| = \alpha_1 + \dots + \alpha_n$. In (31), $\sum_{\alpha, j}$ is the summation taken over the (α, j) such that $pj + |\alpha| \leq pm$ and $0 \leq j < m$. Let us denote by $\{\lambda_k(x, t, \xi)\}_{k=1}^m$ the roots λ of the equation

$$\lambda^m + \sum_{\alpha, j} a_{\alpha, j}(x, t) (i\xi)^\alpha \lambda^j = 0, \quad (32)$$

where $\sum_{\alpha, j}$ is the summation over the (α, j) 's such that $pj + |\alpha| = pm$ and that $0 \leq j < m$. We say that the equation (31) is p -parabolic (or of p -parabolic type) in the sense of I. G. Petrovskii if and only if there exists a positive number δ such that

$$\operatorname{Re} \lambda_k(x, t, \xi) \leq -\delta |\xi|^p, \quad 1 \leq k \leq m, \quad (33)$$

for any (x, t) in the region under consideration and for any $\xi \in \mathbf{R}^n$. The integer p is then seen to be even. Equation (27) is p -parabolic if $-A(t)$ is strongly elliptic of order p . The heat equation (2) is 2-parabolic in this sense. Similarly, we can define the p -parabolic systems of equations [10].

p -parabolic equations are known to be †hypoelliptic if the coefficients are of class C^∞ [11]. S. D. Eidel'man obtained precise estimates of the fundamental solutions and of their derivatives for p -parabolic equations [10]. The mixed initial boundary value problems are investigated in detail also by Eidel'man [10] and by R. Arima (*J. Math. Kyoto Univ.*, 4 (1964)).

328 (V.6) Partitions of Numbers

A **partition** of a positive integer n is an expression of n as the sum of positive integers. The number of partitions of n , where the order of the summands is ignored and repetition is permitted, is denoted by $p(n)$ and is called the **number of partitions of n** . For example $p(5) = 7$ since $5 = 4 + 1 = 3 + 2 = 3 + 1 + 1 = 2 + 2 + 1 = 2 + 1 + 1 + 1 = 1 + 1 + 1 + 1 + 1$. Therefore, $p(n)$ equals the number of †conjugate classes of the †symmetric group of order n and is closely related to the †representation theory of this group.

The †generating function of $p(n)$ is

$$f(x) = 1 + \sum_{n=1}^{\infty} p(n)x^n = \left(\prod_{n=1}^{\infty} (1 - x^n) \right)^{-1}.$$

The unit circle $|x| = 1$ is the †natural boundary of $f(x)$, which is holomorphic in $|x| < 1$. The **Dedekind eta function**, which is closely related to $f(x)$, is defined by the following formula for the complex variable τ taking values in the upper half-plane:

$$\eta(\tau) = \exp(\pi i \tau / 12) \prod_{n=1}^{\infty} (1 - \exp(2\pi i n \tau)).$$

Hence $\eta(\tau + 1) = \exp(\pi i / 12) \eta(\tau)$. L. Euler (1748) obtained the following formula (called the **pentagonal number theorem** because $n(3n - 1)/2$

is a †pentagonal number):

$$\prod_{n=1}^{\infty} (1-x^n) = 1 + \sum_{n=1}^{\infty} (-1)^n (x^{n(3n-1)/2} + x^{n(3n+1)/2}).$$

This follows easily from the **Jacobi-Biehler equality**

$$\prod_{n=1}^{\infty} \{(1-q^{2n})(1+q^{2n-1}z)(1+q^{2n-1}z^{-1})\} = 1 + \sum_{n=1}^{\infty} q^{n^2}(z^n + z^{-n}) \quad (|q| < 1, z \neq 0).$$

By using the †transformation formula for ϑ -functions, we can infer from the pentagonal number theorem that $\eta(-1/\tau) = \sqrt{\tau/i} \eta(\tau)$. Hence, if a, b, c, d are integers satisfying $ad - bc = 1$ and $c > 0$, then

$$\eta\left(\frac{a\tau + b}{c\tau + d}\right) = \varepsilon \sqrt{\frac{c\tau + d}{i}} \eta(\tau),$$

where ε is a 24th root of unity. It is known that $\eta(\tau)$ is a †cusp form of weight $-1/2$ with respect to the full †modular group $\Gamma(1)$ [9, 11]. C. L. Siegel (1955) gave a simple proof of the formula $\eta(-1/\tau) = \sqrt{2/i} \eta(\tau)$. Later S. Iseki (1957) gave another proof by using a new method, known as the $\alpha - \beta$ formula [12].

The size of $p(n)$ increases rapidly with n ; for instance $p(10) = 42$ and $p(100) = 190,569,292$. By making use of a remarkable identity, G. H. Hardy and S. Ramanujan (1918) proved the following inequalities, where A and B are suitable constants:

$$(A/n)e^{2\sqrt{n}} < p(n) < (B/n)e^{2\sqrt{2}\sqrt{n}}.$$

Subsequently they obtained

$$p(n) \sim (1/4\sqrt{3}n) \exp(\pi\sqrt{2n/3}).$$

After, P. Erdős (1942) and D. J. Newman (1951), A. G. Postnikov [8] succeeded in proving

$$p(n) = \frac{\exp(\pi\sqrt{2n/3})}{4\sqrt{3}n} \left(1 + O\left(\frac{\log n}{n^{1/4}}\right)\right)$$

by means of an elementary function-theoretic method. Multiplying both sides of Euler's formula by the generating function of $p(n)$ and comparing the coefficients, we obtain

$$\sum_{0 \leq \omega_k \leq n} (-1)^{k-1} p(n - \omega_k) = 0,$$

where $\omega_k = k(3k-1)/2$ ($k=0, \pm 1, \pm 2, \dots$) is a pentagonal number. From this formula we can calculate $p(n)$ successively; in fact P. A. MacMahon obtained in this way the values of $p(n)$ for n up to 200.

Hardy and Ramanujan proved the following **transformation formula** for the generating

function $f(x)$ of $p(n)$:

$$f\left(\exp\left(\frac{2\pi ih}{k} - \frac{2\pi z}{k}\right)\right) = W_{h,k} \sqrt{z} \exp\left(\frac{\pi}{12kz} - \frac{\pi z}{12k}\right) \times f\left(\exp\left(\frac{2\pi ih'}{k} - \frac{2\pi}{kz}\right)\right),$$

$$(h, k) = 1, \quad hh' \equiv -1 \pmod{k},$$

where $W_{h,k}$ is defined by

$$W_{h,k} = \exp(\pi i s(h, k))$$

and the value of $s(h, k)$ was given by Rademacher in the form

$$s(h, k) = \sum_{m=1}^{k-1} \frac{m}{k} \left(\left(\frac{hm}{k} \right) \right).$$

Here the symbol $((t))$ in the sum denotes the function that is 0 for integral t and $t - [t] - 1/2$ otherwise ($[\]$ is the †Gauss symbol). With regard to the **Dedekind sum** $s(h, k)$, we have the **reciprocity law for Dedekind sums**:

$$s(h, k) + s(k, h) = -\frac{1}{4} + \frac{1}{12} \left(\frac{h}{k} + \frac{k}{h} + \frac{1}{hk} \right).$$

If we make substitutions $a = h', b = (hh' + 1)/k, c = k,$ and $d = -h$ in the Hardy-Ramanujan transformation formula, then the ε appearing in the transformation formula of $\eta(\tau)$ is seen to be equal to $\exp(-\pi i s(c, d) + \pi i (a + d)/12c)$. A direct proof of the transformation formula and the reciprocity law was given by K. Iseki (1952).

According to Cauchy's integral formula, $p(n)$ can be represented as an integral:

$$\frac{1}{2\pi i} \int_{\Gamma} \frac{f(x)}{x^{n+1}} dx,$$

where the contour Γ is taken inside the unit circle around the origin. The generating function $f(x)$ varies greatly: namely, letting $r \rightarrow 1 - 0$ in $x = r \exp(2\pi ip/q)$, where p and q are fixed integers, it follows from the transformation formula that $f(x) \sim \exp(\pi^2/6q^2(1-r))$. Nevertheless, we can deal with the integral by the †circle method, introduced by Hardy and Ramanujan, which threw light on recent additive number theory. Hardy and Ramanujan thus obtained

$$p(n) = \frac{1}{2\pi\sqrt{2}} \frac{d}{dn} \left(\frac{\exp(C\lambda_n)}{\lambda_n} \right) + O(\exp(D\sqrt{n})),$$

where

$$\lambda_n = \sqrt{n - 1/24}, \quad C = \pi\sqrt{2/3}, \quad D > C/2.$$

The theory was improved by Rademacher (1937, 1943), who expanded $p(n)$ into the

series

$$p(n) = \frac{1}{\pi\sqrt{2}} \sum_{k=1}^{\infty} A_k(n) k^{1/2} \frac{d}{dn} \left(\frac{\sinh(C\lambda_n/k)}{\lambda_n} \right),$$

where

$$A_k(n) = \sum_{h(\bmod k), (h, k)=1} W_{h, k} \exp(-2\pi i h n / k).$$

Rademacher (1954) proved further that

$$p(n) = 2\pi \left(\frac{\pi}{12} \right)^{3/2} \times \sum_{k=1}^{\infty} A_k(n) k^{-5/2} L_{3/2} \left(\left(\frac{\pi}{12k} \right)^2 (24n-1) \right),$$

where

$$L_\nu(z) = \sum_{n=0}^{\infty} \frac{z^n}{n! \Gamma(\nu + n + 1)}.$$

Rademacher (1943) had developed an ingenious proof by taking "Ford's circle" as the contour Γ .

Ramanujan observed that $p(5m+4) \equiv 0 \pmod{5}$, $p(7m+5) \equiv 0 \pmod{7}$, and $p(11m+6) \equiv 0 \pmod{11}$. Rademacher (1942) and Newman studied these cases by using $\eta(\tau)$. More generally, A. O. L. Atkin proved that if $24n \equiv 1 \pmod{5^a 7^b 11^c}$ then $p(n) \equiv 0 \pmod{5^a 7^{1+(b/2)} 11^c}$ (*Glasgow Math. J.*, 8 (1967)). At present, this is the best result.

Let $n = n_1 + n_2 + \dots + n_s$ be a partition of n . Many problems arise when we put additional conditions on the n_j . For instance, we may require that the n_j satisfy certain congruence relations (L. K. Hua (1942), S. Iseki (1959)) or are powers of integers (E. M. J. Wright (1934), L. Schoenfeld (1944), S. Iseki (1959)) or are powers of primes (T. Mitsui (1957)). The partition problem can also be extended to the case of an algebraic number field of finite degree (Rademacher, G. Meinardus (1953), Mitsui (1978)).

329 (XXI.38) Pascal, Blaise

Blaise Pascal (June 19, 1623–August 19, 1662) was born in Clermont-Ferrand in southern France. He lost his mother when still an infant and was brought up by his father, Etienne Pascal (discoverer of the curve called Pascal's limaçon). As a youth, he demonstrated a remarkable ability for mathematics. In 1640, under the influence of Desargues, he discovered †Pascal's theorem on conic sections, and in 1642 invented an adding machine. After hearing of Toricelli's experiments in 1646, he became interested in the theory of fluids and on his own began to conduct experiments; this research put to rest the prevailing opinion that nature abhors a vacuum and that, therefore, a vacuum cannot exist. Pascal formulated the principle stating that pressure, when applied at any point within a contained liquid, is transmitted throughout the fluid. By means of this principle, he explained various phenomena concerning fluids such as the atmosphere and laid the foundations for hydrostatics.

Between 1652 and 1654, Pascal was preoccupied with social affairs, but subsequently he began to devote himself to religion. He entered the Abbey Port-Royal of the Jansenist sect, where he remained until his death. Immediately before his entry, however, he and Fermat exchanged correspondence about games of chance, and these letters proved to be the beginning of the theory of †probability. Concerning games of chance, Pascal had conducted research on †Pascal's triangle, and in this study he formulated and used †mathemat-

ical induction. He also indicated a way to obtain the sum of the m th powers of the consecutive terms of an arithmetic progression, and with an intuitive idea of limits obtained the formula $\int_0^a x^m dx = a^{m+1}/(m+1)$. While in Port-Royal, he published *Lettres provinciales* (1657), in which he carried on a dispute with the Jesuits. His book *Pensées* shows his deep involvement with religion; however, he did not abandon mathematics. In 1658, he determined the area enclosed by a cycloid and its base, the barycenter and area of the figure enclosed by a cycloid and straight lines parallel to its base, and the volume of the figure obtained by rotating it around these lines. The study of the methods used by Pascal to obtain these results, which were forerunners of differential and integral calculus, led Leibniz to discover the fundamental theorem of calculus. Pascal also formulated clear ideas about axioms.

**330 (II.8)
Permutations and Combinations**

Let there be given a set Ω of n elements. If we choose k distinct elements of Ω and arrange them in a row, we have a k -array or k -permutation of elements of Ω . The number of such arrays is $(n)_k = n(n-1) \dots (n-k+1)$. The polynomial $(x)_k = x(x-1) \dots (x-k+1)$ in x of degree k is called the **Jordan factorial** of degree k . In particular, $(n)_n = n!$, n **factorial**, is the number of permutations of Ω . A subset of Ω is called a k -subset if it contains exactly k elements. The number of k -subsets (or k -combinations) of Ω is $\binom{n}{k} = (n)_k/k!$. The **binomial coefficients** $\binom{x}{n}$ are defined by the generating function $(1+z)^x = \sum_{n=0}^{\infty} \binom{x}{n} z^n$. For any complex number x , the series is conver-

**330 Ref.
Permutations and Combinations**

gent for $|z| < 1$, and it is verified that $\binom{x}{n} = (x)_n/n!$ in terms of the Jordan factorial $(x)_n$. The same results hold in a \dagger complete field with \dagger valuation, in particular in a $\dagger p$ -adic number field. In any case, we have the recursive relation

$$\binom{x}{n} = \binom{x-1}{n} + \binom{x-1}{n-1} \quad (n \geq 1),$$

$$\binom{x}{0} = 1,$$

and in general

$$\sum_{k=0}^n \binom{x}{k} \binom{y}{n-k} = \binom{x+y}{n},$$

which leads to many identities involving binomial coefficients. The recursive relation allows us to compute the values of $\binom{n}{k}$ easily for small integers n, k , as was noticed by Pascal. The arrangement of these values in a triangular form:

		1			
	1	1			
	1	2	1		
	1	3	3	1	
	1	4	6	4	1

is called **Pascal's triangle**. For integral values x , $(1+z)^x$ are polynomials, and we have $(a+b)^n = \sum_{k=0}^n \binom{n}{k} a^{n-k} b^k$ (**binomial theorem**). As a generalization, we have

$$(a_1 + \dots + a_m)^n = \sum \frac{n!}{p_1! \dots p_m!} a_1^{p_1} \dots a_m^{p_m}$$

(**multinomial theorem**), where the sum is extended over all nonnegative p_i with $\sum p_i = n$.

The number of ways of choosing k elements, allowing repetition, from a set of n elements is

$$(-1)^k \binom{-n}{k} = \binom{n+k-1}{k}.$$

This is also the number of nonnegative integral solutions of $\sum_{i=1}^n x_i = k$. As an example of binomial coefficients with noninteger arguments, we have

$$\binom{-1/2}{n} = (-1)^n 2^{-2n} \binom{2n}{n}.$$

331 (XII.13) Perturbation of Linear Operators

A. General Remarks

Historically, the perturbation method was developed as an approximation device in classical and quantum mechanics. In the perturbation theory of eigenvalues and eigenfunctions, created by L. Rayleigh and E. Schrödinger, the main concern was to find solutions as power series in a parameter κ that could be regarded as small. In the perturbation theory for linear operators, however, we are concerned more generally with the behavior of spectral properties of linear operators when the operators undergo small change. The foundation of the mathematical theory, including a complete convergence proof of perturbation series, was laid down by F. Rellich [1] and T. Kato [2, 3]. Another major topic in the perturbation theory for linear operators is the perturbation of continuous spectra, which was initiated by K. O. Friedrichs (*Math. Ann.*, 115 (1938); [4]). It is closely related to scattering theory and is discussed more fully in 375 Scattering Theory. A standard reference in this field is [5] (also → [6, 7]). Most of the material presented in this article is taken from [5].

For problems in Hilbert spaces there are two general frameworks in which to formulate perturbation situations: the operator formulation and the form formulation. In the former we deal with a family of operators $T(\kappa)$ directly, while in the latter, we deal with associated semibounded Hermitian (or, more generally, sectorial) forms $t(\kappa)$. The latter is applicable only when there is semiboundedness (or a sectorial property) inherent in the problem, but is usually more general than the former in such problems, since the latter (resp. the former) requires roughly the constancy of the domain of the "square root" of $T(\kappa)$ (resp. the domain of $T(\kappa)$). In this article we discuss problems in the operator formulation. For the form formulation → [5] and [7].

In this article X, Y, \dots , are complex Banach spaces and T, A, \dots are linear operators unless other specifications are made. The following notations defined in 251 Linear Operators are used without further explanation: $D(T), R(T), \mathbf{B}(X, Y), \mathbf{B}(X), \Gamma(T)$ (the graph of T), $\sigma(T)$ (the spectrum of T), $\rho(T)$ (the resolvent set of T), and $R(\zeta; T)$ (the resolvent of T). We also use $C(X, Y)$ (resp. $A(X, Y)$) to denote the set of all †closed linear operators (resp. all †linear operators) from X to Y and $C(X) = C(X, X)$.

B. Stability of Basic Properties

(1) Let $T \in C(X, Y)$. Important notions for characterizing the smallness of $A \in A(X, Z)$ relative to T are the following. (i) A is said to be **relatively bounded** with respect to T (or simply **T -bounded**) if $D(A) \supset D(T)$ and there exist $a, b \geq 0$ such that

$$(*) \quad \|Au\|_Z \leq a\|u\|_X + b\|Tu\|_Y \text{ for all } u \in D(T).$$

The infimum, denoted by $\|A\|_T$, of b for which $(*)$ holds with some a is called the T -bound of A . (ii) A is said to be **relatively compact** with respect to T (or **T -compact**) if $D(A) \supset D(T)$ and A is compact from $D(T)$ with the graph norm of T to Z (→ 68 Compact and Nuclear operators F). T -compactness of A implies T -boundedness (and in Hilbert spaces $\|A\|_T = 0$).

(2) Let $T \in C(X, Y)$, and let $A \in A(X, Y)$ be T -bounded. (i) If $\|A\|_T < 1$ (or if A is T -compact), then $T + A \in C(X, Y)$. (ii) If, in addition, $X = Y$ is a Hilbert space, T is †self-adjoint, and A is †symmetric, then $T + A$ is self-adjoint (**Rellich-Kato theorem**) [1, 8]. (iii) Suppose that T is a †Fredholm operator. If either A is T -compact or the inequality $(*)$ holds with constants a, b satisfying $b\rho + a < \rho$ for a certain positive number ρ determined by T , then $T + A$ is a Fredholm operator and $\text{ind}(T + A) = \text{ind } T$ (for $\text{ind } T, \text{nul } T$, and $\text{def } T$ → 251 Linear Operators). In the latter case where $b\rho + a < \rho$, we also have $\text{nul}(T + A) \leq \text{nul } T$ and $\text{def}(T + A) \leq \text{def } T$.

C. Continuity and Analyticity of Families of Closed Operators

In order to handle unbounded operators, which are important in applications, it is necessary to introduce generalized notions of convergence and analyticity of families of closed operators.

(1) $C(X, Y)$ becomes a †metric space by a distance function $\hat{d}(S, T)$ having the property that $\hat{\delta}(\Gamma(S), \Gamma(T)) \leq \hat{d}(S, T) \leq 2\hat{\delta}(\Gamma(S), \Gamma(T))$, where for closed subspaces M and N we put

$$\hat{\delta}(M, N) = \max[\delta(M, N), \delta(N, M)],$$

$$\delta(M, N) = \sup_{u \in M, \|u\|=1} \text{dist}(u, N); \delta(0, N) = 0.$$

$\hat{\delta}(M, N)$ is called the **gap** between M and N [5]. When $T_n \rightarrow T$ in this metric, T_n is said to converge to T in the generalized sense. This **generalized convergence** coincides with the norm convergence if $T_n, T \in \mathbf{B}(X, Y)$. If $X = Y$ and $\rho(T) \neq \emptyset$, then $T_n \rightarrow T$ in the generalized sense if and only if for some (or equivalently all) $\zeta \in \rho(T)$ we have $\zeta \in \rho(T_n)$ for sufficiently large n and $\|R(\zeta; T_n) - R(\zeta; T)\| \rightarrow 0, n \rightarrow \infty$. This is called **norm resolvent convergence**.

(2) When $X = Y$, there is also the notion of strong convergence in the generalized sense [5], which is roughly the strong convergence of resolvents. In particular, when T_n and T are self-adjoint operators in a Hilbert space, $T_n \rightarrow T$ strongly in the generalized sense if $R(\zeta; T_n) \rightarrow R(\zeta; T)$ strongly for some (or equivalently all) ζ with $\text{Im } \zeta \neq 0$. This is called **strong resolvent convergence**.

(3) Let $D \subset \mathbb{C}$ be a domain. The notion of analyticity (holomorphic property) of a family $T(\kappa) \in \mathbf{B}(X, Y)$, $\kappa \in D$, of bounded operators is well known (\rightarrow 37 Banach Spaces K). This notion is generalized to a family $T(\kappa) \in C(X, Y)$, $\kappa \in D$, of closed operators [1, 5]. Namely, $T(\kappa)$ is said to be **holomorphic** in D if at each $\kappa_0 \in D$ there exist a Banach space Z and $U(\kappa) \in \mathbf{B}(Z, X)$, $V(\kappa) \in \mathbf{B}(Z, Y)$, defined near κ_0 , such that (i) $U(\kappa)$ and $V(\kappa)$ are holomorphic at κ_0 as families of bounded operators; (ii) $U(\kappa)$ is one to one and onto $D(T(\kappa))$; (iii) $T(\kappa)U(\kappa) = V(\kappa)$. Let us mention several special cases. (I) if $X = Y$ and if $\zeta \in \rho(T(\kappa))$ for all $\kappa \in D$, then $T(\kappa)$ is holomorphic in D if and only if $R(\zeta; T(\kappa))$ is holomorphic in D . (II) If $D(T(\kappa))$ is independent of κ and if $T(\kappa)u$ is holomorphic in D for every $u \in D(T(\kappa))$ then $T(\kappa)$ is holomorphic in D (holomorphic family of type (A) [5]). (III) Let $T \in C(X, Y)$, and let $T^{(n)} \in A(X, Y)$ such that $D(T^{(n)}) \supset D(T)$ and $\|T^{(n)}u\| \leq c^{n-1}(a\|u\| + b\|Tu\|)$, $u \in D(T)$, where $a, b, c \geq 0$. Then $T(\kappa)u = Tu + \kappa T^{(1)}u + \dots + \kappa^n T^{(n)}u + \dots$, $u \in D(T)$ defines a holomorphic family of type (A) in $D = \{\kappa \mid |\kappa| < (b+c)^{-1}\}$. (IV) If $X = Y$ is a Hilbert space and if $T(\kappa)$ is self-adjoint for real κ , $T(\kappa)$ is said to be a self-adjoint family. In particular, the family discussed in (III) is a self-adjoint holomorphic family if T is self-adjoint and $T^{(n)}$ is symmetric.

D. Perturbation of Isolated Eigenvalues

(1) Separation of the spectrum. Let $T \in C(X)$. Suppose that a bounded subset Δ of $\sigma(T)$ is separated from the rest of $\sigma(T)$ by a simple closed contour Γ (i.e., $\Gamma \subset \rho(T)$ and $\Delta(\sigma(T) \setminus \Delta)$ lies inside (outside) of Γ). Then the operator

$$P = \frac{1}{2\pi i} \int_{\Gamma} R(\zeta; T) d\zeta,$$

which is independent of Γ , is a projection (i.e., $P \in \mathbf{B}(X)$ and $P^2 = P$). The closed subspaces $X_1 \equiv PX$ and $X_2 \equiv (I - P)X$ reduce T and give rise to the decomposition $T = T|_{X_1} \oplus T|_{X_2} \equiv T_1 \oplus T_2$. In particular, $\sigma(T_1) = \sigma(T) \cap \{\text{inside of } \Gamma\}$ and $\sigma(T_2) = \sigma(T) \cap \{\text{outside of } \Gamma\}$.

(2) Let $T(\kappa)$ be holomorphic in D . We assume that $0 \in D$ and regard $T^{(0)} = T(0)$ as the unperturbed operator. Suppose that Δ and Γ are as in (1) with T replaced by $T^{(0)}$. Then

Perturbation of Linear Operators

there exists $\delta > 0$ such that $|\kappa| < \delta$ implies $\Gamma \subset \rho(T(\kappa))$. This follows from the upper continuity of compact components of the spectrum with respect to the metric \hat{d} of $C(X)$ [5]. Thus the separation of the spectrum discussed in (1) is applicable to $T(\kappa)$. In particular, corresponding to the projection

$$P(\kappa) = \frac{1}{2\pi i} \int_{\Gamma} R(\zeta; T(\kappa)) d\zeta, \quad |\kappa| < \delta,$$

$T(\kappa)$ is decomposed as $T(\kappa) = T_1(\kappa) \oplus T_2(\kappa)$; and the problem of determining the spectrum of $T(\kappa)$ inside Γ is reduced to the problem of determining the spectrum of $T_1(\kappa)$ ($|\kappa| < \delta$). Suppose now that $\Delta = \{\lambda_0\}$ is an isolated eigenvalue of $T^{(0)}$ and that $m \equiv \dim P(0)X < \infty$. Then $\dim P(\kappa)X = m$, $|\kappa| < \delta$. Moreover, a base $\{\varphi_1(\kappa), \dots, \varphi_m(\kappa)\}$ of $P(\kappa)X$ can be constructed in such a way that the $\varphi_j(\kappa)$ are holomorphic in $\{|\kappa| < \delta' \leq \delta\}$ [3, 5]. Thus the problem for $T_1(\kappa)$ in this case is just the finite-dimensional eigenvalue problem $\det\{\lambda \delta_{jk} - (T(\kappa)\varphi_j(\kappa), \varphi_k(\kappa))\} = 0$. The totality $\{\lambda_j(\kappa)\}$ of solutions of this equation, i.e., the totality of eigenvalues of $T(\kappa)$ near λ_0 , is expressed by one or several power series of $\kappa^{1/p}$ with a suitable integer $p > 0$. If $T(\kappa)$ is a self-adjoint family, we can take $p = 1$ so that the eigenvalues are holomorphic near λ_0 . If $H(\kappa) = H^{(0)} + \kappa H^{(1)} + \dots$ is a self-adjoint holomorphic family described in example (IV) in (3) of Section C and if $m = 1$, the power series $\lambda(\kappa) = \sum \lambda_j \kappa^j$ can be explicitly computed as $\lambda_1 = (H^{(1)}u_0, u_0)$, $\lambda_2 = (H^{(2)}u_0, u_0) + (SH^{(1)}u_0, H^{(1)}u_0)$, \dots , where $H^{(0)}u_0 = \lambda_0 u_0$ with $\|u_0\| = 1$ and where $S = \lim_{\zeta \rightarrow \lambda_0} R(\zeta; H^{(0)})(I - P(0))$ is the reduced resolvent. This series is known as the **Rayleigh-Schrödinger series**. The power series for the associated eigenvectors $u(\kappa) = \sum \kappa^j u_j$ can also be computed. For details, including the case of a degenerate λ_0 ($m > 1$), in which the situation becomes more complicated due to the splitting of eigenvalues, \rightarrow [5]. The perturbation theory discussed in this subsection is called **analytic (or regular) perturbation theory**.

(3) Even when a problem cannot be handled by means of analytic perturbation, it may happen that the coefficients λ_j and u_j of formal power series can be computed up to a certain j . In many such cases it can be shown under general assumptions that an asymptotic expansion such as $\lambda(\kappa) = \lambda_0 + \lambda_1 \kappa + o(\kappa)$ is valid as long as the coefficients involved can be computed legitimately [2, 5]. Estimates for $o(\kappa)$ can also be given. This provides a rigorous foundation for the perturbation method in many important practical problems. The case of degenerate λ_0 can be treated similarly. The strong convergence in the generalized sense mentioned in (2) of Section C is used here. This theory is called **asymptotic perturbation theory**.

Perturbation of Linear Operators

E. Perturbation of Continuous Spectra

For continuous spectra, studying the mode of change under perturbation is not usually a tractable problem. Rather, certain parts of continuous spectra tend to be stable under perturbation; and the study of this stability has been a major topic in perturbation theory (also → 375 Scattering Theory). In this section we discuss only self-adjoint operators and let $H = \int \lambda dE(\lambda)$, H_0, \dots , be self-adjoint operators in a Hilbert space X . For \mathbf{B}_p and $\| \cdot \|_p$ to be used below → 68 Compact and Nuclear Operators.

(1) The essential spectrum (→ 390 Spectral Analysis of Operators E) is stable under compact perturbation. Namely, if $H = H_0 + K$ with compact K , then $\sigma_e(H) = \sigma_e(H_0)$ (H. Weyl, *Rend. Circ. Mat. Palermo*, 27 (1909)). More generally, it suffices to assume that $R(\zeta; H) - R(\zeta; H_0)$ is compact for some (or equivalently all) $\zeta \in \rho(H) \cap \rho(H_0)$. Conversely, if X is separable and if $\sigma_e(H) = \sigma_e(H_0)$, then there exist a unitary operator U and a compact operator K such that $H = UH_0U^{-1} + K$ (J. von Neumann, *Actualités Sci. Ind.*, 229 (1935)). Moreover, any self-adjoint operator H in a separable Hilbert space can be changed into $H + K$ with a pure point spectrum by adding a $K \in \mathbf{B}_p$ with $\|K\|_p < \varepsilon$ for any $p > 1$ and $\varepsilon > 0$ (S. T. Kuroda, *Proc. Japan Acad.*, 34 (1958)). I. D. Berg (1971), W. Sikonia (1971), J. Voigt (1977), and D. Voiculescu (1979) have extended these results to normal operators and m -tuples of commutative self-adjoint operators. Also → 390 Spectral Analysis of Operators I, J.

(2) The absolutely continuous spectrum (→ 390 Spectral Analysis of Operators E) is stable under perturbation by the †trace class. Namely, if $H = H_0 + K$, with $K \in \mathbf{B}_1$, then the absolutely continuous parts of H_0 and H are †unitarily equivalent, and in particular $\sigma_{ac}(H) = \sigma_{ac}(H_0)$ (M. Rosenblum, *Pacific J. Math.*, 7 (1957); T. Kato, *Proc. Japan Acad.*, 33 (1957)). Among generalizations we mention the following two. (i) If $R(\zeta; H) - R(\zeta; H_0) \in \mathbf{B}_1$ for some $\zeta \in \rho(H) \cap \rho(H_0)$, then the absolutely continuous parts of $\varphi(H_0)$ and $\varphi(H)$ are unitarily equivalent for any smooth strictly increasing real function φ (M. Sh. Birman, *Izv. Akad. Nauk SSSR, ser. mat.*, 27, (1963); T. Kato, *Pacific J. Math.*, 15 (1965)). (ii) If H_0 and H act in different Hilbert spaces X_0 and X , respectively, and if there exists $J \in \mathbf{B}(X_0, X)$ such that $J D(H_0) \subset D(H)$ and such that the closure of $HJ - JH_0$ belongs to $\mathbf{B}_1(X_0, X)$, then the same conclusion as in (i) holds (D. Pearson, *J. Functional Anal.*, 28 (1978)). (i) can be derived from (ii). Perturbation theory for absolutely continuous spectra is closely related to the study of generalized wave operators in scattering theory. In fact,

the existence and the completeness of the latter implies the unitary equivalence of absolutely continuous parts. All the results mentioned above are proved by scattering-theoretic methods, either by the wave operator approach or by the abstract stationary approach (→ 375 Scattering Theory, esp. B, C).

F. Some Other Topics

(1) For the perturbation theory for semigroups of operators and evolution equations, not discussed in this article, → [5, 7, 9].

(2) The detailed structure of continuous spectra is hard to analyze. An eigenvalue λ_0 of H_0 which is embedded in the continuous spectrum may diffuse into the continuous spectrum in the presence of a perturbation. In such a case, $H(\kappa)$, $\kappa \neq 0$, has no eigenvalues near λ_0 but may have a continuous spectrum highly concentrated around λ_0 . This phenomenon of **spectral concentration** is studied, especially for some concrete problems, in relation to **resonance poles** (or poles of the holomorphic continuation of the resolvent or the scattering matrix). In some problems, it is proved that the first few terms of the perturbation series for $\lambda(\kappa)$ that are still computable are related to the real part of the resonance. Some problems of resonance can be treated by the technique of dilation analyticity, a technique which is also effective in other problems of spectral analysis (J. Aguilar and J. M. Combes, *Comm. Math. Phys.*, 22 (1971)).

(3) A vast quantity of results in the spectral theory of the Schrödinger operators appearing in the †Schrödinger equation in quantum mechanics can be obtained by perturbation methods.

For the topics mentioned in (2) and (3) → [7].

332 (VI.7) Pi (π)

The ratio of the circumference of a circle to its diameter in a Euclidean plane is denoted by π, the initial letter of περιμετρος (perimeter). Thus π can be defined as

$$2 \int_0^1 dx / \sqrt{1-x^2}.$$

The symbol π has been used since W. Jones (1675-1749) and L. Euler. The fact that this ratio is a constant is stated in Euclid's *Elements*; however, Euclid gave no statement about the numerical value of π. As an approximate value of π, 3 has been used from antiquity. According to the Rhind Papyrus, (4/3)⁴ was used in ancient Egypt. Let L_n(l_n) be the perimeter of a regular n-gon circumscribed about (inscribed in) a circle of radius 1. Then the relations

$$L_n > \pi > l_n, \quad \frac{2}{L_{2n}} = \frac{1}{L_n} + \frac{1}{l_n},$$

$$l_{2n} = \sqrt{l_n L_{2n}}$$

hold. Archimedes obtained $3\frac{10}{71} < \pi < 3\frac{1}{7}$ by calculating L₉₆ and l₉₆. In 3rd-century China Liu Hui used π ≈ 3.14. In 5th-century China, Tsu Chung-Chih mentioned 22/7 as an inaccurate approximate value and 355/113 as an accurate approximate value of π. These values were obtained by methods similar to those of Archimedes. In 5th-century India, Aryabhata obtained π ≈ 3.1416, and in 16th-century Europe, Adriaen van Roomen obtained π ≈ 355/113.

F. Viète represented 2/π in the following infinite product:

$$\prod_{n=2}^{\infty} \cos \frac{\pi}{2^n} = \sqrt{\frac{1}{2}} \sqrt{\frac{1}{2} + \frac{1}{2}} \sqrt{\frac{1}{2}} \\ \times \sqrt{\frac{1}{2} + \frac{1}{2}} \sqrt{\frac{1}{2} + \frac{1}{2}} \sqrt{\frac{1}{2}} \dots$$

Using this formula, L. van Ceulen (1540-1610) calculated π to 35 decimals. In the 17th and 18th centuries, the Japanese mathematicians T. Seki, K. Takebe, and Y. Matunaga computed π to 50 decimals. Since the 17th century, many formulas that represent π as a sum of infinite series or as a limit have been used to obtain more accurate approximate values. The following are representations of π known in those days:

$$\frac{\pi}{2} = \frac{2 \cdot 2 \cdot 4 \cdot 4 \cdot 6 \cdot 6 \dots}{1 \cdot 3 \cdot 3 \cdot 5 \cdot 5 \cdot 7 \dots} \quad (\text{J. Wallis})$$

$$\frac{\pi}{4} = \frac{1}{1 + \frac{1^2}{2 + \frac{3^2}{2 + \frac{5^2}{2 + \dots}}}} \quad (\text{W. Brouncker; for the notation } \rightarrow \text{83 Continued Fractions})$$

$$= 1 - 1/3 + 1/5 - 1/7 + \dots \quad (\text{J. Gregory, G. W. F. Leibniz})$$

$$= 4 \text{ Arctan } 1/5 - \text{Arctan } 1/239 \quad (\text{J. Machin}).$$

A formula combining Machin's representation of π and the power series Arctan x = x - (1/3)x³ + (1/5)x⁵ - ... is called **Machin's formula** and was often used for calculating an approximate value of π. By utilizing this formula, in 1873 W. Shanks obtained an approximate value of π up to 707 decimals. No improvement of his approximation was obtained until 1946 when D. F. Ferguson calculated 710 digits of π and found that Shanks's value was correct only up to the 527th digit. The computation of an accurate approximate value of π has been made easier by the recent development of computing machines, and an approximate value up to 1,000,000 decimals has been obtained. P. Beckmann [2] gives a detailed and humorous historical account of the calculation of π from ancient times up to the present computer age. Various numerical results obtained by electronic computers are not formally published, some being deposited in the UMT repository of the editorial office of the journal *Mathematics of computation*. Choong et al. [3], using information in [1], obtained the first 21,230 partial denominators of the regular continued fraction representation of π and described how their numerical evidence tallies with theoretical results, obtained by the metrical theory of continued fractions, which is valid for almost all irrational numbers (e.g. → [4]).

In 1761, J. H. Lambert used Brouncker's expression of π in a continued fraction to prove that π is irrational. In 1882, C. L. F. Lindemann proved that π is a transcendental number using Euler's formula e^{πi} = -1. The approximate value of π up to 50 decimals is 3.14159265358979323846264338327950288419716939937510... (→ Appendix B, Table 6).

333 (II.18) Plane Domains

A. Domains in the Complex Plane

A \dagger domain (i.e., a \dagger connected open set) in the \dagger complex plane or on the \dagger complex sphere is called a **plane domain**. The \dagger closure of such a domain is called a **closed plane domain**. In this article, we consider only subsets of the complex plane (or sphere), and a plain domain is called simply a domain. The \dagger interior of a \dagger Jordan curve J in the complex plane is a domain called a **Jordan domain**. In a domain D , a Jordan arc whose two endpoints lie on the boundary of D is called a **cross cut** of D .

For a domain D , each of the following three conditions is equivalent to the condition that D is \dagger simply connected: (1) For every cross cut Q of D , $D - Q$ has exactly two \dagger connected components. (2) Every Jordan curve in D is \dagger homotopic to one point, that is, it can always be continuously deformed to a point. (3) The \dagger monodromy theorem holds in D .

If D is a domain on a complex sphere, each of the following three conditions is equivalent to the condition that D is simply connected: (4) The boundary of D consists of a single \dagger continuum or a single point. (5) For every Jordan curve C in D , either the interior or the exterior of C is contained in D . (6) The complement of D with respect to the complex sphere is a connected (not necessarily arcwise connected) closed set. Jordan domains are simply connected.

Let $n \geq 2$ be an integer and D a plane domain. The \dagger homology group $H_1(D, \mathbf{Z})$ is identical to \mathbf{Z}^{n-1} if and only if the complement of D in the complex sphere has n connected components. Then D is said to be **n -ply connected** or **multiply connected** without specifying n . If D is an n -ply connected domain, there exist $n - 1$ suitable mutually disjoint cross cuts Q_1, \dots, Q_{n-1} such that $D - (Q_1 \cup \dots \cup Q_{n-1})$ is simply connected.

Some typical examples of domains are as

follows: (1) **Circular domain**: $|z - c| < r$. (2) **Half-plane**: $\text{Re } z > 0$, or $\text{Im } z > 0$. (3) **Angular domain**: $\alpha < \arg(z - c) < \beta$. (4) **Annular domain**: $r < |z - c| < R$. (5) **Slit domain**: a domain obtained by excluding a Jordan arc Γ from a domain D , where all points on Γ (except an endpoint lying on the boundary of D) are contained in D . In this case, the Jordan arc Γ is called the **slit** of the domain.

B. Boundary Elements

A boundary point P of a domain D is called **accessible** if there exists a sequence of points P_i tending to P such that the line segments $P_1 P_2, \dots$ lie completely in D . For example, for the domain obtained by removing $x = 1/(n + 1)$, $0 < y \leq 1/2$ ($n = 1, 2, \dots$) from the square $0 < x < 1$, $0 < y < 1$, the boundary points with $x = 0$, $0 \leq y < 1/2$ are all inaccessible (Fig. 1).

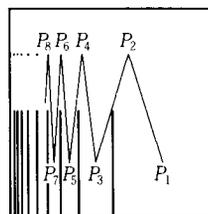

Fig. 1

Let the domain D be bounded by a smooth Jordan curve, and let P be a boundary point of D . Take an angular domain D' with vertex at the point P and the initial parts of the two sides of D' lying in D . A curve in D converging to the point P from the interior of the angular domain D' is called a **Stolz's path** or a **nontangential path** ending at the point P .

Let D be a simply connected domain. A sequence $\{q_v\}$ of cross cuts mutually disjoint except for their endpoints is called a **fundamental sequence of cross cuts** if it satisfies the following two conditions (Fig. 2): (1) Every q_v separates q_{v-1} and q_{v+1} on D . (2) For $v \rightarrow \infty$, the sequence q_v tends to a point on the boundary. Let $\{q'_v\}$ be a fundamental sequence of cross cuts, and denote by D_v the subdomain of D separated by q_v that contains q_{v+1} . The intersection $\bigcap \bar{D}_v$ consists only of the boundary points of D . Two fundamental sequences $\{q_v\}$, $\{q'_v\}$ of cross cuts are equivalent if every D_μ contains all q'_v except for a finite number of v , and every D'_μ contains all q_v except for a finite number of v . Here D_μ, D'_μ are the subdomains constructed from q_μ and q'_μ as above. This condition determines an equivalence relation, under which the equivalence class of fundamental sequences of cross cuts is called a **boundary element**. This notion is due to C. Carathéodory [2]. The boundary element of a

multiply connected domain is defined similarly for each isolated component of the boundary. For example, each point of a slit domain, except for the endpoint of Γ lying on the boundary of the domain, determines two distinct boundary elements on each side. A closed domain is usually considered to be the union of a domain and the set of all its boundary elements. Various notions of †ideal boundary come from considering suitable boundary elements for various purposes (\rightarrow 207 Ideal Boundaries).

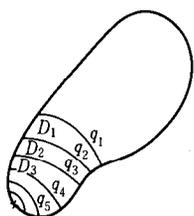

Fig. 2

C. Domain Kernels

Let $\{G_v\}$ be a sequence of domains containing the origin 0. If a suitable neighborhood of the origin is contained in G_v for all v , there exists a domain G such that every closed domain containing the origin and contained in G is contained in G_v except for a finite number of v . The union K of such domains G is called the **domain kernel** of the sequence $\{G_v\}$ (Carathéodory). If there is no neighborhood of the origin contained in G_v for all v , we put $K = \{0\}$.

If every infinite subsequence of $\{G_v\}$ has the same domain kernel K , then we say that the sequence $\{G_v\}$ converges to K . The notion of domain kernel is important in considering the limits of a sequence of conformal mappings (\rightarrow 77 Conformal Mappings).

334 (X.33) Plateau's Problem

A. Origin

Because of surface tension, a soap membrane bounded by a given closed space curve takes

Plateau's Problem

the shape of a minimal surface, i.e., a surface of the least area. This experiment was performed by the Belgian scientist J. A. Plateau (1873) to realize minimal surfaces; hence **Plateau's problem** is that of determining the minimal surfaces bounded by given closed space curves. It is a problem of the †calculus of variations.

B. Formulation

Let Γ be a †simple closed curve in xyz -space such that its projection C on the xy -plane is also a simple closed curve. Let D be the finite domain bounded by C . We consider surfaces $z = z(x, y)$ having common boundary Γ . Then under suitable assumptions on the smoothness of $z(x, y)$, the problem is to minimize the †functional

$$J[z] = \iint_D \sqrt{1 + p^2 + q^2} \, dx \, dy;$$

$$p = \frac{\partial z}{\partial x}, \quad q = \frac{\partial z}{\partial y},$$

with the condition that $z = z(x, y)$ has Γ as its boundary. The †Euler-Lagrange differential equation for the functional $J[z]$ is

$$\frac{\partial}{\partial x} \frac{p}{\sqrt{1 + p^2 + q^2}} + \frac{\partial}{\partial y} \frac{q}{\sqrt{1 + p^2 + q^2}} = 0,$$

or $(1 + q^2)r - 2pqs + (1 + p^2)t = 0$, $r = \partial^2 z / \partial x^2$, $s = \partial^2 z / \partial x \partial y$, $t = \partial^2 z / \partial y^2$, which is a second-order †quasilinear partial differential equation of elliptic type and whose geometric interpretation had already been given by M. C. Meusnier (1776).

To formulate the problem more generally, let a surface be expressed in vector form $\mathbf{x} = \mathbf{x}(u, v)$ by means of parameters u, v . Let its †first fundamental form be $dx^2 = E du^2 + 2F du dv + G dv^2$ and its †second fundamental form be $-dx \, dn = L du^2 + 2M du dv + N dv^2$, with $\mathbf{n} = \mathbf{n}(u, v)$ the unit normal vector. By equating to zero the †first variation of the **areal functional**

$$\iint \sqrt{EG - F^2} \, du \, dv$$

based on infinitesimal displacement in the normal direction, we obtain the Euler-Lagrange equation in the form

$$2H \equiv (NE - 2MF + LG) / (EG - F^2) = 0,$$

where $H = (R_1^{-1} + R_2^{-1})/2$ is the †mean curvature of the surface and R_1 and R_2 are the †radii of principal curvature. Since †Beltrami's second differential form satisfies $\Delta_2 \mathbf{x} = H \mathbf{n}$, the condition for a minimal surface becomes $\Delta \mathbf{x} = 0$ (with Δ the †Laplace operator) provided that **isothermal parameters** u, v satisfying $E =$

$G, F = 0$ are chosen, i.e., the vector $\mathbf{x}(u, v)$ representing a minimal surface is harmonic (the components of this vector are harmonic functions of u, v). Let $\eta(u, v)$ be a harmonic vector conjugate to $\mathbf{x}(u, v)$. Then isothermality is expressed by the condition that the analytic vector $\mathfrak{F}(w) = \mathbf{x}(u, v) + i\eta(u, v)$ ($w = u + iv, i = \sqrt{-1}$) satisfies $\mathfrak{F}'(w)^2 = 0$ (Weierstrass). In general, a **minimal surface** is defined as a surface with everywhere vanishing mean curvature, and Plateau's problem is to determine the minimal surface with a preassigned boundary. In this formulation, the problem can be easily generalized to an n -dimensional Euclidean space \mathbf{R}^n (\rightarrow 275 Minimal Submanifolds).

C. Existence of a Solution

The existence of a solution of Plateau's problem was discussed by S. N. Bernsteĭn (1910) from the viewpoint of a boundary value problem of the first kind for the elliptic partial differential equation in the previous section. A. Haar (1927) dealt with the minimal problem for the functional $J[z]$ by a direct method in the calculus of variations. Previously, Riemann, Weierstrass, Schwarz, and others discussed the case where the given space curve Γ is a polygon, in connection with the monodromy group concerning a second-order linear ordinary differential equation. Subsequently, R. Garnier (1928) investigated the existence of a solution by the limit process when Γ is a simple closed curve with bounded curvature. However, when Γ is assumed merely to be rectifiable, the existence of a solution was first shown by the limit process by T. Radó (1930). He further discussed the general case where Γ can bound a surface with finite area. On the other hand, by introducing a new functional depending on boundary values instead of the areal functional, J. Douglas (1931) succeeded in giving a satisfactory result for the existence problem. R. Courant (1937) gave another existence proof by reducing Plateau's problem to the Dirichlet principle [3].

At present, the methods of discussing the existence of solutions of Plateau's problem can be classified into the following three sorts (represented, respectively, by Radó, Courant, and Douglas):

(1) The first method is to minimize directly the areal functional $\iint \sqrt{EG - F^2} du dv$. The variational equation of the areal functional becomes $H = 0$.

(2) **Dirichlet's functional** for a scalar function $f(u, v)$ is defined by $D[f] = \iint (f_u^2 + f_v^2) du dv$, and for an n -dimensional vector function $\mathfrak{f}(u, v)$ with components $f_j(u, v)$ ($j = 1, \dots, n$) by $D[\mathfrak{f}] = \sum_{j=1}^n D[f_j]$. The existence of a solution of Plateau's problem can be discussed by starting

from the variational problem of minimizing $D[\mathfrak{f}]$. The variational equation of $D[\mathfrak{f}]$ is $\Delta \mathfrak{f} = 0$.

(3) An analytic vector $\mathfrak{F}(w)$ is representable in terms of the boundary values of its real part. For instance, if the domain of w is the unit disk $|w| < 1$, then Poisson's integral formula

$$\mathfrak{F}(w) = \frac{1}{2\pi} \int_0^{2\pi} \mathfrak{h}(\theta) \frac{e^{i\theta} + w}{e^{i\theta} - w} d\theta + i \operatorname{Im} \mathfrak{F}(w)$$

with the boundary function $\mathfrak{h}(\theta) = \operatorname{Re} \mathfrak{F}(e^{i\theta})$ can be used. On the other hand, the vector function that minimizes the Dirichlet integral among functions with fixed boundary values is harmonic. Based on these facts, Douglas transformed Dirichlet's functional with harmonic argument functions into a functional whose arguments are boundary functions. Specifically, by starting from the problem of minimizing **Douglas's functional**

$$A[\mathfrak{h}] = \frac{1}{4\pi} \int_0^{2\pi} \int_0^{2\pi} \frac{(\mathfrak{h}(\theta) - \mathfrak{h}(\varphi))^2}{4 \sin^2(\theta - \varphi)/2} d\theta d\varphi,$$

we can prove the existence of solution of Plateau's problem satisfactorily.

D. The Generalized Case

Up to now we have been concerned with Plateau's problem in the case of a single simple closed curve. Douglas, Courant, and others treated the generalized case of a finite number of boundary curves, where genus and orientability are assigned as the topological structure of the surface to be found. The existence of a solution has been shown in this case also. The problem is further generalized from the case of fixed boundary to the case where the boundary is merely restricted to lie on a given manifold [3]. On the other hand, C. B. Morrey (1948) generalized the problem by replacing the ambient space \mathbf{R}^n by an n -dimensional Riemannian manifold and gave the existence proof in considerable generality [6].

E. Relation to Conformal Mappings

There is a notable relation between Plateau's problem and conformal mapping when the dimension of the space is 2. Namely, the existence proof of the solution of the former for a Jordan domain implies Riemann's mapping theorem together with W. F. Osgood and C. Carathéodory's result on boundary correspondence (\rightarrow 77 Conformal Mappings).

F. New Developments

Among recent contributions to the study of Plateau's problem, the following remarkable

results have emerged. One of them is connected with the final result of Douglas (1939) on the existence of solution surfaces. The mapping of a 2-dimensional manifold with boundary into \mathbf{R}^n defining Douglas's solution of the Plateau problem for a finite number of simple closed curves is a †minimal immersion with the possible exception of isolated points where it fails to be an immersion. These points are called branch points. It was then proved by R. Osserman (1970) and R. D. Gulliver (1973) that for $n = 3$ the mapping of Douglas's theorem, which is a surface of least area, is free of branch points, i.e., is an immersion. Osserman also gave examples of generalized minimal surfaces in \mathbf{R}^n ($n > 3$) with true branch points. In this connection, Gulliver also dealt with an analogous problem for surfaces of prescribed mean curvature.

Next, we mention the question of boundary regularity. H. Lewy (1951) proved that if the boundary of a minimal surface is analytic, then the surface is analytic up to the boundary. Subsequently, S. Hildebrandt (1969) and others proved that if the boundary is of class $C^{m,\alpha}$, $m \geq 1$, the surface is also of class $C^{m,\alpha}$ up to the boundary. There are also some recent results on the number of solutions of Plateau's problem. For instance, J. C. C. Nitsche (1973) proved the uniqueness of solutions for analytic boundaries of †total curvature at most 4π .

Further developments in connection with Plateau's problem have emerged in the work of E. R. Reifenberg (1960) and others, who sought to minimize the †Hausdorff measure among general classes of geometric objects, not as parametrized manifolds, but as subsets of \mathbf{R}^n . The existence and regularity of solutions of Plateau's problem from this point of view have been discussed by H. Federer (1969), W. H. Fleming, F. J. Almgren, and others [10].

335 (XXI.39) Poincaré, Henri

Henri Poincaré (April 29, 1854–July 17, 1912) was born in Nancy, France. After graduating from the Ecole Polytechnique, he taught at the University of Caen in 1879, then at the University of Paris in 1881. He was made a member of the Académie des Sciences in 1887 and of the Académie Française in 1908. He died in Paris.

His achievements center on analysis and applications to theoretical physics and astronomy. However, his work covered many fields of mathematics, including arithmetic, algebraic geometry, spectral theory, and topology. His †uniformization of analytic functions by means of the theory of †automorphic functions in 1880 is especially notable. His paper on the †three-body problem won the prize offered by the king of Sweden in 1889.

The methods he developed in his three-volume *Mécanique céleste* (1892–1899) began a new epoch in celestial mechanics. In addition, Poincaré opened the road to †algebraic topology and made suggestive contributions to the †theory of relativity and †quantum theory. He asserted that science is for science's own sake [4], and his popular philosophical works concerning the foundations of natural science and mathematics exhibit a lucid style.

336 (X.20) Polynomial Approximation

A. General Remarks

On the existence of polynomial approximations, we have **Weierstrass's approximation theorem**, which is formulated in the following two forms: (i) If $f(x)$ is a function that is continuous in the finite interval $[a, b]$, then for every $\varepsilon > 0$ there exists a polynomial $P_n(x)$ of degree $n = n(\varepsilon)$ such that the inequality $|f(x) - P_n(x)| \leq \varepsilon$ holds throughout the interval $[a, b]$. (ii) If $f(\theta)$ is a continuous function of period 2π , then corresponding to every positive number ε there exists a trigonometric polynomial of degree $n = n(\varepsilon)$,

$$P_n(\theta) = a_0 + \sum_{k=1}^n (a_k \cos k\theta + b_k \sin k\theta), \quad (1)$$

such that the inequality $|f(\theta) - P_n(\theta)| \leq \varepsilon$ holds for all values of θ . The second form of Weierstrass's theorem follows from the first, and conversely. M. H. Stone obtained a theorem that generalizes Weierstrass's theorem to the case of functions of several variables. Of the many direct proofs now available for Weierstrass's theorem, we mention two simple ones. To prove version (i) of the theorem, we can assume that the given function $f(x)$ is defined in the segment $[0, 1]$. Consider the **Bernstein polynomial**

$$B_n(x) = \sum_{k=0}^n f\left(\frac{k}{n}\right) \binom{n}{k} x^k (1-x)^{n-k}.$$

Then $B_n(x)$ converges to $f(x)$ uniformly. To prove (ii), we can apply Fejér's theorem on Fourier series. We have the following generalization of (i): Let p_1, p_2, \dots be a sequence of positive numbers such that $\lim p_n = \infty$. Then linear combinations of $x^0 = 1, x^{p_1}, x^{p_2}, \dots$ can uniformly approximate each continuous function on $[0, 1]$ with arbitrary precision if and only if $\sum p_n^{-1} = \infty$ (**Müntz's theorem**).

B. Best Approximations

Let $\varphi_0(x), \varphi_1(x), \dots$ be a sequence of linearly independent continuous functions on a bounded closed domain A in \mathbf{R}^n . For any given continuous function $f(x)$, a function $P_n(x) = \sum_{k=0}^n c_k \varphi_k(x)$ attains

$$\inf_{c_0, \dots, c_n} \max_{x \in A} |f(x) - P_n(x)|$$

is called the **best approximation** of $f(x)$ by a linear combination of $\{\varphi_k(x)\}$. For any given n there is a best approximation of $f(x)$ by a linear combination of $\varphi_0(x), \dots, \varphi_n(x)$, but such an approximation is not always unique. For such an approximation to be unique it is necessary and sufficient that the determinant of the matrix $(\varphi_k(x_i))$ ($k, i = 0, 1, 2, \dots, n$) is not zero, where x_0, x_1, \dots, x_n are $n+1$ arbitrary distinct points of A (**Haar's condition**) (*Math. Ann.*, 78 (1918)). If $\{\varphi_k(x)\}$ satisfies this condition, the system of functions $\{\varphi_k\}_{k=0, \dots, n}$ is called a **Chebyshev system** (or **unisolvant system**). The sets $\{1, x, x^2, \dots, x^n\}$ on $[a, b]$, $\{1, \cos x, \dots, \cos nx\}$ on $[0, \pi]$ and $\{\sin x, \dots, \sin nx\}$ on $[0, \pi]$ are Chebyshev systems. For a Chebyshev system $\{\varphi_k(x)\}$ on $[a, b]$, let $P_n(x)$ be a linear combination of $\varphi_0(x), \dots, \varphi_n(x)$ that is not identical to the function $f \in C[a, b]$. Then $P_n(x)$ is the best approximation for $f(x)$ if and only if there are at least $n+2$ distinct points $x_1 < \dots < x_{n+2}$ of $[a, b]$, where $|f(x) - P_n(x)|$ attains its maximum (these points are called **deviation points**) and $(f(x_i) - P_n(x_i))(f(x_{i+1}) - P_n(x_{i+1})) < 0$ ($i = 1, \dots, n+1$) (**Chebyshev's theorem**).

For example, consider the polynomial $P_n(x) = a_{n-1}x^{n-1} + \dots + a_1x + a_0$ with real coefficients such that

$$\max_{-1 \leq x \leq 1} |x^n - a_{n-1}x^{n-1} - \dots - a_0|$$

takes its smallest value. Then $x^n - P_n(x) = 2^{-(n-1)} T_n(x)$, where $T_n(x) = \cos(n \arccos x)$ is the Chebyshev polynomial of degree n .

Since the best approximation is desired for numerical computation, several methods have been developed to find it (\rightarrow 300 Numerical Methods). However, when the set $A \subset \mathbf{R}^n$ ($n \geq 2$) contains three nonintersecting arcs emanating from a common point, A admits no Chebyshev system. Thus we do not always have a unique best-approximation polynomial [16].

C. Degrees of Approximation and Moduli of Continuity

For a continuous function $f(x)$ defined on $[a, b]$, the **modulus of continuity of k th order** is defined by

$$\omega_k(f; t) = \sup_{\substack{|h| \leq t \\ a \leq x \leq b \\ a \leq x+kh \leq b}} \left| \sum_{v=0}^k (-1)^{k-v} \binom{k}{v} f(x+vh) \right|$$

for $t \leq (b-a)/k$. In particular, ω_1 is the ordinary modulus of continuity. Put $E_n^*(f) = \inf_{a_0, \dots, a_n, b_1, \dots, b_n} \max_{a \leq x \leq b} |f(x) - P_n(x)|$, where f is a continuous periodic function of period 2π and $P_n(x)$ is a trigonometric polynomial of the form (1). Then $E_n^*(f) \leq c_k \omega_k(f; 1/(n+1))$ (**Jackson's theorem** [1]), where c_k is indepen-

dent of f . The best possible coefficient c_k has been determined by J. Favard [2]. Further investigations on the relation between $E_n^*(f)$ and $\omega_k(f; t)$ have been carried out by S. N. Bernshtein [3] and A. Zygmund [4]. S. B. Stechkin obtained the following results:

$$\omega_k\left(f; \frac{1}{n}\right) \leq \frac{c_k}{n^k} \sum_{v=0}^n (v+1)^{k-1} E_v^*(f)$$

[5, 6]. For the approximation of $f \in C^r([-1, 1])$ by polynomials, there exists a polynomial $P_n(x)$ of degree at most n such that for any $x \in [-1, 1]$,

$$|f(x) - P_n(x)| \leq M_r(t(x)) \omega_1(f^{(r)}; t(x)),$$

where M_r is a constant not depending on f , x , and n , $f^{(r)}(x)$ is the r th derivative of $f(x)$, and $t(x) = (1/n)(\sqrt{1-x^2} + |x|/n)$. We also have theorems evaluating $\omega_k(f^{(r)}; t)$ in terms of $|f(x) - P_n(x)|$. For the proof of these theorems, estimation of the magnitude of the derivative of the polynomial of degree n plays an essential role. For example, we have the **Bernshtein inequality** $\max_x |T_n'(x)| \leq n \max_x |T_n(x)|$ for any trigonometric polynomial $T_n(x)$ of degree n and the **Markov inequality**

$$|P_n'(x)| \leq n \min[1/\sqrt{1-x^2}, n] \max_{-1 \leq x \leq 1} |P_n(x)|$$

for $x \in [-1, 1]$ and any polynomial $P_n(x)$ of degree n .

D. Approximation by Fourier Expansions

If $\{\varphi_n(x)\}$ is an orthonormal system of functions in $L_2(a, b)$ and f is any function in $L_2(a, b)$, then among all linear combinations of $\varphi_0(x), \dots, \varphi_n(x)$ the one that gives the best mean square approximation to f (i.e., the one for which the integral

$$\int_a^b \left(f(x) - \sum_{k=0}^n c_k \varphi_k(x) \right)^2 dx$$

attains its minimum) is the Fourier polynomial $\sum_{k=0}^n a_k \varphi_k(x)$, where $a_k = \int_a^b f(x) \varphi_k(x) dx$. Consequently, the **least square approximation** (or best approximation with respect to the L_2 -norm) by trigonometric polynomials is given by the partial sum $s_n(x)$ of the Fourier series of $f(x)$. For L_p ($1 < p < \infty$), $s_n(x)$ also gives the best approximation up to a constant factor, but in the case of uniform approximation we have $|f(x) - s_n(x)| \leq A(\log n) \omega_k(f; n^{-1})$, and this result cannot be improved in general. There is no linear operation that gives the best trigonometric approximation. In approximation with a linear combination of $\varphi_0(x), \dots, \varphi_n(x)$, the saturation phenomenon of approximation often appears. For example, observe the arithmetic means of $s_n(x)$ (i.e., \dagger Fejér means $\sigma_n(x)$). If

$f \in \text{Lip } \alpha$ ($0 < \alpha < 1$) (\rightarrow 84 Continuous Functions A), then $|f(x) - \sigma_n(x)| = O(n^{-\alpha})$. However, $|f(x) - \sigma_n(x)| = O(n^{-1})$ if and only if the \dagger conjugate function $\tilde{f}(x) \in \text{Lip } 1$; $|f(x) - \sigma_n(x)| = o(n^{-1})$ if and only if $f(x)$ is constant (M. Zamansky [7], G. Sunouchi and C. Watari [8]).

E. Trigonometric Interpolation Polynomials

Since the trigonometric system is a Chebyshev system, given $2n+1$ distinct points x_0, x_1, \dots, x_{2n} and arbitrary numbers c_0, c_1, \dots, c_{2n} , there is always a unique trigonometric polynomial of degree n with prescribed values c_k at the points x_k . Given any continuous function $f(x)$ with period 2π , the trigonometric polynomial that coincides with $f(x)$ at the points x_k is called the **trigonometric interpolation polynomial** with nodes at x_k . If $x_k = 2\pi k/(2n+1)$ ($k=0, 1, \dots, 2n$), then the interpolating trigonometric polynomial is given by

$$\begin{aligned} U_n(f, x) &= \frac{1}{2n+1} \sum_{j=0}^{2n} f(x_j) \frac{\sin((n+1/2)(x-x_j))}{\sin((x-x_j)/2)} \\ &= \frac{1}{2\pi} \int_0^{2\pi} f(t) \frac{\sin((n+1/2)(x-t))}{\sin((x-t)/2)} d\varphi_n(t), \end{aligned}$$

where $\varphi_n(t)$ is a step function that has the value $2\pi j/(2n+1)$ in $[2\pi j/(2n+1), 2\pi(j+1)/(2n+1)]$. $U_n(f, x)$ resembles the partial sum $s_n(x)$ of the Fourier series of $f(x)$. If $f(x)$ is continuous and of \dagger bounded variation, then $U_n(f, x)$ converges uniformly to $f(x)$ (D. Jackson [1]). Although the partial sum $s_n(x)$ of the Fourier series of a continuous function $f(x)$ converges almost everywhere to $f(x)$, there is a continuous function for which $U_n(f, x)$ diverges everywhere (J. Marcinkiewicz [9]). Moreover, there exists a continuous function for which $(1/n)(\sum_{k=1}^n U_k(f, x))$ diverges everywhere (P. Erdős [10], G. Grünwald [11]). Restating these facts for the algebraic polynomial case, we can conclude that there is a continuous function defined in $[-1, 1]$ for which the \dagger Lagrange interpolation polynomial and its arithmetic mean are both divergent everywhere if we take as nodes the roots of the Chebyshev polynomial of degree n .

F. The Case of a Complex Domain

If a given function $f(z)$ is holomorphic in a bounded \dagger simply connected domain E in the complex plane and continuous in \bar{E} , then $f(z)$ is approximated uniformly by polynomials on any compact set in E (**Runge's theorem**). This theorem was first studied by C. Runge, and his results were developed by J. L. Walsh and M. V. Keldysh (e.g., [12]). When E contains no interior point, the polynomial approxima-

tion of a continuous function defined in E was given by M. A. Lavrent'ev. Unifying these two results, S. N. Mergelyan obtained the following theorem [13]: A necessary and sufficient condition for an arbitrary function continuous on a compact set E and holomorphic inside E to be approximated on E uniformly by polynomials is that the set E does not divide the complex plane.

On the degree of approximation of polynomials to $f(z)$ on a simply connected domain, there are the following results: Let D be a closed bounded set whose complement K is connected and regular in the sense that K possesses a †Green's function $G(x, y)$ with a pole at infinity. Let D_R be the locus $G(x, y) = \log R > 0$. When $f(z)$ is holomorphic on D , there exists the largest number ρ with the following property: $f(z)$ is single-valued and holomorphic at every interior point of D_ρ . If $R < \rho$, there exist polynomials $P_n(z)$ of degree n ($n = 1, 2, \dots$) such that $|f(z) - P_n(z)| \leq M/R^n$ for $z \in D$, where M is a constant independent of n and z . On the other hand, there exist no such polynomials $P_n(z)$ on D for $R > \rho$ (Bernshtein and Walsh [12]).

G. Lagrange's Interpolation Formula

For each n ($n = 0, 1, \dots$), let $z_1^{(n)}, z_2^{(n)}, \dots, z_{n+1}^{(n)}$ be a given set of real or complex numbers, and let $f(z)$ be an arbitrary function. Then there is a unique polynomial of degree n that coincides with $f(z)$ at each point $z_k^{(n)}$ ($k = 1, \dots, n + 1$). This is called **Lagrange's interpolation polynomial** and is given by

$$P_n(z) = \sum_{k=1}^{n+1} f(z_k^{(n)}) \frac{\omega(z)}{(z - z_k^{(n)})\omega'(z_k^{(n)})},$$

$$\omega(z) = (z - z_1^{(n)}) \dots (z - z_{n+1}^{(n)}).$$

The sequence $P_n(z)$ does not always converge to $f(z)$. For example, if we take $f(z) = 1/z$ and the $(n + 1)$ st roots of 1 as $z_k^{(n)}$, then $P_n(z) = z^n$ and $P_n(z)$ converges to $f(z)$ only at the point 1. For real variables also, there are examples of divergent $P_n(z)$. However, if $f(z)$ is holomorphic in $|z| < \rho$ ($\rho > 1$), then $P_n(z)$ with the $(n + 1)$ st roots of 1 as nodes converges to $f(z)$ uniformly in $|z| \leq 1$.

When $z_k^{(n)}$ is independent of the choice of n , $P_n(z)$ coincides with the sum of the first n terms of †Newton's interpolation formula. In this case, $P_n(z)$ is called **Newton's interpolation polynomial** and is given by

$$P_n(z) = a_0 + a_1(z - z_1) + a_2(z - z_1)(z - z_2) + \dots + a_n(z - z_1) \dots (z - z_n),$$

where $a_0 = f(z_1)$; $a_1 = (f(z_2) - f(z_1))/(z_2 - z_1)$ ($z_2 \neq z_1$), $a_1 = f'(z_1)$ ($z_2 = z_1$); and so on. Suc-

cessive coefficients of the polynomial $P_n(z)$ can be calculated by †finite differences. Convergence of Newton's interpolation polynomial is closely connected to convergence of †Dirichlet series.

H. Chebyshev Approximation

Let D be a bounded closed subset of the complex plane, and $f(z)$ a continuous function on D . Then there exists a polynomial $\pi_n(z)$ of degree n such that $\max_{z \in D} |f(z) - \pi_n(z)|$ attains the infimum $E_n(f)$. The polynomial $\pi_n(z)$ is unique and is called the **best approximation polynomial (in the sense of Chebyshev)**. If D is simply connected and $f(z)$ is single-valued and holomorphic on D , then $\pi_n(z)$ converges to $f(z)$ uniformly on D . Moreover, in this case there exist a number M that does not depend on n and a number $R > 1$ such that $|f(z) - \pi_n(z)| \leq M/R^n$. Assuming that $f(z)$ satisfies certain additional conditions, W. E. Sewell [14] proved the existence of a constant r such that $|f(z) - \pi_n(z)| \leq M/n^r R^n$. Furthermore, by approximating $f(z) = z^n$ by polynomials of degree $n - 1$, we can show that there exists a polynomial $T_n(z)$ of degree n such that

$$\min \left\{ \max_{z \in D} |z^n + a_1 z^{n-1} + \dots + a_n| \right\} = |T_n(z)|.$$

$T_n(z)$ is called a **Chebyshev polynomial** of degree n with respect to the domain D . Similar statements are valid for functions of a real variable. In particular, when $D = [-1, 1]$, we have

$$T_n(x) = \cos(n \arccos x) / 2^{n-1},$$

which is the ordinary (real) Chebyshev polynomial. Generally, the limit

$$\lim_{n \rightarrow \infty} \left(\max_D |T_n(z)| \right)^{1/n} = \rho(D)$$

exists, and $\rho(D)$ coincides with the †capacity and †transfinite diameter of D [15]. For new results and applications of Chebyshev polynomials \rightarrow [17].

If the method of evaluating the degree of approximation using the absolute value $|f(z) - \pi_n(z)|$ is replaced by methods using a †curvilinear integral or †surface integral, as explained below, we still obtain similar results. Let D be a closed domain in the complex plane with a boundary C that is a rectifiable Jordan curve. If $f(z)$ is single-valued and holomorphic on D , then there exists a polynomial $\pi_n(z)$ of degree n that minimizes the integral $\int_C u(z) |f(z) - \pi_n(z)|^p |dz|$ ($p > 0$), where $u(z)$ is a given positive continuous function on C . Moreover, $|f(z) - \pi_n(z)| \leq M/R^n$ for some $R > 1$ (actually $\{\pi_n(z)\}$ is †overconvergent). If D is a closed

Jordan domain and if $f(z)$ is single-valued and holomorphic in D , then there exists a polynomial $\pi_n(z)$ of degree n that minimizes the integral $\int \int_D u(z) |f(z) - \pi_n(z)|^p dS$, where $u(z)$ is a given positive continuous function on D . Moreover, $|f(z) - \pi_n(z)| \leq M/R^n$ for some $R > 1$ on D .

I. Approximation by Orthogonal Polynomials on a Curve

Let C be a rectifiable Jordan curve in the complex plane, and let $p_k(z) \in {}^\dagger L_2(C)$. If $\int_C p_k(z) \bar{p}_n(z) |dz| = \delta_{kn}$, then $\{p_k(z)\}$ is called an orthonormal system on C . Given a holomorphic function $f(z)$ on D , we set $a_k = \int_C f(z) p_k(z) |dz|$ and consider the formal series $\sum_{k=0}^{\infty} a_k p_k(z)$. If we denote the n th partial sum of this series by $s_n(z)$, then $s_n(z)$ is the least square approximation by a linear combination of $p_0(z), \dots, p_n(z)$. This and other results, such as † Bessel's inequality, the † Riesz-Fischer theorem, etc., are all valid here as in the theory of general † orthogonal systems. In particular, if we take $|z| = R$ as C , then $\{1, z, z^2, \dots\}$ is an orthogonal system. Since in this case

$$a_k = \frac{1}{2\pi R^{2k+1}} \int_C f(z) \bar{z}^k |dz| = \frac{1}{2\pi i} \int_C \frac{f(z)}{z^{k+1}} |dz|$$

and $s_n(z) = a_0 + a_1 z + \dots + a_n z^n$, the † Taylor expansion of $f(z)$ coincides with the orthogonal expansion of $f(z)$.

Given a compact domain D and a holomorphic function on D , if there exist orthogonal polynomials $p_n(z)$ such that the orthogonal expansion of $f(z)$ with respect to $p_n(z)$ converges to $f(z)$ uniformly on D , we say that $\{p_n(z)\}$ belongs to the domain D . The problem of existence and determination of such polynomials for any given domain was proposed and first solved by G. Faber. Generalizations were given by G. Szegő, T. Carleman, and Walsh. Roughly speaking, $p_n(z)$ is given by the orthogonalization of the system $\{1, z, z^2, \dots\}$ with respect to the curvilinear integral on $C = \partial D$ or the surface integral on D .

J. Numerical Approximation of Functions

The accuracy of the approximation of a given function $f(z)$ by the partial sums of its † Taylor expansion $\sum a_n(x - x_0)^n$ decreases rapidly as the distance $|x - x_0|$ increases. The accuracy of the approximation of $f(x)$ defined on a compact interval $[A, B]$ by a (polynomial) function $\varphi(x)$ can be evaluated by means of the least square approximation, the best approximation with respect to the uniform norm, and so on. The second method is best suited to numer-

336 Ref. Polynomial Approximation

ical calculation of functions. To get the best approximating polynomial $\varphi(x) = P_n(x) = \sum_{k=0}^n c_k \varphi_k(x)$ of $f(x)$ (\rightarrow Section B), we must determine coefficients c_k that satisfy the conditions of Chebyshev's theorem. The first step in this process is the orthogonal development of $f(x)$ by Chebyshev polynomials $\{T_n(x)\}$: $\varphi_n(x) = \sum_{k=0}^n a_k T_k(u)$, $u = (x - (A+B)/2)/((B-A)/2)$. The error $|f(x) - \varphi_n(x)|$ is estimated by a constant multiple of $T_{n+1}(u)$: $|f(x) - \varphi_n(x)| \leq K |T_{n+1}(u)|$. This **Chebyshev interpolation** is actually given by $a_0 = N^{-1} \sum_{i=1}^N f(x_i)$, $a_k = 2N^{-1} \sum_{i=1}^N f(x_i) T_k(u_i)$ ($k = 1, \dots, n$), where $N = n+1$ and the $u_i = (x_i - (A+B)/2)/((B-A)/2)$ ($i = 1, \dots, N$) are the roots of $T_N(u)$. Let M be the extremum of the error $|f(x) - \varphi_n(x)|$ of such an approximation, and set $f(x_i) - \varphi_n(x_i) = \pm M_i$ ($i = 1, 2, \dots, N$). Consider a function $\bar{\varphi}_n(x) = \sum \bar{a}_k T_k(u)$ satisfying $f(x_i) - \bar{\varphi}_n(x_i) = \pm M$. Then solve the linear equation $\bar{\varphi}_n(x_i) - \varphi_n(x_i) = \pm(M - M_i)$ with respect to $\Delta a_k = \bar{a}_k - a_k$ and M . Repeat this process until Δa_k becomes sufficiently small.

A computer can perform the division very quickly, and the rational approximation of a function, for example by its † continued fraction expansion, is often useful.

**337 (III.4)
Polynomials**

A. Polynomials in One Variable

Let R be a commutative ring and a_0, a_1, \dots, a_n elements of R . An expression $f(X)$ of the form

$$f(X) = a_0 + a_1X + \dots + a_nX^n \tag{1}$$

is called a **polynomial** in a variable X over R ; if $a_n \neq 0$, the number n is called the **degree** of the polynomial $f(X)$ and is denoted by $\deg f$. If $a_n = 1$, the polynomial (1) is called a **monic polynomial**. The totality of polynomials in X over R forms a commutative ring with respect to ordinary addition and multiplication (whose definition will be given later). It is called the **ring of polynomials** (or the **polynomial ring**) of X over R and is denoted by $R[X]$. We say that we **adjoin** X to R to obtain $R[X]$.

B. Polynomials in Several Variables

Let $R[X, Y]$ denote the ring $R[X][Y]$, namely, the ring obtained by adjoining Y to $R[X]$. An element of $R[X, Y]$ can then be expressed as $\sum a_{\mu\nu} X^\mu Y^\nu$. This expression is called a polynomial in X and Y over R . Generally, $R[X_1, \dots, X_m] = R[X_1, \dots, X_{m-1}][X_m]$ is called the **polynomial ring in m variables** (on m inde-

terminates) X_1, \dots, X_m over R , and its element

$$F(X_1, X_2, \dots, X_m) = \sum a_{v_1, v_2, \dots, v_m} X_1^{v_1} X_2^{v_2} \dots X_m^{v_m} \tag{2}$$

(\sum denotes a finite sum for nonnegative integral v_i beginning with $v_1 = v_2 = \dots = v_m = 0$) is called a **polynomial in m variables** X_1, \dots, X_m over R . We call each summand a **term** of the polynomial, a_{v_1, v_2, \dots, v_m} the **coefficient** and $v_1 + v_2 + \dots + v_m$ the **degree** of this term. The greatest degree of terms is called the **degree** of the polynomial F . The term $a_{0, \dots, 0}$ of degree 0 is called the **constant term** of F . If a polynomial F in X_1, \dots, X_m is composed of terms of the same degree n , then F is called a **homogeneous polynomial** (or **form**) of degree n ; a polynomial consisting of a single term, such as $aX_1^{v_1} X_2^{v_2} \dots X_m^{v_m}$, is called a **monomial**. Now let $\alpha_1, \alpha_2, \dots, \alpha_m$ be elements of R (or a commutative ring S containing R), and let $F(\alpha_1, \alpha_2, \dots, \alpha_m)$ denote the element of R (or S) obtained by substitution of $\alpha_1, \alpha_2, \dots, \alpha_m$ for X_1, X_2, \dots, X_m in $F(X_1, X_2, \dots, X_m)$. It is also called a polynomial in $\alpha_1, \alpha_2, \dots, \alpha_m$. If $F(\alpha_1, \alpha_2, \dots, \alpha_m) = 0$, then $(\alpha_1, \alpha_2, \dots, \alpha_m)$ is called a **zero point** (in S) of the polynomial $F(X_1, X_2, \dots, X_m)$ (or a solution of the algebraic equation $F(X_1, \dots, X_m) = 0$). In the case of one variable, it is called a **root** of $F(X_1)$ (or of $F(X_1) = 0$).

C. Polynomial Rings

Addition and multiplication in $R[X]$ are defined by

$$(\sum a_i X^i) + (\sum b_j X^j) = \sum (a_i + b_i) X^i,$$

$$(\sum a_i X^i)(\sum b_j X^j) = \sum_k (\sum_{i+j=k} a_i b_j) X^k.$$

A polynomial $f(X) \in R[X]$ can be regarded as a function of a commutative ring R' containing R into itself such that $c \mapsto f(c)$. In this sense, $f(X) + g(X)$ and $f(X)g(X)$ are the functions such that $c \mapsto f(c) + g(c)$ and $c \mapsto f(c)g(c)$, respectively.

It holds that $\deg(f(X) + g(X)) \leq \max\{\deg f(X), \deg g(X)\}$, $\deg f(X)g(X) \leq \deg f(X) + \deg g(X)$. If R is an integral domain, then the latter inequality is an equality, and therefore $R[X]$ is an integral domain. For these inequalities and for convenience elsewhere, we define the degree of 0 to be indefinite.

Assume that R is a field. For given $f, g \in R[X]$ ($\deg g \geq 1$), we can find unique $q, r \in R[X]$ such that $f = gq + r$ and $\deg r < \deg g$ or $r = 0$ (**division algorithm**). This q is called the **integral quotient** of f by g , and r is called the **remainder** of f divided by g . The same fact remains true in the general $R[X]$ if $g(X)$ is monic. (\rightarrow 369 Rings of Polynomials).

D. Factorization into Primes

Let k be an integral domain. Since $k[X]$ and hence $k[X_1, \dots, X_m]$ are integral domains, we can define the concepts concerning divisibility (such as a divisor, a multiple, etc.) (\rightarrow 67 Commutative Rings). If k is a \dagger unique factorization domain, then so are $k[X]$ and $k[X_1, \dots, X_m]$. A polynomial over k is said to be **primitive** if the greatest common divisor of all the coefficients is equal to 1. Every polynomial over k can be uniquely expressed as a product of some primitive polynomials and an element of k ; a product of primitive polynomials is primitive (**Gauss's theorem**).

If k is a field, then $k[X]$ and $k[X_1, \dots, X_m]$ are unique factorization domains. Furthermore, to find the greatest common divisor (f, g) of $f, g \in k[X]$, we can use the **Euclidean algorithm**, that is, apply the division algorithm repeatedly to obtain

$$f = gq_1 + r_1, \quad g = r_1q_2 + r_2, \quad r_1 = r_2q_3 + r_3, \dots, \\ \deg g > \deg r_1 > \deg r_2 > \dots,$$

so that after a finite number of steps we attain $r_{v-1} = r_vq_{v+1} + r_{v+1}$ ($r_{v+1} = 0$). Then $r_v = (f, g)$. Accordingly, $k[X]$ is a \dagger principal ideal domain. This algorithm is applied to Euclid rings (\rightarrow 67 Commutative Rings L).

E. The Remainder Theorem

Let k be an integral domain, $f(X) \in k[X]$, and let $g(X) = X - \alpha$ ($\alpha \in k$). Then using the division algorithm, we get

$$f(X) = (X - \alpha)q(X) + r,$$

$$q(X) \in k[X], \quad r \in k.$$

Therefore, $f(\alpha) = r$; that is, the remainder of $f(X)$ divided by $X - \alpha$ is equal to $f(\alpha)$. This is called the **remainder theorem**. If $f(\alpha) = 0$, then $f(X)$ is divisible by $X - \alpha$ in $k[X]$.

F. Irreducible Polynomials

Let k be a field. A polynomial $f(X) \in k[X]$ of degree n is said to be **reducible** over k if f is divisible by a polynomial of degree $v < n$ in $k[X]$ ($v \neq 0$); otherwise, it is said to be **irreducible** over k . Any polynomial of degree 1 is irreducible. A polynomial f is a \dagger prime element of $k[X]$ if and only if f is irreducible over k .

Let I be a unique factorization domain. If $f(X)$ is a polynomial (1) in $I[X]$ such that for a prime element p in I , $a_n \not\equiv 0 \pmod{p}$, $a_{n-1} \equiv a_{n-2} \equiv \dots \equiv a_0 \equiv 0 \pmod{p}$ but $a_0 \not\equiv 0 \pmod{p^2}$, then $f(X)$ is irreducible over the field of quotients of I (**Eisenstein's theorem**). If a polynomial (2) in m variables over an

\dagger algebraic number field k is irreducible, we can obtain an irreducible polynomial in X_1, \dots, X_μ ($0 < \mu < m$) from the polynomial $F(X_1, \dots, X_m)$ by assigning appropriate values in k to $X_{\mu+1}, \dots, X_m$ (**Hilbert's irreducibility theorem**, *J. Reine Angew. Math.*, 110 (1892)). These two theorems have been generalized in many ways and given precise formulations. In Hilbert's irreducibility theorem, the algebraic number field may be replaced, for example, by any infinite field that is \dagger finitely generated over its \dagger prime field (K. Dörge, W. Franz, E. Inaba).

G. Derivatives

Given a polynomial

$$f(X_1, \dots, X_m) = \sum a_{v_1 v_2 \dots v_m} X_1^{v_1} X_2^{v_2} \dots X_m^{v_m}$$

over a field k , we define the (formal) **derivative** of f with respect to X_i as $f_i(X_1, \dots, X_m) = \sum v_i a_{v_1 v_2 \dots v_m} X_1^{v_1} \dots X_i^{v_i-1} \dots X_m^{v_m}$ and denote it by $\partial f / \partial X_i$. The map $f \mapsto \partial f / \partial X_i$ is called the (formal) **derivative** with respect to X_i . In particular, if $m = 1$, then $\partial f / \partial X$ is denoted by df/dX . The usual rules of \dagger derivatives also hold for the formal derivative. If $df/dX = 0$ for an irreducible polynomial $f(X)$ in $k[X]$, then $f(X)$ is said to be **inseparable**; otherwise, $f(X)$ is **separable**. If the \dagger characteristic of the field k is 0, then every irreducible polynomial $f(X)$ ($\neq 0$) is separable. When k is of characteristic $p \neq 0$, an irreducible polynomial $f(X)$ is inseparable if and only if we can write $f(X) = g(X^p)$.

H. Rational Expressions

The \dagger field of quotients of the polynomial ring $k[X_1, \dots, X_n]$ over a field k is denoted by $k(X_1, \dots, X_n)$ and is called the **field of rational expressions** (or **field of rational functions**) in variables X_1, \dots, X_n over k . Its element is called a **rational expression** in X_1, \dots, X_n . It can be written as a quotient of one polynomial $f(X_1, \dots, X_n)$ by another polynomial $g(X_1, \dots, X_n) \neq 0$. Also, an expression $f(\alpha_1, \dots, \alpha_n) / g(\alpha_1, \dots, \alpha_n)$ obtained by replacing X_1, \dots, X_n with elements $\alpha_1, \dots, \alpha_n$ of k in the above expression is called a rational expression in $\alpha_1, \dots, \alpha_n$ (provided that $g(\alpha_1, \dots, \alpha_n) \neq 0$).

I. Symmetric Polynomials and Alternating Polynomials

Let $f(X_1, \dots, X_n)$ be a polynomial in variables X_1, \dots, X_n over an integral domain I . If

$f(X_1, \dots, X_n)$ is invariant under every permutation of X_1, \dots, X_n , it is called a **symmetric polynomial** (or **symmetric function**) of X_1, \dots, X_n . If $f(X_1, \dots, X_n)$ is transformed into $-f(X_1, \dots, X_n)$ by every odd permutation of X_1, \dots, X_n , it is called an **alternating polynomial** (or **alternating function**). Also, an expression $f(\alpha_1, \dots, \alpha_n)$ obtained from $f(X_1, \dots, X_n)$ by replacing X_1, \dots, X_n with elements $\alpha_1, \dots, \alpha_n$ of I is called a symmetric (alternating) function of $\alpha_1, \dots, \alpha_n$ if $f(X_1, \dots, X_n)$ is symmetric (alternating).

Let the coefficient of X^{n-k} in the expansion of $(X - X_1) \dots (X - X_n)$ be denoted by $(-1)^k \sigma_k$. Then we have $\sigma_1 = \sum X_i = X_1 + \dots + X_n$, $\sigma_2 = \sum X_i X_j = X_1 X_2 + X_1 X_3 + \dots + X_{n-1} X_n, \dots, \sigma_n = X_1 X_2 \dots X_n$. Obviously, these are symmetric polynomials of X_1, \dots, X_n . Moreover, for every element φ of the polynomial ring $I[Y_1, Y_2, \dots, Y_n]$, $\varphi(\sigma_1, \sigma_2, \dots, \sigma_n)$ is a symmetric polynomial of X_1, \dots, X_n . Conversely, every symmetric polynomial of X_1, \dots, X_n can be uniquely expressed as a polynomial $\varphi(\sigma_1, \sigma_2, \dots, \sigma_n)$. Thus the totality of symmetric polynomials of X_1, \dots, X_n is identical with the ring $I[\sigma_1, \sigma_2, \dots, \sigma_n]$. This is called the **fundamental theorem on symmetric polynomials**, and $\sigma_1, \sigma_2, \dots, \sigma_n$ are called **elementary symmetric polynomials** (or **elementary symmetric functions**). For example, for $s_v = \sum X_i^v$ ($v = 1, 2, \dots$), we have $s_1 = \sigma_1, s_2 = \sigma_1^2 - 2\sigma_2, s_3 = \sigma_1^3 - 3\sigma_1\sigma_2 + 3\sigma_3, s_4 = \sigma_1^4 - 4\sigma_1^2\sigma_2 + 2\sigma_2^2 + 4\sigma_1\sigma_3 - 4\sigma_4$. Concerning the elementary symmetric polynomials and the s_v , we have the relations $s_v - \sigma_1 s_{v-1} + \sigma_2 s_{v-2} - \dots + (-1)^{v-1} \sigma_{v-1} s_1 + (-1)^v v \sigma_v = 0$ ($v = 1, 2, \dots$), and $s_\mu - \sigma_1 s_{\mu-1} + \dots + (-1)^\mu \sigma_\mu s_{\mu-n} = 0$ ($\mu = n+1, n+2, \dots$) (**Newton's formulas**).

Let $p(X_1, \dots, X_n) = (X_2 - X_1)(X_3 - X_1) \dots (X_n - X_1)(X_3 - X_2) \dots (X_n - X_{n-1})$ be the product of $n(n-1)/2$ differences between X_1, \dots, X_n . Then the polynomial p is invariant under even permutations of X_1, \dots, X_n , and p becomes $-p$ under odd permutations. Hence p is an alternating polynomial of X_1, \dots, X_n . It is called the **simplest alternating polynomial** of these variables. Because of its particular expression, p is also called the **difference product** of X_1, \dots, X_n . If the characteristic of I is different from 2, an alternating polynomial f is divisible by the simplest alternating polynomial p ; it can be written as $f = ps$, where s stands for a symmetric polynomial.

J. Discriminants

The square $D(X_1, \dots, X_n) = p^2(X_1, \dots, X_n)$ of the simplest alternating polynomial p is a symmetric polynomial, and it is therefore a polynomial in $\sigma_1, \dots, \sigma_n$. $D(\alpha_1, \alpha_2, \dots, \alpha_n) = 0$

gives a criterion for the condition that some of $\alpha_1, \dots, \alpha_n$ are equal. If $\alpha_1, \dots, \alpha_n$ are the roots of an algebraic equation $a_0 X^n + a_1 X^{n-1} + \dots + a_n = 0$ of degree n , then $D(\alpha_1, \dots, \alpha_n)$ is called the **discriminant of the equation**. It can be expressed in terms of coefficients a_0, a_1, \dots, a_n of the equation. For instance, if $n = 2$, we have $a_0^2 D = a_1^2 - 4a_0 a_2$; if $n = 3$, we have $a_0^4 D = a_1^2 a_2^2 + 18a_0 a_1 a_2 a_3 - 4a_0 a_2^3 - 4a_1^3 a_3 - 27a_0^2 a_3^2$.

338 (X.28)
Potential Theory

A. Newtonian Potential

In dynamics, a **potential** means a function u of n variables x_1, \dots, x_n such that $-\text{grad } u = -(\partial u / \partial x_1, \dots, \partial u / \partial x_n)$ gives a field of force in the n -dimensional ($n \geq 2$) Euclidean space \mathbf{R}^n . Given a point P in \mathbf{R}^n and a measure μ , the functions $u(P)$ given by the integrals

$$u(P) = - \int \log \overline{PQ} \, d\mu(Q), \quad n = 2,$$

$$u(P) = \int \overline{PQ}^{2-n} \, d\mu(Q), \quad n \geq 3,$$

are typical examples of potential functions. They are called the **logarithmic potential** and **Newtonian potential**, respectively. However, some authors mean by Newtonian potential the function $u(P) = \int \overline{PQ}^{-1} \, d\mu(Q)$ in \mathbf{R}^3 . Usually, the measure μ is taken to be a nonnegative Radon measure with compact support. These potentials are superharmonic in \mathbf{R}^n and harmonic outside the support of μ . Conversely, any harmonic function defined on a domain in \mathbf{R}^n can be expressed as the sum of a potential of a single layer and a potential of a double layer (defined in the next paragraph). Because of this close relation between potentials and harmonic functions, sometimes potential

theory means the study of harmonic functions (\rightarrow 193 Harmonic Functions and Subharmonic Functions). (For the representation by potentials of superharmonic functions \rightarrow 193 Harmonic Functions and Subharmonic Functions S.)

Suppose that the measure μ of \mathbf{R}^3 satisfies $d\mu = \rho d\tau$ with sufficiently smooth density ρ and volume element $d\tau$. Then the Newtonian potential u of μ satisfies **Poisson's equation** $\Delta u = -4\pi\rho$. If the support of μ is contained in a surface S and $d\mu = \rho d\sigma$ with density ρ and surface element $d\sigma$, then the potential u of μ is called the potential of a **single layer** (or **simple distribution**). If ρ is continuous on S , then u is continuous in the whole space, and the †directional derivative of u at a point P in the direction of the normal line to S at P_0 tends to

$$-2\pi\rho(P_0) + \int_S \rho \frac{\partial}{\partial n_P} \frac{1}{PQ} \Big|_{P=P_0} d\sigma(Q)$$

as P approaches P_0 along the normal line. Therefore, as P moves on the line, the directional derivative jumps by $-4\pi\rho(P_0)$ at P_0 . If ρ satisfies the †Hölder condition at $P_0 \in S$, then the derivative at P in the direction of any fixed tangent line at P_0 has a finite limit as P tends to P_0 along the normal line. The integral

$$u(P) = \int_S \rho \frac{\partial}{\partial n_Q} \frac{1}{PQ} d\sigma(Q)$$

is called the potential of a **double layer** (or **double distribution**). If ρ is continuous on S , then the limits at P_0 of u from the two directions along the normal line at P_0 exist and are $2\pi\rho(P_0) + u(P_0)$ and $-2\pi\rho(P_0) + u(P_0)$. If, further, ρ is of class C^2 on S , then each partial derivative of u has a finite limit as P tends to a point of S .

B. Generalized Potential

The classical notion of potentials is generalized as follows: Let Ω be a space supplied with a measure $\mu (\geq 0)$ and $\Phi(P, Q)$ a real-valued function on the product space $\Omega \times \Omega$. When the integral $\int \Phi(P, Q) d\mu(Q)$ is well defined at each point $P \in \Omega$, it is called the **potential** of μ with **kernel** Φ and is denoted by $\Phi(P, \mu)$ or $\Phi\mu(P)$. The function $\check{\Phi}(P, Q) = \Phi(Q, P)$ is called the **adjoint kernel** of Φ . When

$$(\mu, \nu) = \iint \Phi(P, Q) d\mu(Q) d\nu(P) = \iint \check{\Phi}(P, Q) d\nu(Q) d\mu(P)$$

exists for measures $\mu, \nu \geq 0$, the value is called the **mutual energy** of μ and ν . In particular, (μ, μ) is called the **energy** of μ . The definition of

potential given above may be too general, and some restrictions are called for. We assume that Ω is a †locally compact Hausdorff space; Φ is a †lower semicontinuous function on $\Omega \times \Omega$ satisfying $-\infty < \Phi \leq \infty$; and μ, ν , and λ are nonnegative Radon measures with compact support in Ω . In particular, when $\Omega = \mathbf{R}^n$, the potential with the kernel $\Phi(P, Q) = \overline{PQ}^{-\alpha}$ ($0 < \alpha < n$) is called a **potential of order α** (sometimes of order $n - \alpha$) or a **Riesz potential**.

C. The Maximum Principle and the Continuity Principle

Let $\Omega = \mathbf{R}^n$, and let $\Phi(P, \mu)$ be the kernel of the Newtonian potential. Then $\Phi(P, \mu)$ satisfies the following principles: (1) **Frostman's maximum principle (first maximum principle)**: $\sup_{P \in \Omega} \Phi(P, \mu) \leq \sup_{P \in S_\mu} \Phi(P, \mu)$ for any μ , where S_μ is the support of μ . (2) **Ugaheri's maximum principle (dilated maximum principle)**: There is a constant $c \geq 0$ such that $\sup_{P \in \Omega} \Phi(P, \mu) \leq c \sup_{P \in S_\mu} \Phi(P, \mu)$ for any μ . (3) A variation of Ugaheri's maximum principle: Given any compact set $K \subset \Omega$, there exists a constant c which may depend on K such that $\sup_{P \in K} \Phi(P, \mu) \leq c \sup_{P \in S_\mu} \Phi(P, \mu)$ for any μ with $S_\mu \subset K$. (4) **Upper boundedness principle**: If $\Phi(P, \mu)$ is bounded from above on S_μ , then it is bounded on Ω also. (5) For any compact set $K \subset \Omega$ and any μ with $S_\mu \subset K$, if $\Phi(P, \mu)$ is bounded above on S_μ , then it is bounded on K also. (6) **Continuity principle**: If $\Phi(P, \mu)$ is continuous as a function on S_μ , then it is also continuous in Ω . Generally, the relations shown in Fig. 1 hold among principles (1)–(6), where (a) \rightarrow (b) means that (a) implies (b), and (c) \rightarrow (d) means the negation of (c) \rightarrow (d).

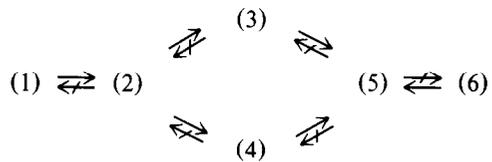

Fig. 1

If the continuity principle holds for a general kernel $\Phi(p, \mu)$ of a potential and if for any μ there is a sequence $\{P_k\}$ of points in $\Omega - S_\mu$ that has an accumulation point on S_μ and along which $\Phi(P_k, \mu) \rightarrow \sup_{\Omega - S_\mu} \Phi(P, \mu)$, then (1) holds also. The second condition is valid, for instance, when $\Omega = \mathbf{R}^n$, $\Phi(P, \mu)$ is †subharmonic in $\mathbf{R}^n - S_\mu$, and $\limsup \Phi(P, \mu) < \sup_{Q \in \mathbf{R}^n} \Phi(Q, \mu)$ as P tends to the point at infinity. T. Ugaheri, G. Choquet, and N. Ninomiya studied (2) and (6). Ugaheri showed that for any nonnegative decreasing function $\varphi(r)$ defined in $[0, \infty)$ and satisfying $\varphi(0) = \infty$, the kernel $\Phi(P, Q) = \varphi(\overline{PQ})$ satisfies (2) in \mathbf{R}^n . M. Ohtsuka established

that (6)→(5) and (5)→(6) in general and proved (5)→(6) in the special case where Φ is continuous on $\Omega \times \Omega$ in the wider sense (i.e., Φ may have ∞ as its value) and Φ is finite outside the diagonal set of $\Omega \times \Omega$. The examples in Sections F, I, and J show that the potentials with kernels satisfying a weak condition such as (6) possess a number of important properties. We note that (6) does not necessarily hold in general. (For literature on (1)–(6) and other related principles → [18].)

D. The Energy Principle

Denote by E the class of all measures of finite energy. A symmetric kernel is called **positive definite** (or of **positive type**) if $(\mu - \nu, \mu - \nu) = (\mu, \mu) + (\nu, \nu) - 2(\mu, \nu) \geq 0$ for any $\mu, \nu \in E$. If the equality $(\mu - \nu, \mu - \nu) = 0$ always implies $\mu = \nu$, then the kernel is said to satisfy the **energy principle**. Some characterizations for a kernel to be of positive type or to satisfy the energy principle were given by Ninomiya. Using them, he showed that a symmetric kernel that satisfies Frostman's maximum principle or the domination principle (→ Section L) and a certain additional condition is of positive type. Choquet and Ohtsuka generalized these definitions and results [18].

E. Topologies on Classes of Measures

Let C_0 be the space of continuous functions with compact support in Ω and M_0^+ be the class of measures in Ω . The \dagger seminorms $\mu \rightarrow \int f d\mu - \int f d\nu$ ($f \in C_0$) define the **vague topology** on M_0^+ . The class of unit distributions can be topologized by the vague topology, which induces a topology on Ω itself. This topology coincides with the original topology in Ω . A subclass M of M_0^+ is relatively compact with respect to the vague topology if on every compact set in Ω , the values of the measures of M are bounded. Denote by L the class of measures λ such that (λ, μ) is finite for all $\mu \in M_0^+$, and define the **fine topology** on M_0^+ by the seminorms $\mu \rightarrow |(\lambda, \mu) - (\lambda, \nu)|$ ($\lambda \in L$). This topology was introduced by H. Cartan [4] for the Newtonian kernel. It is the weakest topology that makes each $\check{\Phi}(P, \lambda)$, $\lambda \in L$, continuous. Further, when the kernel is of positive type, the **weak topology** is defined on E by the seminorms $\mu \rightarrow |(\lambda, \mu) - (\lambda, \nu)|$ ($\lambda \in E$). The **strong topology** is defined on E by the seminorm $\sqrt{(\mu - \nu, \mu - \nu)}$.

For the Newtonian kernel, Cartan [5] showed that vague < fine < weak < strong on E , where vague < fine, for instance, means that the fine topology is stronger than the vague

topology. He proved that the fine, weak, and strong convergences are equivalent for any sequence $\{\mu_n\}$ of measures with bounded energies. B. Fuglede [16] called a kernel of positive type **consistent** when any \dagger Cauchy net with respect to the strong topology that converges vaguely to a measure converges strongly to the same measure. This notion is used to give conditions for E to be \dagger complete with respect to the strong topology [11, 18]. Moreover, Fuglede called a consistent kernel satisfying the energy principle **perfect**, and studied the cases where \dagger convolution kernels on a locally compact topological group are consistent or perfect [11]. For instance, $P\bar{Q}^{-\alpha}$ ($0 < \alpha < n$) in \mathbf{R}^n and the Bessel kernel, which was studied by N. Aronszajn and K. T. Smith, are perfect.

F. Convergence of Sequences of Potentials

We are concerned with determining when a family of potentials corresponding to a class of measures $\{\mu_\omega\}$ with indices ω in a directed set converges. If all S_{μ_ω} are contained in a fixed compact set and μ_ω converges vaguely to μ_0 , then $\liminf \Phi(P, \mu_\omega) \geq \Phi(P, \mu_0)$ in Ω . If, moreover, Φ is continuous in the wider sense and both Φ and $\check{\Phi}$ satisfy the continuity principle, then equality holds quasi-everywhere (q.e.) in Ω in this inequality [18]; we now define the notion q.e. First, for a nonempty compact set K in Ω , define $W(K)$ to be $\inf(\mu, \mu)$, where $S_\mu \subset K$ and $\mu(K) = 1$, and $W(\emptyset)$ to be ∞ for the empty set \emptyset . Next, set $W_i(X) = \inf_{K \subset X} W(K)$ for an arbitrary set X in Ω and $W_e(X) = \sup_{X \subset G} W_i(G)$, where G is an open set in Ω . When a property holds except on a set X such that $W_e(X) = \infty$ (resp. $W_i(X) = \infty$), we say that the property holds **quasi-everywhere** (q.e.) (resp. **nearly everywhere** (n.e.)). The terms q.e. and n.e. are also used in the theory of \dagger capacity, although their meaning is not the same as here. (For results on the convergence of sequences of potentials → [18].)

G. Thin Sets

A set $X \subset \Omega$ is called **thin** at P_0 when either P_0 is an isolated point of the set $X \cup \{P_0\}$ with respect to the original topology of Ω or there exists a measure μ such that $\liminf \Phi(P, \mu) > \Phi(P_0, \mu)$ as $P \in X - \{P_0\}$ tends to P_0 . If P_0 is an isolated point of $X \cup \{P_0\}$ with respect to the topology weakest among those stronger than both the original topology and the fine topology, then X is thin with respect to the adjoint kernel $\check{\Phi}$. The converse is true in a special case [5]. The notion of thinness was

introduced in 1940 by M. Brelot and investigated in detail in [3]. Let $\varphi(r)$ be a positive decreasing function. Suppose there exist positive numbers r_0, δ, a such that $\varphi(r) \leq a\varphi((1 + \delta)r)$ in $0 < r < r_0$. Assume that Ω is a metric space with distance ρ , and take $\varphi(\rho(P, Q))$ as the kernel $\Phi(P, Q)$. Then a necessary and sufficient condition for X to be thin at P_0 is $\sum_{j=1}^{\infty} s^j/W_e(X_j) < \infty$ ($s > 1$) [19], where $X_j = \{P \in X \mid s^j \leq \varphi(\rho(P, P_0)) \leq s^{j+1}\}$. This criterion was obtained by N. Wiener in 1924 and utilized to give a condition for a boundary point P_0 of a domain D in \mathbf{R}^3 to be regular with respect to the \dagger Dirichlet problem for D . In this situation, P_0 is regular if and only if the complement of D is thin at P_0 . When every compact subset of X is thin at P_0 , X is called **internally thin** at P_0 . A necessary and sufficient condition for X to be internally thin at P_0 is $\sum s^j/W_i(X_j) < \infty$.

H. Polar Sets

Brelot (1941) called a set A **polar** when there is a measure μ for which $\Phi(P, \mu) = \infty$ on A . Consider $\check{U}(\Omega, K) (= V(K, \Omega))$ as defined in 48 Capacity C, and define $\check{U}_e(\Omega, X)$ by $\sup_{G \supset X} \inf_{K \subset G} \check{U}(\Omega, K)$ for an arbitrary set X , where G is an open set. Then for any $\mu, X = \{P \mid \Phi(P, \mu) = \infty\}$ is a G_δ set for which the value of $\check{U}_e(\Omega, X)$ is infinite. Conversely, given a G_δ set A of \dagger Newtonian outer capacity zero in \mathbf{R}^n ($n \geq 3$), there is a measure μ such that the set of points where the Newtonian potential of μ is equal to ∞ coincides with A and $\mu(\mathbf{R}^n - A) = 0$ (Choquet [7]). This result is called **Evans's theorem** (or the **Evans-Selberg theorem**) (\rightarrow 48 Capacity) in the special case where A is compact.

I. Quasicontinuity

A function f in Ω is called **quasicontinuous** if there is an open subset G in Ω of arbitrarily small capacity such that the restriction of f to $\Omega - G$ is continuous. Naturally, quasicontinuity depends on the definition of capacity. Suppose that whenever the potential of a measure μ with kernel Φ is continuous as a function on S_μ it is quasicontinuous in Ω ; Φ is then said to satisfy the **quasicontinuity principle**. Assuming in addition that Φ is positive symmetric and taking $1/U(\Omega, G)$ as the capacity of G , we find that every potential is quasicontinuous in Ω (M. Kishi). A similar result is valid for a non-symmetric kernel if the continuity principle is assumed (Choquet [6]).

J. The Gauss Variational Problem

Given a compact set K and a function f on K , the problem of minimizing the **Gauss integral** $(\mu, \mu) - 2 \int f d\mu$ for a measure μ such that $S_\mu \subset K$ is called the **Gauss variational problem**. When an additional condition is imposed on μ , the problem is called conditional. Among many results obtained for this problem [18], the following is typical: If Φ is symmetric, K supports a nonzero measure of finite energy, and f is finite upper semicontinuous on K , then there exists a μ such that $f(P) \leq \Phi(P, \mu)$ n.e. on K and $f(P) \geq \Phi(P, \mu)$ on S_μ . When Φ is not symmetric, the same relations hold for some μ if Φ is positive and $\check{\Phi}$ satisfies the continuity principle (Kishi [15]), although the method using Gauss variation is not applicable. When Φ is symmetric and of positive type, the Gauss integral with $f(P) = \Phi(P, v)$ ($v \in E$) is equal to $\|\mu - v\|^2 - \|v\|^2$, and the minimizing problem is equivalent to finding the projection of v to $\{\mu \in E \mid S_\mu \subset K\}$. In some cases, this projection is equal to the measure obtained by the balayage of v to K (\rightarrow Section L).

K. Equilibrium Mass Distributions

A unit measure μ supported by a compact set K is called an **equilibrium mass distribution** on K if $\Phi(P, \mu)$ is equal to a constant a n.e. on K and $\Phi(P, \mu) \leq a$ in Ω . The kernel is said to satisfy the **equilibrium principle** if there exists an equilibrium mass distribution on every compact set. If $a > 0$, $1/a$ can be regarded as a kind of capacity, and μ/a is called a **capacitary mass distribution**. Corresponding to inner and outer capacities, inner and outer capacity mass distributions and their coincidence can be discussed [11]. When Φ is symmetric, Frostman's maximum principle is equivalent to the equilibrium principle.

L. The Sweeping-Out Principle

A kernel is said to satisfy the **sweeping-out principle** (or **balayage principle**) if for any compact set K and measure μ there exists a measure ν supported by K such that $\Phi(P, \nu) = \Phi(P, \mu)$ n.e. on K and $\Phi(P, \nu) \leq \Phi(P, \mu)$ in Ω . When we find such a ν , we say that we **sweep out** μ to K , and finding ν is called a **sweeping-out process** (or **balayage**). This terminology originated in the classical process for the Newtonian potential in which the exterior of K is covered by a countable number of balls and the masses inside the balls are repeatedly swept out onto the spherical surfaces. For any general kernel, the balayage principle implies

the **domination principle** (also called **Cartan's maximum principle**), which asserts that if the inequality $\Phi(P, \mu) \leq \Phi(P, \nu)$ is valid on S_μ for $\mu \in E$ and any ν , then the same inequality holds in Ω . The converse is true if Φ is positive, symmetric, continuous in the wider sense, and finite outside the diagonal set. In contrast to the domination principle, Φ is said to satisfy the **inverse domination principle** if the inequality $\Phi(P, \mu) \leq \Phi(P, \nu)$ on S_ν for $\mu \in E$ and any ν implies the same inequality in Ω . In a special case, the domination principle implies Frostman's maximum principle [17]. For the equilibrium and domination principles for non-symmetric kernels \rightarrow [14].

Corresponding to inner and outer capacity mass distributions, we can examine inner and outer balayage mass distributions and inner and outer Gauss variational problems and their coincidences [5, 18]. With respect to the Newtonian potential, a point P is called an **internally (externally) irregular point** of X if the inner (outer) balayage mass distribution to X of the unit measure ε_P at P is different from ε_P . X is thin (internally thin) at P if and only if P is an externally (internally) irregular point of X (Cartan [5]).

M. Other Principles

A kernel Φ is said to satisfy the **uniqueness principle** if $\mu \equiv \nu$ follows from the equality $\Phi(P, \mu) = \Phi(P, \nu)$, which is valid n.e. in Ω . Nino-miya and Kishi studied this principle. A kernel Φ is said to satisfy the **lower envelope principle** if given μ and ν , there is a λ such that $\Phi(P, \lambda) = \min(\Phi(P, \mu), \Phi(P, \nu))$. If Φ satisfies the domination principle and Φ satisfies the continuity principle, then Φ satisfies the lower envelope principle on every compact set considered as a space. Conversely, if Φ satisfies the lower envelope principle on every compact set considered as a space, then Φ satisfies the domination principle or the inverse domination principle under some additional conditions (Kishi). A kernel is said to satisfy the **complete maximum principle** if the inequality $\Phi(P, \mu) \leq \Phi(P, \nu) + a$ on S_μ implies the same inequality in Ω for $\mu \in E$, any ν , and $a \geq 0$ (Cartan and J. Deny, 1950). This principle implies both Frostman's maximum principle and the domination principle. Potentials of order α ($n - 2 \leq \alpha < n$) in \mathbf{R}^n and the **Yukawa potential** with kernel $a\overline{PQ}^{-1} \exp(-\lambda\overline{PQ})$ in \mathbf{R}^3 satisfy the complete maximum principle. Relations between this principle and some other principles were studied by Kishi [14].

While all principles discussed so far are global, Choquet and Ohtsuka made a local study.

N. Diffusion Kernels

By means of the bilinear form $\int f d\mu$ ($f \in C$, $\mu \in M_0$), we now introduce weak topologies in the space C of continuous functions in Ω and in the class M_0 of Radon measures of general sign with compact support. Similarly, we introduce weak topologies in C_0 and in the class M of measures of general sign with not necessarily compact support. A positive linear mapping G of M_0 into M that is continuous with respect to these two weak topologies is called a **diffusion kernel**. The linear mapping G^* of C_0 into C that is determined by $\int f dG\mu = \int G^*f d\mu$ is called a **transposed mapping**. We can define the balayage principle for G and the domination principle for G^* as in the case where kernels are functions. Then G satisfies the balayage principle if and only if G^* satisfies the domination principle (Choquet and Deny). The complete maximum principle has been defined and studied for G^* (Deny). G. A. Hunt obtained a relation between this principle and the representation of G^*f in the form $\int_0^\infty P_t f dt$ with a \dagger semigroup P_t . His result is important in the theory of \dagger stochastic processes (\rightarrow 261 Markov Processes).

O. Convolution Kernels

A diffusion kernel G on a locally compact Abelian group induces a convolution kernel κ if G is translation-invariant. It is called a **Hunt kernel** when there exists a vaguely continuous semigroup $\{\alpha_t\}_{t \geq 0}$ such that $\kappa = \int_0^\infty \alpha_t dt$ and $\alpha_0 = \varepsilon_0$, the Dirac measure at the origin. A Hunt kernel satisfies the domination principle and the balayage principle to all open sets, and it satisfies the complete maximum principle if and only if $\{\alpha_t\}_{t \geq 0}$ is sub-Markovian, $\int d\alpha_t \leq 1$. The Fourier transform of such a semigroup has a closed connection with a negative-definite function [1].

For a convolution kernel κ satisfying the domination principle, or, equivalently, the balayage principle, the inequality

$$\kappa(\omega_1)\kappa(\omega_2) \leq \kappa(\omega_1 - \omega_1)\kappa(\omega_1 + \omega_2)$$

is valid for all relatively compact open sets ω_1 and ω_2 [8]. It has a unique decomposition $\kappa = \varphi \cdot (\kappa_0 + \kappa_1)$, where φ is a continuous exponential function, κ_0 is equal to 0 or a Hunt kernel satisfying the complete maximum principle, and κ_1 is a singular kernel satisfying the domination principle such that $\kappa_1 * \varepsilon_x = \kappa_1$ for every $x \in S_{k_0}$ [12].

P. Potentials with Distribution Kernels

A function f in \mathbf{R}^n is called **slowly increasing in the sense of Deny** if there exists a positive

integer q such that $\int f(P)(1 + \overline{OP}^2)^{-q} d\tau(P) < \infty$. A †distribution K is called a **distribution kernel** if the †Fourier transform FK of K is a function $k \geq 0$ and both k and $1/k$ are slowly increasing in the sense of Deny. Given such a distribution K , the family W of distributions T for which FT are functions and $\|T\|^2 = \int k(FT)^2 d\tau < \infty$ (this is called the energy of T) is a †Hilbert space with inner product $(T_1, T_2) = \int kFT_1 FT_2 d\tau$. However, the family of Newtonian potentials of measures with finite energy is not a Hilbert space (Cartan). The family of functions of class C^∞ with compact support is †dense in W . For every $T \in W$ the function $FK \times FT$ is slowly increasing in the sense of Deny. There exists a distribution $U = U^T$ that satisfies $FU = FK \times FT$, called the K -potential of T . Since W is complete, the method of projection is applicable, and problems of equilibrium, balayage, and capacity can be examined. For instance, if †Dirac's distribution δ is taken as a distribution kernel, then the corresponding capacity is the Lebesgue measure. In the case of the Newtonian kernel, $\partial U^T / \partial x_j = f_j$ is defined a.e. in \mathbf{R}^n for any $T \in W$. These f_j are square integrable, $T = -c_n \sum_{j=1}^n \partial f_j / \partial x_j$, and $\|T\|^2 = c_n \sum_{j=1}^n \int |f_j|^2 d\tau$, where $1/c_n = 2(n-2)\pi^{n/2} / \Gamma(n/2)$. Furthermore,

$$U^T = (n-2) \int \sum_{j=1}^n (x_j - y_j) f_j(Q) \overline{PQ}^{-n} d\tau(Q),$$

where x_j, y_j are components of P, Q , respectively. Every ordinary potential of a double layer is a special case of U^T . Conversely, let f be a function in \mathbf{R}^n that is absolutely continuous along almost every line parallel to each coordinate axis and whose partial derivatives are square integrable. Then f is equal to the potential of some $T \in W$ with Newtonian kernel up to an additive constant. These results are due to Deny [9].

Q. Dirichlet Spaces

In this section, functions are assumed to be complex-valued. Let Ω be a locally compact Hausdorff space, $\xi \geq 0$ a Radon measure in Ω , and C_0 the space of continuous functions with compact support. A Hilbert space D consisting of locally ξ -integrable functions is called a **Dirichlet space** if $C_0 \cap D$ is dense in both C_0 and D , the relations $|v(P) - v(Q)| \leq |u(P) - u(Q)|$ and $|v(P)| \leq |u(P)|$ for $u \in D$ and a function v always imply $v \in D$ and $\|v\| \leq \|u\|$, and for any compact set $K \subset \Omega$, there exists a constant $A(K)$ such that $\int_K |u| d\xi \leq A(K) \|u\|$ for every $u \in D$. The notion of Dirichlet space was introduced by A. Beurling. A function $u \in D$ is called a potential if there exists a Radon measure μ such that $(u, \varphi) = \int \bar{\varphi} d\mu$ holds for every

338 Ref. Potential Theory

$\varphi \in C_0 \cap D$. If in addition $\mu \geq 0$, then u is called a pure potential. For any pure potential, the lower envelope principle, the equilibrium principle, the balayage principle, and the complete maximum principle hold [2]. Suppose that Ω is a locally compact Abelian group and D is a Dirichlet space such that $U_y u(x) = u(x - y) \in D$ and $\|U_y u\| = \|u\|$ for every $u \in D$ and $y \in \Omega$. Then we call D special and characterize it in terms of a real-valued continuous function on Ω [2]. (For axiomatic potential theory → 193 Harmonic Functions and Subharmonic Functions.)

339 (XI.2) Power Series

A. General Remarks

Let a and c_0, c_1, c_2, \dots be elements of a \dagger field K and z be a variable. A series of the form $P = \sum_{n=0}^{\infty} c_n(z-a)^n$ is called a **power series** (in one variable). We assume that K is the field of complex numbers. For a given power series P , we can determine a unique real number R ($0 \leq R \leq \infty$) such that P converges if $|z-a| < R$ and diverges if $R < |z-a|$. We call R the **radius of convergence** and the circle $|z-a| = R$ (sometimes $|z-a| < R$) the **circle of convergence** of P . The value of R is given by $R = 1/\limsup \sqrt[n]{|c_n|}$ (**Cauchy-Hadamard formula**) with the conventions $0 = 1/\infty$, $\infty = 1/0$. Also $R = \lim |c_n/c_{n+1}|$, provided that the limit on the right-hand side exists.

A power series \dagger converges absolutely and uniformly on every compact subset inside its circle of convergence and defines there a single-valued complex function. Since the series is \dagger termwise differentiable, the function is actually a holomorphic function of a complex variable. Conversely, any function $f(z)$ holomorphic in a domain can be represented by a power series in a neighborhood of each point a of the domain. Such a representation is called the **Taylor expansion** of $f(z)$ at a (or in the neighborhood of a). A power series that represents a holomorphic function is called a **holomorphic function element**. K. Weierstrass defined an analytic function as the set of all elements that can be obtained by \dagger analytic continuations starting from a given function element (\rightarrow 198 Holomorphic Functions).

Besides the series $\sum_{n=0}^{\infty} c_n(z-a)^n$, a series of the form $Q = \sum_{n=0}^{\infty} c_n z^{-n}$ is called a **power series with center at the point at infinity**, and its value at ∞ is defined to be c_0 . By putting $z-a = t$ when its center a is a finite point and $z^{-1} = t$ when its center is ∞ , every power series can be

written in the form $\sum_{n=0}^{\infty} c_n t^n$, and such a t is called a **local canonical parameter**.

When t is a local canonical parameter, a series of the form $\sum_{n=-\infty}^{\infty} c_n t^n$ is called a **Laurent series** and a series $\sum_{n=-\infty}^{\infty} c_n t^{n/k}$ (k a fixed natural number) is called a **Puiseux series**, after the French mathematicians A. Laurent and V. A. Puiseux. Power series are sometimes called **Taylor series**.

If we perform \dagger analytic continuations of a power series from its center along radii of its circle of convergence, we encounter a \dagger singularity on the circumference for at least one radius. For a power series with the circle of convergence $|z| = R$, the argument α of the singularity on $|z| = R$ nearest $z = R$ is given in the following way. Suppose, for simplicity, that the radius of convergence R of $\sum c_n z^n$ equals 1, and put

$$\rho_n(h) = \sum_{v=0}^n \binom{n}{v} c_{n-v} h^v,$$

$$P(h) = \limsup_{n \rightarrow \infty} \sqrt[n]{|\rho_n(h)|}.$$

Then α is obtained from

$$\cos \alpha = P'_+(0) = \lim_{h \rightarrow +0} (P(h) - 1)/h$$

(S. Mandelbrojt, 1937). In particular, if all the c_n are real and nonnegative, $z = R$ is a singularity (Vivanti's theorem).

B. Abel's Continuity Theorem

As a property of the power series on the circle of convergence, we have **Abel's continuity theorem**: If the radius of convergence of $f(z) = \sum_{n=0}^{\infty} a_n z^n$ is equal to 1 and $\sum_{n=0}^{\infty} a_n$ converges (or is $\dagger(C, k)$ -summable ($k > -1$)) to A , then $f(z) \rightarrow A$ when z approaches 1 in any sector $\{z \mid |z| < 1, |\arg(1-z)| < (\pi/2) - \delta\}$, $\delta > 0$ (\dagger Stolz's path).

The converse of this theorem is not always true. The existence of $\lim_{z \rightarrow 1} f(z)$ does not necessarily lead to the convergence of $\sum_{n=0}^{\infty} a_n$. Even Cesàro summability of $\sum_{n=0}^{\infty} a_n$ does not always follow from the existence of $\lim_{z \rightarrow 1} f(z)$. If $a_n = o(1/n)$ and $f(z) \rightarrow A$ when z approaches 1 along a curve ending at $z = 1$, then $\sum a_n$ converges to A (**Tauber's theorem**, 1897). The theorems concerning additional sufficient conditions for the validity of the converse of Abel's theorem are called **theorems of Tauberian type** (or **Tauberian theorems**). In Tauber's theorem, the hypothesis on the a_n may be replaced by $a_n = O(1/n)$ or $n \operatorname{Re} a_n, n \operatorname{Im} a_n$ may be bounded from above but not necessarily from below (G. H. Hardy and J. E. Littlewood). Here, the condition $a_n = O(1/n)$ cannot be weakened (Littlewood). Sufficient condi-

tions for $\sum a_n$ to be †summable for various summation methods are also known.

C. Lambert Series

A series of the form

$$\sum_{n=1}^{\infty} a_n \frac{z^n}{1-z^n}, \quad |z| \neq 1, \tag{1}$$

is called a **Lambert series**. If $\sum a_n$ is convergent, (1) converges for any z with $|z| \neq 1$, and moreover, it converges uniformly on any compact set contained in $|z| < 1$ or $|z| > 1$. If $\sum a_n$ is divergent, (1) and the power series $\sum a_n z^n$ converge or diverge simultaneously for $|z| \neq 1$.

There is a detailed study of Lambert series by K. Knopp (1913). If R is the radius of convergence of $\sum a_n z^n$ and $\sum_{d|n} a_d = A_n$ is the sum extending over all divisors of n , then we have the reciprocity relation

$$\sum_{n=1}^{\infty} a_n \frac{z^n}{1-z^n} = \sum_{n=1}^{\infty} A_n z^n,$$

which holds for $|z| < \min(R, 1)$. As special cases of this relation, we have

$$z = \sum_{n=1}^{\infty} \mu(n) \frac{z^n}{1-z^n},$$

$$\frac{z}{(1-z)^2} = \sum_{n=1}^{\infty} \varphi(n) \frac{z^n}{1-z^n},$$

where μ and φ are the †Möbius function and †Euler function, respectively.

If the na_n are real and bounded from below,

$$\lim_{z \rightarrow 1-0} \sum_{n=1}^{\infty} (1-z)na_n \frac{z^n}{1-z^n} = s$$

implies $\sum a_n = s$. Hardy and Littlewood (1921) showed that this theorem of Tauberian type is equivalent to the †prime number theorem.

D. Singularities of Power Series

Given a power series $P = \sum a_n z^n$, if the †branch in $|z| < R^*$ of the analytic function $f(z)$ determined by P is single-valued meromorphic but the branch in $|z| < R'$ with $R' > R^*$ has singularities other than poles, then R^* is called the **radius of meromorphy** of P and $|z| = R^*$ (sometimes $|z| < R^*$) is called the **circle of meromorphy** of P . R^* can be computed in the following way. Put

$$l_p = \limsup_{n \rightarrow \infty} |\sqrt[n]{D_n^{(p)}}|,$$

$$D_n^{(p)} = \begin{vmatrix} a_n & a_{n+1} & \dots & a_{n+p} \\ a_{n+1} & a_{n+2} & \dots & a_{n+p+1} \\ \dots & \dots & \dots & \dots \\ a_{n+p} & a_{n+p+1} & \dots & a_{n+2p} \end{vmatrix}.$$

Then the sequence of numbers l_{p-1}/l_p is increasing, and $\lim l_{p-1}/l_p = R^*$. If R_1, R_2, \dots are different valued of l_{p-1}/l_p , then $f(z)$ is holomorphic at points not lying on $|z| = R_n$ (**Hadamard's theorem**, 1892).

When a point a and a set A of points in the complex plane are given, the set of points that can be joined with a by a segment disjoint from A is called the **star region** determined by a and A . Take any half-line starting at a ; the point of A lying on it and nearest to a is called a **vertex**. For a power series $\sum c_n z^n$, the set of centers of the function elements obtained by analytic continuations along half-lines starting at the origin is called the **star region** of $\sum c_n z^n$ with respect to the origin. Let $\{\alpha\}$ and $\{\beta\}$ be the set of vertices of the star regions with respect to the origin of $\sum a_n z^n$ and $\sum b_n z^n$, respectively. Then the star region determined by the origin and the set $\{\alpha\beta\}$ is contained in the star region of $\sum a_n b_n z^n$ (**Hadamard's multiplication theorem**, 1892).

The following are some results concerning conditions for the coincidence of the circle of convergence of a power series and its †natural boundary. Let the a_n be positive numbers and b a natural number greater than 1. If the radius of convergence of $\sum_{n=0}^{\infty} a_n z^{bn}$ is equal to 1, then $|z| = 1$ is its natural boundary (Weierstrass, E. I. Fredholm). If the radius of convergence of $\sum_{n=0}^{\infty} a_n z^{\lambda_n}$ (with $\{\lambda_n\}$ an increasing sequence of natural numbers) is 1 and $\liminf_{n \rightarrow \infty} (\lambda_{n+1} - \lambda_n)/\lambda_n > 0$, then $|z| = 1$ is the natural boundary (**Hadamard's gap theorem**). The latter condition was weakened to $\liminf_{n \rightarrow \infty} (\lambda_{n+1} - \lambda_n)/\sqrt{\lambda_n} > 0$ by E. Borel (1896). E. Fabry (1896) showed that with the radius of convergence of $\sum_{n=0}^{\infty} a_n z^n$ being 1, if there exist a suitable sequence of natural numbers $m_1 < m_2 < \dots$ and a number θ ($0 < \theta < 1$) such that $\lim s_i/m_i = 0$, where the s_i are the number of nonzero a_n contained in the interval $(m_i(1-\theta), m_i(1+\theta))$, then $|z| = 1$ is the natural boundary of $\sum a_n z^n$. By applying this theorem to $\sum a_n z^{\lambda_n}$ with radius of convergence 1, it can be shown that if $\lim_{n \rightarrow \infty} \lambda_n/n = \infty$, then $|z| = 1$ is its natural boundary. These theorems are called **gap theorems** because they concern power series with gaps in their exponents. A generalization of Fabry's theorem was obtained by G. Pólya. It is known that Fabry's last condition above is in a sense the best possible (Pólya, 1942).

Regarding the natural boundary of a power series, we also have the following result: When the radius of convergence of $\sum a_n z^n$ is 1, by a suitable choice of the sequence $\{\varepsilon_n\}$ ($\varepsilon_n = \pm 1$), the series $\sum \varepsilon_n a_n z^n$ has $|z| = 1$ as its natural boundary (A. Hurwitz, P. Fatou, Pólya).

E. Overconvergence

If the radius of convergence of $f(z) = \sum a_n z^n$ is 1, the sequence of partial sums $S(1, z), S(2, z), \dots$, where $S(n, z) = \sum_{v=0}^n a_v z^v$, is naturally divergent for $|z| > 1$, but a suitable subsequence $S(n_k, z)$ ($k = 1, 2, \dots$) may still be convergent. A. Ostrowski [7, 8] called this phenomenon **overconvergence** and proved the following result: By definition, $f(z) = \sum_{n=0}^{\infty} a_n z^n$ has a **lacunary structure** if the sequence $\{\lambda_n\}$ has a subsequence $\{\lambda_{n_k}\}$ such that $\lambda_{n_{k+1}} > \lambda_{n_k}(1 + \theta)$ ($\theta > 0$). If this situation occurs, then in a sufficiently small neighborhood of a point on $|z| = 1$ where $f(z)$ is holomorphic, $S(\lambda_{n_k}, z)$ ($k = 1, 2, \dots$) converges uniformly. This result includes Hadamard's gap theorem as a special case. Conversely, any power series for which overconvergence takes place can be represented as the sum of a power series having a lacunary structure and a power series whose radius of convergence is greater than 1. G. Bourion [9] gave a unified theory of these results using †superharmonic functions.

R. Jentsch [10] showed that all singularities of a power series on its circle of convergence are accumulation points of the zeros of the partial sums. On the other hand, if the zeros of a subsequence $S(n_k, z)$ ($k = 1, 2, \dots$) has no accumulation point on $|z| = 1$, then the power series has a lacunary structure and overconvergence takes place for $S(n_k, z)$ ($k = 1, 2, \dots$). If $\log n_{k+1} = O(n_k)$ and $S(n_k, z)$ ($k = 1, 2, \dots$) is overconvergent, then all boundary points of the domain of overconvergence are accumulation points of the zeros of $S(n_k, z)$ (Ostrowski [8]).

A power series is completely determined by its coefficients, but little is known about the relations between the arithmetical properties of its coefficients and the function-theoretic properties of the function represented by the series. A known result is that if the power series $\sum c_n z^n$ with rational coefficients represents a branch of an †algebraic function, then we can find an integer γ such that the $c_n \gamma^n$ ($n \geq 1$) are all integers (Eisenstein's theorem, 1852).

Probabilistic Methods in
Statistical Mechanics**

A. Introduction

Probabilistic methods are often very useful in the rigorous treatment of the mathematical foundations of statistical mechanics and also in some other problems related to statistical mechanics. As examples of such methods, we explain here (1) Ising models, (2) Markov statistical mechanics, (3) percolation processes, (4) random Schrödinger equations, and (5) the †Boltzmann equation.

B. Ising Models

The **Ising model** was proposed by E. Ising [1] to explain the **phenomena of phase transitions** of a ferromagnet, in which either a + or – spin is put on each site of a crystal lattice, and interaction between nearest neighboring sites is taken into consideration.

Let V be a cube in the d -dimensional integer lattice space \mathbf{Z}^d and $X_v = \{+1, -1\}^V$ be the totality of spin configurations in V . Each ele-

ment of X_V is denoted by $\sigma = \{\sigma_i\}_{i \in V}$ ($\sigma_i = +1$ or -1). We suppose that a spin configuration σ has a potential of the type

$$U_V(\sigma) = - \sum_{\langle i,j \rangle \subset V} \sigma_i \sigma_j + h \sum_{i \in V} \sigma_i,$$

where $\langle i,j \rangle$ means that (i,j) is a nearest neighboring pair of sites and h stands for the parameter of an external field. A †probability measure on X_V is called a **state** on V . For each state μ , the **free energy** is defined by

$$F_V(\mu) = \sum_{\sigma \in X_V} \mu(\sigma) U_V(\sigma) + \frac{1}{\beta} \sum_{\sigma \in X_V} \mu(\sigma) \log \mu(\sigma),$$

where $\beta = 1/kT$ (k is the †Boltzmann constant, T is the †absolute temperature). Then there exists a unique state

$$g_V^{\beta,h}(\sigma) = \frac{\exp(-\beta U_V(\sigma))}{\sum_{\gamma \in X_V} \exp(-\beta U_V(\gamma))}, \quad \sigma \in X_V,$$

on V which minimizes the free energy F_V (**variational principle**). $g_V^{\beta,h}$ is called a **Gibbs state** on V of the Ising model with parameter (β, h) . Physically, a Gibbs state is an **equilibrium state**, in which various physical quantities are calculated.

Since for each \mathbf{Z}^d -homogeneous (i.e., translationally invariant with respect to \mathbf{Z}^d) state μ the **mean free energy**

$$f(\mu) = \lim_{V \rightarrow \mathbf{Z}^d} \frac{1}{|V|} F_V(\mu)$$

is well defined, a (limiting) Gibbs state can also be defined for the infinite domain $V = \mathbf{Z}^d$ by the above mentioned variational principle. However, at present the probabilistic definition of Gibbs states given by Dobrushin [2] and Lanford and Ruelle [3] is prevalent.

It is known that if an external field is present (i.e., $h \neq 0$) there is only one Gibbs state for any β . On the other hand when an external field is absent ($h = 0$) and $d \geq 2$, there are at least two Gibbs states, i.e., a phase transition occurs, for a sufficiently low temperature.

Finally, we mention some known facts in this field. In the following we assume $h = 0$. (1) In the 1-dimensional case, the phase transition never occurs. (2) For $d \geq 2$, there exists a **critical value** $\beta_c(d)$ such that the phase transition does not occur for any $\beta < \beta_c(d)$ but it occurs for every $\beta > \beta_c(d)$. The calculation of $\beta_c(2)$ has been carried out by Onsager [4]. (3) In the 2-dimensional case, every Gibbs state is \mathbf{Z}^2 -homogeneous [5, 6]. (4) For $d \geq 3$, there is a \mathbf{Z}^d -inhomogeneous Gibbs state for sufficiently large β [7].

C. Markov Statistical Mechanics

Stochastic Ising models, infinite interacting particle systems, and many models occurring

in physics, biology, and sociology are formulated as a class of infinite-dimensional †Markov processes. The field of investigation of stationary states and statistical or ergodic properties of these processes is called **Markov statistical mechanics**, which has made rapid progress during the last decade. We explain this field by looking at a typical class of processes.

Let \mathbf{Z}^d be the d -dimensional integer lattice space. Putting $+$ or $-$ spin on each site on \mathbf{Z}^d , let us consider a random motion of spins which evolves while interacting with neighboring spins. Let $X = \{+1, -1\}^{\mathbf{Z}^d}$ be the totality of spin configurations and an element of X be denoted by $\eta = \{\eta(i)\}_{i \in \mathbf{Z}^d}$ ($\eta(i) = +1$ or -1). The process is described in terms of a collection of nonnegative functions $c_i(\eta)$ defined for $i \in \mathbf{Z}^d$ and $\eta \in X$. For the configuration η_t at time t , $\eta_t(i)$ changes to $-\eta_t(i)$ in the time interval $[t, t + \Delta t]$ with probability $c_i(\eta_t) \Delta t + o(\Delta t)$. This process on X is called a spin-flip model. For an initial distribution μ we denote by μ_t the distribution at time t . If $\mu_t = \mu$ for all $t \geq 0$, μ is called a **stationary state**.

Example 1. Stochastic Ising models. A **stochastic Ising model** was proposed by Glauber [8] to describe the random motion in a ferromagnet upon contact with a heat bath. Then the flip rate $\{c_i(\eta)\}$ is defined by the potential of the Ising model. It is known that any Gibbs state of the Ising model is a reversible stationary state of the stochastic Ising model, and the converse is also valid. Free energy plays an important role in the study of the ergodic properties of these models. In particular, the mean free energy is a nondecreasing functional along the distributions μ_t , $0 \leq t < \infty$.

Example 2. Contact processes. A **contact process** was introduced by Harris [11] to investigate the spread of infection. The flip rate of the contact process is given by

$$c_i(\eta) = \begin{cases} 1 & \text{if } \eta(i) = +1, \\ k\lambda & \text{if } \eta(i) = -1 \quad \text{and} \\ & \# \{j \mid |j-i|=1, \eta(j) = +1\} = k. \end{cases}$$

Here $+1$ denotes an infected individual and -1 denotes a healthy one. Denote by δ_{-1} the configuration at which all sites are healthy and by δ_{-1} the unit point mass at -1 ; then δ_{-1} is a stationary state. The most important result is the following: There exists a **critical value** λ_d ($0 < \lambda_d < \infty$) such that if $\lambda < \lambda_d$ δ_{-1} is a unique stationary state, and if $\lambda > \lambda_d$ there is another stationary state μ satisfying

$$\mu[\eta \in X; \eta(i) = +1 \text{ for infinitely many } i] = 1.$$

D. Percolation Processes

A **percolation process** is a mathematical model which describes the random spread of a fluid

through a medium. It can be used to describe phenomena such as the penetration through a porous solid by a liquid or the spread of an infectious disease [14]. Usually, the process is identified as a **site percolation process** or a **bond percolation process**. Here we describe the latter only.

Let $L = \{S, B\}$ be a countable connected \dagger graph with a set of sites (\dagger vertices) S and a set of bonds (\dagger edges) B . Each bond b is open with probability p and closed with probability $1 - p$ independently of all other bonds. Suppose that a fixed point o is the source of a fluid which flows from o along open bonds only.

Let $\theta(p)$ be the probability that the fluid spreads infinitely far, and define the **critical percolation probability** $p_H = \inf\{p | \theta(p) > 0\}$. Then it is known that (1) $p_H = 1/2$ for the square lattice [16], (2) $p_H = 2 \sin(\pi/18)$ for the triangular lattice, and (3) $p_H = 1 - 2 \sin(\pi/18)$ for the honeycomb lattice.

E. Random Schrödinger Equations

Random Schrödinger equations are \dagger Schrödinger equations in \mathbf{R}^n with random potentials $U(x, \omega)$; therefore the corresponding operators are of the form

$$A(\omega) = -\Delta + U(\cdot, \omega),$$

where ω denotes a random parameter in a probability space $(\Omega, \mathfrak{F}, P)$ and Δ denotes the \dagger Laplacian in \mathbf{R}^n . It is assumed that this system of potentials forms a spatially homogeneous random field with the \dagger ergodic property. This system of equations is considered to be a model describing the motion of quantum-mechanical particles in a random medium. Mathematically, the problem is to investigate various spectral properties of the self-adjoint operators $A(\omega)$. Since $A(\omega)$ and its shifted operator $A(\omega(\cdot + x))$ are \dagger unitarily equivalent, the above assumption on the potentials $U(\cdot, \omega)$ implies that the spectral structures are independent of each sample ω a.s. if their structures of $A(\omega)$ are measurable with respect to (Ω, \mathfrak{F}) .

Several rigorous results have been obtained. In the 1-dimensional case, if the potentials $U(\cdot, \omega)$ are functionals of a strongly ergodic \dagger Markov process, then it is proved that $A(\omega)$ has only a pure point spectrum [17], and each eigenfunction decays exponentially fast [18]. In multidimensional cases, asymptotic behavior at the left edge of the mean of the resolutions of the identity for a certain $A(\omega)$ have been investigated [19]. It is assumed that the random potential for this $A(\omega)$ takes the form

$$U(x, \omega) = \int_{\mathbf{R}^n} \varphi(x - y) \pi(dy, \omega),$$

where $\{\pi(dy, \omega)\}$ is a \dagger Poisson random measure with mean measure dy and $\varphi(x)$ is a non-negative measurable function satisfying $\varphi(x) = o(|x|^{-n-2})$ as $|x| \rightarrow \infty$. Let $E_\lambda(x, y, \omega)$ be the continuous kernel for the resolution of the identity for $A(\omega)$, and denote by $N(\lambda)$ the mean of $E_\lambda(0, 0, \omega)$. Then $N(\lambda)$ is a nondecreasing function vanishing on $(-\infty, 0)$ and has the following asymptotic form at $\lambda = 0$:

$$\lambda^{n/2} \log N(\lambda) \rightarrow -\gamma_1^{n/2} \quad \text{as } \lambda \rightarrow 0,$$

where γ_1 is the first eigenvalue of $-\Delta$ with a Dirichlet boundary condition on the ball in \mathbf{R}^n with unit volume. The quantity $N(\lambda)$ can be identified with a limiting state density of $A(\omega)$, namely, the limit function of

$$N_V(\lambda, \omega) = \# \{j | \lambda_j^V(\omega) \leq \lambda\} / |V|$$

as V tends to \mathbf{R}^n regularly, where $\{\lambda_j^V(\omega)\}$ is the set of eigenvalues of $A(\omega)$ in a smooth bounded domain V in \mathbf{R}^n with a Dirichlet boundary condition and $|V|$ is the volume of V . To obtain the above asymptotic behavior of $N(\lambda)$, the theory of \dagger large deviation for Markov processes plays a crucial role [20].

F. Boltzmann Equation

In the kinetic theory of gases the \dagger Boltzmann equation is derived from the \dagger Liouville equation by considering the BBGKY hierarchy of particle distribution functions for N particles and then by taking the limit $N \rightarrow \infty$ under certain conditions (\rightarrow 402 Statistical Mechanics). Mathematically rigorous discussions were given by O. E. Lanford [21] for a gas of hard spheres; he showed that solutions of the BBGKY hierarchy converge to those of the Boltzmann hierarchy for small time under the Boltzmann-Grad limit ($N \rightarrow \infty, Nd^2 \rightarrow 1, d =$ the diameter of the hard spheres).

An approach to the Boltzmann equation in the spatially homogeneous case can also be based on a \dagger master equation. M. Kac [22] considered a Poisson-like process describing the random time evolution of the n -tuple of the velocities of n particles. For a gas of hard spheres this is determined by the master equation

$$\begin{aligned} & \frac{\partial}{\partial t} u(t, x_1, \dots, x_n) \\ &= \frac{1}{n} \sum_{1 \leq i < j \leq n} \int_{S^2} \{u(t, x_1, \dots, x'_i, \dots, x'_j, \dots, x_n) \\ & \quad - u(t, x_1, \dots, x_n)\} |(x_i - x_j, l)| dl, \\ & \quad t > 0, \quad x_1, \dots, x_n \in \mathbf{R}^3, \quad (1) \end{aligned}$$

where S^2 is the 2-dimensional unit sphere, dl is

the uniform distribution on S^2 and

$$x'_1 = x_i + (x_j - x_i, l)l, \quad x'_j = x_j - (x_j - x_i, l)l.$$

Let σ be a positive constant and $S(\sqrt{n\sigma})$ denote the $(3n-1)$ -dimensional sphere with center 0 and radius $\sqrt{n\sigma}$. Given a symmetric probability density u_n on $S(\sqrt{n\sigma})$ for each $n \geq 1$, a sequence $\{u_n\}$ is said to have **Boltzmann's property** or to be **chaotic** (or u -chaotic to stress u), if there exists a probability density u on \mathbb{R}^3 such that

$$\lim_{n \rightarrow \infty} \int_{S(\sqrt{n\sigma})} \varphi_1(x_1) \dots \varphi_m(x_m) u_n(x_1, \dots, x_n) dx_1 \dots dx_n = \prod_{k=1}^m \int_{\mathbb{R}^3} \varphi_k(x) u(x) dx$$

for each $m \geq 1$ and $\varphi_k \in C_0(\mathbb{R}^3)$, $1 \leq k \leq m$. Kac's assertion is that the Boltzmann equation is to be derived from the master equation via the **propagation of chaos**; more precisely, if $\{u_n\}$ is a u -chaotic sequence, then $\{u_n(t)\}$ is also $u(t)$ -chaotic, where $u_n(t)$ is the solution of the master equation (1) with $u_n(0) = u_n$ and $u(t)$ is the solution of the following Boltzmann equation with $u(0) = u$:

$$\begin{aligned} \frac{\partial}{\partial t} u(t, x) = \int_{S^2 \times \mathbb{R}^3} \{u(t, x')u(t, y') - u(t, x)u(t, y)\} \\ \times |(x-y, l)| dl dy, \\ x' = x + (y-x, l)l, \quad y' = y - (y-x, l)l. \end{aligned}$$

The propagation of chaos was verified by Kac [22], H. P. McKean [24], and others for a considerably wide class of nonlinear equations of Boltzmann type (with cutoff). The propagation of chaos is the stage corresponding to the law of large numbers. The next stage is the central limit theorem or fluctuation theory, which was also discussed by Kac [23] and McKean [25]. Moreover, based on Kac's work [22], McKean [26] introduced a class of Markov processes associated with certain nonlinear evolution equations including the Boltzmann equation; a process of this type describes the time evolution of the velocity of a particle interacting with other similar particles. In the case of the spatially homogeneous Boltzmann equation of Maxwellian molecules without cutoff, such a Markov process was constructed by solving a certain stochastic differential equation [27]. This implies the existence of probability measure-valued solutions of the equation.

341 (XVII.2) Probability Measures

A. General Remarks

A **probability measure** Φ on a \dagger measurable space (S, \mathfrak{E}) is defined to be a \dagger measure on (S, \mathfrak{E}) with $\Phi(S) = 1$ (\rightarrow 270 Measure Theory). In probability theory, probability measure appears usually as the \dagger probability distribution of a \dagger random variable (\rightarrow 342 Probability Theory). Unless stated otherwise, we regard a \dagger topological space T as a measurable space endowed with the topological σ -algebra $\mathfrak{B}(T)$ on T , i.e., the $\dagger\sigma$ -algebra generated by the \dagger open subsets of T . Hence the distribution of an \mathbf{R}^n -valued random variable is a probability measure on $(\mathbf{R}^n, \mathfrak{B}^n = \mathfrak{B}(\mathbf{R}^n))$. From this probabilistic background we often call a probability measure on $(\mathbf{R}^n, \mathfrak{B}^n)$ an n -dimensional (probability) distribution. For probability measures on topological spaces \rightarrow 270 Measure Theory.

B. Quantities Characterizing Probability Distributions

Several different quantities characterize the properties of probability distributions in one dimension: the **mean** (or **mathematical expectation**) $m = \int_{-\infty}^{\infty} x d\Phi(x)$, the **variance** $\sigma^2 = \int_{-\infty}^{\infty} |x - m|^2 d\Phi(x)$, the **standard deviation** σ , the k th **moment** $\alpha_k = \int_{-\infty}^{\infty} x^k d\Phi(x)$, the k th **absolute moment** $\beta_k = \int_{-\infty}^{\infty} |x|^k d\Phi(x)$, the k th **moment about the mean** $\mu_k = \int_{-\infty}^{\infty} (x - m)^k d\Phi(x)$, etc.

A one-to-one correspondence exists between a 1-dimensional distribution Φ and its (**cumulative**) **distribution function** F defined by $F(x) = \Phi((-\infty, x])$. A distribution function is characterized by the following properties: (1) It is monotone nondecreasing; (2) it is right continuous; (3) $\lim_{x \rightarrow -\infty} F(x) = 0$ and $\lim_{x \rightarrow +\infty} F(x) = 1$. Similar statements hold for the multi-dimensional case.

Let $X(\omega)$ be a real random variable on a \dagger probability space $(\Omega, \mathfrak{F}, P)$. Then the distribution of X is given by $\Phi(E) = P(\{\omega | X(\omega) \in E\})$, $E \in \mathfrak{B}^1$, and the characteristic quantities of Φ defined above are given in terms of $X(\omega)$ as follows: $m = E(X)$, $\sigma^2 = E(X - m)^2$, $F(x) = P(\{\omega | X(\omega) \leq x\})$, etc. The moments and the moments about the mean are connected by

the relation $\mu_r = \sum_{k=0}^r \binom{r}{k} \alpha_{r-k} (-m)^k$ ($r = 1, 2, \dots$).

When Φ is an n -dimensional distribution, the following quantities are frequently used: the **mean vector**, which is an n -dimensional vector whose i th component is given by $m_i = \int x_i d\Phi(x)$; the **covariance matrix**, which is an $n \times n$ matrix whose (i, j) -element is $\sigma_{ij} = \int (x_i - m_i)(x_j - m_j) d\Phi(x)$; the **moment matrix**, which is an $n \times n$ matrix whose (i, j) -element is $m_{ij} = \int x_i x_j d\Phi(x)$. (The covariance matrix is also called the **variance matrix** or the **variance-covariance matrix**.) The covariance matrix and the moment matrix are \dagger positive definite and symmetric. The quantities listed above are defined only under some integrability conditions.

C. Characteristic Functions

Consider a probability measure Φ defined on a measurable space $(\mathbf{R}^n, \mathfrak{B}^n)$, where \mathfrak{B}^n is the σ -algebra of all \dagger Borel sets in \mathbf{R}^n . The **characteristic function** of Φ is the \dagger Fourier transform φ defined by

$$\varphi(z) = \int_{\mathbf{R}^n} e^{i(z, x)} d\Phi(x), \quad z \in \mathbf{R}^n, \quad (1)$$

where (z, x) denotes the \dagger scalar product of z and x ($z, x \in \mathbf{R}^n$). Let X be an n -dimensional random variable with probability distribution Φ defined on a \dagger probability space $(\Omega, \mathfrak{B}, P)$.

Then the Fourier transform of Φ is also called the **characteristic function** of X , which can also be written as $E(e^{i(z, X)})$ (\rightarrow 342 Probability Theory).

The following properties play a fundamental role in the study of the relationship between probability distributions and characteristic functions: (i) the correspondence defined by (1) between the n -dimensional probability distribution Φ and its characteristic function φ is one-to-one. (ii) For any $a_p, b_p \in \mathbf{R}, a_p < b_p$ ($p = 1, 2, \dots, n$), we have

$$\int_{\mathbf{R}^n} \prod_{p=1}^n f(x_p; a_p, b_p) d\Phi(x) = \lim_{c \rightarrow \infty} \left(\frac{1}{2\pi} \right)^n \int_{-c}^c \dots \int_{-c}^c \prod_{p=1}^n \frac{e^{-ib_p z_p} - e^{-ia_p z_p}}{-iz_p} \times \varphi(z_1, \dots, z_n) dz_1, \dots, dz_n, \quad (2)$$

where $f(t; a, b)$ denotes the **modified indicator function** of $[a, b]$ defined by

$$f(t; a, b) = \begin{cases} 1, & t \in (a, b), \\ 1/2, & t = a \text{ or } b, \\ 0, & t \notin [a, b], \end{cases}$$

and $x = (x_1, \dots, x_n) \in \mathbf{R}^n$. If an n -dimensional interval $I = [a_1, \dots, a_n; b_1, \dots, b_n]$ defined by $a_i \leq x_i \leq b_i$ ($i = 1, 2, \dots, n$) is an **interval of continuity** for the probability distribution Φ , i.e., $\Phi(\partial I) = 0$, where ∂I denotes the boundary of I , then the left-hand side of (2) is equal to $\Phi(I)$. Equation (2) is called the **inversion formula** for the characteristic function φ .

The characteristic function φ of an n -dimensional probability distribution has the following properties: (i) For any points $z^{(1)}, \dots, z^{(p)}$ of the n -dimensional space \mathbf{R}^n and any complex numbers a_1, \dots, a_p , we have

$$\sum_{j,k=1}^p \varphi(z^{(j)} - z^{(k)}) a_j \bar{a}_k \geq 0.$$

(ii) $\varphi(z^{(k)})$ converges to $\varphi(0)$ as $z^{(k)} \rightarrow 0$. (iii) $\varphi(0) = 1$. A complex-valued function φ of $z \in \mathbf{R}^n$ is called **positive definite** if it satisfies the inequality in (i). Any continuous positive definite function φ on \mathbf{R}^n such that $\varphi(0) = 1$ is the characteristic function of an n -dimensional probability distribution (\dagger Bochner's theorem) (\rightarrow 192 Harmonic Analysis). A counterpart to Bochner's theorem holds for any positive definite sequence as well (\dagger Herglotz's theorem).

The characteristic function is often useful for giving probability distributions explicitly. (For characteristic functions of typical probability distributions \rightarrow Appendix A, Table 22. For general information about criteria that can be used to decide whether a given function is a characteristic function \rightarrow [8].)

The **moment generating function** defined by $f(z) = \int \exp(-\langle z, x \rangle) d\Phi(x)$ ($z \in \mathbf{R}^n$) does not

necessarily exist for all n -dimensional distributions but does exist for a number of useful probability distributions Φ , and then $f(z)$ uniquely determines Φ .

Given a 1-dimensional distribution Φ with $\beta_k < +\infty$, we denote by γ_k the coefficient of $(iz)^k/k!$ in the \dagger Maclaurin expansion of $\log \varphi(z)$. We call γ_k the (k th order) **semi-invariant** of Φ . The moments and semi-invariants are connected by the relations $\gamma_1 = \alpha_1, \gamma_2 = \alpha_2 - \alpha_1^2 = \sigma^2, \gamma_3 = \alpha_3 - 3\alpha_1\alpha_2 + 2\alpha_1^3, \gamma_4 = \alpha_4 - 3\alpha_2^2 - 4\alpha_1\alpha_3 + 12\alpha_1^2\alpha_2 - 6\alpha_1^4, \dots$

D. Specific Distributions

Given an n -dimensional distribution Φ , a point a with $\Phi(\{a\}) > 0$ is called a **discontinuity point** of Φ . The set D of all discontinuity points of Φ is at most countable. When $\Phi(D) = 1$, Φ is called a **purely discontinuous distribution**. In particular, if D is a lattice, Φ is called a **lattice distribution**. If the distribution function of Φ is a continuous function, Φ is called a **continuous distribution**. By virtue of the \dagger Lebesgue decomposition theorem, every probability distribution can be expressed in the form

$$\Phi = a_1 \Phi_1 + a_2 \Phi_2 + a_3 \Phi_3, \\ a_1, a_2, a_3 \geq 0, \quad a_1 + a_2 + a_3 = 1,$$

where Φ_1 is purely discontinuous, Φ_2 is \dagger absolutely continuous with respect to \dagger Lebesgue measure, and Φ_3 is continuous and \dagger singular. Let Φ be an absolutely continuous distribution. Then there exists a unique (up to Lebesgue measure zero) measurable nonnegative function $f(x)$ ($x \in \mathbf{R}^n$) such that $\Phi(E) = \int_E f(x) dx$. This function $f(x)$ is called the **probability density** of Φ .

We now list some frequently used 1-dimensional lattice distributions (for explicit data \rightarrow Appendix A, Table 22): the **unit distribution** with $\Phi(\{0\}) = 1$; the **binomial distribution** $Bin(n, p)$ with parameters n and p ; the **Poisson distribution** $P(\lambda)$ with parameter λ ; the **geometric distribution** $G(p)$ with parameter p ; the **hypergeometric distribution** $H(N, n, p)$ with parameters N, n , and p ; and the **negative binomial distribution** $NB(m, q)$ with parameters m and q . The following k -dimensional lattice distributions are used frequently: the **multinomial distribution** $M(n, p)$ with parameters n and p ; the **multiple hypergeometric distribution**; the **negative multinomial distribution**; etc.

The following 1-dimensional distributions are absolutely continuous: the **normal distribution** (or **Gaussian distribution**) $N(\mu, \sigma^2)$ with mean μ and variance σ^2 (sometimes $N(0, 1)$ is called the **standard normal distribution**); the

Cauchy distribution $C(\mu, \sigma)$ with parameters μ (\dagger median) and σ ; the **uniform distribution** $U(\alpha, \beta)$ on an interval $[\alpha, \beta]$; the **exponential distribution** $e(\sigma)$ with parameter σ ; the **gamma distribution** $\Gamma(p, \sigma)$; the $\dagger\chi^2$ distribution $\chi^2(n)$; the **beta distribution** $B(p, q)$; the **F-distribution** $F(m, n)$; the **Z-distribution** $Z(m, n)$; the **t-distribution** $t(n)$; etc. Furthermore, there are several k -dimensional absolutely continuous distributions, such as the **k -dimensional normal distribution** $N(\mu, \Sigma)$ with mean vector $\mu = (\mu_1, \mu_2, \dots, \mu_k)$ and covariance matrix $\Sigma = (\sigma_{ij})$, the **Dirichlet distribution**, etc.

E. Convolution

Given any two n -dimensional distributions Φ_1, Φ_2 , the n -dimensional distribution $\Phi(E) = \int_{\mathbb{R}^{2n}} \chi_E(x+y) d\Phi_1(x) d\Phi_2(y)$ is called the **composition** (or **convolution**) of Φ_1 and Φ_2 and is denoted by $\Phi_1 * \Phi_2$, where χ_E is the indicator function of the set E . Let X_1 and X_2 be \dagger independent random variables with distributions Φ_1 and Φ_2 . Then the distribution of $X_1 + X_2$ is $\Phi_1 * \Phi_2$. When F_i is the distribution function of Φ_i ($i = 1, 2$), the distribution function $F_1 * F_2$ of $\Phi_1 * \Phi_2$ is expressed in the form $F_1 * F_2(x) = \int_{\mathbb{R}^n} F_1(x-y) dF_2(y)$. If Φ_1 has a density $f_1(x)$, then $\Phi_1 * \Phi_2$ has a density $f(x) = \int_{\mathbb{R}^n} f_1(x-y) dF_2(y)$. If $\varphi(z)$ is the characteristic function of the convolution of two probability distributions Φ_1 and Φ_2 with characteristic functions φ_1 and φ_2 , then φ is the product of φ_1 and φ_2 : $\varphi(z) = \varphi_1(z) \cdot \varphi_2(z)$. Therefore, for every k , the k th order semi-invariant of the convolution of two distributions is equal to the sum of their k th order semi-invariants. Suppose that we are given a family of distributions $\Phi = \{\Phi(\alpha, \beta, \dots)\}$ indexed with parameters α, β, \dots . If for $(\alpha_1, \beta_1, \dots)$ and $(\alpha_2, \beta_2, \dots)$ there exists $(\alpha_3, \beta_3, \dots)$ such that $\Phi(\alpha_1, \beta_1, \dots) * \Phi(\alpha_2, \beta_2, \dots) = \Phi(\alpha_3, \beta_3, \dots)$, then we say that Φ has a **reproducing property**. Some of the distributions listed above have the reproducing property: $P(\lambda_1) * P(\lambda_2) = P(\lambda_1 + \lambda_2)$, $Bin(n_1, p) * Bin(n_2, p) = Bin(n_1 + n_2, p)$, $NB(m_1, q) * NB(m_2, q) = NB(m_1 + m_2, q)$, $N(\mu_1, \sigma_1^2) * N(\mu_2, \sigma_2^2) = N(\mu_1 + \mu_2, \sigma_1^2 + \sigma_2^2)$, $\Gamma(p_1, \sigma) * \Gamma(p_2, \sigma) = \Gamma(p_1 + p_2, \sigma)$, $C(\mu_1, \sigma_1) * C(\mu_2, \sigma_2) = C(\mu_1 + \mu_2, \sigma_1 + \sigma_2)$, etc.

Given a 1-dimensional distribution function $F(x)$,

$$Q_F(l) = \max_{-\infty < x < \infty} (F(x+l) - F(x-l)), \quad l > 0,$$

is called the **maximal concentration function** of F (P. Lévy [6]). Since it satisfies the relation $Q_{F_1 * F_2}(l) \leq Q_{F_1}(l)$ ($i = 1, 2$), we can use it to study the properties of sums of independent

random variables. The **mean concentration function** defined by

$$C_F(l) = \frac{1}{2l} \int_{-\infty}^{\infty} (F(x+l) - F(x-l))^2 dx$$

is also useful for similar purposes.

Let $N(m, v)$ be the 1-dimensional normal distribution with mean m and variance v , and let $P(\lambda, a)$ be the distribution obtained through translation by a of the Poisson distribution with parameter λ . If 1-dimensional distributions Φ_k, Ψ_k ($k = 1, 2$) exist such that $N(m, v) = \Phi_1 * \Phi_2$, $P(\lambda, a) = \Psi_1 * \Psi_2$, we have $\Phi_k = N(m_k, v_k)$, $\Psi_k = P(\lambda_k, a_k)$ ($k = 1, 2$) for some m_k, v_k, λ_k, a_k ($k = 1, 2$). These are known, respectively, as Cramér's theorem and Raikov's theorem. Yu. V. Linnik proved a similar fact (the decomposition theorem) for a more general family with reproducing property by using the theory of analytic functions [9].

F. Convergence of Probability Distributions

The concept of convergence of distributions plays an important role in limit theorems and other fields of probability theory. When Ω is a topological space, we consider **convergence** of probability measures on Ω with respect to the \dagger weak topology introduced in the space of measures on Ω (\rightarrow 37 Banach Spaces). Such convergence is called **weak convergence** in probability theory. For a sequence of n -dimensional distributions Φ_k ($k = 1, 2, \dots$) to converge to Φ weakly, each of the following conditions is necessary and sufficient. (1) For every continuous function with compact support, $\lim_{k \rightarrow \infty} \int_{\mathbb{R}^n} f(x) d\Phi_k(x) = \int_{\mathbb{R}^n} f(x) d\Phi(x)$. (2) At every continuity point of the distribution function $F(x_1, \dots, x_n)$ of Φ , $\lim_{k \rightarrow \infty} F_k(x_1, \dots, x_n) = F(x_1, \dots, x_n)$ (F_k is the distribution function of Φ_k). (3) For every continuity set E of Φ (namely, a set such that $\Phi(\bar{E} - E^0) = 0$), $\lim_{k \rightarrow \infty} \Phi_k(E) = \Phi(E)$. (4) For all open $G \subset \mathbb{R}^n$, $\liminf_{k \rightarrow \infty} \Phi_k(G) \geq \Phi(G)$. (5) For all closed $F \subset \mathbb{R}^n$, $\limsup_{k \rightarrow \infty} \Phi_k(F) \leq \Phi(F)$. (6) $\lim_{k \rightarrow \infty} \rho(\Phi_k, \Phi) = 0$, where ρ is a metric defined in the following way: Given any n -dimensional distributions Φ_1, Φ_2 , we put $\varepsilon_{ij} = \inf\{\varepsilon | \Phi_i(F) < \Phi_j(F^\varepsilon) + \varepsilon \text{ for every closed } F\}$ (F^ε is the ε -neighborhood of F) and define $\rho(\Phi_1, \Phi_2) = \max(\varepsilon_{12}, \varepsilon_{21})$. The metric ρ , called the **Lévy distance**, was introduced by Lévy [6] in one dimension and by Yu. V. Prokhorov in metric spaces [10]. Each of these conditions except (2) is still necessary and sufficient for Φ_n to converge weakly to Φ when Φ_n and Φ are probability measures on a \dagger complete separable metric space. It should also be noted that the probability measures on a complete separable metric space consti-

tute a complete separable metric space with respect to the Lévy distance.

A family $\Phi_\alpha (\alpha \in \Lambda)$ of probability measures on a complete separable metric space is said to be **tight** if for every $\varepsilon > 0$ there exists a compact set $K = K(\varepsilon)$ such that $\Phi_\alpha(K^c) < \varepsilon$ for all $\alpha \in \Lambda$. A family $\Phi_\alpha (\alpha \in \Lambda)$ is tight if and only if it is **totally bounded** with respect to the topology induced by the Lévy distance. Hence a tight family $\Phi_\alpha (\alpha \in \Lambda)$ has a weakly convergent subsequence.

We can give a criterion for the convergence of probability measures in terms of their characteristic functions. Suppose that Φ_k and Φ are n -dimensional probability measures with characteristic functions φ_k and φ . Then Φ_k converges weakly to Φ if and only if for every z , $\lim_k \varphi_k(z) = \varphi(z)$. Let φ_k be the characteristic function of an n -dimensional probability distribution Φ_k . If the sequence $\{\varphi_k\}$ converges pointwise to a limit function φ and the convergence of φ_k is uniform in some neighborhood of the origin, then φ is also the characteristic function of an n -dimensional probability distribution Φ and the sequence $\{\Phi_k\}$ converges weakly to Φ [7] (**Lévy's continuity theorem**).

For any probability distribution concentrated on $[0, \infty)$, the use of Laplace transforms as a substitute for Fourier transforms provides a powerful tool. The method of **probability generating functions** is available for the study of arbitrary probability distribution concentrated on the nonnegative integers [14]. The method of moment-generating functions is also useful. There are many results on the relation between these functions, probability distributions, and their convergence [14-16].

Let Φ_1, Φ_2, \dots and Φ be 1-dimensional distributions. If all absolute moments exist, $\sum_{j=1}^\infty \beta_j^{-1/j} = \infty$ for $\beta_j = \int_{-\infty}^\infty |x|^j d\Phi(x) < \infty$, and $\lim_{k \rightarrow \infty} \int_{-\infty}^\infty x^j d\Phi_k(x) = \int_{-\infty}^\infty x^j d\Phi(x)$ ($j = 0, 1, 2, \dots$), then Φ_k weakly converges to Φ . This condition is sufficient but not necessary.

G. Infinitely Divisible Distributions

An n -dimensional probability distribution Φ is called **infinitely divisible** if for every positive integer k , there exists a probability distribution Φ_k such that $\Phi = \Phi_k * \Phi_k * \dots * \Phi_k$ ($= \Phi_k^{*k}$). Both normal distributions and Poisson distributions are infinitely divisible. If an n -dimensional distribution Φ satisfies the condition $\int_{|x| > \varepsilon} \Phi(dx) < \varepsilon$, we say that $\Phi \in v(\varepsilon)$. Then Φ is an infinitely divisible distribution if and only if for every $\varepsilon > 0$ we can find $\Phi_1, \Phi_2, \dots, \Phi_k \in v(\varepsilon)$ such that $\Phi = \Phi_1 * \Phi_2 * \dots * \Phi_k$.

Let $X_{ki}, i = 1, 2, \dots, n(k)$, be independent random variables for every k , and assume that the distribution of X_{ki} belongs to $v(\varepsilon_k), i = 1, 2, \dots, n(k)$, where $\varepsilon_k \rightarrow 0$ as $k \rightarrow \infty$. If the probability distributions of the sums $X_k = \sum_{i=1}^{n(k)} X_{ki}$ converge to a probability distribution as $k \rightarrow \infty$, then the limit distribution is infinitely divisible.

The characteristic function of a 1-dimensional infinitely divisible distribution can be written in the form

$$\varphi(z) = \exp\left(irz - \frac{v}{2} z^2 + \int_{-\infty}^\infty A(u, z) \frac{1+u^2}{u^2} dG(u) \right), \quad (3)$$

where γ is a constant, v is a nonnegative constant, $G(u)$ is a nondecreasing bounded function with $G(-\infty) = 0, A(u, z) = \exp(iuz) - 1 - izu/(1+u^2)$, and the value of $A(u, z)(1+u^2)/u^2$ at $u = 0$ is defined to be $-z^2/2$. Formula (3) is called **Khinchin's canonical form**. For the characteristic function of an infinitely divisible n -dimensional distribution, the canonical form is as follows:

$$\varphi(z) = \exp\left(i(m, z) - \sum_{p,q=1}^n c_{pq} z_p z_q + \int_{\mathbf{R}^n} \left(e^{i(z,x)} - 1 - \frac{i(z,x)}{1+|x|^2} \right) n(dx) \right), \quad (4)$$

$z = (z_1, \dots, z_n) \in \mathbf{R}^n,$

where $m \in \mathbf{R}^n, (c_{pq})$ is a positive semidefinite matrix, and $n(dx)$ is a measure on \mathbf{R}^n such that $n(\{0\}) = 0$ and

$$\int_{\mathbf{R}^n} \frac{|x|^2}{1+|x|^2} n(dx) < \infty.$$

Formula (4) is called **Lévy's canonical form**. If a 1-dimensional infinitely divisible distribution Φ satisfies $\int_{\mathbf{R}^1} x^2 d\Phi(x) < \infty$, then its characteristic function is given by

$$\varphi(z) = \exp\left(imz - \frac{v}{2} z^2 + \int_{-\infty}^\infty (e^{izu} - 1 - izu) \frac{1}{u^2} dK(u) \right), \quad (5)$$

where m is a real constant, v is a nonnegative constant, and $K(u)$ is a nondecreasing bounded function such that $K(-\infty) = 0$. It is called **Kolmogorov's canonical form**. (For infinitely divisible distributions on a homogeneous space \rightarrow 5 Additive Processes.)

Let Φ and Ψ be n -dimensional distributions. If for some $\lambda > 0, \Psi(E) = \Phi(\lambda E)$ ($\lambda E = \{\lambda \xi \mid \xi \in E\}$) for every set E , we say that Φ and Ψ are equivalent. Let Φ and Ψ be probability distributions with distribution functions F and G

and characteristic functions φ and ψ . Then the following three statements are equivalent: (1) Φ and Ψ are equivalent; (2) $G(x) = F(\lambda x)$ for every x ; and (3) $\psi(\lambda z) = \varphi(z)$ for every z . We call Φ a **stable distribution** if for every pair of distributions Φ_1, Φ_2 equivalent to Φ , the convolution $\Phi_1 * \Phi_2$ is equivalent to Φ . If Φ is stable, every distribution equivalent to Φ is also stable. We can characterize stable distributions in terms of their characteristic functions $\varphi(z)$ as follows: For every pair $\lambda_1, \lambda_2 > 0$, there exists a $\lambda = \lambda(\lambda_1, \lambda_2) > 0$ such that $\varphi(\lambda z) = \varphi(\lambda_1 z)\varphi(\lambda_2 z)$. We can restate this characterization as follows: Φ is stable if and only if for every pair of independent random variables X_1 and X_2 with identical distribution Φ and for any positive numbers λ_1 and λ_2 , there exists a positive number λ such that $(\lambda_1 X_1 + \lambda_2 X_2)/\lambda$ has the distribution Φ . By the definition we see that all stable distributions are infinitely divisible.

In the 1-dimensional case, putting $\varphi(z) = \exp \psi(z)$, we have $\psi(\lambda z) = \psi(\lambda_1 z) + \psi(\lambda_2 z)$, which implies $\psi(z) = (-c_0 + i(z/|z|)c_1)|z|^\alpha$, where $c_0 \geq 0, -\infty < c_1 < \infty, 0 < \alpha \leq 2$. The parameter α is called the **exponent** (or **index**) of the stable distribution. The stable distributions with exponent $\alpha = 2$ are the normal distributions, and the stable distributions with exponent $\alpha = 1$ are the Cauchy distributions. We have $\psi(z) = -c_0|z|^\alpha$ for a symmetric stable distribution. (For the stable distribution with exponent $1/2 \rightarrow$ Appendix A, Table 22).

Generalizing stable distributions, we can define **quasistable distributions**, which B. V. Gnedenko and A. N. Kolmogorov [17] called stable distributions also. Let F be the distribution function of a 1-dimensional distribution Φ . Φ is said to be quasistable if to every $b_1 > 0, b_2 > 0$ and real λ_1, λ_2 there correspond a positive number b and a real number λ such that we have the relation $F((x - \lambda_1)/b_1) * F((x - \lambda_2)/b_2) = F((x - \lambda)/b)$.

Let $\{X_i\}$ be a sequence of independent random variables with identical distribution. If for suitably chosen constants A_n and B_n the distributions of the sums $B_n^{-1}(\sum_{i=1}^n X_i) - A_n$ converge to a distribution, the limit distribution is a quasistable distribution (Lévy). A necessary and sufficient condition for a distribution to be quasistable is that its characteristic function $\varphi(z)$ satisfy the relation $\varphi(b_1 z)\varphi(b_2 z) = \varphi(bz)e^{i\gamma z}$ ($\gamma = \lambda - \lambda_1 - \lambda_2$). The characteristic function of a quasistable distribution has the canonical representation

$$\varphi(z) = \exp \psi(z),$$

$$\psi(z) = imz - c|z|^\alpha(1 + i\beta(z/|z|)\omega(z, \alpha)),$$

where m is a real number, $c \geq 0, 0 < \alpha \leq 2, |\beta| \leq 1$, and $\omega(z, \alpha) = \tan(\pi\alpha/2)$ ($\alpha \neq 1$), $\omega(z, \alpha) =$

$(2/\pi)\log|z|$ ($\alpha = 1$). The parameter α is called the exponent of the quasistable distribution. A quasistable distribution with $\alpha \neq 1$ is obtained from a stable distribution by translation, but quasistable distributions with $\alpha = 1$ are not.

Semistable distributions are another generalization of stable distributions. A distribution is called semistable if its characteristic function $\varphi(z)$ satisfies the relation $\psi(qz) = q^\alpha \psi(z)$ for a positive number $q (\neq 1)$, where $\varphi(z) = \exp(\psi(z))$. Also in this case, the general form was obtained by Lévy [6].

A 1-dimensional probability distribution Φ is called an **L-distribution** if the distribution function F of Φ is the convolution of $F(x/a)$ and some other distribution function $F_a(x)$ for every $0 < a < 1$. Φ is an **L-distribution** if and only if there exists a sequence of independent random variables $\{X_k\}$ such that for suitably chosen constants $B_n > 0$ and A_n the distributions of the sums $B_n^{-1}(\sum_{k=1}^n X_k) - A_n$ converge to Φ and $\sup_{1 \leq k \leq n} P(|X_k/B_n| > \varepsilon) \rightarrow 0$ as $n \rightarrow \infty$ for every $\varepsilon > 0$. Quasistable distributions are **L-distributions**.

H. The Shape of Distributions

Let $F(x)$ be a 1-dimensional distribution function. The quantity ζ_p such that $F(\zeta_p - 0) \leq p \leq F(\zeta_p)$ ($0 < p < 1$) is called the **quantile of order p** of F . In particular, the quantity $\zeta_{1/2}$ is called a **median**. If F satisfies the relation $1 - F(m+x) = F(m-x)$, it is called **symmetric**. In any 1-dimensional symmetric distribution, every moment of odd order about the mean (if it exists) is equal to zero.

The ratio $\gamma_1 = \mu_3/\sigma^3$ is used as a measure of departure from symmetry of a distribution and is called the **coefficient of skewness**. Furthermore, the ratio $\gamma_2 = \mu_3/\sigma^4 - 3$ is called the **coefficient of excess**. For the normal distribution, we have $\gamma_1 = \gamma_2 = 0$. If $\gamma_2 \neq 0$, γ_2 expresses the degree of deviation from the normal distribution.

A distribution function $F(x)$ is called **unimodal** if there exists one value $x = a$ such that $F(x)$ is convex for $x < a$ and concave for $x > a$. All **L-distributions** (and hence quasistable distributions) are unimodal [18].

I. Kolmogorov's Extension Theorem

Let $\Omega = \mathbf{R}^T$, where T is an arbitrary index set. We associate with \mathbf{R}^T the σ -algebra \mathfrak{B}^T generated by the cylinder sets, i.e., $\{\omega \in \Omega | \pi_i(\omega) \in E_1, \dots, \pi_{i_n}(\omega) \in E_n\}$, where $\pi_i(\omega)$ denotes the i th coordinate of ω , $E_k \in \mathfrak{B}(\mathbf{R}^1)$, $1 \leq k \leq n$, $t_1 < t_2 < \dots < t_n$, and $n = 1, 2, \dots$. Given a probability

measure Φ on $(\mathbf{R}^T, \mathfrak{B}^T)$, we can define a finite-dimensional \dagger marginal distribution Φ_S for any finite subset S of T by $\Phi_S(E) = \Phi(\pi_S^{-1}(E))$, $E \in \mathfrak{B}^S$, where π_S is the natural \dagger projection $\pi_S: \mathbf{R}^T \rightarrow \mathbf{R}^S$. The measures $\{\Phi_S\}$ satisfy the following **consistency condition**: If $S_1 \subset S_2 (\subset T)$ are finite and if $E \in \mathfrak{B}^{S_1}$, then

$$\Phi_{S_1}(E) = \Phi_{S_2}(\pi_{S_1, S_2}^{-1}(E)), \tag{6}$$

where $\pi_{S_1, S_2}: \mathbf{R}^{S_2} \rightarrow \mathbf{R}^{S_1}$ is the natural projection.

Conversely, if we are given a family of finite-dimensional probability measures $\{\Phi_S\}$ which satisfies the consistency condition (6), then **Kolmogorov's extension theorem** [1] asserts that there exists a unique probability measure Φ on $(\mathbf{R}^T, \mathfrak{B}^T)$ such that $\Phi_S(E) = \Phi(\pi_S^{-1}(E))$, $E \in \mathfrak{B}^S$, for any finite $S \subset T$.

This theorem is useful in constructing \dagger stochastic processes. For example, let $\Phi_{n_1, n_2, \dots, n_k}$ be the \dagger product measure of k copies of a given probability measure Φ on \mathbf{R}^1 . Then the family $\{\Phi_{n_1, n_2, \dots, n_k}; n_1, n_2, \dots, n_k \in \mathbf{Z}, k \in \mathbf{N}\}$ satisfies the consistency condition and hence, by Kolmogorov's extension theorem, determines a probability measure on $\mathbf{R}^{\mathbf{Z}}$, which is denoted by $\Phi^{\mathbf{Z}}$. Thus $X_n(\omega) = \pi_n(\omega)$, $n \in \mathbf{Z}$, $(\omega \in (\mathbf{R}^{\mathbf{Z}}, \mathfrak{B}^{\mathbf{Z}}, \Phi^{\mathbf{Z}}))$, are independent identically Φ -distributed random variables.

Kolmogorov's extension theorem is generalized to the case where the component spaces are \dagger standard measurable spaces (\rightarrow 270 Measure Theory) instead of \mathbf{R}^1 , and also to the case where product spaces are replaced by \dagger projective systems [19].

J. Characteristic Functionals on Infinite-Dimensional Spaces

Contrary to the finite-dimensional case, Bochner's theorem does not necessarily hold in infinite-dimensional spaces. For example, let $(T, \|\cdot\|)$ be an infinite-dimensional \dagger Hilbert space and $\varphi(t) = \exp(-\|t\|^2)$. φ is continuous and positive definite, and $\varphi(0) = 1$. But it is known that there is no probability measure on $T = T^*$ (topological dual of T) which corresponds to φ . Bochner's theorem is generalized to infinite-dimensional spaces as follows.

Let T be a real \dagger vector space endowed with the topology τ defined by a system of \dagger Hilbertian seminorms $\{\|\cdot\|_\alpha, \alpha \in A\}$. Define a new topology $I(\tau)$ of T by all Hilbertian seminorms $\|\cdot\|$ each of which is HS-dominated by some $\|\cdot\|_\alpha$, $\alpha \in A$, i.e., $\sup\{(\sum_i \|e_i\|^2)^{1/2}; \{e_i\}: \alpha$ -orthonormal $\} < \infty$. If $I(\tau) = \tau$, then (T, τ) is called a \dagger nuclear space.

Let T_τ^* be the topological dual of (T, τ) (i.e., the set of all τ -continuous real valued linear functionals on T). Define a Borel structure

341 Ref. Probability Measures

$\mathfrak{B}(T_\tau^*)$ of T_τ^* as the σ -algebra generated by the system of half-spaces $\{x \in T_\tau^*; x(t) < a\}$, $t \in T, a \in \mathbf{R}^1$. For a probability measure Φ on $(T_\tau^*, \mathfrak{B}(T_\tau^*))$, define

$$\varphi(t) = \int_{T_\tau^*} \exp(i\langle x, t \rangle) d\Phi(x), \quad t \in T,$$

which is called the characteristic functional of Φ . A functional φ on T is the characteristic functional of a probability measure Φ on $(T_\tau^*, \mathfrak{B}(T_\tau^*))$ such that $\Phi^*(\bigcup_n T_{\alpha_n}^*) = 1$ for some sequence $\{\alpha_n\} \subset A$, where Φ^* is the \dagger outer measure (\rightarrow 270 Measure Theory) and T_τ^* is the topological dual of $(T, \|\cdot\|_\alpha)$, if and only if φ is positive definite, $\varphi(0) = 1$, and continuous with respect to the topology $I(\tau)$ [23].

As special cases of the foregoing theorem, we have the following. If (T, τ) is a nuclear space, then every positive definite τ -continuous functional φ with $\varphi(0) = 1$ is the characteristic functional of a probability measure on T_τ^* (Minlos [24]). Schwartz's spaces $\mathcal{S}(\mathbf{R}^n)$ and $\mathcal{D}(\mathbf{R}^n)$ are nuclear. Let $(T, \tau = \|\cdot\|)$ be a Hilbert space. A \dagger Hilbert-Schmidt operator U is, by definition, a \dagger bounded linear operator on T such that $\sum_i \|Ue_i\|^2 < \infty$, by any \dagger complete orthonormal system $\{e_i\}$ (this quantity does not depend on the choice of $\{e_i\}$). Define a seminorm $\|\cdot\|_U$ by $\|t\|_U = \|Ut\|$, $t \in T$, for a Hilbert-Schmidt operator U . Then the topology $I(\tau)$ coincides with the topology induced by the system of seminorms $\|\cdot\|_U$, where U are Hilbert-Schmidt operators, which is called the **Sazonov topology**. Thus every functional φ on T , which is positive definite, $\varphi(0) = 1$, and continuous with respect to the Sazonov topology, is the characteristic functional of a probability measure on T_τ^* (Sazonov [25]).

The probability measure on \mathcal{S}' with the characteristic functional $\exp(-\int_{-\infty}^{\infty} |f(s)|^2 ds)$, $f \in \mathcal{S}$, is the probability measure of a Gaussian \dagger white noise on \mathcal{S}' .

342 (XVII.1) Probability Theory

A. History

The origin of the **theory of probability** goes back to the mathematical problems connected with dice throwing that were discussed in letters exchanged by B. Pascal and P. de Fermat in the 17th century. These problems were concerned primarily with concepts such as *permutations, *combinations, and *binomial coefficients, whose theory was established at about the same time [1]. This elementary theory of probability was later enriched by the work of scholars such as Jakob Bernoulli [2], A. de Moivre [3], T. Bayes, L. de Buffon, Daniel Bernoulli, A. M. Legendre, and J. L. Lagrange. Finally, P. S. Laplace completed the classical theory of probability in his book *Théorie analytique des probabilités* (1812). In this work, Laplace not only systematized but also greatly extended previous important results by introducing new methods, such as the use of *difference equations and *generating functions. Since the 19th century, the theory of probability has been extensively applied to the natural sciences and even to the social sciences.

The definition of a priori probability due to Laplace provoked a great deal of argument when it was applied. For example, R. von Mises advocated an empirical theory of probability based on the notion of **Kollektiv (collective)**, which is a mathematical model of mass phenomena [5]. However, these arguments are concerned with philosophical rather than mathematical aspects. Nowadays, the main concern of mathematicians lies not in the intuitive or practical meaning of probability but in the logical setup governing probability. From this viewpoint the mathematical model of a random phenomenon is given by a probability measure space $(\Omega, \mathfrak{B}, P)$, where Ω is the set of all possible outcomes of the phenomenon, $P(E)$ represents the probability that an outcome belonging to E be realized, and \mathfrak{B} is a σ -algebra consisting of all sets E for which $P(E)$ is defined. All probabilistic concepts, such as random variables, independence, etc., are defined on $(\Omega, \mathfrak{B}, P)$ in terms of measure theory. Such a measure-theoretic basis of probability theory is due to A. Kolmogorov [6], though similar considerations had been made before him for special problems, for example, in the work of E. Borel concerning the strong law of large numbers [7] and in the rigorous definition of Brownian motion by N. Wiener [8].

Ever since probability theory was given

solid foundations by Kolmogorov, it has made tremendous progress. The most important concept in today's probability theory is that of **stochastic processes**, which correspond to functions in analysis. In applications a stochastic process is used as the mathematical model of a random phenomenon varying with time. The following types of stochastic processes have been investigated extensively: **additive processes**, **Markov processes** and **Markov chains**, **martingales**, **stationary processes**, and **Gaussian processes**. **Brownian motion** and **branching processes** are important special stochastic processes. In the same way as functions are often defined by differential equations, there are stochastic processes which can be defined by **stochastic differential equations**. The theory of stochastic processes and stochastic differential equations can be applied to **stochastic control**, **stochastic filtering**, and **statistical mechanics**. The **ergodic theory** that originated in statistical mechanics is now regarded as an important branch of probability theory closely related to the theory of stationary processes.

B. Probability Spaces

Let Ω be an abstract space and \mathfrak{B} be a σ -algebra of subsets of Ω . A **probability measure** (or **probability distribution**) over $\Omega(\mathfrak{B})$ is a set function $P(E)$ defined for $E \in \mathfrak{B}$ and satisfying the following conditions: (P1) $P(E) \geq 0$; (P2) for every sequence $\{E_n\}$ ($n = 1, 2, \dots$) of pairwise disjoint sets in \mathfrak{B} ,

$$P\left(\bigcup_n E_n\right) = \sum_n P(E_n);$$

(P3) $P(\Omega) = 1$. The triple $(\Omega, \mathfrak{B}, P)$ is called a **probability space**. The space Ω (resp. each element ω of Ω) is called the **basic space**, **space of elementary events**, or **sample space** (resp. **sample point** or **elementary event**). We say that a condition $\varepsilon(\omega)$ involving a generic sample point ω is an **event**; in particular, it is called a **measurable event** or **random event** if the set E of all sample points satisfying $\varepsilon(\omega)$ belongs to \mathfrak{B} . We assume that an event is always a measurable one, since we encounter only measurable events in the theory of probability. Because of the obvious one-to-one correspondence between measurable events and \mathfrak{B} -measurable sets (i.e., the correspondence of each event ε with the set E of all sample points ω satisfying ε), a \mathfrak{B} -measurable set itself is frequently called an event. If ε is an event and E is the \mathfrak{B} -measurable set corresponding to ε , we call $P(E)$ or $\text{Pr}(\varepsilon)$ the **probability that the event ε occurs**, i.e., the **probability of the event E** . The **complementary event** (resp. **impossible**

event, sure event) is the complementary set E^c (empty set \emptyset , whole space Ω). For a finite or infinite family $\{E_\lambda\}$ ($\lambda \in \Lambda$), the **sum event** (resp. **intersection** or **product event**) of E_λ is the set $\bigcup_\lambda E_\lambda$ ($\bigcap_\lambda E_\lambda$). If $E \cap F = \emptyset$, then we say that E and F are mutually exclusive or that they are **exclusive events**.

By the definition of P , we have $0 \leq P(E) \leq 1$ for any event E , $P(\emptyset) = 0$, and $P(\Omega) = 1$. Moreover, if $\{E_n\}$ ($n = 1, 2, \dots$) is a sequence of pairwise exclusive events and E is the sum event of E_n , we have

$$P(E) = \sum_{n=1}^{\infty} P(E_n).$$

This property is called the **additivity of probability**. If $P(E) = 1$, the event E is said to occur **almost certainly** (almost surely (abbrev. a.s.), for almost all ω , or with probability 1).

Given a finite sequence $\{E_n\}$ ($n = 1, 2, \dots, N$) of events, we say that the events E_n ($n = 1, 2, \dots, N$) are mutually **independent** or that the sequence $\{E_n\}$ ($n = 1, 2, \dots, N$) is **independent** if every subsequence satisfies

$$P(E_{i_1} \cap E_{i_2} \cap \dots \cap E_{i_k}) = \prod_{j=1}^k P(E_{i_j}).$$

Given an infinite family $\{E_\lambda\}$ ($\lambda \in \Lambda$) of events, we say that the events E_λ ($\lambda \in \Lambda$) are mutually **independent** or that the family $\{E_\lambda\}$ ($\lambda \in \Lambda$) is **independent** if every finite subfamily is independent. The concept of independence of events can be generalized to a family $\{\mathfrak{B}_\lambda\}$ ($\lambda \in \Lambda$) of σ -subalgebras of \mathfrak{B} as follows. A family $\{\mathfrak{B}_\lambda\}$ ($\lambda \in \Lambda$) of σ -subalgebras of events is said to be independent if for every choice of $E_\lambda \in \mathfrak{B}_\lambda$, the family $\{E_\lambda\}$ ($\lambda \in \Lambda$) of events is independent.

For a sequence $\{E_n\}$ ($n = 1, 2, \dots$) of events, the sets $\limsup_n E_n$ and $\liminf_n E_n$ are called the **superior limit event** and **inferior limit event**, respectively. The superior limit event (inferior limit event) is the set of all ω for which infinitely many events among E_n (all events except finitely many E_n) occur. Therefore $P(\liminf_n E_n)$ is the probability that infinitely many events among E_n occur, and $P(\limsup_n E_n)$ is the probability that the events E_n occur for all n after some number n_0 , where n_0 depends on ω in general. The **Borel-Cantelli lemma**, which is concerned with the evaluation of $P(\limsup_n E_n)$, reads as follows: Given a sequence $\{E_n\}$ ($n = 1, 2, \dots$) of events, we have (i) whether the events E_n ($n = 1, 2, \dots$) are mutually independent or not, $\sum_n P(E_n) < \infty$ implies that $P(\limsup_n E_n) = 0$; and (ii) if the events E_n ($n = 1, 2, \dots$) are mutually independent, $\sum_n P(E_n) = \infty$ implies that $P(\limsup_n E_n) = 1$. Frequently, applications of part (ii) are greatly hampered by the requirement of independence; a number of sufficient conditions for depen-

dent events to have the same conclusion as (ii) have been discovered. The **Chung-Erdős theorem** [9] is quite useful in this connection.

C. Random Variables

Let $(\Omega, \mathfrak{B}, P)$ be a probability space. A **random variable** is a real-valued function X defined on Ω that is \mathfrak{B} -measurable (i.e., for every real number a , the set $\{\omega | X(\omega) < a\}$ is in \mathfrak{B}). If X_1, X_2, \dots, X_n are random variables, the mapping $X = (X_1, X_2, \dots, X_n)$ from Ω into \mathbf{R}^n is said to be an **n -dimensional (or \mathbf{R}^n -valued) random variable**. More generally, a mapping X from (Ω, \mathfrak{B}) into another measurable space (S, \mathfrak{C}) is called an **(S, \mathfrak{C}) -valued random variable** if it is measurable, that is, for every set A of \mathfrak{C} , the set $\{\omega | X(\omega) \in A\}$ belongs to \mathfrak{B} .

Let \mathfrak{B}^1 be the σ -algebra of all Borel subsets of the real line \mathbf{R} . Then each random variable X induces a probability measure Φ on $(\mathbf{R}, \mathfrak{B}^1)$ such that

$$\Phi(A) = P(\{\omega | X(\omega) \in A\}), \quad A \in \mathfrak{B}^1.$$

The measure Φ is called the **(1-dimensional) probability distribution of the random variable X** or simply the **distribution of X** . The point function F defined by

$$F(a) = P(\{\omega | X(\omega) \leq a\}), \quad a \in \mathbf{R},$$

is a monotone nondecreasing and right continuous function such that $\lim_{a \rightarrow -\infty} F(a) = 0$, $\lim_{a \rightarrow \infty} F(a) = 1$. The function F is called the **cumulative distribution function** (or simply the **distribution function**) of the random variable X . Similarly, an n -dimensional random variable $X = (X_1, \dots, X_n)$ induces its **n -dimensional probability distribution** (or simply **n -dimensional distribution**) and its **n -dimensional distribution function** $F(a_1, \dots, a_n) = P(\{\omega | X_1(\omega) \leq a_1, \dots, X_n(\omega) \leq a_n\})$. If the X_n ($n = 1, 2, \dots, N$) are k_n -dimensional random variables ($n = 1, 2, \dots, N$), we say that the $l (= \sum_{n=1}^N k_n)$ -dimensional random variable $X = (X_1, X_2, \dots, X_N)$ is the **joint random variable** of X_n ($n = 1, 2, \dots, N$) and that the l -dimensional distribution Φ of X is the **joint distribution** (or **simultaneous distribution**) of X_n ($n = 1, 2, \dots, N$). On the other hand, the k_n -dimensional distribution Φ_n of X_n is called the **marginal distribution** of the l -dimensional distribution Φ .

Given a finite sequence $\{X_n\}$ ($n = 1, 2, \dots, N$) of random variables, if the relation

$$P(\{\omega | X_n(\omega) \in A_n \ (n = 1, 2, \dots, N)\}) = \prod_{n=1}^N P(\{\omega | X_n(\omega) \in A_n\}) \quad (1)$$

holds for every choice of 1-dimensional Borel sets A_n ($n = 1, 2, \dots, N$), we say that the random variables X_n ($n = 1, 2, \dots, N$) are mutually inde-

pendent or that the sequence $\{X_n\}$ ($n = 1, 2, \dots, N$) is **independent**. Given an infinite family $\{X_\lambda\}$ ($\lambda \in \Lambda$) of random variables, we say that the random variables are mutually **independent** or that the family is independent if every finite subfamily is independent. The latter definition of independence of random variables is compatible with the previous definition of independence of σ -subalgebras of \mathfrak{B} ; i.e., if $\mathfrak{B}[X_\lambda]$ denotes the σ -subalgebras of \mathfrak{B} generated by the sets $\{\omega | X_\lambda(\omega) \in A_\lambda\}$, with A_λ an arbitrary 1-dimensional Borel set, the independence of the family $\{X_\lambda\}$ ($\lambda \in \Lambda$) in the latter sense is equivalent to the independence of the family $\{\mathfrak{B}[X_\lambda]\}$ ($\lambda \in \Lambda$) in the previous sense. If the X_n ($n = 1, 2, \dots, N$) (X_λ ($\lambda \in \Lambda$)) are k_n - (k_λ -) dimensional random variables, then the independence of the family $\{X_n\}$ ($n = 1, 2, \dots, N$) ($\{X_\lambda\}$ ($\lambda \in \Lambda$)) is defined similarly; it is enough to take k_n - (k_λ -) dimensional Borel sets A_n (A_λ) for 1-dimensional Borel sets in equation (1).

Given a family $\{X_\lambda\}$ ($\lambda \in \Lambda$) of random variables, the smallest σ -algebra with respect to which every X_λ is measurable is called the σ -algebra generated by $\{X_\lambda\}$ ($\lambda \in \Lambda$) and is denoted by $\mathfrak{B}[X_\lambda | \lambda \in \Lambda]$. Each element of this class is said to be **measurable with respect to the family $\{X_\lambda\}$ ($\lambda \in \Lambda$) of random variables**.

Since a random variable X is a \mathfrak{B} -measurable function, we can speak of the integral of X relative to the measure P on \mathfrak{B} . If X is integrable relative to P , the integral of X over A is denoted by $E(X; A)$. $E(X; \Omega)$, usually denoted by $E(X)$, is called the **mean, expectation, or expected value** of X , denoted also by $M(X)$ or m_X . If $(X - E(X))^2$ is integrable,

$$V(X) = E((X - E(X))^2)$$

is called the **variance** of X , denoted by $\sigma^2(X)$. The **standard deviation** of X is the nonnegative square root $\sigma(X)$ of the variance. If X and Y are two random variables for which $E((X - E(X))(Y - E(Y)))$ exists, the value $E((X - E(X))(Y - E(Y)))$ is called the **covariance** of X and Y . When X and Y have finite variances, the **correlation coefficient** of X and Y is defined by

$$\rho(X, Y) = \frac{E((X - E(X))(Y - E(Y)))}{\{E((X - E(X))^2)E((Y - E(Y))^2)\}^{1/2}}.$$

It follows that $E(aX + bY) = aE(X) + bE(Y)$, $V(aX + b) = a^2V(X)$ for any real numbers a, b , and that, in particular, $E(XY) = E(X)E(Y)$, $V(X + Y) = V(X) + V(Y)$ for mutually independent random variables X and Y . It also follows from the definition that $-1 \leq \rho(X, Y) \leq 1$ in all cases. The independence of X and Y implies that $\rho(X, Y) = 0$, but the converse is false in general. The variance is important because of the well-known **Chebyshev inequal-**

ity: If X is a random variable with finite variance σ^2 ,

$$P(|X - E(X)| \geq c) \leq \sigma^2/c^2$$

for every positive number c .

D. Convergence of Random Variables

If $P(\lim_{n \rightarrow \infty} X_n = X_\infty) = 1$, the sequence $\{X_n\}$ is said to **converge almost everywhere** (almost certainly, almost surely (a.s.), or with probability 1) to X_∞ . If $\lim_{n \rightarrow \infty} P(|X_n - X_\infty| > \varepsilon) = 0$ for every positive number ε , the sequence $\{X_n\}$ is said to **converge in probability** to X_∞ . For a given positive number p the sequence $\{X_n\}$ is said to **converge in the mean of order p** to X_∞ if $\lim_{n \rightarrow \infty} E(|X_n - X_\infty|^p) = 0$. Finally, if the random variables $X_n (n = 1, 2, \dots, \infty)$ have distributions $\Phi_n (n = 1, 2, \dots, \infty)$, respectively, and if

$$\lim_{n \rightarrow \infty} \int_{-\infty}^{\infty} f(x) d\Phi_n(x) = \int_{-\infty}^{\infty} f(x) d\Phi_\infty(x)$$

for every continuous function f with compact support, the sequence $\{X_n\}$ is said to **converge in distribution** to X_∞ . Note that the sequence of random variables converging in distribution may not converge in any ordinary sense. For example, random variables converging in distribution may even be defined on different probability spaces. On one hand, almost sure convergence does not in general imply convergence in the mean. On the other hand, either almost sure convergence or convergence in the mean implies convergence in probability, and convergence in probability implies convergence in distribution. However, P. Lévy [10] proved that if the $X_n (n = 1, 2, \dots)$ are mutually independent, the sequence

$$Y_k = \sum_{n=1}^k X_n, \quad k = 1, 2, \dots,$$

is convergent almost everywhere if and only if it is convergent in distribution (or in probability). The famous **three-series theorem** of Khinchin and Kolmogorov [11] claims that the series $\sum_n X_n$ with X_1, X_2, \dots independent is convergent almost surely if and only if there exists a sequence of independent random variables X'_1, X'_2, \dots such that each of the three series

$$\sum_n P(X_n \neq X'_n), \quad \sum_n E(X'_n), \quad \sum_n V(X'_n)$$

is convergent.

E. Conditional Probability and Conditional Expectation

Let $(\Omega, \mathfrak{B}, P)$ be a probability space and \mathfrak{F} a σ -subalgebra of \mathfrak{B} . If X is a random variable

with finite mean, the function

$$\mu(E) = \int_E X(\omega) dP, \quad E \in \mathfrak{F},$$

defines on (Ω, \mathfrak{F}) a completely additive set function which is †absolutely continuous with respect to P . Therefore, by the †Radon-Nikodym theorem, there is an \mathfrak{F} -measurable function f such that

$$\mu(E) = \int_E f(\omega) dP \quad \text{for every } E \in \mathfrak{F}.$$

This function is unique up to a set of P -measure zero and is called the **conditional expectation** (or **conditional mean**) of X relative to \mathfrak{F} , denoted by $E(X | \mathfrak{F})$. When \mathfrak{F} is generated by a random variable Y , we also write $E(X | Y)$ for $E(X | \mathfrak{F})$ and call it the conditional expectation of X relative to Y . In this case, there is a †Borel measurable function f such that $E(X | Y) = f(Y(\omega))$, and we write $E(X | Y = y)$ for $f(y)$. The same fact holds when Y is a multidimensional random variable. It follows from the definition that the conditional expectation has the following properties, up to a set of P -measure zero: (i) if $X \geq 0$, then $E(X | \mathfrak{F}) \geq 0$; (ii) $E(aX + bY | \mathfrak{F}) = aE(X | \mathfrak{F}) + bE(Y | \mathfrak{F})$; (iii) $E(E(X | \mathfrak{F})) = E(X)$; (iv) if X and \mathfrak{F} are mutually independent, i.e., $\mathfrak{B}[X]$ and \mathfrak{F} are mutually independent, then $E(X | \mathfrak{F}) = E(X)$; (v) if X is \mathfrak{F} -measurable, then $E(X | \mathfrak{F}) = X$ and $E(XY | \mathfrak{F}) = XE(Y | \mathfrak{F})$; (vi) if $\lim_{n \rightarrow \infty} X_n = X_\infty$ with $|X_n| \leq Y$ and Y is an integrable random variable, then $\lim_{n \rightarrow \infty} E(X_n | \mathfrak{F}) = E(X_\infty | \mathfrak{F})$; (vii) if \mathfrak{G} is a σ -subalgebra of \mathfrak{F} , then $E(E(X | \mathfrak{F}) | \mathfrak{G}) = E(X | \mathfrak{G})$; (viii) if X^2 is integrable and Y is any \mathfrak{F} -measurable random variable, then $E((X - E(X | \mathfrak{F}))^2) \leq E((X - Y)^2)$.

When X is the **indicator function** (i.e., the †characteristic function) χ_E of a set E in \mathfrak{B} , $E(\chi_E | \mathfrak{F})$ is called the **conditional probability** of E relative to \mathfrak{F} and is denoted by $P(E | \mathfrak{F})$. In particular, if $\mathfrak{F} = \{F, F^c, \emptyset, \Omega\}$ with $1 > P(F) > 0$, $P(E | \mathfrak{F})$ is the simple function which takes the values $P(E \cap F)/P(F)$ on F and $P(E \cap F^c)/P(F^c)$ on F^c . These values are denoted respectively by $P(E | F)$ and $P(E | F^c)$. The definition of $P(E | Y)$ or $P(E | Y = y)$ is also the same as in the case of the conditional expectation.

Let \mathfrak{F} be a σ -subalgebra of \mathfrak{B} and Y a real random variable. According to the foregoing definition, $P(Y \in E | \mathfrak{F})$ or $P(Y^{-1}(E) | \mathfrak{F})$ is the conditional probability of the occurrence of the event $Y \in E$ under \mathfrak{F} . Since $P(Y \in E | \mathfrak{F})$ is determined except on a P -null set depending on E , an arbitrary version of $P(Y \in E | \mathfrak{F})$, viewed as a function of E , does not always satisfy the conditions of a probability measure. However, we can prove that there exists a nice version of $P(Y \in E | \mathfrak{F})$ which is a proba-

bility measure in $E \in \mathfrak{B}^1$ for every $\omega \in \Omega$ and that such a version is unique almost surely. This version is called a **regular conditional probability** of $Y \in E$ under \mathfrak{F} or the **conditional probability distribution** of Y under \mathfrak{F} ; this is written as $P_Y(E|\mathfrak{F})$. $P(Y \in E|X)$, $P(Y \in E|X = x)$, $P_Y(E|X)$, and $P_Y(E|X = x)$ are interpreted similarly. The conditional probability distribution can be defined not only for real random variables but also for every random variable which takes values in a σ -analytic measurable space.

F. Bayes's Formula

Let E_1, E_2, \dots, E_n be pairwise exclusive events, and assume that one of them must occur. If E is another random event, we have

$$P(E_i|E) = \frac{P(E_i)P(E|E_i)}{P(E_1)P(E|E_1) + \dots + P(E_n)P(E|E_n)},$$

where $P(E_i)$ is the probability of the event E_i and $P(E|E_i)$ is the conditional probability of E under the assumption that the event E_i has occurred. This is called **Bayes's formula**. In practical applications E_1, \dots, E_n usually represent n unknown hypotheses. Suppose that the probabilities on the right-hand side of the formula are given. We then apply Bayes's formula to reevaluate the probability of each hypothesis E_i knowing that some event E has occurred as the result of a trial. This is why $P(E_i)P(E|E_i)$ is called the **a priori (a posteriori) probability**. However, the determination of the values of a priori probabilities is sometimes difficult, and we often set $P(E_i) = 1/n$ in practical applications, although this has caused a great deal of criticism.

When X is a random variable subject to the distribution with continuous probability density $f(x)$, Bayes's formula is extended to the following form:

$$f(x_0|E) = \frac{f(x_0)P(E|X = x_0)}{\int_{-\infty}^{\infty} P(E|X = x)f(x)dx},$$

where $f(x|E)$ is the conditional probability density of the random variable X under the assumption that the event E has occurred, and $P(E|X = x_0)$ is the conditional probability of E relative to X .

G. Zero-One Laws

In probability theory there are many theorems claiming that an event with certain properties has probability 0 or 1. Such theorems are called **zero-one laws**. Here, we mention two famous examples, Kolmogorov's zero-one law

[6] and the Hewitt-Savage zero-one law. Let $\alpha = \alpha(X_1, X_2, \dots)$ be an event concerning a sequence of random variables $\{X_n\}$. α is called a **tail event** concerning $\{X_n\}$ if for every n , occurrence or nonoccurrence of α depends only on $\{X_n, X_{n+1}, \dots\}$. For example, $\{\lim_{n \rightarrow \infty} X_n = 0\}$ is a tail event. α is called a **symmetric event** concerning $\{X_n\}$ if occurrence or nonoccurrence of α is invariant under every finite permutation of X_1, X_2, \dots . For example, the event that $\sum_{k=1}^n X_k > 0$ for infinitely many n 's is a symmetric event. **Kolmogorov's zero-one law**: Every tail event concerning a sequence of independent random variables has probability 0 or 1. **Hewitt-Savage zero-one law**: Every symmetric event concerning a sequence of independent and identically distributed random variables has probability 0 or 1.

Kolmogorov's zero-one law can be extended as follows: Let $\mathfrak{F}_n, n = 1, 2, \dots$, be a sequence of independent σ -subalgebras of \mathfrak{B} . Then the σ -algebra $\mathfrak{I} = \bigcap_k \bigcup_{n>k} \mathfrak{F}_n$, called the **tail σ -algebra** of $\{\mathfrak{F}_n\}$, is trivial, i.e., $P(A) = 0$ or 1 for every $A \in \mathfrak{I}$. Kolmogorov's zero-one law is a special case where \mathfrak{F}_n is the σ -algebra generated by X_n for every n .

343 (VI.14) Projective Geometry

A. Introduction

Projective geometry is the most fundamental of classical geometries and one of the first examples of axiomatized mathematics.

B. Construction of Projective Geometry

We construct projective geometry axiomatically [4]. Given two sets P, Q and a relation $\Gamma \subset P \times Q$, consider the triple $\mathfrak{P} = \{P, Q, \Gamma\}$. We call each element of P a **point** and each element of Q a **line**. If $(p, l) \in \Gamma$ holds for a point p and a line l , then we say that the line l contains the point p . When two lines l_1 and l_2 contain a point p , we say that they intersect at p . When several points are contained in the same line, these points are said to be **collinear**, and when several lines contain the same point, these lines are said to be **concurrent**. For \mathfrak{P} we impose the following axioms:

- (I) There exists one and only one line that contains two given distinct points.
- (II) Suppose that we are given noncollinear points p_0, p_1 , and p_2 , and distinct points q_1, q_2 . Now suppose that $\{p_0, p_1, q_1\}$ and $\{p_0, p_2, q_2\}$ are collinear triples. Then the line containing p_1, p_2 and the line containing q_1, q_2 necessarily intersect (Fig. 1).

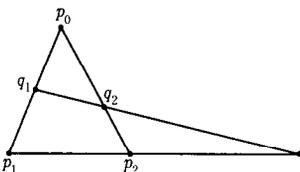

Fig. 1

- (III) Every line contains at least three distinct points.

The \mathfrak{P} that satisfy axioms (I) and (II) and axioms (I), (II), and (III) are called **general projective geometry** and **projective geometry**,

respectively. The set of all points that are contained in a line is called the **point range** with the line as its **base**. In projective geometry, there exists a one-to-one correspondence between the set of lines and the set of point ranges, so we can identify every line with a point range. In this case a line $l \in Q$ is represented as a subset of P , and the relation $(p, l) \in \Gamma$ means that the point p belongs to the set l .

Let S be a subset of P and p_1, p_2 be any two distinct points of S . If the line that contains p_1 and p_2 is always contained in S , then S is called a **subspace**. Points and lines are subspaces. Now we impose the following axiom:

- (IV) There exist a finite number of points such that any subspace that contains all of them contains P .

We call a projective geometry satisfying axiom (IV) a **finite-dimensional projective geometry**, which from this point on will be the sole object of our consideration. We call P a **projective space**. Consider sequences of subspaces of the type $P \supseteq P_{n-1} \supseteq \dots \supseteq P_1 \supseteq P_0 \neq \emptyset$, where \emptyset is the empty set. The number n of the longest sequence is called the **dimension** of P . If P is of dimension n , we write P^n instead of P . We call P^1 a **projective line** and P^2 a **projective plane**. Each subspace S of P , together with the set of lines of P contained in S , gives a finite-dimensional projective geometry, and so S is a projective space. Lines and points are projective spaces of dimensions 1 and 0, respectively. By convention, the empty set is a (-1) -dimensional projective space. We call each 2-dimensional subspace a **plane** and each $(n-1)$ -dimensional subspace in P^n a **hyperplane**.

Let M, N be subspaces of P , and for a pair of points $p \in M, q \in N$ consider the set $p \cup q$ of all points on the line that contains p and q . The set $\{p \cup q | p \in M, q \in N\}$ is denoted by $M \cup N$, and we call it the set spanned by M and N . By convention, we put $\emptyset \cup M = M$ and $p \cup p = p$. Then $P^r \cup P^s$ is the projective space of the lowest dimension which contains P^r and P^s . On the other hand, if we denote the intersection of P^r and P^s by $P^r \cap P^s$, then it is the projective space of highest dimension that is contained in both of them. We call $P^r \cup P^s$ and $P^r \cap P^s$ the **join** and the **intersection** of P^r and P^s , respectively. When the dimension of the space spanned by $r+1$ points is r , we say that these points are **independent**; otherwise they are **dependent**. If any $r+1$ points of a given subset M of P^n are independent for each $r \leq n$, we say that points of M lie in a **general position**. The space P^r necessarily contains $r+1$ independent points, and there necessarily exists a P^r that contains $r+1$ arbitrary given points in a projective space; it is unique if the points are indepen-

dent. If $P^r \cup P^s = P^t$ and $P^r \cap P^s = P^u$, then $r + s = t + u$. We call the latter the **dimension theorem** (or **intersection theorem**) of projective geometry.

The set Σ_1 of all hyperplanes that contain a P_0^{n-2} in P^n is called a **pencil of hyperplanes**, and the P_0^{n-2} common to them is called the **center** of Σ_1 . If a pencil of hyperplanes contains two distinct hyperplanes of P^n , then the pencil is determined uniquely by these two. When $n = 2$ and 3, it is called a **pencil of lines** and a **pencil of planes**, respectively. Each pencil of hyperplanes of P^n , or more generally, each pencil of hyperplanes of a subspace of an arbitrary dimension in P^n , is called a **linear fundamental figure** of P^n or simply a **fundamental figure**. In P^n , the set Σ_r of all $P_0^{n-r}, P_0^{n-r+1}, \dots, P_0^{n-1}$ that contain the same P_0^{n-r-1} is called the **star** with center P_0^{n-r-1} . Each set that consists of the totality of subspaces of an arbitrary dimension in the same P^r or a subset of it is called a **P^r -figure**.

Under the assumption that P^r and P^s do not have points in common, the operation of constructing $P^r \cup P^s$ from P^r and P^s is called **projecting** P^s from P^r . Assuming that P^r and P^s have points in common the operation of constructing $P^r \cap P^s$ from P^r and P^s is called **cutting** P^s by P^r . Suppose that we are given spaces P_0, P_1 , and P_2 , and a fundamental figure Σ in the space P_1 . By projecting Σ from P_0 and then cutting it by P_2 , we can construct a fundamental figure Σ' on P_2 . This operation is called **projection** of Σ from P_0 onto P_2 , and we call P_0 the **center of projection** (Fig. 2). In this case, we say that Σ and Σ' are **in perspective** and denote the relation by $\Sigma \bar{\wedge} \Sigma'$. If for two fundamental figures Σ and Σ' there exist a finite number of fundamental figures F_i ($1 \leq i \leq l$) such that $\Sigma \bar{\wedge} F_1 \bar{\wedge} \dots \bar{\wedge} F_l \bar{\wedge} \Sigma'$, then we say that Σ and Σ' are **projectively related** to each other and denote this by $\Sigma \bar{\wedge} \Sigma'$ (Fig. 3). Now for arbitrary subspaces P_1^r, P_2^r ($0 \leq r \leq n$), we take P_0^{n-r-1} that

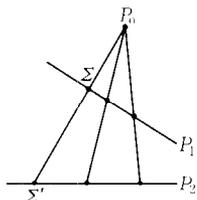

Fig. 2

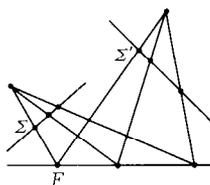

Fig. 3

have no points in common with them and project each point of P_1^r onto P_2^r from P_0^{n-r-1} . The one-to-one correspondence $P_1^r \rightarrow P_2^r$ thus obtained is called a **perspective mapping**. If a one-to-one correspondence $P_1^r \rightarrow P_2^r$ is represented as the composite of a finite number of perspective mappings, then we call it a **projective mapping**. These mappings are extended to those of fundamental figures, too.

Suppose that in a proposition or a figure in P^n , we interchange P^r and P^{n-r-1} ($0 \leq r \leq n$) and also interchange *contains* and *is contained* (and related terms). The proposition or the figure thus obtained is said to be **dual** to the original one. In projective geometry, if a proposition is true, then its dual proposition is also true (**duality principle**). This is assured because propositions dual to axioms (I)–(IV) hold; and P^r and Σ_r are dual to each other. The projective space P_*^n obtained by the principle of duality, by regarding the hyperplanes of P^n as points of P_*^n , is called the **dual space** of P^n .

C. Projective Coordinates

Here we introduce **projective coordinates** in P^n . Consider **Desargues's theorem**: Suppose that p_1, p_2, p_3 and q_1, q_2, q_3 , are two sets of points in P^n , each of which is independent and satisfies $p_i \neq q_i$ ($i = 1, 2, 3$). If the three lines $p_i \cup q_i$ ($i = 1, 2, 3$) are concurrent, then the three points $(p_2 \cup p_3) \cap (q_2 \cup q_3)$, $(p_3 \cup p_1) \cap (q_3 \cup q_1)$, $(p_1 \cup p_2) \cap (q_1 \cup q_2)$ are collinear. The converse is also true. This theorem holds for $n \geq 3$ generally. However, when $n = 2$, there exist projective geometries for which it does not hold; we call these **non-Desarguesian geometries**. In such cases it is impossible to introduce coordinates, so we assume Desargues's theorem for $n = 2$.

When four points p_i ($1 \leq i \leq 4$) in P^n lie on the same plane and in general position, we call the figure that consists of these four points and the six straight lines $g_{ij} = p_i \cup p_j$ ($1 \leq i < j \leq 4$) a **complete quadrangle** $p_1 p_2 p_3 p_4$; each p_i is called a **vertex**, and each g_{ij} is called a **side**. If six points q_i ($1 \leq i \leq 6$) on a line l are points of intersection of six sides $g_{12}, g_{13}, g_{14}, g_{34}, g_{24}, g_{23}$ of a complete quadrangle with l , we call

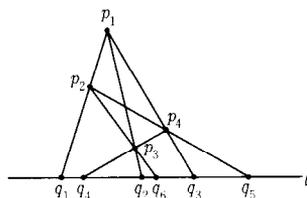

Fig. 4

them a **quadrangular set of six points** (Fig. 4). By Desargues's theorem, we can show that if there are given three fixed distinct points on a line l , then any pair of distinct points on l determines uniquely a point on l such that the six points thus obtained constitute a quadrangular set. The quadrangular property is invariant under projective mappings. On a line l we fix three mutually distinct points p_0, p_1, p_∞ . For any two points p_x, p_y different from p_∞ on l , we take the point s such that $p_\infty, p_x, p_0, p_\infty, p_y, s$ constitute a quadrangular set of six points and call s the **sum** of p_x and p_y with respect to $[p_0, p_\infty, p_1]$ (Fig. 5). On the other hand, the point t such that $p_0, p_x, p_1, p_\infty, p_y, t$ constitute a quadrangular set of six points is called the **product** of p_x and p_y with respect to $[p_0, p_\infty, p_1]$ (Fig. 6). When we are given a fixed triple $[p_0, p_\infty, p_1]$ on a line l , as before, the set of points on l not equal to p_∞ is called a **point range of the number system**, provided that we exclude p_∞ from the point range. We call the set of three points $[p_0, p_\infty, p_1]$ a **frame (or projective frame)** of l , and we call p_0 the **origin**, p_1 the **unit point**, and p_∞ the **supporting point**.

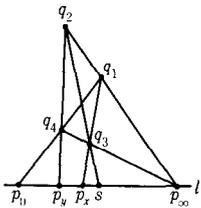

Fig. 5

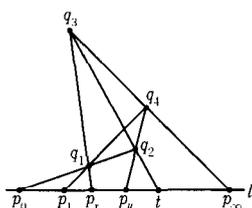

Fig. 6

A point range of the number system constitutes a field (which may be noncommutative) with respect to the previously defined sum and product. We call the field a **Staudt algebra**, and an abstract algebra isomorphic to it is called a **coefficient field** of P^n . We denote by $K(p_0, p_\infty, p_1)$ the Staudt algebra that is determined by a frame $[p_0, p_\infty, p_1]$. A projective mapping of l onto itself that leaves invariant each of three distinct points p_0, p_∞, p_1 on l is necessarily an inner automorphism of the field $K(p_0, p_\infty, p_1)$. Denoting by $[p_0, p_\infty, p_1]$ a frame on a line l of P^n with coefficient field K , we call each isomorphism $\theta: K(p_0, p_\infty, p_1) \rightarrow K$ a **coordinate system** of l . For each point p on l we call the element $\xi = \theta(p)$ of K the **inhomogeneous**

coordinate of p with respect to this frame. Also, we call the pair (x^0, x^1) such that $x^0, x^1 \in K$ and $x^1(x^0)^{-1} = \xi$ **homogeneous coordinates** of p . Since the supporting point p_∞ is excluded from $K(p_0, p_\infty, p_1)$, we fix $(0, x^1)$ such that $x^1 \neq 0$ as the homogeneous coordinates of p_∞ . In order for (x^0, x^1) and (y^0, y^1) to be homogeneous coordinates of the same point, it is necessary and sufficient that there exist an element $\lambda \neq 0$ of K such that $y^\alpha = x^\alpha \lambda$ ($\alpha = 0, 1$).

In conformity with these results, we now introduce coordinates in P^n . A set $\mathfrak{F} = [a_0, a_1, \dots, a_n, u]$ of ordered $n+2$ points in a general position is called a **frame (or projective frame)** of P^n ; each of a_α ($0 \leq \alpha \leq n$) is called a **fundamental point**, and u is called a **unit point**. For $A = a_{\alpha_0} \cup \dots \cup a_{\alpha_r}$ ($0 \leq \alpha_0 < \dots < \alpha_r \leq n$), we denote by A^* the space spanned by the remaining fundamental points. For any point p that is not contained in A^* , we put $p_A = A \cap (p \cup A^*)$ and call it the **component** of p on A . Then $\mathfrak{F}_A = [a_{\alpha_0}, \dots, a_{\alpha_r}, u_A]$ is a frame of A . Hereafter, we shall omit u_A for brevity. Suppose that isomorphisms $\theta_{\alpha\beta}: K(a_\alpha, a_\beta) \rightarrow K$ are assigned for each pair α, β ($0 \leq \alpha < \beta \leq n$). Under a certain condition, the system $\{\theta_{\alpha\beta}\}$ is determined by one of the $\theta_{\alpha\beta}$. In this case we denote $\{\theta_{\alpha\beta}\}$ by θ and call $\{\mathfrak{F}, \theta\}$ a **projective coordinate system** of P^n . For any point p of P^n not contained in $A_0 = a_1 \cup \dots \cup a_n$, we denote by p_i the component of p on $a_0 \cup a_i$ ($1 \leq i \leq n$), and we put $\xi^i = \theta(p_i)$. The elements of the ordered set $(\xi^1, \xi^2, \dots, \xi^n)$ are called the **inhomogeneous coordinates** of p with respect to \mathfrak{F} , and those of the set (x^0, x^1, \dots, x^n) such that $x^1(x^0)^{-1} = \xi^i$ are called the **homogeneous coordinates** of p . When p is contained in A_0 , we define $(0, x^1, \dots, x^n)$ as homogeneous coordinates of p with respect to \mathfrak{F} , provided that (x^1, \dots, x^n) are homogeneous coordinates of p with respect to \mathfrak{F}_{A_0} .

Now we represent the point whose coordinates are (x^0, x^1, \dots, x^n) simply by x . In P^n , when coordinates are introduced, a necessary and sufficient condition for points z to be on the line that passes through two distinct points x and y is that $z^\alpha = x^\alpha \lambda + y^\alpha \mu$ ($0 \leq \alpha \leq n$), when $\lambda, \mu \in K$ are parameters. More generally, a point z is contained in the space spanned by $r+1$ independent points x_β ($0 \leq \beta \leq r$) in P^n if and only if $z^\alpha = \sum_{\beta=0}^r x_\beta^\alpha \lambda^\beta$ ($0 \leq \alpha \leq n, \lambda^\beta \in K$). In particular, the equation of a hyperplane is represented in the form $\sum_{\alpha=0}^n X_\alpha z^\alpha = 0$ ($X_\alpha \in K$) with respect to variable coordinates z^α . Therefore each hyperplane is uniquely determined by the ratio of X_0, X_1, \dots, X_n . We call X_0, X_1, \dots, X_n **hyperplane coordinates** of the hyperplane. If $n=2$, they are called **coordinates** of a line, and if $n=3$, **plane coordinates** of a plane. (For coordinates of P^r in $P^n \rightarrow 90$ Coordinates B.)

D. Projective Transformations

A one-to-one correspondence φ between the point sets of two projective spaces P^n and \bar{P}^n is called a **collineation in the wider sense** if for any three points p_1, p_2, p_3 that are collinear, $\varphi(p_i)$ ($i = 1, 2, 3$) are also collinear and vice versa. If $\bar{P}^n = P^n$, we call φ a **correlation**; if $\bar{P}^n = P^n$, we call φ a **collineation**. If we denote a correlation by τ_0 , any other correlation is obtained as a composite of τ_0 and a collineation. If τ is a correlation, it naturally induces a mapping $P^n \rightarrow P^n$, which we also denote by τ . Then $\tau \circ \tau$ is a collineation. If $\tau \circ \tau$ is an identity, we call τ an **involution correlation**. Suppose that $\varphi: P^n \rightarrow \bar{P}^n$ is a collineation in the wider sense and $0 \leq r \leq n-1$. Then φ induces a one-to-one correspondence between the set of r -dimensional subspaces of P^n and the set of r -dimensional subspaces of \bar{P}^n ; and if $P^r \supset P^s$ in P^n , then $\varphi P^r \supset \varphi P^s$.

Next, suppose that we are given two projective spaces P^n and \bar{P}^n that are subspaces of a space P^N ($n < N$). (When Desargues's theorem holds, any two projective spaces of the same dimension can be identified with subspaces of a projective space of higher dimension.) In this case, when a collineation in the wider sense $\varphi: P^n \rightarrow \bar{P}^n$ is a projective mapping, we call it a **projective collineation in the wider sense**. A **projective collineation** is also called a **projective transformation**. The totality of collineations of P^n constitutes a \dagger transformation group and is called the **group of collineations of P^n** ; we denote it by $\mathfrak{C}(P^n)$. The totality of projective transformations of P^n constitutes a \dagger normal subgroup of $\mathfrak{C}(P^n)$; we denote it by $\mathfrak{G}(P^n)$ and call it the **group of projective transformations**. The totality of projective transformations that leave invariant a frame \mathfrak{F} of P^n constitutes a subgroup $\mathfrak{G}_0^{n+1}(\mathfrak{F})$. It is isomorphic to the group of \dagger inner automorphisms $\mathfrak{I}(K)$ of the coefficient field K of P^n . A collineation is not necessarily a projective transformation. The former is obtained as a composite of a projective transformation and an automorphism of the coefficient field. Specifically, if we denote the group of \dagger automorphisms of K by $\mathfrak{A}(K)$, then $\mathfrak{C}(P^n)/\mathfrak{G}(P^n) \cong \mathfrak{A}(K)/\mathfrak{I}(K)$. Hence in order for all collineations to be projective transformations, it is necessary and sufficient that all automorphisms of the coefficient field be inner automorphisms. If the coefficient field is the real number field, then collineations are always projective transformations. For the complex number field, however, this is not necessarily true.

Now, we consider the following three propositions: (1) The coefficient field of P^n is commutative. (2) Given frames \mathfrak{F} and \mathfrak{F}' of P^n , there exists a unique projective transformation

sending \mathfrak{F} onto \mathfrak{F}' . (3) Given two distinct lines l_1 and l_2 contained in a plane in P^n and two sets of three distinct points p_i ($i = 1, 2, 3$) and q_i ($i = 1, 2, 3$) that lie on l_1 and l_2 respectively, then the three points $(p_2 \cup q_3) \cap (p_3 \cup q_2)$, $(p_3 \cup q_1) \cap (p_1 \cup q_3)$, and $(p_1 \cup q_2) \cap (p_2 \cup q_1)$ are collinear. These three propositions are mutually equivalent. We call proposition (2) the **fundamental theorem of projective geometry** and proposition (3) the **theorem of Pappus**. If the coefficient field is the real (complex) number field, we call the projective space a **real (complex) projective space**. In classical geometry, only these cases were studied.

Suppose that the coefficient field is commutative. Then, if we assign an isomorphism $\theta_0: K(p_0, p_\infty, p_1) \rightarrow K$ for the Staudt algebra $K(p_0, p_\infty, p_1)$ on a line in a space, then the isomorphism θ of the Staudt algebra $K(q_0, q_\infty, q_1)$ on an arbitrary line onto K can be uniquely determined so that $\theta^{-1} \circ \theta_0$ is a projective mapping. Utilizing such isomorphisms, we can determine homogeneous coordinates in an arbitrary subspace of P^n by a frame on it.

Suppose that the coefficient field is a commutative field whose characteristic is not 2. For four collinear points p_i ($1 \leq i \leq 4$) in P^n , where p_1, p_2, p_3 are distinct and $p_4 \neq p_1$, we consider a frame such that p_1, p_2 , and p_3 are, respectively, the supporting point, the origin, and the unit point. The inhomogeneous coordinate λ of p_4 with respect to this frame is called the **anharmonic ratio (cross ratio or double ratio)** of these four points and is denoted by $[p_1, p_2; p_3, p_4]$. If we denote the inhomogeneous coordinates of p_i with respect to a general frame by (x_i^0, x_i^1) ($i = 1, 2, 3, 4$), then λ can be expressed as

$$\lambda = [p_1, p_2; p_3, p_4] = \frac{(x_1^0 x_3^1 - x_3^0 x_1^1)(x_2^0 x_4^1 - x_4^0 x_2^1)}{(x_1^0 x_4^1 - x_4^0 x_1^1)(x_2^0 x_3^1 - x_3^0 x_2^1)}$$

Moreover, if we interchange the order of the four points, then we have

$$\begin{aligned} \lambda &= [p_2, p_1; p_4, p_3] \\ &= [p_3, p_4; p_1, p_2] \\ &= [p_4, p_3; p_2, p_1], \\ [p_1, p_2; p_4, p_3] &= \frac{1}{\lambda}, \\ [p_1, p_3; p_2, p_4] &= 1 - \lambda, \\ [p_1, p_3; p_4, p_2] &= \frac{1}{1 - \lambda}, \\ [p_1, p_4; p_2, p_3] &= \frac{\lambda - 1}{\lambda}, \\ [p_1, p_4; p_3, p_2] &= \frac{\lambda}{\lambda - 1}. \end{aligned}$$

In general, these six values are different; however, there are the following two exceptions: when $\lambda = -1, 1/2$, and 2 ; and when λ is a root of $\lambda^2 - \lambda + 1 = 0$. When $\lambda = -1$, these four points are called a **harmonic range of points**, and the points p_3, p_4 are called **harmonic conjugates** with respect to p_1, p_2 ; or p_1, p_2 and p_3, p_4 are said to be **harmonically separated** from each other. When $\lambda^2 - \lambda + 1 = 0$, these four points are said to be an **equianharmonic range of points**. For the dual of these, we can consider the anharmonic ratio of four hyperplanes of a pencil of hyperplanes. The concept of the anharmonic ratio can be extended further to the case of four elements of fundamental figures in general. The anharmonic ratio is a quantity that is invariant under projective transformations.

Each projective transformation $x \rightarrow \bar{x}$ is expressed with respect to homogeneous coordinates x^α ($0 \leq \alpha \leq n$) of P^n as

$$\bar{x}^\alpha = \sum_{\beta=0}^n t_{\beta}^{\alpha} x^{\beta}, \quad \rho, t_{\beta}^{\alpha} \in K, \quad (1)$$

$$\rho \neq 0, \quad \det(t_{\beta}^{\alpha}) \neq 0.$$

Conversely, if $T = (t_{\beta}^{\alpha})$ is a regular matrix ($t_{\beta}^{\alpha} \in K$), then (1) determines a projective transformation. So there is a one-to-one correspondence between projective transformations and equivalence classes of the regular matrices $T = (t_{\beta}^{\alpha})$ with the equivalence relation $T \sim \lambda T$ ($\lambda \in K \setminus \{0\}$). Therefore, when K is commutative, the group of projective transformations $\mathfrak{G}(P^n)$ of P^n is isomorphic to the factor group $PGL(n+1, K)$ of the general linear group $GL(n+1, K)$ with the coefficient field K by its center $\{\rho I | \rho \in K \setminus \{0\}\}$; that is, $\mathfrak{G}(P^n) \cong PGL(n+1, K)$.

Extending the definition of projective transformations, we call the transformation represented by (1), with an arbitrary square matrix that is not necessarily regular, a projective transformation. When T is regular, it is called a **regular projective transformation**, and when T is not regular, it is called a **singular projective transformation**. In particular, if the rank of T is $n+1-h$, then we say that the projective transformation is **singular of the h th species**. If (1) is singular of the h th species, $n+1$ hyperplanes $\sum_{\beta=0}^n t_{\beta}^{\alpha} x^{\beta} = 0$ ($0 \leq \alpha \leq n$) have a space P^{h-1} in common. We call P^{h-1} the **singular subspace** of this transformation. A projective transformation is not defined on its singular subspace. A singular projective transformation of the h th species is the composite of the projection of P^n onto some P^{n-h} with the singular subspace as its center and a regular projective transformation of P^{n-h} .

If the coordinates of a point are denoted by (x^α) and hyperplane coordinates with

Projective Geometry

respect to some frame by (X_α) , then the linear transformation

$$\tau_*: \rho X_\alpha = \sum_{\beta=0}^n t_{\alpha\beta}^* x^\beta, \quad \rho, t_{\alpha\beta}^* \in K, \quad (2)$$

is a correlation. (Here also, we extend the definition of correlation and include the case where $T_* = (t_{\alpha\beta}^*)$ is not regular.) The condition that τ_* is an involutive correlation is given by $T_* = \pm {}^t T_*$. When $T_* = -{}^t T_*$, the involutive correlation τ_* is called a **null system**. The correlation τ_* is a null system if and only if any point x of P^n is contained in the hyperplane $\tau_*(x)$. When $T_* = {}^t T_*$, we call the involutive correlation τ_* a **polar system**. For a polar system τ_* , the set of points x that are contained in hyperplanes $\tau_*(x)$ constitutes a **quadric hypersurface** (or **hyperquadric**).

E. Quadric Hypersurfaces

Let τ_* be a polar system, and let Q_2^{n-1} be the totality of points x contained in $\tau_*(x)$. Then the equation of the quadric hypersurface Q_2^{n-1} is given by

$$\sum_{\alpha, \beta=0}^n t_{\alpha\beta}^* x^\alpha x^\beta = 0. \quad (3)$$

For such a correlation τ_* we call a relation between the set of points x of P^n and the set of hyperplanes $\tau_*(x)$ a **polarity** with respect to Q_2^{n-1} . We call $\tau_*(x)$ the **polar** of x with respect to Q_2^{n-1} , and x the **pole** of $\tau_*(x)$ with respect to Q_2^{n-1} . If the points of intersection of a line passing through a point x with Q_2^{n-1} and $\tau_*(x)$ are denoted by $z_1, z_2; y$, then $x, y; z_1, z_2$ is a harmonic range of points. When a point x lies on the polar of a point y , we say that x and y are mutually **conjugate**. Each point on Q_2^{n-1} is conjugate with itself, and the converse is also true. We call the polar of a point on Q_2^{n-1} the **tangent hyperplane** of Q_2^{n-1} at that point.

If τ_* is regular or singular of the h th species, we call the corresponding quadric hypersurface **regular** or **singular of the h th species**. If τ_* is singular of the h th species, its singular subspace is contained in Q_2^{n-1} . We call points on this singular subspace **singular points** of Q_2^{n-1} . Q_2^{n-1} , which is singular of the first species (i.e., Q_2^{n-1} with just one singular point), is called a **cone**.

We call a subspace contained in Q_2^{n-1} a **generating space**. If it is a line we call it a **generating line**. We put $q = (n-2)/2$ or $(n-1)/2$ according as n is even or odd. Then, if the coefficient field is an algebraically closed field, for each regular Q_2^{n-1} there necessarily exist q -dimensional generating spaces. Also, Q_2^2 is a ruled surface covered by two families

of generating lines, and Q_2^{2k} is covered by two families of k -dimensional generating spaces.

If p_i ($1 \leq i \leq 5$) are five points in a general position in a plane, then there exists one and only one Q_2^1 passing through these points; we call Q_2^1 a **conic**. In order that six points p_i ($1 \leq i \leq 6$) in a plane lie on Q_2^1 , it is necessary and sufficient that the three points $(p_1 \cup p_2) \cap (p_4 \cup p_5)$, $(p_2 \cup p_3) \cap (p_5 \cup p_6)$, and $(p_3 \cup p_4) \cap (p_6 \cup p_1)$ be collinear (**Pascal's theorem**). The dual of the last theorem is called **Brianchon's theorem**.

Given two hypersurfaces Q_2^{n-1} , \bar{Q}_2^{n-1} in P^n , we consider another \bar{Q}_2^{n-1} such that the polar of an arbitrary point x with respect to \bar{Q}_2^{n-1} belongs to the pencil of hyperplanes determined by polars of x with respect to Q_2^{n-1} and \bar{Q}_2^{n-1} . The set of all such \bar{Q}_2^{n-1} is called a **pencil of quadric hypersurfaces**. It is the set of all \bar{Q}_2^{n-1} that pass through the intersection of Q_2^{n-1} and \bar{Q}_2^{n-1} . In the cases $n=2$ and 3 , we call it a **pencil of conics** and a **pencil of quadrics**, respectively.

Denoting by l^{ij} and \bar{l}^{ij} ($0 \leq i < j \leq 3$) the \dagger Plücker coordinates of two straight lines l and \bar{l} in P^3 , we put

$$(l, \bar{l}) = l^{01}\bar{l}^{23} - l^{02}\bar{l}^{13} + l^{03}\bar{l}^{12} + \bar{l}^{01}l^{23} - \bar{l}^{02}l^{13} + \bar{l}^{03}l^{12}. \quad (4)$$

Then $(l, l) = 0$ holds. If we regard these l^{ij} as homogeneous coordinates of P^5 , then there exists a one-to-one correspondence between the points on the regular quadric hypersurface Q_2^4 defined by $(l, l) = 0$ and the lines in P^3 . We say that each point of Q_2^4 is the **image** of the line corresponding to it in P^3 . Two lines l and \bar{l} intersect if and only if $(l, \bar{l}) = 0$. Geometrically, this means that the images of l and \bar{l} are conjugate with respect to Q_2^4 . Therefore the line passing through the images of l and \bar{l} is a generating line of Q_2^4 . The image of a pencil of lines in P^3 is a generating line of Q_2^4 . Quadric hypersurfaces and sets of lines in P^3 are important objects of study in both projective and algebraic geometry. In particular, **linear line congruences (linear line complexes)** that are families of lines dependent upon two (three) parameters are of great interest. In these theories, quadric hypersurfaces play a fundamental role. When the coefficient field is noncommutative, the above theory has to be greatly modified.

F. Projective Geometry and the Erlangen Program

From the standpoint of the \dagger Erlangen program of F. Klein, the aim of projective geometry is to study properties that are invariant under the group of projective transformations.

Utilizing various subgroups of this group, we can reconstruct various classical geometries. For example, consider the projective space P^n whose coefficient field is the real number field, and fix a hyperplane Π_∞ . Let $\mathfrak{S}(P^n)$ be the subgroup of projective transformations formed by all projective transformations that leave Π_∞ invariant. Then the geometry that belongs to this group is \dagger affine geometry. Similarly, fix an imaginary regular quadric hypersurface Q_2^{n-2} in Π_∞ and consider the geometry that belongs to the subgroup of $\mathfrak{S}(P^n)$ leaving this Q_2^{n-2} invariant. We thus obtain Euclidean geometry. Moreover, if we assign some regular quadric hypersurface Q_2^{n-1} , then the geometry belonging to the subgroup of $\mathfrak{S}(P^n)$ that leaves the Q_2^{n-1} invariant is a \dagger non-Euclidean or \dagger conformal geometry according as the transformation space is the set of inner points of Q_2^{n-1} or the whole Q_2^{n-1} .

G. Projective Geometry and Modular Lattices

\dagger Lattices (lattice-ordered sets) and projective geometry are intimately related. The totality of subspaces of each dimension in general projective geometry \mathfrak{P} constitutes a \dagger complete \dagger modular lattice $L(\mathfrak{P})$ with respect to the inclusion relation. If \mathfrak{P} is a finite-dimensional projective geometry, then it is an \dagger irreducible complemented modular lattice of finite \dagger height. Conversely, suppose that L is a modular lattice with \dagger minimum element Φ , and denote by P the totality of elements p \dagger prime over Φ (i.e., \dagger atomic elements) and by Q the totality of elements l \dagger prime over atomic elements. Then, if $p < l$ and $(p, l) \in \Gamma$, $\mathfrak{P}(L) = \{P, Q, \Gamma\}$ is a general projective geometry. If L is an irreducible complemented modular lattice of finite height, then $\mathfrak{P}(L)$ is a finite-dimensional projective geometry; in this case we have $\mathfrak{P} \approx \mathfrak{P}(L(\mathfrak{P}))$ and $L \approx L(\mathfrak{P}(L))$. So we may consider projective geometry and irreducible complemented modular lattices as having the same mathematical structure. If a lattice L is an n -dimensional projective geometry, its \dagger dual lattice is also an n -dimensional projective geometry, and this is the principle of duality.

H. Analytic Representations of Projective Geometry

Let K be an arbitrary field, commutative or noncommutative. For an arbitrary natural number n , we consider an $(n+1)$ -dimensional (for the noncommutative case, right or left) linear space $V^{n+1}(K)$ over K . The totality of linear subspaces in it constitutes an irreducible complemented modular lattice $P^n(K)$ with

respect to the inclusion relation, and $P^n(K)$ gives rise to an n -dimensional projective geometry. We call it a **right** or **left projective space**. Points of $P^n(K)$ correspond to (right or left) 1-dimensional linear subspaces. Conversely, it can be shown that an n -dimensional projective geometry over K is isomorphic to $P^n(K)$. Therefore projective geometries can be completely classified by means of the natural number n and the field K except when $n=2$ and the geometry is non-Desarguesian. We may restate this fact as follows: We consider a space $\tilde{P} = V^{n+1}(K) - \{0\}$. If we fix a basis of $V^{n+1}(K)$, then we can represent $\tilde{P} = \{x = (x^0, x^1, \dots, x^n) \mid x^\alpha \in K, 0 \leq \alpha \leq n, x \neq (0, 0, \dots, 0)\}$. If there exists a nonzero element λ of K such that $y = x\lambda$, then the elements x and y are called equivalent; we write $x \sim y$. We denote by $P^n(K)$ the factor set of \tilde{P} under the foregoing equivalence relation, and by $[x]$ the equivalence class that contains x . We put $l([x], [y]) = \{[z] \mid z^\alpha = x^\alpha \lambda + y^\alpha \mu, \forall \lambda, \mu \in K\}$ and $Q = \{l([x], [y]) \mid [x], [y] \in P^n(K)\}$. We call each element of $P^n(K)$ a point and each element of Q a line. Then these points and lines and the natural inclusion relation satisfy axioms (I)–(IV) and give an n -dimensional projective geometry. When K is a †topological field (e.g., the real number field, the complex number field, or the †quaternion field), we may define the topology of $P^n(K)$ as the factor space $P^n(K) = \tilde{P}/\sim$. In particular, if K is the real number field \mathbf{R} , then $P^n(\mathbf{R})$ is homeomorphic to the factor space obtained from the n -dimensional hypersphere $S^n: (x^0)^2 + \dots + (x^n)^2 = 1$ in the $(n+1)$ -dimensional Euclidean space E^{n+1} by identifying the end points of each diameter. Hence $P^n(\mathbf{R})$ is compact. Similar facts hold for the cases of the complex and quaternion number fields. Since the group of projective transformations $\mathfrak{G}(P^n(K))$ acts †transitively on $P^n(K)$, if K is a topological field we can regard $P^n(K)$ as a †homogeneous space of the topological group $\mathfrak{G}(P^n(K))$. Moreover, the totality of r -dimensional subspaces in $P^n(K)$ constitutes a †Grassmann manifold. In algebraic geometry the †direct product of two projective spaces is important; we call it a **biprojective space**.

I. Tits's Theory of Buildings (Generalization of Projective Geometry)

In a situation when a triple (G, B, N) consisting of a group G and its subgroups B, N satisfies the axioms of a **BN -pair** or **Tits system** (\rightarrow 13 Algebraic Groups R), a new geometric object, called a "building," was introduced by J. Tits [9]. His theory contains projective geometry as a particular case. The theory of buildings has deep connection with algebraic groups.

The Tits system corresponds to a projective geometry in the following case. Let k be any commutative field, and let G be the general linear group of degree n over k , i.e., G consists of all nonsingular square matrices of degree n with entries in k . Let B be the subgroup of G consisting of all upper triangular matrices (i.e., matrices whose entries below the principal diagonal are all zero). Let N be the subgroup of G consisting of all monomial matrices (i.e., matrices such that each column and each row contain just one nonzero entry). Then (G, B, N) forms a Tits system called type (A_{n-1}) . The corresponding **theory of buildings** of the type above is nothing but the projective geometry. Thus by means of Tits's theory of buildings the relationships among projective geometry and other geometries have been clarified [9].

344 (VII.22) Pseudoconformal Geometry

A. Definitions

Let A and A' be subsets (with relative topology) of †complex manifolds X and X' of dimension n , respectively. A homeomorphism f of A onto A' is called a **pseudoconformal transformation** if there exists a †biholomorphic mapping \tilde{f} of an open neighborhood of A in X onto an open neighborhood of A' in X' such

that $\tilde{f}(x) = f(x)$ for $x \in A$. If there exists such a mapping f , A is said to be **pseudoconformally equivalent** to A' . **Pseudoconformal geometry** is a geometry that studies geometric properties invariant under the pseudoconformal equivalence. However, most studies in pseudoconformal geometry so far have concentrated mainly on the investigation of smooth hypersurfaces in a complex manifold—more specifically, the smooth (or real analytic) boundaries of bounded domains in \mathbb{C}^n . In fact, to pseudoconformal geometry on hypersurfaces we can apply the methods of differential geometry as well as those of the theory of functions of several complex variables.

H. Poincaré [1] studied perturbations of the boundary of the unit ball in \mathbb{C}^2 that are pseudoconformally equivalent. F. Cartan [2] studied the equivalence problem of hypersurfaces in \mathbb{C}^2 and gave the complete list of all simply connected hypersurfaces on which the group of pseudoconformal automorphisms acts transitively. Such a hypersurface is called **homogeneous**.

Let M be a smooth hypersurface in a complex manifold X with the †almost complex structure tensor J , i.e., $J_x: T_x X \rightarrow T_x X$ is an involutive linear automorphism of the tangent space $T_x X$ of X at x induced by the complex structure of X . Put $H_x M = T_x M \cap J_x T_x M$ for $x \in M$. The union of all $H_x M$ is called the bundle of holomorphic tangent vectors of M and is denoted by $H(M)$. $H(M)$ is also called the **CR (Cauchy-Riemann) structure** of M . Let M' be a smooth hypersurface in a complex manifold X' . A diffeomorphism $f: M \rightarrow M'$ is called a **CR-equivalence** if the †differential mapping $Tf: TM \rightarrow T M'$ of f preserves the CR-structures, where TM denotes the †tangent bundle of M . If $f: M \rightarrow M'$ is a pseudoconformal transformation, then f is clearly a CR-equivalence. Let E_x be the annihilator of $H_x M$ in $T_x^*(M)$. Then the union of E_x ($x \in M$) defines a †line bundle E over M . The **Levi form** L_x at $x \in M$, defined only up to a multiplier, is the quadratic form on $H_x M$ defined by $L_x(u, v) = d\theta(u, v)$ for $u, v \in H_x M$, where θ is a nonvanishing section of E in a neighborhood of x . If the Levi form is nondegenerate at every point of M , M is called a **nondegenerate hypersurface**. In particular, if the Levi form is definite, then M is called **strictly pseudoconvex**.

B. Equivalence Problem

Cartan studied the equivalence problem for the case $n = 2$, and obtained a criterion for two hypersurfaces in \mathbb{C}^2 to be pseudoconformally equivalent. N. Tanaka (1965) generalized the method of Cartan for the case $n \geq 3$ and ob-

tained a criterion in terms of †Cartan connections in some fiber bundle over the hypersurfaces. However, he did not publish the proof of his result until S. S. Chern and J. Moser [4], independently of Tanaka [3], obtained a similar result and gave the first proof of this result. Let M be a real analytic hypersurface in \mathbb{C}^{n+1} ($n \geq 1$) whose Levi form has p positive and q negative eigenvalues ($p + q = n$). Let H be the subgroup of $SU(p + 1, q + 1)$ leaving the point $(1, 0, \dots, 0) \in \mathbb{C}^{n+2}$ fixed. According to the Cartan-Tanaka-Chern-Moser result, we can construct functorially a principal fiber bundle Y over M with structure group H and a Cartan connection ω on Y with values in the Lie algebra of $SU(p + 1, q + 1)$ such that if M and M' are pseudoconformally equivalent, then there is a bundle isomorphism φ of Y to Y' preserving the Cartan connections: $\varphi^* \omega' = \omega$, where Y' is the corresponding principal fiber bundle over M' and ω' is the Cartan connection on Y' . Conversely, if there is a bundle isomorphism φ of Y to Y' such that $\varphi^* \omega' = \omega$, then M and M' are pseudoconformally equivalent. By using this solution of the equivalence problem, we can prove that the group $A(M)$ of all pseudoconformal automorphisms of a nondegenerate real analytic hypersurface M in a complex manifold X of dimension n is a Lie transformation group of dimension not exceeding $n^2 + 2n$. H. Jacobowitz [5] constructed a similar bundle B over M and a Cartan connection on B in a different way from that of Chern and Moser. We do not know whether B and Y actually coincide.

C. Classification

Cartan (1932) classified all simply connected homogeneous hypersurfaces in \mathbb{C}^2 . In particular, he proved that if M is a compact homogeneous strictly pseudoconvex hypersurface with $\dim M = 3$, then M is pseudoconformally equivalent to either (1) S^3 or its quotient by the action of a root of unity or (2) the hypersurface given in the 2-dimensional projective space by the equation in homogeneous coordinates: $(z_1 \bar{z}_1 + z_2 \bar{z}_2 + z_3 \bar{z}_3)^2 = m^2 |z_1^2 + z_2^2 + z_3^2|^2$ ($m > 1$) or the double covering of such a surface. A. Morimoto and T. Nagano [6] and later H. Rossi [7] tried to generalize this result and obtained a partial classification of simply connected compact homogeneous hypersurfaces with dimension ≥ 5 . D. Burns and S. Shnider [8] classified all simply connected compact homogeneous strictly pseudoconvex hypersurfaces M with $\dim M = 2n + 1 \geq 5$. They proved that M is pseudoconformally equivalent to S^{2n+1} or the tangent sphere bundle of a rank one †symmetric space

or the unit circle bundle of a homogeneous negative line bundle over a homogeneous algebraic manifold.

On the other hand, a real hypersurface M in a complex manifold X of complex dimension $n + 1$ is called **spherical** if at every point $p \in M$, there is a neighborhood of p in X such that $U \cap M$ is pseudoconformally equivalent to an open submanifold of S^{2n+1} . The hyperquadric $Q^{n+1} = \partial U_{n+1}$ is spherical, where $U_{n+1} = \{(z_1, \dots, z_{n+1}) \in \mathbb{C}^{n+1} \mid \text{Im}(z_{n+1}) > |z_1|^2 + \dots + |z_n|^2\}$. If M is spherical, then the universal covering space \tilde{M} of M is also spherical. If M is a homogeneous spherical hypersurface, then there is a covering into mapping $f: \tilde{M} \rightarrow S^{2n+1}$, and $f(\tilde{M})$ is a homogeneous domain in S^{2n+1} . We know that the only compact simply connected spherical M is S^{2n+1} . Burns and Shnider classified all homogeneous domains M in S^{2n+1} : M is pseudoconformally equivalent to (I) or (II) of the following: (Ia) $S^{2n+1} - V \cap S^{2n+1}$, where V is a complex vector subspace of \mathbb{C}^{n+1} with $0 \leq \dim_{\mathbb{C}} V \leq n$. (Ib) $Q^{n+1} - L_m \cdot 0$, $0 \leq m \leq n$, where L_m is a certain subgroup of $SU(n+1, 1)/(\text{center})$. (II) $S^{2n+1} - S^{2n+1} \cap \mathbb{R}^{n+1}$. At present, it seems difficult to extend Cartan's classification of all simply connected homogeneous hypersurfaces to higher dimensions. K. Yamaguchi (1976) treated a hypersurface M in a complex manifold of dimension n with a large automorphism group $A(M)$. He showed that if $\dim A(M) = n^2 + 2n$, then M is a real hyperquadric in the n -dimensional complex projective space $P_n \mathbb{C}$ (\rightarrow Section B). He then showed that the second largest dimension for $A(M)$ is equal to $n^2 + 1$ except when $n = 3$ and the index $r = 1$, for which $\dim A(M) = 11 (= n^2 + 1)$. Under the additional assumption that M is homogeneous, he showed that if $\dim A(M) = n^2 + 1$, then M is the affine part of a real hyperquadric in $P_n \mathbb{C}$ (except when $n = 5$ and $r = 2$). He also obtained a similar result in the nonhomogeneous case.

D. Relations to Other Equivalences

Let D_1 and D_2 be bounded domains in \mathbb{C}^n with smooth boundary $\partial D_i = M_i$ ($i = 1, 2$) for which we denote by $H(M_i)$ the CR structures. We consider the following propositions (A)–(D) for these domains: (A) D_1 is biholomorphically equivalent to D_2 . (B) M_1 is CR equivalent to M_2 . (C) M_1 is pseudoconformally equivalent to M_2 . (D) There is a diffeomorphism $f: D_1 \rightarrow D_2$ such that $f|_{D_1}: D_1 \rightarrow D_2$ is biholomorphic.

It is clear that (C) implies (D) and that (D) implies (A). On the other hand, we can prove that (B) is equivalent to (D). When does (A) imply (B) and when does (B) imply (C)?

C. Fefferman [10] proved that (A) implies (D) when D_1 and D_2 are strictly pseudoconvex. S. Bell generalized the result of Fefferman in the case when one of D_1 and D_2 is strictly pseudoconvex. Bell and E. Ligoicka [11] proved that if M_1 and M_2 are real analytic and if D_1 and D_2 are pseudoconvex, then (A) implies (D). When D_1 and D_2 are not strictly pseudoconvex and M_i is not real analytic, we do not know whether (A) implies (D) or not. As remarked by Burns, Shnider, and Wells (1978), by using the theorem of Fefferman, we can prove that (A) implies (C) when M_1 and M_2 are real analytic and if D_1 and D_2 are strictly pseudoconvex. I. Naruki [12] obtained the same result. We do not know whether (A) implies (C) when M_1 and M_2 are real analytic and D_1 and D_2 are pseudoconvex, though we know that (A) implies (B). We do not know whether (B) implies (C) in general.

S. I. Pinchuk [13] proved the following: Let D, D' be strictly pseudoconvex domains in \mathbb{C}^n with simply connected real analytic boundaries $\partial D, \partial D'$. Let $f: U \rightarrow \mathbb{C}^n$ be a nonconstant holomorphic mapping from a connected neighborhood U of a point $p \in \partial D$ in \mathbb{C}^n into \mathbb{C}^n such that $f(U \cap \partial D) \subset \partial D'$. Then we can find a holomorphic mapping $\tilde{f}: D \rightarrow D'$ such that $\tilde{f}(x) = f(x)$ for $x \in D \cap U$. Combining this theorem with Fefferman's result we see that for two domains as above, D is biholomorphically equivalent to D' if and only if ∂D is locally pseudoconformally equivalent to $\partial D'$, i.e., there are neighborhoods U and V of a point $p \in \partial D$ and $q \in \partial D'$, respectively, such that $U \cap \partial D$ and $V \cap \partial D'$ are pseudoconformally equivalent.

Concerning the †proper holomorphic mappings rather than diffeomorphisms, Burns and Shnider (1979) proved the following theorem: Let $M_i = \partial D_i$ ($i = 1, 2$) be strictly pseudoconvex, and let $f: D_1 \rightarrow D_2$ be a proper holomorphic mapping. (a) If $D_1 = D_2$, then f extends smoothly up to the boundary D_1 . (b) If ∂D_i is real analytic for $i = 1, 2$, then f extends holomorphically past the boundary.

E. Deformations of Domains

Let M be a compact connected strictly pseudoconvex real hypersurface in a complex manifold X of dimension $n + 1$. Let φ be a smooth strictly †plurisubharmonic function defined on a neighborhood V of M such that $M = \{x \in V \mid \varphi(x) = 0\}$ and $d\varphi \neq 0$ on M . Let $U = \{x \in V \mid -\varepsilon < \varphi(x) < \varepsilon\}$ for small $\varepsilon > 0$ such that \bar{U} is compact and ∂U is smooth. Let $\mathcal{P}(\bar{U})$ be the open set in $\mathbb{C}^\infty(\bar{U})$ of strictly plurisubharmonic functions ψ with $d\psi \wedge \bar{d}\psi \wedge (d\bar{d}\psi)^n \neq 0$ on \bar{U} . Let $B \subset \mathbb{R}^k$ be a small open ball around 0. We denote by $\mathcal{P}(\bar{U} \times \bar{B})$ the set of $\psi \in \mathbb{C}^\infty(\bar{U})$

$\times \bar{B}$) such that $\psi(x, t) = \psi_t(x) \in \mathcal{P}(\bar{U})$ for all $t \in \bar{B}$. For $\psi \in \mathcal{P}(\bar{U} \times \bar{B})$ we set $M_{t, \delta} = \{x \in U \mid \psi_t(x) = \delta\}$. After introducing these notations, Burns, Shnider, and Wells (1978) proved the following theorem. There exists an open dense set $\mathcal{V} \subset \mathcal{P}(\bar{U} \times \bar{B})$ with $\varphi \in \mathcal{V}$ and a set of "second category" $\mathcal{R} \subset \mathcal{V}$ such that for every $\psi \in \mathcal{R}$, $t_i \in \bar{B}$ and $\delta_i \in \mathbf{R}$ small enough, (i) M_{t_1, δ_1} is CR-equivalent to M_{t_2, δ_2} if and only if $t_1 = t_2$, $\delta_1 = \delta_2$. (ii) The group of CR-automorphisms of $M_{t, \delta}$ reduces to the identity only. For $\psi \in \mathcal{P}(\bar{U} \times \bar{B})$, taking $t \in B$, $\delta \in \mathbf{R}$ small enough, $M_{t, \delta}$ is a compact connected strictly pseudoconvex hypersurface in X . If M bounds the relatively compact region D in X then $M_{t, \delta}$ also bounds a relatively compact region $D_{t, \delta}$. In particular, there exist smooth families of deformations of the unit ball in \mathbf{C}^{n+1} of arbitrary high dimension. There are arbitrary small perturbations of the unit sphere in \mathbf{C}^{n+1} that admit no pseudoconformal transformations other than the identity.

F. Topics Related to Pseudoconformal Geometry

(1) Pinchuk (1975) proved the following: Let D_1, D_2 be strictly pseudoconvex domains in \mathbf{C}^n with C^ω boundary $\partial D_1, \partial D_2$. Let U be a neighborhood of a point $p \in \partial D_1$ in \mathbf{C}^n . If there is a C^1 -mapping $f: U \cap \bar{D}_1 \rightarrow \mathbf{C}^n$ such that f is holomorphic on $U \cap D_1$ and $f(U \cap \partial D_1) \subset \partial D_2$, then there is a holomorphic mapping $\tilde{f}: U' \rightarrow \mathbf{C}^n$ of a neighborhood U' of $U \cap \partial D_1$ into \mathbf{C}^n such that $\tilde{f}(x) = f(x)$ for $x \in U \cap \bar{D}_1 \cap U'$. This result is related to the implication (B) \Rightarrow (C) in Section D.

(2) H. Alexander [14] proved the following: Let U be a connected neighborhood of a point $p \in S^{2n-1}$ in \mathbf{C}^n and $f: U \rightarrow \mathbf{C}^n$ a holomorphic mapping such that $f(U \cap S^{2n-1}) \subset S^{2n-1}$. Then either f is a constant mapping or there is a biholomorphic automorphism $\tilde{f}: B_n \rightarrow B_n$ of the unit open ball B_n such that $\tilde{f}(x) = f(x)$ for $x \in U \cap B_n$. He also proved that every proper holomorphic mapping $f: B_n \rightarrow B_n$ is necessarily an automorphism of B_n if $n > 1$. G. M. Henkin (1973) proved that every proper holomorphic mapping $f: D_1 \rightarrow D_2$ of a strictly pseudoconvex domain D_1 into a strictly pseudoconvex D_2 can be extended continuously to a function $\tilde{f}: \bar{D}_1 \rightarrow \bar{D}_2$. More precisely, there is a constant $c > 0$ such that $|f(z_1) - f(z_2)| \leq c|z_1 - z_2|^{1/2}$ for every $z_1, z_2 \in D_1$.

(3) Let M be a real hypersurface in \mathbf{C}^{n+1} with $H(M)$ the bundle of holomorphic tangent vectors to M . We take a real nonvanishing 1-form θ that annihilates $H(M)$. S. M. Webster (1978) called the pair (M, θ) a **pseudo-Hermitian manifold**. He considered the equiv-

alence problem of pseudo-Hermitian manifolds by applying Cartan's method of equivalence. He proves, among other things, that the group of all pseudo-Hermitian transformations of the nondegenerate pseudo-Hermitian manifold (M, θ) of dimension $2n + 1$ is a Lie transformation group of dimension not exceeding $(n + 1)^2$. Webster considered the relation between pseudo-Hermitian manifolds and pseudoconformal geometry and proved that for $n \geq 2$ the ellipsoid E given by the equation $A_1 x_1^2 + B_1 y_1^2 + \dots + A_{n+1} x_{n+1}^2 + B_{n+1} y_{n+1}^2 = 1$, where $z_k = x_k + iy_k$ ($k = 1, \dots, n + 1$) is pseudoconformally equivalent to the hypersphere S^{2n+1} if and only if $A_k = B_k$ ($k = 1, \dots, n + 1$). This result gives, by virtue of Fefferman's theorem, a necessary and sufficient condition for an ellipsoidal domain to be biholomorphically equivalent to the unit ball.

345 (XIII.33) Pseudodifferential Operators

A. Pseudodifferential Operators

Pseudodifferential operators are a natural extension of linear partial differential operators. The theory of pseudodifferential operators grew out of the study of singular integral operators, and developed rapidly after 1965 with the systematic studies by J. J. Kohn and L. Nirenberg [1], L. Hörmander [2], and others. The term “pseudodifferential operator” first appeared in Kohn and Nirenberg [1].

Let P be a †linear partial differential operator of the form

$$P = p(x, D_x) = \sum_{|\alpha| \leq m} a_\alpha(x) D_x^\alpha, \tag{1}$$

and let $u(x)$ be a function of class $C_0^\infty(\Omega)$ ($\subset C_0^\infty(\mathbf{R}^n)$). Then by means of the †Fourier inversion formula, $Pu(x)$ can be written in the form

$$Pu(x) = (2\pi)^{-n/2} \int_{\mathbf{R}^n} \exp(ix \cdot \xi) p(x, \xi) \hat{u}(\xi) d\xi, \tag{2}$$

where $\hat{u}(\xi)$ denotes the †Fourier transform of $u(x)$ (\rightarrow 160 Fourier Transform H). But this representation of $Pu(x)$ has a meaning even if $p(x, \xi)$ is not a polynomial in ξ . Thus, for a general function $p(x, \xi)$, the **pseudodifferential operator** $P = p(x, D_x)$ with the **symbol** $p(x, \xi)$ is defined by (2). A symbol class is determined in accordance with various purposes, but it is always required that the corresponding operators have essential properties in common with partial differential operators. Hörmander [3] defined a symbol class $S_{\rho, \delta}^m(\Omega)$ for real numbers m, ρ , and δ with $\rho \geq 0$ and $\delta \geq 0$ in the following way: Let $p(x, \xi)$ be a C^∞ -function defined in $\Omega \times \mathbf{R}^n$. If for any pair of multi-indices α, β and any compact set $K \subset \mathbf{R}^n$, there

exists a constant $C_{\alpha, \beta, K}$ such that

$$|D_x^\alpha D_\xi^\beta p(x, \xi)| \leq C_{\alpha, \beta, K} (1 + |\xi|)^{m + |\alpha| - \rho|\beta|},$$

$$x \in K, \quad \xi \in \mathbf{R}^n,$$

then $p(x, \xi)$ is said to be of class $S_{\rho, \delta}^m(\Omega)$. The operator P defined by (2) is called a pseudodifferential operator (of order m) of class $S_{\rho, \delta}^m(\Omega)$ and is often denoted by $P = p(x, D_x) \in S_{\rho, \delta}^m(\Omega)$. When $\Omega = \mathbf{R}^n$ and constants $C_{\alpha, \beta, K} = C_{\alpha, \beta}$ are independent of K , we denote $S_{\rho, \delta}^m(\mathbf{R}^n)$ simply by $S_{\rho, \delta}^m$, and set

$$S^{-\infty} = \bigcap_{-\infty < m < \infty} S_{1,0}^m \left(= \bigcap_{-\infty < m < \infty} S_{\rho, \delta}^m \right),$$

$$S_{\rho, \delta}^m = \bigcup_{-\infty < m < \infty} S_{\rho, \delta}^m.$$

Differential operators (1) with coefficients of class \mathcal{B} (\rightarrow 168 Function Spaces B(13)) belong to $S_{1,0}^m$. The complex power $(1 - \Delta)^{s/2}$ of $1 - \Delta = 1 - \sum_{j=1}^n \partial^2 / \partial x_j^2$ is defined as a pseudodifferential operator of class $S_{1,0}^{\text{Re } s}$ by the symbol $(1 + |\xi|^2)^{s/2}$. Operators of class $S_{\rho, \delta}^m$ are continuous mappings of \mathcal{S} into \mathcal{S} . Therefore, for any real s , the operator $(1 - \Delta)^{s/2}$ can be uniquely extended to be a mapping of \mathcal{S}' into \mathcal{S}' by the relation

$$\langle (1 - \Delta)^{s/2} u, v \rangle = \langle u, (1 - \Delta)^{s/2} v \rangle,$$

$$u \in \mathcal{S}', \quad v \in \mathcal{S}.$$

For any $1 \leq r \leq \infty$ and real s , the †Sobolev space $H^{s,r}$ is defined by

$$H^{s,r} = \{u \in \mathcal{S}' \mid (1 - \Delta)^{s/2} u \in L_r(\mathbf{R}^n)\},$$

which is a Banach space provided with the norm $\|u\|_{s,r} = \|(1 - \Delta)^{s/2} u\|_{L_r}$. In particular, $H^s = H^{s,2}$ is a Hilbert space with the norm $\|u\|_s = \|u\|_{s,2}$. Set

$$H^{-\infty, r} = \bigcup_{-\infty < s < \infty} H^{s,r}, \quad H^{-\infty} = H^{-\infty, 2},$$

$$H^{\infty, r} = \bigcap_{-\infty < s < \infty} H^{s,r}, \quad H^\infty = H^{\infty, 2}.$$

Then

$$\mathcal{S}' \supset H^{-\infty} \supset \mathcal{E}', \quad H^{-\infty} \supset L_2(\mathbf{R}^n) \supset H^\infty (\subset \mathcal{B}).$$

Choosing the Hörmander class $S_{\rho, \delta}^m$ in the case $0 \leq \delta \leq \rho \leq 1$ and $\delta < 1$ as a model class, we here list the main results of the theory of pseudodifferential operators:

(i) Pseudolocal property. The operator P of class $S_{\rho, \delta}^m$ in general does not have the **local property** $u \in \mathcal{S}' \Rightarrow \text{supp } Pu \subset \text{supp } u$, but if $\rho > 0$, then P has the **pseudolocal property** $u \in \mathcal{S}' \Rightarrow \text{sing supp } Pu \subset \text{sing supp } u$ [3].

(ii) Algebra of pseudodifferential operators. Let $P = p(x, D_x) \in S_{\rho, \delta}^m$ and $P_j = p_j(x, D_x) \in S_{\rho, \delta}^{m_j}$, $j = 1, 2$. Then there exist $P^* = p^*(x, D_x) \in S_{\rho, \delta}^m$ and $Q = q(x, D_x) \in S_{\rho, \delta}^{m_1 + m_2}$ such that $(Pu, v) = (u, P^*v)$ for $u, v \in \mathcal{S}$, i.e., P^* is the formal ad-

joint of P , and $Q = P_1 P_2$. Furthermore, if we set $p_x^*(x, \xi) = D_x^\alpha (iD_\xi)^\alpha \overline{p}(x, \xi)$ and $q_\alpha(x, \xi) = (iD_\xi)^\alpha p_1(x, \xi) D_x^\alpha p_2(x, \xi)$, then for any integer N we have

$$p^*(x, \xi) - \sum_{|\alpha| < N} \frac{1}{\alpha!} p_x^*(x, \xi) \in S_{\rho, \delta}^{m - (\rho - \delta)N} \quad (3)$$

and

$$q(x, \xi) - \sum_{|\alpha| < N} \frac{1}{\alpha!} q_\alpha(x, \xi) \in S_{\rho, \delta}^{m_1 + m_2 - (\rho - \delta)N}. \quad (4)$$

Hence the operator class $S_{\rho, \delta}^m$ is an algebra in the sense

$$P \in S_{\rho, \delta}^m, \quad P_j \in S_{\rho, \delta}^{m_j}, \quad j = 1, 2, \\ \Rightarrow P^* \in S_{\rho, \delta}^m, \quad P_1 + P_2 \in S_{\rho, \delta}^{m_0}, \quad P_1 P_2 \in S_{\rho, \delta}^{m_1 + m_2},$$

where $m_0 = \max(m_1, m_2)$. In particular, if $0 \leq \delta < \rho \leq 1$, we have $m - (\rho - \delta)N \rightarrow -\infty$ and $m_1 + m_2 - (\rho - \delta)N \rightarrow -\infty$ as $N \rightarrow \infty$. Then, we say that $p^*(x, \xi)$ and $q(x, \xi)$ have **asymptotic expansions** in the sense of (3) and (4), respectively:

$$p^*(x, \xi) \sim \sum_{\alpha} \frac{1}{\alpha!} p_x^*(x, \xi)$$

and

$$q(x, \xi) \sim \sum_{\alpha} \frac{1}{\alpha!} q_\alpha(x, \xi)$$

[3, 4].

(iii) H^s -boundedness. For $P \in S_{\rho, \delta}^m$ and any real s there exists a constant C_s such that

$$\|Pu\|_s \leq C_s \|u\|_{s+m}, \quad u \in H^{s+m} \quad (5)$$

[4].

(iv) A sharp form of Gårding's inequality. Let $p(x, \xi) = (p_{jk}(x, \xi); j, k = 1, \dots, l)$ be a Hermitian symmetric and nonnegative matrix of $p_{j,k}(x, \xi) \in S_{\rho, \delta}^m$. Then for $P = p(x, D_x)$ there exists a constant C such that

$$\operatorname{Re}(Pu, u) \geq -C \|u\|_{(m - (\rho - \delta)/2)}^2, \quad (6)$$

where $u = (u_1, \dots, u_l)$ with $u_j \in H^{m/2}$, $j = 1, \dots, l$, and $\|u\|_{m/2}^2 = \sum_{j=1}^l \|u_j\|_{m/2}^2$.

(v) Invariance under coordinate transformations. Assume that $0 \leq 1 - \rho \leq \delta \leq \rho \leq 1$. Let $x(y) = (x_1(y), \dots, x_n(y))$ be a C^∞ -coordinate transformation from \mathbf{R}_y^n onto \mathbf{R}_x^n such that $\partial x_k(y)/\partial y_j \in \mathcal{B}$, $j, k = 1, \dots, n$, and $C^{-1} \leq |\det(\partial_j x(y))| \leq C$ for a constant $C > 0$, where $\det(\partial_j x(y))$ denotes the determinant of the Jacobian matrix $(\partial_j x(y)) = (\partial x_k(y)/\partial y_j)$. Then for any $P = p(x, D_x) \in S_{\rho, \delta}^m$ in \mathbf{R}_x^n , there exists an operator $Q = q(x, D_x) \in S_{\rho, \delta}^m$ in \mathbf{R}_y^n such that $(Qw)(y) = (Pu)(x(y))$ for $w(y) = u(x(y)) \in \mathcal{S}$. This fact enables us to define pseudodifferential operators on C^∞ -manifolds [3, 4].

(vi) Parametrix. For a given $P \in S_{\rho, \delta}^m$, an operator $E \in S_{\rho, \delta}^\infty$ is called a **left** (resp. **right**) **parametrix** of P if $EP - I$ (resp. $PE - I$) is of class $S^{-\infty}$. If E is a left and right parametrix of

P , we call it a **parametrix** of P . For a differential operator P , the existence of a left (resp. right) parametrix is a sufficient condition for P to be hypoelliptic if $\rho > 0$, (resp. the equation $Pu = f \in \mathcal{S}'$ is locally solvable).

The estimate (5), in particular, when $m = s = 0$, has been obtained by Hörmander [3], V. V. Grushin (*Functional Anal. Appl.*, 4 (1970)), H. Kumano-go (*J. Fac. Sci. Univ. Tokyo*, 17 (1970)) when $0 \leq \delta < \rho \leq 1$, and A. P. Calderón and R. Vaillancourt [5], H. O. Cordes (*J. Functional Anal.* 18 (1975)), T. Kato (*Osaka J. Math.*, 13 (1976)), Kumano-go [4], and others when $0 \leq \delta \leq \rho \leq 1$ and $\delta < 1$. A sharp form of Gårding's inequality has been proved by Hörmander [6], P. D. Lax and L. Nirenberg [7], and sharpened by A. Melin (*Ark. Mat.*, 9 (1971)), C. Fefferman and D. H. Phong (*Proc. Nat. Acad. Sci. US*, 76 (1979)), and Hörmander [8]. A general sufficient condition for the existence of a parametrix for an operator of class $S_{\rho, \delta}^m$ was obtained by Hörmander [3]. Let $P = p(x, D_x)$ belong to $S_{\rho, \delta}^m$ with $0 \leq \delta < \rho \leq 1$. Assume that the symbol $p(x, \xi)$ satisfies the following conditions: (i) for some $C_0 > 0$, real m' ($\leq m$), and $R > 0$, we have $|p(x, \xi)| \geq C_0 |\xi|^{m'}$ ($|\xi| \geq R$); (ii) for any α, β there exists a constant $C_{0, \alpha, \beta}$ such that

$$|D_x^\beta D_\xi^\alpha p(x, \xi)/p(x, \xi)| \leq C_{0, \alpha, \beta} |\xi|^{|\beta| - \rho|\alpha|}, \quad |\xi| \geq R.$$

Then there exists a parametrix $Q = q(x, D_x)$ of P in the class $S_{\rho, \delta}^{m'}$.

By means of operators of class $S_{1,0}^m(\Omega)$ we can define the wave front set of $u \in \mathcal{D}'(\Omega)$, which enables us to resolve $\operatorname{sing\,supp} u$ on $T^*(\Omega) \setminus 0$, the cotangent bundle of Ω minus its zero section. An operator $P = p(x, D_x) \in S_{1,0}^m(\Omega)$ is said to be **microlocally elliptic** at $(x^0, \xi^0) \in T^*(\Omega) \setminus 0$ if $\lim_{\tau \rightarrow \infty} |p(x^0, \tau \xi^0)| / |\tau \xi^0|^m > 0$. For a distribution $u \in \mathcal{D}'(\Omega)$, we say that a point $(x^0, \xi^0) \in T^*(\Omega) \setminus 0$ does not belong to the **wave front set** (or the **singular spectrum**) of u , denoted by $\operatorname{WF}(u)$, if there exist $a(x), b(x) \in C_0^\infty(\Omega)$, $a(x^0) \neq 0$, $b(x^0) \neq 0$, and $P \in S_{1,0}^m(\Omega)$, which is microlocally elliptic at (x^0, ξ^0) , such that $aPbu \in C_0^\infty(\Omega)$. Then we easily see that $\operatorname{WF}(u)$ is a closed conic subset of $T^*(\Omega) \setminus 0$. An important fact is that the relation $\operatorname{sing\,supp} u = \operatorname{Proj}_x \operatorname{WF}(u)$ (the projection of $\operatorname{WF}(u)$ on Ω) holds, from which we can perform a so-called **microlocal analysis**, the analysis on $T^*(\Omega) \setminus 0$, of $\operatorname{sing\,supp} u$. As the sharp form of the pseudolocal property of an operator $P \in S_{\rho, \delta}^m$, if $0 \leq \delta < \rho \leq 1$, P has the **micro-pseudolocal property**: $u \in \mathcal{S}' \Rightarrow \operatorname{WF}(Pu) \subset \operatorname{WF}(u)$.

Pseudodifferential operators of multiple symbol have been defined by K. O. Friedrichs (*Courant Inst.*, 1968) and Kumano-go [4]. More refined and useful classes of pseudo-

differential operators have been defined by R. Beals (*Duke Math. J.*, 42 (1975)) Hörmander [8], and others.

The theory of pseudodifferential operators has found many fields of application, such as M. F. Atiyah and R. Bott (*Ann. Math.*, 86 (1967)) on the †Lefschetz fixed-point formula; Friedrichs and P. D. Lax (*Comm. Pure Appl.*, 18 (1965)) on symmetrizable systems; Hörmander [6], Yu. V. Egorov (*Russian Math. Surveys*, 30 (1975)) on subelliptic operators; Kumano-go (*Comm. Pure Appl. Math.*, 22 (1969)), F. Trèves (*Amer. J. Math.*, 94 (1972)), S. J. Alinhac and M. S. Bouendi (*Amer. J. Math.*, 102 (1980)) on uniqueness of the Cauchy problem; S. Mizohata and Y. Ohya (*Publ. Res. Inst. Math. Sci.*, 4 (1968)), Hörmander (*J. Analyse Math.*, 32 (1977)) on †weakly hyperbolic equations; C. Morawetz, J. V. Ralston, and W. A. Strauss (*Comm. Pure Appl. Math.*, 30 (1977)), M. Ikawa (*Pub. Res. Inst. Math. Sci.*, 14 (1978)) on the exponential decay of solutions; and Nirenberg and Trèves [16], Beals and Fefferman [17] on local solvability theory.

For recent developments in the theory of pseudodifferential operators and its applications → Kumano-go [4], M. Taylor (Princeton Univ. Press, 1981), Trèves (Plenum, 1981), and others.

B. Fourier Integral Operators

A **Fourier integral operator** $A: C_0^\infty(\mathbf{R}^n) \rightarrow \mathcal{D}'(\mathbf{R}^n)$ is a locally finite sum of linear operators of the type

$$Af(x) = (2\pi)^{-(n+N)/2} \int_{\mathbf{R}^{n+N}} \exp(i\varphi(x, \theta, y)) \times a(x, \theta, y) f(y) dy d\theta. \quad (7)$$

Here $a(x, \theta, y)$ is a C^∞ -function satisfying the inequality

$$|D_x^\alpha D_\theta^\beta D_y^\gamma a(x, \theta, y)| \leq C(1 + |\theta|)^{m-\rho|\beta|+(1-\rho)(|\alpha|+|\gamma|)}$$

for some fixed m and ρ , $1/2 \leq \rho \leq 1$, and any triple of multi-indices α, β, γ , and for $\varphi(x, \theta, y)$ a real-valued function of class C^∞ for $\theta \neq 0$ and homogeneous of degree 1 in θ there. The function φ is called the **phase function** and a the **amplitude function**.

Let $C_\varphi = \{(x, \theta, y) \mid d_\theta \varphi(x, \theta, y) = 0, \theta \neq 0\}$ and $W = \{(x, y) \in \mathbf{R}^n \times \mathbf{R}^n \mid \exists \theta \neq 0 \text{ such that } (x, \theta, y) \in C_\varphi\}$. If $d_{x, \theta, y} \varphi(x, \theta, y) \neq 0$ for $\theta \neq 0$, then the kernel distribution $k(x, y)$ of A is of class C^∞ outside W . There have been detailed studies of the case where the $d_{x, \theta, y}(\partial \varphi(x, \theta, y)/\partial \theta_j)$, $j = 1, 2, \dots, N$, are linearly independent at every point of C_φ . In this case, C_φ is a smooth manifold in $\mathbf{R}^n \times (\mathbf{R}^N \setminus 0) \times \mathbf{R}^n$, and the mapping $\Phi: C_\varphi \ni (x, \theta, y) \rightarrow (x, y, \xi, \eta)$, $\xi = d_x \varphi(x, \theta, y)$, $\eta =$

$d_y \varphi(x, \theta, y)$, is an immersion of C_φ to $T^*(\mathbf{R}^n \times \mathbf{R}^n) \setminus 0$, the cotangent bundle of $\mathbf{R}^n \times \mathbf{R}^n$ minus its zero section. The image $\Phi C_\varphi = \Lambda_\varphi$ is a **conic Lagrange manifold**, i.e., the canonical 2-form $\sigma = \sum_j d\xi_j \wedge dx_j - \sum_j d\eta_j \wedge dy_j$ vanishes on Λ_φ and the multiplicative group of positive numbers acts on Λ_φ . Let $\lambda_1, \dots, \lambda_{2n}$ be a system of local coordinates in Λ_φ . These, together with $\partial \varphi / \partial \theta_1, \dots, \partial \varphi / \partial \theta_N$, constitute a system of local coordinate functions of $\mathbf{R}^n \times (\mathbf{R}^N \setminus 0) \times \mathbf{R}^n$ in a conic neighborhood of C_φ . Let J denote the Jacobian determinant

$$\frac{D\left(\lambda_1, \dots, \lambda_{2n}, \frac{\partial \varphi}{\partial \theta_1}, \dots, \frac{\partial \varphi}{\partial \theta_N}\right)}{D(x, \theta, y)}$$

The function $a_{\Lambda_\varphi} = \sqrt{|J|} a|_{C_\varphi} \Phi^{-1}$ is called the local **symbol** of A . Here $a|_{C_\varphi}$ is the restriction of a to C_φ . The conic Lagrange manifold $\Lambda_\varphi = \Lambda_\varphi(A)$ and the symbol $a_{\Lambda_\varphi} = a_{\Lambda_\varphi}(A)$ essentially determine the singularity of the kernel distribution $k(x, y)$ of the Fourier integral operator A . Conversely, given a conic Lagrange manifold Λ in $T^*(\mathbf{R}^n \times \mathbf{R}^n) \setminus 0$ and a function a_Λ on it, one can construct a Fourier integral operator A such that $\Lambda_\varphi(A) = \Lambda$ and $a_{\Lambda_\varphi}(A) = a_\Lambda$. Those Fourier integral operators whose associated conic Lagrange manifolds are the graphs of homogeneous †canonical transformations of $T^*(\mathbf{R}^n) \setminus 0$ are most frequently used in the theory of linear partial differential equations. Let A be a Fourier integral operator such that $\Lambda_\varphi(A)$ is the graph of a homogeneous canonical transformation χ . Then the adjoint of A is a Fourier integral operator such that the associated conic Lagrange manifold is the graph of the inverse transformation χ^{-1} . Let A_1 be another such operator; if the associated conic Lagrange manifold is the graph of χ_1 , then the composed operator $A_1 A$ is also a Fourier integral operator and the associated conic Lagrange manifold is the graph of the composed homogeneous canonical transformation $\chi_1 \chi$.

A pseudodifferential operator of class $S_{\rho, 1-\rho}^m(\mathbf{R}^n)$ is a particular type of Fourier integral operator. In fact, a Fourier integral operator A is a pseudodifferential operator of class $S_{\rho, 1-\rho}^m(\mathbf{R}^n)$ if and only if $\Lambda_\varphi(A)$ is the graph of the identity mapping of $T^*(\mathbf{R}^n) \setminus 0$. Hence for any Fourier integral operator A , A^*A and AA^* are pseudodifferential operators.

The following theorem is due to Egorov [11]: Let P and Q be pseudodifferential operators of class $S_{\rho, 1-\rho}^m(\mathbf{R}^n)$ with the symbols $p(x, \xi)$ and $q(x, \xi)$, respectively, and let A be a Fourier integral operator such that the associated conic Lagrange manifold $\Lambda_\varphi(A)$ is the graph of a homogeneous canonical transformation χ of $T^*(\mathbf{R}^n) \setminus 0$. If the equality $PA = AQ$

holds, then $q(x, \xi) - p(\chi(x, \xi))$ belongs to the class $S_{\rho, 1-\rho}^{m+1-2\rho}(\mathbf{R}^n)$.

Assume that $m = 1$, $\rho = 1$, and that $p_1(x, \xi)$ is a real-valued C^∞ -function, homogeneous of degree 1 in ξ for $|\xi| > 1$, such that $p(x, \xi) - p_1(x, \xi) \in S_{1,0}^0(\mathbf{R}^n)$ and $d_\xi p_1(x^0, \xi^0) \neq 0$ at (x^0, ξ^0) , $|\xi^0| > 1$, where $p_1(x^0, \xi^0) = 0$. Then one can find a Fourier integral operator A such that the function $q(x, \xi)$ of Egorov's theorem satisfies the relation $q(x, \xi) - \xi_1 \in S_{1,0}^0(\mathbf{R}^n)$.

The theory of Fourier integral operators has its origin in the asymptotic representation of solutions of the wave equation (→ 325 Partial Differential Equations of Hyperbolic Type L; also, e.g., [12, 13, 14]). G. I. Eskin (*Math. USSR-Sb.*, 3 (1976)) used a type of Fourier integral operator in deriving the energy estimates and constructing the fundamental solutions for strict hyperbolic operators. Hörmander (*Acta Math.*, 121 (1968)) introduced the term "Fourier integral operators," and applied these operators to the derivation of highly accurate asymptotic formulas for spectral functions of elliptic operators. Egorov (*Math. USSR-Sb.*, 11 (1970)) applied his theorem and the corollary stated above to the study of hypoellipticity and local solvability for pseudodifferential operators of principal type. Using Egorov's theorem and the same corollary, Nirenberg and Treves [16] obtained decisive results concerning local solvability for linear partial differential operators of principal type; these results were completed by Beals and Fefferman [17]. Hörmander and J. J. Duistermaat [9, 15] constructed a general global theory of Fourier integral operators making use of Maslov's theory [14], which was originally published in 1965. By virtue of this research, the Fourier integral operator has come to be recognized as a powerful tool in the theory of linear partial differential operators. An interesting application of the global theory of Fourier integral operators appeared in J. Chazarain (*Inventiones Math.*, 24 (1974)). The boundedness of Fourier integral operators in the spaces $L^2(\mathbf{R}^n)$ (or the space H^s) has been studied in several cases. Some sufficient conditions for boundedness have been obtained by Eskin (*Math. USSR-Sb.*, 3 (1967)), Hörmander [9], D. Fujiwara [18], Kumano-go (*Comm. Partial Diff. Eq.*, 1 (1976)), K. Asada and Fujiwara (*Japan. J. Math.*, 4 (1978)), and others. A calculus of Fourier integral operators in \mathbf{R}^n was given in Kumano-go [4].

The propagation of wave front sets by means of a Fourier integral operator is described as follows. Let us consider a phase function of the form $\varphi(x, \xi, y) = S(x, \xi) - y \cdot \xi$ in $\mathbf{R}_x^n \times \mathbf{R}_\xi^n \times \mathbf{R}_y^n$, and let $a(x, \xi)$ be an amplitude

function independent of y of class $S_{1,0}^m$. Then by (7) the Fourier integral operator $A = A_S$ is defined by

$$A_S u(x) = (2\pi)^{-n/2} \int_{\mathbf{R}^n} \exp(iS(x, \xi)) a(x, \xi) \hat{u}(\xi) d\xi. \quad (8)$$

Let T be the canonical transformation with the generating function $S(x, \xi)$, i.e., T is defined by $y = \nabla_\xi S(x, \eta)$, $\xi = \nabla_x S(x, \eta)$. Then for the Fourier integral operator A_S we have

$$\text{WF}(A_S u) \subset \{(x, \xi) = T(y, \eta) \mid (y, \eta) \in \text{WF}(u)\}, \quad u \in \mathcal{S}'. \quad (9)$$

Next consider a hyperbolic operator $L = D_t + p(t, x, D_x)$ for a real-valued symbol $p(t, x, \xi) \in \mathcal{B}^0([0, T_0]; S_{1,0}^1)$ with some $T_0 > 0$. For a small $0 < T \leq T_0$ the solution $S(t, x, \xi)$ of the eikonal equation $\partial_t S + p(t, x, \nabla_x S) = 0$ on $[0, T]$ with the initial condition $S|_{t=0} = x \cdot \xi$ exists in $\mathcal{B}^1([0, T]; S_{1,0}^1)$. Consider the Cauchy problem $Lu = 0$ on $[0, T]$, $u|_{t=0} = u_0$. Then there exists an amplitude function $e(t, x, \xi) \in \mathcal{B}^1([0, T]; S_{1,0}^1)$ such that the solution $u(t)$ is found in the form $u(t) = E_S(t)u_0$. On the other hand, let $(x, \xi) = (X(t, y, \eta), \Xi(t, y, \eta))$ be the bicharacteristic strip defined by Hamilton's canonical equation $dx/dt = \nabla_\xi p(t, x, \xi)$, $d\xi/dt = -\nabla_x p(t, x, \xi)$ with $(x, \xi)|_{t=0} = (y, \eta)$. Then $(X(t, y, \eta), \Xi(t, y, \eta))$ can be solved by means of the relations $y = \nabla_\xi S(t, X, \eta)$, $\Xi = \nabla_x S(t, X, \eta)$, as a family of canonical transformations with a parameter $t \in [0, T]$. Thus by means of (9) we have

$$\text{WF}(u(t)) \subset \{(x, \xi) = (X(t, y, \eta), \Xi(t, y, \eta)) \mid (y, \eta) \in \text{WF}(u_0)\}, \quad (10)$$

which is the fundamental result in the study of the propagation of wave front sets as solutions of general hyperbolic equations (→ 325 Partial Differential Equations of Hyperbolic Type M).

The works of Egorov, Nirenberg and Treves, and Hörmander motivated the theory of hyperfunctions developed by M. Sato and gave rise to the concept of quantized contact transformations, which correspond to Fourier integral operators in the theory of distributions. The above-stated transformation theorem of Egorov has been studied in detail with reference to systems of pseudodifferential equations with analytic coefficients [19] (→ 274 Microlocal Analysis).

346 (XVIII.17) Psychometrics

A. General Remarks

Psychometrics is a collection of methods for drawing statistical conclusions from various psychological phenomena which are expressed numerically or quantitatively. It consists chiefly of statistical methods to deal with psychological measurements and of theories dealing with mathematical models concerning learning processes, social attitudes, and mental abilities.

B. Sensory Tests

A measurement wherein human senses are taken as the gauge is called a **sensory test**. The panel of judges must be composed appropriately, and the examining circumstances must be controlled. Various methods of psychological measurements are applied. In the following sections we describe the basic statistical procedures used in sensory testing.

C. Paired Comparison

When there are t objects (treatments or stimuli in some cases) O_1, O_2, \dots, O_t , the method of comparing them two at a time in every possible way is called **paired comparison**. The following are typical mathematical models of this method.

(1) **Thurstone-Mosteller Model.** Suppose that the probability that O_i is preferred to O_j for a pair (O_i, O_j) is p_{ij} . Of the n judges who compare this pair, the number who prefer O_i is n_{ij} , and the number who prefer O_j is $n_{ji} = n - n_{ij}$. In this comparison it is assumed that the strengths of the stimuli O_i, O_j to the senses are random variables X_i, X_j , and O_i is preferred when $X_i > X_j$. Furthermore, it is assumed that the joint probability distribution of X_i and X_j is the 2-dimensional normal distribution with μ_i and σ^2 as mean and variance of X_i , and ρ as correlation coefficient of X_i and X_j . There is no loss of generality in assuming that $2\sigma^2(1 - \rho) = 1$ and $\sum_{i=1}^t \mu_i = 0$. Let $\Phi(x)$ be the standardized normal distribution function and $p_{ij} = \Phi(\mu_i - \mu_j)$. Using $p'_{ij} = n_{ij}/n$ as estimates of the true p_{ij} , we can obtain the estimates $\hat{\mu}_i$. Using $p''_{ij} = \Phi(\hat{\mu}_i - \hat{\mu}_j)$ and p'_{ij} we can test the hypothesis that $\mu_1 = \mu_2 = \dots = \mu_t$.

(2) **The Bradley-Terry Model.** The experimental method in the Bradley-Terry model

is the same as in the Thurstone-Mosteller model. It is postulated that, associated with O_1, O_2, \dots, O_i , there exist parameters π_i for O_i ($\pi_i \geq 0, \sum_{i=1}^I \pi_i = 1$) such that $p_{ij} = \pi_i / (\pi_i + \pi_j)$. Obtaining the maximum likelihood estimator of π_i , we can test the appropriateness of the models.

(3) Scheffé's Model. Each pair O_i, O_j is presented to $2n$ judges; n of them examine O_i first and O_j next, and the remaining n examine the pair in the opposite order. A judgment is recorded on a 7-point (or 9-, 5-, or 3-point) scale. In the 7-point scaling system a judge presented with the ordered pair (O_i, O_j) marks one of the seven points 3, 2, 1, 0, -1, -2, -3, meaning, respectively, that O_i is strongly preferable to O_j , O_i is moderately preferable to O_j , O_i is slightly preferable to O_j , no preference, O_j is slightly preferable to O_i , etc. The mark given by the k th judge on his preference of O_i to O_j is denoted by X_{ijk} , which can be regarded as the sum of a main effect, deviation of subtractivity, order effect, and error. Significance tests for these effects and estimates of various parameters are given by using statistical linear models. †BIBD, †PBIBD, etc., can also be applied to paired comparisons.

D. The Pair Test, Triangle Test, and Duo-Trio Test

The pair test, triangle test, and duo-trio test are sensory difference tests. The methods are as follows. **Pair test:** A judge is requested to designate a preference between the paired samples A and B . **Triangle test:** A judge is requested to select two samples of the same kind out of A, A, B . **Duo-trio test:** A judge is first acquainted with a sample A and then is requested to choose from A and B the one he has seen in the previous step. In all the above cases, the hypothesis that A and B are different and that the judge has no ability to determine the difference between them is tested by using the binomial distribution.

E. Scaling

(1) One-Dimensional Case. Psychometric scaling methods are procedures for constructing scales for psychological phenomena. Some of them require judgments concerning a particular attitude that is considered unidimensional. Under the assumption that a psychological phenomenon is a random variable with some distribution law and the parameters of the distribution law determine psychological scales, a psychological scaling is given by estimating the parameters. The Thurstone-

Mosteller model is a method for scaling a set of stimuli by means of observable proportions.

(2) Multidimensional Scaling (MDS). Multidimensional scaling is a collection of methods to deal with data consisting of many measurements on many objects and to characterize the mutual distance (dissimilarity), or closeness (affinity), by representing those objects by a small number of indices or by points in a small-dimensional Euclidean space. It has seen useful applications in the analysis of people's attitude and perception and their characterizations by means of a few numbers or points in a space of low dimension.

Historically, MDS was first developed by Torgerson (1958) and refined further by Shepard (1962) and Kruskal (1964). The method developed by Torgerson and also the INDSCAL method by Carroll and Chang (1970) are called **metric multidimensional scaling**, while the method by Shepard and Kruskal is called the **nonmetric MDS**. The former is applied when the data are represented in continuous scales and the latter when the data are in discrete nominal or ordinal scales. Techniques of multidimensional scaling are closely related and sometimes actually equivalent to various methods of multivariate analysis, especially principal component analysis, canonical correlation analysis, and discriminant analysis (→ 280 Multivariate Analysis).

F. Factor Analysis

Though factor analysis can be considered to be a method to deal with multivariate data in general (→ 280 Multivariate Analysis), it has had close connections with psychometric studies, in both theoretical developments and applications. Historically, it was initiated by Spearman (1927) and developed further by Thurston (1945) in order to measure human abilities from test scores. Mathematically, the model of factor analysis is formulated as follows: Let z_{jk} be the standardized score of the j th test achieved by the k th subject, $j = 1, \dots, p$; $k = 1, \dots, N$; then it is assumed that it can be represented as a linear combination of r common factors and one specific factor as

$$z_{jk} = a_{j1}f_{1k} + a_{j2}f_{2k} + \dots + a_{jr}f_{rk} + u_{jv_{jk}}, \quad (1)$$

where f_{ik} , $i = 1, \dots, r$, $k = 1, \dots, N$, represents the magnitude of the i th common factor (ability) in the k th subject and a_{ji} is the size of contribution of the i th factor to the score of the j th test.

Usually it is assumed that (i) $V(z_j) = 1$, (ii) $V(f_i) = 1$ and $\text{Cov}(f_i, f_{i'}) = 0$ for $i \neq i'$, (iii) $V(v_j) = 1$ and $\text{Cov}(v_j, v_{j'}) = 0, j \neq j'$, (iv) $\text{Cov}(f_i, v_j) = 0$.

Then it follows that

$$r_{j'j''} = \text{Cor}(z_j, z_{j'}) = a_{j1}a_{j'1} + a_{j2}a_{j'2} + \dots + a_{jr}a_{j'r},$$

and

$$1 = a_{j1}^2 + a_{j2}^2 + \dots + a_{jr}^2 + u_j^2 = h_j^2 + u_j^2,$$

where h_j^2 is called the **communality** of the j th variable z_j and u_j^2 is called the **specificity**. It follows easily from (1) that any orthogonal transformation of the scores does not affect the model.

Problems of factor analysis are classified into three types:

- (1) Estimation of communality: There are several methods of determining communality or initial estimates of it when some iterative procedure is used.
- (2) Determination of **factor loadings**, which is the estimation of the a_{ji} : A number of methods have been proposed, among which those often used are the MINRES by Harman (1967), the varimax by Kaiser (1958), and the maximum likelihood based on the normal model by Lawley and Maxwell.
- (3) Estimation of **factor scores** f_{ik} : Usually factor scores are estimated after factor loadings have been determined. Thurstone proposed $\hat{F} = ZR^{-1}A$ and Harman $\hat{F} = ZA(A'A)^{-1}$, where F , Z , A are the matrices of factor scores, test scores, factor loadings, respectively, and R is the correlation matrix of the z 's.

G. Learning Theory

(1) General Description. Assume that a sequence of trials is done in order to study some given behavior and that on each trial particular events occur (stimuli, responses, reinforcements, etc.) that influence the ensuing behavior. Then the behavior itself is modified by such a sequence of trials. **Learning models** refer to such processes of behavior modification, and they are frequently represented by recursive formulas for response probabilities.

Assume that two mutually exclusive response alternatives A_1 and A_2 occur on the n th trial ($n = 1, 2, \dots$) with respective probabilities P_n and $1 - P_n$, and that an event E_i occurs on the n th trial with $\text{Pr}(\mathcal{E}_n = E_i) = \pi_i$ ($i = 1, 2, \dots, t$; $\sum_{i=1}^t \pi_i = 1$). Then the recursive formula for P_n is of the form $P_{n+1} = f(P_n; \mathcal{E}_n, \mathcal{E}_{n-1}, \dots, \mathcal{E}_1)$. If the formula can be written as $f = f(P_n; \mathcal{E}_n, \mathcal{E}_{n-1}, \dots, \mathcal{E}_{n-d})$, then the response probability is called **d -trial path dependent**. In the special case $d = 0$, it is called **path independent**. For simplicity we write $f(P_n; \mathcal{E}_n = E_i, \mathcal{E}_{n-1} = E_j, \dots, \mathcal{E}_1 = E_k) = f_{ij\dots k}(P_n)$ ($i, j, \dots, k = 1, 2, \dots, t$). If the response probability is path independent, then $f_{ij\dots k}(P_n) = f_{ij}f_j\dots f_k(P_1)$, where $f_v(P_n) =$

$f(P_n; \mathcal{E}_n = E_v)$ ($v = i, j, \dots, k$). When the recursive formula can be expressed as $f = f(P_n; \mathcal{E}_n, n)$, the response probability is said to be **quasi-independent of path** [11]. In the recursive formula f , two events E_i and E_j ($i \neq j$) are said to be commutative if $f_{\dots i \dots j \dots}(P_n) = f_{\dots j \dots i \dots}(P_n)$. If any two events are commutative, the condition of **event commutativity** is satisfied. By making f explicit with respect to n , we write $P_n = F(n; \mathcal{E}_{n-1}, \dots, \mathcal{E}_1; P_1)$. Under the condition of event commutativity, the explicit formula can be written $P_n = F(N_1, N_2, \dots, N_t; P_1)$, where N_i is the frequency of occurrence of E_i in the first $(n - 1)$ trials ($\sum_{i=1}^t N_i = n - 1$). If both event commutativity and path independence of response probability are satisfied, the explicit formula $P_n = f_1^{N_1} f_2^{N_2} \dots f_t^{N_t}(P_1)$ can be obtained.

(2) Linear Models. In a linear model, the recursive formula is written as a linear function of P_n .

Example (1). Bush-Mosteller model [6]. The Bush-Mosteller model assumes the response probability to be path independent. The recursive formula is expressed as $f_i(P_n) = \alpha_i P_n + (1 - \alpha_i)\lambda_i$, $\mathcal{E}_n = E_i$. Here α_i ($0 \leq \alpha_i \leq 1$) represents the degree of ineffectiveness of E_i for learning and λ_i ($0 \leq \lambda_i \leq 1$) is the fixed point of f_i . A necessary and sufficient condition for E_i and E_j ($i \neq j$) to be commutative is that either f_i or f_j be an identity operator or $\lambda_i = \lambda_j$.

Example (2). Estes's stimulus-sampling model [7]. We can consider the stimulus as a set composed of m elements, each of which corresponds to either response A_1 or A_2 ; the manner of their correspondences depends on each trial. If J_n elements correspond to A_1 on the n th trial, then we have $P_n = J_n/m$. Suppose that on the n th trial s ($\leq m$) elements are sampled, among which X_n elements correspond to A_2 , and the remaining X'_n ($= s - X_n$) elements correspond to A_1 . As a result of the n th trial, if A_1 is reinforced, we set $Y_n = 1$; otherwise, we set $Y_n = 0$. Furthermore, assume that $J_{n+1} = J_n + X_n Y_n - X'_n(1 - Y_n)$. Hence, we obtain the recursive formula $P_{n+1} = P_n + \{X_n Y_n - X'_n(1 - Y_n)\}/m$. In this model, the response probability is path independent and $\mathcal{E}_n = (X_n, Y_n)$. Other linear models have been proposed in which the response probability is either quasi-independent of path [8] or path dependent [10].

(3) Nonlinear Models. In nonlinear models the recursive formula cannot be written as a linear function of P_n .

Example (3). Luce's β -model [9]. Let the response strengths of A_1 and A_2 on the n th trial be v_n and v'_n , respectively (both positive), and assume that P_n , the response probability of A_1 , is expressed as $v_n/(v_n + v'_n)$. The response

strengths v_n and v'_n depend on each trial. Under the assumption that the response strength is path independent and that v_{n+1} changes independently from v'_n , the recursive formula of v_n is written as $v_{n+1} = \varphi_i(v_n)$, $\mathcal{E}_n = E_i$. Here, if we assume $\varphi_i(v) > 0$ for $v > 0$ and $\varphi_i(cv) = c\varphi_i(v)$ for $v > 0$ and $c > 0$, then $\varphi_i(v_n) = \beta_i v_n$ with $\beta_i > 0$. In a similar way, the recursive formula for v'_n can be expressed as $\varphi'_i(v'_n) = \beta'_i v'_n$ ($\beta'_i > 0$). Therefore we have $P_{n+1} = P_n / \{P_n + b_i(1 - P_n)\}$ ($b_i = \beta'_i / \beta_i$), $\mathcal{E}_n = E_i$. This model is nonlinear, and the response probability is path independent. By making the recursive formula explicit, we obtain $P_n = P_1 / \{P_1 + (1 - P_1) \exp(\sum_{i=1}^n N_i \log b_i)\}$. Hence it is clear that the events are commutative. Other nonlinear models in which the response probability is either quasi-independent of path [5] or path dependent [9] have also been proposed.

Here we have taken up only the case in which the number of response alternatives is 2, but we can generalize to the case of more than two alternatives. For fitting a model and experimental data, expected response probabilities and various other statistics deduced from the model (total error, trial number of first success or last error, and sequential statistics such as length of response run or autocorrelation between responses) are used. Estimation methods have also been devised for the parameters involved.

Q

347 (V.12) Quadratic Fields

A. General Remarks

Any \dagger extension field of the rational number field \mathbf{Q} of degree 2 is called a **quadratic field**. Any quadratic field k is obtained from \mathbf{Q} by adjoining a square root of a **square-free integer** (i.e., an integer $\neq 0, 1$ with no square factor) $m: k = \mathbf{Q}(\sqrt{m})$. If m is positive (negative), k is called a **real (imaginary or complex) quadratic field** (\rightarrow 14 Algebraic Number Fields). Let

$$\omega = \begin{cases} (1 + \sqrt{m})/2 & \text{for } m \equiv 1 \pmod{4}, \\ \sqrt{m} & \text{for } m \equiv 2, 3 \pmod{4}. \end{cases}$$

Then $(1, \omega)$ is a \dagger minimal basis of k . That is, any \dagger algebraic integer α of k has the unique expression $\alpha = a + b\omega$ with $a, b \in \mathbf{Z}$. The \dagger discriminant d of k is given by $d = m$ in case $m \equiv 1 \pmod{4}$ and $d = 4m$ in case $m \equiv 2, 3 \pmod{4}$. The conjugate element of an element $\alpha = a + b\sqrt{m}$ ($a, b \in \mathbf{Q}$) of k over \mathbf{Q} is given by $\alpha' = a - b\sqrt{m}$. The mapping $\sigma: \alpha \rightarrow \alpha'$ is an \dagger automorphism of the field k .

B. Units

Let k be an imaginary quadratic field. The \dagger units of k are $\pm 1, \pm i$ in case $m = -1; \pm 1, \pm \omega_0, \pm \omega_0^2$ ($\omega_0 = (1 + \sqrt{-3})/2$) in case $m = -3$; and ± 1 in all other cases.

Let k be a real quadratic field. There exists a unit ε_0 that is the smallest one among the units (> 1) of k . Any unit ε of k can be uniquely expressed in the form $\varepsilon = \pm \varepsilon_0^n$ ($n \in \mathbf{Z}$). That is, $\pm \varepsilon_0^{\pm 1}$ is a \dagger fundamental unit of k . The fundamental unit $\varepsilon_0 = (x + y\sqrt{d})/2$ (> 1) can be calculated by finding a minimal positive integral solution (x, y) of \dagger Pell's equation $x^2 - dy^2 = \pm 4$ by using continued fractions (\rightarrow 83 Continued Fractions; for a table of the fundamental unit of k for $m < 100 \rightarrow$ [1]).

C. Prime Ideals

The decomposition of a prime number p in the \dagger principal order \mathfrak{o} of k is given as follows: (i) Let $p \nmid d$, where d is the discriminant of k . Then p is decomposed in \mathfrak{o} in the form $(p) = \mathfrak{p}^2$. (ii) Let $p \neq 2$ and $(p, m) = 1$. If $(m/p) = 1$, then $(p) = \mathfrak{p}\mathfrak{p}'$ in \mathfrak{o} ($\mathfrak{p} \neq \mathfrak{p}'$) and $N(\mathfrak{p}) = N(\mathfrak{p}') = p$. If $(m/p) = -1$, then $(p) = \mathfrak{p}$ in \mathfrak{o} and $N(\mathfrak{p}) = p^2$. Here $\mathfrak{p}, \mathfrak{p}'$ are prime ideals of \mathfrak{o} , N means the \dagger norm, and (m/p) is the \dagger Legendre symbol. (iii) Let $2 \nmid d$, that is, $m \equiv 1 \pmod{4}$. If $m \equiv 1 \pmod{8}$, then $(2) = \mathfrak{p}\mathfrak{p}'$ ($\mathfrak{p} \neq \mathfrak{p}'$) and $N(\mathfrak{p}) = N(\mathfrak{p}') = 2$. If $m \equiv 5 \pmod{8}$, then $(2) = \mathfrak{p}$ and $N(\mathfrak{p}) = 4$.

D. The Kronecker Symbol

Let $k = \mathbf{Q}(\sqrt{m})$, and let d be the discriminant of k . We define the symbol χ for k as follows: (i) $\chi(p) = 1$ if $(p) = \mathfrak{p}\mathfrak{p}'$ ($\mathfrak{p} \neq \mathfrak{p}'$) in \mathfrak{o} ; (ii) $\chi(p) = -1$ if $(p) = \mathfrak{p}$ in \mathfrak{o} ; (iii) $\chi(p) = 0$ if $(p) = \mathfrak{p}^2$ in \mathfrak{o} ; and (iv) $\chi(n) = \prod_i \chi(p_i)^{e_i}$ for $n = \prod_i p_i^{e_i} > 0$. In particular, we define $\chi(1) = 1$. If $(n, d) = 1$, the symbol χ can also be defined using the \dagger Jacobi symbol as follows: If $m \equiv 1 \pmod{4}$, then $\chi(n) = (n/m)$; and if $m \equiv 2, 3 \pmod{4}$, then $\chi(n) = \chi_2^*(n)(n/m')$ for $d = 2^e m'$, where (i) $\chi_2^*(n) = (-1)^{(n-1)/2}$ for $e = 2, m' \equiv 3 \pmod{4}$; (ii) $\chi_2^*(n) = (-1)^{(n^2-1)/8}$ for $e = 3, m' \equiv 1 \pmod{4}$; and (iii) $\chi_2^*(n) = (-1)^{(n^2-1)/8 + (n-1)/2}$ for $e = 3, m' \equiv 3 \pmod{4}$. If $(n, d) \neq 1$, then $\chi(n) = 0$. For a negative integer $-n$, we define $\chi(-n) = (\text{sgn } d)\chi(n)$. The symbol $\chi(n)$ for $n \in \mathbf{Z}$ is called the **Kronecker symbol** for k .

The Kronecker symbol for k has the following four properties: (1) $\chi(n) = 0$ if $(n, d) \neq 1$, and $\chi(n) = \pm 1$ if $(n, d) = 1$; (2) $\chi(m) = \chi(n)$ if $m \equiv n \pmod{d}$; (3) $\chi(mn) = \chi(m)\chi(n)$; (4) $\chi(n) = 1$ if and only if $n \equiv N(\mathfrak{a}) \pmod{d}$ for some integral ideal \mathfrak{a} of k such that $(\mathfrak{a}, d) = 1$. (Property (4) shows that a quadratic field provides a class field; \rightarrow 59 Class Field Theory.)

E. Ideal Classes

The \dagger class number h of k was calculated by P. G. L. \dagger Dirichlet (1840) by analytical methods as follows:

$$h \log \varepsilon_0 = -\frac{1}{2} \sum_{r=1}^{d-1} \chi(r) \log \sin \frac{r\pi}{d} \quad \text{for } m > 0,$$

$$h = \frac{-w|d|^{-1}}{2|d|} \sum_{r=1}^{|d|-1} \chi(r)r \quad \text{for } m < 0,$$

where d is the discriminant of k , ε_0 is the positive fundamental unit (> 1) of k , w is the number of roots of unity in k , and χ is the Kronecker symbol.

Denote by $h(d)$ the class number of the imaginary quadratic field with discriminant d . It was conjectured from the time of C. F. \dagger Gauss that $h(d) \rightarrow \infty$ as $|d| \rightarrow \infty$. This conjecture was proved by H. Heilbronn (1934). More precisely, C. L. Siegel (*Acta Arith.*, 1 (1935)) proved

$$\lim_{|d| \rightarrow \infty} (\log h(d)) / (\log \sqrt{|d|}) = 1.$$

$h(d) = 1$ holds for $|d| = 3, 4, 7, 8, 11, 19, 43, 67, 163$. In 1934, Heilbronn and E. H. Linfoot proved that there can be at most one more such d , and finally A. Baker and H. M. Stark independently proved that these nine numbers are the only ones for which $h(d) = 1$ (Baker, *Mathematica*, 13 (1966); Stark, *Michigan Math*

J., 14 (1967)). Also, Baker and Stark proved independently (*Ann. Math.*, (2) 94 (1971); *Math. Comp.*, 29 (1975)) that $h(d)=2$ holds only for $|d|=15, 20, 24, 35, 40, 51, 52, 88, 91, 115, 123, 148, 187, 232, 235, 267, 403, \text{ and } 427$.

For real quadratic fields, we have

$$\lim_{d \rightarrow \infty} (\log(h(d) \log \varepsilon_d)) / (\log \sqrt{d}) = 1,$$

where ε_d is the fundamental unit of $k = \mathbf{Q}(\sqrt{d})$ ($\varepsilon_d > 1$). However, it is not yet determined whether there exist infinitely many d with $h(d) = 1$ (\rightarrow Appendix B, Table 4).

F. Genera

Let G be the group of all (\dagger fractional) ideals of k , and let H be the group of all (\dagger principal) ideals (α) of k such that $N(\alpha) > 0$. Each coset of G modulo H is called an **ideal class in the narrow sense**. (This notion is a special case of the notion of ideal classes in the narrow sense of algebraic number fields; \rightarrow 14 Algebraic Number Fields G.) In the cases (i) $m < 0$ and (ii) $m > 0$, $N(\varepsilon_0) = -1$, the usual classification of ideals and classification of ideals in the narrow sense are identical. When $m > 0$, $N(\varepsilon_0) = 1$, each ideal class is divided into two ideal classes in the narrow sense. We call an ideal class in the narrow sense simply an ideal class.

Let p_1, \dots, p_t be the set of all prime numbers dividing d . For $n \in \mathbf{Z}$ with $(n, d) = 1$, we define $\chi_1(n), \dots, \chi_t(n)$ as follows: For $p_i \neq 2$, we define $\chi_i(n) = (n/p_i)$; for $p_i = 2$, we identify χ_i with χ_i^* in the definition of the Kronecker symbol. In order that $\chi_1(n) = \dots = \chi_t(n) = 1$ for $n \in \mathbf{Z}$ with $(n, d) = 1$, it is necessary and sufficient that $n \equiv N(\alpha) \pmod{d}$ for an integer α of k (where $N(\alpha) = \alpha\alpha'$). Since $\chi_1\chi_2\dots\chi_t$ is equal to the Kronecker symbol, it follows that $n \equiv N(\mathfrak{a}) \pmod{d}$ for an integral ideal \mathfrak{a} of k is a necessary and sufficient condition for $\chi_1(n) \dots \chi_t(n) = 1$ to hold for $n \in \mathbf{Z}$ with $(n, d) = 1$. Put $\varepsilon_i = \chi_i(N(\mathfrak{a}))$ ($i = 1, \dots, t$), where \mathfrak{a} is an integral ideal with $(\mathfrak{a}, d) = 1$. Then $(\varepsilon_1, \dots, \varepsilon_t)$ is uniquely determined for the ideal class C containing \mathfrak{a} and does not depend on the choice of \mathfrak{a} . The set \mathfrak{H} of all ideal classes of k such that $(\varepsilon_1, \dots, \varepsilon_t) = (1, \dots, 1)$ is called the **principal genus** of k , and \mathfrak{H} is a subgroup of the ideal class group \mathfrak{C} of k . Each coset of \mathfrak{C} modulo \mathfrak{H} is called a **genus** of k . For each genus, the values $\varepsilon_i = \chi_i(N(\mathfrak{a}))$ ($i = 1, \dots, t$) are uniquely determined. We call $(\varepsilon_1, \dots, \varepsilon_t)$ the **character system** of this genus, and each genus is uniquely determined by its character system. A necessary and sufficient condition for $(\varepsilon_1, \dots, \varepsilon_t)$ to be a character system for some genus is that $\varepsilon_i = \pm 1$ and $\varepsilon_1\varepsilon_2\dots\varepsilon_t = 1$. Hence there are 2^{t-1}

genera of k , and $\mathfrak{C}/\mathfrak{H}$ is an Abelian group of type $(2, 2, \dots, 2)$.

In order that an ideal class C belong to the principal genus, it is necessary and sufficient that $C = C_1^{1-\sigma} = C_1^2$ hold for some ideal class C_1 . From this it follows that there are $t-1$ \dagger invariants of the ideal class group \mathfrak{C} of k that are powers of 2. Each ideal class C such that $C^\sigma = C$ is called an **ambig class** of k . There are 2^{t-1} ambig classes, and they form an Abelian group of type $(2, 2, \dots, 2)$. Each ideal \mathfrak{a} of k with $\mathfrak{a}^\sigma = \mathfrak{a}$ is called an **ambig ideal** of k . Let $(p_i) = p_i^2$ ($i = 1, \dots, t$). Then each ambig ideal is uniquely expressed in the form $\mathfrak{a} = p_1^{v_1} \dots p_t^{v_t}(\mathfrak{a})$ by some $\mathfrak{a} \in \mathbf{Q}$ and $v_i = 0, 1$. Each ambig class contains exactly two ambig ideals of the form $p_1^{v_1} \dots p_t^{v_t}$. For example, for $k = \mathbf{Q}(\sqrt{-65})$ we have $d = -2^2 \cdot 5 \cdot 13$, $t = 3$, $h = 8$, $\mathfrak{C} = \{E, A, A^2, A^3, B, AB, A^2B, A^3B\}$, where $A^4 = E$, $B^2 = E$, $A^\sigma = A^3$, and $B^\sigma = B$; the principal genus is $\mathfrak{H} = \{E, A^2\}$, and the ambig classes are $\{E, A^2, B, A^2B\}$.

G. Norm Residues

A quadratic field k is the \dagger class field over \mathbf{Q} for an ideal group H . The \dagger conductor of H is said to be the **conductor** of k/\mathbf{Q} or simply the conductor of k . The conductor $f = \prod_p f_p$ of $k = \mathbf{Q}(\sqrt{m})$ is given by $f = d$ for $m > 0$ and $f = dp_\infty$ for $m < 0$. That is, the p -conductor $f_p = p$ for $p|d$, $p \neq 2$; and $f_2 = 2^e$ for $2|d$, $d = 2^e m'$ ($(2, m') = 1$). By means of the \dagger Hilbert norm-residue symbol, the Kronecker symbol χ is expressed by

$$\chi(a) = \begin{cases} \prod_{p|d} \left(\frac{a, d}{p} \right) & \text{for } (a, d) = 1, \\ 0 & \text{for } (a, d) \neq 1. \end{cases}$$

H. History

The arithmetic of quadratic fields was originally developed in terms of the theory of binary quadratic forms with rational integral coefficients by Gauss and Dirichlet [2]. The theory was then translated into the terms of ideal theory by J. W. R. Dedekind [2] (\rightarrow 348 Quadratic Forms M). For example, the theory of genera for quadratic fields explained in Section F was first developed by Gauss in terms of binary quadratic forms, and the class number formula was obtained by Dirichlet as a formula for binary quadratic forms. Hilbert [4, ch. 2] developed the arithmetic of quadratic fields systematically by introducing the Hilbert norm-residue symbol (\rightarrow [1, 5, 6]). Later the arithmetic of quadratic fields assumed the aspect of a simple example of class field theory (\rightarrow 59 Class Field Theory).

348 (III.15) Quadratic Forms

A. General Remarks

A **quadratic form** Q is a quadratic homogeneous polynomial with coefficients in a †field K , written

$$Q(x_1, \dots, x_n) = \sum_{1 \leq i \leq k \leq n} c_{ik} x_i x_k.$$

If the coefficients c_{ik} belong to the field of real (complex) numbers, we call Q a **real (complex) quadratic form**. Let V be an n -dimensional vector space over K . For a vector x in V whose coordinates are x_1, \dots, x_n , we put $Q(x) = Q(x_1, \dots, x_n)$. This gives rise to a mapping $x \rightarrow Q(x)$ of V into K . Such a mapping satisfies the following two conditions: (i) $Q(ax) = a^2 Q(x)$ ($a \in K$); and (ii) $Q(x+y) - Q(x) - Q(y) = B(x, y)$ is a †symmetric bilinear form on V . Conversely, if a mapping $Q: V \rightarrow K$ satisfies these two conditions, then Q must come from a quadratic form (\rightarrow 256 Linear Spaces). $B(x, y)$ is called the **symmetric bilinear form associated with Q** .

We assume that the †characteristic of K is not 2. Putting $a_{ik} = a_{ki} = c_{ik}/2$ ($i < k$), $a_{ii} = c_{ii}$ ($i = 1, \dots, n$), we have $Q(x) = \sum_{i,k=1}^n a_{ik} x_i x_k$. The matrix $A = (a_{ik})$ is the **matrix of the quadratic form Q** , and the determinant $|A|$ is the **discriminant** of Q , denoted by $\Delta(Q)$. (Sometimes, instead of $|A|$, we call $(-1)^{n(n-1)/2} 2^n |A|$, the discriminant of Q .) The rank of the matrix A is called the **rank** of Q . Using the notation for the †inner product of vectors, we can write $Q(x)$

$= (x, Ax) = {}^t x Ax$; $2^{-1} B(x, y) = (x, Ay) = {}^t x Ay$. We say that Q is **nondegenerate** if $B(x, y)$ is nondegenerate (i.e., if $|A| \neq 0$).

Consider a linear substitution $x_i = \sum_{j=1}^m P_{ij} x'_j$ (i.e., $x = Px'$, with an $n \times m$ matrix P). Then we get a new quadratic form $Q'(x')$ with the matrix ${}^t P A P$. If each p_{ij} belongs to the field K (to a subring R of K that contains the unit element of K), we say that Q represents Q' over K (resp. R). A basic problem in the theory of quadratic forms is to determine the exact conditions under which a given quadratic form Q represents another quadratic form Q' . The problem of representing numbers by a quadratic form (representation problem) is the particular case corresponding to $m = 1$. Any quadratic form Q represents 0 by taking the zero matrix as P . Hence, by the expression “ Q represents 0 over K ,” we usually mean the nontrivial representation of 0 over K by Q , i.e., $Q(x) = 0$ for some nonzero vector x . If Q is nondegenerate and represents 0, then it represents any element of K^* . Given an element μ in K^* , we consider the quadratic form Q' defined by $Q'(x_1, \dots, x_{n+1}) = Q(x) - \mu x_{n+1}^2$. Then Q represents μ if and only if Q' represents 0.

Another important special case is that of $n = m$. Then the discriminant of Q' is given by $|P|^2 |A|$. In particular, if $|P| \neq 0$ ($|P|$ is an invertible element of R), we say that Q is **equivalent** to Q' over K (resp. R). This gives rise to an equivalence relation. Equivalent forms have the same rank. On the other hand, if the rank of Q is r , then Q is equivalent to a form $\sum_{i=1}^r a_i x_i^2$ over K ($a_i \neq 0$, $i = 1, \dots, r$). Generally, for elements a and b in $K^* = K - \{0\}$, we write $a \sim b$ if $a \cdot b^{-1} \in (K^*)^2$. Then if Q is equivalent to Q' , we have $\Delta(Q) \sim \Delta(Q')$.

When we specify a field K , we assume that the coefficients of the quadratic forms and the coordinates of linear transformations are all contained in the field K . In particular, the equivalence of the forms is equivalence over K .

B. Complex Quadratic Forms

If K is the field of complex numbers \mathbb{C} , then a form of rank r is equivalent to the form $\sum_{i=1}^r x_i^2$; hence over \mathbb{C} two forms of the same dimension are equivalent if and only if they are of the same rank.

C. Real Quadratic Forms

Now let K be the field of real numbers \mathbb{R} . If Q is of rank r , then it is equivalent to the form $\sum_{i=1}^p x_i^2 - \sum_{j=1}^q x_{p+j}^2$ ($p+q=r$). Here, p and q are uniquely determined by Q (**Sylvester's law of inertia**). We call (p, q) the **signature** of Q . Two quadratic forms of the same dimension

are equivalent if and only if they have the same signature. A quadratic form with the signature $(n, 0)$ (resp. $(0, n)$) is called a **positive (negative) definite quadratic form**. Q is called a **definite quadratic form** if it is either positive or negative definite; otherwise it is an **indefinite quadratic form**. Each of the following conditions is necessary and sufficient for a form Q to be positive definite: (i) for any nonzero real vector x we have $Q(x) > 0$; (ii) all the principal minors of the matrix of Q are positive. Q is negative definite if and only if $-Q$ is positive definite. A form with n variables is called a **positive (negative) semidefinite quadratic form** if its signature is $(r, 0)$ (resp. $(0, r)$), where $1 \leq r < n$.

A linear transformation $x' \rightarrow x = Px'$ that leaves invariant the unit form $\sum_{i=1}^n x_i^2$ is an **orthogonal transformation**. Then P is an orthogonal matrix. Any quadratic form can be transformed into a diagonal form $\sum_{i=1}^n a_i x_i^2$ via an orthogonal transformation. Here a_1, \dots, a_n are the eigenvalues of the matrix of the form. Two forms Q and Q' are equivalent with respect to an orthogonal transformation if and only if the corresponding matrices have the same eigenvalues.

D. Quadratic Forms over Finite Fields and p -adic Number Fields

Let Q and Q' be nondegenerate quadratic forms over the finite field F_q . They are equivalent if and only if they have the same rank and $\Delta(Q) \sim \Delta(Q')$. Moreover, if the rank of Q is not less than 3, then Q represents 0.

Next, suppose that Q and Q' are nondegenerate quadratic forms over the p -adic number field K . They are equivalent if and only if they have the same rank, $\Delta(Q) \sim \Delta(Q')$, and they have the same **Minkowski-Hasse character** χ , where χ is defined as follows: Let $C(Q)$ be the Clifford algebra of Q , and let $C^*(Q)$ denote $C(Q)$ if n is even and $C^+(Q)$ if n is odd. Then $\chi(Q) = 1$ or -1 according as $C^*(Q) \cong M_t(K)$ or $M_t(K) \otimes D(K)$. (Here M_t is the total matrix algebra of degree t over K and $D(K)$ is the unique quaternion algebra over K .) Also, if Q has rank not less than 5, then Q represents 0 in K .

E. Quadratic Forms over a General Field K

The following facts are valid on any field K whose characteristic is not 2. Given a quadratic form Q_1 with variables x_1, \dots, x_n and another form Q_2 with variables x_{n+1}, \dots, x_{n+m} , we get a new quadratic form $Q_1 \oplus Q_2$ or $Q_1 + Q_2$ defined by $Q_1 \oplus Q_2(x_1, \dots, x_{n+m}) =$

Quadratic Forms

$Q_1(x_1, \dots, x_n) + Q_2(x_{n+1}, \dots, x_{n+m})$. $Q_1 \oplus Q_2$ is called the **direct sum** of Q_1 and Q_2 . The matrix of $Q_1 \oplus Q_2$ is the direct sum of the matrices of Q_1 and Q_2 . If Q_1 and Q'_1 are equivalent and Q_2 and Q'_2 are also equivalent, then $Q_1 \oplus Q_2$ and $Q'_1 \oplus Q'_2$ are also equivalent, then Q_2 and Q'_2 are equivalent (**Witt's theorem**).

The quadratic form $x_1 x_2 + x_3 x_4 + \dots + x_{2r-1} x_{2r}$ is called the **kernel form** and is denoted by N_r . Any nondegenerate quadratic form $Q(x_1, \dots, x_n)$ is equivalent to the direct sum of a kernel form $N_r(x_1, \dots, x_{2r})$ and a form $Q_0(x_{2r+1}, \dots, x_n)$, where if $Q_0 \neq 0$, i.e., $n > 2r$, we have $Q_0(x_{2r+1}, \dots, x_n) = 0$ only if $x_{2r+1} = \dots = x_n = 0$. N_r and Q_0 are uniquely determined by Q up to equivalence. The decomposition $N_r \oplus Q_0$ is called the **Witt decomposition** of Q (E. Witt [5]). The number r is called the **index** of Q . An element x in V is said to be **singular** with respect to Q if $Q(x) = 0$. A subspace W of V is said to be **totally singular** if all the elements in W are singular. Let B be the symmetric bilinear form associated with Q . Then x is singular with respect to Q if and only if $B(x, x) = 0$ (characteristic of $K \neq 2$). We say that x is **isotropic** if $B(x, x) = 0$. Thus a subspace W is totally singular if and only if it is **totally isotropic** (i.e., $B(x, y) = 0$ for all $x, y \in W$). The index r of Q is the dimension of a maximal totally singular subspace of V . In particular, if $K = \mathbf{R}$ and (p, q) is the signature of Q , then the index $r = \min(p, q)$. Here we must be careful, since some authors call the number $p - q$ or p or q the index of Q . To make the distinction clear, we also call our r the **index of total isotropy**, and the number $p - q$ the **index of inertia**.

Necessary and sufficient conditions for a nondegenerate Q to be a kernel form are: $n =$ the rank of $Q \equiv 0 \pmod{2}$ when $K = \mathbf{C}$; $n \equiv 0 \pmod{2}$ and $p - q = 0$ when $K = \mathbf{R}$; $n \equiv 0 \pmod{2}$ and $\Delta(Q) \sim 1$ when $K = F_q$; $n \equiv 0 \pmod{2}$, $\Delta(Q) \sim 1$, and $\chi(Q) = 1$ when K is a p -adic number field.

Let $N_r \oplus Q_0, N_s \oplus Q'_0$ be Witt decompositions of Q and Q' , respectively. We say that Q and Q' belong to the same **type** if Q_0 and Q'_0 are equivalent and denote the set of types of nondegenerate quadratic forms over K by \mathbf{W} . We define the sum of the types of Q and Q' as the type of $Q \oplus Q'$, and this gives \mathbf{W} the structure of a commutative group. The type of a kernel form is the identity element of this group \mathbf{W} , called the **Witt group**. The structure of the Witt group depends on K . If $K = \mathbf{C}$, then $\mathbf{W} \cong \mathbf{Z}/2\mathbf{Z}$; if $K = \mathbf{R}$, then $\mathbf{W} \cong \mathbf{Z}$; if K is a local field with a non-Archimedean valuation, then \mathbf{W} is a finite group; if $K = F_q$, then $\mathbf{W} \cong (\mathbf{Z}/2\mathbf{Z}) + (\mathbf{Z}/2\mathbf{Z})$ if $q \equiv 1 \pmod{4}$, $\mathbf{W} \cong \mathbf{Z}/4\mathbf{Z}$ if $q \equiv 3 \pmod{4}$, and $\mathbf{W} \cong \mathbf{Z}/2\mathbf{Z}$ if q is a power of 2.

F. Hermitian Forms

An expression $H(x) = \sum_{i,k=1}^n a_{ik} \bar{x}_i x_k$ is called a **Hermitian form** if $a_{ik} \in \mathbb{C}$, $a_{ik} = \bar{a}_{ki}$. (Here \bar{a}_{ik} , \bar{x}_i are the complex conjugates of a_{ik} , x_i , respectively.) The value $H(x)$ is a real number. As for quadratic forms, we define the notions of the matrix of H and the discriminant, rank, and \dagger sesquilinear form associated with H . The matrix A of H is a \dagger Hermitian matrix whose principal minors are real numbers. If we apply a linear transformation $P(x') = x$, we obtain a Hermitian form with respect to x' whose matrix is given by $\dagger \bar{P}AP$. Any Hermitian form is equivalent to a form $\sum_{i=1}^p \bar{x}_i x_i - \sum_{j=1}^q \bar{x}_{p+j} x_{p+j}$; (p, q) is called the **signature** of H . We define the notions of **positive definite**, **negative definite**, and **indefinite Hermitian forms** as we did for quadratic forms over the field of real numbers. Each of the following conditions is necessary and sufficient for H to be positive definite: (i) $H(x) > 0$ for any nonzero complex vector x ; (ii) all the principal minors of the matrix of H are positive. The definition of a **semidefinite Hermitian form** is given in the same manner as for a quadratic form.

A linear transformation that leaves the Hermitian form $\sum_{i=1}^n \bar{x}_i x_i$ invariant is called a **unitary transformation**, and its matrix is a \dagger unitary matrix. Any Hermitian form can be transformed via a unitary transformation into a diagonal form $\sum_{i=1}^n a_i \bar{x}_i x_i$, where a_1, \dots, a_n are the eigenvalues of the matrix of the Hermitian form.

The notion of Hermitian forms can be generalized as follows: Suppose that K is a \dagger division ring with an **involution** $a \rightarrow \bar{a}$ ($a \in K$) (i.e., $a \rightarrow \bar{a}$ is a linear mapping of K onto itself such that $\overline{\bar{a}} = a$, $\overline{ab} = \bar{b}\bar{a}$). Then a Hermitian form H over K is defined by

$$H(x) = \sum_{i,k=1}^n \bar{x}_i a_{ik} x_k,$$

where $x_i \in K$, $a_{ik} \in K$, $a_{ik} = \bar{a}_{ki}$. In particular, if we have, for any given vector x whose coordinates belong to K , an element a in K such that $H(x) = a + \bar{a}$, then we have a Witt decomposition for H . Two examples of such K having involutions that differ from the identity mapping are a separable quadratic extension K of a field L and a \dagger quaternion algebra K over a field L .

G. Quadratic Forms over Algebraic Number Fields

Let K be an algebraic number field of finite degree, \mathfrak{p} be an \dagger Archimedean or non-Archimedean \dagger prime divisor of K , $K_{\mathfrak{p}}$ be the

\mathfrak{p} -completion of K , and Q and Q' be nondegenerate quadratic forms over K . Then Q represents Q' over K if and only if Q represents Q' over $K_{\mathfrak{p}}$ for all \mathfrak{p} , and Q represents 0 in K (i.e., there exists a nonzero vector x whose coordinates belong to K such that $Q(x) = 0$) if and only if it represents 0 in $K_{\mathfrak{p}}$ for all \mathfrak{p} [3, 4]. In particular, Q and Q' are equivalent over K if and only if they are equivalent over $K_{\mathfrak{p}}$ for all \mathfrak{p} . Hence the invariants with respect to equivalence over K of a nondegenerate quadratic form Q over K are n = the rank of Q , Δ = the discriminant of Q , the Minkowski-Hasse character $\chi_{\mathfrak{p}}$ for \dagger prime divisors \mathfrak{p} of K , and the index of inertia j_{λ} of Q over $K_{\mathfrak{p}_{\infty, \lambda}}$ for each \dagger real infinite prime divisor $\mathfrak{p}_{\infty, \lambda}$ ($\lambda = 1, \dots, r_1$) of K . Here the following properties hold: (i) $\chi_{\mathfrak{p}} = 1$ for all but finitely many \mathfrak{p} ; (ii) $\prod_{\mathfrak{p}} \chi_{\mathfrak{p}} = 1$ (this is equivalent to the \dagger product formula of norm-residue symbols); (iii) $\Delta \sim (-1)^{(n^2 + j_{\lambda})/2}$ in $K_{\mathfrak{p}_{\infty, \lambda}}$; and (iv) $\chi_{\mathfrak{p}_{\infty, \lambda}} = 1$ if $j_{\lambda} \equiv 0, 1, 2, 7 \pmod{8}$, $= -1$ if $j_{\lambda} \equiv 3, 4, 5, 6 \pmod{8}$ [3, 4]. Conversely, if the system $\{n, \chi_{\mathfrak{p}}, \chi_{\mathfrak{p}_{\infty, \lambda}}, j_{\lambda}, \Delta\}$ satisfies conditions (i)–(iv), then it is the set of invariants of a quadratic form over K (**Minkowski-Hasse theorem**). In general, if a property concerning K holds if and only if it holds for all $K_{\mathfrak{p}}$, we say that the **Hasse principle** holds for the property.

H. Class and Genus of a Quadratic Form

Let K be an algebraic number field of finite degree. Quadratic forms Q and Q' over K are said to be of the same **class** if they are equivalent over the \dagger principal order \mathfrak{o} in K . On the other hand, Q and Q' are said to be of the same **genus** if (i) they are equivalent over the principle order $\mathfrak{o}_{\mathfrak{p}}$ in $K_{\mathfrak{p}}$ for all non-Archimedean prime divisors \mathfrak{p} of K and (ii) they are equivalent over $K_{\mathfrak{p}}$ for all the Archimedean prime divisors \mathfrak{p} of K . A genus is decomposed into a finite number of classes. For example, if K is the field of rational numbers, the number of classes in the genus of $\sum_{i=1}^m x_i^2$ is 1 for $m \leq 8$, while it is ≥ 2 for $m > 8$.

I. Reduction of Real Quadratic Forms

Let A be an $m \times m$ matrix and X an $m \times n$ matrix. We put $A[X] = \dagger XAX$. Then we can write $Q(x) = S[x] = \dagger xSx$, where S is the matrix of the quadratic form Q . In this section we put $K = \mathbb{R}$ and define two forms to belong to the same **class** if they are equivalent over the ring of rational integers. We identify the form Q with its matrix $S = (s_{ij})$. Let S be a positive definite form in m variables. Then S is said to be a **reduced quadratic form** if $S[\mathfrak{g}_k] \geq s_{kk}$ and $s_{ll+1} \geq 0$ ($1 \leq k \leq m$, $1 \leq l \leq m-1$), where \mathfrak{g}_k is an

arbitrary vector whose coordinates g_1, \dots, g_m are integers such that $(g_k, \dots, g_m) = 1$. Any class of positive definite quadratic forms contains at least one (and generally only one) reduced form. For a reduced form $R = (r_{kl})$, the following inequalities hold: $0 < r_{11} \leq r_{22} \leq \dots \leq r_{mm}$; $\pm 2r_{kl} \leq r_{ll}$, $k < l$; $r_{11}r_{22} \dots r_{mm} < c(m)|R|$, where $c(m)$ depends only on m . The set of all symmetric matrices of degree m forms a linear space of dimension $m(m+1)/2$ in which the subset \mathfrak{P} formed by the positive definite symmetric matrices is a convex open subset. Moreover, the subset \mathfrak{R} formed by all reduced positive definite symmetric matrices is a convex cone whose boundary consists of finitely many hypersurfaces and whose vertex is the origin. Let S be an indefinite quadratic form whose signature is $(n, m-n)$. The set of positive definite quadratic forms H such that $S^{-1}[H] = S$ forms a variety of dimension $n(m-n)$, which is denoted by $H(S)$. We say that S is reduced if $H(S) \cap \mathfrak{R} \neq \emptyset$. Given a natural number D , there are only a finite number of definite or indefinite reduced quadratic forms with rational integral coefficients whose discriminant is $\pm D$. Hence the number of classes of quadratic forms with rational integral coefficients and discriminant $\pm D$ is also finite.

J. Units

Let S be a symmetric matrix of degree m with rational coordinates. Let $O(S)$ be the set of all real $m \times m$ matrices W for which $S[W] = S$, and $\Gamma(S)$ be the subset of $O(S)$ consisting of the integral matrices. An element of $\Gamma(S)$ is called a **unit** of S . $\Gamma(S)$ is a finite group if S is definite, but otherwise it is infinite (except for the case $m=2$, $-|S|=r^2$, with rational r). $O(S)$ is a \dagger Lie group, and $\Gamma(S)$ is a discrete subgroup with a finite number of generators. The \dagger homogeneous space $O(S)/\Gamma(S)$ is of finite measure with respect to a \dagger Haar measure defined on the space.

K. Minkowski-Siegel-Tamagawa Theory

Let S and T be rational integral positive definite symmetric matrices of degree m and n , respectively ($m \geq n$). Let $A(S, T)$ be the number of rational integral solutions for the equation $S[X] = T$, and $E(S)$ be the order of the group of units $\Gamma(S)$. We put

$$M(S, T) = \frac{A(S_1, T)}{E(S_1)} + \frac{A(S_2, T)}{E(S_2)} + \dots,$$

$$M(S) = \frac{1}{E(S_1)} + \frac{1}{E(S_2)} + \dots,$$

$$A_0(S, T) = \frac{M(S, T)}{M(S)},$$

where S_1, S_2, \dots is a complete system of representatives of the classes in the genus of S . $M(S)$ is called the **measure of genus** of S . On the other hand, for a natural number q , we denote by $A_q(S, T)$ the number of the solutions of the congruence equation $S[X] \equiv T \pmod{q}$. If q is a prime power p^a , then the ratio $\varepsilon_{m,n} q^{-mn+n(n+1)/2} A_q(S, T)$ takes a constant value $\alpha_p(S, T)$ for sufficiently large a (where $\varepsilon_{m,n} = 1/2$ if $m=n \geq 2$; $=1$ otherwise). Furthermore, let us consider a domain B in the Euclidean space of dimension $n(n+1)/2$ formed by the set of $n \times n$ symmetric matrices containing T , and let B_1 be the domain formed by the matrices X such that $S[X] \in B$. Then B_1 is a domain in the space of dimension mn formed by all $m \times n$ matrices. Let $\alpha_\infty(S, T)$ be the limit of the ratio $v(B_1)/v(B)$ of the volumes of B and B_1 as the domain B shrinks toward the point T . Then **Siegel's theorem** states: $\alpha_\infty(S, T) \prod_p \alpha_p(S, T) = \varepsilon A_0(S, T)$, where $\varepsilon = 2$ if $m=n+1$ or $m=n \geq 2$ and $\varepsilon = 1$ otherwise. The infinite product of the left-hand side of this equation does not converge absolutely if either $m=n=2$ or $m=n+2$, and in those cases the order of the product \prod_p is considered to be the natural order of the primes p .

A special case of Siegel's theorem was proved by H. Minkowski, but it was C. L. Siegel [6] who proved it in its general form. Except for a finite number of p , the numbers $\alpha_p(S, T)$ have been calculated. The explicit form of $\alpha_\infty(S, T)$ is also known. In particular, if we take the identity matrix $E^{(m)}$ of degree m as S , then the formula in Siegel's theorem is related to the problem of expressing natural numbers as sums of m squares. For $m=2, 3, \dots, 8$, the genus of $E^{(m)}$ contains only one class. Hence, putting $n=1$, $T=t$ ($=$ a natural number), we obtain from Siegel's theorem the number of ways in which we can express t as the sum of m squares [6, pt. I]. Siegel's result was generalized by Siegel himself to the case where the form S is indefinite [6, pt. II] and where the coefficients of the forms are elements of an algebraic number field of finite degree [6, pt. III]. Also, regarding the number of possible ways to express a natural number t as a sum of m squares, the following formula was obtained by C. G. J. Jacobi for the case where $m=4, n=1$:

$$A(E^{(4)}, t) = 8 \left(\sum_{d|t} d - \sum_{4d|t} d \right).$$

For the case $m=3, n=1$, it is known that if t is odd and $A(E^{(3)}, t) > 0$, then $t \not\equiv 7 \pmod{8}$ (for details \rightarrow P. T. Batemann, *Trans. Amer. Math. Soc.*, 71 (1951)).

T. Tamagawa used the theory of \dagger adelized algebraic groups and proved that the \dagger Tamagawa number $\tau(SO(n, S))$ of the special ortho-

gonal group is 2. He also showed that from this fact, Siegel's theory in this section can be deduced (\rightarrow 13 Algebraic Groups P) [10].

L. Theta Series

Let $Q(x_1, \dots, x_m)$ be a positive definite form with integral coefficients. For a complex number z , we put

$$F(z, Q) = \sum_{x_1, \dots, x_m} \exp(2\pi i Q(x_1, \dots, x_m)z),$$

where x_1, \dots, x_m run over all the integers. If $\text{Im } z > 0$, the series converges and represents an entire function of z . These series are called **theta series**. If we denote by $A(n)$ the number of integral solutions of the equation $Q(x_1, \dots, x_m) = n$, we have

$$F(z, Q) = \sum_{n=0}^{\infty} A(n)e^{2\pi inz}.$$

Moreover, if $m = 2k$, we have the following **transformation formula**:

$$F\left(\frac{az+b}{cz+d}, Q\right) = \varepsilon(d)(cz+d)^k F(z, Q),$$

where a, b, c, d are integers such that $ad - bc = 1$, $c \equiv 0 \pmod{N}$, N is a natural number determined by Q , and ε is a character mod N . In other words, $F(z, Q)$ is a modular form with respect to the congruence subgroup of level N . Using the theory of modular forms, E. Hecke showed that $A(n) = A_0(n) + O(n^{k/2})$, where $A_0(n)$ is a number-theoretic function of n determined by the genus of Q .

M. Binary Quadratic Forms with Integral Coefficients

Now put $m = 2$. Given a form $Q(x, y) = ax^2 + bxy + cy^2$, we put $D(Q) = b^2 - 4ac$ and call it the **discriminant** of Q (i.e., $D(Q) = -4\Delta(Q)$). Q is said to be **primitive** if $(a, b, c) = 1$. When $D(Q)$ is not a square, the theory concerning Q is closely related to the arithmetic theory of the quadratic field $\mathbf{Q}(\sqrt{D}) = k$. Let d be the discriminant of k and put $D = df^2$. When $f = 1$, there is a one-to-one correspondence between the ideal classes of k and the classes of quadratic forms with discriminant d (when $D < 0$, we consider the classes of positive definite forms). The correspondence is given in the following manner: If \mathfrak{a} is an ideal in k with a basis α_1, α_2 , then the corresponding form is given by $Q(x, y) = N(\mathfrak{a})^{-1} N(\alpha_1 x + \alpha_2 y)$, where N is the absolute norm. If $f > 1$, we must replace the ring of integers \mathfrak{o} by the order of the conductor f . That is, if we consider the ring formed by the elements $x + fy\omega$ (x, y are rational integers; the meaning of ω is ex-

plained shortly), we again have a one-to-one correspondence between the classes of ideals of this order and the classes of quadratic forms [3]. We let $\omega = \sqrt{d}/2$ if $d \equiv 0 \pmod{4}$; $\omega = (1 + \sqrt{d})/2$ if $d \equiv 1 \pmod{4}$. When $D > 0$, we can introduce the notion of proper equivalence as follows: Q and Q' are **properly equivalent** if the matrix of Q is transformed to the matrix of Q' by a linear transformation P whose determinant is 1. Then, in the correspondence for the case $f = 1$, if we take $\alpha_1 = r > 0$, $\alpha_2 = s + t\omega$, $t > 0$ ($r, s, t \in \mathbf{Q}$), then we get a relation between the classification of the forms and the classification in the finer sense of the ideals in k .

Suppose that $D > 0$ is not a square. Let (t, u) be an integral solution of Pell's equation $t^2 - Du^2 = \pm 4$. Then the units of the form $Q(x, y) = ax^2 + bxy + cy^2$ with discriminant D are given by

$$\pm \begin{pmatrix} (t-bu)/2 & -cu \\ au & (t+bu)/2 \end{pmatrix}.$$

Let (t_0, u_0) be the smallest positive integral solution of $t^2 - Du^2 = 4$, put $\varepsilon_D = (t_0 + u_0\sqrt{D})/2$, and let h_D be the class number in the finer sense of the forms of discriminant D . Then the following formula holds (Dirichlet):

$$\frac{1}{\sqrt{D}} h_D \log \varepsilon_D = \sum_{n=1}^{\infty} \frac{1}{n} \left(\frac{D}{n}\right),$$

where (D/n) is the Kronecker symbol (here $D = f^2 d$; we put $(D/n) = 0$ if $(f, n) \neq 1$, and $(D/n) = (d/n)$ if $(f, n) = 1$). For $D < 0$, the order w_D of the units is known: it is 6 if $D = -3$; 4 if $D = -4$; and 2 otherwise. We also have

$$\frac{2\pi}{\sqrt{|D|}} \frac{h_D}{w_D} = \sum_{n=1}^{\infty} \frac{1}{n} \left(\frac{D}{n}\right).$$

With respect to the numbers h_D and ε_D , little else is known.

349 (XIX.3) Quadratic Programming

A. Problems

A **quadratic programming problem** is a special type of mathematical programming (\rightarrow 264 Mathematical Programming) where the objective function is quadratic while the constraints are linear. A typical formulation of the problem is as follows.

(Q) Maximize $z = c'x - \frac{1}{2}x'Dx$ under the condition $Ax \leq b$ and $x \geq 0$, $x \in \mathbf{R}^n$.

Let the Lagrangian form for this problem be

$$\varphi(x, \lambda) = c'x - \frac{1}{2}x'Dx + \lambda'(b - Ax).$$

Then, from the general properties of Lagrangian forms, the following theorem can be proved.

Theorem: If $x = x^*$ is an optimal solution of the problem (Q), there exists a vector λ^* satisfying the conditions

$$-Dx^* + c \leq \lambda^*, \quad \lambda^* \geq 0;$$

$$b'\lambda^* = (c - Dx^*)'x^*.$$

Moreover, if the matrix D is nonnegative definite, the above conditions are also sufficient for $x = x^*$ to be optimal. The second condition can be shown to be equivalent to

$$\lambda^*(b - Ax^*) = 0 \quad \text{and} \quad x^{*'}(A'\lambda^* + Dx^* - c) = 0.$$

By introducing the slack vectors $u \geq 0$ and $v \geq 0$, the conditions can be expressed as

$$x \geq 0, \quad y \geq 0, \quad u \geq 0, \quad v \geq 0;$$

$$(C) \quad Ax + u = b, \quad A'y + Dx - v = c;$$

$$y'u = 0, \quad x'v = 0.$$

When D is nonnegative definite, any feasible solution of the above system of equalities gives an optimal solution of the primary problem (Q), and when D is positive definite, the solution is unique. When D is not nonnegative definite, the optimal solution of (Q), if it exists, is one of the feasible solutions of (C). The last line of (C) implies that the solution must be a basic solution of the linear system of equalities, and it also restricts the possible combinations of the basic variables. Since there exist only a finite number of possible combinations of the basic variables, the quadratic programming problem can be solved in a finite number of steps, if it has an optimal solution.

B. Duality

The **dual problem** of (Q) is the following.

(QD) Minimize $w = b'y + \frac{1}{2}x'Dx$ under the condition $A'y + Dx \geq c$ and $x \geq 0$, $y \geq 0$.

If D is nonnegative definite, the following theorem holds.

Theorem: If the primary problem (Q) has a solution $x = x^*$, then the dual problem has a solution $x = x^*$ and $y = y^*$, and $\max z = \min w$.

A more general form of the quadratic programming problem can be given as follows.

(Q) Maximize $z = c'x - \frac{1}{2}x'Dx$ under the condition $x \in V$ and $b - Ax \in W$, where V and W are closed convex cones in \mathbf{R}^n and \mathbf{R}^m , respectively.

Then the dual problem is expressed as follows.

(QD) Minimize $w = b'y - \frac{1}{2}x'Dx$ under the condition $x \in V$, $y \in W^*$ and $A'y + Dx - c \in V^*$, where V^* and W^* are the dual cones of V and W .

The above theorem holds for both (Q) and (QD).

C. Algorithms

Various algorithms have been proposed for quadratic programming [1, 2, 4], most of which are based on condition (C). Wolfe [4] proposed a method based on the simplex method for linear programming. If we introduce the artificial vectors ξ and η , we can find a feasible solution of (C) by solving the following linear programming problem.

(LQ) Maximize $z = -1'\xi - 1'\eta$ under the condition that

$$Ax + u - \xi = b, \quad A'y + Dx - v + \eta = c;$$

$$x \geq 0, \quad y \geq 0, \quad u \geq 0, \quad v \geq 0, \quad \xi \geq 0, \quad \eta \geq 0;$$

$$y'u = 0, \quad x'v = 0.$$

(LQ) can be solved by applying the simplex algorithm with the only modification being

that the last line of the condition restricts the possible changes in the basic variables. When D is positive definite, we can always obtain a solution if there is a feasible solution of the original problem, and Wolfe proposed a modification of the foregoing algorithm for the case when D is nonnegative definite that tells whether or not it has an optimal solution, and gives it if it has one. Some other algorithms are also effective when D is positive or nonnegative definite, but when D is not nonnegative definite, no simple effective method has been found to reach the optimal solution even when its existence has been established.

**350 (VI.10)
 Quadric Surfaces**

A. Introduction

A subset F of a 3-dimensional Euclidean space E^3 is called a **quadric surface (surface of the second order** or simply **quadric**) if F is the set of zeros of a quadratic equation $G(x, y, z)=0$, where the coefficients of G are real numbers. The equation $G(x, y, z)=0$ is written as

$$ax^2 + by^2 + cz^2 + d + 2fyz + 2gzx + 2hxy + 2f'x + 2g'y + 2h'z = 0. \tag{1}$$

In general, a straight line intersects a quadric surface at two points. If it intersects the surface at more than two points, then the whole straight line lies on the surface. Suppose that we are given a quadric surface and a point O . Suppose further that we are given a straight line passing through the point O and intersecting the quadric surface at two points A and A' . If $AO = OA'$ for all such straight lines, then the point O is called the **center** of the quadric surface.

B. Classification

The subset defined by equation (1) may be empty; for example, $x^2 + y^2 + z^2 + 1 = 0$. In this article, we consider only quadric surfaces that are not the empty set. When a quadric surface F without singular points has a center or centers, we say that F is **central**.

If we choose a suitable rectangular coordinate system, the equation of a central quadric surface is written in one of the following forms:

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} = 1, \tag{2}$$

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} - \frac{z^2}{c^2} = 1, \tag{3}$$

$$-\frac{x^2}{a^2} - \frac{y^2}{b^2} + \frac{z^2}{c^2} = 1, \tag{4}$$

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1, \tag{5}$$

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1, \tag{6}$$

$$\frac{x^2}{a^2} = 1. \tag{7}$$

When the equation takes the form (2), (3), (4), (5), or (6), we call the quadric surface an **ellipsoid, hyperboloid of one sheet, hyperboloid of two sheets, elliptic cylinder (or elliptic cylindrical surface), or hyperbolic cylinder (hyperbolic cylindrical surface)**, respectively. When the equation takes the form (7), the surface coincides with a pair of parallel planes. If $a = b$ in (2), (3), (4), or (5), the surface is a surface of revolution with the z -axis as the axis of revolution. In this case, we call the surface an **ellipsoid of revolution, hyperboloid of revolution of one sheet, hyperboloid of revolution of two sheets, or circular cylinder (or circular cylindrical surface)**, respectively. If $a = b = c$ for an ellipsoid of revolution, then the surface is a sphere with radius a .

If we choose a suitable rectangular coordinate system, the equation of a noncentral surface of the second order is written in one of the following forms:

$$2z = \frac{x^2}{a^2} + \frac{y^2}{b^2}, \tag{8}$$

$$2z = \frac{x^2}{a^2} - \frac{y^2}{b^2}, \tag{9}$$

$$2z = \frac{x^2}{a^2}. \tag{10}$$

When the equation takes the form (8), (9), or (10), we call the surface an **elliptic paraboloid, hyperbolic paraboloid, or parabolic cylinder (or parabolic cylindrical surface)**, respectively. If a

$= b$ in (8), the surface is called an **elliptic paraboloid of revolution**.

Among these, (2), (3), (4), (8), and (9) are sometimes called **proper quadric surfaces**, and the others **degenerate quadric surfaces**.

Equations (2)–(10) are called the **canonical forms of the equations** of these surfaces (a, b, c in canonical forms should not be confused with a, b, c in (1)). The planes $x=0, y=0,$ and $z=0$ in surfaces (2), (3), and (4) and the planes $x=0$ and $y=0$ in surfaces (8) and (9) are called **principal planes** of the respective surfaces; and lines of intersection of principal planes are called **principal axes**. For a surface of revolution, positions of principal planes and principal axes are indeterminate. We call a, b, c in equations of canonical form the lengths of the principal axes, or simply the principal axes. If F is a hyperboloid of one sheet or a hyperbolic paraboloid, there are two systems of straight lines lying on F ; two straight lines belonging to the same system never meet (and are not parallel), and two straight lines belonging to different systems always meet (or are parallel). If F satisfies (3), these systems of straight lines are given by

$$\begin{cases} \frac{x}{a} - \frac{z}{c} = \lambda \left(1 - \frac{y}{b}\right) \\ \frac{x}{a} + \frac{z}{c} = \frac{1}{\lambda} \left(1 + \frac{y}{b}\right) \end{cases} \quad \begin{cases} \frac{x}{a} - \frac{z}{c} = \mu \left(1 + \frac{y}{b}\right) \\ \frac{x}{a} + \frac{z}{c} = \frac{1}{\mu} \left(1 - \frac{y}{b}\right) \end{cases}$$

If F satisfies (9), then two such systems are given by

$$\begin{cases} \frac{x}{a} - \frac{y}{b} = \lambda \\ \frac{x}{a} + \frac{y}{b} = \frac{2z}{\lambda} \end{cases} \quad \begin{cases} \frac{x}{a} + \frac{y}{b} = \mu \\ \frac{x}{a} - \frac{y}{b} = \frac{2z}{\mu} \end{cases}$$

(λ and μ are parameters). We call these straight lines **generating lines** of the respective surfaces. A hyperboloid of one sheet and a hyperbolic paraboloid are **ruled surfaces** described by these generating lines.

When a quadric surface has singular points, they are double points. The set of double points of a quadric surface F is either a single point O , a straight line l , or a plane π . In the second case, F consists of two planes passing through l or l itself, and in the third case, F coincides with π . In the first case, we say that F is a **quadric conical surface** (or **quadric cone**) with vertex O . Its equation is written in the form $Ax^2 + By^2 + Cz^2 = 0$ ($ABC \neq 0$). When A, B, C are of the same sign, F consists of only one point O . Otherwise, we can assume that $A, B > 0, C = -1$. In this case, if $A = B$, F is called a **right circular cone**, and if $A \neq B$, F is called an **oblique circular cone**.

Given hyperboloids (3) and (4), we call the

quadric cones

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} - \frac{z^2}{c^2} = 0 \quad (3')$$

and

$$-\frac{x^2}{a^2} - \frac{y^2}{b^2} + \frac{z^2}{c^2} = 0 \quad (4')$$

asymptotic cones of (3) and (4), respectively.

C. Poles and Polar Planes

Suppose that we are given a straight line S passing through a fixed point P not contained in a quadric surface F , and S intersects the surface at two points X, Y . The locus of the point Q that is the harmonic conjugate of P with respect to X and Y is a plane. We call this plane π the **polar plane** of P with respect to the quadric surface F , and P the **pole** of the plane π . If the polar plane of a point P contains a point Q , then the polar plane of Q contains P . In this case, we say that the two points P and Q are **conjugate** to each other with respect to the quadric surface. When the point P is on the quadric surface, the tangent plane at P is regarded as the polar plane of P . If the polar plane (with respect to a quadric surface) of each vertex of a tetrahedron is the face corresponding to that vertex, we call this tetrahedron a **self-polar tetrahedron**. If the polar planes (with respect to a quadric surface) of four vertices of a tetrahedron A are four faces of a tetrahedron B , the same property holds when we interchange A and B . We say that such tetrahedrons are **polar tetrahedrons** with respect to the quadric surface. Suppose that we are given a quadric surface and two planes. If the pole (with respect to the quadric surface) of one plane is on the other plane, these two planes are said to be **conjugate** with respect to the surface.

When we are given two pencils of planes in projective correspondence, the locus of lines of intersection of two corresponding planes is generally a hyperboloid of one sheet or a hyperbolic paraboloid. In particular, if the axes of these pencils of planes intersect, the locus is a quadric conical surface, and if the axes are parallel, the locus is a quadric cylindrical surface (i.e., an elliptic or hyperbolic cylinder). When there exists a projective correspondence between two straight lines not on a plane, the locus of lines joining corresponding points is a quadric surface (M. Chasles).

D. Surfaces of the Second Class

A surface F in E^3 is called a **surface of the second class** if it admits two tangent planes

passing through an arbitrary straight line L provided that $F \cap L = \emptyset$. This surface can be represented as the set of zeros of a homogeneous equation of the second order in \dagger plane coordinates u_1, u_2, u_3, u_4 . It is possible that a surface of the second class degenerates into a conic or two points. In general, quadrics are surfaces of the second class, and vice versa.

As in the case of quadrics, we can define poles, polar planes, and polar tetrahedrons with reference to surfaces of the second class. Four straight lines joining corresponding vertices of two tetrahedrons polar with respect to a surface of the second class are on the same quadric. We say that two such tetrahedrons are in **hyperboloid position**.

E. Confocal Quadrics

A family of central quadrics represented by the following equations is called a **family of confocal quadrics**:

$$\frac{x^2}{a+k} + \frac{y^2}{b+k} + \frac{z^2}{c+k} = 1, \quad a > b > c > 0, \quad (11)$$

where k is a parameter. For a quadric belonging to this family, any point on the ellipse $x^2/(a-c) + y^2/(b-c) = 1, z=0$ or the hyperbola $x^2/(a-b) - z^2/(b-c) = 1, y=0$ is called a **focus**. This ellipse and hyperbola are called **focal conics** of the quadric.

Given an ellipsoid F and a point $X(x, y, z)$ not contained in the principal plane, we can draw three quadrics F', F'', F''' passing through X and confocal with F . These surfaces F', F'', F''' intersect each other and are mutually perpendicular. One of them is an ellipsoid, another one a hyperboloid of one sheet, and the third a hyperboloid of two sheets. Let k_1, k_2, k_3 be the values of the parameter k in (11) corresponding to these three surfaces. Then the coordinates x, y, z of the point X are given by

$$x = \sqrt{\frac{(a+k_1)(a+k_2)(a+k_3)}{(b-a)(c-a)}},$$

$$y = \sqrt{\frac{(b+k_1)(b+k_2)(b+k_3)}{(a-b)(c-b)}},$$

$$z = \sqrt{\frac{(c+k_1)(c+k_2)(c+k_3)}{(a-c)(b-c)}}.$$

We call k_1, k_2, k_3 the **elliptic coordinates** of the point X .

Two points $(x, y, z), (x', y', z')$ are called **corresponding points** if they belong to confocal quadrics of the same kind,

$$\frac{x^2}{a} + \frac{y^2}{b} + \frac{z^2}{c} = 1,$$

$$\frac{(x')^2}{a+k} + \frac{(y')^2}{b+k} + \frac{(z')^2}{c+k} = 1,$$

and satisfy

$$\frac{x}{\sqrt{a}} = \frac{x'}{\sqrt{a+k}}, \quad \frac{y}{\sqrt{b}} = \frac{y'}{\sqrt{b+k}},$$

$$\frac{z}{\sqrt{c}} = \frac{z'}{\sqrt{c+k}}.$$

If $P_1, P_2; Q_1, Q_2$ are corresponding points, then $P_1Q_2 = P_2Q_1$ (J. Ivory).

F. Circular Sections

When the intersection of a plane and a quadric is a circle, the intersection is called a **circular section**. In general, circular sections are cut off by two systems of parallel planes through a quadric. The point of contact on the tangent plane parallel to these is an **umbilical point** of the quadric.

G. Quadric Hypersurfaces

A subset F of an n -dimensional Euclidean space E^n is called a **quadric hypersurface** (or simply **hyperquadric**) if it is the set of points (x_1, \dots, x_n) satisfying the following equation of the second degree:

$$\sum_{i,k=1}^n a_{ik}x_i x_k + 2 \sum_{i=1}^n b_i x_i + c = 0, \quad (12)$$

where a_{ik}, b_i, c are all real numbers. We can assume without loss of generality that the matrix $A = (a_{ik})$ is symmetric. Assume that A is not a zero matrix. In the case $n=2$, F is a conic, and in the case $n=3$, it is a quadric surface. The theory of classification of quadric surfaces can be generalized to the n -dimensional case as follows: Let $r(A^*) = r^*$ be the rank of the $(n+1) \times (n+1)$ matrix

$$A^* = \begin{bmatrix} a_{11} & \dots & a_{1n} & b_1 \\ & & \dots & \dots \\ a_{n1} & \dots & a_{nn} & b_n \\ b_1 & \dots & b_n & c \end{bmatrix} = \begin{bmatrix} & & & b_1 \\ & A & & \vdots \\ & & & b_n \\ b_1 & \dots & b_n & c \end{bmatrix},$$

and put $r(A) = r$. Then we have the following three cases: (I) $r = r^*$; (II) $r + 1 = r^*$; and (III) $r + 2 = r^*$. Corresponding to each case, equation (12) can be simplified (by a coordinate transformation in E^n) to the following canonical forms, respectively:

$$(I) \quad \sum_{i=1}^r \lambda_i x_i^2 = 0,$$

$$(II) \quad \sum_{i=1}^r \lambda_i x_i^2 + 1 = 0,$$

$$(III) \quad \sum_{i=1}^r \lambda_i x_i^2 + 2x_{r+1} = 0,$$

where $(\lambda_1, \dots, \lambda_r, 0, \dots, 0)$ (with $n-r$ zeros) is proportional to the eigenvalues of the matrix A . In general, we have $1 \leq r \leq n$. In the cases where $r=n$ in forms (I) and (II) and $r+1=n$ in (III), the hypersurface is called a **properly $(n-1)$ -dimensional quadric hypersurface**, and in other cases, a **quadric cylindrical hypersurface**. In cases (I) and (II), the quadric cylindrical hypersurface is the locus of $(n-r)$ -dimensional subspaces passing through each point of a properly $(r-1)$ -dimensional quadric hypersurface and parallel to a fixed $(n-r)$ -dimensional subspace. In case (III), the quadric cylindrical hypersurface is the locus of $(n-r-1)$ -dimensional subspaces passing through each point of a properly r -dimensional quadric hypersurface and being parallel to a fixed $(n-r-1)$ -dimensional subspace. For form (I) with $\lambda_i > 0$ ($i=1, \dots, n$), a properly $(n-1)$ -dimensional quadric hypersurface reduces to a point in E^n ; for form (II) with $\lambda_i > 0$ ($i=1, \dots, n$) it becomes the empty set. Suppose that we are given a quadric hypersurface F that is neither a point nor empty. Then the system $\{\lambda_1, \dots, \lambda_r\}$ associated with F in its canonical equation is unique up to order (and signature in form (III)). Suppose that we are given a quadric surface F and a point P on F . Suppose further that if a point X other than P is on F , then the whole straight line PX lies on F . In this case, the hypersurface is called a **quadric conical hypersurface** (or simply **quadric cone**). For example, for case (I), we can take $P=O$ (the origin), and the hypersurface is a quadric cone. In cases (I) and (II), the hypersurface is symmetric with respect to the origin. In these cases, a hypersurface is called a **central quadric hypersurface**, and in case (III), it is called a **noncentral quadric hypersurface** or **parabolic quadric hypersurface**. When we cut a parabolic quadric hypersurface by a (2-dimensional) plane containing the x_{n+1} -axis, the section is a parabola. If $\lambda_i < 0$ ($i=1, \dots, r$) in form (II), then the surface is called an **elliptic quadric hypersurface**, and if there are both positive and negative numbers among the λ_i , the surface is called a **hyperbolic quadric hypersurface**. The section of an elliptic quadric hypersurface by a plane is always an ellipse. The section of a hyperbolic quadric hypersurface by a plane is an ellipse, a hyperbola, or two straight lines. In general, the section of a quadric hypersurface by a subspace is a quadric hypersurface on that subspace.

H. Quadric Hypersurfaces in an Affine Space

In Section G we considered a quadric hypersurface defined by (12) in an n -dimensional Euclidean space E^n and transformed the equation to canonical form by an orthogonal

transformation of coordinates in E^n . If we regard E^n as an n -dimensional affine space over the real number field and reduce (12) to the simplest form by a coordinate transformation in the affine space, we have the following canonical forms corresponding to cases (I), (II), and (III) discussed in Section G:

$$(I) \quad (s, t): \sum_{i=1}^s x_i^2 - \sum_{j=s+1}^r x_j^2 = 0,$$

$$(II) \quad (s, t): \sum_{i=1}^s x_i^2 - \sum_{j=s+1}^r x_j^2 + 1 = 0,$$

$$(III) \quad (s, t): \sum_{i=1}^s x_i^2 - \sum_{j=s+1}^r x_j^2 + 2x_{r+1} = 0,$$

where $0 \leq s \leq r$ and $r-s=t$. The terms *properly $(n-1)$ -dimensional, cylindrical, conical, parabolic, elliptic, and hyperbolic* can be defined in terms of this affine classification. For example, a cone is of type (I), a parabolic hypersurface is of type (III), an elliptic hypersurface is of type (II) $(0, r)$, a hyperbolic hypersurface is of type (II) (s, t) $(s, t > 0)$, and type (II) $(s, 0)$ represents the empty set. A necessary and sufficient condition for a (nonempty) hypersurface to be represented by two canonical forms $N(s, t)$, $N'(s', t')$ is that (i) $N=N'$ and (ii) if $N=(I)$ or $N=(III)$, then $s=s', t=t'$ or $s=t', t=s'$, and if $N=(II)$, then $s=s', t=t'$.

I. Quadric Hypersurfaces in a Projective Space

Suppose that we are given a field K of characteristic not equal to 2 and an n -dimensional projective space P^n over K . A subset F of P^n is called a **quadric hypersurface** (or simply **hyperquadric**) if F is represented by a homogeneous equation of the second degree $\sum_{i,k=0}^n a_{ik}x_i x_k = 0$, where (x_0, x_1, \dots, x_n) are homogeneous coordinates in P^n and $a_{ik} \in K$; $A=(a_{ik})$ is a nonzero symmetric matrix. The problem of classifying such surfaces is reduced to that of quadratic forms or, equivalently, to that of symmetric matrices in K . Two symmetric matrices A and B are equivalent if there exists a regular matrix T such that $B=TAT$ (\rightarrow 348 Quadratic Forms). In particular, when K is an algebraically closed field or a real closed field, a simple result is obtained. If K is an algebraically closed field, then the equation of the quadric hypersurface is reduced to the canonical form $\sum_{i=0}^r x_i^2 = 0$, where $r=r(A)$ is the rank of A . When K is a real closed field, then the canonical form is $\sum_{i=0}^s x_i^2 - \sum_{j=s+1}^r x_j^2 = 0$.

351 (XX.23) Quantum Mechanics

A. Historical Remarks

†Newtonian mechanics (classical mechanics) successfully explained the motion of mechanical objects, both celestial and terrestrial, on a macroscopic scale. It failed, however, to explain blackbody radiation, which was discovered in the last decade of the 19th century. M. Planck introduced a hypothesis of discrete energy quanta, each of which contains an amount of energy E equal to the frequency of the radiation ν multiplied by a universal constant h (called **Planck's constant**). He applied this hypothesis to derive a new formula for radiation that gives predictions in good agreement with observations. A. Einstein proposed the hypothesis of the photon as a particlelike discrete unit of light rays. Assuming that many physical quantities, including energy, have only discrete values, N. H. Bohr explained the stability of electronic states in atoms. As illustrated in these examples, **quantum mechanics** is applied to study the motion of microscopic objects, including molecules, atoms, nuclei, and elementary particles.

B. Quantum-Mechanical Measurement

Fundamental differences between the new mechanics and classical mechanics are due to the facts that many physical quantities, for example, energy, can take only discrete values in the microscopic world, and that states of microscopic objects are disturbed by observation.

A (pure) **state** at a certain time is expressed by a unit vector ψ in a †Hilbert space \mathcal{K} , and **observables**, or physical quantities, are expressed by †self-adjoint operators in such a space.

Let a_n ($n = 1, 2, \dots$) be †eigenvalues of an observable A , and let P_n be a †projection opera-

tor onto the eigenspace spanned by †eigenvectors belonging to the eigenvalue a_n . Suppose that $A = \sum_n a_n P_n$. Then the hypothesis on measurement in quantum mechanics is given as follows.

When an observable A is observed in a state ψ , one of the eigenvalues a_n is found with probability proportional to $(\psi, P_n \psi)^2$. When an eigenvalue a_n is once observed, a state jumps from ψ to an eigenstate $P_n \psi$ which belongs to the eigenvalue a_n . Quantum mechanics predicts only a probability p_n with which a certain value a_n is found when an observable A is observed. This probability, given by $(\psi, P_n \psi)$, is not changed even if ψ is replaced by $e^{i\theta} \psi$, $0 \leq \theta \leq 2\pi$. Therefore $e^{i\theta} \psi$ represents the same state as ψ . The set of $e^{i\theta} \psi$, $0 \leq \theta \leq 2\pi$, for a fixed ψ ($\|\psi\| = 1$) is called a **unit ray**.

If P_n is 1-dimensional and $P_n \varphi = \varphi$, $\|\varphi\| = 1$, then $(\psi, P_n \psi) = |(\psi, \varphi)|^2$ is called the **transition probability** between the two states.

The **expectation value** (or **expectation**) of an operator A in a state ψ , usually normalized to $(\psi, \psi) = 1$, is defined to be $\langle A \rangle = (\psi, A \psi) = \sum_n a_n p_n$.

A general self-adjoint operator A can be written as $A = \int \lambda dP(\lambda)$. When A is observed in a state ψ , the probability for a value to be found between λ_1 and λ_2 ($\lambda_2 > \lambda_1$; λ_2 included and λ_1 excluded if $P(\lambda)$ is right continuous) is $(\psi(P(\lambda_2) - P(\lambda_1)), \psi)$ (\rightarrow 390 Spectral Analysis of Operators).

The quantity $(\varphi, A \psi)$ is called the **matrix element** of A between the two states φ and ψ . A state ψ can be viewed as a functional $\psi(A) = \langle A \rangle$ on the set of all observables A (its value being the expectation), which is linear in A , positive in the sense $\psi(A^* A) \geq 0$ for any operator A , and normalized: $\psi(1) = 1$. If $0 \leq \lambda \leq 1$ and $\psi(A) = \lambda \psi_1(A) + (1 - \lambda) \psi_2(A)$ for all observables A , then the state ψ is called a **mixture** of states ψ_1 and ψ_2 with weights λ and $(1 - \lambda)$. If a state is not a nontrivial (i.e., $\lambda \neq 0, 1, \psi_1 \neq \psi_2$) mixture, it is called **pure**. The state $\langle A \rangle = (\psi, A \psi)$ on the set of all self-adjoint operators A given by a vector ψ is pure in this sense. If $\sup_x \psi(A_x) = \psi(A)$ whenever A_x is an increasing net of positive operators with A as its limit, then ψ is called **normal**. Any normal positive linear functional on the set of all self-adjoint operators can be described by a trace-class positive operator ρ , called the **density matrix**, as $\langle A \rangle = \text{tr}(A \rho)$. If $\{\psi_n\}$ is a complete orthonormal set, where each ψ_n is an eigenvector of ρ belonging to the eigenvalue λ_n , then $\langle A \rangle = \sum_n \lambda_n (\psi_n, A \psi_n)$.

C. Canonical Commutation Relations

In quantum mechanics, canonical variables are represented by the self-adjoint operators

Q_k (coordinates) and P_k (momenta), $k = 1, \dots, N$, which satisfy the **canonical commutation relations**

$$[Q_k, P_l] = i\hbar\delta_{kl}\mathbf{1},$$

where $\mathbf{1}$ is the identity operator, $[A, B]$ denotes the commutator $AB - BA$, $\hbar = h/(2\pi)$, and the relation is supposed to hold on a certain dense domain of vectors. Self-adjoint operators Q_k and P_k satisfying the above relations are unique up to quasi-equivalence under a suitable domain assumption, e.g., if $\sum_k Q_k^2 + \sum_k P_k^2$ is essentially self-adjoint on a dense domain invariant under multiplication of the Q 's and P 's and on which the above relations are satisfied. Under such an assumption, Q_k and P_k are unitarily equivalent to a direct sum of the **Schrödinger representation** on $L_2(\mathbf{R}^N, dx_1 \dots dx_N)$, where Q_k is multiplication by the k th coordinate x_k and P_k is the differentiation $-i\hbar(\partial/\partial x_k)$ (**Rellich-Dixmier theorem**).

The above Schrödinger representation is called the **position representation** (or q -representation). The formulation using the function space L_2 of real variables p_k , $k = 1, 2, \dots, N$, on which the operators P_k act as multiplications by p_k , is called the **momentum representation** (or p -representation).

If Hermitian operators A and B satisfy the canonical commutation relations in the form $(A\psi, B\psi) - (B\psi, A\psi) = i\hbar(\psi, \psi)$, then the following **Heisenberg uncertainty relation** holds for the expectation:

$$\langle(A - \langle A \rangle)^2\rangle \langle(B - \langle B \rangle)^2\rangle \geq \frac{\hbar^2}{4}.$$

This gives the **uncertainty** in observations, which means that two observables A and B cannot simultaneously be observed with accuracy. This is another important property of microscopic motion that cannot be found in macroscopic motion.

In a direct sum of the Schrödinger representation of the canonical commutation relations, the unitary operators

$$U(a) = \exp i \sum_k a_k Q_k, \quad V(b) = \exp i \sum_k b_k P_k$$

with real parameters a_k and b_k , $k = 1, \dots, N$, satisfy the following **Weyl form** of the canonical commutation relations:

$$U(a)U(a') = U(a+a'), \quad V(b)V(b') = V(b+b'),$$

$$U(a)V(b) = V(b)U(a) \exp\left(-i \sum_k a_k b_k\right).$$

Conversely, any pair of families of unitary operators $U(a)$ and $V(b)$ satisfying these relations and depending continuously on parameters a and b are unitarily equivalent to those obtained as above (**von Neumann uniqueness theorem**).

D. Time Evolution and the Schrödinger Equation

The time t of an observation is fixed in the foregoing discussion. A state changes, however, as the time t changes, in such a way that the transition probability between states is preserved. By Wigner's theorem (\rightarrow Section H), this time evolution of states can be implemented by unitary operators U_t defined by the transformation of vectors $\psi \rightarrow U_t \psi = \psi_t$. Furthermore, under some continuity assumption, such as that of $(\varphi, U_t \psi)$, U_t can be made a continuous one-parameter group. By Stone's theorem, $U_t = e^{-iHt/\hbar}$ for a self-adjoint operator H . This operator is called the **Hamiltonian operator** (or simply **Hamiltonian**) determined by the structure of a system. An infinitesimal change in ψ corresponding to an infinitesimal change in t can be generated by this operator H as follows:

$$i\hbar \frac{\partial \psi_t}{\partial t} = H\psi_t.$$

This equation is called the **time-dependent Schrödinger equation**.

A state ψ changes but observables do not change with time in the **Schrödinger picture** above. The other picture, known as the **Heisenberg picture**, is equally possible. In this picture, the state is expressed by a time-independent vector, while operators A vary with time as follows: $A \rightarrow U_t^* A U_t = A(t)$. Rates of change of operators $A(t)$ can be calculated by means of the equation

$$\frac{dA(t)}{dt} = \frac{i}{\hbar} [H, A(t)],$$

which is called the **Heisenberg equation of motion**. When time t changes, the expectation value of an operator A in a state ψ changes in both pictures according to

$$d\langle A \rangle / dt = i\langle [H, A] \rangle / \hbar.$$

According to classical analytical dynamics, a change of a dynamical quantity that is a function of canonical variables q_i (positions) and p_i (momenta) is given by

$$dA/dt = -(H, A),$$

where H is a \dagger Hamiltonian function and the parentheses $(,)$ denote the \dagger Poisson bracket. A replacement of the Poisson bracket (A, B) by $[A, B]/i\hbar$ transforms this classical equation into the quantum-mechanical equation above. It should be noticed that the mathematical structure of the Poisson bracket is similar to that of commutator. In this transition from classical to quantum mechanics the **correspondence principle** can be used. This requires that the laws of quantum mechanics must lead

to the equations of classical mechanics in the classical situation, where many quanta are involved and \hbar can be regarded as infinitesimally small in the commutation relation. The correspondence principle suggests that Hamiltonian operators in quantum mechanics can be obtained from Hamiltonian functions $H(p_k, q_k)$ of canonical variables p_k and q_k in classical mechanics after replacing p_k and q_k by the operators P_k and Q_k in the Schrödinger representation (up to uncertainty of about the order of operators). This process of moving from canonical variables and the Hamiltonian function in classical mechanics to canonical operators and the Hamiltonian in quantum mechanics is called **quantization**. Taking a system of s particles and letting $x_k, y_k,$ and z_k be the Cartesian coordinates of the k th particle, we usually write the equation of motion as

$$i\hbar \frac{\partial \psi}{\partial t} = \left(- \sum_{k=1}^s \frac{\hbar^2}{2m_k} \Delta_k + V(x_1, y_1, z_1, \dots, x_s, y_s, z_s) \right) \psi,$$

which is a second-order partial differential equation. Here m_k is the mass of the k th particle; Δ_k is the Laplacian of $x_k, y_k,$ and z_k ; and V is a real function called the potential energy. This equation is the time-dependent **Schrödinger equation**. The partial differential operator on the right-hand side is called the (s -body) **Schrödinger operator** and $\psi(x_1, y_1, z_1, \dots, x_s, y_s, z_s, t)$ is called a **wave function**. The probability of finding a particle in the volume $dx_k dy_k dz_k$ bounded by $x_k, x_k + dx_k, y_k, y_k + dy_k,$ and $z_k, z_k + dz_k$ is proportional to $|\psi(x_1, y_1, z_1, \dots, x_s, y_s, z_s, t)|^2$. Usually $|\psi|^2$ is normalized so that its integral over the whole space is 1. We sometimes call ψ the **probability amplitude**. When ψ is given by $e^{-iEt/\hbar} \phi(x_1, \dots, z_s)$, the expectation value of an operator A in a state $\psi, \langle A \rangle = \int \psi^* A \psi dx_1 \dots dz_s,$ does not depend on time. When this is the case, ψ is called a **stationary state**.

A real value E and a function $\phi(x_1, \dots, z_s)$ are found by solving an eigenvalue problem $H\phi = E\phi$. This equation is the **time-independent Schrödinger equation**, which is a second-order partial differential equation. Since the Hamiltonian H stands for the energy of this system, the eigenvalues E are the energy values that this system can take.

When a potential function V is given, it is a nontrivial matter to prove that the (s -body) Schrödinger operator with the given V is essentially self-adjoint on the set of, for example, all C^∞ -functions with compact supports so that its closure H defines mathematically the continuous one-parameter group of unitaries $U_t = e^{-iHt/\hbar}$ for the time evolution of the quan-

tum system of s particles with the given interaction potential V . If V satisfies an estimate $\|V\psi\| \leq \lambda \|H_0\psi\| + \mu \|\psi\|$ (called the **Kato perturbation** on H_0) for some nonnegative $\lambda < 1$ and $\mu \geq 0$ and for all ψ in a dense domain on which H_0 is essentially self-adjoint, where H_0 denotes the Schrödinger operator with $V=0$ (called the **free Hamiltonian** or the **kinetic energy** term), then $H_0 + V$ is essentially self-adjoint on the same domain. For the case where V consists of Coulomb interactions between electrons and Coulomb potentials on electrons by fixed nuclei, for example, such an estimate and hence the essential self-adjointness of Hamiltonians for atoms and molecules were established first by T. Kato (*Trans. Amer. Math. Soc.*, 70 (1951)).

For a 1-body Schrödinger operator (or 2-body Schrödinger operator after the center of mass motion has been separated out), the point spectrum is that of the particle trapped by the potential, and the state represented by its eigenvector is called a **bound state**. The eigenvalue is nonpositive for a reasonable class of potentials V (for example, if $V(x)$ ($x \in \mathbf{R}^3$) is continuous and $\mathcal{O}(|x|^{-\epsilon})$ as $|x| \rightarrow \infty$ for some $\epsilon > 0$), and its absolute value is called the **binding energy**. The eigensolutions of the Schrödinger equation are what have been called stationary states above.

There are also stationary solutions that do not correspond to the point spectrum and hence are not square integrable. They are used in the stationary methods of scattering theory (\rightarrow 375 Scattering Theory).

E. Some Exact Solutions for the 1-Body Schrödinger Equation

(1) **Harmonic oscillator**. First consider the case in which the space is of 1 dimension, so that the Laplacian Δ is $(d/dx)^2$. Let m be the mass of the particle and $V(x) = m\omega^2 x^2/2$ for a positive constant ω (called the **angular frequency**). The Hamiltonian

$$H = -(\hbar^2/2m)(d/dx)^2 + m\omega^2 x^2/2$$

has simple eigenvalues

$$E_n = \hbar\omega(n + (1/2)), \quad n = 0, 1, 2, \dots,$$

with a complete orthonormal set of eigenfunctions

$$\psi_n(x) = c_n H_n(q) e^{-q^2/2}, \quad q = (m\omega/\hbar)^{1/2} x,$$

where $H_n(q)$ is a Hermite polynomial and c_n is the normalization constant:

$$H_n(q) = \sum_{k=0}^{\lfloor n/2 \rfloor} (-1)^k n! (2q)^{n-2k} / \{(n-2k)! k!\},$$

$$c_n = \{2^{2n} (n!)^2 \pi \hbar / (m\omega)\}^{-1/4}.$$

When the space is of r dimensions, n in E_n is replaced by $n_1 + \dots + n_r$, with nonnegative integers n_1, \dots, n_r , and the corresponding eigenfunction is $\prod_{j=1}^r \psi_{n_j}(x_j)$.

(2) **One-dimensional square-well potential.**

Let $V(x) = V$ for $|x| \leq a/2$ and $V(x) = 0$ for $|x| > a/2$ ($x \in \mathbf{R}$). If $V \geq 0$, there are no point spectra. If $V < 0$ and

$$N - 1 < a(-2mV)^{1/2}/(\pi\hbar) \leq N,$$

then there are N eigenvalues ($N = 1, 2, \dots$) obtained as the roots $E < 0$ of one of the following equations:

$$\{(V/E) - 1\}^{1/2} = \tan\{a(-2mE)^{1/2}/(2\hbar)\},$$

$$\{(V/E) - 1\}^{1/2} = -\cot\{a(-2mE)^{1/2}/(2\hbar)\}.$$

(3) **Separation of angular dependence for central potential.** If $V(x)$ ($x \in \mathbf{R}^3$) depends only on $r = |x| = (\sum_{j=1}^3 x_j^2)^{1/2}$ (called a **central potential**), then all eigenvalues E and a basis for eigenfunctions $\psi(x)$ can be obtained in terms of the polar coordinate r, θ, φ ($x_1 = r \sin \theta \cos \varphi, x_2 = r \sin \theta \sin \varphi, x_3 = r \cos \theta$) as

$$\psi(x) = Y_{lm}(\theta, \varphi) r^{-1} u(r),$$

$$-(\hbar^2/(2m))u''(r) + \{\hbar^2 l(l+1)/(2mr) + V(r) - E\}u(r) = 0,$$

$$\|\psi\| = \int_0^\infty |u(r)|^2 dr < \infty,$$

where the angular function Y_{lm} is an eigenfunction of the square L^2 of the **orbital angular momentum** $L = -ix \times \nabla$:

$$Y_{lm} = c_{lm} P_l^m(\cos \theta) e^{im\varphi},$$

$$c_{lm} = (-1)^m \{(2l+1)(l-m)!/(4\pi(l+m)!)\}^{1/2},$$

$$m = l, l-1, \dots, -l+1, -l, \quad l = 0, 1, 2, \dots$$

Here $P_l^m(x)$ is an associated Legendre polynomial:

$$P_l^m(x) = (1-x^2)^{m/2} (d^{l+m}(x^2-1)^l/dx^{l+m})/(2^l l!).$$

The above equation for $u(r)$ is called the **radial equation**. The nonnegative integer l is the **azimuthal quantum number**, and the integer m is the **orbital magnetic quantum number**. The wave function $\psi(x)$ with the angular dependence $Y_{lm}(\theta, \varphi)$ is called the **S-wave, P-wave, D-wave, ...** according as $l = 0, 1, 2, \dots$

(4) **Hydrogen-type atom.** Let $V(r) = -Ze^2/r$ ($Z > 0$). For each l and m , there are eigenvalues $-e^2 Z^2/(2an^2)$ with eigenfunctions $\psi_{nlm} = r^{-1} u_{nl}(r) Y_{lm}(\theta, \varphi)$, where $n = l+1, l+2, \dots$ is the **principal quantum number**,

$$u_{nl}(r) = c_{nl} L_{n-l-1}^{(2l+1)}(s) s^{l+1} e^{-s/2}, \quad s = 2Zr/(na),$$

$$c_{nl} = -\{(n-l-1)! [2Z/(na(n+l)!)]^3 / (2n)\}^{1/2},$$

and $L_N^\mu(x)$ is the μ th derivative of the \dagger Laguerre

polynomial

$$L_N(x) = \sum_{v=0}^N (N!)^2 (-x)^v / \{(N-v)!(v!)^2\}.$$

The eigenvalue is determined by n , and its multiplicity is n^2 , corresponding to the different possible values of l and m .

F. Path Integrals

R. P. Feynman (*Rev. Mod. Phys.*, 20 (1948)) has given the solution of the Schrödinger equation as an integral of $e^{iL/\hbar}$ over all possible paths $q(t)$, where $L = L(q, \dot{q})$ ($\dot{q} = (d/dt)q(t)$) is the classical Lagrangian for the Hamiltonian system. This integral is called the Feynman path integral. Mathematical reformulation of the formula in terms of the Wiener measure has been given by M. Kac (*Proc. 2nd Berkeley Symp. Math. Statist. Probability*, 1950; *Probability and related topics in the physical sciences*, Wiley, 1959).

Consider the 1-body Schrödinger operator $H = H_0 + V$ (form sum), where V is the sum of a locally integrable function bounded below and a Kato perturbation on H_0 . Let $b(t)$ ($t \geq 0$) be the Wiener process and $q(t) = \hbar b(t)/(2m)^{1/2}$. For any L_2 functions f ,

$$(e^{-tH/\hbar} f)(x) = E \left(f(x + q(t)) \exp \left\{ - \int_0^t V(x + q(s)) ds / \hbar \right\} \right)$$

for almost all x , where E denotes the expectation for the Wiener process. If V is a sum of L_2 and L_∞ functions (for spatial dimension ≤ 3), then the right-hand side is continuous in x for $t > 0$. This is called the **Feynman-Kac formula**.

Let L_0 be the Hamiltonian for a 1-dimensional harmonic oscillator with $m = \omega = \hbar = 1$ and ψ_0 be the eigenfunction $\psi_0(x) = \pi^{-1/4} \exp(-x^2/2)$. Consider $H = L_0 + V$ (form sum), where V is a sum of a locally integrable function bounded below and a Kato perturbation on L_0 . Let $q(t)$ ($t \in \mathbf{R}$) be Gaussian random variables with mean 0 and covariance $E(q(t)q(s)) = 2^{-1} \exp(-|t-s|)$ (called the **oscillator process**). For any $f_j(x)$ in $L_2(\mathbf{R}, \psi_0^2 dx)$ ($j = 1, \dots, n$) and $t_0 \leq t_1 \leq \dots \leq t_n \leq t_{n+1}$,

$$(\psi_0, e^{-(t_1-t_0)H} f_1 e^{-(t_2-t_1)H} f_2 \dots f_n e^{-(t_{n+1}-t_n)H} \psi_0) = E \left(\left\{ \prod_{j=1}^n f_j(q(t_j)) \right\} \exp \left\{ - \int_{t_0}^{t_{n+1}} V(q(s)) ds \right\} \right).$$

The above path integral formulas are closely related to the **Trotter product formula**

$$e^{-t(A+B)} = \lim_{n \rightarrow \infty} (e^{-tA/n} e^{-tB/n})^n \quad (t \geq 0),$$

where A and B are self-adjoint operators

bounded below and $A + B$ is essentially self-adjoint. (The same formula holds without the boundedness assumption when $t \in i\mathbf{R}$.)

G. The Dirac Equation

The Schrödinger equation is not relativistically invariant. The **Klein-Gordon equation**

$$(\square - \kappa^2)\psi = 0, \quad \square \equiv \Delta - \frac{1}{c^2} \frac{\partial^2}{\partial t^2}, \quad \kappa = \frac{mc}{\hbar}$$

is obtained by replacing p_k by $(\hbar/i)\partial/\partial x_k$ ($k = 1, 2, 3$) and E by $i\hbar\partial/\partial t$ in the relativistic identity

$$E^2 = m^2 c^4 + \mathbf{p}^2 c^2,$$

where c is the speed of light. Wave functions of free particles are believed to satisfy this equation. P. A. M. Dirac assumed that the ψ of a free electron is expressed in terms of a spinor with four components satisfying a linear differential equation that automatically implies the Klein-Gordon equation. Relativity requires the equal handling of space and time.

The Dirac equation

$$\sum_{\mu=0}^3 \gamma^\mu \frac{\partial \psi}{\partial x^\mu} + i\kappa\psi = 0 \tag{8}$$

($x^0 = ct$) satisfies these requirements. The coefficients γ^μ can be so determined that every component of ψ also satisfies the Klein-Gordon equation. Thus the γ^μ are found to be 4×4 matrices satisfying the commutation relations $\gamma^\mu \gamma^\nu + \gamma^\nu \gamma^\mu = 2g^{\mu\nu}$ ($\mu, \nu = 0, 1, 2, 3$), where $g^{\mu\nu} = 0$ for $\mu \neq \nu$ and $g^{00} = -g^{kk} = 1$ ($k = 1, 2, 3$). Sixteen linearly independent matrices are obtained by repeated multiplication of five matrices, which include the four matrices $\gamma^0, \gamma^1, \gamma^2, \gamma^3$ and the identity matrix. Any 4×4 matrix can be expressed as a linear combination of these sixteen matrices.

The Dirac equation has plane wave solutions

$$\psi(\mathbf{x}, t) = u \exp((i/\hbar)\mathbf{p} \cdot \mathbf{x} - (i/\hbar)Et),$$

where the energy eigenvalues E are

$$\pm \sqrt{m^2 c^4 + p^2 c^2}.$$

There are four independent eigensolutions $u^{(1)}, u^{(2)}, u^{(3)},$ and $u^{(4)}$, because u has four components. Two of them are of positive energy and the other two are of negative energy. Although the negative energy case is physically undesirable, it has to be taken into account in order to obtain a mathematically complete set. To solve this difficulty, Dirac proposed the hypothesis (**Dirac's hole theory**) that all the negative energy states are filled up by an infinite num-

ber of electrons in the normal state of the vacuum. The absence from the vacuum of a negatively charged electron in a negative energy state could then be expected to manifest itself as a positively charged particle (positron) with positive mass and kinetic energy. If gamma rays are absorbed to excite an electron from a negative energy state into a positive energy state, an electron-positron pair must be created. Y. Nishina and O. Klein calculated the cross section of Compton scattering (the **Klein-Nishina formula**) by use of the Dirac equation and found good agreement with observations, thus providing evidence that the Dirac equation is correct. The existence of negative energy states, however, forces us to give up considering the Dirac equation as an equation of one electron. The positron theory is introduced, and the Dirac equation is considered as the classical field of electron waves and is second-quantized (\rightarrow 377 Second Quantization).

The Klein-Gordon equation can also be considered to be the classical wave equation of matter and can be second-quantized. Motions of particles with zero spin, pi mesons (π) for example, obey this equation.

We can rewrite the Dirac equation as $i\hbar\partial\psi/\partial t = H\psi$, $H = c\boldsymbol{\alpha} \cdot \mathbf{p} + mc^2\beta$, where $\gamma^k = \beta\alpha_k$ ($k = 1, 2, 3$), and $\gamma^0 = \beta$. Since H cannot commute with the orbital angular momentum of an electron $\mathbf{L} = \mathbf{r} \times \mathbf{p} = -i\hbar\mathbf{r} \times \nabla$, \mathbf{L} is not conserved. However, the total angular momentum $\mathbf{J} = \mathbf{L} + (\hbar/2)\boldsymbol{\sigma}$ can be conserved when $\boldsymbol{\sigma}$ is a vector whose components can be given as $\begin{pmatrix} \sigma_k & 0 \\ 0 & \sigma_k \end{pmatrix}$, where $\beta = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$, $\alpha_k = \begin{pmatrix} 0 & \sigma_k \\ \sigma_k & 0 \end{pmatrix}$, and the σ_k , called **Pauli spin matrices**, are given by $\sigma_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, $\sigma_y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}$, $\sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$. (The γ^μ are called **Dirac's γ matrices**.) The

quantity $\mathbf{S} = \frac{\hbar}{2}\boldsymbol{\sigma}$ is the **intrinsic angular momentum** of the electron, also called the **spin**. Many particles besides the electron, the neutron for example have spin. The matrix $\mathbf{S}^2 = S_x^2 + S_y^2 + S_z^2$ is diagonal and is equal to $s(s+1)\hbar^2 I$ (I is the identity matrix). For the electron $s = 1/2$, and $\hbar/2$ is called the absolute value of the spin. Therefore we say that electrons are particles of spin $\hbar/2$. This was predicted in the theory of light spectra.

When the speed of an electron is very small, so that $(v/c)^2$ can be neglected, states of the electron can be expressed in terms of two-component wave functions. This approximation is called the **Pauli approximation**. If the spin-orbit term that appears in the Pauli approximation is also neglected, these two components become independent of each

other and individually satisfy the Schrödinger equation.

H. Application of Representation Theory of Lie Groups

A **symmetry** (with active interpretation) is a bijective mapping of pure states (represented by unit rays in a Hilbert space) preserving transition probabilities between them.

Wigner's theorem says that any symmetry can be implemented by either a unitary or an antiunitary mapping of the underlying Hilbert space as a mapping of unit rays onto themselves. Furthermore a connected Lie group of symmetries is implemented by unitaries, which form a projective representation. Eigenstates ψ of the Schrödinger equation are functions of the coordinates of each particle. Let these coordinates be denoted together as x .

Suppose that an operator T operates on the x , as, for example, a rotation of the coordinate system or a permutation of the labels of the particles. If T commutes with H or H is invariant under the transformation $x \rightarrow x' = Tx$, then $T\psi(x) = \psi'(x) = \psi(T^{-1}x)$ satisfies the same Schrödinger equation as ψ , where the transformation of the function is defined by $\psi'(x) = \psi(x)$. The set of transformations $x \rightarrow x' = Tx$ forms a group $\{T\}$, and the corresponding transformations $\psi \rightarrow T\psi$ give a (generally infinite-dimensional) representation of this group, which should be unitary on L_2 -space relative to the Lebesgue measure dx if T leaves the measure invariant. There are **degeneracies** of the energy eigenvalues, each of which is equal to the dimension of the corresponding representation of the group $\{T\}$. If the representation for each eigenvalue is decomposed into irreducible ones, then the decomposed stationary state can be labeled by an irreducible representation.

When H is spherically symmetric, i.e., H is invariant under the 3-dimensional rotation group, states are classified by the irreducible representations D_L of the rotation group (\rightarrow 258 Lorentz Group). The square of the sum \mathbf{L} of all orbital angular momenta has eigenvalues $L(L+1)\hbar^2$, where L must be 0 or a positive integer. There are $2L+1$ degenerate states, each of which belongs to a different M , the z -component of \mathbf{L} , where M ranges from L to $-L$ by unit steps. Even when there is an interaction between the orbital angular momentum and the spin angular momentum, states are labeled by the irreducible representations D_J of the rotation group, where \mathbf{J} is the sum of the orbital angular momentum \mathbf{L} and the spin angular momentum \mathbf{S} ($\mathbf{J} = \mathbf{L} + \mathbf{S}$) and eigen-

values of \mathbf{J}^2 are given by $J(J+1)\hbar^2$. Each J must be zero, a positive integer, or a half-integer. Adding inversions to the pure rotations, we obtain the 3-dimensional orthogonal group (\rightarrow 60 Classical Groups I). Irreducible representations of this group are written as D_J^\pm , where \pm corresponds to the characters of the inversion relative to the origin. States with $+$ are called **even states** and those with $-$, **odd states**. For example, energy levels of atoms and nuclei can be classified by D_J^\pm .

To obtain matrix elements of observables between two stationary states, group representation theory is useful. The transformation of every observable obeys a certain rule under the transformation of coordinates. The scalar is transformed according to D_0^+ , the vector according to D_1^- , the pseudovector according to D_1^+ , and the traceless tensor according to D_2^+ . If the transformation of an observable is given by D_J , then a matrix element of this observable between the states belonging to $D_{J'}$ and $D_{J''}$ vanishes unless the tensor product representation $D_{J'} \otimes D_{J''}$ contains as a factor a representation equivalent to D_J . In electromagnetic transitions in atoms or nuclei, $D_1 \otimes D_{J'} = D_{J'+1} + D_{J'} + D_{J'-1}$ ($J' \geq 1$) if the electric dipole transition dominates ($J=1$). This implies the **selection rule** $J' \rightarrow J'+1, J', J'-1$. When $J'=0$, only the transition $0 \rightarrow 1$ is possible. More general selection rules can be obtained in the same way for general multipole transitions. Representation theory is useful in determining general formulas of transition strengths.

There is a class of particles, many of which can occupy the same state, called **bosons**. There is another class of particles, of which only one can occupy a given state, called **fermions**. For example, the electron, neutron, and proton are fermions, while the photon and pi meson are bosons. Two identical particles, both of which are either fermions of the same kind or bosons of the same kind, cannot be distinguished. Therefore the Hamiltonian should be invariant under permutations between identical fermions, or between identical bosons. A system consisting of N identical particles can be classified by the irreducible representations of the symmetric group S_N of N elements. When the particles are fermions, two of them cannot occupy the same state (this law is called the **Pauli principle**), so that only totally antisymmetric states are permissible for fermions. When a system consists only of fermions of the same kind with spin $\hbar/2$ and a Hamiltonian of this system does not include terms depending on spins, then the wave functions are just products of spin and orbital parts. In order to make wave functions totally

Quantum Mechanics

antisymmetric, orbital wave functions with a total spin $v/2$ should be limited to those corresponding to the †Young diagram $[2^{N-v}, 1^v] = T(2, 2, \dots, 1, 1)$.

I. Polyatomic Molecules

The group generated by the 2-dimensional rotations about the axis connecting two atoms and the reflections with respect to the planes containing this axis is used to classify states of diatomic molecules. Stationary states can be classified by the absolute value Λ of the angular momentum of the diatomic system around this axis, which can be zero or a positive integer. When $\Lambda \geq 1$, the corresponding state has twofold degeneracy, whereas when $\Lambda = 0$, two states (labeled by \pm) arise, depending on the character of the reflections. If these two atoms are identical, the molecular states can be classified further as even and odd according to the character of reflections with respect to the plane containing the center of mass and perpendicular to the axis. The classification of the spectral terms of a polyatomic molecule is related to its symmetry, described by the set of all transformations that interchange identical atoms. For example, stationary states of methane molecules CH_4 are classified by the irreducible representations of the group T_d (which is generated by adjoining reflection symmetry to the †tetrahedral group T). Level structures of a crystal are classified by the irreducible representations of its symmetry groups.

In the approximation of many-body problems by means of independent particles, the wave function of the total system is constructed by multiplying the wave functions of the individual particles. To construct such a wave function, it is useful to consider the reduction to irreducible parts of the †tensor products of representations of the groups attached to the individual particles. For example, an atom with two electrons carrying the angular momenta J_1 and J_2 has $2J' + 1$ different angular momentum states, where $J' = \min(J_1, J_2)$ corresponding to the decomposition $D_{J_1} \otimes D_{J_2} = D_{J_1+J_2} + D_{J_1+J_2-1} + \dots + D_{|J_1-J_2|}$. The right-hand side of this equation gives all possible states of the atom.

J. Charge Symmetry

The proton and the neutron can be considered to be different states of the same particle, called the nucleon, because these two particles have very similar natures except for their charges, masses, etc. As an approximation, the Hamiltonian of a system consisting of protons

and neutrons may be taken to be invariant under the interchange of protons and neutrons. This invariance is called **charge symmetry**. Analogous to ordinary spin, **isospin** can be introduced to describe the two states of nucleons. The up state of the isospin corresponds to the proton and the down state corresponds to the neutron. Consider transformations belonging to the †special unitary group $SU(2)$ in the 2-dimensional space spanned by the proton state and the neutron state. If a Hamiltonian of N nucleons is invariant under any transformation belonging to $SU(2)$, then the eigenstate of these N nucleons is classified by its irreducible representations D_T , where T stands for the total isospin of each state. This invariance, called **isospin invariance**, holds in the nucleus and elementary particles if electromagnetic and weak interactions, and possibly the interaction responsible for the proton-neutron mass difference, are neglected. When a state of N nucleons has an isospin $T = v/2$, the orbital-spin wave function of this state must correspond to the Young diagram $[2^{N-v}, 1^v]$, since the isospin wave function multiplied by the orbital-spin wave function is a totally antisymmetric wave function. If this Hamiltonian is also independent of spin, it is invariant under unitary transformations in the 4-dimensional space spanned by the four internal states of the nucleon: up and down spins, up and down isospins. Therefore the states of N nucleons can be classified by the irreducible representations of the group $U(4)$ (Wigner's **supermultiplet theory**).

K. The C^* -Algebra Approach

The uniqueness of operators satisfying the canonical commutation relations (representations of CCR's) up to quasi-equivalence (\rightarrow Section C) no longer holds if the number of canonical variables become infinite (a so-called system of infinitely many degrees of freedom), a point first emphasized by K. O. Friedrichs (*Mathematical aspects of the quantum theory of fields*, Interscience, 1953), and physical examples illustrating this point were given by L. van Hove (*Physica*, 18 (1952)) and R. Haag (*Mat. Fys. Medd. Danske Vid. Selsk.*, 29 (1955)). The use of C^* -algebras in physics was first advocated by I. E. Segal (*Ann. Math.*, 48 (1947)), and the physical relationship among all inequivalent representations of a C^* -algebra was first discussed by R. Haag and D. Kastler (*J. Math. Phys.*, 5 (1964)).

In C^* -algebra approach, a physical observable is an element of a C^* -algebra \mathfrak{A} and a state is a functional φ on \mathfrak{A} (its value $\varphi(A)$ is

the expectation value of the observable $A \in \mathfrak{A}$ when measured in that state) that is linear, positive in the sense $\varphi(A^*A) \geq 0$ for any $A \in \mathfrak{A}$, and normalized, i.e., $\|\varphi\| = 1$ or equivalently $\varphi(1) = 1$ if $1 \in \mathfrak{A}$. The \dagger GNS construction associates with every state φ a Hilbert space H_φ , a representation $\pi_\varphi(A)$, $A \in \mathfrak{A}$, of \mathfrak{A} by bounded linear operators on H_φ , and a unit cyclic vector Ω_φ in H_φ such that $\varphi(A) = (\Omega_\varphi, \pi_\varphi(A)\Omega_\varphi)$. Two states φ and ψ (or rather π_φ and π_ψ) are called disjoint if there is no nonzero mapping T from H_φ to H_ψ such that $T\pi_\varphi(A) = \pi_\psi(A)T$ for all $A \in \mathfrak{A}$. Abundant disjoint states occur for a system of infinitely many degrees of freedom, e.g., equilibrium states of a infinitely extended system with different temperatures (\rightarrow 402 Statistical Mechanics), superselection sectors explained below (\rightarrow 150 Field Theory) and equilibrium or ground states with broken symmetry.

Because actual measurement can be performed only on a finite number of observables (though chosen at will from an infinite number of possibilities) and only with nonzero experimental errors, information on any state φ can be obtained by measurements only up to a neighborhood in the weak topology: $|\varphi(A_i) - a_i| < \varepsilon_i$, $i = 1, \dots, n$. A set K_1 of states can describe measured information on states at least equally well as another set K_2 (K_1 **physically contains** K_2) if the closure of K_1 in the weak topology contains K_2 . From another viewpoint, all states of K_2 are weak limits of states in K_1 and are physically relevant if states in K_1 are physically relevant. The set of all mixtures of vector states $(\psi, \pi(A)\psi)$ for any fixed faithful representation π of \mathfrak{A} is weakly dense in the set of all states of \mathfrak{A} , a point emphasized by Haag and Kastler as a foundation of the algebraic viewpoint in the formulation of quantum theory.

Under 360° rotation a vector representing a state of a particle with spin $\hbar/2$ acquires a factor -1 (\rightarrow 258 Lorentz Group), while the vacuum vector would be unchanged. A nontrivial linear combination (superposition) of these two would then be changed to a vector in a different ray. If the 360° rotation is not to produce a physically observable effect, then we should either forbid nontrivial superpositions of states of the two classes or, equivalently, restrict observables to those leaving the subspace spanned by vectors in each class invariant so that the relevant linear combinations of vectors, when considered as states on the algebra of observables in the form of expectation functionals $(\psi, A\psi)$, are actually mixtures (rather than superpositions) of states in two classes and are invariant under the 360° rotation. This is called the **univalence superselection rule** and has been pointed out by A. S.

Wightman, G. C. Wick, and E. P. Wigner (*Phys. Rev.*, 88 (1952)).

In quantum field theory, the vacuum state can be taken to be pure (by central decomposition if necessary) and in the associated GNS representation (called the vacuum sector) all vectors can be assumed to be physically relevant pure states. In principle, all physically relevant information is in the vacuum representation; for example, a particle with spin $\hbar/2$ can also be discussed in the vacuum sector if we consider a state of this particle in the presence of its antiparticle at a far distance, such as behind the moon (the **behind-the-moon argument**). However, it is mathematically more convenient to consider the states of the particle without any compensating object (in the same way that an infinitely extended gas is more convenient for some purposes than a finitely extended gas surrounded by walls), which can be obtained as weak limits of states in the vacuum sector by removing the compensating particle to spatial infinity and which produce inequivalent representations called **superselection sectors**.

L. Foundation of Quantum Mechanics

Hilbert spaces and the underlying field of complex numbers, which constitute a mathematical background for quantum mechanics, are not immediately discernible from physical observations, and hence there are various attempts to find axioms for quantum mechanics that imply the usual mathematical structure and at the same time allow direct physical interpretation.

One approach of this kind focuses attention on the set of all observables that have only two possible measured values 1 (yes) and 0 (no), called **questions**, together with their order structure (logical implications) and associated lattice structure (join, meet, and orthocomplementation as logical sum, product, and negation). This is called **quantum logic** in contrast to the situation in classical physics, where it would form a Boolean lattice. The lattice of all orthogonal projections (corresponding to all closed subspaces of a Hilbert space) in quantum mechanics is a \dagger complete, \dagger orthocomplemented, **weakly modular** (also called **orthomodular**) \dagger atomic lattice satisfying the **covering law**, where weak modularity means $c \wedge (c' \vee b) = b$ and $b \vee (b' \wedge c) = c$ whenever $b \leq c$, and the covering law means that every $b \neq 0$ possesses an atom p under it ($p \leq b$) and that if an atom q satisfies $q \wedge b = 0$, then any c between $q \vee b$ and b ($q \vee b \geq c \geq b$) is b or $q \vee b$. Conversely any such lattice is a di-

rect sum of irreducible ones, each of which, if of dimension (length of longest chain) > 3 , can be obtained as the lattice of subspaces V satisfying $(V^\perp)^\perp = V$ in a vector space over a (generally noncommutative) field with an anti-automorphic involution $*$, equipped with a nondegenerate Hermitian form. In this approach, an additional requirement is needed to restrict the underlying field and its $*$ to be more familiar ones, such as real, complex, or quaternion fields and their usual conjugations $*$. If that is done, then the set of all probability measures on the lattice (i.e., assignment of expectation values $0 \leq \mu(a) \leq 1$ for all elements a in the lattice such that $\mu(\bigvee_i a_i) = \sum_i \mu(a_i)$ if $a_i \perp a_j$ for all pairs $i \neq j$, $\mu(a) \geq 0$, $\mu(1) = 1$) is exactly the restriction to questions of states $\rho(A) = \text{tr}(\rho A)$ given by the density matrices ρ (**Gleason's theorem**).

It is also possible to characterize the set of all states equipped with the convex structure (mixtures) geometrically. The set of all states (without the normalization condition) of a finite-dimensional, formally real, irreducible \dagger Jordan algebra over the field of reals (the positivity of a state φ is defined by $\varphi(a^2) \geq 0$) has been characterized as a transitively homogeneous self-dual cone in a finite-dimensional real vector space (a cone V is transitively homogeneous if the group of all nonsingular linear transformations leaving V invariant is transitive on the topological interior of V) by E. B. Vinberg (*Trans. Moscow Math. Soc.*, 12 (1963); 13 (1965)), where the relevant Jordan algebras were completely classified earlier by P. Jordan, J. von Neumann, and E. P. Wigner (*Ann. Math.*, 36 (1934)) as direct sums of the following irreducible ones: the Jordan algebra (with the product $A \circ B = (AB + BA)/2$) of all Hermitian $n \times n$ matrices over the real, complex, or quaternion field, all 3×3 Hermitian matrices over octonions, or the so-called **spin balls** (the set of all normalized states being a ball) linearly generated by the identity and γ_j ($j = 1, \dots, n$) satisfying $\gamma_j \circ \gamma_k = 0$ if $j \neq k$ and $\gamma_j^2 = 1$.

In infinite-dimensional cases, this type of characterization extends to the "natural" positive cones of vectors (A. Connes, *Ann. Inst. Fourier*, 24 (1974); J. Bellissard and B. Iochum, *Ann. Inst. Fourier*, 28 (1978)); while the convex cone of all states (without normalization) of Jordan algebras and C^* -algebras have been characterized in terms of a certain class of projections associated with faces of the cone, called P -projections, by E. M. Alfsen, F. W. Shultz, and others (*Acta Math.*, 140 (1978); 144 (1980)). In finite-dimensional cases, Araki (*Commun. Math. Phys.*, 75 (1980)) has given a characterization allowing direct physical interpretation by replacing P -projection with a

notion of filtering corresponding to quantum-mechanical measurement.

Due to some features of quantum-mechanical measurement not in conformity with common sense, there have arisen **hidden variable theories** that are deterministic and reproduce the quantum-mechanical prediction. For a situation where a pair of (correlated) particles in states a and b are created and their spins (1 or -1 , i.e., up or down spin) measured at positions distant from each other, the expectation value $E(a, b)$ for the product would be given in a hidden variables theory

by $E(a, b) = \int A_a(\lambda) B_b(\lambda) d\rho(\lambda)$ for a probability measure ρ and the functions A_a and B_b of hidden variables λ , representing spins and hence satisfying $|A_a| \leq 1$ and $|B_b| \leq 1$. Then the following **Bell's inequality** holds:

$$|E(a, b) - E(a, b') + E(a', b) + E(a', b')| \leq 2.$$

This contradicts both quantum-mechanical predictions and experimental results, so that hidden variable theories of this type have been rejected.

352 (XI.15) Quasiconformal Mappings

A. History

H. Grötzsch (1928) introduced quasiconformal mappings as a generalization of conformal mappings. Let $f(z)$ be a continuously differentiable homeomorphism with positive Jacobian between plane domains. The image of an infinitesimal circle $|dz| = \text{constant}$ is an infinitesimal ellipse with major axis of length $(|f_z| + |f_{\bar{z}}|)|dz|$ and minor axis of length $(|f_z| - |f_{\bar{z}}|)|dz|$. When the ratio $K(z) = (|f_z| + |f_{\bar{z}}|)/(|f_z| - |f_{\bar{z}}|)$ is bounded, f is called **quasiconformal**. If $K \equiv 1$, then f is conformal.

Grötzsch noticed that Picard's theorem still holds under the weaker condition; he determined the quasiconformal mappings between two given domains, which are not conformally equivalent to each other, providing the smallest sup K , that is, those closest to conformality [1].

We cannot speak of the history of quasiconformal mappings without mentioning the discovery of extremal length by A. Beurling and L. V. Ahlfors (→ 143 *Extremal Length*), which has led to the precise definition for quasiconformality itself.

Quasiconformal mappings have less rigidity than conformal mappings, and for this reason they have been utilized for the type problem or the classification of open Riemann surfaces (Ahlfors, S. Kakutani, O. Teichmüller, K. I. Virtanen, Y. Tôki; → 367 *Riemann Surfaces*). Quasiconformal mappings have important applications in other fields of mathematics, e.g., in the theory of partial differential equations of elliptic type (M. A. Lavrent'ev [2]) and especially in the problem of moduli of Riemann surfaces, including the theory of Teichmüller spaces (→ 416 *Teichmüller Spaces*). These applications are explained in Sections C and D.

B. Definitions

The current definitions of quasiconformality, which dispense with continuous differentiability, are due to Ahlfors [3], A. Mori [4], and

Quasiconformal Mappings

L. Bers [5] (→ C. B. Morrey [6]). Consider an orientation-preserving topological mapping f of a domain D on the $z (= x + iy)$ -plane. The quasiconformality of f is defined as follows. (1) (the geometric definition) Let Q be a curvilinear quadrilateral, i.e., a closed Jordan domain with four specified points on the boundary, and let the interior of Q be mapped conformally onto a rectangular domain I . The ratio (≥ 1) of the sides of I , called the modulus of Q and denoted by $\text{mod } Q$, is uniquely determined. If $\text{mod } f(Q) \leq K \text{ mod } Q$ for any curvilinear quadrilateral Q in D , then f is called a **K -quasiconformal mapping** of D . This is equivalent to: (2) (the analytic definition) f is absolutely continuous on almost every line segment parallel to the coordinate axes contained in D (this condition is often referred to as ACL

in D) and satisfies the inequality $|f_{\bar{z}}| \leq \frac{K-1}{K+1} |f_z|$

almost everywhere in D with some constant $K \geq 1$. When the value of K is irrelevant to the problem considered, K -quasiconformal mappings are simply said to be quasiconformal.

The K -quasiconformal mapping f satisfies the so-called **Beltrami differential equation**

$$f_{\bar{z}} = \mu f_z$$

almost everywhere in D with the measurable coefficient μ . The **maximal dilatation** $(1 + \|\mu\|_{\infty})/(1 - \|\mu\|_{\infty})$ does not exceed K . Sometimes f is called, for short a μ -conformal mapping. These notions are also defined for mappings between Riemann surfaces, where the $(-1, 1)$ -form $\mu d\bar{z} dz^{-1}$ is independent of the choice of the local parameter z .

If in the above statements f is not necessarily topological but merely a continuous function satisfying the same requirements, we call it a **μ -conformal function**. (If in addition $\|\mu\|_{\infty} < (K-1)/(K+1)$, we call it a **K -quasiregular function** or **K -pseudanalytic function**.) A μ -conformal function is represented as the composite $g \circ h$ of an analytic function g with a μ -conformal mapping h .

C. Principal Properties and Results

The inverse mapping of a K -quasiconformal mapping is also K -quasiconformal. The composite mapping $f_2 \circ f_1$ of a K_1 -quasiconformal mapping f_1 with a K_2 -quasiconformal mapping f_2 , if it can be defined, is $K_1 K_2$ -quasiconformal. A 1-quasiconformal mapping is conformal. Every quasiconformal mapping is totally differentiable a.e. (almost everywhere), its Jacobian is positive a.e., and $(|f_z| + |f_{\bar{z}}|)/(|f_z| - |f_{\bar{z}}|) \leq K$ a.e.

Let f be a K -quasiconformal mapping of $|z| < 1$ onto $|w| < 1$. Then f extends to a homeo-

Quasiconformal Mappings

morphism of $|z| \leq 1$ onto $|w| \leq 1$. If, furthermore, $f(0) = 0$, then the Hölder condition

$$\left(\frac{|z_1 - z_2|}{16}\right)^K \leq |f(z_1) - f(z_2)| \leq 16|z_1 - z_2|^{1/K}$$

holds for $|z_1| \leq 1, |z_2| \leq 1$, and 16 is the best coefficient obtainable independently of K (Mori). This shows that any family of K -quasiconformal mappings of $|z| < 1$ onto $|w| < 1$ is \dagger normal. For further properties and bibliography \rightarrow O. Lehto and Virtanen [7] and Ahlfors [8].

(a) Boundary Correspondences and Extensions.

Ahlfors and Bcurling characterized the correspondence between $|z| = 1$ and $|w| = 1$ induced by f [9]. What amounts to the same thing, the following theorem holds: Let $\mu(x)$ be a real-valued monotone increasing continuous function on R such that $\lim_{x \rightarrow \pm\infty} \mu(x) = \pm\infty$. Then there exists a quasiconformal mapping of the upper half-plane $y > 0$ onto itself with boundary correspondence $x \mapsto \mu(x)$ if and only if

$$\frac{1}{\rho} \leq \frac{\mu(x+t) - \mu(x)}{\mu(x) - \mu(x-t)} \leq \rho$$

for some constant $\rho \geq 1$ and for all $x, t \in R$.

Theorem of quasiconformal reflection (Ahlfors [10]). Let L denote a curve which passes through ∞ and divides $C \cup \{\infty\}$ into two domains Ω, Ω^* such that $\Omega \cup L \cup \Omega^* = C \cup \{\infty\}$. Then there exists an orientation-reversing quasiconformal mapping of Ω onto Ω^* which keeps every point of L fixed if and only if some constant C exists satisfying $|\zeta_3 - \zeta_1|/|\zeta_2 - \zeta_1| \leq C$ for any three points $\zeta_1, \zeta_2, \zeta_3$ on L such that $\zeta_3 \in \widehat{\delta_1 \zeta_2}$.

(b) Mapping Problem. Given a measurable function μ in a simply connected domain D with $\|\mu\|_\infty < 1$, there exists a μ -conformal mapping of D onto a plane domain Δ which is unique up to conformal mappings of Δ [8]. When μ is real analytic and the derivatives of functions are defined in the usual manner, a classical result concerning the \dagger conformal mapping of surfaces asserts the existence of a solution of Beltrami's differential equation $f_{\bar{z}} = \mu f_z$.

Concerning the dependence of μ -conformal mapping on μ , Ahlfors and Bers [11] obtained the following important result: Denote by f^μ a μ -conformal mapping of the whole finite plane onto itself that preserves 0 and 1. The space of functions μ has the structure of a Banach space with L_∞ -norm, and the space of mappings f^μ also has the structure of a Banach space with respect to a suitable norm. If $\{\mu(t) = \mu(z; t)\}$ is a family of μ depending on the parameter t with $\|\mu(t)\|_\infty \leq k < 1$ and $\mu(t)$ is

continuous (resp. continuously differentiable, real analytic, complex analytic) in t , then $f^{\mu(t)}$ is also continuous (continuously differentiable, real analytic, complex analytic). For the proofs of these important results, which have opened up a new way to study \dagger Teichmüller space, the extension and reflection of quasiconformal mappings are made essential use of.

(c) Extremal Quasiconformal Mappings. Let $K(f)$ denote the maximal dilatation of a quasiconformal mapping f . Suppose that a family $\mathcal{F} = \{f\}$ of quasiconformal mappings is given. If some $f_0 \in \mathcal{F}$ exists such that $K(f_0)$ attains the infimum of $K(f)$ for all $f \in \mathcal{F}$, then f_0 is called an **extremal quasiconformal mapping** in \mathcal{F} .

Let $R = \{(x, y) | 0 < x < a, 0 < y < b\}$, $R' = \{(x', y') | 0 < x' < a', 0 < y' < b'\}$ be a pair of rectangular domains. Let \mathcal{F} be the family of all quasiconformal mappings of R onto R' which map each vertex to a vertex with $(0, 0) \mapsto (0, 0)$. Then the unique extremal quasiconformal mapping for \mathcal{F} is the affine mapping $x' = (a'/a)x, y' = (b'/b)y$ (Grötzsch [1]).

Next suppose that we are given two homeomorphic closed Riemann surfaces R, S and a \dagger homotopy class \mathcal{F} of orientation-preserving homeomorphisms of R onto S . Then \mathcal{F} contains a unique extremal quasiconformal mapping. More precisely, either R and S are conformally equivalent to each other or else R admits an essentially unique analytic $(2, 0)$ -form Φ such that the respective local coordinates z, w of R, S satisfy the differential equation

$$(\partial w / \partial \bar{z}) / (\partial w / \partial z) = [(K - 1) / (K + 1)] \bar{\Phi} / \Phi \tag{1}$$

with some constant $K > 1$ everywhere on R , at which $\Phi \neq 0$ (Teichmüller [12], Ahlfors [3]). This turns out to be a generalization of Grötzsch's extremal affine mapping. The extremal mapping f satisfying equation (1) is sometimes referred to as the **Teichmüller mapping**.

Consider again a μ -conformal mapping g of the unit disk $D: |z| < 1$ onto itself which induces a topological automorphism of the boundary $|z| = 1$. If we define \mathcal{F} as the family of all quasiconformal automorphisms f of D satisfying $f(e^{i\theta}) = g(e^{i\theta})$, then the extremal quasiconformal mapping in \mathcal{F} exists but is not always determined uniquely (K. Strebel [13]). As to the Teichmüller mapping, the uniqueness theorem is as follows: If the norm $\|\Phi\| = \iint_D |\Phi(z)| dx dy$ of Φ in (1) is finite, the Teichmüller mapping is the unique extremal quasiconformal mapping in \mathcal{F} . Otherwise, the uniqueness does not hold in general (Strebel [13]). On the other hand, a necessary and sufficient condition is proved for the Beltrami

coefficient μ of a quasiconformal mapping of \mathcal{F} to be extremal (R. S. Hamilton [14], E. Reich and Strebel in [15]). Moreover, this last result can be extended to the extremal quasiconformal mapping between arbitrary Riemann surfaces.

D. Applications

In the earlier stage of development of this theory, quasiconformal mappings were applied only to the †type problem of simply connected Riemann surfaces and to the classification of Riemann surfaces of infinite genus (\rightarrow 367 Riemann Surfaces). This application is based on the fact that it is often possible to find a quasiconformal mapping with the prescribed boundary correspondence even when no equivalent conformal mapping exists and the fact that the classes O_G and O_{HD} (\rightarrow 367 Riemann Surfaces) of Riemann surfaces are invariant under quasiconformal mappings, as they are under conformal mappings.

It is worth remarking that the investigation of quasiconformal mappings is intimately connected with the recent development of the theory of †Kleinian groups via Teichmüller spaces.

The theory of quasiconformal mappings was also applied by Lavrent'ev [16] and Bers [2] to partial differential equations, particularly to those concerning the behavior of fluids. They utilized the fact that if the density and its reciprocal are bounded in a steady flow of a 2-dimensional †compressible fluid, then the mapping of the physical plane to the potential plane (the plane on which the values of the †velocity potential and the †stream function are taken as coordinates) is quasiconformal, and that if in addition the supremum of the †Mach number is smaller than 1, then the mapping from the physical plane to the †hodograph plane is pseudoanalytic.

E. Similar Notions

The term *quasiconformal* was used differently by Lavrent'ev, as follows: A topological mapping $f = u + iv$ is called **quasiconformal** with respect to a certain system of linear partial differential equations when u and v satisfy the system. This is a generalized definition because the system may not be equivalent to a Beltrami equation. However, it is reduced to a quasiconformal mapping if the system is uniformly elliptic. Bers used the term **pseudoanalytic** to describe a certain function related to linear partial differential equations of elliptic type. This function is pseudoanalytic in the sense of Section B on every relatively

352 Ref.

Quasiconformal Mappings

compact subset and has properties similar to those of analytic functions.

Analytic transformations in the theory of functions of several variables are called pseudoconformal by some mathematicians, and there is a similar term *quasi-analytic*. The latter is an entirely different notion from the one discussed in this article.

F. Generalization to Higher Dimensions

Let f be a continuous ACL-mapping of a subdomain G of \mathbf{R}^n into \mathbf{R}^n whose Jacobian matrix is denoted by $f'(x)$. Furthermore, the operator norm and the determinant of f' are denoted by $\|f'\|$ and $\det f'$, respectively. Then f is said to be quasiregular if all the partial derivatives of f are locally of class L^n on G and if there exists a constant $K \geq 1$ such that $(\|f'\|(x))^n \leq K \cdot \det f'(x)$ almost everywhere in G . The smallest $K \geq 1$ for which this inequality is true is called the outer dilatation of f and is denoted by $K_o(f)$. If f is quasiregular, then the smallest $K \geq 1$ for which the inequality $\det f'(x) \leq K \cdot [\min_{|y|=1} |f'(x+y)|]^n$ holds almost everywhere in G is called the inner dilatation of f and is denoted by $K_I(f)$. If $\max(K_I(f), K_o(f)) \leq K'$, then f is said to be K' -quasiregular. An orientation-preserving mapping is called K -quasiconformal (J. Väisälä [17]) if it is a K -quasiregular homeomorphism. When $n=2$, these definitions agree with those given in Section B.

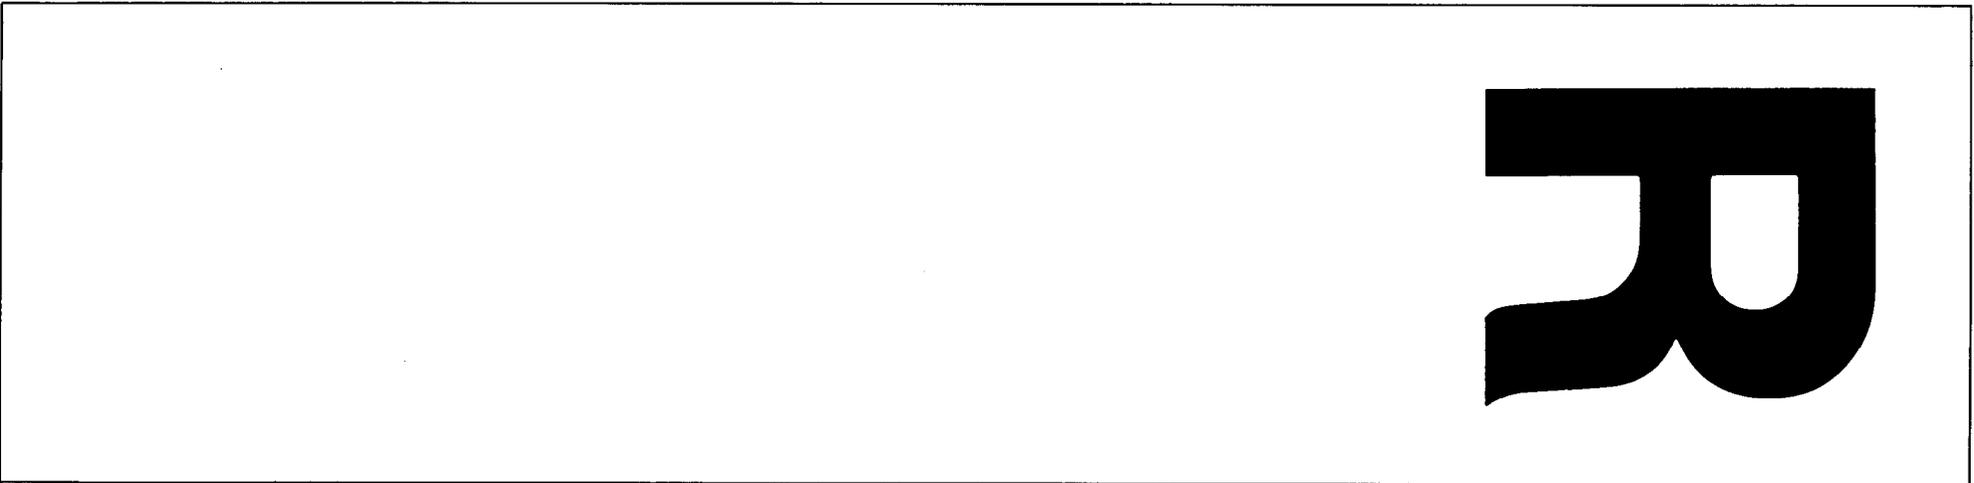

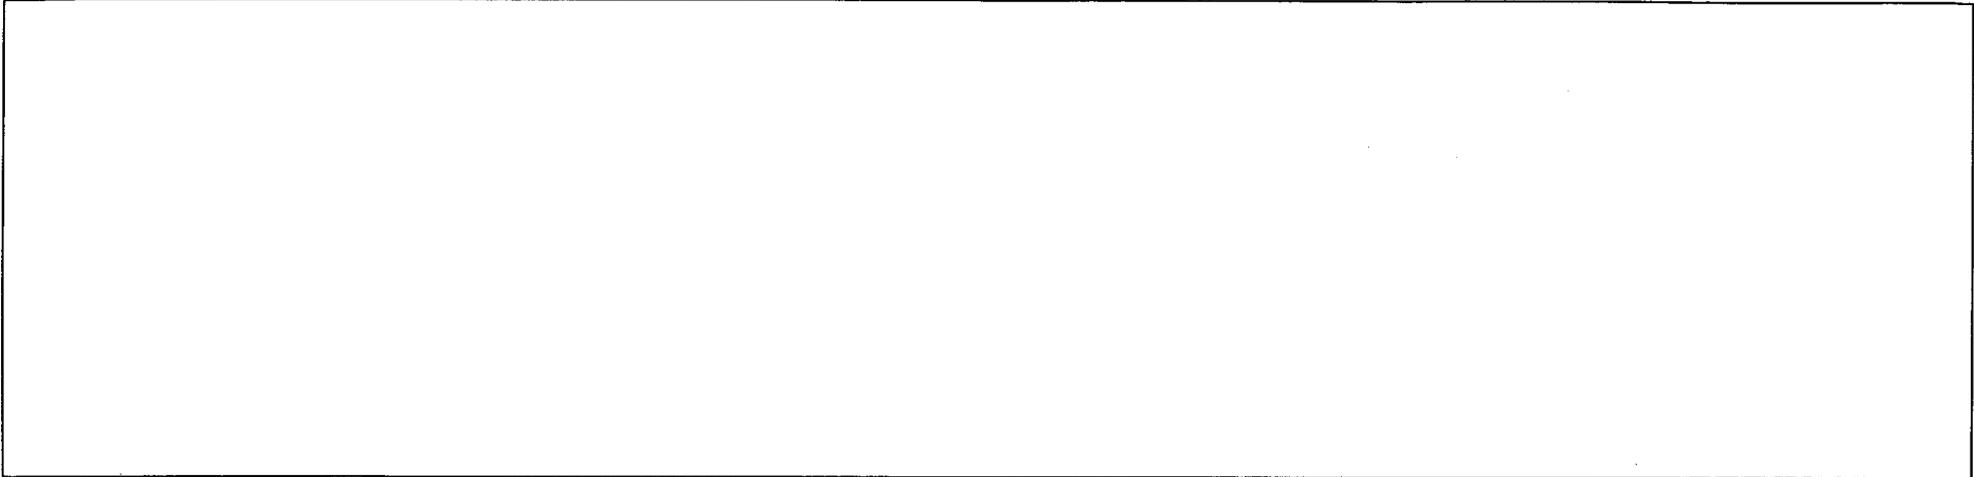

For $n \geq 3$ the following properties also still hold: A quasiregular mapping is discrete, open, totally differentiable a.e. and is absolutely continuous (O. Martio, S. Rickman, and Väisälä [18]). Quasiconformal extension of higher-dimensional half-spaces have been studied by Ahlfors and L. Carleson [15].

353 (XX.25) Racah Algebra

A. General Remarks

Racah algebra is a systematic method of calculating the †matrix element $\langle \psi, A\psi \rangle$ in †quantum mechanics, where A is a dynamical quantity and ψ and ψ' are irreducible components of the state obtained by combining n †angular momenta. The angular momentum \mathbf{j} has x -, y -, z -components j_x, j_y, j_z , respectively. Each component is i times the infinitesimal rotation around the respective axis and is the generator of the infinitesimal rotation for every irreducible component ψ . The addition of two angular momenta leads to a †tensor representation $D(j_1) \otimes D(j_2)$ of two †irreducible representations of the 3-dimensional rotation group. The problem is to decompose this tensor representation into the direct sum of irreducible representations.

B. Irreducible Representations of the Three-Dimensional Rotation Group

Irreducible representations of the group $SO(3)$ of 3-dimensional rotations can be obtained from irreducible representations $D(j)$ ($j = 0, 1, 2, \dots$) of its †universal covering group $SU(2)$ of 2×2 matrices with determinant 1, through the 2-fold covering isomorphism $SO(3) \cong SU(2)/\{\pm I\}$ (\rightarrow 60 Classical Groups I). The representation $D(j)$ ($j = 0, 1/2, 1, 3/2, \dots$) of $SU(2)$ is the $2j$ -fold tensor product $A \otimes \dots \otimes A$ of $A \in SU(2)$ restricted to the totally symmetric part of the $2j$ -fold tensor product space. Let $u = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$ and $v = \begin{pmatrix} 0 \\ 1 \end{pmatrix}$ be a basis for the complex 2-dimensional space on which $SU(2)$ operates. The symmetrized tensor product of $(j+m)$ -fold u and $(j-m)$ -fold v multiplied by a positive normalization constant ($m = j, j-1, \dots, -j$) defines an orthonormal basis of the representation space of $D(j)$, which we shall denote by $\psi(jm)$.

Decomposition of the tensor product of two irreducible representations $D(j_1)$ and $D(j_2)$ into irreducible components leads to

$$D(j_1) \otimes D(j_2) = \sum D(j),$$

$$j = j_1 + j_2, \quad j_1 + j_2 - 1, \dots, |j_1 - j_2|.$$

For the basis we can write

$$\psi(jm) = \sum_{m_1, m_2} \psi(j_1 m_1) \psi(j_2 m_2) \langle j_1 m_1 j_2 m_2 | j_1 j_2 jm \rangle,$$

and the coefficients are called the **Clebsch-Gordan coefficients** or **Wigner coefficients**. The vectors $\psi(jm)$ in each irreducible represen-

tation space are determined only up to an overall phase factor (a complex number of modulus 1). By a suitable choice of the resulting arbitrary phase (which may depend on j_1, j_2, j), the coefficients are given by

$$j_1 + j_2 \geq j \geq |j_1 - j_2|,$$

$$\langle j_1 m_1 j_2 m_2 | j_1 j_2 jm \rangle = \delta(m_1 + m_2, m)$$

$$\times \sqrt{\frac{(2j+1)(j_1+j_2-j)!(j+j_1-j_2)!(j+j_2-j_1)!}{(j_1+j_2+j+1)!}}$$

$$\times \sum_v \left((-1)^v \frac{\sqrt{(j_1+m_1)!(j_1-m_1)!(j_2+m_2)!}}{v!(j_1+j_2-j-v)!(j_1-m_1-v)!} \right)$$

$$\times \frac{\sqrt{(j_2-m_2)!(j+m)!(j-m)!}}{(j_2+m_2-v)!(j-j_2+m_1+v)!(j-j_1-m_2+v)!}.$$

They satisfy †orthogonality relations. Another concrete expression for the same coefficients, but of a different appearance, was obtained earlier by Wigner. Wigner introduced the **3j-symbol**, given by

$$\begin{pmatrix} j_1 j_2 j_3 \\ m_1 m_2 m_3 \end{pmatrix} = (-1)^{j_1 - j_2 - m_3} (2j_3 + 1)^{-1/2}$$

$$\times \langle j_1 m_1 j_2 m_2 | j_1 j_2 j_3 -m_3 \rangle$$

for $m_1 + m_2 + m_3 = 0$ and zero otherwise. This is invariant under cyclic permutations of 1, 2, 3 and is multiplied by $(-1)^{j_1+j_2+j_3}$ under transpositions of indices as well as under the simultaneous sign change of all the m 's. The 3j-symbol multiplied by $(-1)^{j_2+j_3-j_1}$ is the V -coefficient of Racah.

There are two ways, $(D(j_1) \otimes D(j_2)) \otimes D(j_3)$ and $D(j_1) \otimes (D(j_2) \otimes D(j_3))$, to reduce the tensor product of three irreducible representations, and two corresponding sets of basis vectors. The transformation coefficient for the two ways of reduction is written in the form

$$\langle j_1 j_2 (j_{12}) j_3; j | j_1 j_2 j_3 (j_{23}); j \rangle$$

$$= \sqrt{(2j_{12} + 1)(2j_{23} + 1)} W(j_1 j_2 j_3; j_{12} j_{23}).$$

Here $W(abcd; ef)$, called the **Racah coefficient**, can be written as the sum of products of four Wigner coefficients. W has the following symmetry properties:

$$W(abcd; ef) = W(badc; ef)$$

$$= W(cdab; ef)$$

$$= W(acbd; fe)$$

$$= (-1)^{e+f-a-d} W(efbc; ad)$$

$$= (-1)^{e+f-b-c} W(aefd; bc)$$

and satisfies an orthogonality relation. The **6j-symbol** $\begin{Bmatrix} abc \\ cdf \end{Bmatrix}$ is related to the Racah coefficient by

$$W(abdc; ef) = (-1)^{a+b+c+d} \begin{Bmatrix} abc \\ cdf \end{Bmatrix}.$$

C. Irreducible Tensors

A dynamical quantity T_q^k ($q = k, k - 1, \dots, -k$) that transforms in the same way as the basis of $D(k)$ under rotation of coordinates is called an **irreducible tensor of rank k** . That is, it satisfies

$$[j_x \pm ij_y, T_q^k] = \sqrt{(k \mp q)(k \pm q + 1)} T_{q \pm 1}^k,$$

$$[j_z, T_q^k] = q T_q^k.$$

Here $[a, b] = ab - ba$. The matrix element of this quantity between two irreducible components can be written in the form

$$\begin{aligned} &(\alpha jm | T_q^k | \alpha' j' m') \\ &= (1/\sqrt{2j+1})(\alpha j || T^{(k)} || \alpha' j') (j' m' k q | j' k j m), \end{aligned}$$

where α is a parameter to distinguish multiple components with the same j , and components of different α are assumed to be orthogonal. In this formula the Clebsch-Gordan coefficients are determined from group theory, while $(\alpha j || T^{(k)} || \alpha' j')$ depends on the dynamics of the system.

When $T^{(k)}$ and $U^{(k)}$ operate only on the state vectors in the subspaces H_1 and H_2 , respectively, of the total space (\dagger Hilbert space) $H = H_1 \times H_2$, their scalar product $(T^{(k)}, U^{(k)}) = \sum_q (-1)^q T_q^k U_q^k$ has the matrix element

$$\begin{aligned} &(\alpha_1 \alpha_2 j_1 j_2 jm | (T^{(k)}, U^{(k)}) | \alpha'_1 \alpha'_2 j'_1 j'_2 jm) \\ &= (-1)^{j_1 + j_2 - j} W(j_1 j_2 j'_1 j'_2; jk) \\ &\quad \times (\alpha_1 j_1 || T^{(k)} || \alpha'_1 j'_1) (\alpha_2 j_2 || U^{(k)} || \alpha'_2 j'_2). \end{aligned}$$

For an irreducible component of the tensor product of two irreducible tensors,

$$\begin{aligned} &[T^{(k_1)} \otimes U^{(k_2)}]_q^k \\ &= \sum_{q_1 + q_2 = q} T_{q_1}^{k_1} U_{q_2}^{k_2} (k_1 q_1 k_2 q_2 | k_1 k_2 k q), \end{aligned}$$

the matrix can be written as

$$\begin{aligned} &(\alpha j_1 j_2 j || [T^{(k_1)} \otimes U^{(k_2)}]^{(k)} || \alpha' j'_1 j'_2 j') \\ &= \sqrt{(2k+1)(2j+1)(2j'+1)} \\ &\quad \times \sum_{q''} (\alpha j_1 || T^{(k_1)} || \alpha'' j'_1) (\alpha'' j_2 || U^{(k_2)} || \alpha' j'_2) \\ &\quad \times \left\{ \begin{matrix} j_1 & j_2 & j \\ j'_1 & j'_2 & j' \\ k_1 & k_2 & k \end{matrix} \right\}. \end{aligned}$$

The last factor, the **$9j$ -symbol**, is defined as the matrix element between basis vectors of $[D(j_1) \times D(j_2)] \times [D(j_3) \times D(j_4)]$ and $[D(j_1) \times D(j_3)] \times [D(j_2) \times D(j_4)]$:

$$\begin{aligned} &\langle j_1 j_2 (j_1 j_2) j_3 j_4 (j_3 j_4) jm | j_1 j_3 (j_1 j_3) j_2 j_4 (j_2 j_4) jm \rangle \\ &= \sqrt{(2j_{12}+1)(2j_{34}+1)(2j_{13}+1)(2j_{24}+1)} \\ &\quad \times \left\{ \begin{matrix} j_1 & j_2 & j_{12} \\ j_3 & j_4 & j_{34} \\ j_{13} & j_{24} & j \end{matrix} \right\}. \end{aligned}$$

354 B
Random Numbers

The $9j$ -symbol can be written as a weighted sum of the products of the three W 's.

See [6] and [7] for explicit formulas of Clebsch-Gordan coefficients and [8] for Racah coefficients.

354 (XVI.5)
Random Numbers

A. General Remarks

A sequence of numbers that can be regarded as realizations of independent and identically distributed random variables is called a sequence or table of **random numbers**. It is a basic tool for the \dagger Monte Carlo method, \dagger simulation of stochastic phenomena in nature or in society, and \dagger sampling or \dagger randomization techniques in statistics. Random numbers used in practice are pseudorandom numbers (\rightarrow Section B); theoretically, the definition of random numbers leads to an algorithmic approach to the foundations of probability [1, 2].

B. Pseudorandom Numbers

Tables of numbers generated by random mechanisms have been statistically tested and

published. To generate random numbers on a large scale, electronic devices based on stochastic physical phenomena, such as thermoelectron noise or radioactivity, can be used. For digital computers, however, numbers generated by certain simple algorithms can be viewed practically as a sequence of random numbers; this is called a sequence of **pseudorandom numbers**.

Distribution of random numbers that are easily generated and suitable for general use is the continuous uniform distribution on the interval (0, 1), which is approximated by the discrete distribution on $\{0, 1, \dots, N-1\}$ ($N \gg 1$). Random numbers with distribution function $F(\cdot)$ are obtained by transforming uniform distributions by $F^{-1}(\cdot)$. For typical distributions, computation tricks avoiding the direct computation of $F^{-1}(\cdot)$ have been devised. Among them the use of \dagger order statistics and acceptance-rejection techniques have wide applicability.

For the generation of uniform pseudorandom numbers on $\{0, 1, \dots, N-1\}$, $N = n^s$ ($n = a$ a computer word length), the following algorithms are used. Each of them is written in terms of simple computer instructions. (1) The **middle-square method** was proposed by von Neumann. We square an integer of s digits of radix (or base) n and take out the middle s digits as the next term. We repeat this process and obtain a sequence of pseudorandom numbers. The sequence thus generated might be cyclic with a short period, possibly after many repetitions. The lengths from initial values to the terminal cycles are empirically checked. (2) The \dagger Fibonacci sequence $\{u_n\}$ defined by $u_{k+1} \equiv u_{k-1} + u_k \pmod{n^s}$ is apparently regular, but it is uniformly distributed. (3) The **congruence method** [3]: Define a sequence by $u_{k+1} \equiv au_k + c \pmod{n^s}$ or $\pmod{n^s \pm 1}$. If $c = 0$, the procedure is called the multiplicative congruence method, otherwise the mixed congruence method. The cycle, that is, the minimum k such that $u_k = u_0$, and the constants a , c , and u_0 that make the cycle maximum for given n and s are determined by number theory. The points $(u_{kl}, u_{kl+1}, \dots, u_{kl+l-1})$, $k = 0, 1, 2, \dots$, lie on a small number of parallel hyperplanes in the l -dimensional cube. Good choice of the constant a makes the sequence quite satisfactory. (4) H. Weyl considered sequences $f(k) = k\alpha \pmod{1}$, where α is an irrational number and $k = 1, 2, \dots$, whose values are uniformly distributed on the interval (0, 1). They are not independent, though they can be used for some special purposes. A modified sequence $x_k = k^2\alpha \pmod{1}$ is known to be random for any irrational α in the sense that the \dagger serial correlation $N^{-1} \sum_{k=1}^N x_k x_{k+l} - 1/4$ converges to 0 uniformly in l as $N \rightarrow \infty$.

C. Statistical Tests

To check uniform random numbers on (0, 1) the following tests are used: (1) Divide (0, 1) into subintervals; then the frequency of random numbers falling into these is a multinomial sample. \dagger Goodness of fit can be tested by the \dagger chi-square test; independence can be tested by observing the frequency of transitions of subintervals in which a pair of consecutive numbers falls, as well as by observing the overall properties, such as uniformity of the frequency of patterns of subintervals in which a set of random numbers falls. (2) For a set of random numbers, the distance of the empirical distribution function from that of the theoretical one is tested by the \dagger Kolmogorov-Smirnov test. (3) Observe the rank orders of a set of random numbers, and test the randomness of their permutations (test the number of runs up and down).

D. Kolmogorov-Chaitin Complexity and Finite Random Sequences

As Shannon's entropy is a quantity for measuring the randomness of random variables, the Kolmogorov-Chaitin complexity [4, 5] is that of individual objects based on logic instead of probability. For constructive objects $x \in X$, $y \in Y$ and a partial recursive function $A: Y \times \{1, 2, \dots\} \rightarrow X$, define

$$K_A(x|y) = \begin{cases} \min(\log_2 n | A(y, n) = x), \\ \infty \quad (\text{if } A(y, n) = x \text{ for no } n). \end{cases}$$

The function A is said to be **asymptotically optimal** if for any B there exists a constant C such that $K_A(x|y) \leq K_B(x|y) + C$ for any $x \in X$ and $y \in Y$. For an asymptotically optimal A , which is known to exist, $K_A(x|y)$ is simply denoted by $K(x|y)$ and is called the **Kolmogorov-Chaitin complexity** of x given y .

P. Martin-Löf [6] discussed a relation between complexity and randomness. Consider any statistical test for the randomness on the set of (say) finite decimal sequences which is effective in the sense that it has a finite algorithm. Then there exists a constant C independent of L and M such that

$$K(\xi_1, \dots, \xi_L | L) \geq L \log_2 10 - M$$

implies the acceptance of the decimal sequence ξ_1, \dots, ξ_L by the test at the level $1 - 2^{-M-C}$. This condition on the complexity is satisfied by at least $(1 - 2^{-M})10^L$ sequences among the decimal sequences of length L .

E. Collective and Infinite Random Sequences

For finite sequences, the notion of randomness is obscure by nature. For infinite sequences,

however, clearer definition is possible. Based on the notion of collectives by R. von Mises, a definition of infinite random sequences has been given by A. Church [7]. A **selection function** is a $\{0, 1\}$ -valued function on the set of (say) finite decimal sequences such that $\{n, \varphi(\xi_1, \xi_2, \dots, \xi_{n-1}) = 1\}$ is an infinite set for any infinite sequence ξ_1, ξ_2, \dots . For a selection function φ and an infinite sequence ξ_1, ξ_2, \dots , the φ -**subsequence** is defined as $\xi_{n_1}, \xi_{n_2}, \dots$, where $\{n_1 < n_2 < \dots\} = \{n, \varphi(\xi_1, \dots, \xi_{n-1}) = 1\}$. For a class ψ of selection functions, an infinite decimal sequence is called a ψ -**collective** if each of the numbers 0, 1, ..., 9 appears in it with a limiting relative frequency of $1/10$, and the same thing holds for any φ -subsequence with $\varphi \in \psi$. By definition, a **random sequence** is a ψ -collective for the class ψ of recursive selection functions. Almost all real numbers are random in their decimal expansions.

F. Normal Numbers

Let $x - [x] = \sum x_n r^{-n}$ be the r -adic expansion of the fractional part of a real number x . For any ordered set $B_k = (b_1, \dots, b_k)$ of numbers 0, 1, ..., $r-1$, let $N_n(x, B_k)$ be the number of occurrences of the block B_k in the sequence x_1, \dots, x_n . If $N_n(x, B_k)/n \rightarrow r^{-k}$ as $n \rightarrow \infty$ for every k and every B_k , then x is said to be **normal** to base r . Almost all real numbers are normal to any r . D. G. Champernowne [8] constructed a normal number given by the decimal expansion 0.1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, No one has so far been able to prove or disprove the normality of such irrational numbers as π , e , $\sqrt{2}$, $\sqrt{3}$, W. Schmidt [9] proved that the normality to base r implies the normality to base p if and only if $\log r / \log p$ is rational. A real number whose decimal expansion is random in the above sense is normal to base 10. For the converse, a necessary and sufficient condition for a selection function φ (for which $\varphi(\xi_1, \dots, \xi_L)$ depends only on L) to have the property that the normality implies the $\{\varphi\}$ -collectiveness has been obtained in [10].

355 (II.10) Real Numbers

A. Axioms for the Real Numbers

The set \mathbf{R} of all **real numbers** has the following properties:

(1) **Arithmetical properties:** (i) For each pair of numbers $x, y \in \mathbf{R}$, there exists one and only one number $w \in \mathbf{R}$, called their **sum** and denoted by $x + y$, for which $x + y = y + x$ (commutative law) and $(x + y) + z = x + (y + z)$ (associative law) hold. Furthermore, there exists a unique number 0 (**zero**) such that $x + 0 = x$ for every $x \in \mathbf{R}$ (existence of \dagger zero element). Also, for each x , there exists one and only one number $-x \in \mathbf{R}$ for which $x + (-x) = 0$. (ii) For each pair of numbers $x, y \in \mathbf{R}$, there exists one and only one number $w \in \mathbf{R}$, called their **product** and denoted by xy , for which $xy = yx$ (commutative law), $(xy)z = x(yz)$ (associative law), and $(x + y)z = xz + yz$ (distributive law) hold. Furthermore, there exists a unique number 1 (**unity**) $\in \mathbf{R}$ such that $1x = x$ for every $x \in \mathbf{R}$ (existence of \dagger unity element). Also, for each $x \neq 0$ ($x \in \mathbf{R}$) there exists one and only one number $x^{-1} \in \mathbf{R}$ for which $xx^{-1} = 1$. Owing to properties (i) and (ii), all \dagger four arithmetic operations obey the usual laws (with the single exception of division by zero); in other words, \mathbf{R} is a \dagger field.

(2) **Order properties:** (i) For each $x, y \in \mathbf{R}$, one and only one of the following three relations holds: $x < y$, $x = y$, or $x > y$. With $x \leq y$ meaning $x < y$ or $x = y$, the relation \leq obeys the transitive law: $x \leq y$ and $y \leq z$ imply $x \leq z$, which makes \mathbf{R} \dagger totally ordered. (ii) **Order and**

arithmetical properties are related by: $x \leq y$ implies $x + z \leq y + z$ for any $z \in \mathbf{R}$, and $x \leq y$ and $0 \leq z$ imply $xz \leq yz$; in other words, \mathbf{R} is an \dagger ordered field.

In particular, $x \in \mathbf{R}$ with $x > 0$ is called a **positive number**, and $x \in \mathbf{R}$ with $x < 0$ a **negative number**. We write $|x| = x$ if $x \geq 0$ and $|x| = -x$ if $x < 0$, and call $|x|$ the **absolute value** of x .

(3) Continuity property: If nonempty subsets A and B of \mathbf{R} , with $a < b$ for each pair $a \in A$ and $b \in B$, satisfy $\mathbf{R} = A \cup B$ and $A \cap B = \emptyset$ (empty set), then the pair (A, B) of sets is called a **cut** of \mathbf{R} . For each cut (A, B) of \mathbf{R} , there exists a number $x \in \mathbf{R}$ (necessarily unique) such that for every $a \in A$, $a \leq x$, and for every $b \in B$, $b \geq x$ (i.e., $x = \sup A = \inf B$). This property of \mathbf{R} is called **Dedekind's axiom of continuity** (\rightarrow 294 Numbers).

The set \mathbf{R} of all real numbers is determined uniquely up to an isomorphism, with respect to arithmetic operations and ordering, by properties (1)–(3). \mathbf{R} forms an additive Abelian group; its subgroup $\{0, \pm 1, \pm 2, \dots, \pm n, \dots\}$ generated by 1 can be identified with the group \mathbf{Z} of integers. The subset of all positive integers $\{1, 2, \dots, n, \dots\}$ may be identified with the set \mathbf{N} of all natural numbers. The subset $\{m/n \mid m, n \in \mathbf{Z}, n \neq 0\}$ of \mathbf{R} forms the subfield of \mathbf{R} generated by 1. It can be identified with the field \mathbf{Q} of all rational numbers. A real number that is not rational is called an **irrational number**.

B. Properties of Real Numbers

(1) For each pair of positive numbers a and $b > a$, there exists a natural number n with $a < nb$ (**Archimedes' axiom**).

(2) For each pair of positive real numbers a and b with $a < b$, there exists a rational number x such that $a < x < b$ (**denseness of rational numbers**).

(3) For any subset A in \mathbf{R} \dagger bounded from above (below), the \dagger least upper bound of A : $a = \sup A$ (\dagger greatest lower bound of A : $b = \inf A$) exists.

Let $\{a_n\}$ be a \dagger sequence of real numbers. Assume that for each arbitrary positive number ε there exists a number n_0 such that $|a_n - b| < \varepsilon$ for all $n > n_0$. Then we write $\lim_{n \rightarrow \infty} a_n = b$ (or $a_n \rightarrow b$) and call b the **limit** of $\{a_n\}$. We also say that $\{a_n\}$ is a **convergent sequence** or that a_n **converges** to b .

(4) If for two sequences $\{a_n\}, \{b_n\}$, we have $a_1 \leq a_2 \leq \dots \leq a_n \leq \dots \leq b_n \leq \dots \leq b_2 \leq b_1$ and $\lim(b_n - a_n) = 0$, then there exists one and only one number $c \in \mathbf{R}$ with $\lim a_n = \lim b_n = c$ (**principle of nested intervals**).

(5) Let $\{a_n\}$ be a sequence of real numbers. If for any arbitrary positive ε there exists a natural number n_0 satisfying $|a_m - a_n| < \varepsilon$ for all $m, n > n_0$, then $\{a_n\}$ is called a **fundamental sequence** or **Cauchy sequence**. Any fundamental sequence of real numbers is convergent (**completeness of real numbers**).

For a set with properties 1 and 2 of Section A, it can be proved that property 3 of Section A is equivalent to property 3, or properties 1 and 4, or properties 1 and 5 of this section.

C. Intervals

For two numbers $a, b \in \mathbf{R}$ with $a < b$, we write

$$(a, b) = \{x \mid a < x < b\},$$

$$(a, b] = \{x \mid a < x \leq b\},$$

$$[a, b) = \{x \mid a \leq x < b\},$$

$$[a, b] = \{x \mid a \leq x \leq b\},$$

and call them (**finite**) **intervals**, of which a and b are their **left** and **right endpoints**, respectively. Specifically, (a, b) is called an **open interval** and $[a, b]$ a **closed interval**. The symbols ∞ and $-\infty$ are introduced as satisfying $\infty > x, x > -\infty, \infty > -\infty$ for all $x \in \mathbf{R}$. Writing $+\infty$ for ∞ , we call $+\infty$ and $-\infty$ **positive infinity** and **negative infinity**, respectively. To extend the concept of intervals, we define $(-\infty, b) = \{x \mid x < b, x \in \mathbf{R}\}$, $(-\infty, b] = \{x \mid x \leq b, x \in \mathbf{R}\}$, $(a, \infty) = \{x \mid a < x, x \in \mathbf{R}\}$, $[a, \infty) = \{x \mid a \leq x, x \in \mathbf{R}\}$, and $(-\infty, \infty) = \mathbf{R}$, and call them **infinite intervals**.

Let $\{a_n\}$ be a sequence of real numbers. If for each infinite interval (a, ∞) ($(-\infty, a)$) there exists a number n_0 such that $a_n \in (a, \infty)$ ($a_n \in (-\infty, a)$) for all $n > n_0$, then we write $a_n \rightarrow +\infty$ ($a_n \rightarrow -\infty$) and call ∞ ($-\infty$) the limit of a_n , denoted as before by $\lim a_n$.

D. Topology of \mathbf{R}

With the collection of all its open intervals (a, b) as an \dagger open base, \mathbf{R} is a \dagger topological space (\dagger order topology) that satisfies the \dagger separation axioms $\mathbf{T}_2, \mathbf{T}_3, \mathbf{T}_4$. In \mathbf{R} every (finite or infinite) interval (including \mathbf{R} itself) is \dagger connected, and the set \mathbf{Q} of rational numbers is dense. A necessary and sufficient condition for a subset F of \mathbf{R} to be \dagger compact is that F be bounded and closed (**Weierstrass's theorem**). In particular, any finite closed interval is compact. \mathbf{R} is a locally compact space satisfying the second \dagger countability axiom. Further, any (finite or infinite) open interval is homeomorphic to \mathbf{R} . The topology of \mathbf{R} may also be

defined by the notion of convergence (\rightarrow 87 Convergence).

Arithmetic operations in \mathbf{R} are all continuous: If $a_n \rightarrow a$ and $b_n \rightarrow b$, then $a_n + b_n \rightarrow a + b$, $a_n - b_n \rightarrow a - b$, $a_n b_n \rightarrow ab$, and $a_n/b_n \rightarrow a/b$ (where $b \neq 0, b_n \neq 0$). Hence \mathbf{R} is a †topological field (regarding the characterization of \mathbf{R} as a topological group or a topological field \rightarrow 422 Topological Abelian Groups).

\mathbf{R} as a topological Abelian group (with respect to addition) is isomorphic to the topological Abelian group \mathbf{R}^+ of all positive real numbers with respect to multiplication. To be precise, there exist topological mappings $f: \mathbf{R} \rightarrow \mathbf{R}^+$ with $f(x+y) = f(x)f(y)$ and $g: \mathbf{R}^+ \rightarrow \mathbf{R}$ with $g(xy) = g(x) + g(y)$. If $f(1) = a, g(b) = 1$, then f, g are uniquely determined and are written $f(x) = a^x, g(x) = \log_b x$.

Regarding \mathbf{R} as a topological Abelian group (with respect to addition), any proper closed subgroup Γ of \mathbf{R} is discrete and isomorphic to the additive group \mathbf{Z} of integers. That is, for some $\varepsilon > 0$ we have $\Gamma = \{n\varepsilon \mid n \in \mathbf{Z}\}$. In particular, the quotient group \mathbf{R}/\mathbf{Z} as a topological group is isomorphic to the rotation group of a circle (1-dimensional †torus group). Elements of \mathbf{R}/\mathbf{Z} are called **real numbers mod 1**.

E. The Real Line

Let l be a Euclidean straight line considered to lie horizontally, say from left to right. Let p_0, p_1 be two distinct points on l , with p_0 situated to the left of p_1 . Then there exists one and only one bijection φ from the set L of all points of l to \mathbf{R} satisfying (i) $\varphi(p_0) = 0, \varphi(p_1) = 1$; (ii) if p lies to the left of q , then $\varphi(p) < \varphi(q)$; and (iii) for two line segments pq and $p'q'$ (where p and p' are to the left of q and q' , respectively), $pq \equiv p'q'$ (pq and $p'q'$ are †congruent) $\Leftrightarrow \varphi(q) - \varphi(p) = \varphi(q') - \varphi(p')$. Then $\varphi(p)$ is called the **coordinate** of the point p , and (p_0, p_1) the **frame** of the line l . A Euclidean straight line with a fixed frame is called a **real line** (identified with \mathbf{R} by the mapping φ) and is usually denoted by the same notation \mathbf{R} or \mathbf{R}^1 .

356 (I.9) Recursive Functions

A. General Remarks

A function whose †domain and †range are both the set of natural numbers $\{0, 1, 2, \dots\}$ is called a **number-theoretic function**. In this article, the term *natural number* is used to mean a non-negative integer. Hilbert (1926) and K. Gödel [1] considered certain number-theoretic functions, called recursive functions by them and now called **primitive recursive functions** after S. C. Kleene [2] (the definition is given in Section B). Gödel introduced an efficient method of arithmetizing metamathematics based on representing certain finitary procedures in metamathematics by primitive recursive functions. Then the following problem naturally arises: How shall we define a finitary method? In other words, how shall we characterize a number-theoretic function that is effectively computable, or provided with an algorithm of computation? Gödel defined the notion of general recursive function by introducing a formal system for the elementary calculation of functions, following the suggestion given by J. Herbrand. Kleene later improved Gödel's definition and developed the theory of general recursive functions [2]. Furthermore, A. Church and Kleene defined λ -calculable functions using the λ -notation (Church [4]), and E. L. Post and A. M. Turing defined the notion of computable functions by introducing the concept of Turing machines. These notions, introduced independently and almost simultaneously, were found to be equivalent. Hence such functions are now simply called recursive functions. Here, instead of giving the definition of recursive functions in the original style (the Herbrand-Gödel-Kleene definition), we give it by utilizing the idea of introducing schemata, a natural extension of the notion of primitive recursive functions. We employ the letters x, y, z, x_1, x_2, \dots for variables ranging over the natural numbers.

B. Primitive Recursive Functions

Consider the following five definition schemata:

- (I) $\varphi(x) = x' \quad (= x + 1),$
- (II) $\varphi(x_1, \dots, x_n) = q$
(q a given natural number),
- (III) $\varphi(x_1, \dots, x_n) = x_i \quad (1 \leq i \leq n),$
- (IV) $\varphi(x_1, \dots, x_n) = \psi(\chi_1(x_1, \dots, x_n), \dots,$
 $\chi_m(x_1, \dots, x_n)),$
- (V) $\varphi(0, x_2, \dots, x_n) = \psi(x_2, \dots, x_n),$
 $\varphi(y', x_2, \dots, x_n) = \chi(y, \varphi(y, x_2, \dots, x_n),$
 $x_2, \dots, x_n),$

where $\psi(\)$ is a constant natural number if $n = 1$. A function is called **primitive recursive** if it is definable by a finite series of applications of the operations (IV) and (V) ($\psi, \chi, \chi_1, \dots, \chi_m$ are already-introduced functions) starting from functions each of which is given by (I), (II), or (III). Given the functions ψ_1, \dots, ψ_l , we define the **relativization** (with respect to ψ_1, \dots, ψ_l) of the definition of primitive recursive functions as follows: A function is called **primitive recursive in ψ_1, \dots, ψ_l** if it is definable by a finite series of applications of (IV) and (V) starting from ψ_1, \dots, ψ_l and from functions each of which is given by (I), (II), or (III).

We say that a function $\varphi(x_1, \dots, x_n)$ is the **representing function** of a \dagger predicate $P(x_1, \dots, x_n)$ if φ takes only 0 and 1 as values and satisfies

$$P(x_1, \dots, x_n) \Leftrightarrow \varphi(x_1, \dots, x_n) = 0.$$

Then we call P a **primitive recursive predicate** if its representing function φ is primitive recursive. The following functions and predicates are examples of primitive recursive ones: $a + b$, $a \cdot b$, a^b , $a!$, $\min(a, b)$, $\max(a, b)$, $|a - b|$, $a = b$, $a < b$, $a | b$ (a divides b), $\text{Pr}(a)$ (a is a prime number), p_i (the $(i + 1)$ st prime number, $p_0 = 2$, $p_1 = 3, \dots$), $(a)_i$ (the exponent of p_i of the unique factorization of a into prime numbers if $a \neq 0$; otherwise, 0).

Whenever we are given a concept or a theorem, we always transform it by replacing the predicates contained in it (if any) by corresponding representing functions. Then an operation Ω is called **primitive recursive** if the function or the predicate $\Omega(\psi_1, \dots, \psi_l, Q_1, \dots, Q_m)$ that results from the application of Ω to functions ψ_1, \dots, ψ_l and predicates Q_1, \dots, Q_m ($l, m \geq 0, l + m > 0$) is primitive recursive in $\psi_1, \dots, \psi_l, Q_m$. Put $\varphi(x_1, \dots, x_n, z) = \sum_{y < z} \psi(x_1, \dots, x_n, y)$. Then φ is primitive recursive in ψ , and the finite sum $\sum_{y < z}$ is a primitive recursive operation in this sense.

Similarly, the following operations are primitive recursive: the finite product $\prod_{y < z}$, the logical connectives $\neg, \vee, \wedge, \rightarrow$ (\rightarrow 411 Symbolic Logic), definitions by cases, the **bounded quantifiers** $\exists y_{y < z}, \forall y_{y < z}$, and the **bounded μ -operator** $\mu y_{y < z}$ defined as follows: $\mu y_{y < z} R(x, y)$ is the least y such that $y < z$ and $R(x, y)$ holds, if there exists such a number y ; otherwise, it equals z . The following operation is also primitive recursive:

$$\varphi(y, x_2, \dots, x_n) = \chi(y, \tilde{\varphi}(y; x_2, \dots, x_n), x_2, \dots, x_n),$$

where

$$\tilde{\varphi}(y; x_2, \dots, x_n) = \prod_{i < y} p_i^{\varphi(i, x_2, \dots, x_n)}.$$

A function φ is said to be primitive recursive **uniformly** in ψ_1, \dots, ψ_l when φ is definable by applying a primitive recursive operation to ψ_1, \dots, ψ_l .

Almost all results mentioned in this section were given by Gödel [1]. There are further investigations on primitive recursive functions by R. Péter (1934), R. Robinson (1947), and others. Note that a function definable by a \dagger double recursion is not necessarily primitive recursive. Péter (1935, 1936) investigated in detail functions that are definable, in general, by k -fold recursions for every positive interger k [8].

C. General Recursive Functions

The following μ -operator is used to define general recursive functions by extending primitive recursive functions. For a predicate $R(y)$ on the natural numbers, $\mu y R(y)$ is the least y such that $R(y)$, if $\exists y R(y)$; otherwise, $\mu y R(y)$ is undefined. Generally, $\mu y(\psi(x_1, \dots, x_n, y) = 0)$ is not necessarily defined for each n -tuple (x_1, \dots, x_n) of natural numbers. Now, a function is called a **general recursive function** (or simply **recursive function**) if it is definable by a series of applications of schemata including a new schema

$$(VI) \quad \varphi(x_1, \dots, x_n) = \mu y(\psi(x_1, \dots, x_n, y) = 0)$$

for the definition of φ from any function ψ that satisfies

$$\forall x_1 \dots \forall x_n \exists y(\psi(x_1, \dots, x_n, y) = 0),$$

in addition to those used to define the primitive recursive functions. Thus, by definition, a primitive recursive function is general recursive. A **general recursive predicate** is a predicate such that its representing function is general recursive. The facts, including the ones concerning relativization, that are valid for pri-

mitive recursive functions are also valid for general recursive functions.

Kleene's Normal Form Theorem. For each n , we can construct a primitive recursive predicate $T_n(z, x_1, \dots, x_n, y)$ and a primitive recursive function $U(y)$ such that given any general recursive function $\varphi(x_1, \dots, x_n)$, a natural number e can be found such that

$$\forall x_1 \dots \forall x_n \exists y T_n(e, x_1, \dots, x_n, y), \quad (1)$$

$$\varphi(x_1, \dots, x_n) = U(\mu y T_n(e, x_1, \dots, x_n, y)). \quad (2)$$

Any natural number e for which (1) and (2) hold is said to **define φ recursively** or to be a **Gödel number** of a recursive function φ . Let ψ_1, \dots, ψ_l (abbreviated Ψ) be any given functions. We can relativize Kleene's normal form theorem with respect to them as follows: For each n , we can construct a predicate $T_n^\Psi(z, x_1, \dots, x_n, y)$ that is primitive recursive in Ψ such that given any function φ that is general recursive in Ψ , a natural number e can be found such that

$$\forall x_1 \dots \forall x_n \exists y T_n^\Psi(e, x_1, \dots, x_n, y), \quad (3)$$

$$\varphi(x_1, \dots, x_n) = U(\mu y T_n^\Psi(e, x_1, \dots, x_n, y)), \quad (4)$$

where $U(y)$ is the primitive recursive function mentioned in Kleene's normal form theorem. A natural number e for which (3) and (4) hold is said to **define φ recursively in Ψ** or to be a **Gödel number** of φ from Ψ . In particular, a Gödel number e of φ from Ψ can be found independently of Ψ (except for l and the respective numbers of variables of ψ_1, \dots, ψ_l) when φ is general recursive uniformly in Ψ .

Now let S be a formal system containing ordinary number theory. A number-theoretic predicate $P(x_1, \dots, x_n)$ is said to be **decidable** within S if there is a formula $P(a_1, \dots, a_n)$ (with no free variables other than the distinct variables a_1, \dots, a_n) of S such that for each n -tuple (x_1, \dots, x_n) of natural numbers (the symbol \vdash means provable in S),

$$(i) \quad \vdash P(x_1, \dots, x_n) \quad \text{or} \quad \vdash \neg P(x_1, \dots, x_n)$$

and

$$(ii) \quad P(x_1, \dots, x_n) \Leftrightarrow \vdash P(x_1, \dots, x_n),$$

where x_1, \dots, x_n designate the numerals corresponding to x_1, \dots, x_n in S . If S is a consistent system such that primitive recursive predicates are decidable within S and the predicates Pf_A (for any formula A , $Pf_A(x_1, \dots, x_n, y)$ means that y is the Gödel number of a proof of $A(x_1, \dots, x_n)$) are primitive recursive, then a necessary and sufficient condition for P to be decidable within S is that P is a general recursive predicate (A. Mostowski, 1947).

Church (1936) proposed the following state-

ment: Every **effectively calculable function** is a general recursive function. The converse of this is evidently true by the definition of recursiveness. So **Church's thesis** and its converse provide the exact definition of the notion of effectively computable functions. Though this notion is somewhat vague and intuitive, the definition seems to be satisfactory, as mentioned at the beginning of this article. Therefore, any function with a computation procedure or **algorithm** can be assumed to be general recursive. Utilizing this, various decision problems have been negatively solved (\rightarrow 97 Decision Problem). Furthermore, traditional descriptive set theory can be reinvestigated from this point of view, and the concept of effectiveness used in \dagger semi-intuitionism is clarified using general recursive functions (\rightarrow 22 Analytic Sets).

D. Recursive Enumerability

A set $\{\varphi(0), \varphi(1), \varphi(2), \dots\}$ enumerated by a general recursive function φ (allowing repetitions) is called a **recursively enumerable set**. The empty set is also considered recursively enumerable. It is known that in this definition "general recursive" can be replaced by "primitive recursive" (J. B. Rosser, 1936). A set E of natural numbers is recursively enumerable if and only if there is a primitive recursive predicate $R(x, y)$ such that $x \in E \Leftrightarrow \exists y R(x, y)$ (Kleene [2]).

Generally, a predicate $E(x_1, \dots, x_m)$ is called a **recursively enumerable predicate** if there is a general recursive predicate $R(x_1, \dots, x_m, y_1, \dots, y_n)$ such that $E(x_1, \dots, x_m) \Leftrightarrow \exists y_1 \dots \exists y_n R(x_1, \dots, x_m, y_1, \dots, y_n)$. (Here "general recursive" can be replaced by "primitive recursive.")

We call a set E a **recursive set** if the predicate $x \in E$ is general recursive. The set $C = \{x \mid \exists y T_1(x, x, y)\}$ is an example of a set that is recursively enumerable but not recursive, and it has the following remarkable property: For every recursively enumerable set E , there is a primitive recursive function such that $x \in E \Leftrightarrow \varphi(x) \in C$. In this sense, the set C is said to be **complete** for the class of recursively enumerable sets. Post's problem, which asked whether the sets that are recursively enumerable but not recursive have the same \dagger degree of (recursive) unsolvability as that of C , was negatively solved simultaneously by R. M. Friedberg (1957) and A. A. Muchnik (1956–1958). A recursively enumerable set E is general recursive if and only if there is a general recursive predicate $R(x, y)$ such that $x \notin E \Leftrightarrow \exists y R(x, y)$ (Kleene [5], Post [6]).

E. Partial Recursive Functions

A function $\varphi(x_1, \dots, x_n)$ is called a **partial function** if it is not necessarily defined for all n -tuples (x_1, \dots, x_n) of natural numbers. For two partial functions $\psi(x_1, \dots, x_n)$ and $\chi(x_1, \dots, x_n)$, $\psi(x_1, \dots, x_n) \simeq \chi(x_1, \dots, x_n)$ means that if either $\psi(x_1, \dots, x_n)$ or $\chi(x_1, \dots, x_n)$ is defined for x_1, \dots, x_n , so is the other, and the values are the same. For any given natural number e , $\varphi(x_1, \dots, x_n) \simeq U(\mu y T_n^e(e, x_1, \dots, x_n, y))$ (or $\simeq U(\mu y T_n^{\Psi}(e, x_1, \dots, x_n, y))$) is a partial function, in general. We say that such a function is **partial recursive (partial recursive (uniformly) in Ψ)** and that a natural number e defines φ **recursively (uniformly) in Ψ** or is a **Gödel number** of a partial recursive function φ (from Ψ). When a natural number e is a Gödel number of $\varphi(x_1, \dots, x_n)$ (a Gödel number of φ from Ψ), $\varphi(x_1, \dots, x_n)$ is sometimes written as $\{e\}(x_1, \dots, x_n)$ ($\{e\}^{\Psi}(x_1, \dots, x_n)$). If a predicate $R(x_1, \dots, x_n, y)$ is general recursive, then $\mu y R(x_1, \dots, x_n, y)$ is partial recursive. Therefore, $\{z\}(x_1, \dots, x_n)$ is a partial recursive function of the variables of z and of x_1, \dots, x_n .

On the partial recursive functions, the following two theorems, given by Kleene [3], are most useful. (1) For natural numbers m, n , a primitive recursive function $S_n^m(z, y_1, \dots, y_m)$ can be found such that, for any natural number e , $\{e\}(y_1, \dots, y_m, x_1, \dots, x_n) \simeq \{S_n^m(e, y_1, \dots, y_m)\}(x_1, \dots, x_n)$. (2) For any partial recursive function $\psi(z, x_1, \dots, x_n)$, a natural number e can be found such that $\{e\}(x_1, \dots, x_n) \simeq \psi(e, x_1, \dots, x_n)$.

The notion of partial recursive functions appeared first in the theory of constructive ordinal numbers of Church and Kleene (1963). Partial recursive functions can be defined in the Herbrand-Gödel-Kleene style as a natural extension of general recursive functions, and they are also definable by a finite series of applications of the schemata (IV), (V), and (VI) (in each schema, = used for the definition of φ should be replaced by \simeq) starting from functions given by (I), (II), and (III).

F. Extension of Recursive Functions to Number-Theoretic Functionals

Let $\alpha_1, \dots, \alpha_m$ be number-theoretic functions of one variable. If $\varphi(x_1, \dots, x_n)$ is (partial) recursive uniformly in $\alpha_1, \dots, \alpha_m$, then a Gödel number e of φ is found independently of $\alpha_1, \dots, \alpha_m$, and $\varphi(x_1, \dots, x_n)$ is expressed as $U(\mu y T_n^{\alpha_1, \dots, \alpha_m}(e, x_1, \dots, x_n, y))$. Now suppose that $\alpha_1, \dots, \alpha_m$ range over the set N^N of all number-theoretic functions of one variable,

and put

$$\varphi(\alpha_1, \dots, \alpha_m, x_1, \dots, x_n) \simeq U(\mu y T_n^{\alpha_1, \dots, \alpha_m}(e, x_1, \dots, x_n, y)).$$

We call such a functional $\varphi(\alpha_1, \dots, \alpha_m, x_1, \dots, x_n)$ (partial) recursive, and with it we can develop a theory of recursive functions of variables of two types.

Extending the notion of recursive functionals, Kleene introduced and investigated the recursive functionals of variables of arbitrary (finite) types [10, 11]. The natural numbers are the **objects of type 0**, and the one-place functions from type- j objects to natural numbers are **objects of type $j + 1$** . Denote variables ranging over the type- j objects by $\alpha^j, \beta^j, \gamma^j, \dots$, or $\alpha_1^j, \alpha_2^j, \alpha_3^j, \dots$, etc. Consider a functional (simply called a function) of a given finite number of such variables of types taking natural numbers as values. A function φ is called a **primitive recursive function** if it is definable by a finite series of applications of the following schemata (I)–(VIII), where a is a variable of type 0, b is any list (possibly empty) of variables that are mutually distinct and different from the other variables of the schema, and ψ, χ are given functions of the indicated variables. (I) $\varphi(a, b) = a'$; (II) $\varphi(b) = q$ (q is a natural number); (III) $\varphi(a, b) = a$; (IV) $\varphi(b) = \psi(\chi(b), b)$; (V) $\varphi(0, b) = \psi(b)$, $\varphi(a', b) = \chi(a, \varphi(a, b), b)$; (VI) $\varphi(a) = \psi(\alpha_1)$ (α_1 is a list of variables from which a is obtained by changing the order of two variables of the same type); (VII) $\varphi(\alpha^1, a, b) = \alpha^1(a)$; (VIII) $\varphi(\alpha^j, b) = \alpha^j(\lambda \alpha^{j-2} \chi(\alpha^j, \alpha^{j-2}, b))$ ($\lambda \alpha^{j-2}$ designates that χ is a function of the variables α^{j-2}).

We assign to each function $\varphi(a)$ a natural number called an **index** (which plays the same role as a Gödel number) in such a way that it reflects the manner of application of the schemata used to introduce $\varphi(a)$. Now, we write $\varphi(a)$ with an index e as $\{e\}(a)$. We call a function $\varphi(a)$ **partial recursive** if it is definable by a finite series of applications of the schemata (I)–(VIII) (\simeq is employed instead of = in (IV)–(VI) and (VIII)), and (IX) $\varphi(a, b, c) \simeq \{a\}(b, c)$ (c is a finite list of variables of arbitrary types). In particular, $\varphi(a)$ is called a **general recursive function** if it is defined for all values of the argument a . These notions can be **relativized** also with respect to any given functions. Note that for the case of types ≤ 1 , primitive recursive functions, partial recursive functions, and also general recursive functions in the present sense are equivalent to the corresponding notions (introduced via relativization with uniformity) in the ordinary sense already described. The following theorem is important: Let r be the maximum type of a . Then there

are two primitive recursive predicates M, N such that

$$\{e\}(a) \simeq w \Leftrightarrow \forall \xi^{r-1} \exists \eta^{r-2} M(e, a, w, \xi^{r-1}, \eta^{r-2}), \quad r \geq 2,$$

$$w \Leftrightarrow \exists \xi^{r-1} \forall \eta^{r-2} N(e, a, w, \xi^{r-1}, \eta^{r-2}), \quad r > 2.$$

Every function definable using (IX') $\psi(a) \simeq \mu x(\psi(a, x) = 0)$ instead of (IX) is partial recursive. However, not all the partial recursive functions of variables of types ≥ 2 can be obtained by applying schemata (I)–(VIII) and (IX').

Further developments have been pursued by J. E. Fenstad, J. Moldestad, and others in abstract computation theory [20–23].

G. Recursive Functions of Ordinal Numbers

G. Takeuti introduced a notion of primitive recursiveness for functions from a segment of the ordinal numbers to ordinal numbers. Using this, he constructed a model of set theory in ordinal number theory. In connection with recursive functions of ordinal numbers, there are also investigations by A. Lévy, M. Machover, Takeuti and A. Kino, T. Tugué, S. Kripke, and others.

Early treatments of recursive functions of ordinal numbers dealt only with functions on infinite cardinals. For example, Takeuti considered functions with a fixed infinite cardinal κ as a domain and a range, and defined κ -recursive functions using schemata similar to the abovementioned (I)–(VI). Subsequently Kripke observed that the assumption that κ is a cardinal is not necessary, and introduced the notion of **admissible ordinals**. An admissible ordinal κ has the closure properties required for the construction of the calculus, and whenever $\alpha, \beta < \kappa$ and $\beta = f(\alpha)$ is computable, then $\beta = f(\alpha)$ is computable in fewer than κ stages. Given an admissible ordinal κ , κ -**recursiveness** can be defined, as in the case of general recursiveness, by various equivalent methods, e.g., schemata, the equation calculus, and definability in both quantifier forms. Most of the elementary properties of general recursive functions (e.g., the normal form theorem, parametrization theorem, enumeration theorem, etc.) are also valid for κ -recursive functions. The notions of degrees of unsolvability and recursive enumerability can also be generalized, yielding the notions of κ -degrees and κ -recursive enumerability, respectively. The fine structures of these properties are currently the objects of intensive research.

Every infinite cardinal is admissible. The least admissible ordinal is ω , and the next is the ordinal ω_1 of Church and Kleene, i.e., the first nonconstructive ordinal. In fact, for every $n \geq 1$, the first ordinal not expressible as the order type of a Δ_n^1 predicate is admissible (\dashv Section H). For each infinite cardinal κ there are κ^+ admissible ordinals of power κ . Platek investigated recursion theory in a still wider setting. He dealt with functions defined, not on a segment of ordinal numbers, but on a set, and introduced the notion of admissible sets, i.e., sets on which a well-behaved recursion theory can be developed. An admissible set is a transitive ε -model of a certain weak set theory, and an ordinal κ is admissible if and only if there exists an admissible set A such that $A \cap O_n = \kappa$, where O_n is the class of all ordinal numbers.

Recent developments have shown that generalized recursion theory, set theory, and infinitary logic are closely related. In addition to the abovementioned, there are some investigations by Y. N. Moschovakis and others [14–27].

H. Hierarchies

Utilizing the theory of \dagger recursive functions, S. C. Kleene succeeded in establishing a theory of hierarchies that essentially contains classical descriptive set theory as an extreme case [5, 10, 31, 32]. Although research following a similar line had also been done by M. Davis, A. Mostowski, and others, it was Kleene who succeeded in bringing the theory to its present form.

Sets or functions are described by \dagger predicates, which we classify as follows. Let $a, b, \dots, a_1, a_2, \dots, x, y, \dots$, be variables ranging over the set \mathbb{N} of natural numbers, and $\alpha, \beta, \dots, \alpha_1, \alpha_2, \dots, \xi, \eta, \dots$ be variables ranging over the set $\mathbb{N}^{\mathbb{N}}$ of all \dagger number-theoretic functions with one argument. Let $\psi_1, \dots, \psi_l (l \geq 0)$ be number-theoretic functions. A predicate $P(\alpha_1, \dots, \alpha_m, a_1, \dots, a_n) (m, n \geq 0, m + n > 0)$ with variables of two \dagger types is called **analytic** in $\psi_1, \dots, \psi_l (l \geq 0)$ if it is expressible syntactically by applying a finite number of logical symbols: $\rightarrow, \vee, \wedge, \neg, \exists x, \forall x, \exists \xi, \forall \xi$, to \dagger general recursive predicates in ψ_1, \dots, ψ_l . In particular, when P is expressible without function quantifiers $\exists \xi, \forall \xi$, it is called **arithmetical** in $\psi_1, \dots, \psi_l (l \geq 0)$. When $l = 0$, they are called simply analytic and arithmetical, respectively.

For brevity, consider the case $l = 0$, and denote by a a finite list of variables $(\alpha_1, \dots, \alpha_m, a_1, \dots, a_n)$. Every arithmetical predicate $P(a)$ is expressible in a form contained

in the following table (a):

(a) $R(\alpha)$:

$$\exists x R(\alpha, x), \quad \forall x \exists y R(\alpha, x, y), \dots,$$

$$\forall x R(\alpha, x), \quad \exists x \forall y R(\alpha, x, y), \dots,$$

where each R is \dagger general recursive. In order to obtain such an expression we first transform the given predicate into its \dagger prenex normal form and then contract successive quantifiers of the same kind by the formula

$$\begin{aligned} \exists x_1 \dots \exists x_n A(x_1, \dots, x_n) \\ \Leftrightarrow \exists x A((x)_0, \dots, (x)_{n-1}) \quad (1) \end{aligned}$$

and its "dual form." Each form in (a) (or the class of all predicates with that form) is denoted by Σ_k^0 or Π_k^0 , where the suffix k refers to the number of quantifiers prefixed, and Σ or Π shows that the outermost quantifier is existential or universal, respectively. A predicate that is expressible in both forms Σ_k^0 and Π_k^0 (or the class of such predicates) is denoted by Δ_k^0 . A predicate belongs to Δ_1^0 if and only if it is general recursive (an analog of \dagger Suslin's theorem).

For $k \geq 1$, there exists in Σ_k^0 (or Π_k^0) an **enumerating predicate** that specifies every predicate in Σ_k^0 (Π_k^0). For example, for Π_2^0 and $m = n = 1$, there is a \dagger primitive recursive predicate $S(\alpha, z, a, x, y)$ such that, given a general recursive predicate $R(\alpha, a, x, y)$, we have a natural number e such that

$$\forall x \exists y R(\alpha, a, x, y) \Leftrightarrow \forall x \exists y S(\alpha, e, a, x, y)$$

(**enumeration theorem**). In this theorem, we can take $T_2^2(z, a, x, y)$ (\rightarrow Section F) as $S(\alpha, z, a, x, y)$. For each $k \geq 0$, there exists a Σ_{k+1}^0 (Π_{k+1}^0) predicate that is not expressible in its dual form Π_{k+1}^0 (Σ_{k+1}^0) (hence, of course, in neither Σ_k^0 nor Π_k^0) (**hierarchy theorem**). Therefore, table (a) gives the classification of the arithmetical predicates in a hierarchy. This hierarchy is called the **arithmetical hierarchy**. For each $k \geq 1$, there exists a **complete** predicate with respect to Σ_k^0 (Π_k^0), that is, a Σ_k^0 (Π_k^0) predicate with only one variable such that any Σ_k^0 (Π_k^0) predicate is expressible by substituting a suitable general (or more strictly, primitive) recursive function for its variable (**theorem on complete form**). When $m = 0$, all the general recursive predicates in Σ_k^0 exhaust Δ_{k+1}^0 (**Post's theorem**).

Concerning the function quantifiers, we have

$$\begin{aligned} \exists \alpha_1 \dots \exists \alpha_m A(\alpha_1, \dots, \alpha_m) \\ \Leftrightarrow \exists \alpha A(\lambda t(\alpha(t))_0, \dots, \lambda t(\alpha(t))_{m-1}) \quad (2) \end{aligned}$$

$$\exists x A(x) \Leftrightarrow \exists \alpha A(\alpha(0)), \quad (3)$$

$$\forall x \exists \alpha A(x, \alpha) \Leftrightarrow \exists \alpha \forall x A(x, \lambda t \alpha(2^x \cdot 3^t)), \quad (4)$$

and their dual forms. For any general recursive predicate R , there is a primitive recursive predicate S such that

$$\exists \alpha R(\alpha, a) \Leftrightarrow \exists \alpha \exists x S(\alpha(x), a) \Leftrightarrow \exists y S(y, a) \quad (5)$$

and its dual hold. Using these facts, we can classify the forms of all analytic predicates by the table (b):

(b) $A(\alpha)$:

$$\forall \alpha \exists x R(\alpha, \alpha, x), \quad \exists \alpha \forall \beta \exists x R(\alpha, \alpha, \beta, x), \dots,$$

$$\exists \alpha \forall x R(\alpha, \alpha, x), \quad \forall \alpha \exists \beta \forall x R(\alpha, \alpha, \beta, x), \dots,$$

where A is arithmetical and each R is general recursive. Similarly, denote by Σ_k^1 , Π_k^1 each form of predicate in (b) (or the class of all predicates reducible to that form), where k is the number of function quantifiers prefixed; also, denote by Δ_k^1 the (class of) predicates expressible in both forms Σ_k^1 and Π_k^1 . For Σ_k^1 , Π_k^1 ($k \geq 1$), we have the enumeration theorem, the hierarchy theorem, and the theorem on complete form. The hierarchy given by table (b) is called the **analytic hierarchy**.

For $l > 0$ (namely, when predicates are arithmetical or analytic in ψ_1, \dots, ψ_l), we can \dagger uniformly \dagger relativize the above results with respect to ψ_1, \dots, ψ_l . Now let $\{\Sigma_r^* \psi_1, \dots, \psi_l\}$, $\{\Pi_r^* \psi_1, \dots, \psi_l\}$ ($r = 0, 1$) be the corresponding hierarchy relative to ψ_1, \dots, ψ_l . Given a set C ($\subset \mathbb{N}^{\mathbb{N}}$) of functions with one argument, we can consider hierarchies of predicates which are arithmetical or analytic in a finite number of functions in C . Such a hierarchy is called a **C-arithmetical** or **C-analytic hierarchy** and denoted by $\{\Sigma_k^0[C], \Pi_k^0[C]\}_k$ or $\{\Sigma_k^1[C], \Pi_k^1[C]\}_k$, respectively. That is, when we regard $\Sigma_k^r[C]$ as a class of predicates (or sets) P , it is the family $\{P \mid P \in \Sigma_k^r \xi_1, \dots, \xi_l, \xi_1, \dots, \xi_l \in C, l = 0, 1, 2, \dots\}$. These notations have been given by J. W. Addison [28, 29]. The $\mathbb{N}^{\mathbb{N}}$ -arithmetical hierarchy and the $\mathbb{N}^{\mathbb{N}}$ -analytic hierarchy for sets correspond respectively to the finite Borel hierarchy and the projective hierarchy in the \dagger space of irrational numbers. Addison called the theory of those hierarchies **classical descriptive set theory**, and in contrast to this, the theory of arithmetical and analytic hierarchies for sets ($C = \emptyset$) **effective descriptive set theory** [28].

We now restrict our consideration to predicates for natural numbers (i.e., to the case $m = 0$). Define the predicates L_k by $L_0(a) \Leftrightarrow a = a$, $L_{k+1}(a) \Leftrightarrow \exists x T_1^{L_k}(a, a, x)$. For each $k \geq 0$, $L_{k+1}(a)$ is a Σ_{k+1}^0 predicate which is of the highest \dagger degree of recursive unsolvability among the Σ_{k+1}^0 predicates, and its degree is properly higher than that of $L_k(a)$. Thus L_k , $k = 0, 1, 2, \dots$, determine the **arithmetical hierarchy of degrees of recursive unsolvability**. Kleene has extended the series of L_k by using

the system S_3 (\rightarrow 81 Constructive Ordinal Numbers) of notations for the constructive ordinal numbers as follows [6]: $H_1(a) \Leftrightarrow a = \alpha$; for $y \in O$, $H_{2^y}(a) \Leftrightarrow \exists x T_1^{H_y}(a, a, x)$; for $3 \cdot 5^y \in O$, $H_{3 \cdot 5^y}(a) \Leftrightarrow H_{y(a)}$, where $y_n = \{y\}(n_0)$. This H_y is defined for each $y \in O$, and it is of a properly higher degree than that of H_z when $z <_O y$. If $|y| = |z|$ ($|y|$ is the ordinal number represented by y), then H_y and H_z are of the same degree (C. Spector [34]). Thus a hierarchy of degrees is uniquely determined by constructive ordinal numbers. This hierarchy is called the **hyperarithmetical hierarchy of degrees of recursive unsolvability**. A function or predicate is said to be **hyperarithmetical** if it is recursive in H_y for some $y \in O$. These concepts and the results mentioned below can be related to any given functions or predicates.

A necessary (Kleene [31]) and sufficient (Kleene [32]) condition for a predicate to be hyperarithmetical is that it be expressible in both one-function quantifier forms Δ_1^1 (an effective version of Suslin's theorem). Denote by Hyp the set ($\subset \mathbb{N}^{\mathbb{N}}$) of all hyperarithmetical functions α . For an arithmetical predicate $A(\alpha, a)$, $\exists \alpha_{\alpha \in \text{Hyp}} A(\alpha, a)$ is always a Π_1^1 predicate (Kleene [33]). Conversely, for any Π_1^1 predicate P , there is a general recursive predicate R such that $P(a) \Leftrightarrow \exists \alpha_{\alpha \in \text{Hyp}} \forall x R(a, \alpha, x)$ (Spector [35]). As to uniformization, for a Π_1^1 predicate $P(a, b)$, we have $\forall x \exists y P(x, y) \Rightarrow \exists \alpha_{\alpha \in \text{Hyp}} \forall x P(x, \alpha(x))$ (G. Kreisel, 1962). Let \mathbf{E} be an object of type 2 defined by: $\mathbf{E}(\alpha) = 0$ if $\exists x(\alpha(x) = 0)$, otherwise $\mathbf{E}(\alpha) = 1$. A function $\varphi(a_1, \dots, a_n)$ is hyperarithmetical if and only if it is general recursive in \mathbf{E} (Kleene [10]). A predicate that is hyperarithmetical relative to Π_k^1 predicates ($k \geq 0$) is of Δ_{k+1}^1 (Kleene [32]), but the converse does not hold in general (Addison and Kleene, 1957).

Kleene extended his theory of hierarchy to the case of predicates of variables of any type by utilizing the theory of general recursive functions with variables of finite types $0, 1, 2, \dots$ [10]. Let α^t be a list of variables of types $\leq t$. We say a predicate $P(\alpha^t)$ is of order r in completely defined functions ψ_1, \dots, ψ_l ($l \geq 0$) (for brevity, denote them by Ψ) if P is syntactically expressible in terms of variables of finite types, predicates that are general recursive in Ψ , and symbols of the \dagger predicate calculus with quantification consisting only of variables of types $< r$. The predicates of order 0 in Ψ are exactly the general recursive ones in Ψ . When $t \geq 1$, and Ψ are functions of variables of type 0, a predicate $P(\alpha^t)$ is of order 1 (of order 2) in Ψ if and only if P is arithmetical (analytic).

We have theorems similar to (2)–(4) and the following theorem and its dual for $r \geq 2$: For any given general recursive predicate

356 Ref.
Recursive Functions

$P(\alpha^r, \sigma^r, \xi^{r-2})$, there is a primitive recursive predicate $R(\alpha^r, \eta^{r-1}, \xi^{r-2})$ such that

$$\begin{aligned} \exists \sigma^r \forall \xi^{r-2} P(\alpha^r, \sigma^r, \xi^{r-2}) \\ \Leftrightarrow \exists \eta^{r-1} \forall \xi^{r-2} R(\alpha^r, \eta^{r-1}, \xi^{r-2}). \end{aligned} \quad (6)$$

Using these equivalences, each predicate $P(\alpha^t)$ of order $r+1$ ($r \geq 0$) is expressible in one of the following forms:

$$\begin{aligned} (c) \quad & B(\alpha); \\ & \forall \alpha^r \exists \xi^{r-1} R(\alpha, \alpha^r, \xi^{r-1}), \\ & \exists \alpha^r \forall \beta^r \exists \xi^{r-1} R(\alpha, \alpha^r, \beta^r, \xi^{r-1}), \dots, \\ & \exists \alpha^r \forall \xi^{r-1} R(\alpha, \alpha^r, \xi^{r-1}), \\ & \forall \alpha^r \exists \beta^r \forall \xi^{r-1} R(\alpha, \alpha^r, \beta^r, \xi^{r-1}), \dots, \end{aligned}$$

where B is of order r and each R is general recursive. When $t = r+1$, table (c) gives the classification of the predicates of order $r+1$ into the hierarchy. In fact, for the predicates $P(\alpha^{r+1})$ in each form, we have the enumeration theorem, the hierarchy theorem, and the theorem on complete form (Kleene [10]). D. A. Clarke [30] has published a detailed review of the general theory of hierarchies.

357 (VI.6) Regular Polyhedra

A. Regular Polygons

A †polygon in a Euclidean plane bounding a †convex cell whose sides and interior angles are all respectively congruent is called a **regular polygon**. When the number of vertices (which equals the number of sides) is n , it is called a **regular n -gon**. There exist a circle (**circumscribed circle**) passing through all the vertices of a regular n -gon and a concentric circle (**inscribed circle**) tangent to all the sides. We call the center of these circles the **center** of the regular n -gon. The n vertices of a regular n -gon are obtained by dividing a circle into n equal parts. (When a polygon in a Euclidean plane bounds a †convex cell, this 2-cell is sometimes called a convex polygon. Thus *regular polygon* sometimes means the convex cell bounded by a regular polygon as described above.) A necessary and sufficient condition for a regular n -gon to be geometrically constructible is that n be decomposable into the product of prime numbers $n = 2^m p_1 \dots p_k$ ($m \geq 0$), where the p_i ($i = 1, 2, \dots$) are different †Fermat numbers (\dashv 179 Geometric Construction).

B. Regular Polyhedra

Consider a regular polygon on a plane, and take a point on the line perpendicular to the plane at the center of the polygon. The set of points on all half-lines joining this point and points on the polygon (considered as a convex cell) is called a **regular polyhedral angle** having this point as vertex (Fig. 1).

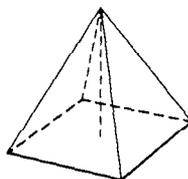

Fig. 1

When a †convex polyhedron \mathfrak{F} in E^3 satisfies the following two conditions, we call it a **regular polyhedron**: (1) Each face of \mathfrak{F} , which is a 2-dimensional cell, is a regular polygon, and all faces of \mathfrak{F} are congruent to each other. (2) Its vertices are all surrounded alike. That is, by the projection of \mathfrak{F} from each vertex of \mathfrak{F} , we obtain a regular polyhedral angle; these regular polyhedral angles are all congruent to each other. From (2) we see that the number of edges emanating from each vertex of \mathfrak{F} is

independent of the vertex. It has been known since Plato's time that there are only five kinds of regular polyhedra: **tetrahedrons** (Fig. 2), **octahedrons** (Fig. 3), **icosahedrons** (Fig. 4), **cubes** or **hexahedrons** (Fig. 5), and **dodecahedrons** (Fig. 6) (see also see Table 1).

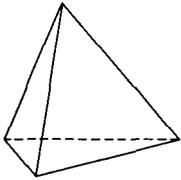

Fig. 2
Regular tetrahedron.

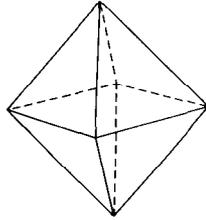

Fig. 3
Regular octahedron.

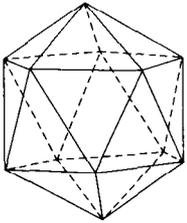

Fig. 4
Regular icosahedron.

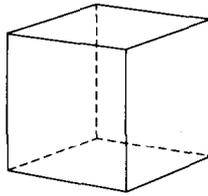

Fig. 5
Regular hexahedron
(or cube).

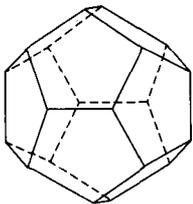

Fig. 6
Regular dodecahedron.

From a given regular polyhedron, we can obtain another one by taking as vertices the centers of all the faces of the given polyhedron (Fig. 7). We say that the given regular polyhedron and the one obtained in this way are **dual** to each other. The octahedron and hexa-

hedron are dual to each other, as are the icosahedron and dodecahedron. The tetrahedron is dual to itself. For a regular polyhedron \mathfrak{F} , there exist concentric circumscribed and inscribed spheres whose center is the center of symmetry of \mathfrak{F} and is called the **center** of \mathfrak{F} . Drawing tangent planes to the circumscribed sphere at each vertex, we can obtain a regular polyhedron dual to the given one (Fig. 8).

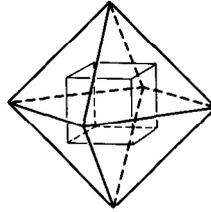

Fig. 7

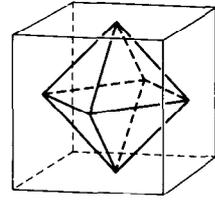

Fig. 8

In a regular polyhedron, let a be the length of an edge, θ the magnitude of the dihedral angle at each edge, and R and r the radii of circumscribed and inscribed spheres, respectively. Then the following relations hold (we assume that each face is a regular p -gon and q faces meet at each vertex):

$$\sin \frac{\theta}{2} = \cos \frac{\pi}{q} / \sin \frac{\pi}{p},$$

$$R = \frac{a}{2} \sin \frac{\pi}{q} / \sin \frac{\pi}{p} \cos \frac{\theta}{2}, \tag{1}$$

$$r = \frac{a}{2} \cot \frac{\pi}{p} \tan \frac{\theta}{2}, \quad \frac{R}{r} = \tan \frac{\pi}{p} \tan \frac{\pi}{q}$$

(see Table 2). Corresponding to these polyhedra, we have finite subgroups of $O(3)$ called regular polyhedral groups (\rightarrow 151 Finite Groups).

C. Higher-Dimensional Cases

It is possible to generalize these considerations to higher dimensions to define inductively

Table 1. Regular Polyhedra in 3-Dimensional Euclidean Space E^3

358 (II.2) Relations

A. General Remarks

In its wider sense the term *relation* means n -ary relation ($n = 1, 2, 3, \dots$) (\rightarrow 411 Symbolic Logic G), but in this article we restrict ourselves to its most ordinary meaning, i.e., to the case $n = 2$. Let X, Y be two sets and x, y be two variables taking their values in X, Y , respectively. A proposition $R(x, y)$ containing x, y is called a **relation** or a **binary relation** if it can be determined whether $R(a, b)$ is true or false for each pair (a, b) in the Cartesian product $X \times Y$. For example, if both X and Y are the set of rational integers, then the following propositions are relations: $x \leq y$, $x - y$ is even, x divides y . A relation $R(x, y)$ is sometimes written as xRy .

For a given relation R , we define its **inverse relation** R^{-1} by $yR^{-1}x \Leftrightarrow xRy$. Then R is the

inverse relation of R^{-1} . In the example above, the inverse relation of $x \leq y$ is $y \geq x$, and the inverse relation of x is a divisor of y is y is a multiple of x . A relation R is called **reflexive** if xRx holds. R is called **symmetric** if $xRy \Leftrightarrow yRx$ (namely, if R and R^{-1} are identical). R is called **transitive** if xRy and yRz imply xRz . R is called **antisymmetric** if xRy and yRx imply $x = y$. A reflexive, symmetric, and transitive relation is called an **equivalence relation** (\rightarrow 135 Equivalence Relations). A reflexive and transitive relation is called a \dagger preordering. A reflexive, transitive, and antisymmetric relation is called an \dagger ordering (\rightarrow 311 Ordering).

Suppose that we are given a relation xRy ($x \in X, y \in Y$). Then the set $G = \{(x, y) | xRy\}$, which consists of elements (x, y) of the Cartesian product $X \times Y$ satisfying xRy , is called the **graph** of the relation R . Conversely, for any subset G of $X \times Y$, there exists a unique relation R with the graph G given by $xRy \Leftrightarrow (x, y) \in G$.

B. Correspondences

For a subset G of the Cartesian product $X \times Y$, the triple $\Gamma = (G, X, Y)$ is called a **correspondence** from X to Y . The set X is called the **initial set** of the correspondence Γ , and Y the **final set** of Γ . A relation xRy ($x \in X, y \in Y$) determines a correspondence $\Gamma = (G, X, Y)$ by its graph G , and conversely, a correspondence Γ determines a relation R . Given a correspondence $\Gamma = (G, X, Y)$, the sets $A = \text{pr}_X G$ and $B = \text{pr}_Y G$, where $\text{pr}_X: X \times Y \rightarrow X$ and $\text{pr}_Y: X \times Y \rightarrow Y$ are the \dagger canonical projections, are called the **domain** and **range** of the correspondence Γ , respectively. For $x \in X$, the set $\{y \in Y | (x, y) \in G\}$ is denoted by $G(x)$ or $\Gamma(x)$, and we say that any element y of $G(x)$ **corresponds** to x by Γ .

For a subset G of $X \times Y$, we define a subset G^{-1} of $Y \times X$ by $(x, y) \in G \Leftrightarrow (y, x) \in G^{-1}$. Given a correspondence $\Gamma = (G, X, Y)$, the correspondence (G^{-1}, Y, X) is denoted by Γ^{-1} and is called the **inverse correspondence** of Γ . If G is the graph of a relation R , then G^{-1} is the graph of the inverse relation R^{-1} . The domain of the correspondence Γ is the range of Γ^{-1} , and vice versa. We have $(\Gamma^{-1})^{-1} = \Gamma$.

Suppose that we are given correspondences $\Gamma_1 = (G_1, X, Y)$ and $\Gamma_2 = (G_2, Y, Z)$. We define a subset G of $X \times Z$ by: $(x, z) \in G \Leftrightarrow$ there exists $y \in Y$ satisfying $(x, y) \in G_1$ and $(y, z) \in G_2$. Then the correspondence $\Gamma = (G, X, Z)$ is denoted by $\Gamma_2 \circ \Gamma_1$ and is called the **composite** of Γ_1 and Γ_2 . We have the **associative law** $(\Gamma_3 \circ \Gamma_2) \circ \Gamma_1 = \Gamma_3 \circ (\Gamma_2 \circ \Gamma_1)$ and the law $(\Gamma_2 \circ \Gamma_1)^{-1} = \Gamma_1^{-1} \circ \Gamma_2^{-1}$.

Let Γ be a correspondence from X to Y , and

**359 B
Relativity**

assume that to any x belonging to the domain A of Γ there corresponds one and only one $y \in Y$, namely, $\Gamma(x) = \{y\}$ for any $x \in A$. Then Γ is called a **univalent correspondence**. If Γ and Γ^{-1} are both univalent correspondences, Γ is called a **one-to-one correspondence**. For given sets A and B , a univalent correspondence with domain A and range B is called a \dagger mapping (or \dagger function) with domain A and range B (\rightarrow 381 Sets C).

**359 (XX.21)
Relativity**

A. History

The theory of relativity is a system of theoretical physics established by A. Einstein and is composed of special relativity and general relativity. Toward the end of the 19th century, it was believed that electromagnetic waves propagate through the ether, a hypothetical medium. A number of experimenters tried to find the motion of the earth relative to the ether, but all these attempts were unsuccessful (A. A. Michelson, E. W. Morley). Studying these results, in 1905 Einstein proposed the **special theory of relativity**, which extended Galileo's relativity principle of \dagger Newtonian mechanics to \dagger electromagnetism and radically revised the concepts of space and time. Almost all the conclusions of special relativity theory are now confirmed by experiments, and this theory has even become a guiding principle for developing new theories in physics. By extending special relativity, Einstein established (1915) the **general theory of relativity**. Its principal part is a new theory of gravitation containing Newton's theory as a special case. Its conclusions about the solar system are compatible with observed facts that are regarded as experimental support for the theory. Effects due to general relativity other than those just described have been studied to a considerable extent, but it is hard at present to test theoretical results experimentally, and there are some doubts about the limit of its applicability.

B. Special Relativity

In Newtonian mechanics, natural phenomena are described in a 3-dimensional Euclidean

space considered independent of time. In special relativity, however, it is postulated that space and time cannot be separated but are unified into a 4-dimensional pseudo-Euclidean space with the †fundamental form

$$ds^2 = \sum_{a,b} g_{ab} dx^a dx^b \equiv c^2 dt^2 - dx^2 - dy^2 - dz^2,$$

where $a, b = 0, 1, 2, 3$ and

$$(x^0, x^1, x^2, x^3) = (ct, x, y, z).$$

Here (x, y, z) are spatial Cartesian coordinates, t is time, and c is the speed of light. This space was introduced by H. Minkowski and is called **Minkowski space-time**. By means of it Minkowski gave an ingenious geometric interpretation to special relativity.

A nonzero vector V is called timelike, null (or lightlike), or spacelike according as $V^2 > 0$, $= 0$, or < 0 , where $V^2 = \sum_{a,b} g_{ab} V^a V^b$.

The group of motions in Minkowski space-time is called the **inhomogeneous Lorentz group**. Its elements can be written as

$$x^{i'} = \sum_a c_a^i x^a + c^i, \quad \sum_{a,b} g_{ab} c_a^i c_b^j = g_{ij},$$

where c_j^i and c^i are constants. The transformations with $c^i = 0$ are usually called **Lorentz transformations**, and the group G composed of these transformations is called the **homogeneous Lorentz group** or simply the **Lorentz group**. These are important concepts in special relativity. If G_0 denotes the †connected component of the identity element of G , the factor group G/G_0 is an Abelian group of type (2, 2) and of order 4. We call G_0 the **proper Lorentz group**. A frequently used element of G_0 is

$$L_v: x' = \frac{x - vt}{\sqrt{1 - v^2/c^2}}, \quad t' = \frac{t - (v/c^2)x}{\sqrt{1 - v^2/c^2}},$$

$$y' = y, \quad z' = z; \quad |v| < c. \quad (1)$$

Such transformations form a 1-dimensional subgroup of G_0 with v as a parameter, and the composition law of the subgroup is given by

$$L_u \cdot L_v = L_w, \quad w = \frac{u + v}{1 + uv/c^2}.$$

Elements of G not belonging to G_0 are

$$T: x^{0'} = -x^0, \quad x^{i'} = x^i; \quad i = 1, 2, 3,$$

$$S: x^{0'} = x^0, \quad x^{i'} = -x^i; \quad i = 1, 2, 3.$$

Both T (**time reversal**) and S (**space reflection** or **parity transformation**) have aroused much interest among physicists.

Historically, the transformation formula (1) was first obtained by H. A. Lorentz, under the assumption of contraction of a rod in the direction of its movement in order to overcome the difficulties of the ether hypothesis, but his theoretical grounds were not satisfactory. On the other hand, Einstein started with

the following two postulates: (i) **Special principle of relativity**: A physical law should be expressed in the same form in all **inertial systems**, namely, in all coordinate systems that move relative to each other with uniform velocity. (ii) **Principle of invariance of the speed of light**: The speed of light in a vacuum is the same in all inertial systems and in all directions, irrespective of the motion of the light source. From these assumptions Einstein derived (1) as the transformation formula between inertial systems $\mathbf{x} = (ct, x, y, z)$ and $\mathbf{x}' = (ct', x', y', z')$ that move relative to each other with uniform velocity v along the common x -axis. This was the first step in special relativity, and along this line of thought, Einstein solved successively the problems of the Lorentz-Fitzgerald contraction, the dilation of time as measured by moving clocks, the aberration of light, the Doppler effect, and Fresnel's dragging coefficient.

C. Relativity and Electromagnetism

In special relativity, a physical quantity is represented by a †tensor (or a scalar or a vector) in Minkowski space-time, and physical laws are written in tensor form and are invariant under Lorentz transformations of coordinates. This is the mathematical expression of the special principle of relativity. Since the transformation (1) tends to a **Galileo transformation** in Newtonian mechanics as $c \rightarrow \infty$, the special principle of relativity is a generalization of the Newton-Galileo principle of relativity. To summarize mathematically, it may safely be said that special relativity is a theory of invariants with respect to the Lorentz group. To illustrate this conclusion we consider electromagnetic theory.

The electric field \mathbf{E} is usually represented by a "polar vector" and the magnetic field \mathbf{H} by an "axial vector" in a 3-dimensional Euclidean space. Even if the magnetic field does not exist in one inertial system, the field can arise in another system that moves uniformly relative to the original system. In view of this, electric and magnetic fields are considered in relativity to form one physical quantity with components

$$(F_{ij}) = \begin{pmatrix} 0 & -E_x & -E_y & -E_z \\ E_x & 0 & H_z & -H_y \\ E_y & -H_z & 0 & H_x \\ E_z & H_y & -H_x & 0 \end{pmatrix}.$$

This quantity transforms as a †alternating tensor of degree 2 under Lorentz transformations. In like manner, the electric charge density ρ and the electric current density \mathbf{J} are unified into a †contravariant vector with

respect to Lorentz transformations:

$$s = (s^0, s^1, s^2, s^3) \\ = (\rho, J_x/c, J_y/c, J_z/c).$$

Such a vector s in Minkowski space-time is sometimes called a **four-vector** as distinguished from an ordinary vector such as \mathbf{J} . If the electromagnetic field F_{ij} and the current four-vector s are thus defined, the †Maxwell equations, the basic equations of electromagnetism, can be written in tensor form:

$$\sum_a \frac{\partial F^{ia}}{\partial x^a} = s^i, \quad \frac{\partial F_{jk}}{\partial x^i} + \frac{\partial F_{ki}}{\partial x^j} + \frac{\partial F_{ij}}{\partial x^k} = 0,$$

where

$$F^{ij} = \sum_{a,b} g^{ia} g^{jb} F_{ab}, \quad \sum_a g^{ia} g_{ja} = \delta_j^i.$$

In the same way, the equation of motion for a charged particle in an electromagnetic field can be expressed as

$$\frac{d^2 x^i}{ds^2} = \frac{e}{mc} \sum_a F_a^i \frac{dx^a}{ds}, \quad F_j^i = \sum_a g^{ia} F_{ja},$$

where e and m are the charge and mass of the particle, respectively, and s is the arc length along the particle trajectory (\rightarrow 130 Electromagnetism).

Though special relativity originated in studies of electromagnetic phenomena, it has gradually become clear that the theory is valid also for other phenomena. One interesting result is that the energy of a particle moving with uniform velocity v is given by

$$E = mc^2 / \sqrt{1 - v^2/c^2},$$

and accordingly even a particle at rest has energy mc^2 (**rest energy**). This shows the equivalence of mass and energy, with the conversion formula given by $E = mc^2$. This conclusion has been verified experimentally by studies of nuclear reactions and has become the basis of the development of nuclear power. The special principle of relativity also showed its validity in the electron theory of P. A. M. Dirac (1928) and the quantum electrodynamics of S. Tomonaga (1943) and others. It has, however, been shown that the invariance for space reflection (namely for the coset SG_0 of the Lorentz group G) is violated in the decay of elementary particles (T. D. Lee and C. N. Yang, 1956; C. S. Wu et al., 1957). Similar results have been obtained for time reversal (J. H. Christenson, J. W. Cronin, V. L. Fitch, and R. Turlay, 1964).

D. General Relativity

Special relativity has its origin in studies of electromagnetic phenomena, while the central

part of general relativity is a theory of gravitation founded on the **general principle of relativity** and the **principle of equivalence**. The first principle is an extension of the special principle of relativity to accelerated systems in general. It requires that a physical law should be independent of the choice of local coordinates in a 4-dimensional †differentiable manifold representing space and time (**space-time manifold**). Since a physical quantity is represented by a tensor on the space-time manifold, physical laws are expressed in tensor form, in agreement with the first principle. The second principle claims that gravitational and inertial mass are equal, and accordingly fictitious forces due to acceleration (such as centrifugal force) cannot be distinguished from gravitational force. This had been shown with high accuracy by the experiments of R. von Eötvös (1890) and others.

Starting from these two principles, Einstein was led to the following conclusion. If a gravitational field is produced by matter, the corresponding space-time structure is altered; namely, flat Minkowski space-time is changed into a curved 4-dimensional manifold with †pseudo-Riemannian metric of †signature (1, 3). The †fundamental tensor g_{ij} of this manifold represents the gravitational potential, and the gravitational equation satisfied by g_{ij} can be expressed as a geometric law of the manifold. Gravitational phenomena are thus reduced to properties of the geometric structure of the space-time manifold. This idea, which was not seen in the older physics, became the motif in the development of †unified field theories.

Now the gravitational law proposed by Einstein is an analog of the †Poisson equation in Newtonian mechanics. Let R_{ij} and R be the †Ricci tensor and the †scalar curvature formed from g_{ij} . Then outside the source of a gravitational field, g_{ij} must satisfy

$$G_{ij} \equiv R_{ij} - g_{ij}R/2 = 0, \quad \text{that is, } R_{ij} = 0, \quad (2)$$

and inside the source,

$$G_{ij} = \kappa T_{ij}, \quad (3)$$

where κ is the gravitational constant. Here the **energy-momentum tensor** T_{ij} is a †symmetric tensor representing the dynamical state of matter (energy, momentum, and stress). Usually (2) and (3) are called the **exterior** and **interior field equations**, respectively.

Next, the **equation of motion** of a particle in a gravitational field is given by

$$\delta^2 x^i / \delta s^2 = 0, \quad \sum_{a,b} g_{ab} \frac{dx^a}{ds} \frac{dx^b}{ds} = +1, \quad (4)$$

if the particle mass is so small that its effect on the field is negligible. Here $\delta/\delta s$ stands for †covariant differentiation with respect to the

arc length s along the particle trajectory. In other words, a particle in a gravitational field moves along a timelike †geodesic in the space-time manifold. Similarly, the path of light is represented by a **null geodesic**, whose equation is formally obtained from (4) by replacing the right-hand side of the second equation by zero.

Experimental verification of the theory of general relativity has been obtained by detection of the following effects: the shift of spectral lines due to the gravity of the earth and of white dwarfs, the deflection of light or radio waves passing near the sun, the time delay of radar echo signals passing near the sun, and the advance of the perihelion of Mercury. All the observational data are compatible with the theoretical results. Time delay and the advance of the perihelion have been observed in a binary system of neutron stars. It is generally accepted that these results are experimental verifications of general relativity.

It should be noted that (2) has wave solutions, which have no counterpart in Newton's gravitational theory. This fact implies that gravitational effects propagate with the velocity of light. The gravitational waves transport energy and momentum, and the gravitational mass is decreased by the emission of the waves. Experiments to detect gravitational waves generated in the universe have been planned, and the decrease of the orbital period of a binary star system due to the emission of gravitational waves has been observed.

The concept of gravitational waves suggests the existence of a quantum of the gravitational field (graviton); however, the detection of the graviton is far from feasible.

In the interior equation (3), the matter producing a gravitational field is represented by a tensor T_{ij} of class C^0 . But there is also a way of representing it by singularities of a solution of the exterior equation (2). From this point of view, the equation of motion of a material particle (i.e., singularity) is not assumed a priori as in (4), but is derived as a result of (2) (A. Einstein, L. Infeld, and B. Hoffman, 1938).

In the static and weak field limits, the fundamental form is approximately given by Newton's gravitational potential φ as

$$ds^2 \approx c^2(1 - \varphi/c^2)dt^2 - (1 + \varphi/c^2)(dx^2 + dy^2 + dz^2),$$

and (2) and (3) reduce in this limit to Laplace's and Poisson's equations, respectively. Newton's theory of gravity is valid in the limit $\varphi/c^2 \ll 1$.

Stimulated by the discoveries of neutron stars and black holes and by the big-bang theory of the universe in the 1960s, numerous studies of general relativity have been carried

out on such problems as the gravitational field of a spinning mass, the dynamical process of gravitational collapse, the space-time structure of black holes, the generation of gravitational waves, the global structure and dynamics of the universe, and so on. A comparison of the theoretical predictions and the observations is generally favorable, but the phenomena in the universe are so complex that the effects of general relativity cannot always be isolated.

E. Solutions of Einstein's Equations

The isometric symmetry of space-time is described by †Killing vectors. The stationary metric is characterized by a timelike Killing vector, in which case equation (2) reduces to an †elliptic partial differential equation on a 3-dimensional manifold. If the space-time is axially symmetric as well as stationary, (2) reduces to the **Ernst equation**:

$$(\varepsilon + \varepsilon^*)\nabla^2 \varepsilon = 2\nabla \varepsilon \cdot \nabla \varepsilon, \tag{5}$$

where ∇ represents divergence in a flat space. The metric tensors are derived from the complex potential ε . The solutions of (5) can be obtained using techniques developed for the soliton problem.

One example of stationary and axially symmetric solutions is the **Kerr metric**, which is written as

$$ds^2 = c^2 dt^2 - \frac{2mr}{\rho^2} (a \sin^2 \theta d\varphi - c dt)^2 - \rho^2 \left(\frac{dr^2}{\Delta} + d\theta^2 \right) - (r^2 + a^2) \sin^2 \theta d\varphi^2, \tag{6}$$

with $\rho^2 = r^2 + a^2 \cos^2 \theta$ and $\Delta = r^2 - 2mr + a^2$. This metric solution represents a gravitational field around a spinning mass with mass $M = mc^2/G$ and angular momentum $J = Mac$. When $a=0$, this metric reduces to the Schwarzschild metric.

Applying a Bäcklund transformation to the Kerr metric, an infinite series of stationary and axially symmetric solutions can be derived. All these solutions belong to the space-time metric with, in general, two Killing vectors.

The dynamical evolution of space-time structure has been studied by means of the †Cauchy problem of general relativity. Choosing appropriate dynamical variables, equation (2) or (3) is divided into constraint equations in terms of the initial data and evolution equations in terms of the dynamical variables. The latter †hyperbolic equations may also be written in Hamiltonian form.

A typical example of such a problem is the dynamics of a spatially homogeneous 3-

dimensional manifold; this has been studied as a cosmological model. The space-time with a constant scalar curvature R is called **de Sitter space**, and reduces to the Minkowski space if $R=0$. If the 3-dimensional space is isotropic as well as homogeneous, the metric takes the form

$$ds^2 = c^2 dt^2 - a(t)^2 \{ dx^2 + f(x)^2 \times (d\theta^2 + \sin^2 \theta d\phi^2) \},$$

where $f(x) = \sin x$, x , or $\sinh x$. These are called **Robertson-Walker metrics** and are considered to describe a realistic expanding universe.

F. Global Structure of Space-Time

Following the advances of modern differential geometry, manifestly coordinate-independent techniques to analyze space-time properties have been applied to general relativity. The mathematical model of space-time is a connected 4-dimensional Hausdorff C^∞ -manifold endowed with a metric of signature (1,3). The metric allows the physical description of local causality and of local conservation of energy and momentum. The metric functions obey the Einstein field equation (2) or (3).

In order to clarify the global structure of the solutions of Einstein's equations, maximally analytic extension of the solutions has been studied. The maximal extension of the Schwarzschild metric is given as

$$ds^2 = \frac{32m^3}{r} e^{-r/2m} (dv^2 - du^2) - r^2 (d\theta^2 + \sin^2 \theta d\phi^2),$$

using the **Kruskal coordinates**, which are related to the coordinates of (6) by

$$\left(\frac{r}{2m} - 1 \right) e^{r/2m} = u^2 - v^2,$$

$$\tanh t/4m = u/v \quad \text{or} \quad v/u.$$

To study the global structure at infinity, a conformal mapping of the metric is used. For example, the Minkowski metric is written in the form $ds^2 = \Omega^2 d\bar{s}^2$, where

$$ds^2 = dp dq - \frac{1}{4} \sin^2(p-q) (d\theta^2 + \sin^2 \theta d\phi^2)$$

and $\Omega = \sec p \sec q$, $\tan p = t + r$, $\tan q = t - r$. By means of this mapping, all points, including infinity, are assigned finite p, q coordinate values in $-\pi/2 \leq q \leq p \leq \pi/2$.

Singularities in space-time are one of the major problems concerning the global structure of the manifold. For some Cauchy problems relevant to cosmology and gravitational collapse, the inevitable occurrence of a singularity has been proved (**singularity theorem**).

359 Ref. Relativity

A sufficient condition for occurrence of a singularity is that there be some point p such that all the null geodesics starting from p converge to p again. In addition to this condition, for the proof of the singularity theorem it is presumed that the space-time is free of closed nonspacelike curves, that a Cauchy surface exists, and that the energy-momentum tensor satisfies the condition

$$\sum_{i,j} \left(T_{ij} - \frac{1}{2} T g_{ij} \right) V^i V^j \geq 0$$

for any timelike vector V^i . The singularity whose existence is implied by this theorem means that the space-time manifold is geodesically incomplete (the space-time is complete if every geodesic can be extended to arbitrary values of its affine parameter).

The causal structure of space-time is also related to the global structure of the manifold. In this regard, black holes have been introduced as the final state of gravitational collapse. In the black-hole structure of space-time, there exists a closed surface called an **event horizon** in an asymptotically flat space. The event horizon is the boundary (the set of points) in space-time from which one can escape to infinity, or the boundary of the set of points that one can see from the infinite future. Then the black hole is a region from which no signal can escape to the exterior of the event horizon.

If we assume that singularities do not exist in the exterior of the event horizon, a stationary black-hole structure is uniquely described by the Kerr metric [6]. In the case of spherically symmetric collapse, this assumption is verified and the final metric is given by the Schwarzschild metric. However, it is not known whether this assumption is true in more general gravitational collapse.

360 (XXI.8) Renaissance Mathematics

Toward the middle of the 13th century, scholastic theology and philosophy were at their height with the *Summa theologiae* of Thomas Aquinas (1225?–1274); but in the latter half of the century, the English philosopher Roger Bacon (1214–1294) attacked Aquinian philosophy in his *Opus majus*, insisted on the importance of experimental methods in science, and strongly urged the study of mathematics. The Renaissance flourished first in Italy, then in other European countries in the 15th and 16th centuries, in the domains of the arts and literature. Newer ideas in mathematics and the natural sciences dominated the 17th century. However, it was the invention of printing in the 15th century, the translation of the Greek texts of Euclid and Archimedes into European languages, and the importation of Arabian science into Europe during the Renaissance that prepared for this development.

In the 15th century, the German priest Nicolaus Cusanus (1401–1464) discussed infinity, the convergence of infinite series, and some problems of quadrature. During the same period, the German scholar Regiomontanus (1436–1476) wrote the first systematic treatise on trigonometry independent of astronomy. Leonardo da Vinci (1452–1519), the all-encompassing genius born in the same century, left manuscripts in which he wrote about mechanics, geometric optics, and perspective. Da Vinci's contemporary, the German painter A. Dürer (1471–1528), wrote a textbook on perspective. In 1494, L. Pacioli (1445?–1514) published *Summa de arithmetica*, one of the first printed books on mathematics. Its content, influenced by Arabian mathematics, includes practical arithmetic and double-entry bookkeeping. The book enjoyed wide popularity.

The best known result of 16th-century mathematics is the solution of algebraic equations of degrees 3 and 4 by the Italian mathematicians Scipione del Ferro, N. Tartaglia (1506–1557), G. Cardano (1501–1576), and L. Ferrari (1522–1565). Cardano published the

solution of equations of the third degree in his book *Ars magna* (1545). The solution was due to Tartaglia, to whom acknowledgment was made, although publication of the method was against his will. This constitutes a famous episode in the history of mathematics, but what is historically more important is the fact that essential progress beyond Greek mathematics was made by mathematicians of this period, since the Greeks were able to solve equations only of degrees 1 and 2. Algebra was subsequently systematized by the French mathematician F. Viète (1540–1603).

By the end of the 15th century, practical mathematics (influenced by the Arabians) had become popular in Europe, and more advanced mathematics began to be studied in European universities, especially in Italy. In 1543, N. Copernicus (1473–1543) published his heliocentric theory (1543); G. Galilei (called Galileo) (1564–1642), the indomitable proponent of this theory, was also born in the 16th century. Copernicus studied at the Universities of Bologna, Padua, and Ferrara; Galileo studied at the University of Pisa and taught at the Universities of Pisa, Padua, and Florence. A system of numeration was imported from Arabia to Europe in the 13th century; by the time of S. Stevin (1548?–1620?) it took the definite form of a decimal system, and with the development and acceptance of printing, the forms of the numerals became fixed.

361 (XX.32) Renormalization Group

A. Introduction

The concept of renormalization was introduced by S. Tomonaga, J. S. Schwinger, M. Gell-Mann, and F. E. Low in order to overcome the difficulty of divergence in field theory. If the upper bound of the momentum is limited to a finite cutoff value Λ , then physical quantities, for example, the mass m of an electron, can be obtained as finite quantities by letting

Λ go to infinity after summing all divergent terms. This is called the **renormalization method** using **subtraction**. Since the cutoff Λ is arbitrary insofar as it is finite, the Green's functions are indefinite because they depend on Λ . This dependence on the cutoff Λ corresponds to the response for the scale transformation of length, and this transformation is a certain (semi) group, called a **renormalization group**. Several kinds of renormalization group have been used in field theory, as well as in the statistical mechanics of phase transition.

B. Renormalization Group in Field Theory
[1-3]

A typical method to resolve the ultraviolet divergence is to add **subtraction terms** in the Lagrangian so that they cancel the divergence. This cancellation is usually performed in each order of the perturbation expansion. When the addition of a finite number of subtraction terms cancels the divergence, the relevant Hamiltonian is said to be **renormalizable**. Otherwise it is called **unrenormalizable**. The Lagrangian density

$$\mathcal{L}_0 = \frac{1}{2} \partial^\mu \varphi_0 \partial_\mu \varphi_0 - \frac{1}{2} m_0^2 \varphi_0^2 - \frac{1}{4!} g_0 \varphi_0^4,$$

for example, can be renormalized by the transformation $\varphi_0 = Z_3^{1/2} \varphi$, $g_0 = Z_1 Z_3^{-2} g$, and $m_0^2 = m^2 + \delta m^2$. All the divergences are taken into the renormalization constants Z_3 , Z_1 , and δm^2 , so that the renormalized quantities φ , g , and m are finite. These renormalization constants can be calculated by means of a perturbation method, but the requirement of circumventing the divergences alone is not sufficient to determine them explicitly. This indeterminacy is usually expressed as $Z_3(\mu)$ and $Z_1(\mu)$, i.e., in terms of a parameter μ , called the renormalization point. The μ -dependence of these functions can be determined by means of the following renormalization conditions:

$$\lim_{p^2 + \mu^2 \rightarrow 0} (p^2 + m^2) G^{(2)}(p, \mu) = 1;$$

$$\Gamma(p_i, \mu) = 1, \quad p_i p_j = \frac{\mu^2}{3} (1 - 4\delta_{ij}).$$

Since the renormalization constants depend on the continuous parameter μ , the renormalized Green's function and coupling constant g are also functions of μ , and consequently the quantity $d^{(2N)}(\{p_i\}, \mu, g(\mu))$ defined by

$$d^{(2N)}(\{p_i\}, \mu, g(\mu)) \equiv \left[\prod_{i=1}^{2N} (p_i^2 + m^2) \right] G^{(2N)}(p_i, \mu, g(\mu))$$

satisfies the **renormalization equation**

$$\left(\mu \frac{\partial}{\partial \mu} + \beta \frac{\partial}{\partial g} - 2N\gamma \right) d^{(2N)}(\{p_i\}, \mu, g) = 0,$$

where $\beta = \mu dg/d\mu$ and $\gamma = \frac{1}{2} \mu d \log Z_3(\mu)/d\mu$. If the coefficients β and γ are calculated perturbationally up to a certain order, the renormalized Green's function is obtained up to the same order by solving the foregoing renormalization equation. This is the first kind of renormalization group. A second kind expresses the response of the renormalized Green's function to the change in the mass and coupling constant, and is expressed by the **Callan-Symanzik equation** [4, 5]

$$\left(m \frac{\partial}{\partial m} + \beta(g) \frac{\partial}{\partial g} + 2N\gamma_\varphi(g) \right) G_R^{(2N)} = \Delta G_G^{(2N)},$$

where $\beta(g) = Z m_0 \partial g / \partial m_0$ and $\gamma_\varphi(g) = \frac{1}{2} Z m_0 \partial \log Z_3 / \partial m_0$, and where Z is determined by $Z m_0 \partial m / \partial m_0 = m$. The inhomogeneous term is defined by

$$\Delta G_R^{(2N)} = Z m_0 \frac{\partial}{\partial m_0} G_R^{(2N)} + Z m_0 \frac{\partial}{\partial m_0} (N \log Z_3) G_R^{(2N)}.$$

The irreducible Green's function $\Gamma_R^{(2N)}$ satisfies

$$\left(m \frac{\partial}{\partial m} + \beta(g) \frac{\partial}{\partial g} - 2N\gamma_\varphi(g) \right) \Gamma_R^{(2N)} = i \Delta \Gamma_R^{(2N)}.$$

Since the inhomogeneous term can be neglected in the high-energy region, the foregoing equation becomes homogeneous, and consequently its solution is

$$\Gamma_R^{(2N)} \left(p_i, \frac{m}{\lambda}, g \right) = \exp \left[-2N \int_a^{g(\lambda)} \gamma(g') \beta^{-1}(g') dg' \right] \times \Gamma_R^{(2N)}(p_i, m, g(\lambda)).$$

Here $g(\lambda)$ is the solution of the equation $\int_a^{g(\lambda)} \beta^{-1}(g') dg' = \log \lambda$. Since dimensional analysis yields $\Gamma_R^{(2N)}(\lambda p_i, m, g) = \lambda^{4-2N} \Gamma_R(p_i, m/\lambda, g)$, the foregoing solution shows that high-energy phenomena can be described by the low-energy phenomena whose coupling constant is given by $g_\infty \equiv g(\infty)$. In particular, when $g_\infty = 0$, high-energy phenomena are described by the asymptotically free field. This circumstance is called **asymptotic freedom**.

C. Renormalization Group Theory in Statistical Physics

The renormalization group technique has proved to be powerful in statistical physics,

Renormalization Group

particularly in studies of phase transitions and critical phenomena [6–10]. The correlation length ξ diverges like $\xi(T) \sim (T - T_c)^{-\nu}$ near the critical point T_c , where ν is called the **critical exponent** of ξ . Similarly, the correlation function $C(R)$ for the distance R behaves like $C(R) \sim R^{-(d-2+\eta)} \times \exp(-\kappa R)$, $\kappa = \xi^{-1}$, where d is the dimensionality of the system and η is the exponent describing the deviation of the singular behavior of $C(R)$ from classical theory. Renormalization is useful in evaluating these critical exponents systematically. The fundamental idea is to eliminate some degrees of freedom, to find recursion formulas for interaction parameters, and then to evaluate critical exponents from their asymptotic behavior near the fixed point. There are many different ways of carrying out this idea explicitly. Roughly classifying these into two groups, we have (i) momentum-space renormalization group theories [6–10] and (ii) real-space renormalization group theories [10, 11].

The common fundamental structure of these renormalization group techniques is explained as follows. First the momentum space or real space is divided into cells and rapidly fluctuating parts, namely, small-momentum parts inside each cell are integrated or eliminated, and consequently the remaining slowly fluctuating parts, namely, long-wave parts, are renormalized. The original Hamiltonian \mathcal{H}_0 is transformed into \mathcal{H}_1 by means of this elimination process and by some scale transformation that preserves the phase space volume. This renormalization operation is written as \mathbf{R}_b ; i.e., $\mathcal{H}_1 = \mathbf{R}_b \mathcal{H}_0$. Similarly we have $\mathcal{H}_2 = \mathbf{R}_b \mathcal{H}_1 = \mathbf{R}_b^2 \mathcal{H}_0, \dots, \mathcal{H}_n = \mathbf{R}_b \mathcal{H}_{n-1} = \mathbf{R}_b^n \mathcal{H}_0, \dots$. This transformation \mathbf{R}_b has the (semi) group property $\mathbf{R}_{bb'} = \mathbf{R}_b \mathbf{R}_{b'}$. A generator \mathbf{G} is defined by $\mathbf{G} = \lim_{b \rightarrow 1+0} (\mathbf{R}_b - 1)/(b - 1)$. That is, $\mathbf{R}_b = \exp(b\mathbf{G})$, $e^1 = b$. The transformation of \mathcal{H} is expressed as $d\mathcal{H}/d\ln b = \mathbf{G}[\mathcal{H}]$. The fixed point $\mathcal{H}^* = \mathbf{R}_b \mathcal{H}^*$ is the solution of $\mathbf{G}[\mathcal{H}^*] = 0$. In order to find critical exponents from the asymptotic behavior of \mathbf{G} near \mathcal{H}^* , we consider a Hamiltonian of the form $\mathcal{H} = \mathcal{H}^* + wQ$ and expand $\mathbf{G}[\mathcal{H}]$ as $\mathbf{G}[\mathcal{H}^* + wQ] = w\mathbf{K}Q + O(w^2)$. If the operator \mathbf{K} thus defined has a negative eigenvalue λ_i , the corresponding physical quantity Q_i becomes irrelevant after repeating the renormalization procedure, and the physical quantity Q_j corresponding to a positive eigenvalue $\lambda_j > 0$ becomes relevant. Thus, by introducing a field h_j conjugate to the relevant operator Q_j , we study the Hamiltonian $\mathcal{H} = \mathcal{H}^* + \sum_j h_j Q_j$. The free energy per unit volume $f[\mathcal{H}] \equiv f(h_1, h_2, \dots)$ is found to have the scaling property

$$f(h_1, \dots, h_j, \dots) \simeq b^{-d} f(b^{\lambda_1} h_1, \dots, b^{\lambda_j} h_j, \dots).$$

By taking Q_1 as the energy operator, we have $h_1 \sim T - T_c \equiv t$. By the normalization $b^{\lambda_1} h_1 = 1$, we obtain the scaling law

$$f(t, \dots, h_j, \dots) \simeq t^{d/\lambda_1} f(1, \dots, h_j/t^{\varphi_j}, \dots).$$

The critical exponent of the specific heat defined by $C \sim t^{-\alpha}$ is given by the formula $\alpha = 2 - d/\lambda_1$. Other scaling exponents $\{\varphi_j\}$ can be obtained via the formula $\varphi_j = \lambda_j/\lambda_1$ from the eigenvalues of \mathbf{K} . The simplest example of \mathbf{R}_b is the case where a single interaction parameter K is transformed into a new parameter K' by $K' = f_b(K)$. The fixed point K^* is given by the solution of $K^* = f_b(K^*)$. The correlation exponent ν defined by $\xi \sim (K - K^*)^{-\nu}$ is given by the Wilson formula $\nu = \log b / \log \Lambda$, $\Lambda = (df_b/dK)_{K=K^*}$. In most cases, \mathbf{R}_b is constructed perturbationally, and critical exponents are usually calculated in power series of $\varepsilon \equiv d_c - d$, as $\varphi = \varphi_0 + \varphi_1 \varepsilon + \varphi_2 \varepsilon^2 + \dots$, where d_c denotes the critical dimension. This is called the ε -**expansion**. The first few terms are calculated explicitly for specific models, such as the φ^4 -model. By applying the Borel sum method to these ε -expansions, one can estimate critical exponents [10, 11].

The renormalization group method can be applied to other many-body problems, such as the Kondo effect [12].

362 (IV.16) Representations

A. General Remarks

For a mathematical system A , a mapping from A to a similar (but in general “more concrete”) system preserving the structure of A is called a **representation** of A . In this article, we consider the representations of \dagger groups and \dagger associative algebras. For representations of other algebraic systems \rightarrow 42 Boolean Algebras; 231 Jordan Algebras; 248 Lie Algebras. For topological, analytic, and algebraic groups \rightarrow 13 Algebraic Groups; 69 Compact Groups; 249 Lie Groups; 422 Topological Abelian Groups; 423 Topological Groups; 437 Unitary Representations. For specific groups \rightarrow 60 Classical Groups; 61 Clifford Algebras.

B. Permutation Representations of Groups

We denote by \mathfrak{S}_M the group of all \dagger permutations of a set M (\rightarrow 190 Groups B). A **permutation representation** of a group G in M is a homomorphism $G \rightarrow \mathfrak{S}_M$. We denote by a_M the permutation of M corresponding to $a \in G$ and write $a_M(x) = ax$ ($x \in M$). Then we have a condition $(ab)x = a(bx)$, $1x = x$ ($a, b \in G$, 1 is the identity element, $x \in M$). In general, if the product $ax \in M$ of $a \in G$ and $x \in M$ is defined and satisfies this condition, then G is said to **operate on M from the left**, and M is called a **left**

G -set. Giving a permutation representation of G in M is equivalent to giving the structure of a left G -set to M . A **reciprocal permutation representation** of G in M is an \dagger antihomomorphism $G \rightarrow \mathfrak{S}_M$, which becomes a homomorphism if we define the multiplication in \mathfrak{S}_M by the right notation $x(fg) = (xf)g$. If the product $xa \in M$ of $a \in G$ and $x \in M$ is defined and satisfies the conditions $x(ab) = (xa)b$ and $x1 = x$, then, as before, G is said to **operate on M from the right**, and M is called a **right G -set**. Giving a reciprocal permutation representation of G in M is equivalent to giving the structure of a right G -set to M .

A (reciprocal) permutation representation is said to be **faithful** if it is injective; the corresponding G -set is also said to be faithful. In particular, we can take G itself as M and define the left (right) operation by the multiplication from the left (right). Then we have a faithful permutation representation (reciprocal permutation representation), which is called the **left (right) regular representation** of G . For $a \in G$, the induced permutation $a_G: x \rightarrow ax$ (xa) is called the **left (right) translation** by a .

We call a left G -set simply a G -set. If a subset N of a G -set M satisfies the condition that $a \in G$, $x \in N$ implies $ax \in N$, then N forms a G -set, which is called a **G -subset** of M . If a G -set M has no proper G -subset (i.e., one different from M itself and the empty subset), then for any two elements $x, y \in M$ there exists an element $a \in G$ satisfying $ax = y$. In this case, the operation of G on M is said to be **transitive**, and the corresponding permutation representation is also said to be transitive. If an equivalence relation R in a G -set M is compatible with the operation of G (i.e., R satisfies the condition that $a \in G$, $R(x, y)$ implies $R(ax, ay)$), then the quotient set M/R forms a G -set in the natural way, called the **quotient G -set** of M by R . If a G -set M has no nontrivial quotient G -set, i.e., if the only equivalence relations compatible with the operation are

$$R(x, x') \text{ for any } x, x' \in M$$

and

$$R(x, x') \text{ if and only if } x = x',$$

then the operation of G on M and the corresponding permutation representation are said to be **primitive**.

A mapping $f: M \rightarrow M'$ of G -sets is called a **G -mapping (G -map)** if the condition $f(ax) = af(x)$ ($a \in G$, $x \in M$) is satisfied. G -injection, G -surjection, and G -bijection are defined naturally. The inverse mapping of a G -bijection is also a G -bijection. Two permutation representations are said to be **similar** if there exists a G -bijection between the corresponding G -sets.

Let M be a transitive G -set, and fix any element $x \in M$. If we view G as a G -set, the mapping $f: G \rightarrow M$ defined by $f(a) = ax$ is a G -surjection and induces a G -bijection $\bar{f}: G/R \rightarrow M$. Here an equivalence class of R is precisely a left coset of the **stabilizer (stability group or isotropy group)** $H_x = \{a \in G \mid ax = x\}$. Hence we have a G -bijection $G/H_x \rightarrow M$. Conversely, for any subgroup H of G , G/H is a transitive left G -set. A transitive G -set is called a **homogeneous space of G** .

For a family $\{M_\lambda\}_{\lambda \in \Lambda}$ of G -sets, the Cartesian product $\prod_{\lambda \in \Lambda} M_\lambda$ and the direct sum $\sum_{\lambda \in \Lambda} M_\lambda$ become G -sets in the natural way; they are called the **direct product** of G -sets and the **direct sum** (i.e., disjoint union) of G -sets, respectively. Every G -set M is the direct sum of a family $\{M_\lambda\}$ of transitive G -subsets, and each M_λ is called an **orbit** (or **system of transitivity**). For a G -set M , the direct product G -set $M^k = M \times \dots \times M$ (k times) contains a G -subset $M^{(k)} = \{(x_1, \dots, x_k) \mid i \neq j \text{ implies } x_i \neq x_j\}$. If $M^{(k)}$ is transitive, M is said to be **k -ply transitive**. If M is transitive and the stabilizer of each point of M consists of the identity element alone, M is said to be **simply transitive**.

If M has n elements, a permutation representation of a group G in M is said to be of **degree n** . When G is a group of permutations of M , the canonical injection $G \rightarrow \mathfrak{S}_M$ is a faithful permutation representation; this case has been studied in detail (\rightarrow 151 Finite Groups G).

C. Linear Representations of Groups and Associative Algebras

Let K be a commutative ring with unity element and M be a K -module. Though we shall mainly treat the case where K is a field and M is a finite-dimensional linear space over K , the case where K is an integral domain and M is a free module over K of finite rank is also important. Since K is commutative, we can write $\lambda x = x\lambda$ ($\lambda \in K, x \in M$). Let $\mathcal{E}_K(M)$ be the associative algebra over K consisting of all K -endomorphisms of M , and let $GL(M)$ be the group of all invertible elements in $\mathcal{E}_K(M)$, where we assume $M \neq \{0\}$. Let A be an associative algebra over K . A **linear representation of the algebra A** in M is an algebra homomorphism $A \rightarrow \mathcal{E}_K(M)$. We always assume that A has a unity element and the homomorphisms are unitary. For convenience, we can also consider a linear representation in the trivial space $M = \{0\}$, which is called the **zero representation**. A **reciprocal linear representation** is an antihomomorphism $A \rightarrow \mathcal{E}_K(M)$. A **linear representation of a group G** in M is a group homomorphism $G \rightarrow GL(M)$. This can

be extended uniquely to a linear representation of the group ring $K[G]$ in M , and conversely, the restriction of a linear representation of $K[G]$ in M to G is a linear representation of G ; and similarly for reciprocal linear representations. Thus the study of (reciprocal) linear representations of a group G in M can be reduced to the study of (reciprocal) linear representations of the group ring $K[G]$ in M .

We now consider the linear representation of associative algebras, which we call simply "algebras." (Note that a group ring has a canonical basis—the group itself—and allows a more detailed investigation; \rightarrow Sections G, I.)

Given a commutative ring K with unity and a linear representation ρ of a K -algebra A in a K -module M , we introduce the structure of a left A -module into M by defining $ax = \rho(a)x$ ($a \in A, x \in M$); the structure of a K -module in M obtained by the canonical homomorphism $K \rightarrow A$ coincides with the original one. This A -module is called the **representation module** of ρ . Conversely, for any left A -module M we can define a linear representation ρ of A in M (with M viewed as a K -module via $K \rightarrow A$) by putting $\rho(a)x = ax$; the representation module of ρ coincides with the original one. This representation ρ is called the **linear representation associated with M** . A reciprocal linear representation of A corresponds to a right A -module. Thus the study of (reciprocal) linear representations of A is equivalent to the study of left (right) A -modules. For instance, if the operation of a group G on M is trivial: $\sigma x = x$ ($\sigma \in G, x \in M$), the corresponding representation of G in M assigns the identity mapping I_M to every $\sigma \in G$. Furthermore, if $M = K$, this representation is called the **unit representation** of G (over K).

Let ρ, ρ' be linear representations of A in K -modules M, M' , respectively. Then an A -homomorphism $M \rightarrow M'$ is precisely a K -homomorphism $f: M \rightarrow M'$ satisfying the condition $f \circ \rho(a) = \rho'(a) \circ f$ ($a \in A$); this is sometimes called a **homomorphism** from ρ to ρ' . In particular, an A -isomorphism is a K -isomorphism $f: M \rightarrow M'$ satisfying the condition $f \circ \rho(a) \circ f^{-1} = \rho'(a)$ ($a \in A$); in this case we say that ρ and ρ' are **similar (isomorphic or equivalent)** and write $\rho \cong \rho'$.

Let M be the representation module of a linear representation ρ of an algebra A . If ρ is injective, ρ and the corresponding M are said to be **faithful**. For example, the linear representation associated with the left A -module A is faithful; this is called the **(left) regular representation** of A . If M is simple as an A -module, ρ is said to be **irreducible (or simple)**. A homomorphism from an irreducible representation ρ to ρ must be an isomorphism or the zero

homomorphism (**Schur's lemma**). In particular, if K is an algebraically closed field and M is finite-dimensional, then such a homomorphism is a scalar multiplication. A linear representation is said to be **reducible** if it is not irreducible. If M is semisimple as an A -module, ρ is said to be **completely reducible** (or **semisimple**). If A is a semisimple ring, any linear representation of A is completely reducible. The converse also holds (\rightarrow 368 Rings G).

The linear representations associated with a submodule and a quotient module of M as an A -module are called a **subrepresentation** and a **quotient representation**, respectively. The linear representation associated with the direct sum $M_1 + \dots + M_r$ of the representation modules M_1, \dots, M_r of linear representations ρ_1, \dots, ρ_r is written $\rho_1 + \dots + \rho_r$ and called the **direct sum** of representations. If ρ is never similar to the direct sum of two nonzero linear representations, then ρ is said to be **indecomposable**; this means that M is indecomposable as an A -module.

For linear representations ρ, ρ' of a group G in M, M' , we define the linear representation $\rho \otimes \rho'$ in $M \otimes M'$ by $(\rho \otimes \rho')(g) = \rho(g) \otimes \rho'(g)$ ($g \in G$); this is called the **tensor product** of representations ρ and ρ' .

D. Matrix Representations

Let K^n be the K -module consisting of all n -tuples (ξ_i) of elements in a commutative ring K . $\mathcal{E}_K(K^n)$ is identified with the K -algebra $M_n(K)$ of all $n \times n$ matrices (λ_{ij}) over $K: (\lambda_{ij})(\xi_j) = (\sum_{j=1}^n \lambda_{ij} \xi_j)$. Thus a linear representation of A in K^n , i.e., a homomorphism $A \rightarrow M_n(K)$, is called a **matrix representation** of A over K , and n is called its **degree**. A matrix representation of a group G over K of degree n is a homomorphism $G \rightarrow GL(n, K)$, where $GL(n, K)$ is the group of all $n \times n$ invertible matrices. If (e_1, \dots, e_n) is a basis of a K -module M , then by the K -isomorphism $K^n \rightarrow M$ given by the assignment $(\xi_i) \rightarrow \sum_{i=1}^n e_i \xi_i$, we have a bijective correspondence between the matrix representations of A of degree n and the linear representations of A in M , and the corresponding representations are similar. Explicitly, the linear representation ρ corresponding to a matrix representation $a \rightarrow (\lambda_{ij}(a))$ is given by

$$\rho(a)e_j = \sum_{i=1}^n e_i \lambda_{ij}(a), \quad a \in A.$$

Hence giving the finite-dimensional linear representations over a field K is equivalent to giving the matrix representations over K . Let T, T' be matrix representations of degree n, n' . Then a homomorphism from T to T' is an $n' \times n$ matrix P satisfying $PT(a) = T'(a)P$ ($a \in A$).

Therefore T and T' are similar if and only if $n = n'$ and $PT(a)P^{-1} = T'(a)$ ($a \in A$) for some $n \times n$ invertible matrix P . For a representation of a group G , it suffices that this equation is satisfied by all $a \in G$.

We always assume that K is a field. Then a K -module is a linear space over K . A linear representation ρ over K of a K -algebra A is said to be of **degree n** if its representation module M is of dimension n over K . Suppose that a sequence $\{0\} = M_0 \subset M_1 \subset \dots \subset M_r = M$ of A -submodules of M is given. We take a basis (e_1, \dots, e_n) of M over K such that (e_1, \dots, e_{m_i}) forms a basis of M_i over K ($1 \leq i \leq r$). Then the matrix representation corresponding to ρ relative to the basis (e_1, \dots, e_n) has the form

$$a \rightarrow T(a) = \begin{pmatrix} T_{11}(a) & T_{12}(a) & \dots & T_{1r}(a) \\ & T_{22}(a) & \dots & T_{2r}(a) \\ & & \ddots & \vdots \\ 0 & & & T_{rr}(a) \end{pmatrix}$$

where, if we put $n_i = \dim M_i/M_{i-1} = m_i - m_{i-1}$, $T_{ij}(a)$ is an $n_i \times n_j$ matrix and $T_{ij}(a) = 0$ for $i > j$. The residue classes of $e_{m_{i-1}+1}, \dots, e_{m_i}$ form a basis of the quotient space M_i/M_{i-1} over K , and the matrix representation corresponding to the linear representation ρ_i associated with M_i/M_{i-1} relative to this basis is given by T_{ii} . The sequence $\{M_i\}$ is a **composition series** if and only if each ρ_i (hence T_{ii}) is irreducible. In this case, ρ_1, \dots, ρ_r are uniquely determined by ρ up to their order and similarity (**Jordan-Hölder theorem**). An irreducible representation ρ' similar to some ρ_i is called an **irreducible component** of ρ . The number $p > 0$ of ρ_i similar to ρ' is called the **multiplicity** of ρ' as an irreducible component of ρ . We also say that ρ contains ρ' p times or ρ' appears p times as an irreducible component of ρ . The representation ρ is completely reducible if and only if it is similar to the direct sum of its irreducible components (admitting repetition). In this case, ρ is similar to the matrix representation

$$a \rightarrow \begin{pmatrix} T_{11}(a) & & 0 \\ & \ddots & \\ 0 & & T_{rr}(a) \end{pmatrix}.$$

E. Coefficients and Characters of Linear Representations

We consider the linear representations of an algebra over a field K . A right (left) A -module M is regarded as a linear space over K . In its dual space M^* , we introduce the structure of a left (right) A -module using the inner product $\langle \cdot, \cdot \rangle$ as follows: $\langle x, ax^* \rangle = \langle xa, x^* \rangle$ ($\langle x, x^* a \rangle$

Representations

$= \langle ax, x^* \rangle$, where $a \in A$, $x \in M$, $x^* \in M^*$. If ρ is the representation associated with M , the representation associated with M^* is called the **transposed representation (dual representation or adjoint representation)** of ρ , and is denoted by ${}^t\rho$. The linear mapping ${}^t\rho(a)$ is the t transposed mapping of $\rho(a)$. If M is finite-dimensional over K , we have $(M^*)^* = M$ as an A -module. For a linear representation ρ of a group G , the mapping $g \rightarrow {}^t\rho(g)^{-1}$ ($g \in G$) is called the **contragredient representation** of ρ . The reciprocal linear representation associated with the right A -module A is called the **right regular representation** of A , and its transposed representation (i.e., the representation associated with the left A -module A^*) is called the **coregular representation** of A . For any finite-dimensional semisimple algebra and group ring of a finite group, the regular representation and the coregular representation are similar (\rightarrow 29 Associative Algebras H).

Let ρ be a linear representation of A over K and M be its representation module. For any $x \in M$, $x^* \in M^*$, we define a t linear form $\rho_{x,x^*} \in A^*$ on A by $\rho_{x,x^*}(a) = \langle ax, x^* \rangle$ ($a \in A$). This is called the **coefficient** of ρ relative to x, x^* and is determined by its values at generators of A as a linear space. In particular, a coefficient of a linear representation ρ of a group G can be regarded as a function on G taking values in K . For a fixed $x^* \in M^*$ the assignment $x \rightarrow \rho_{x,x^*}$ gives an A -homomorphism $M \rightarrow A^*$, where A^* is considered as a left A -module. Therefore any nonzero coefficient ρ_{x,x^*} of an irreducible representation ρ generates an A -submodule of A^* isomorphic to M . In other words, any irreducible representation of A is similar to some subrepresentation of the coregular representation of A . In particular, any irreducible representation of a finite-dimensional semisimple algebra or a finite group is an irreducible component of the regular representation. Let A_ρ^* be the subspace of A^* generated by all coefficients ρ_{x,x^*} ($x \in M$, $x^* \in M^*$) for a given linear representation ρ . Then $\rho \cong \rho'$ implies $A_\rho^* = A_{\rho'}^*$. If ρ_1, \dots, ρ_r are irreducible representations of A such that ρ_i and ρ_j are not similar unless $i=j$, the sum $A_{\rho_1}^* + \dots + A_{\rho_r}^*$ in A^* is direct. In particular, for a semisimple algebra A , let the ρ_i ($1 \leq i \leq r$) be the irreducible representations associated with the minimal left ideals of the t simple components A_i of A . Then any irreducible representation is similar to one and only one of ρ_1, \dots, ρ_r , and A^* can be decomposed into the direct sum of $A_{\rho_1}^*, \dots, A_{\rho_r}^*$. In addition, each $A_{\rho_i}^*$ is canonically identified with A_i^* .

We shall treat finite-dimensional representations exclusively. Let (e_1, \dots, e_n) be a basis of the representation module M of ρ over K , and let $a \rightarrow T(a) = (\lambda_{ij}(a))$ be the matrix representa-

tion that corresponds to ρ with respect to this basis. Then $\lambda_{ij} = \rho_{e_j, e_i^*}$ ($1 \leq i, j \leq n$), where (e_1^*, \dots, e_n^*) is the dual basis. If K is algebraically closed and ρ is irreducible (or more generally, t absolutely irreducible), then $\{\lambda_{ij}\}$ is linearly independent; therefore we have $\dim A_\rho^* = n^2$ (G. Frobenius and I. Schur). We take a matrix representation T corresponding to ρ and put $\chi_\rho(a) = \text{tr } T(a)$ ($a \in A$). Then χ_ρ is a function on A that is uniquely determined by ρ and belongs to A_ρ^* ; χ_ρ is called the **character** of ρ . For a linear representation ρ of a group G , the character of ρ can be regarded as a function on G . Moreover, it can be viewed as a function on the set of all t conjugate classes of G . The character of ρ is equal to the sum of the characters of the irreducible components of ρ taken with their multiplicities. The character of an irreducible representation is called an **irreducible character** (or **simple character**). If K is of characteristic 0, then $\rho \cong \rho'$ is equivalent to $\chi_\rho = \chi_{\rho'}$, and the different irreducible characters are linearly independent. The character of an absolutely irreducible representation (\rightarrow Section F) is called an **absolutely irreducible character**. If we consider absolutely irreducible characters only, the statement holds irrespective of the characteristic of K .

The sum of all absolutely irreducible characters of A is called the **reduced character** (or **reduced trace**) of A . The direct sum of all absolutely irreducible representations of A is called the **reduced representation** of A , and its character is equal to the reduced character. The determinant of the reduced representation is called the **reduced norm** of A .

F. Scalar Extension of Linear Representations

Let K, L be commutative rings with unity element, and fix a homomorphism $\sigma: K \rightarrow L$. We denote by M^σ the scalar extension $\sigma^*(M) = M \otimes_K L$ of a K -module M relative to $\sigma: x\lambda \otimes \mu = x \otimes \lambda^\sigma \mu$ ($x \in M; \lambda \in K, \mu \in L$) (\rightarrow 277 Modules L). For an algebra A over K , the scalar extension A^σ of the K -module A has the natural structure of an algebra over $L: (a \otimes \lambda)(b \otimes \mu) = ab \otimes \lambda\mu$ ($a, b \in A; \lambda, \mu \in L$). For a group G , we can regard $(K[G])^\sigma = L[G]: g \otimes \lambda = g\lambda$ ($g \in G, \lambda \in L$). If M is a left A -module, then M^σ has the natural structure of a left A^σ -module; $(a \otimes \lambda)(x \otimes \mu) = ax \otimes \lambda\mu$ ($a \in A, x \in M; \lambda, \mu \in L$). For the linear representation ρ associated with M , the linear representation ρ^σ over L associated with M^σ is called the **scalar extension** of ρ relative to $\sigma: \rho^\sigma(a \otimes 1) = \rho(a) \otimes 1_L$. Let (e_1, \dots, e_n) be a basis of M over K . If the matrix representation $a \rightarrow (\lambda_{ij}(a))$ corresponds to M relative to this basis, then the matrix representation corre-

sponding to M^σ relative to the basis $(e_1 \otimes 1, \dots, e_n \otimes 1)$ over L is given by $a \otimes 1 \rightarrow (\lambda_{ij}(a)^\sigma)$. A linear representation over L is said to be **realizable** in K if it is similar to the scalar extension ρ^σ of some linear representation ρ over K .

In particular, if $\sigma: K \rightarrow L$ is an isomorphism, ρ^σ is called the **conjugate representation** of ρ relative to σ . The conjugate representation relative to the automorphism $\sigma: \lambda \rightarrow \bar{\lambda}$ (complex conjugation) of the complex number field is called the **complex conjugate representation**. If \mathfrak{m} is an ideal of K and $\sigma: K \rightarrow K/\mathfrak{m}$ (\dagger residue class ring) is the canonical homomorphism, then the construction of ρ^σ from ρ is called the **reduction modulo \mathfrak{m}** (\rightarrow Section I). If \mathfrak{p} is a prime ideal of K and $\sigma: K \rightarrow K_{\mathfrak{p}}$ (\dagger local ring) is the canonical homomorphism, then the construction of ρ^σ from ρ is called the **localization** relative to \mathfrak{p} . If K is an integral domain and $\mathfrak{p} = K - \{0\}$, then $K_{\mathfrak{p}}$ is the \dagger field of quotients of K . We can also consider the "completion of representation" with respect to \mathfrak{p} .

Let K be a field, L a field extension, and $\sigma: K \rightarrow L$ the canonical injection. Then for a linear representation ρ of A and its representation module M , the scalar extensions ρ^σ, M^σ are written ρ^L, M^L , respectively. In view of $M \subset M^L, A \subset A^L, \mathcal{E}_K(M) \subset \mathcal{E}_L(M^L)$ by the natural injections, we can regard ρ^L as an extension of the mapping ρ . We shall consider finite-dimensional representations exclusively. For linear representations ρ_1, ρ_2 over $K, \rho_1 \cong \rho_2$ is equivalent to $\rho_1^L \cong \rho_2^L$. An irreducible representation ρ over K is said to be **absolutely irreducible** if its scalar extension ρ^L to any field extension L is irreducible; an equivalent condition is that the scalar extension $\rho^{\bar{K}}$ to the \dagger algebraic closure \bar{K} is irreducible. Another equivalent condition is that every endomorphism of the representation module M of ρ must be a scalar multiplication. If every irreducible representation of A over K is absolutely irreducible, K is called a **splitting field** for A . For a group G , if the field K is a splitting field for the group ring $K[G]$, then K is called a splitting field for G . Let A be finite-dimensional over K . If K is a splitting field for A , any irreducible representation of A^L is realizable in K for any field extension L of K . For an arbitrary field K , the scalar extension ρ^L of an irreducible representation ρ to a \dagger separable algebraic extension L of K is completely reducible. For simplicity, we assume that K is \dagger perfect and $L = \bar{K}$. Then the multiplicities of all irreducible components of ρ^L are the same; this multiplicity is called the **Schur index** of ρ .

The set $S(K)$ of \dagger algebra classes over K , each of which is represented by a (central) simple component of the group algebra $K[G]$ of

some finite group G , is a subgroup of the \dagger Brauer group $B(K)$ of K , known as the **Schur subgroup** of $B(K)$. Recent research has clarified considerably the structure of this group [19].

G. Linear Representations of Finite Groups

Let G be a finite group of order g . The linear representation of G over K is equivalent to the linear representation of the group ring $K[G]$, concerning which we have already stated the general facts. If K is the ring \mathbf{Z} of rational integers, a linear representation over K is sometimes called an **integral representation**. We assume that K is a field. If the characteristic of K is zero or more generally not a divisor of g , every linear representation of G over K is completely reducible (H. Maschke). Such a representation is called an **ordinary representation**. If g is divisible by the characteristic of K , we have a **modular representation** (\rightarrow Section I).

The **exponent** of G is the smallest positive integer n satisfying $a^n = 1$ for every element $a \in G$. A field containing all the n th roots of unity is a splitting field for G (R. Brauer, 1945). Consequently, for such a field K , any scalar extension of an irreducible representation over K is irreducible, and any irreducible representation over any field extension of K is realizable in K . We fix a splitting field K for G and assume that K is of characteristic 0; for example, we can assume $K = \mathbf{C}$.

The number of nonsimilar irreducible representations of G is equal to the number of conjugate classes in G . Each irreducible representation appears as an irreducible component of the regular representation with multiplicity equal to the degree. In addition, each degree is a divisor of the order g of G . Let ρ be a linear representation of a subgroup H of G and M be its representation module. Then the linear representation of G associated with the $K[G]$ -module $K[G] \otimes_{K[H]} M$ is called the **induced representation** and is denoted by ρ^G . If the matrix representation T corresponds to ρ , then using the partition of G into the cosets $G = a_1 H \cup \dots \cup a_r H$ we can write the matrix representation corresponding to ρ^G as

$$a \rightarrow \begin{bmatrix} T(a_1^{-1} a a_1) & \dots & T(a_1^{-1} a a_r) \\ \dots & \dots & \dots \\ T(a_r^{-1} a a_1) & \dots & T(a_r^{-1} a a_r) \end{bmatrix},$$

where we define $T(b) = 0$ for $b \notin H$. The induced representation from a representation of degree 1 of a subgroup is called a **monomial representation**. To such a representation corresponds a matrix representation T such that $T(a)$ has exactly one nonzero entry in each row and column for every $a \in G$. For the trivial sub-

group $H = \{e\}$, we obtain the regular representation of G . In general, for an irreducible representation σ of G and an irreducible representation ρ of a subgroup H , the multiplicity of σ in ρ^G coincides with that of ρ in the restriction σ_H of σ to H (the **Frobenius theorem**). The following **orthogonality relations** hold for irreducible characters χ and ψ of G :

$$\sum_{a \in G} \chi(a)\psi(a^{-1}) = \begin{cases} g, & \chi = \psi, \\ 0, & \chi \neq \psi, \end{cases}$$

$$\sum_{\chi} \chi(a)\chi(b^{-1}) = \begin{cases} g/g_a, & C(a) = C(b), \\ 0, & C(a) \neq C(b). \end{cases}$$

In the second formula, χ ranges over all the irreducible characters of G , $C(a)$ denotes the conjugate class of G containing a , and g_a is the number of elements in $C(a)$.

H. Linear Representations of Symmetric Groups

All irreducible representations of a symmetric group \mathfrak{S}_n over the field \mathbf{Q} of rational numbers are absolutely irreducible. Hence the representation theory of \mathfrak{S}_n over a field of characteristic zero reduces to that over \mathbf{Q} . Since the group algebra $A = \mathbf{Q}[\mathfrak{S}_n]$ is semisimple, to obtain an irreducible representation of \mathfrak{S}_n it is sufficient to find a primitive idempotent (i.e., an idempotent that is not the sum of two orthogonal nonzero idempotents) of A . Such an idempotent can be obtained in the following way. As in Fig. 1, we draw a diagram T consisting of n squares arranged in rows of decreasing lengths, the left ends of which are arranged in a single column. Such a diagram T is called a **Young diagram**; if it has k rows of lengths $f_1 \geq f_2 \geq \dots \geq f_k > 0$, $f_1 + f_2 + \dots + f_k = n$, then it is written $T = T(f_1, \dots, f_k)$. We put the numerals 1 to n in any order into the n squares of $T = T(f_1, f_2, \dots, f_k)$, as in Fig. 1, for example. We then denote by σ any permutation of \mathfrak{S}_n that preserves each row and construct an element of $A: s = \sum \sigma$. Similarly, we denote by τ any permutation of \mathfrak{S}_n that preserves each column and set $t = \sum (\text{sgn } \tau)\tau$. If we set $u = t \cdot s = \sum \pm \tau \cdot \sigma$, then u is a primitive idempotent of A except for a numerical factor. This implies that u yields an irreducible representation of \mathfrak{S}_n . The element u of A is called the **Young symmetrizer** associated with T .

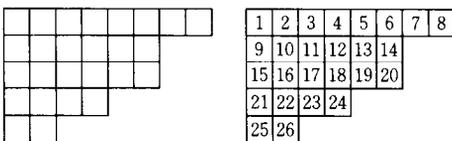

Fig. 1
Young diagram. $n = 26; f_1 = 8, f_2 = 6, f_3 = 6, f_4 = 4, f_5 = 2$.

If we put the numerals 1 to n into the n squares of T in a different order, we obtain another symmetrizer u' associated with T . However, these two irreducible representations associated with u and u' are similar. Hence there corresponds to T a fixed class of irreducible representations of \mathfrak{S}_n , i.e., a fixed irreducible character of \mathfrak{S}_n . Moreover, any two different Young diagrams yield different irreducible characters, and any irreducible character is obtained by a suitable Young diagram. Thus there exists a one-to-one correspondence between the Young diagrams and the irreducible characters of \mathfrak{S}_n .

The method of determining the character associated with a given diagram was found by Schur and H. Weyl (\rightarrow 60 Classical Groups).

I. Modular Representations of Finite Groups

Let G be a finite group of order g , and let K be a splitting field of G of characteristic $p \neq 0$. If p is a divisor of g , we have the case of modular representation, in which the situation is quite different from the case of ordinary representation. The theory of modular representations of a finite group was developed mainly by Brauer after 1935.

The elements of G whose orders are prime to p are called **p -regular**. Let k be the number of p -regular classes of G , i.e., conjugate classes of G containing the p -regular elements. Then there exist exactly k nonsimilar absolutely irreducible modular representations F_1, F_2, \dots, F_k . The number of nonsimilar indecomposable components of the regular representation R of G is also equal to k , and we denote these representations by U_1, U_2, \dots, U_k . We can number them in such a way that F_k appears in U_k as both its top and bottom component. If the degree of F_k is f_k and that of U_k is u_k , then U_k appears f_k times in R and F_k appears u_k times in R . The multiplicities $c_{\kappa\lambda}$ of F_λ in U_κ are called the **Cartan invariants** of G .

Take an algebraic number field Ω that is a splitting field of G . Let \mathfrak{p} be a prime ideal in Ω dividing p , and let \mathfrak{o} be the domain of \mathfrak{p} -integers of Ω . Then the residue class field $\mathfrak{o}/\mathfrak{p}$ is a finite field of characteristic p and a splitting field of G . Hence we can assume that $\mathfrak{o}/\mathfrak{p} = K$, where K is the field considered at the beginning of this section. Let Z_1, Z_2, \dots, Z_n be the nonsimilar irreducible representations of G in Ω . We can assume that all the coefficients of Z_i are contained in \mathfrak{o} . Replacing every coefficient in Z_i by its residue class mod \mathfrak{p} , we obtain a modular representation \bar{Z}_i . The modular representations $\bar{Z}_1, \dots, \bar{Z}_n$ thus obtained may be reducible. The multiplicities $d_{i\kappa}$ of F_κ in \bar{Z}_i are called the **decomposition numbers** of G .

They are related to the Cartan invariants by the fundamental relations

$$c_{\kappa\lambda} = \sum_{i=1}^n d_{i\kappa} d_{i\lambda}.$$

The determinant $|c_{\kappa\lambda}|$ of degree k is a power of p . We set $g = p^e g'$, $(p, g') = 1$. Then we may assume that Ω contains a primitive g' th root of unity $\delta (\in \mathfrak{o})$. Since $(p, g') = 1$, the residue class $\bar{\delta} (\in K)$ of δ is a primitive g' th root of unity. Let M be a modular representation of G . The characteristic roots of $M(a)$ for a p -regular element a are powers $\bar{\delta}^\nu$ of $\bar{\delta}$. We replace each $\bar{\delta}^\nu$ by δ^ν and obtain an element $\xi(a)$ of Ω as the sum of these δ^ν . In this manner we define a complex-valued function ξ on the set of p -regular elements of G . We call ξ the **modular character** (or **Brauer character**) of M . Two modular representations have the same irreducible components if and only if their modular characters coincide. Denoting by φ_κ the modular character of F_κ and by η_κ that of U_κ , we have the following orthogonality relations for the modular characters:

$$\sum_a \varphi_\kappa(a) \eta_\lambda(a^{-1}) = \begin{cases} g, & \kappa = \lambda, \\ 0, & \kappa \neq \lambda, \end{cases}$$

$$\sum_\kappa \varphi_\kappa(a) \eta_\kappa(b^{-1}) = \begin{cases} g/g_\alpha, & C(a) = C(b), \\ 0, & C(a) \neq C(b). \end{cases}$$

In the first sum, a ranges over all p -regular elements of G .

We say that F_κ and F_λ belong to the same **block** if there exists a sequence of indices $\kappa, \alpha, \beta, \dots, \gamma, \lambda$ such that $c_{\kappa\alpha} \neq 0, c_{\alpha\beta} \neq 0, \dots, c_{\gamma\lambda} \neq 0$. This is obviously an equivalence relation, and F_1, F_2, \dots, F_k are classified into a finite number, say s , of blocks B_1, B_2, \dots, B_s . If F_κ belongs to a block B_τ , we say by a stretch of language that the corresponding U_κ also belongs to B_τ . All the irreducible components of \bar{Z}_i belong to the same block since $c_{\kappa\lambda} \neq 0$ if $d_{i\kappa} \neq 0$ and $d_{i\lambda} \neq 0$. If the irreducible components of \bar{Z}_i belong to B_τ , we say that Z_i belongs to B_τ . Let x_τ be the number of Z_i belonging to B_τ and y_τ the number of F_κ belonging to B_τ . Then $x_\tau \geq y_\tau$. If χ_i is the ordinary character of Z_i , then χ_i can be considered as the modular character of \bar{Z}_i . If we denote the degree of Z_i by z_i , then $g_a \chi_i(a)/z_i$ for $a \in G$ is an algebraic integer and hence belongs to \mathfrak{o} . Now Z_i and Z_j belong to the same block if and only if $g_a \chi_i(a)/z_i \equiv g_a \chi_j(a)/z_j \pmod{p}$ for all p -regular elements a of G .

If p^e is the highest power of p that divides all the degrees z_i of Z_i belonging to B_τ , then it is also the highest power of p dividing all the degrees f_κ of F_κ belonging to B_τ . We call $d = e - \alpha$ the **defect** of B_τ ; obviously $0 \leq d \leq e$. If Z_i belongs to a block of defect d , then the power of p dividing z_i is p^{e-d+h_i} ($h_i \geq 0$). A block of

defect 0 contains exactly one ordinary representation Z_i , hence also exactly one modular representation F_κ ($x_\tau = y_\tau = 1$). Moreover, we have $Z_i = F_\kappa = U_\kappa$. It follows that all the degrees z_i of Z_i belonging to a block of defect 1 are exactly divisible by p^{e-1} ; the converse is also true. Z_i belongs to a block of defect 0 if and only if $\chi_i(a) = 0$ for any element a of G whose order is divisible by p .

Let D be any p -Sylow subgroup of the centralizer $C_G(a)$ of an element a of G , and let $(D:1) = p^d$. Then d is called the **defect** of the class $C(a)$, and D is called a **defect group** of $C(a)$. The number of blocks of defect e is equal to the number of p -regular classes of defect e . Let B_τ be a block of defect d . Then there exists a p -regular class of defect d containing an element a such that $g_a \chi_i(a)/z_i \not\equiv 0 \pmod{p}$ for any Z_i in B_τ . The defect group D of $C(a)$ is called the **defect group** of B_τ , and D is uniquely determined up to conjugacy in G . The number of blocks of G with defect group D is equal to the number of blocks of the normalizer $N_G(D)$ with defect group D .

An arbitrary element x of G can be written uniquely as a product $x = sr = rs$, where s , called the p -factor of x , is an element whose order is a power of p , and r is a p -regular element. We say that two elements of G belong to the same **section** if and only if their p -factors are conjugate in G . This is an equivalence relation. Obviously, each section is the union of conjugate classes of G . If the p -factor of x is not conjugate to any element of the defect group D of B_τ , then $\chi_i(x) = 0$ for all Z_i in B_τ . Let $\varphi_1^s, \varphi_2^s, \dots, \varphi_{k(s)}^s$ be the absolutely irreducible modular characters of $C_G(s)$, and let χ'_i be the absolutely irreducible ordinary characters of $C_G(s)$. Since

$$\chi'_i(sr) = \varepsilon_i \chi'_i(r) = \varepsilon_i \sum_\sigma d'_{i\sigma} \varphi_\sigma^s(r), \quad r \in C_G(s),$$

we have

$$\chi_i(sr) = \sum_\tau r_{i\tau} \chi'_i(sr) = \sum_\sigma d_{i\sigma}^s \varphi_\sigma^s(r).$$

The $d_{i\sigma}^s$ are called the **generalized decomposition numbers** of G . If the order of s is p^l , then the $d_{i\sigma}^s$ are algebraic integers of the field of the p^l th roots of unity. Let s be conjugate to an element of D . There corresponds to B_τ a union \bar{B}_τ of blocks of $C_G(s)$, and if $\sigma \neq \rho$, then \bar{B}_τ and \bar{B}_ρ contain no irreducible modular representations in common. We have $d_{i\sigma}^s = 0$ for any Z_i in B_τ (i.e., $\varphi_\sigma^s \notin \bar{B}_\tau$). Brauer's original proof of this result was considerably complicated; simpler proofs were given independently by K. Iizuka and H. Nagao. From these relations we get the following refinement of the orthogonality relations for group characters. If Z_i and Z_j belong to different blocks of G , then $\sum_{a \in S} \chi_i(a) \chi_j(a^{-1}) = 0$, where a ranges over all

the elements belonging to a fixed section S of G . If elements a and b of G belong to different sections, then $\sum \chi_i(a)\chi_i(b^{-1})=0$, where χ_i ranges over all the characters of G belonging to a fixed block B_i .

J. Projective Representations of Finite Groups

Let V be a finite-dimensional linear space over a field K , and let $P(V)$ be the \dagger projective space associated with V (\rightarrow 343 Projective Geometry). The set of all projective transformations of $P(V)$ forms the group $PGL(V)$, which can be identified with the quotient group $GL(V)/K^*1_V$. Here $K^*=K-\{0\}$ and K^*1_V is the set of all scalar multiples of the identity transformation 1_V of V and is the center of $GL(V)$. A homomorphism $G \rightarrow PGL(V)$ is called a **projective representation** of G in V or simply a projective representation of G over K . Two projective representations (ρ, V) and (ρ', V') of G are said to be **similar** if there exists an isomorphism $\varphi: PGL(V) \rightarrow PGL(V')$ induced by a suitable isomorphism $V \rightarrow V'$ such that $\varphi \circ \rho(a) \circ \varphi^{-1} = \rho'(a)$ ($a \in G$). Let $V_1 \neq \{0\}$ be a subspace of V . We can assume that $P(V_1) \subset P(V)$. If (ρ, V) is a projective representation of G such that each $\rho(a)$ ($a \in G$) leaves $P(V_1)$ invariant, we get a projective representation (ρ_1, V_1) by restricting the $\rho(a)$ to $P(V_1)$. In this case (ρ_1, V_1) is called a **subrepresentation** of ρ . A projective representation is said to be **irreducible** if there exists no proper subrepresentation of ρ .

A mapping $\sigma: G \rightarrow GL(V)$ is called a section for (ρ, V) if $\pi(\sigma(a)) = \rho(a)$ for each $a \in G$, where π is the natural projection of $GL(V)$ onto $PGL(V)$. Any section σ defines a mapping $f: G \times G \rightarrow K^*$ satisfying $\sigma(a)\sigma(b) = f(a, b)\sigma(ab)$ ($a, b \in G$). The set $\{f(a, b)\}_{a, b \in G}$ is called the **factor set** of ρ with respect to σ . The mapping f is a \dagger 2-cocycle of G with values in K^* . The 2-cohomology class $c_\rho \in H^2(G, K^*)$ of f is determined by ρ and is independent of the choice of sections for ρ . A projective representation ρ has a section σ which is a linear representation of G in V if and only if $c_\rho = 1$. If G is a finite group, for any $c \in H^2(G, K^*)$ there exists an irreducible projective representation ρ of G over K which belongs to c , i.e., $c_\rho = c$. If ρ and ρ' are similar, then $c_\rho = c_{\rho'}$. The tensor product $\rho \otimes \rho'$ of two projective representations ρ and ρ' can be defined as in the case of linear representations, and we have $c_{\rho \otimes \rho'} = c_\rho \cdot c_{\rho'}$. If K is algebraically closed, then $H^2(G, K^*)$ is determined by the characteristic of K . When K is the complex field \mathbb{C} , the group $H^2(G, \mathbb{C}^*) = \mathfrak{M}(G)$ is called the **multiplier** of G . If $\mathfrak{M}(G) = 1$, then G is called a **closed group**, and any projective representation of G is induced by a

linear representation of G . In general, if ρ is a projective representation of G over \mathbb{C} , then the order of c_ρ is a divisor of the degree of ρ (dimension of V). Moreover, if ρ is irreducible, then both the degree of ρ and the square of the order of c_ρ are divisors of the order of G . K. Yamazaki, among others, studied the projective representations of finite groups in detail.

K. Integral Representations

Every complex matrix representation of G is equivalent to a matrix representation in the ring of algebraic integers. If an algebraic number field K is specified, every $K[G]$ -module V contains G -invariant R -lattices (briefly, G -lattices), where R is the ring of integers in K . A G -lattice L is characterized as an $R[G]$ -module, which is finitely generated and \dagger torsion free (hence \dagger projective) as an R -module. It provides an **integral representation** of G as an automorphism group of the R -projective module L .

$R[G]$ -modules L and M need not be isomorphic even when the $K[G]$ -modules $K \otimes L$ and $K \otimes M$ are isomorphic. The set of G -lattices in a fixed $K[G]$ -module V is divided into a finite number of $R[G]$ -isomorphism classes (**Jordan-Zassenhaus theorem**). Let \mathfrak{p} be a prime ideal of R and $R_\mathfrak{p}$ be the localization of R at \mathfrak{p} . The study of $R_\mathfrak{p}$ -representations is intimately related with modular representation theory. For any $R[G]$ -module L there is an associated family of $R_\mathfrak{p}[G]$ -modules $L_\mathfrak{p} = R_\mathfrak{p} \otimes L$, where \mathfrak{p} ranges over all primes of R . G -lattices L and M in a $K[G]$ -module V are said to be of the same **genus** if $L_\mathfrak{p} \cong M_\mathfrak{p}$ for every \mathfrak{p} . The number of genera of G -lattices in V is given by $\prod_{\mathfrak{p}|g} h_\mathfrak{p}$ ($g = \text{order } G$), where $h_\mathfrak{p}$ denotes the number of $R_\mathfrak{p}[G]$ -equivalence classes of $R_\mathfrak{p}[G]$ -lattices in V . When V is absolutely irreducible, the number of $R[G]$ -equivalence classes in a genus equals the (ideal) \dagger class number of K (J. M. Maranda and S. Takahashi).

The \dagger Krull-Schmidt theorem, asserting the uniqueness of a direct sum decomposition into indecomposable $R[G]$ -modules, holds if R is a complete discrete valuation ring or if R is a discrete valuation ring and K is a splitting field of G . The condition for the finiteness of the number of nonisomorphic indecomposable G -lattices is known. In particular, for $R = \mathbb{Z}$ it reduces to the requirement that the Sylow p -subgroup of G be cyclic of order p or p^2 for every $p|g$. Regarding projective $\mathbb{Z}[G]$ -modules \rightarrow 200 Homological Algebra G.

The **isomorphism problem**, i.e., the question of whether the isomorphism $\mathbb{Z}[G] \cong \mathbb{Z}[H]$ of integral group algebras implies the isomor-

phism $G \cong H$ of groups, has been answered affirmatively for certain special cases such as \dagger meta-Abelian groups.

$R[G]$ is an R - \dagger order in $K[G]$, and in this context, a considerable portion of the integral representation theory has been extended to more general orders in separable algebras [14–16].

Riemann, Georg Friedrich Bernhard

Georg Friedrich Bernhard Riemann (September 17, 1826–July 20, 1866) was born the son of a minister in Breselenz, Hanover, Germany. He attended the universities of Göttingen and Berlin. In 1851 he received his doctorate at the University of Göttingen and in 1854 became a lecturer there. In 1857 he rose to assistant professor, and in 1859 succeeded P. G. L. \dagger Dirichlet as full professor. In 1862 he contracted tuberculosis, and he died at age 40. Despite his short life, his contributions encompassed all aspects of mathematics.

His doctoral thesis (1851) stated the basic theorem on \dagger conformal mapping and became the foundation for the geometric theory of functions. In his paper presented for the position of lecturer (1854), he defined the \dagger Riemann integral and gave the conditions for convergence of trigonometric series. In his inaugural lecture in the same year, he discussed the foundations of geometry, introduced n -dimensional manifolds, formulated the concept of \dagger Riemannian manifolds, and defined their curvature. In his paper of 1857 on \dagger Abelian functions, he systematized the theory of \dagger Abelian integrals and Abelian functions. In his paper of 1858 on the distribution of prime numbers, he considered the \dagger Riemann zeta function as a function of a complex variable and stated \dagger Riemann's hypothesis concerning the distribution of its zeros. It remains for modern mathematics to investigate whether this hypothesis is correct. In his later years, influenced by W. Weber, Riemann became interested in theoretical physics. He gave lectures on the uses of partial differential equations in physics that were edited and published by H. Weber.

364 (VII.3) Riemannian Manifolds

A. Riemannian Metrics

Let M be a †differentiable manifold of class C^r ($1 \leq r \leq \omega$), and g be a †Riemannian metric of class C^{r-1} on M . Then (M, g) or simply M is called a **Riemannian manifold** (or **Riemannian space**) of class C^r (→ 105 Differentiable Manifolds). The metric g is a †covariant tensor field of order 2 and of class C^{r-1} ; it is called the **fundamental tensor** of M . Using the value g_p of g at each point $p \in M$, a positive definite inner product $g_p(X, Y)$, $X, Y \in T_p$, is introduced on the †tangent vector space T_p to M at p , and hence T_p can be considered as a †vector space over \mathbf{R} with inner product that can be identified with the Euclidean space E^n of dimension $n = \dim M$. Utilizing the properties of the space E^n , we can introduce various notions on T_p and M . (For example, given a tangent vector $L \in T_p$, we define the length $\|L\| = \|L\|_{g_p}$ of L to be the quantity $g_p(L, L)^{1/2}$. A **normal vector** at a point p of a submanifold N of M is well defined as an element of the orthogonal complement of the subspace $T_p(N)$ of $T_p(M)$ with respect to g_p ; a differential form of degree 1 is identified with a tangent vector field.) A necessary and sufficient condition for a differentiable manifold M of class C^r to have a Riemannian metric is that M be †paracompact. A Euclidean space E^n has a Riemannian metric expressed by $\sum_{i=1}^n dx^i \otimes dx^i$ in terms of an orthogonal coordinate system (x^i) .

We assume that M is connected and of class C^∞ . A curve $x: [a, b] \rightarrow M$ is called **piecewise smooth** or of **class D^∞** if x is continuous and there exists a partition of $[a, b]$ into finite subintervals $[t_{i-1}, t_i]$ such that the restrictions $x|_{[t_{i-1}, t_i]}$ are †immersions of class C^∞ . The length $\|x\|$ of such a curve x is defined to be $\int_a^b \|x'(t)\| dt$, where $x'(t)$ is the tangent vector of x defined for almost all values of t . As in a Euclidean space, the length $\|x\|$ is independent of the choice of parameter t , and the concepts of †canonical parameter and orientation of x can be defined (→ 111 Differential Geometry of Curves and Surfaces). A function $d: M \times M \rightarrow [0, \infty)$ is defined so that the value $d(p, q)$, $p, q \in M$, is the infimum of the lengths of curves of class D^∞ joining p and q . The function d is a †distance function on M , and the topology of M defined by d coincides with the original

topology of M . There exists an essentially unique structure of a Riemannian manifold on (real or complex) †elliptic or †hyperbolic space (→ 285 Non-Euclidean Geometry), and d is the distance function of these spaces.

If there exists an immersion φ of a differentiable manifold N in a Riemannian manifold (M, g) , then a Riemannian metric φ^*g is defined on N by the †pullback process ($\|L\|_{\varphi^*g} = \|d\varphi(L)\|_g$). (For example, a submanifold and a †covering manifold of M have Riemannian manifold structures induced by the natural mappings (→ 365 Riemannian Submanifolds).) If $M = E^3$ and N is a 2-dimensional submanifold of M , then φ^*g is the †first fundamental form of N . Assume further that φ is a diffeomorphism and N has a Riemannian metric h . If $\varphi^*g = h$, then (N, h) is said to be **isometric** to (M, g) , and φ is called an **isometry**. The set $I(M)$ of all isometries (isometric transformations) of M onto M is a group. A necessary and sufficient condition for a mapping $\psi: N \rightarrow M$ to be an isometry is that $d_N(p, q) = d_M(\psi(p), \psi(q))$, $p, q \in N$. In particular, $I(E^n)$ is the †congruent transformation group.

If a differentiable manifold M is the product manifold of Riemannian manifolds (M_1, g_1) and (M_2, g_2) , then $(M, \pi_1^*g_1 + \pi_2^*g_2)$ is called the **Riemannian product** of M_1 and M_2 , where π_α , $\alpha = 1, 2$, are projections from M to M_α .

Let F be the †tangent n -frame bundle over M and $B = B_g(M)$ be the subset of F consisting of all orthonormal frames with respect to g . Then B is an $O(n)$ -subbundle of F of class C^∞ , called the **tangent orthogonal n -frame bundle** (or **orthogonal frame bundle**). In this way we get a one-to-one correspondence between the set of all $O(n)$ -subbundles of F and the set of all Riemannian metrics of M .

B. Riemannian Connections

There exists a unique †affine connection in the orthogonal frame bundle B whose †torsion tensor is zero. This connection is called the **Riemannian connection** (or **Levi-Civita connection**; → 80 Connections K). Let ∇ denote the †covariant differential operator defined by this connection (→ 80 Connections, 417 Tensor Calculus). (For a vector field X , the covariant differential operator ∇_X acts on any tensor field T defined on a submanifold having X as a tangent vector field.) The covariant differential ∇g of the fundamental tensor g vanishes identically. The †connection form of the Riemannian connection is expressed by n^2 differential 1-forms $(\omega_j^i)_{1 \leq i, j \leq n}$ on B , and we have $\omega_j^j + \omega_i^i = 0$. Let $(\omega^i)_{1 \leq i \leq n}$ be the †canonical 1-forms on B . Then $(\omega_j^i)_{1 \leq i \leq j \leq n}$ together with (ω^i) give rise to an absolute parallelism on B (that is, they are linearly independent at

every point). Let (θ^i) and (θ_j^i) be the corresponding set of differential 1-forms on the orthogonal frame bundle B_N over another Riemannian manifold N with $\dim N = \dim M$. If there exists an isometry $\psi: M \rightarrow N$, then the differential $d\psi$ is a diffeomorphism from $B = B_M$ to B_N , and we get $(d\psi)^*(\theta^i) = \omega^i$, $(d\psi)^*(\theta_j^i) = \omega_j^i$. Conversely, if there exists a diffeomorphism $\Psi: B_M \rightarrow B_N$ satisfying $\Psi^*(\theta^i) = \omega^i$, $\Psi^*(\theta_j^i) = \omega_j^i$ and M is orientable, then there exists an isometry $\psi: M \rightarrow N$ such that $d\psi = \Psi$ holds on a connected component B_0 of B . Moreover, ψ is uniquely determined if we choose one B_0 . In this way the problem of the existence of an isometry from M may be reduced to one of the existence of a diffeomorphism from B preserving absolute parallelism (as well as the order of the basis (ω^i, ω_j^i)).

According to the general theory of affine connections, the Riemannian connection on M determines a \dagger Cartan connection uniquely with $E^n = I(E^n)/O(n)$ as \dagger fiber, which is called the **Euclidean connection**. As a consequence, every tangent vector space $T_p(M)$ is regarded as a Euclidean space E_p^n , and for a given curve $x: [a, b] \rightarrow M$ of class D^∞ and for $t \in [a, b]$ there exists an isometry $I_{x,t}: E_{x(t)}^n \rightarrow E_{x(a)}^n$ satisfying the following three conditions (we denote $I_{x,t}$ by I_x): (1) If x is a composite of two curves y and z , then $I_x = I_y \cdot I_z$. (2) Differentiability: If x is of class C^∞ at t_0 , then $t \rightarrow I_{x,t}$ is of class C^∞ at t_0 . (3) I_x depends on the orientation of x but not on the choice of its parameter. The **development** \bar{x} of x is the curve in $E_{x(a)}^n$ defined by $\bar{x}(t) = I_{x,t}(x(t))$, and we get $\|\bar{x}\| = \|x\|$. (I_x is sometimes called the **development along x** .) Utilizing the concept of development, the theory of curves in E^n can be used to study curves on M (\rightarrow 111 Differential Geometry of Curves and Surfaces). For example, if \bar{x} is a segment, then x or $x([a, b])$ is called the **geodesic arc** (\rightarrow 80 Connections L); the \dagger Frenet formula is automatically formulated and proved. The rotation part I_x^R of I_x (the composite of I_x and the parallel displacement of E_p^n translating $I_x(x(b))$ to $x(a)$) is regarded as an isomorphism of the inner product space $T_{x(b)}$ to $T_{x(a)}$. I_x^R is extended to an isomorphism of the \dagger tensor algebra $\mathcal{T}(T_{x(b)})$ to $\mathcal{T}(T_{x(a)})$, which is denoted by the same symbol I_x^R and called the **parallel displacement** or **parallel translation along x** . Given a tensor field K on M , we have $\nabla_{x'(a)} K = [dI_{x,t}^R(K(x(t)))/dt]_{t=a}$. In particular, a necessary and sufficient condition for $\nabla K = 0$ is that $I_x^R(K(x(b))) = K(x(a))$ for any x , in which case K is said to be **parallel**.

C. Exponential Mapping (\rightarrow 178 Geodesics)

A curve x on M or the image of x is called a **geodesic** if any subarc $x|[a, b]$ of x is a geo-

desic arc. Let $N(S)$ be the **normal bundle** of a submanifold S of M , that is, the differentiable vector bundle over S consisting of all normal vectors at all points of S . Then S is contained in $N(S)$ as the set of zero vectors at all points of S . There exist a neighborhood U of S in $N(S)$ and a mapping $\text{Exp}_S: U \rightarrow M$ of class C^∞ with the following property: There exists a geodesic arc x with the initial tangent vector $L \in U$, length $\|x\| = \|L\|$, and final point $\text{Exp}_S(L)$. Let U_S be the largest U with this property. Then $\text{Exp}_S: U_S \rightarrow M$ is determined uniquely by S . The mapping Exp_S is called the **exponential mapping** on S . If the rank of the Jacobian matrix of Exp_S is less than n at $L \in U_S$, then L or $\text{Exp}_S(L)$ is called the **focal point** of S on the geodesic $s \rightarrow \text{Exp}_S(sL)$ ($0 \leq s, sL \in U_S$). If S is compact, then S has an open neighborhood V_S in $N(S)$ satisfying the following three conditions: (i) $V_S \subset U_S$; (ii) $\|L\| = d(\text{Exp}_S(L), S)$ for $L \in V_S$, where the right-hand member expresses the infimum of the distance between the point $\text{Exp}_S(L)$ and points of S ; (iii) the restriction $\text{Exp}_S|_{V_S}$ is an embedding. The image $\text{Exp}_S(V_S)$ is the **tubular neighborhood** of S . In the special case where S consists of only one point p , $N(\{p\})$ coincides with the tangent vector space $T_p(M)$, and the focal point of p is called the **conjugate point** of p , given as the zero point of the \dagger Jacobi field (\rightarrow 178 Geodesics, 279 Morse Theory). In this case, V_S is denoted by V_p . If T_p is identified with \mathbf{R}^n (or E^n) by means of an orthonormal basis of T_p , then $(\text{Exp}_p)^{-1}$ defined on $\text{Exp}_p(V_p)$ is a coordinate mapping, called the **normal coordinate mapping**. Furthermore, $\text{Exp}_p(V_p)$ contains a neighborhood W_p of p such that there exists a unique geodesic arc x joining any two points q and r of W_p with $\|x\| = d(q, r)$ and contained in W_p . W_p is called a **convex neighborhood** of p .

D. Curvature

The set of differential 1-forms (ω^i, ω_j^i) , by means of which absolute parallelism is given in the orthogonal frame bundle B of M , satisfies the \dagger structure equation $d\omega^i = -\sum_j \omega_j^i \wedge \omega^j$, $d\omega_j^i = -\sum_k \omega_k^i \wedge \omega_j^k + \Omega_j^i$, and (Ω_j^i) is called the **curvature form** of the Riemannian connection of M . This form is expressed by a tensor field R (\rightarrow 80 Connections; 417 Tensor Calculus) of type (1, 3) on M , called the **curvature tensor**; if R_{jki}^i are the components of R with respect to an orthonormal frame $b \in B$ of the tangent vector space T_p of M , then $\Omega_j^i = (1/2)\sum R_{jki}^i \omega^k \wedge \omega^l$ at b . Let (X, Y) be an orthonormal basis of a 2-dimensional subspace P of T_p . Then the inner product $K_p(P)$ of X and $R(X, Y)Y$ is determined by P independently of the choice of the basis (X, Y) , where the i -component of

$R(X, Y)Z$ with respect to the basis b of T_p is given by $\sum R_{jkl}^i Z^j X^k Y^l$. $K_p(P)$ is the †Gaussian curvature of the surface $\text{Exp}_p(V_p \cap P)$ and is called the **sectional curvature** (or **Riemannian curvature**) of P . The curvature tensor R is uniquely determined by the function $K_p(P)$ of p and P . If $\dim M \geq 3$ and if at every point p of M , $K_p(P)$ has a constant value M_p independent of the choice of P , then M_p is a constant independent of the choice of p (F. Schur). If $K_p(P)$ is constant, then M is called a **space of constant curvature**. If $\nabla R = 0$, then M is called a **locally symmetric space** (\rightarrow 412 Symmetric Riemannian Spaces and Real Forms; 413 Symmetric Spaces). In a local sense, Riemannian metrics of these spaces are uniquely determined by the curvature tensor R up to a constant factor. If M is of constant curvature K , complete, and simply connected, then M is isometric to E^n , the sphere (which is the universal covering Riemannian manifold of a real †elliptic space), or a real †hyperbolic space according as K is 0, positive, or negative. The compact spaces of positive constant curvature, that is, the Riemannian manifolds having the sphere as the universal covering Riemannian manifold, were completely classified by J. A. Wolf [1]. A complete, simply connected, and locally symmetric space is a †symmetric Riemannian space. The **Ricci tensor** (R_{ij}) is defined by $R_{ij} = -\sum_k R_{ijk}^k$. Let Q be the quadratic form on T_p given by (R_{ij}) . Then the value $Q(L)$ for a unit vector $L \in T_p$ is the mean of $K_p(P)$ for all sections P (2-dimensional subspaces of T_p) containing L and is called the **Ricci curvature** (or **mean curvature**) of the direction L at p . The mean R of $Q(L)$ for all the unit vectors L at p is called the **scalar curvature** at p (\rightarrow 417 Tensor Calculus). $Q(L)$ and R are expressed by $Q(L) = \sum_i g_p(R(X_i, L)L, X_i)$ and $R = \sum_i Q(X_i)$, up to positive constant factors, in terms of an orthonormal basis (X_i) of T_p . If the Ricci tensor of M is a scalar multiple of the fundamental tensor, then M is called an **Einstein space**. (When $\dim M \geq 3$, this scalar is constant.) If M is a †Kähler manifold and P is restricted to a complex plane (invariant under the almost complex structure), then $K(P)$ is called the **holomorphic sectional curvature**. A Kähler manifold M of constant holomorphic sectional curvature is locally isometric to a complex Euclidean space, elliptic space, or hyperbolic space.

The properties of the sectional curvature and the Ricci curvature are closely related to the behavior of geodesics of Riemannian manifolds, and these properties reflect those of the topological structures of the manifolds (\rightarrow 178 Geodesics). The compact simply connected homogeneous Riemannian manifolds of strictly positive sectional curvature have been

classified [2–4]. Related to algebraic geometry, as the solution of the Frankel conjecture, the following holds: If a compact Kähler manifold has strictly positive sectional curvature, then it is biholomorphic to the complex projective space [5, 6] (\rightarrow 232 Kähler Manifolds). Furthermore, curvature tensors are related to †characteristic classes. For example, we have the **Gauss-Bonnet formula**: If M is an even-dimensional compact and oriented Riemannian manifold, the integral of $a_n K_{(n)} \omega$ on M is equal to the †Euler-Poincaré characteristic, where

$$a_n = n! / (2^n \pi^{n/2} (n/2)!),$$

ω is the volume element of M , and $K_{(n)}$ is defined as follows: For a positive even number s , $K_{(s)}$ is a real-valued function of the s -dimensional subspaces P of the tangent vector spaces T_p of M , which is given by

$$K_{(s)}(P) = b_s \sum \varepsilon_{i_1 \dots i_s} \langle R_p(X_{i_1}, X_{i_2})X_{j_1}, X_{j_2} \rangle \dots \langle R_p(X_{i_{s-1}}, X_{i_s})X_{j_{s-1}}, X_{j_s} \rangle$$

in terms of an orthonormal basis (X_1, \dots, X_n) of P , where $b_s = (-1)^{s/2} / (2^{s/2} s!)$, \sum is summation over all pairs of s -tuples satisfying $\{i_1, \dots, i_s\}, \{j_1, \dots, j_s\} \subset \{1, 2, \dots, n\}$, $\varepsilon_{i_1 \dots i_s}$ is the sign of (i_1, \dots, i_s) , $\langle \cdot, \cdot \rangle$ is the inner product in T_p with respect to g_p , R_p is the value of the tensor R at p , and $R_p(X_i, X_j)X_k$ is as already defined at the beginning of this section. In particular, $K_{(2)} = K$. If $K_{(s)}$ of a compact and orientable M is constant for a certain s , then the k th †Pontryagin class of M (with real coefficients) vanishes for all $k \geq s/2$.

E. Holonomy Groups

Let p be a fixed point of M , and let Ω_p be the set of all closed oriented curves of class D^∞ with initial and final points p and with parameters neglected. The set $H = \{I_x | x \in \Omega_p\}$, called the **holonomy group** of M , is a subgroup of $I(T_p)$ (T_p is identified with E^n) independent of the choice of p (\rightarrow 80 Connections), and $x \rightarrow I_x$ is a homomorphism from Ω_p to H . The restriction H_0 of this homomorphism to all closed curves homotopic to zero is called the **restricted holonomy group**. The rotation part h of H , called the **homogeneous holonomy group**, is a subgroup of the orthogonal group $O(n)$ of T_p . The rotation part h_0 of H_0 , called the **restricted homogeneous holonomy group**, is a connected component of h and a †compact Lie group. The †Lie algebra of h_0 is spanned by $\{I_x(R_{x(b)}(X, Y)) | x: [a, b] \rightarrow M \text{ is of class } D^\infty, x(a) = p, \text{ and } X, Y \in T_{x(b)}\}$, where $R_{x(b)}(X, Y)$ is the endomorphism of the linear space $T_{x(b)}$ defined in Section D.

If $M = E^n$, then $H = \{e\}$, where e is the identity element. If $h = \{e\}$ ($h_0 = \{e\}$), then M is called **flat (locally flat)** (\rightarrow 80 Connections E). Local flatness is equivalent to M being locally isometric to E^n . If M is complete and H (regarded as a transformation group of E^n) has a fixed point, then M is isometric to E^n . Any finite rotation group h is the homogeneous holonomy group of some locally flat and compact Riemannian manifold.

With respect to the linear group h of T_p , we get a unique decomposition $T_p = V_{(0)} \oplus V_{(1)} \oplus \dots \oplus V_{(r)}$ of mutually orthogonal subspaces, where $V_{(0)}$ ($\dim V_{(0)} \geq 0$) consists of all h -invariant vectors and $V_{(i)}$, $i = 1, \dots, r$, are irreducible h -invariant subspaces. If h or h_0 is irreducible (reducible) on T_p , then M is called **irreducible (reducible)**. If M is complete and simply connected (hence $h = h_0$), then M is the Riemannian product of closed submanifolds $M_{(\alpha)}$, $\alpha = 0, 1, \dots, r$, satisfying $V_{(\alpha)} = T(M_{(\alpha)})$. This decomposition $M = \prod M_{(\alpha)}$ is determined uniquely by M and called the **de Rham decomposition** of M [7]. In this case h is the direct product of closed subgroups $h_{(\alpha)}$, where every $h_{(\alpha)}$ acts on $V_{(\beta)}$, $\beta \neq \alpha$ as the identity, and can be regarded as the homogeneous holonomy group of $M_{(\alpha)}$. If h_0 is irreducible and M is not locally symmetric, then h_0 acts \dagger transitively on the unit sphere of T_p . The classification of possible candidates for such h_0 has been made [8, 9]. For example, if n is even and h_0 is the \dagger unitary group $U(n/2)$, then h acts transitively on the unit sphere. A necessary and sufficient condition for h to be contained in $U(n/2)$ is that M have a \dagger complex structure and the structure of a Kähler manifold.

The group h acts naturally on the \dagger tensor algebra $\mathcal{T}(T_p)$ of T_p . If a tensor field A on M is parallel, then A_p is invariant under h . Conversely, if $A_0 \in \mathcal{T}(T_p)$ is invariant under h , there exists a unique parallel tensor field A satisfying $A_p = A_0$. The orthogonal frame bundle B is \dagger reducible to the h -bundle.

F. Transformation Groups

The group $I(M)$ consisting of all isometries of M with the \dagger compact-open topology is a \dagger Lie transformation group. The isotropy subgroup at any point is compact. In particular, if M is compact, so is $I(M)$. The differential $d\varphi$ of $\varphi \in I(M)$ is a transformation of the orthogonal frame bundle B . If b_0 is a fixed point of B , then the mapping β defined by $\varphi \rightarrow d\varphi(b_0)$ embeds $I(M)$ as a closed submanifold of B , and the differentiable structure of $I(M)$ is thus determined. If β is surjective, it follows from the structure equation that M is of constant curva-

ture and equals E^n , a real \dagger hyperbolic space, or a real \dagger elliptic space (or a sphere). A necessary and sufficient condition for the image of β to be a subbundle of B is that $I(M)$ be transitive. If the image of β contains the h -bundle, then M is a symmetric space. If M is compact and $I(M)$ is transitive, then the image of β is contained in the h -bundle (\rightarrow 191 G-Structures). If $I(M)$ is transitive on M , then M is complete and is the \dagger homogeneous space of $I(M)$. Conversely, a homogeneous space $M = G/K$ of a Lie group G by a compact subgroup K has a Riemannian metric invariant under G . In general, an element of $I(M)$ preserves quantities uniquely determined by the Riemannian metric g , such as the Riemannian connection, its curvature, the set of all geodesics, etc. Furthermore, any element of $I(M)$ commutes with ∇ and the \dagger Laplace-Beltrami operator. If M is compact and oriented, then the connected component $I_0(M)$ of $I(M)$ preserves any \dagger harmonic differential form. If M is complete and simply connected, then $I_0(M)$ is clearly decomposed into a direct product by the de Rham decomposition of M . An element of the Lie algebra of $I(M)$ is regarded as a vector field X on M , called the **infinitesimal motion**, which satisfies the equation $L_X g = 0$; that is, $\nabla_j \xi_i + \nabla_i \xi_j = 0$, where L_X denotes \dagger Lie derivation and the ξ_i are \dagger covariant components of X with respect to a natural frame $(\partial/\partial X_i)$, $i = 1, \dots, n$ (\rightarrow 417 Tensor Calculus). This equation is called **Killing's differential equation**, and a solution X of this equation is called a **Killing vector field**. The set of all Killing vector fields is a Lie algebra of finite dimension ($\leq \dim B$). If M is complete, then this Lie algebra coincides with that of $I(M)$. If M is compact and the Ricci tensor is negative definite, then $I(M)$ is discrete. If, furthermore, the sectional curvature is nonpositive, then an isometry of M homotopic to the identity transformation is the identity transformation itself.

It is known that $\dim I(M) \leq n(n+1)/2$ if $\dim M = n$, and the maximum dimension is attained only when M is a space of constant curvature. For Riemannian manifolds with large $I(M)$, extensive work on the structures of M and $I(M)$ has been done by I. P. Egorov, S. Ishihara, N. H. Kuiper, L. N. Mann, Y. Muto, T. Nagano, M. Obata, H. Wakakuwa, K. Yano, and others [10, 11].

The fixed point set of a family of isometries has interesting differential geometric properties [10]. For example, let G be any subset of $I(M)$ and F the set of points of M which are left fixed by all the elements of G . Then each connected component of F is a closed \dagger totally geodesic submanifold of M . If M is compact and f is an isometry of M , then $\Lambda_f = \chi(F)$, where Λ_f denotes the \dagger Lefschetz number and

$\chi(F)$ the \dagger Euler characteristic of the fixed point set F of f . As for the existence of fixed points of an isometry, the following are known: Let f be an isometry of a compact, orientable Riemannian manifold M with positive sectional curvature. If $\dim M$ is even and f is orientation preserving, or if $\dim M$ is odd and f is orientation reversing, then f has a fixed point. In the case of nonpositive curvature, the following is basic: Every compact group of isometries of a complete, simply connected Riemannian manifold with nonpositive sectional curvature has a fixed point (E. Cartan). If a compact, orientable Riemannian manifold admits a fixed-point-free 1-parameter group of isometries, then its \dagger Pontryagin numbers vanish.

On a Riemannian manifold M , a transformation of M which preserves the Riemannian connection, or equivalently which commutes with covariant differentiation ∇ is called an **affine transformation**. Let $A(M)$ denote the group of all affine transformations of M . A transformation preserving the set of all geodesics is called a **projective transformation**. Let $P(M)$ denote the group of all projective transformations of M . A transformation preserving the angle between tangent vectors is called a **conformal transformation**. Let $C(M)$ denote the group of all conformal transformations. They are Lie transformation groups with respect to suitable topologies. Clearly, $I(M) \subset A(M) \subset P(M)$, $I(M) \subset C(M)$ (\rightarrow 191 *G-Structures*).

$A_0(M)$, the connected component of $A(M)$, is decomposed into a direct product according to the de Rham decomposition of M when M is complete and simply connected (J. Hano). If M is complete and irreducible, then $A(M) = I(M)$ except when M is a 1-dimensional Euclidean space. If M is complete and its restricted homogeneous holonomy group h_0 leaves no nonzero vectors, then $A_0(M) = I_0(M)$. If M is compact, then $A_0(M) = I_0(M)$ always.

If M is complete and has a parallel Ricci tensor, then the connected component $P_0(M) = A_0(M)$, unless M is a space of positive constant sectional curvature ($n > 2$) (Nagano, N. Tanaka, Y. Tashiro). If M is compact, simply connected, and has constant scalar curvature, then $P_0(M) = I_0(M)$, unless M is a sphere ($n > 2$) (K. Yamauchi).

Similarly to the case of $P(M)$, it is known that if M is complete and has a parallel Ricci tensor, then the connected component $C_0(M) = I_0(M)$, unless M is a sphere ($n > 2$) (Nagano). A conformal transformation remains conformal if the Riemannian metric g is changed conformally, namely, to $e^{2f}g$, f being any smooth function on M . A subset of $C(M, g)$ is called **essential** if it cannot be reduced to a subset of $I(M, \bar{g})$ for any metric \bar{g} conformal to

g . When M is compact, $C(M)$ or $C_0(M)$ is essential if and only if it is not compact. If $C_0(M)$ is essential, then M is conformally diffeomorphic to a sphere or a Euclidean space ($n > 2$) [12–15]. When M is compact and has constant scalar curvature and $C_0(M) \neq I_0(M)$, sufficient conditions for M to be isometric to a sphere have been obtained by S. I. Goldberg and S. Kobayashi, C. C. Hsiung, S. Ishihara, A. Lichnerowicz, Obata, S. Tanno, Tashiro, K. Yano, and others. For example, if $C_0(M)$ is essential, then M is a sphere [14]. In general, however, there are compact Riemannian manifolds with constant scalar curvature for which $C_0(M) \neq I_0(M)$ (N. Ejiri).

G. Spheres as Riemannian Manifolds

A Euclidean n -sphere S^n ($n \geq 2$) has the properties of a Riemannian manifold. It is a space of positive constant sectional curvature $1/r^2$ (r = radius) with respect to the natural Riemannian metric as a hypersurface of the Euclidean $(n + 1)$ -space E^{n+1} . A sphere is characterized by the existence of solutions of certain differential equations on a Riemannian manifold. On a unit sphere S^n in E^{n+1} , the eigenvalues of the \dagger Laplace-Beltrami operator Δ on smooth functions are given by $0 < \lambda_1 < \dots < \lambda_k < \dots$, $\lambda_k = k(n + k - 1)$. It is known that eigenfunctions f corresponding to λ_k , $\Delta f = \lambda_k f$, are the restrictions to S^n of harmonic homogeneous polynomial functions F of degree k on E^{n+1} . On a compact Riemannian manifold M , if the Ricci curvature of M is not less than that of S^n , then the first eigenvalue $\bar{\lambda}_1$ of Δ on M satisfies $\bar{\lambda}_1 \geq \lambda_1 = n$ [16]. Conversely, under the same assumption on the Ricci curvature, if $\bar{\lambda}_1 = n$, then M is a sphere (Obata). On the other hand, if g is the standard metric on S^n , then $\Delta f = nf$ is equivalent to the system of differential equations

$$\nabla_j \nabla_j f + f g_{ji} = 0. \tag{E_1}$$

A complete Riemannian manifold M ($n \geq 2$) admits a nontrivial solution of (E₁) if and only if M is a sphere (Obata, Tashiro). In general, the restriction f to S^n of a harmonic homogeneous polynomial of degree k satisfies $\Delta f = k(n + k - 1)f$ as well as a certain system (E_k) of differential equations of degree $k + 1$ involving the Riemannian metric. For example,

$$\nabla_k \nabla_j \nabla_i f + 2g_{ji} \nabla_k f + g_{ik} \nabla_j f + g_{kj} \nabla_i f = 0. \tag{E_2}$$

If a complete Riemannian manifold M admits a nontrivial solution of (E_k) for some integer $k \geq 2$, then M is locally isometric to a sphere (Obata, Tanno, S. Gallot [17]). The gradient of a solution of (E₁) is an infinitesimal conformal

transformation and that of (E_2) is an infinitesimal projective transformation.

As the Kähler or quaternion Kähler version of (E_2) , there is a system of differential equations characterizing the complex projective space or the quaternion projective space as a Kähler manifold (Obata, Tanno, D. E. Blair, Y. Maeda).

On a sphere, a Riemannian metric which is conformal to the standard metric and has the same scalar curvature as the standard one is always standard, namely, it has a positive constant sectional curvature [14].

H. Scalar Curvature

On a 2-dimensional Riemannian manifold M , the sectional curvature, the Ricci curvature, and the scalar curvature all coincide with the †Gaussian curvature, which is a function on M . If M is compact, by the †Gauss-Bonnet theorem the Gaussian curvature K of M must satisfy the following sign condition in terms of the †Euler characteristic $\chi(M)$:

if $\chi(M) > 0$, then K is positive somewhere;

if $\chi(M) = 0$, then K changes sign unless it is identically zero;

if $\chi(M) < 0$, then K is negative somewhere.

This sign condition is also sufficient for a given function K to be the Gaussian curvature of some metric on M . More precisely, starting with a Riemannian metric with constant Gaussian curvature, one can say that a smooth function K is the Gaussian curvature of some metric conformally equivalent to the original metric if and only if K satisfies the foregoing sign condition [18].

H. Yamabe [19] announced that on every compact Riemannian manifold (M, g) of dimension $n \geq 3$, there exists a strictly positive function u such that the Riemannian metric $\bar{g} = u^{4/(n-2)}g$ has constant scalar curvature. N. S. Trudinger, however, pointed out that his original proof contains a gap in some cases. The problem reduces to the following nonlinear partial differential equation on a compact manifold M :

$$\bar{R}u^{(n+2)/(n-2)} = 4 \frac{n-1}{n-2} \Delta u + Ru,$$

where R is the scalar curvature of g and \bar{R} a constant which should be the scalar curvature of $\bar{g} = u^{4/(n-2)}g$ (\rightarrow 183 Global Analysis). Nevertheless, Yamabe's original proof can be pushed to cover a large class of metrics with $\int_M R dM < 0$. Furthermore, it has since been solved for a wider class: namely, if M is not conformally flat and $n \geq 6$, or if it is conformally flat and its fundamental group is finite,

then the problem has been solved affirmatively [20].

On the other hand, any smooth function on a compact manifold M of dimension $n \geq 3$ that is negative somewhere is the scalar curvature of some metric on M . In particular, on a compact manifold ($n \geq 3$) there always exists a Riemannian metric with constant negative scalar curvature [18]. Any smooth function can be the scalar curvature if and only if M admits a metric of constant positive scalar curvature. The foregoing results show that there is no topological obstruction to the existence of metrics with negative scalar curvature of a compact manifold of dimension $n \geq 3$.

For positive scalar curvature, there is a topological obstruction. A compact †spin structure (spin manifold) having nonvanishing † \hat{A} -genus cannot carry a Riemannian metric of positive scalar curvature. The existence of such a manifold has been shown. If a compact, simply connected manifold M of dimension $n \geq 5$ is not a spin manifold, then there exists a Riemannian metric of positive scalar curvature. Furthermore, if M is a spin manifold and spin †cobordant to M' with positive scalar curvature, then M carries a Riemannian metric of positive scalar curvature [22]. A torus T^n cannot carry a metric of positive scalar curvature. In fact, any metric of nonnegative scalar curvature on T^n must be flat [22].

Let K_g and R_g denote the sectional curvature and the scalar curvature, respectively, of a Riemannian metric g . Then the following are known for a compact manifold M of dimension ≥ 3 : If M carries a metric g with $K_g \leq 0$, then it carries no metric with $R > 0$. If M carries a metric g with $K_g < 0$, then it carries no metric with $R \geq 0$. If M carries metrics g_1, g_2 with $K_{g_1} \leq 0$ and $R_{g_2} \geq 0$, then both metrics are flat [22].

If the assignment of the scalar curvature to a Riemannian metric is viewed as a mapping of a space of Riemannian metrics into a space of functions on a manifold M , then locally it is almost always surjective when M is compact (A. E. Fischer and J. E. Marsden, O. Kobayashi, J. Lafontaine).

I. Ricci Curvature and Einstein Metrics

In this paragraph the manifolds under consideration are assumed to be of dimension $n \geq 3$. The Ricci tensor (R_{ij}) is a symmetric tensor field of type $(0, 2)$ on a Riemannian manifold. The problem of finding a Riemannian metric g which realizes a given Ricci tensor reduces to the one of solving a system of nonlinear second-order partial differential equations for g . The Bianchi identity (\rightarrow 417

Tensor Calculus)

$$g^{kj}\nabla_k R_{ji} - \frac{1}{2}\nabla_i R = 0$$

must be satisfied. There is a symmetric (0, 2)-tensor on \mathbf{R}^n which cannot be the Ricci tensor for any Riemannian metric in a neighborhood of $0 \in \mathbf{R}^n$. However, if a C^∞ (or C^ω) symmetric tensor field (R_{ij}) of type (0, 2) is invertible at a point p , then in a neighborhood of p there exists a C^∞ (or C^ω) Riemannian metric g such that (R_{ij}) is the Ricci tensor of g [24].

The positivity of the Ricci curvature on a Riemannian manifold puts rather strong restrictions on the topology of the manifold (\rightarrow 178 Geodesics). However, nonnegative Ricci curvature and positive Ricci curvature are not too far from each other. If, on a complete Riemannian manifold M with nonnegative Ricci curvature, there is a point at which the Ricci curvature is positive, then there exists a complete metric on M with positive Ricci curvature [25–27].

If a Riemannian manifold (M, g) is an Einstein space, then g is called an **Einstein metric** on the manifold M . Let v_g denote the volume element determined by g . When M is compact, \mathcal{M} denotes the space of Riemannian metrics on M with total volume 1. The integral of the scalar curvature $\mathcal{G}(g) = \int_M R_g v_g$ is a functional on \mathcal{M} . The critical points of \mathcal{G} are Einstein metrics (D. Hilbert). Let $\mathcal{M}_1 (\subset \mathcal{M})$ denote the space of metrics with constant scalar curvature. Then if \mathcal{G} is restricted to \mathcal{M}_1 , then the \dagger nullity and \dagger coindex at the critical point are finite [28, 29].

An Einstein metric is always real analytic in some coordinate system. In particular, if two simply connected Einstein spaces have neighborhoods on which metrics are isometric, then they are isometric [30]. Though S^n with standard Riemannian metric is a typical example of an Einstein space, S^{4k+3} ($k \geq 1$) carries an Einstein metric that is not standard [31].

365 (VII.13) Riemannian Submanifolds

A. Introduction

If an \dagger immersion (or an \dagger embedding) f of a \dagger Riemannian manifold (M, g) into a Riemannian manifold (\tilde{M}, \tilde{g}) satisfies the condition $f^*\tilde{g} = g$, then f is called an **isometric immersion** (or embedding) and M is called a **Riemannian submanifold** of \tilde{M} . In this article, $f(M)$ will be identified with M except where there is danger of confusion. Suppose $\dim M = n$ and $\dim \tilde{M} = n + p$. Then the \dagger bundle $F(M)$ of orthonormal tangent frames of M , the bundle $F_\nu(M)$ of orthonormal normal frames of M , and their \dagger Whitney sum $F(M) \oplus F_\nu(M)$ are \dagger principal fiber bundles over M with \dagger structure groups $O(n)$, $O(p)$, and $O(n) \times O(p)$, respectively. These are subbundles of the restriction to M of the bundle $F(\tilde{M})$ of orthonormal frames of \tilde{M} . The vector bundles associated with $F(M)$, $F_\nu(M)$, and $F(M) \oplus F_\nu(M)$ are, respectively, the \dagger tan-

gent bundle $T(M)$, the \dagger normal bundle $\nu(M)$, and their Whitney sum $T(M) \oplus \nu(M)$.

B. General Results for Immersibility

An n -dimensional real analytic Riemannian manifold can be locally isometrically embedded into any real analytic Riemannian manifold of dimension $n(n+1)/2$ (M. Janet (1926), E. Cartan (1927)). The generalization to the C^∞ case is an open question even when the ambient space is Euclidean.

An n -dimensional compact C^r Riemannian manifold ($3 \leq r \leq \infty$) can be isometrically embedded into an $(n(3n+1)/2)$ -dimensional Euclidean space (J. F. Nash (1956)). An n -dimensional noncompact C^r Riemannian manifold ($3 \leq r \leq \infty$) can be isometrically embedded into a $2(2n+1)(3n+7)$ -dimensional Euclidean space (Nash (1956), R. E. Greene (1970)).

Let M be an n -dimensional Riemannian manifold with \dagger sectional curvature K_M and \tilde{M} an $(n+p)$ -dimensional Riemannian manifold with sectional curvature $K_{\tilde{M}}$. Then M cannot be isometrically immersed into \tilde{M} in the following cases:

- (1) $p \leq n-2$ and $K_M < K_{\tilde{M}}$ (T. Otsuki (1954));
- (2) $p \leq n-1$, $K_M \leq K_{\tilde{M}} \leq 0$, M is compact, and \tilde{M} is complete and simply connected (C. Tompkins (1939), S. S. Chern and N. H. Kuiper (1952), B. O’Neill (1960));
- (3) $p \leq n-1$, $K_M \leq 0$, $K_{\tilde{M}}$ is constant (≤ 0), M is compact, and \tilde{M} is complete and simply connected [2].

C. Fundamental Equations

Let $f: (M, g) \rightarrow (\tilde{M}, \tilde{g})$ be an isometric immersion. Let ∇ and $\tilde{\nabla}$ denote the \dagger covariant differentiations with respect to the \dagger Riemannian connections of M and \tilde{M} , respectively. For vector fields X and Y on M , the tangential component of $\tilde{\nabla}_X Y$ is equal to $\nabla_X Y$. Put

$$\sigma(X, Y) = \tilde{\nabla}_X Y - \nabla_X Y. \tag{1}$$

Then σ is a $\nu(M)$ -valued symmetric $(0, 2)$ tensor field on M , which is called the **second fundamental form** of M (or of f). For a normal vector ξ at $x \in M$, put $g(A_\xi X, Y) = \tilde{g}(\sigma(X, Y), \xi)$. Then A_ξ defines a symmetric linear transformation on $T_x(M)$, which is called the second fundamental form in the direction of ξ . The eigenvalues of A_ξ are called the **principal curvatures** in the direction of ξ . The connection on $\nu(M)$ induced from the Riemannian connection of \tilde{M} is called the **normal connection** of M (or of f). Let ∇^\perp denote the covariant differentiation with respect to the normal con-

nection. For a tangent vector field X and a normal vector field ξ on M , the tangential (resp. normal) component of $\bar{\nabla}_X \xi$ is equal to $-A_\xi X$ (resp. $\nabla_X^\perp \xi$), that is to say, the relation

$$\bar{\nabla}_X \xi = -A_\xi X + \nabla_X^\perp \xi \tag{2}$$

holds. (1) is called the **Gauss formula**, and (2) is called the **Weingarten formula**.

Let R, \bar{R} , and R^\perp be the \dagger curvature tensors of $\nabla, \bar{\nabla}$, and ∇^\perp , respectively. Then the \dagger integrability condition for (1) and (2) implies

$$\begin{aligned} \bar{R}(X, Y)Z &= R(X, Y)Z + A_{\sigma(X, Z)}Y - A_{\sigma(Y, Z)}X \\ &\quad + (\nabla_X^\perp \sigma)(Y, Z) - (\nabla_Y^\perp \sigma)(X, Z) \end{aligned} \tag{3}$$

for vector fields X, Y, Z tangent to M , where ∇' denotes covariant differentiation with respect to the connection in $T(M) \oplus \nu(M)$. (3) is called the equation of Gauss and Codazzi.

More precisely, the tangential component of (3) is given by the **equation of Gauss** and the normal component of (3) is given by the **equation of Codazzi**. Similarly, for vector fields ξ and η normal to M , the relation

$$\begin{aligned} \tilde{g}(\bar{R}(X, Y)\xi, \eta) &= \tilde{g}(R^\perp(X, Y)\xi, \eta) \\ &\quad - g([A_\xi, A_\eta]X, Y) \end{aligned} \tag{4}$$

holds, which is called the **equation of Ricci**. Formulas (1)–(4) are the fundamental equations for the isometric immersion $f: M \rightarrow \bar{M}$.

As a particular case, suppose \bar{M} is a \dagger space form of constant curvature c . Then the equations of Gauss, Codazzi, and Ricci reduce respectively to

$$R(X, Y)Z = c(g(Y, Z)X - g(X, Z)Y) + A_{\sigma(Y, Z)}X - A_{\sigma(X, Z)}Y, \tag{3}_t$$

$$(\nabla_X^\perp \sigma)(Y, Z) - (\nabla_Y^\perp \sigma)(X, Z) = 0, \tag{3}_n$$

$$\tilde{g}(R^\perp(X, Y)\xi, \eta) = g([A_\xi, A_\eta]X, Y). \tag{4}_c$$

Conversely, let (M, g) be an n -dimensional simply connected Riemannian manifold, and suppose there is given a p -dimensional \dagger Riemannian vector bundle $\nu(M)$ over M with curvature tensor R^\perp and a $\nu(M)$ -valued symmetric $(0, 2)$ tensor field σ on M . For a \dagger cross section ξ of $\nu(M)$, define A_ξ by $g(A_\xi X, Y) = \langle \sigma(X, Y), \xi \rangle$, where $\langle \cdot, \cdot \rangle$ is the fiber metric of $\nu(M)$. If they satisfy $(3)_t, (3)_n$, and $(4)_c$, then M can be immersed isometrically into an $(n + p)$ -dimensional complete and simply connected space form $M^{n+p}(c)$ of curvature c in such a way that $\nu(M)$ is the normal bundle and σ is the second fundamental form. Moreover, such an immersion is unique up to an \dagger isometry of $M^{n+p}(c)$.

Let $(e_A)_{1 \leq A \leq n+p}$ be a local cross section of $F(\bar{M})$ such that its restriction to M gives a local cross section of $F(M) \oplus F_\nu(M)$, and let (ω^A) be its dual. Then $f^* \omega^\alpha = 0$ for $n + 1 \leq \alpha \leq$

$n + p$. Let $(\tilde{\omega}_B^A)_{1 \leq A, B \leq n+p}$ and $(\tilde{\Phi}_B^A)_{1 \leq A, B \leq n+p}$ be the \dagger connection form and the \dagger curvature form of \bar{M} with respect to (e_A) , and put $\omega_B^A = f^* \tilde{\omega}_B^A$. Then $(\omega_j^i)_{1 \leq i, j \leq n}$ is the connection form of M with respect to $(e_i)_{1 \leq i \leq n}$. $(\omega_i^\alpha)_{1 \leq i \leq n < \alpha \leq n+p}$ gives the second fundamental form, that is,

$$\sigma(e_i, e_j) = \sum \omega_i^\alpha(e_j) e_\alpha. \tag{1'}$$

Put $\omega_j^\alpha = \sum h_{ij}^\alpha \omega^j$. Then (h_{ij}^α) is the matrix representing the symmetric linear transformation A_{e_α} with respect to (e_i) , that is,

$$A_{e_\alpha} e_i = \sum h_{ij}^\alpha e_j. \tag{2'}$$

Moreover, $(\omega_\beta^\alpha)_{n+1 \leq \alpha, \beta \leq n+p}$ is the connection form of the normal connection with respect to $(e_\alpha)_{n+1 \leq \alpha \leq n+p}$. Let $(\Phi_j^i)_{1 \leq i, j \leq n}$ and $(\Phi_\beta^\alpha)_{n+1 \leq \alpha, \beta \leq n+p}$ be the curvature forms of (ω_j^i) and (ω_β^α) , respectively. Then the equations of Gauss, Codazzi, and Ricci are given respectively by

$$f^* \tilde{\Phi}_j^i = \Phi_j^i + \sum_{\alpha=n+1}^{n+p} \omega_\alpha^i \wedge \omega_j^\alpha \quad (1 \leq i, j \leq n), \tag{3'}$$

$$f^* \tilde{\Phi}_i^\alpha = d\omega_i^\alpha + \sum_{A=1}^{n+p} \omega_A^\alpha \wedge \omega_i^A \quad (1 \leq i \leq n < \alpha \leq n+p), \tag{3''}$$

$$f^* \tilde{\Phi}_\beta^\alpha = \Phi_\beta^\alpha + \sum_{k=1}^n \omega_k^\alpha \wedge \omega_\beta^k \quad (n+1 \leq \alpha, \beta \leq n+p). \tag{4'}$$

D. Basic Notions

Let M be a Riemannian submanifold of \bar{M} . A point $x \in M$ is called a **geodesic point** if $\sigma = 0$ at x . If every point of M is a geodesic point, then M is called a **totally geodesic submanifold** of \bar{M} . M is a totally geodesic submanifold of \bar{M} if and only if every geodesic of M is a geodesic of \bar{M} .

A mapping $h: M \rightarrow \nu(M)$ defined by $x \rightarrow \frac{1}{n} \sum_{i=1}^n \sigma(e_i, e_i)$ is independent of the choice of an orthonormal basis (e_i) . h is called the **mean curvature vector** and $\|h\|$ is called the **mean curvature**. M is called a **minimal submanifold** of \bar{M} if $h \equiv 0$ (\rightarrow 275 Minimal Submanifolds).

A point $x \in M$ is called an **umbilical point** if $\sigma = g \otimes h$ at x . $x \in M$ is an umbilical point if and only if A_ξ is proportional to the identity transformation for all $\xi \in \nu_x(M)$. If every point of M is an umbilical point, then M is called a **totally umbilical submanifold** of \bar{M} .

A point $x \in M$ is called an **isotropic point** if $\|\sigma(X, X)\|/\|X\|^2$ does not depend on $X \in T_x(M)$. If every point of M is an isotropic point, then M is called an **isotropic submanifold** of \bar{M} . It is clear that an umbilical point is an isotropic point.

$\mu(x) = \dim \bigcap_{\xi \in \nu_x(M)} \ker A_\xi$ is called the **index of relative nullity** at $x \in M$.

E. Rigidity

An isometric immersion $f: M \rightarrow \tilde{M}$ is said to be **rigid** if it is unique up to an isometry of \tilde{M} , that is, if $f': M \rightarrow \tilde{M}$ is another isometric immersion, then there exists an isometry φ of \tilde{M} such that $f' = \varphi \circ f$. If $f: M \rightarrow \tilde{M}$ is rigid, then every isometry of M can be extended to an isometry of \tilde{M} .

An isometric immersion $f: M \rightarrow M^{n+1}(c)$ of an n -dimensional Riemannian manifold into an $(n+1)$ -dimensional complete and simply connected space form is rigid in each of the following cases:

- (1) $n=2$, $c=0$, and M is compact and of positive curvature (S. Cohn-Vossen (1929)).
- (2) The index of relative nullity is $\leq n-3$ at each point (R. Beez (1876); — [8]).
- (3) $n \geq 5$, $c > 0$, M is complete, and the index of relative nullity is $\leq n-2$ at each point (D. Ferus (1970)).
- (4) $n \geq 4$, $c \neq 0$, and the \dagger scalar curvature of M is constant ($\neq n(n-1)c$) (C. Harle (1971)).

A generalization of (2) for the case of higher codimension was obtained by C. Allendoerfer (1939). Various rigidity conditions have been studied by S. Dolbeault-Lemoine, R. Sacksteder, E. Kaneda and N. Tanaka, and others.

F. Totally Geodesic and Totally Umbilical Submanifolds

A totally geodesic submanifold of a space form is also a space form of the same curvature. Totally geodesic submanifolds of compact \dagger symmetric spaces of rank 1 were completely classified by J. A. Wolf (1963), and totally geodesic submanifolds of symmetric spaces of rank ≥ 2 were studied by Wolf and B. Y. Chen and T. Nagano [4].

Let $f: M \rightarrow M^{n+p}(\tilde{c})$ be a totally umbilical immersion of an n -dimensional Riemannian manifold M into an $(n+p)$ -dimensional space form. Then M is a space form $M^n(c)$ with $c \geq \tilde{c}$, and $f(M)$ is contained in a certain $(n+1)$ -dimensional totally geodesic submanifold $M^{n+1}(\tilde{c})$ of $M^{n+p}(\tilde{c})$. If $\tilde{c} > 0$, then $f(M)$ is locally a hypersphere; if $\tilde{c} = 0$, then $f(M)$ is locally a hyperplane or a hypersphere; if $\tilde{c} < 0$, then $f(M)$ is locally a geodesic sphere, a horosphere, or a parallel hypersurface of a totally geodesic hypersurface [2].

G. Minimal Submanifolds

For general properties of minimal submanifolds — 275 Minimal Submanifolds.

There is no compact minimal submanifold in a simply connected Riemannian manifold with nonpositive sectional curvature (O'Neill

(1960)). On the contrary, a sphere has plenty of compact minimal submanifolds.

For each positive integer s , an n -dimensional sphere of curvature $\frac{n}{s(s+n-1)}$ can be minimally immersed into a $\left\{ (2s+n-1) \frac{(s+n-2)!}{s!(n-1)!} - 1 \right\}$ -dimensional unit sphere and the immersion is rigid if $n=2$ or $s \leq 3$ (E. Calabi (1967), M. do Carmo and N. Wallach (1971)).

Among all n -dimensional compact minimal submanifolds of an $(n+p)$ -dimensional unit sphere, the totally geodesic submanifold is isolated in the sense that it is characterized by each of the following conditions:

- (1) sectional curvature $> \frac{n}{2(n+1)}$ (T. Itoh (1978)),
- (2) Ricci curvature $> n-2$ (N. Ejiri (1979)),
- (3) scalar curvature $> n(n-1) - \frac{n}{2-1/p}$ (J. Simons (1968)).

H. Submanifolds of Constant Mean Curvature

A manifold of constant mean curvature is a solution to a variational problem. In particular, with respect to any volume-preserving variation of a domain D in a Euclidean space, the mean curvature of $M = \partial D$ is constant if and only if the volume of M is critical.

The interesting question "If the mean curvature of an isometric immersion $f: M \rightarrow M^{n+1}(c)$ of an n -dimensional compact Riemannian manifold M into an $(n+1)$ -dimensional space form $M^{n+1}(c)$ is constant, is M a sphere?" has not yet been completely solved, where $M^{n+1}(c)$ denotes a Euclidean space, a hyperbolic space, or an open hemisphere according as $c=0$, <0 , or >0 . The answer is affirmative in the following cases: (1) $\dim M=2$, and the \dagger genus of M is zero (H. Hopf (1951), Chern (1955)). (2) f is an embedding (A. D. Alexandrov (1958); — [8]).

These results remain true even if the assumption "the mean curvature is constant" is replaced by the weaker condition "the principal curvatures $k_1 \geq \dots \geq k_n$ satisfy a relation $\varphi(k_1, \dots, k_n) = 0$ such that $\partial\varphi/\partial k_i > 0$."

Unlike an open hemisphere, a sphere S^{n+1} admits many compact hypersurfaces of constant mean curvature, among which totally umbilical hypersurfaces and the product of two spheres are the only ones with nonnegative sectional curvature (B. Smyth and K. Nomizu (1969)).

A nonnegatively or nonpositively curved complete surface of nonzero constant mean curvature in a 3-dimensional space form $M^3(c)$ is either a sphere or a \dagger Clifford torus if $c > 0$ and is either a sphere or a right circular

cylinder if $c \leq 0$ (T. Klotz and R. Osserman (1966–1967), D. Hoffman (1973)).

I. Isoparametric Hypersurfaces

A hypersurface M of \tilde{M} is said to be **isoparametric** if M is locally defined as the \dagger level set of a function f on (an open set of) \tilde{M} with property

$$df \wedge d\|df\|^2 = 0 \quad \text{and} \quad df \wedge d(\Delta f) = 0.$$

A hypersurface M of a complete and simply connected space form $M^{n+1}(c)$ is isoparametric if and only if M has locally constant principal curvatures (Cartan). If $c \leq 0$, M has at most two distinct principal curvatures (Cartan). If $c > 0$, the number of distinct principal curvatures of M is 1, 2, 3, 4, or 6 (H. Münzner (1980)). If $c = 0$, then M is locally $S^k \times E^{n-k}$, and if $c < 0$, then M is locally E^n or $S^k \times H^{n-k}$ (Cartan). Isoparametric hypersurfaces of S^{n+1} having at most three distinct principal curvatures were completely classified by Cartan. R. Takagi, T. Takahashi, and H. Ozeki and M. Takeuchi obtained several results for isoparametric hypersurfaces of S^{n+1} with four or six distinct principal curvatures [7].

If a subgroup of the isometry group of $M^{n+1}(c)$ acts transitively on M , then M is isoparametric. The converse is true if $c \leq 0$, or if $c > 0$ and M has at most three distinct principal curvatures (Cartan), but not true in general (Ozeki and Takeuchi [7]).

J. Isometric Immersions between Space Forms

Let $f: M^n(c) \rightarrow M^{n+p}(\tilde{c})$ be an isometric immersion of an n -dimensional space form into an $(n+p)$ -dimensional space form.

- (1) If $n = 2, p = 1, c > 0, c \geq \tilde{c}, M^2(c)$ is complete, and $M^3(\tilde{c})$ is complete and simply connected, then f is totally umbilical (H. Liebmann (1901); \rightarrow [2]).
- (2) If $n = 2, p = 1, c < 0, c < \tilde{c}, M^2(c)$ is complete, and $M^3(\tilde{c})$ is complete and simply connected, then f does not exist (D. Hilbert (1901); \rightarrow [2]).
- (3) If $n = 2, p = 1, c = 0 < \tilde{c}, M^2(0)$ is complete, and $M^3(\tilde{c})$ is complete and simply connected, then there exist infinitely many f (L. Bianchi (1896); \rightarrow [2]).
- (4) If $n = 2, p = 1, c = 0 > \tilde{c}, M^2(0)$ is complete, and $M^3(\tilde{c})$ is complete and simply connected, then $f(M^2(0))$ is either a horosphere or a set of points at a fixed distance from a geodesic (J. Volkov and S. Vladimirova, S. Sasaki; \rightarrow [2]).
- (5) If $n \geq 3, p = 1$, and $c > \tilde{c}$, then f is totally umbilical.
- (6) If $p = 1, c = \tilde{c} = 0, M^n(0)$ is complete, and $M^{n+1}(0)$ is complete and simply connected,

then f is cylindrical (A. Pogorelov (1956), P. Hartman and L. Nirenberg (1959), and others).

- (7) If $p \leq n - 1, c = \tilde{c} > 0$, and both $M^n(c)$ and $M^{n+p}(\tilde{c})$ are complete, then f is totally geodesic (D. Ferus (1975)).
- (8) If $p \leq n - 1, \tilde{c} > c > 0, M^n(c)$ is complete, and $M^{n+p}(\tilde{c})$ is complete and simply connected, then f does not exist (J. Moore (1972)).

K. Homogeneous Hypersurfaces

Let M be an n -dimensional \dagger homogeneous Riemannian manifold which is isometrically immersed into an $(n+1)$ -dimensional complete and simply connected space form $M^{n+1}(c)$.

- (1) If $c = 0$, then M is isometric to $S^k \times E^{n-k}$ (S. Kobayashi (1958), Nagano (1960), Takahashi [9]).
- (2) If $c > 0$, then M is isometric to E^2 or else is given as an orbit of a subgroup of the isometry group of $M^{n+1}(c)$ (W. Y. Hsiang, H. B. Lawson, Takagi; \rightarrow [7]).
- (3) If $c < 0$, then M is isometric to $E^n, S^k \times H^{n-k}$, or a 3-dimensional group manifold

$$B = \left\{ \begin{pmatrix} e^t & 0 & x \\ 0 & e^{-t} & y \\ 0 & 0 & 1 \end{pmatrix} \mid x, y, t \in \mathbf{R} \right\}$$

with the metric $ds^2 = e^{-2t} dx^2 + e^{2t} dy^2 + dt^2$ (Takahashi (1971)). Each of the hypersurfaces above except E^2 in (2) and B in (3) is given as an orbit of a certain subgroup of the isometry group of $M^{n+1}(c)$.

L. Kähler Submanifolds

A \dagger complex submanifold of a \dagger Kähler manifold is a Kähler manifold with respect to the induced Riemannian metric. A complex analytic and isometric immersion of a Kähler manifold (M, J, g) into a Kähler manifold $(\tilde{M}, \tilde{J}, \tilde{g})$ is called a **Kähler immersion**, and M is called a **Kähler submanifold** of \tilde{M} . A Kähler submanifold is a minimal submanifold. A compact Kähler submanifold M of a Kähler manifold \tilde{M} can never be homologous to 0, that is, there exists no submanifold M' of \tilde{M} such that $M = \partial M'$. If $[M] \in H_*(\tilde{M}, \mathbf{Z})$ denotes the \dagger homology class represented by a Kähler submanifold M of \tilde{M} , then $\text{vol}(M) \leq \text{vol}(M')$ holds for any submanifold $M' \in [M]$ with equality if and only if M' is a Kähler submanifold (W. Wirtinger (1936)).

A Kähler manifold of constant \dagger holomorphic sectional curvature is called a **complex space form**. An n -dimensional complete and simply connected complex space form is either $P_n(C), C^n$, or D_n . Every Kähler submanifold of a complex space form is rigid (Calabi [10]).

Kähler immersions of complex space forms

into complex space forms were completely determined by Calabi [10] and by H. Nakagawa and K. Ogiue (1976).

C^n (resp. D_n) is the only \dagger Hermitian symmetric space that can be immersed in C^m (resp. D_m) as a Kähler submanifold (Nakagawa and Takagi [11]), and Kähler immersions of Hermitian symmetric spaces into $P_m(C)$ were precisely studied by Nakagawa, Y. Sakane, Takagi, Takeuchi, and others. More generally, Kähler immersions of homogeneous Kähler manifolds into $P_m(C)$ were determined by Takeuchi (1978).

$Q_n = \{[z_i] \in P_{n+1}(C) \mid \sum z_i^2 = 0\}$ in $P_{n+1}(C)$ is the only Einstein-Kähler hypersurface of a complex space form that is not totally geodesic (B. Smyth (1967), S. S. Chern (1967)). The result remains true even if "Einstein" is replaced by "parallel Ricci tensor" (Takahashi (1967)). Besides linear subspaces, Q_n is the only Einstein-Kähler submanifold of $P_m(C)$ that is a complete intersection (J. Hano (1975)).

Integral theorems and pinching problems with respect to various curvatures for compact Kähler submanifolds of $P_m(C)$ have been studied by K. Ogiue, S. Tanno (1973), S. T. Yau (1975), and others [12]. For example, if the holomorphic sectional curvature of $P_{n+p}(C)$ is 1, then each of the following is sufficient for an n -dimensional compact Kähler submanifold to be totally geodesic:

- (1) holomorphic sectional curvature $> 1/2$ (A. Ros (1985)),
- (2) sectional curvature $> 1/8$ (A. Ros and L. Verstraelen (1984)),
- (3) Ricci curvature $> n/2$ [12],
- (4) embedded and scalar curvature $> n^2$ (J. H. Cheng (1981)).

The index of relative nullity $\mu(x)$ of an n -dimensional complete Kähler submanifold M of $P_m(C)$ satisfies $\text{Min}_{x \in M} \mu(x) = 0$ or $2n$ (K. Abe (1973)).

M. Totally Real Submanifolds

An isometric immersion of a Riemannian manifold (M, g) into a Kähler manifold $(\tilde{M}, \tilde{J}, \tilde{g})$ satisfying $\tilde{J}T_x(M) \subset v_x(M)$ at each point $x \in M$ is called a **totally real immersion**, and M is called a **totally real submanifold** of \tilde{M} . A totally geodesic submanifold $P_n(R)$ in $P_n(C)$, $S^1 \times S^1$ in $P_2(C)$ and an immersion $P_n(C) \rightarrow P_{n(n+2)}(C)$ defined by $[z_i] \rightarrow [z_i \bar{z}_j]$ give typical examples of totally real submanifolds.

N. Submanifolds with Planar Geodesics

A surface in E^3 whose geodesics are all plane curves is (a part of) a plane or sphere. More

generally, let $f: M \rightarrow M^m(c)$ be an isometric immersion of M into a complete and simply connected space form $M^m(c)$. If the image of each geodesic of M is contained in a 2-dimensional totally geodesic submanifold of $M^m(c)$, then f is either a totally geodesic immersion, a totally umbilical immersion or a minimal immersion of a compact symmetric space of rank 1 by harmonic functions of degree 2; the last case occurs only when $c > 0$ (S. L. Hong (1973), J. Little (1976), K. Sakamoto [14]).

A Kähler submanifold of a complete and simply connected complex space form with the same property as above is either a totally geodesic submanifold or a Veronese submanifold (a Kähler immersion of $P_n(C)$ into $P_{n(n+3)/2}(C)$) (K. Nomizu (1976)).

Submanifolds with the above property are closely related to isotropic submanifolds with $\nabla^* \sigma = 0$. Submanifolds with $\nabla^* \sigma = 0$ in symmetric spaces have been studied by Ferus, H. Naito, Takeuchi, K. Tsukada, and others.

O. Total Curvature

Let $f: M \rightarrow E^m$ be an isometric immersion of an n -dimensional compact Riemannian manifold M into a Euclidean space. Let $v_1(M)$ be the unit normal bundle, S^{m-1} the unit sphere centered at $O \in E^m$, and let $f_{\perp}: v_1(M) \rightarrow S^{m-1}$ be the parallel translation. Let ω and Ω be the \dagger volume elements of $v_1(M)$ and S^{m-1} , respectively. Then for each $\xi \in v_1(M)$, $f_{\perp}^* \Omega = (\det A_{\xi}) \omega$ holds. As a generalization of the \dagger total curvature for a space curve, the **total curvature** of the immersion f is defined as

$$\begin{aligned} \tau(f) &= \frac{1}{\text{vol}(S^{m-1})} \int_{v_1(M)} |f_{\perp}^* \Omega| \\ &= \frac{1}{\text{vol}(S^{m-1})} \int_{v_1(M)} |\det A_{\xi}| \omega. \end{aligned}$$

If $\beta(M)$ is the least number of critical points of a \dagger Morse function on M , then

$$\inf_f \tau(f) = \beta(M) \geq 2$$

holds (Chern and R. Lashof (1957, 1958), Kuiper (1958)). $\tau(f) = 2$ if and only if f is an embedding and $f(M)$ is a convex hypersurface of some E^{n+1} in E^m (Chern and Lashof (1958)). If $\tau(f) < 3$, then M is homeomorphic to S^n (Chern and Lashof (1958)). These results generalize theorems for space curves by W. Fenchel (1929), I. Fary (1949), J. Milnor (1950), and others.

An isometric immersion f which attains $\inf(f)$ is called a **minimum immersion** or a **tight immersion**. \dagger Exotic spheres do not have minimum immersions (Kuiper (1958)). $\dagger R$ -

Riemannian Submanifolds

spaces have minimum immersions and, in particular, a minimum immersion of a symmetric R -space is a †minimal immersion into a hypersphere (Kobayashi and Takeuchi (1968)).

The **total mean curvature** of an isometric immersion $f: M \rightarrow E_m$ of an n -dimensional compact Riemannian manifold into a Euclidean space is, by definition,

$$\int_M \|b\|^n * 1.$$

It satisfies

$$\int_M \|b\|^n * 1 \geq \text{vol}(S^n),$$

where S^n is the n -dimensional unit sphere. The equality holds if and only if f is totally umbilical (T. J. Willmore (1968), Chen [3]).

Riemann-Roch Theorems

A. General Remarks

The †Riemann-Roch theorem (abbreviation: R. R. theorem) is one of the most significant results in the classical theory of †algebraic functions of one variable. Let X be a compact †Riemann surface of †genus g , and let $D = \sum m_i P_i$ be a †divisor on X . We denote by $\deg D$ the degree of D , which is defined to be $\sum m_i$. The divisor D is said to be positive if $D \neq 0$ and $m_i \geq 0$ for all i . A nonzero †meromorphic function f on X determines a divisor $(f) = \sum a_i Q_i - \sum b_j R_j$ ($a_i, b_j > 0$), where the Q_i are the zeros of order a_i and the R_j are the poles of order b_j . The set of meromorphic functions f such that $(f) + D$ is positive, together with the constant $f = 0$, forms a finite-dimensional linear space $L(D)$ over \mathbb{C} . The R. R. theorem asserts that $\dim L(D) = \deg D - g + 1 + r(D)$, where $r(D)$ is a nonnegative integer determined by D . If K is the †canonical divisor of X , then $r(D) = \dim L(K - D)$ (\rightarrow 9 Algebraic Curves C; 11 Algebraic Functions D). (For the R. R. theorem for algebraic surfaces \rightarrow 15 Algebraic Surfaces D.)

Generalizations of this important theorem to the case of higher-dimensional compact †complex manifolds were obtained by K. Kodaira, F. Hirzebruch, A. Grothendieck, M. F. Atiyah and I. M. Singer, and others. Let X be a compact complex manifold, B be a †complex line bundle over X , and $\mathcal{O}(B)$ be the †sheaf of germs of holomorphic cross sections of B . When B is determined by a divisor D of X , we have $H^0(X, \mathcal{O}(B)) \cong L(D)$. Hence a desirable generalization of the R. R. theorem will provide a description of $\dim_{\mathbb{C}} H^0(X, \mathcal{O}(B))$ in terms of quantities relating to the properties of X and B . Following this idea, various theorems of Riemann-Roch type have been obtained.

B. Hirzebruch's Theorem of R. R. Type

Keeping the notation given in Section A, we put $\chi(X, \mathcal{O}(B)) = \sum_{q=0}^n (-1)^q \dim H^q(X, \mathcal{O}(B))$.

Generally, if \mathcal{F} is an arbitrary †coherent analytic sheaf on X , we can define $\chi(X, \mathcal{F})$ using the same formula (replacing $\mathcal{O}(B)$ by \mathcal{F}). The quantity $\chi(X, \mathcal{F})$ has simple properties in various respects. For example, if the sequence $0 \rightarrow \mathcal{F}' \rightarrow \mathcal{F} \rightarrow \mathcal{F}'' \rightarrow 0$ is exact, we have $\chi(X, \mathcal{F}) = \chi(X, \mathcal{F}') + \chi(X, \mathcal{F}'')$. If an †analytic vector bundle F depends continuously on auxiliary parameters, then $\chi(X, \mathcal{O}(F))$ remains constant. Let X be a projective algebraic manifold of complex dimension n . We consider the †Chern class $c = 1 + c_1 + \dots + c_n$ of X and express it formally as the product $\prod_{i=1}^n (1 + \gamma_i)$. Thus the i th Chern class c_i is expressed as the i th elementary symmetric function of $\gamma_1, \dots, \gamma_n$. Consider the formal expression $T(X) = \prod_{i=1}^n \gamma_i / (1 - e^{-\gamma_i})$. $T(X)$ can be expanded as a formal power series in the γ_i , and each homogeneous term, being symmetric in the γ_i , can be expressed as a polynomial in c_1, \dots, c_n , and thus determines a cohomology class of X . Similarly, we consider the formal expression of the Chern class of the vector bundle F as $1 + d_1 + \dots + d_q = \prod_{j=1}^q (1 + \delta_j)$, where q is the dimension of the fiber of F . We put $ch(F) = \sum_{j=1}^q e^{\delta_j}$. The formal series $ch(F)$ is also an element of the cohomology ring of X whose $(v+1)$ st term consists of a $2v$ -dimensional cohomology class. We call $ch(F)$ the †Chern character of F (→ 237 K-Theory B), and define $T(X, F)$ to be the value of $ch(F) T(X)$ at the †fundamental cycle X . (The multiplication $ch(F) \cdot T(X)$ is formal. $T(X, F)$ is determined by the term of dimension $2n$ alone.) $T(X, F)$ is called the **Todd characteristic** with respect to F . **Hirzebruch's theorem of R. R. type** asserts that $\chi(X, \mathcal{O}(F)) = T(X, F)$. In particular, when $n = 1$, $F = [D]$ (the line bundle determined by the divisor D), Hirzebruch's formula yields the classical R. R. theorem. If F satisfies the conditions for the vanishing theorem of cohomologies, the formula gives an estimate for $\dim H^0(X, \mathcal{O}(F))$ [11].

In 1963, Atiyah and Singer developed a theory on indices of elliptic differential operators on a compact orientable differentiable manifold and obtained a general result that includes the proof of Hirzebruch's theorem for an arbitrary compact complex manifold [4, 5] (→ 237 K-Theory H).

C. R. R. Theorem for Surfaces

If X is a compact complex surface, i.e., a compact complex manifold of dimension 2, then for complex line bundles F_1 and F_2 , the intersection number $(F_1 F_2)$ is defined to be $c_1(F_1) \cup c_1(F_2)[X]$. The **R. R. theorem for a line bundle F on X** is stated as follows: $\chi(X, \mathcal{O}(F)) = (F^2)/2 - (KF)/2 + ((K^2) + c_2(X))/12$, where

Riemann-Roch Theorems

K is the canonical line bundle of X and $c_2(X)$ denotes the value at X of the 2nd Chern class of X , that is, the Euler number of X .

The Noether formula $\chi_X = ((K^2) + c_2(X))/12$ follows from the above identity. The R. R. theorem for surfaces is a powerful tool for the study of compact complex surfaces.

D. Grothendieck's Theorem of R. R. Type

Grothendieck took an entirely new point of view in generalizing Hirzebruch's theorem. The following is a description of his idea as reformulated by A. Borel and J.-P. Serre [8]. We consider a nonsingular quasiprojective algebraic variety X (→ 16 Algebraic Varieties) over a ground field of arbitrary characteristic. Namely, X is a closed subvariety of an open set in a projective space (over an algebraically closed ground field). Consider the group $K(X)$, which is the quotient of the free Abelian group generated by the equivalence classes of algebraic vector bundles over X modulo the subgroup generated by the elements of the form $F - F' - F''$, where F, F', F'' are classes of bundles such that there exists an exact sequence $0 \rightarrow F' \rightarrow F \rightarrow F'' \rightarrow 0$. A similar construction for the (equivalence classes of the) †coherent algebraic sheaves instead of the vector bundles yields another Abelian group $K'(X)$. It can be shown that $K(X)$ is isomorphic to $K'(X)$ by the correspondence $F \rightarrow \mathcal{O}(F)$ (= the sheaf of germs of regular cross sections of F). Addition in $K(X)$ is induced by the †Whitney sum of the bundles, and $K(X)$ has the structure of a ring with multiplication induced by the tensor product. For a vector bundle F , its Chern class $c(F) = 1 + c_1(F) + \dots + c_q(F)$ (q = the dimension of the fiber) is defined as an element of the †Chow ring $A(X)$ with appropriate properties. ($A(X)$ is the ring of the rational equivalence classes of algebraic cycles on X , and $c_i(F)$ is the class of a cycles of codimension i .) We define $ch(F)$ as before. It can be shown that $c(F)$ and $ch(F)$ are determined by the image of F in $K(X)$, and we have $c(\xi + \eta) = c(\xi)c(\eta)$, $ch(\xi + \eta) = ch(\xi) + ch(\eta)$, $ch(\xi\eta) = ch(\xi)ch(\eta)$ ($\xi, \eta \in K(X)$). If we have a †proper morphism $f: Y \rightarrow X$ between quasiprojective algebraic varieties Y and X , we have homomorphisms $f^!: K(X) \rightarrow K(Y)$ and $f_*: K(Y) \rightarrow K(X)$. The former is defined by taking the induced vector bundle and the latter by the correspondence

$$\mathcal{F} \rightarrow \sum (-1)^q (\mathcal{R}^q f) \mathcal{F},$$

where \mathcal{F} is a coherent algebraic sheaf on Y and $(\mathcal{R}^q f) \mathcal{F}$ is the q th †direct image of \mathcal{F} under f . (Since f is proper, $(\mathcal{R}^q f) \mathcal{F}$ is coherent.) Between Chow rings we have homomor-

Riemann-Roch Theorems

phisms $f^*: A(X) \rightarrow A(Y)$ and $f_*: A(Y) \rightarrow A(X)$, defined by taking inverse and direct images of cycles. With this notation, the theorem asserts that if X and Y are quasiprojective and $f: Y \rightarrow X$ is a proper morphism, then $f_*(ch(\xi)T(Y)) = ch(f_*(\xi))T(X)$. This is called **Grothendieck's theorem of R. R. type**. If X consists of a single point, the theorem gives Hirzebruch's theorem for algebraic bundles. Since algebraic and analytic theories of coherent sheaves on a complex projective space are isomorphic, this result covers Hirzebruch's theorem (\rightarrow 237 *K-Theory*).

The subgroup $R(Y)$ of $A(Y)$ given by $R(Y) = \{ch(\xi) \cdot T(Y) \mid \xi \in K(Y)\}$ is called the **Riemann-Roch group** of Y . Thus, using the notions developed by Grothendieck, the R. R. theorem can be expressed as follows: $R(Y)$ is mapped into $R(X)$ by a proper morphism $f: Y \rightarrow X$. Generalizations to \dagger almost complex manifolds and \dagger differentiable manifolds were made by Atiyah and Hirzebruch in this latter form [1]. One of the remarkable results is that an element of $R(Y)$ takes an integral value at the fundamental cycle. This theorem is obtained by taking X to be a single point.

E. R. R. Theorem for Singular Varieties

Let X be a projective variety over \mathbb{C} and let $H_*(X)$ (resp. $H^*(X)$) denote the singular homology (resp. cohomology) group with rational coefficients. Note that $K(X)$ may not agree with $K'(X)$ when X is singular. The R. R. theorem for X formulated by P. Baum, W. Fulton, and R. MacPherson [6] says that there exists a unique natural transformation $\tau: K'(X) \rightarrow H_*(X)$ such that (1) if $\xi \in K(X)$ and $\eta \in K'(X)$, then $\xi \otimes \eta \in K'(X)$ and $\tau(\xi \otimes \eta) = ch(\xi)(\tau(\eta))$; (2) whenever X is nonsingular, $\tau(\mathcal{O}_X) = T(X)(X)$. Note that the naturality of τ means that for any $f: X \rightarrow Y$ and any $\eta \in K'(X)$, $f_*\tau(\eta) = \tau(f_*\eta)$.

367 (XI.12) Riemann Surfaces

A. General Remarks

Riemann considered certain surfaces, now named after him, obtained by modifying in a suitable manner the domains of definition of multiple-valued \dagger analytic functions on the complex plane in order to obtain single-valued functions defined on the surfaces. For example, consider the function $z = f(w) = w^2$, where w varies in the complex plane, and its inverse function $w = g(z) = \sqrt{z}$. Then $g(0) = 0$ and $g(\infty) = \infty$, whereas if $z \neq 0, \infty$, there exist two values of w satisfying $g(z) = w$. By setting $z = re^{i\theta}$ ($r > 0, 0 \leq \theta < 2\pi$), the corresponding two values of w are $w_1 = \sqrt{r} e^{i\theta/2}$ and $w_2 = \sqrt{r} e^{i(\theta/2 + \pi)}$. Now consider how we should modify the complex z -plane so that we can obtain a single-valued function on the modified surface representing the same relationship

between z and w . Let π_1 and π_2 be two copies of the complex plane. Delete the nonnegative real axes from π_1 and π_2 and patch them crosswise along the slits (Fig. 1). The surface R thus obtained is locally homeomorphic to the complex plane except for the origin and the point at infinity, and situations at the origin and the point at infinity are as indicated in Fig. 1. For $z \neq 0, \infty$, there are two points z_1 and z_2 in π_1 and π_2 , respectively, with the same coordinate z . Let w_1 and w_2 correspond to z_1 and z_2 , respectively. Then the function $w = \sqrt{z}$ becomes single-valued on R , and w_1 and w_2 are holomorphic functions of z_1 and z_2 , respectively. The surface R is called the Riemann surface determined by $w = \sqrt{z}$.

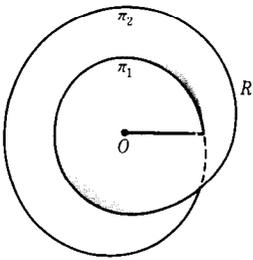

Fig. 1

Working from the idea illustrated by this example, H. Weyl and T. Radó gave rigorous definitions of Riemann surfaces. The usual definition nowadays is as follows: Let \mathfrak{A} be a set of pairs (U, ψ_U) of open sets U in a \dagger connected \dagger Hausdorff space R and topological mappings ψ_U of U onto plane regions satisfying the following two conditions: (i) $R = \bigcup_{(U, \psi_U) \in \mathfrak{A}} U$; (ii) for each $(U_1, \psi_{U_1}), (U_2, \psi_{U_2}) \in \mathfrak{A}$ with $V = U_1 \cap U_2 \neq \emptyset$, $\psi_{U_1} \circ \psi_{U_2}^{-1}$ gives an (orientation-preserving) \dagger conformal mapping of each connected component of $\psi_{U_2}(V)$ onto a corresponding one of $\psi_{U_1}(V)$. Two such sets \mathfrak{A}_1 and \mathfrak{A}_2 are equivalent, by definition, if $\mathfrak{A}_1 \cup \mathfrak{A}_2$ also satisfies conditions (i) and (ii). The equivalence class (\mathfrak{A}) of such \mathfrak{A} is called a **conformal structure (analytic structure or complex structure)** on R (\rightarrow 72 Complex Manifolds). A pair $(R, (\mathfrak{A}))$ consisting of a connected Hausdorff space R and a conformal structure (\mathfrak{A}) is called a **Riemann surface**, with R its **base space** and (\mathfrak{A}) its **conformal structure**. (A Riemann surface in this sense is sometimes called an **abstract Riemann surface**.) It is a complex manifold of \dagger complex dimension 1. For (U, ψ_U) in (\mathfrak{A}) , (U, ψ_U) (or sometimes U itself) is called an **analytic neighborhood**, and ψ_U is called a **local uniformizing parameter** (or simply a **local parameter**). In the remainder of this article we call R itself a Riemann surface.

From condition (i) it follows that a Riemann surface R is a real 2-dimensional \dagger topological

manifold. Moreover, by condition (ii) it can be deduced that R satisfies the \dagger second countability axiom and consequently is a \dagger surface and admits a \dagger simplicial decomposition (T. Radó, 1925). It is also orientable (\rightarrow 410 Surfaces). Therefore R is a \dagger locally compact metric space. It is not possible to define curve lengths on R compatible with the conformal structure, but since angles can be defined, R is considered to be a real 2-dimensional space with a \dagger conformal connection. It is customary in the theory of functions to call R **closed** if it is compact and **open** otherwise. A plane region D is considered an open Riemann surface with the conformal structure $\mathfrak{A} = (D, 1: D \rightarrow D)$. A Riemann sphere is also considered to be a closed Riemann surface whose analytic neighborhoods are given by $\{U_1, \varphi\}$ and $\{U_2, 1/\varphi\}$, where $U_1(U_2)$ is the domain corresponding to $\{|z| < 2\}(\{|z| > 1/2\} \cup \{\infty\})$ under the stereographic projection φ .

A function f on a Riemann surface is said to be meromorphic, holomorphic, or harmonic on R if $f \circ \psi_U^{-1}$ is \dagger meromorphic, \dagger holomorphic, or \dagger harmonic in the usual sense on $\psi_U(U)$ for every analytic neighborhood (U, ψ_U) . More generally, suppose that for mappings between plane regions we are given a property \mathfrak{P} that is invariant under conformal mappings. A mapping T of a Riemann surface R_1 onto another Riemann surface R_2 is said to have the property \mathfrak{P} if the mapping $\psi_{U_2} \circ T \circ \psi_{U_1}^{-1}$ of $\psi_{U_1}(U_1)$ into $\psi_{U_2}(U_2)$ has the property \mathfrak{P} for every pair of analytic neighborhoods (U_1, ψ_{U_1}) and (U_2, ψ_{U_2}) in R_1 and R_2 , respectively. Thus such a mapping T may be conformal, \dagger analytic, \dagger quasiconformal, harmonic, etc. If there exists a one-to-one conformal mapping of a Riemann surface R_1 onto another Riemann surface R_2 , then R_1 and R_2 are said to be **conformally equivalent**. Two such Riemann surfaces are sometimes identified with each other.

B. Covering Surfaces

One of the main themes of the theory of functions is the study of analytic mappings of a Riemann surface R into another Riemann surface R_0 , i.e., the theory of covering surfaces of Riemann surfaces.

Suppose, in general, that there are two surfaces R and R_0 and a continuous open mapping T of R into R_0 such that the inverse image of a point in R_0 under T is an \dagger isolated set in R . Then T is called an **inner transformation** in the sense of Stoilow and $(R, R_0; T)$ a **covering surface** with R_0 its **basic surface** and T its **projection**. Often R is called simply a covering surface of R_0 . A point p_0 with $p_0 =$

Riemann Surfaces

$T(p)$ is called the projection of p , and p is said to lie above p_0 . In this case, there exist surface coordinates (U, ψ) and (U_0, ψ_0) at p and p_0 , respectively, such that $\psi(U) = \{z \mid |z| < 1\}$, $\psi(p) = 0$, $\psi_0(U_0) = \{w \mid |w| < 1\}$, $\psi_0(p_0) = 0$, and $w = (\psi_0 \circ T \circ \psi^{-1})(z) = z^n$, with the positive integer n independent of the choice of coordinate neighborhoods. If $n > 1$, then p is called a **branch point**, n the **multiplicity**, and $n - 1$ the **degree of ramification**. The set of all branch points forms an at most countably infinite set of isolated points. If there is no branch point, then the covering surface $(R, R_0; T)$ and the projection T are said to be **unramified**. For a given curve C_0 in R_0 and a point p in R lying above the initial point of C_0 , a curve C in R with p its initial point satisfying $T(C) = C_0$ is called the **prolongation** along C_0 (or the **lift** of C_0) starting from p . If any proper subarc of C_0 sharing the initial point with C_0 admits a prolongation along itself starting from p but C_0 does not admit a prolongation along itself starting from p , then R is said to have a **relative boundary** above the endpoint of C_0 . A covering surface without a relative boundary is called **unbounded**. A †simply connected surface R^∞ that is an unramified unbounded covering surface of R_0 is said to be a **universal covering surface** of R_0 . The universal covering surface exists for every R .

Suppose that R is an unbounded covering surface of R_0 . Then the number of points on R that lie above each point of R_0 is always constant, say n ($\leq +\infty$), where the branch points of R are counted with their multiplicities. n is called the **number of sheets** of R over R_0 , or R is said to be **n -sheeted** over R_0 . If R and R_0 are compact surfaces with †Euler characteristic χ and χ_0 , respectively, and if R is an n -sheeted covering surface of R_0 , then we have the **Riemann-Hurwitz relation**: $\chi = n\chi_0 - V$, V being the sum of the degrees of ramification. A topological mapping S of an unramified unbounded covering surface R of R_0 onto itself such that $T \circ S = T$ is called a **covering transformation**. The group of all covering transformations of a universal covering surface of R_0 is isomorphic to the †fundamental group (i.e., the 1-dimensional homotopy group) of R_0 .

In a covering surface $(R, R_0; T)$ whose basic surface R_0 is a Riemann surface, T can be regarded as an analytic mapping of R onto R_0 by giving R a conformal structure in a natural manner. In particular, if R_0 is the sphere, then its covering surface is a Riemann surface. Conversely, any Riemann surface can be regarded as a covering surface of the sphere. This fact had long been known for closed Riemann surfaces; for open Riemann surfaces, it can be deduced from the existence theorem of an-

alytic functions proved by H. Behnke and K. Stein, which states that an open Riemann surface is a †Stein manifold. Historically, by a Riemann surface mathematicians meant either the abstract Riemann surface or a covering surface of the sphere, until the two notions were proved identical.

Suppose that R is a covering surface of the z -sphere R_0 with the projection $T: R \rightarrow R_0$, and denote by R_a the region that lies above $0 < |z - a| < r_0$. If there exists a topological mapping ψ of R_a onto $\{(r, \theta) \mid 0 < r < r_0, -\infty < \theta < \infty\}$ such that $a + re^{i\theta} = T(\psi^{-1}(r, \theta))$, then R is said to have a **logarithmic branch point** above a ; in contrast, a branch point of multiplicity n of the type defined previously is sometimes called an **algebraic branch point**.

Ahlfors's theory of covering surfaces, which treats covering surfaces $(R, R_0; T)$ not only from the topological viewpoint but also from the metrical one, is particularly important. Let R and R_0 be either compact surfaces with simplicial decompositions or their closed subregions with boundaries consisting of 1-simplexes and vertices such that T preserves simplicial decompositions. Here we call the part of the boundary of R whose projection is in the interior of R_0 the relative boundary. With respect to a suitable metric on R_0 , let S be the ratio of areas of R and R_0 , L the length of the relative boundary, and $-\rho$ and $-\rho_0$ the †Euler characteristics of R and R_0 , respectively. Then **Ahlfors's principal theorem** asserts that $\max(0, \rho) \geq \rho_0 S - hL$, where $h > 0$ is a constant determined only by R_0 . This has been applied widely in various branches of mathematics, including the theory of distribution of values of analytic mappings between Riemann surfaces.

C. Uniformization

Suppose that we are given a correspondence between the z -plane and w -plane determined by a †function element $p_0 = (z_0^*, w_0^*)$ ($z_0^* = P_0(t)$, $w_0^* = Q_0(t)$). This correspondence generally gives rise to a multiple-valued analytic function $w = f(z)$. We show how to construct a Riemann surface so that the function $w = f(z)$ can be considered a single-valued function on it. We use f again to mean the connected component of the set of function elements $p = (z^*, w^*)$ ($z^* = P(t)$, $w^* = Q(t)$) in the wider sense containing p_0 , where the analytic neighborhood of each point p is defined to be the set of elements that are direct analytic continuations of p . Then f is a Riemann surface. For a point $p = (z^*, w^*)$ ($z^* = P(t)$, $w^* = Q(t)$) in f , set $z = F(p) = P(0)$, $w = G(p) = Q(0)$. Then two meromorphic functions $z = F(p)$ and $w = G(p)$

are defined on f , and f can be considered as a covering surface of the z -sphere and the w -sphere. We call f an †analytic function in the wider sense. Thus we obtain a single-valued function $w = G(p)$ on the Riemann surface f that can be regarded as a modification of the original function $w = f(z)$. Suppose that there exist two meromorphic functions $z = \varphi(\zeta)$ and $w = \psi(\zeta)$ on a region D in the ζ -plane, and let $z = P(\zeta - \zeta_0)$ and $w = Q(\zeta - \zeta_0)$ be †Laurent expansions of φ and ψ at each point ζ_0 in D . If the function element $p_{\zeta_0} = (z^*, w^*)$ ($z^* = P(t)$, $w^* = Q(t)$) belongs to the Riemann surface f , then the correspondence $w = f(z)$ determined by the function element p_{ζ_0} is said to be **locally uniformized** on D by $z = \varphi(\zeta)$ and $w = \psi(\zeta)$. In particular, if $\{p_\zeta | \zeta \in D\} = f$, then f is said to be **uniformized** by $z = \varphi(\zeta)$ and $w = \psi(\zeta)$. If an analytic function f in the wider sense, considered as a Riemann surface, is conformally equivalent to a region D in the ζ -plane, then f can be uniformized by $z = F(p)$ and $w = G(p)$. In general, f is not conformally equivalent to a plane region, but if an unramified unbounded covering surface $(\hat{f}, f; T)$ of f is conformally equivalent to a region D in the ζ -plane, then f is uniformized by $z = F \circ T(\zeta)$ and $w = G \circ T(\zeta)$ (**Schottky's uniformization**). In particular, since the universal covering surface $(f^\infty, f; T)$ of f is simply connected, it is conformally equivalent to the sphere $|\zeta| \leq \infty$, the finite plane $|\zeta| < \infty$, or the unit disk $|\zeta| < 1$. Consequently, f is uniformized by $z = F \circ T(\zeta)$ and $w = G \circ T(\zeta)$. Therefore analytic functions in the wider sense are always uniformizable.

For example, an †algebraic function f considered as a Riemann surface is always closed. If its †genus $g = 0$, then f is the sphere and is thus uniformized by rational functions $z = F(\zeta)$ and $w = G(\zeta)$. If $g > 0$, then $(f^\infty, f; T)$ is conformally equivalent to $|\zeta| < 1$ or $|\zeta| < \infty$, and hence f is uniformized by $z = F \circ T(\zeta)$ and $w = G \circ T(\zeta)$. When $|\zeta| < 1$, z and w are †automorphic functions with respect to the group of linear transformations preserving $|\zeta| < 1$, while if $|\zeta| < \infty$, they are †elliptic functions.

D. The Type Problem

A simply connected Riemann surface R is conformally equivalent to the sphere, the finite plane, or the unit disk. Then R is said to be **elliptic**, **parabolic**, or **hyperbolic**, respectively. The problem of determining the types of simply connected covering surfaces of the sphere by their structures, such as the distributions of their branch points, is called the **type problem** for Riemann surfaces. For example, if a simply connected covering surface does not cover three points on the sphere, it must be hyper-

bolic (Picard's theorem). The Nevanlinna theory of meromorphic functions stimulated this type problem. However, it is difficult to measure the ramifications of covering surfaces, and many detailed results of the type problem obtained in the 1930s are limited mainly to the case where all branch points lie above a finite number of points on the sphere. A sufficient condition for R to be of parabolic type, given by Z. Kobayashi (using the so-called Kobayashi net, and a sufficient condition for R to be of hyperbolic type, given by S. Kaku-tani (using quasiconformal mappings), are significant results on the type problem. The type problem had by then been extensively generalized to the following classification theory.

E. Classification Theory of Riemann Surfaces

Riemann surfaces are, as pointed out by Weyl, "not merely devices for visualizing the many-valuedness of analytic functions, but rather an essential component of the theory ... the only soil in which the functions grow and thrive." So the problem naturally arises of how to extend various results in the theory of analytic functions of a complex variable to the theory of analytic mappings between Riemann surfaces. In general, open Riemann surfaces can have infinite genus and are quite complicated. So to obtain fruitful results and systematic development, one usually sets certain restrictions on the properties of the Riemann surfaces. In connection with this, R. Nevanlinna, L. Sario, and others initiated the **classification theory of Riemann surfaces**, which classifies Riemann surfaces by the existence (or non-existence) of functions with certain properties.

Denote by $\mathfrak{X}(R)$ the totality of functions on a Riemann surface R with a certain property \mathfrak{X} . The set of all Riemann surfaces R for which $\mathfrak{X}(R)$ does not contain any function other than constants is denoted by $O_{\mathfrak{X}}$. The family of analytic functions and the family of harmonic functions are denoted by $A(R)$ and $H(R)$, respectively. The family of positive functions, that of bounded functions, and that of functions with finite Dirichlet integrals are denoted by $P(R)$, $B(R)$, and $D(R)$, respectively. From these families, various new families are created, e.g., $ABD(R) = A(R) \cap B(R) \cap D(R)$. Usually O_{HB} , O_{HD} , O_{HBD} , O_{AB} , O_{AD} , O_{ABD} , and also O_G , the family of Riemann surfaces on which there are no Green's functions, are considered. P. J. Myrberg found an example of a Riemann surface of infinite genus which has a large boundary but belongs to O_{AB} . The idea behind Myrberg's example is often used to construct examples in classification theory. From works

of Y. Tôki, L. Sario, K. I. Virtanen, H. L. Royden, M. Parreau, M. Sakai, and others, it can be seen that there are inclusion relations, as indicated in Fig. 2, among the classes just mentioned. There is no inclusion relation between O_{AB} and O_{HD} . For Riemann surfaces of finite genus, $O_G = O_{HD}$. Closed Riemann surfaces are all in O_G .

Open Riemann surfaces in O_G are also said to be **parabolic** (or of **null boundary**), and those not in O_G , **hyperbolic** (or of **positive boundary**). Several characterizations for parabolic Riemann surfaces are known.

$$O_G \supseteq O_{HP} \supseteq O_{HB} \supseteq O_{HD} = O_{HBD} \supseteq O_{AD} = O_{ABD} \\ \supseteq O_{AB}$$

Fig. 2

From a similar point of view, the classification problem for subregions was studied in detail by Parreau, A. Mori, T. Kuroda, and others. We call a noncompact region Ω which is the complement of a compact subset of a Riemann surface a **Heins's end**. M. Heins called the minimal number ($\leq \infty$) of generators of the semigroup of the additive class of *HP*-functions that vanish continuously at the relative boundary of a Heins's end Ω the **harmonic dimension** of Ω . Its properties were investigated by Z. Kuramochi, M. Ozawa, and others. Generally, a function f is said to be **\mathfrak{X} -minimal** if f is positive and contained in $\mathfrak{X}(R)$ and there exists a constant C_g for every g in $\mathfrak{X}(R)$ with $f \geq g \geq 0$ such that $g \equiv C_g f$. The family of Riemann surfaces R not belonging to O_G and admitting \mathfrak{X} -minimal functions on R is denoted by $U_{\mathfrak{X}}$. C. Constantinescu and A. Cornea and others studied Riemann surfaces in U_{HB} and U_{HD} where HD is the class of positive functions in HD or limits of monotone decreasing sequences of such functions. There are inclusion relations $U_{HB} \supseteq O_{HB} - O_G$, $U_{HD} \supseteq O_{HD} - O_G$, and $U_{HD} \supseteq U_{UB}$. One of the interesting results in classification theory is the fact, discovered by Kuramochi, that $U_{HB} \cup O_G \supseteq O_{AB}$ and $U_{HD} \cup O_G \supseteq O_{AD}$.

Classification theory has a very deep connection with the theory of ideal boundaries. A. Pfluger and Royden showed that the classes O_G and O_{HD} are invariant under quasiconformal mappings. However, it is still an open problem whether O_{HB} is invariant in this sense.

F. Prolongations of Riemann Surfaces

As classification theory shows, pathological phenomena occur for Riemann surfaces from the viewpoint of function theory in the plane. These are caused by the complexity of ideal

boundaries of Riemann surfaces, and in particular by the complexity of the set of ideal boundary points at which handles of Riemann surfaces (i.e., parts with cycles not homologous to 0) accumulate. Hence it is desirable to find larger Riemann surfaces so that ideal boundary points of original surfaces that are not accumulating points of handles become interior points. Suppose that a Riemann surface R is conformally equivalent to a proper subregion R' of another Riemann surface R_1 . Then R_1 is said to be a **prolongation** of R , and R is **prolongable**. A nonprolongable Riemann surface is said to be **maximal**. Closed Riemann surfaces are always maximal, but there also exist maximal open Riemann surfaces (Radó). However, every open Riemann surface is homeomorphic to a prolongable Riemann surface (S. Bochner). Characterizations of prolongable Riemann surfaces and relationships between the various null classes mentioned in Section E and prolongations were investigated from several viewpoints by R. de Possel, J. Tamura, and others.

G. Analytic Mappings of Riemann Surfaces

Apart from the development of the classification theory of Riemann surfaces, efforts have been made to extend various results in the theory of analytic functions of a complex variable to the case of analytic mappings between Riemann surfaces. L. Sario studied the method of **normal operators**, which is utilized to construct harmonic functions on Riemann surfaces with given singularities at their ideal boundaries; and he extended the main theorems of Nevanlinna to analytic mappings between arbitrary Riemann surfaces (\rightarrow 124 Distributions of Values of Functions of a Complex Variable). M. Heins introduced the notions of Lindelöf type, Blaschke type, and others which are special classes of analytic mappings. Utilizing these notions, Constantinescu and Cornea, Kuramochi, and others extended various results in the theory of cluster sets (\rightarrow 62 Cluster Sets) by studying the behavior of analytic mappings at ideal boundaries. The theory of capacities on ideal boundaries has also been developed.

On every open Riemann surface R there exists a nonconstant holomorphic function (Behnke and Stein). Furthermore, Gunning and Narasimhan proved that there exists a holomorphic function on R whose derivative never vanishes. In other words, R is conformally equivalent to an unramified covering surface of the sphere. Such a locally homeomorphic analytic mapping is called the **immersion** of R . The proof is based on the fol-

lowing deep result (S. Mergelyan's theorem): Suppose that K is a compact set on R such that $R - K$ has no relatively compact connected component. Then every continuous function which is holomorphic on the interior of K can be approximated uniformly on K by a holomorphic function on R [22].

A surface of genus 0 is said to be **planar** (or **of planar character** or **schlichtartig**). A simply connected surface is planar. Using the Dirichlet principle, P. Koebe proved the following **general uniformization theorem**: Every planar Riemann surface R can be mapped conformally to the canonical slit regions on the extended complex plane C . More precisely, given a point p on R , there exists the **extremal horizontal (vertical) slit mapping** $F_1(F_2)$ such that (i) $F_1(F_2)$ maps R conformally to a region on C whose boundary consists of horizontal (vertical) slits and possibly points; (ii) F_1 and F_2 have a simple pole at p with residue 1; (iii) the total area of the slits and points is zero. Suppose that $F_i = 1/z + a_i + c_i z + \dots$ ($i = 1, 2$) in terms of local parameter z at p . Then $s = (c_1 - c_2)/2$ is called the **span** of R . It is known that s ($= \|d(F_1 - F_2)/2\|^2$) ≥ 0 , where the equality holds if and only if R belongs to O_{AD} . In the case of finite genus g , there also exist the conformal mappings of R onto the parallel slit regions on the $(g + 1)$ -sheeted covering surface of C (Z. Nehari, Y. Kusunoki, and others). L. Ahlfors proved that a Riemann surface of genus g bounded by m contours can be mapped conformally to an at most $(2g + m)$ -sheeted unbounded covering surface of the unit disk.

The structures of closed Riemann surfaces are determined by the algebraic structures of meromorphic function fields on them. H. Iss'sa obtained a noteworthy result which established that open Riemann surfaces are also determined by their meromorphic function fields [24]. It is known too that open Riemann surfaces are determined by their rings of holomorphic functions.

H. Differential Forms on Riemann Surfaces

Since Riemann surfaces are considered real 2-dimensional differentiable manifolds of class C^∞ , differential 1-forms $\omega = u dx + v dy$ and differential 2-forms $\Omega = c dx \wedge dy$ are defined on them, and operations such as the exterior derivative $d\omega = (\partial v/\partial x - \partial u/\partial y) dx \wedge dy$ and exterior product can be defined (\rightarrow 105 Differentiable Manifolds). Since coordinate transformations satisfy the Cauchy-Riemann differential equation, the **conjugate differential** $*\omega = -v dx + u dy$ of ω can be defined. A differential form ω satisfying $d\omega = d*\omega = 0$ is

called a **harmonic differential**, and one with $*\omega = -i\omega$ is said to be **pure**. A pure differential is expressed as $\omega = f dz$. Here, if f is a holomorphic function, then ω is called a **holomorphic** (or **analytic**) **differential**, and if f is a meromorphic function, then ω is called a **meromorphic** (or **Abelian**) **differential**. The differential form ω is a holomorphic differential if and only if it is **closed** (i.e., $d\omega = 0$) and pure. The differential ω is called **exact** (or **total**) if ω is written as $dF = F_x dx + F_y dy$ with a globally single-valued function F .

Next, the set of all measurable differentials ω with $\|\omega\|^2 = \iint_R \omega \wedge *\bar{\omega} < \infty$ forms a \dagger Hilbert space with respect to the norm $\|\omega\|$. The method of orthogonal decomposition in the theory of Hilbert spaces is the main device to study this space and also its suitable subspaces and to obtain the existence theorem of harmonic and holomorphic differentials with various properties (\rightarrow 194 Harmonic Integrals). However, in contrast to differentiable manifolds, it should be noted that finer orthogonal decompositions into subspaces with specific properties hold for open Riemann surfaces. For instance, let $\Gamma_a(\Gamma_h)$ be the Hilbert space of analytic (harmonic) differentials with finite norm, and set $\Gamma_{ae} = \{\omega \in \Gamma_a \mid \omega \text{ is exact}\}$, $\Gamma_{hse} = \{\omega \in \Gamma_h \mid \omega \text{ is } \dagger\text{semixact}\}$; then we have the orthogonal decompositions

$$\Gamma_a = \Gamma_{ae} \dot{+} \Gamma_{as},$$

$$\Gamma_h = *\Gamma_{hse} \dot{+} \Gamma_{hm} = \Gamma_{hse} \dot{+} *\Gamma_{hm}, \text{ etc.,}$$

where $*\Gamma_x$ stands for the space $\{\omega \mid *\omega \in \Gamma_x\}$ and Γ_{as} and Γ_{hm} are known as the space of analytic Schottky differentials and the space of differentials of harmonic measures, respectively. Both spaces Γ_{as} and Γ_{hm} have remarkable properties [9].

I. Abelian Integrals on Open Riemann Surfaces

The systematic effort to extend the theory of Abelian integrals on closed Riemann surfaces to open Riemann surfaces was initiated by Nevanlinna in 1940. At the first stage of the development, only those Riemann surfaces with small boundaries (i.e., ones in O_G or O_{HD}) were treated; later a more general treatment was made possible by the discovery of the notion of semixact differentials (K. Virtanen, Ahlfors).

Let R be an arbitrary open Riemann surface. A 1-dimensional cycle C is called a **dividing cycle** if for any compact set in R there exists a cycle outside the compact set homologous to C . A differential is said to be **semiexact** if its period along every dividing cycle vanishes.

Ahlfors defined the distinguished (complex harmonic) differentials with polar singularities and obtained in terms of them a generalization of Abel's theorem. Independently, Y. Kusunoki defined the semiexact canonical (meromorphic) differentials and gave in terms of them a formulation of Abel's theorem and the Riemann-Roch theorem on R [27]. It was proved that a meromorphic differential $df = du + idv$ is semiexact canonical if and only if du is (real) distinguished, and then u is almost constant on every ideal boundary component of R (in appropriate compactification of R). Hence every meromorphic function f for which df is distinguished is almost constant on every ideal boundary component, and therefore f reduces to a constant by the boundary theorem of Riesz type if R has a large boundary. Whereas by the Riemann-Roch theorem above a nonconstant meromorphic function f such that df is (exact) canonical exists on any open Riemann surface R with finite genus, and f gives a canonical parallel slit mapping of R (\rightarrow Section G). H. L. Royden [28] and B. Rodin also gave generalizations of the Riemann-Roch theorem. M. Yoshida, H. Mizumoto, M. Shiba, and others further generalized the Kusunoki type theorems. The Riemann-Roch theorem for a closed Riemann surface can be deduced from that for open Riemann surfaces by considering an open Riemann surface obtained from a closed surface by deleting a point.

Riemann's period relation on R has been studied for various classes of differentials, but for the case of infinitely many nonvanishing periods, no definitive result has been obtained. The same is true for the theory of Abelian differentials with infinitely many singularities. On the other hand, the analogy to the classical theory is lost completely if no restriction is posed on the differentials on R . In this context the following results due to Behnke and Stein [26] are outstanding: (1) There exists an Abelian differential of the first kind on R with infinitely many given periods. (2) For two discrete sequences $\{p_n\}$ and $\{q_n\}$ of points in R , there exists a single-valued meromorphic function with zeros at p_n and poles at q_m . It is further proved that there exists an Abelian differential with prescribed divisor and periods (Kusunoki and Sainouchi). This generalizes the results above and the Gunning-Narasimhan theorem.

368 (III.9) Rings

A. Definition

A nonempty set A is called a **ring** if the following conditions are satisfied.

(1) Two \dagger operations, called **addition** and **multiplication** (the **ring operations**), are defined, which send an arbitrary pair of elements a, b of A to elements $a + b$ and ab of A .

(2) For arbitrary elements a, b, c of A , these operations satisfy the following four laws: (i) $a + b = b + a$ (**commutative law of addition**); (ii) $(a + b) + c = a + (b + c)$, $(ab)c = a(bc)$ (**associative laws**); (iii) $a(b + c) = ab + ac$, $(a + b)c = ac + bc$ (**distributive laws**); and (iv) for every pair a, b of elements of A , there exists a unique element c of A such that $a + c = b$. Thus a ring A is an \dagger Abelian group under addition. Each element a of a ring A determines operations L_a and R_a defined by $L_a(x) = ax$, $R_a(x) = xa$ ($x \in A$). Thus a ring A has the structure of a \dagger left A -module and a \dagger right A -module. Since the operations L_a and R_b commute for every pair a, b of elements of A , the ring A is also an A - A -bimodule (\rightarrow 277 Modules).

The identity element of A under addition is called the **zero element** and is denoted by 0. It satisfies the equation $a0 = 0a = 0$ ($a \in A$). An element $e \in A$ is called a **unity element** (**identity element** or **unit element**) of A if it satisfies $ae = ea = a$ ($a \in A$). If A has such a unity element, it is unique and is often denoted by 1. A ring with unity element is called a **unitary ring**. Most of the important examples of rings are unitary.

368 B Rings

Hence we often call a unitary ring simply a ring. If a ring has only one member (namely, 0), then 0 is the unity element of the ring. Such a ring is called a **zero ring**. However, if a ring has more than one element, the unity element is distinct from the zero element. A ring is called a **commutative ring** if it satisfies (v) $ab = ba$ ($a, b \in A$) (**commutative law for multiplication**) (\rightarrow 67 Commutative Rings).

In this article we shall discuss associative rings. Certain nonassociative rings are important; an example is \dagger Lie algebra. (An algebra is a ring having a \dagger ground ring.)

B. Further Definitions

An element $a \neq 0$ of a ring A is called a **zero divisor** if there exists an element $b \neq 0$ such that $ab = 0$ or $ba = 0$. A commutative unitary ring having more than one element is called an **integral domain** if it has no zero divisors (\rightarrow 67 Commutative Rings). Elements a and b of a ring are said to be **orthogonal** if $ab = ba = 0$. An element a satisfying $a^n = 0$ for some positive integer n is called a **nilpotent element**, and a nonzero element a satisfying $a^2 = a$ is called an **idempotent element**. An idempotent element is said to be **primitive** if it cannot be represented as the sum of two orthogonal idempotent elements. For any subsets S and T of a ring A , let $S + T$ (ST) denote the set of elements $s + t$ (st) ($s \in S, t \in T$). In particular, SS is denoted by S^2 (similarly for S^3, S^4 , etc.), and furthermore, $\{a\} + S(\{a\}S)$ is denoted by $a + S(aS)$. If $ST = TS = \{0\}$, then subsets S and T are said to be **orthogonal**. A subset S of a ring is said to be **nilpotent** if $S^n = 0$ for some positive integer n , and **idempotent** if $S^2 = S$.

For an element a of a unitary ring A , an element a' such that $a'a = 1$ ($aa' = 1$) is called a **left (right) inverse element** of a . There exists a left (right) inverse element of a if and only if A is generated by a as a left (right) A -module. If there exist both a right inverse and a left inverse of a , then they coincide and are uniquely determined by a . This element is called the **inverse element** of a and is denoted by a^{-1} . An element that has an inverse element is called an **invertible element** (**regular element** or **unit**). The set of all invertible elements of a unitary ring forms a group under multiplication. A nonzero unitary ring is called a \dagger **skew field** (or \dagger **division ring**) if every nonzero element is invertible. Furthermore, a skew field that satisfies the commutative law is called a **commutative field** or simply a field (\rightarrow 149 Fields). In a general ring A , if we define a new operation $(a, b) \rightarrow a \circ b$ by setting $a \circ b = a + b - ab$, then A is a \dagger semigroup with the identity element 0 with respect to this operation. The inverse

element under this operation is called the **quasi-inverse element**, and an element that has a quasi-inverse element is called a **quasi-invertible element** (or **quasiregular element**). An element a of a unitary ring is quasi-invertible if and only if the element $1 - a$ is invertible.

C. Examples

(1) Rings of numbers. The ring \mathbf{Z} of rational integers, the rational number field \mathbf{Q} , the real number field \mathbf{R} , and the complex number field \mathbf{C} are familiar examples (\rightarrow 14 Algebraic Number Fields, 257 Local Fields).

(2) Rings of functions. The set K^I of functions defined on a set I and taking values in a ring K forms a commutative ring under pointwise addition and multiplication. In particular, let $K = \mathbf{R}$, and let I be an interval of \mathbf{R} . Then the set $C^0(I)$ of continuous functions, the set $C^r(I)$ of functions that are r -times continuously differentiable, and the set $C^\omega(I)$ of analytic functions on I are subrings (\rightarrow Section E) of \mathbf{R}^I .

(3) Rings of expressions. The set $K[X_1, \dots, X_n]$ of polynomials and the set $K[[X_1, \dots, X_n]]$ of formal power series in indeterminates X_1, \dots, X_n with coefficients in a commutative ring K are commutative rings (\rightarrow 369 Rings of Polynomials, 370 Rings of Power Series).

(4) **Endomorphism rings** of modules. The set $\mathcal{E}_K(M)$ of endomorphisms of a module M over a ring K is in general a noncommutative ring. In particular, if M is a finite-dimensional linear space over a field K , then $\mathcal{E}_K(M)$ can be identified with a full matrix ring (\rightarrow 256 Linear Spaces, 277 Modules).

(5) For other examples \rightarrow 29 Associative Algebras, 36 Banach Algebras, 67 Commutative Rings, 284 Noetherian Rings, and 439 Valuations.

D. Homomorphisms

A mapping $f: A \rightarrow B$ of a ring A into a ring B satisfying conditions (i) $f(a+b) = f(a) + f(b)$ and (ii) $f(ab) = f(a)f(b)$ ($a, b \in A$) is called a **homomorphism**. If a homomorphism f is bijective, then the inverse mapping $f^{-1}: B \rightarrow A$ is also a homomorphism, and in this case f is called an **isomorphism**. More precisely, a homomorphism (isomorphism) of rings is often called a **ring homomorphism** (**ring isomorphism**). There exists only one homomorphism of any ring onto the zero ring. For unitary rings A and B , a homomorphism $f: A \rightarrow B$ is said to be **unitary** if it maps the unity element of A to the unity element of B . By a homomorphism, a unitary homomorphism is usually meant. In this sense there exists a unique homomorphism

of the ring \mathbf{Z} of rational integers into an arbitrary unitary ring. A composite of homomorphisms is also a homomorphism. The identity mapping 1_A of a ring A is an isomorphism. A homomorphism of a ring A into itself is called an **endomorphism**, and an isomorphism of A onto itself is called an **automorphism** of A . If a is an invertible element of a unitary ring A , then the mapping $x \rightarrow axa^{-1}$ ($x \in A$) is an automorphism of A , called an **inner automorphism**.

When condition (ii) $f(ab) = f(b)f(a)$ ($a, b \in A$), a mapping satisfying (i) and (ii) is called an **antihomomorphism**. In particular, if an antihomomorphism f is bijective, then the inverse mapping f^{-1} is also an antihomomorphism, and f is called an **anti-isomorphism**. **Antiendomorphisms** and **antiautomorphisms** are defined similarly.

E. Subrings, Factor Rings, and Direct Products

A subset S of a ring A is called a **subring** of A if a ring structure is given on S and the canonical injection $S \rightarrow A$ is a ring homomorphism. Thus the ring operations of S are the restrictions of those of A . If we deal only with unitary rings and unitary homomorphisms, then a subring S necessarily contains the unity element of A . The smallest subring containing a subset T of a ring A is called the subring **generated** by T . The set of elements that commute with every element of T forms a subring and is called the **commutor** (or **centralizer**) of T . In particular, the commutor of A itself is called the **center** of A .

A quotient set A/R of a ring A by an equivalence relation R is called a **factor ring** (quotient ring) of A if a ring structure is given on A/R and the canonical surjection $A \rightarrow A/R$ is a ring homomorphism. This is the case if and only if the equivalence relation R is compatible with the ring operations (i.e., aRa' and bRb' imply $(a+b)R(a'+b')$ and $(ab)R(a'b')$). Let α and β be elements of the factor ring A/R , represented by a and b , respectively. Then the definition of factor ring implies that $\alpha + \beta$ ($\alpha\beta$) is the equivalence class represented by $a + b$ (ab). Every ring A has two trivial factor rings, namely, A itself and the zero ring 0 . If A has no nontrivial factor rings, then A is called a **quasisimple ring** (\rightarrow Section G). If $f: A \rightarrow B$ is a ring homomorphism, then the image $f(A)$ is a subring of B , and the equivalence relation R in A defined by $f(aRb) \Leftrightarrow f(a) = f(b)$ is compatible with the ring operations of A . Thus f induces an isomorphism $A/R \rightarrow f(A)$ (\rightarrow Section F).

If $\{A_i\}_{i \in I}$ is a family of rings, the Cartesian

product $A = \prod_{i \in I} A_i$ forms a ring under the componentwise operations $(a_i) + (b_i) = (a_i + b_i)$ and $(a_i)(b_i) = (a_i b_i)$. This ring is called the **direct product** of the family of rings $\{A_i\}_{i \in I}$. The mapping $p_i: A \rightarrow A_i$ that assigns to each (a_i) its i th component a_i is called a **canonical homomorphism**. For any set of homomorphisms $f_i: B \rightarrow A_i$ ($i \in I$), there exists a unique homomorphism $f: B \rightarrow A$ such that $f_i = p_i \circ f$ for each i .

F. Ideals

A subset of a ring A is called a **left (right) ideal** of A if it is a submodule of the left (right) A -module of A (\rightarrow 277 Modules). In other words, a left (right) ideal J of A is an additive subgroup of A such that $AJ \subset J$ ($JA \subset J$). Under the operations induced from A , J is a ring (however, J is not necessarily unitary). A subset of A is called a **two-sided ideal** or simply an **ideal** of A if it is a left and right ideal.

For an ideal J of a ring A , we define a relation R in A by $aRb \Leftrightarrow a - b \in J$. Then R is an equivalence relation that is compatible with the operations of A . Each equivalence class is called a **residue class** modulo J , and the quotient ring A/R is denoted by A/J and called the **residue (class) ring** (or **factor ring**) modulo J . If it is a field, it is called a **residue (class) field**.

Conversely, given an equivalence relation R that is compatible with the operations of A , the equivalence class of 0 forms an ideal J of A , and the equivalence relation defined by J coincides with R .

If $f: A \rightarrow B$ is a ring homomorphism, then the \dagger kernel of f as a homomorphism of additive groups forms an ideal J of A , and f induces an isomorphism $A/J \rightarrow f(A)$. If S is a subring and J is an ideal of a ring A , then $S + J$ is a subring of A and $S \cap J$ is an ideal of S . Furthermore, the natural homomorphism $S \rightarrow (S + J)/J$ induces an isomorphism $S/S \cap J \rightarrow (S + J)/J$ (**isomorphism theorem**).

A left (right) ideal of a ring A is said to be **maximal** if it is not equal to A and is properly contained in no left (right) ideal of A other than A . Similarly, a left (right) ideal of A is said to be **minimal** if it is nonzero and properly contains no nonzero left (right) ideal of A .

If e is an idempotent element of a unitary ring A , then $1 - e$ and e are orthogonal idempotent elements, and $A = Ae + A(1 - e)$ is the direct sum of left ideals. This is called **Peirce's left decomposition**. **Peirce's right decomposition** is defined similarly. A left ideal J of A can be expressed as $J = Ae$ for some idempotent element e if and only if there exists a left ideal J' such that $A = J + J'$ is a direct sum decomposition. More generally, if e_1, \dots, e_n are orthogonal idempotent elements whose sum is equal

to 1, then $A = Ae_1 + \dots + Ae_n$ is the direct sum of left ideals. Conversely, if $A = J_1 + \dots + J_n$ is the direct sum of left ideals and $1 = e_1 + \dots + e_n$ ($e_i \in J_i$) is the corresponding decomposition of the unity element, then e_1, \dots, e_n are orthogonal idempotent elements. In particular, if J_1, \dots, J_n are two-sided ideals, then each J_i is a ring with unity element e_i , and by a natural correspondence, the ring A is isomorphic to the direct product $\prod_{i=1}^n J_i$. In this case, A is called the **direct sum** of ideals J_1, \dots, J_n and is denoted by $A = \bigoplus_{i=1}^n J_i$, or $A = \sum_{i=1}^n J_i$.

A ring A is called a **left (right) Artinian ring** if it is \dagger Artinian as a left (right) A -module (i.e., if A satisfies the \dagger minimal condition for left (right) ideals of A). A ring A is called a **left (right) Noetherian ring** if it is \dagger Noetherian as a left (right) A -module (i.e., if A satisfies the \dagger maximal condition for left (right) ideals of A). If A is commutative, *left* and *right* are omitted in these definitions. The property of being Artinian or Noetherian is inherited by quotient rings and the direct product of a finite family of rings, but not necessarily by subrings. For general rings, the maximal and minimal conditions for left (right) ideals are independent, but for unitary rings, left (right) Artinian rings are necessarily left (right) Noetherian (Y. Akizuki, C. Hopkins).

G. Semisimple Rings

The statement that a unitary ring A is \dagger semisimple as a left A -module is equivalent to the statement that A is semisimple as a right A -module; in this case A is called a **semisimple ring** (\rightarrow Section H). Every module over a semisimple ring is also semisimple. A semisimple ring is left (right) Artinian and Noetherian. A semisimple ring is called a **simple ring** if it is nonzero and has no proper ideals except $\{0\}$, that is, if A is a quasisimple ring. Thus A is a simple ring if and only if A is a nonzero, unitary, quasisimple, left (right) Artinian ring. If A is a semisimple ring, then it has only a finite number of minimal ideals A_1, \dots, A_n , and A is expressible as the direct sum $A = A_1 + \dots + A_n$, where each A_i is a simple ring, called a **simple component** of A . Any ideal of A is the direct sum of a finite number of simple components of A . Quotient rings of a semisimple ring and the direct product of a finite number of semisimple rings are also semisimple.

Any left (right) ideal of a semisimple ring A is expressible as Ae (eA) for some idempotent element e , and Ae (eA) is minimal if and only if e is primitive. In particular, a minimal left (right) ideal is a simple left (right) A -module that is contained in a certain simple component. Two minimal left (right) ideals are iso-

morphic as A -modules if and only if they are contained in the same simple component. If A_i , $1 \leq i \leq n$, are the simple components of A , then for each simple left A -module M there exists a unique i such that $A_i M \neq \{0\}$, and M is isomorphic to a minimal left ideal contained in A_i .

If M is a finite-dimensional linear space over a (skew) field D , then the endomorphism ring $A = \mathcal{E}_D(M)$ of M over D is a simple ring. Conversely, for any ring A , the endomorphism ring $D = \mathcal{E}_A(M)$ of a simple A -module M is a (skew) field (**Schur's lemma**). If A is a simple ring, then any simple A -module M can be considered as a finite-dimensional linear space over $D = \mathcal{E}_A(M)$, and A is isomorphic to $\mathcal{E}_D(M)$ (**Wedderburn's theorem**). Furthermore, if r is the dimension of M over D , then $\mathcal{E}_D(M)$ is isomorphic to the full matrix ring $M_r(D^\circ)$ of degree r over the field D° , which is anti-isomorphic to D . The dimension r is also equal to the length of A as an A -module. The center of $A = \mathcal{E}_D(M)$ is isomorphic to the center of D , which is a commutative field. Thus a simple ring is an associative algebra over a commutative field (\rightarrow 29 Associative Algebras).

H. Radicals

Let A be a ring. Then among ideals consisting only of quasi-invertible elements of A , there exists a largest one, which is called the **radical** of A and denoted by $\mathfrak{R}(A)$. The radical of the residue ring $A/\mathfrak{R}(A)$ is $\{0\}$. A ring A is called a **semiprimitive ring** if $\mathfrak{R}(A)$ is $\{0\}$. On the other hand, A is called a left (right) **primitive ring** if it has a faithful simple left (right) A -module. The radical $\mathfrak{R}(A)$ is equal to the intersection of all ideals J such that A/J is a left (right) primitive ring. In a unitary ring A , $\mathfrak{R}(A)$ coincides with the intersection of all maximal left (right) ideals of A . Furthermore, in a left (right) Artinian ring A , $\mathfrak{R}(A)$ is the largest nilpotent ideal of A , and the condition $\mathfrak{R}(A) = \{0\}$ is equivalent to the condition that A is a semi-simple ring.

Among ideals consisting only of nilpotent elements of A , there exists a largest one, which is called the **nilradical** (or simply the radical) and denoted by $\mathfrak{N}(A)$ (\rightarrow 67 Commutative Rings). The nilradical of $A/\mathfrak{R}(A)$ is $\{0\}$. In general, $\mathfrak{N}(A)$ is contained in $\mathfrak{R}(A)$, and if A is left (right) Artinian, we have $\mathfrak{N}(A) = \mathfrak{R}(A)$. A ring A is called a **semiprimary ring** if $A/\mathfrak{R}(A)$ is left (right) Artinian and therefore semisimple. Furthermore, a ring A is called a **primary ring** (**completely primary ring**) if $A/\mathfrak{R}(A)$ is a simple ring (skew field). A primary ring is isomorphic to a full matrix ring over a completely primary ring.

**369 (III.13)
Rings of Polynomials**

A. General Remarks

In this article, we mean by a *ring* a \dagger commutative ring with \dagger unity element. Let R be a ring, and let X_1, \dots, X_n be **variables** (**letters**, **indeterminates**, or **symbols**). Then the set of \dagger polynomials in X_1, \dots, X_n with coefficients in R is called the **ring of polynomials** (or **polynomial ring**) in n variables X_1, \dots, X_n over R and is denoted by $R[X_1, \dots, X_n]$ (\rightarrow 67 Commutative Rings; 284 Noetherian Rings; 337 Polynomials; 368 Rings). On the other hand, when R and R' are rings with common unity element and $R \subset R'$, then for a subset S of R' we denote the subring of R' , generated by S over R , by $R[S]$. When $S = \{x_1, \dots, x_n\}$, then there is a homomorphism φ of the polynomial ring $R[X_1, \dots, X_n]$ onto $R[S]$ defined by

$$\varphi(\sum a_{i_1 \dots i_n} X_1^{i_1} \dots X_n^{i_n}) = \sum a_{i_1 \dots i_n} x_1^{i_1} \dots x_n^{i_n} \quad (a_{i_1 \dots i_n} \in R).$$

If φ is an isomorphism, then x_1, \dots, x_n are said to be **algebraically independent** over R ; and otherwise, **algebraically dependent** over R . Thus the ring of polynomials in n variables over R may be regarded as a ring $R[x_1, \dots, x_n]$ generated by a finite system of algebraically independent elements x_1, \dots, x_n over R .

B. Ideals, Homogeneous Rings, and Graded Rings

Consider the polynomial ring $R[X] = R[X_1, \dots, X_n]$ in n variables over a ring R . A polynomial $f \in R[X]$ is a \dagger zero divisor if and only if there is a nonzero member a of R for which $af = 0$. If \mathfrak{a} is an \dagger ideal of R , then $R[X]/\mathfrak{a}R[X] \cong (R/\mathfrak{a})[X_1, \dots, X_n]$. Therefore, if \mathfrak{p} is a \dagger prime ideal of R , then $\mathfrak{p}R[X]$ is a prime ideal of $R[X]$. If R is a \dagger unique factorization domain (u.f.d.), then $R[X]$ is also a u.f.d. If R is a normal ring, then so is $R[X]$. By the \dagger Hilbert basis theorem, if R is \dagger Noetherian, then $R[X]$ is also Noetherian. If m is the \dagger Krull dimension of R , then $\text{Krull dim } R[X] \geq n + m$; the equality holds if R is Noetherian. If R is a field, then $R[X]$ is not only a u.f.d. but also a \dagger Macaulay ring.

A **homogeneous ideal** of $R[X]$ is an ideal generated by a set of \dagger homogeneous polynomials f_λ (the degree of f_λ may depend on λ). When \mathfrak{a} is a homogeneous ideal, an element in $R[X]/\mathfrak{a}$ is defined to be a **homogeneous element** of degree d if it is the class of a homogeneous polynomial of degree d modulo \mathfrak{a} , and the quotient ring $R[X]/\mathfrak{a}$ is called a **homogeneous ring**. More generally, assume that a ring R is, as a \dagger module, the \dagger direct sum $\sum_{i=0}^{\infty} R_i$ of its submodules R_i ($i = 0, 1, 2, \dots$) and that $R_i R_j \subset R_{i+j}$ for every pair (i, j) . Then we call R a **graded ring**, and an element in R_d a **homogeneous element** of degree d . (In some literature the term graded ring is used in a wider sense; see below) In a graded ring R , if an ideal is generated by homogeneous elements, then the ideal is called a **homogeneous ideal** (or **graded ideal**). In a graded ring $R = \sum_{i=0}^{\infty} R_i$, if the ideal $\sum_{i=1}^{\infty} R_i$ has a finite basis, then R is generated (as a ring) by a finite number of elements over its subring R_0 . Therefore, the graded ring $R = \sum R_i$ is Noetherian if and only if R_0 is Noetherian and R is generated by a finite number of elements over R_0 . In this case, every homogeneous ideal is the intersection of a finite number of homogeneous \dagger primary ideals, and every prime divisor of a homogeneous ideal is a homogeneous prime ideal.

The notion of a graded ring is generalized further as follows: A ring R is **graded** by an additive semigroup I (containing 0) if $R = \sum_{i \in I} R_i$ (direct sum) and if $R_i R_j \subset R_{i+j}$.

C. Zero Points

(1) Zero Points in an Affine Space. We consider the polynomial ring $K[X] = K[X_1, \dots, X_n]$ in n variables over a field K and a field Ω containing K . A point (a_1, \dots, a_n) of an n -dimensional \dagger affine space $\Omega^n = \{(a_1, \dots, a_n) \mid a_i \in$

$\Omega\}$ is called a **zero point** of a subset S of $K[X]$ if $f(a_1, \dots, a_n) = 0$ for every $f(X_1, \dots, X_n) \in S$. A point (a_1, \dots, a_n) is called **algebraic** over K (**K -rational**) if every a_i is algebraic over K (is an element of K). In this way we define algebraic zero points and rational zero points. Zero points of S are zero points of the \dagger ideals generated by S . Therefore, in order to investigate the set of zero points of S , we may restrict ourselves to the case where S is an ideal. Denote by $V(S)$ the set of zero points of S . If $\mathfrak{a}_1, \mathfrak{a}_2$ are ideals of $K[X]$, then (i) $V(\mathfrak{a}_1 \cap \mathfrak{a}_2) = V(\mathfrak{a}_1 \mathfrak{a}_2) = V(\mathfrak{a}_1) \cup V(\mathfrak{a}_2)$; (ii) $V(\mathfrak{a}_1 + \mathfrak{a}_2) = V(\mathfrak{a}_1) \cap V(\mathfrak{a}_2)$; and (iii) if \mathfrak{a}_1 and \mathfrak{a}_2 have a common \dagger radical, then $V(\mathfrak{a}_1) = V(\mathfrak{a}_2)$.

(2) Zero Points in a Projective Space. A point $(\lambda a_1, \dots, \lambda a_n)$ of an $(n-1)$ -dimensional \dagger projective space over Ω (with $a_i \in \Omega$, some $a_i \neq 0, \lambda \in \Omega, \lambda \neq 0$) is called a **zero point** of a polynomial $f(X_1, \dots, X_n)$ if, f being expressed as $\sum f_i$ with homogeneous polynomials f_i of degree i , $f_i(a_1, \dots, a_n) = 0$ for every i (this condition holds if and only if $f(\lambda a_1, \dots, \lambda a_n) = 0$ for any element λ in Ω , provided that Ω contains infinitely many elements). Therefore, zero points of a subset S of $K[X]$ are zero points of the smallest homogeneous ideal containing S . Thus, in order to study the sets of zero points, it is sufficient to consider sets of zero points of homogeneous ideals, and propositions similar to (i), (ii), and (iii) of part 1 of this section hold for homogeneous ideals $\mathfrak{a}_1, \mathfrak{a}_2$.

D. The Normalization Theorem

Let \mathfrak{a} be an ideal of \dagger height h in the polynomial ring $K[X] = K[X_1, \dots, X_n]$ in n variables over a field K . Then there exist elements Y_1, \dots, Y_n of $K[X]$ such that (i) $K[X]$ is \dagger integral over $K[Y] = K[Y_1, \dots, Y_n]$ and (ii) Y_1, \dots, Y_h generate $\mathfrak{a} \cap K[Y]$ (**normalization theorem for polynomial rings**).

Using this theorem, we obtain the following important theorems on finitely generated rings.

(1) Normalization theorem for finitely generated rings. If a ring R is finitely generated over an integral domain I , then there exist an element a ($\neq 0$) of I and algebraically independent elements z_1, \dots, z_r of R over I such that the \dagger ring of quotients R_S (where $S = \{a^n \mid n = 1, 2, \dots\}$) is integral over $I[a^{-1}, z_1, \dots, z_r]$.

(2) If \mathfrak{p} is a prime ideal of an integral domain R that is finitely generated over a field K , then $(\text{height of } \mathfrak{p}) + (\dagger\text{depth of } \mathfrak{p}) = (\dagger\text{transcendence degree of } R \text{ over } K)$, and the depth of \mathfrak{p} coincides with the transcendence degree of R/\mathfrak{p} over K . In particular, if \mathfrak{m} is a maximal ideal of R , then R/\mathfrak{m} is algebraic over K .

(3) **Hilbert's zero point theorem (Hilbert Nullstellensatz).** Let \mathfrak{a} be an ideal of the polynomial ring $K[X] = K[X_1, \dots, X_n]$ over the field K , and assume that the field Ω containing K is \dagger algebraically closed. If $f \in K[X]$ satisfies the condition that every algebraic zero point (\rightarrow Section C) of \mathfrak{a} is a zero point of f , then some power of f is contained in \mathfrak{a} .

E. Elimination Theory

Let f_1, \dots, f_N be elements of the polynomial ring $R = I[X_1, \dots, X_m, Y_1, \dots, Y_n]$ in $m + n$ variables over an integral domain I . For each maximal ideal \mathfrak{m} of I , let $\varphi_{\mathfrak{m}}$ be the canonical homomorphism with modulus \mathfrak{m} , and let $\Omega_{\mathfrak{m}}$ be an algebraically closed field containing I/\mathfrak{m} . Let $W_{\mathfrak{m}}$ be the set of points (a_1, \dots, a_n) of the n -dimensional affine space $\Omega_{\mathfrak{m}}^n$ over $\Omega_{\mathfrak{m}}$ such that the system of equations $\varphi_{\mathfrak{m}}(f_i)(X_1, \dots, X_m, a_1, \dots, a_n) = 0$ ($i = 1, 2, \dots, N$) has a solution in $\Omega_{\mathfrak{m}}^m$. To **eliminate** X_1, \dots, X_m from f_1, \dots, f_N is to obtain $g(Y_1, \dots, Y_n) \in I[Y_1, \dots, Y_n]$ such that every point of $W_{\mathfrak{m}}$ is a zero point of $\varphi_{\mathfrak{m}}(g)$ for every \mathfrak{m} ; such a g (or an equation $g = 0$) is called a **resultant** of f_1, \dots, f_N . The set \mathfrak{a} of resultants forms an ideal of $I[Y_1, \dots, Y_n]$, and $\{g_1, \dots, g_M\}$ is called a **system of resultants** if the radical of the ideal generated by it coincides with \mathfrak{a} . If I is finitely generated over a field, then, denoting by \mathfrak{b} the radical of the ideal generated by f_1, \dots, f_N , we have $\mathfrak{a} = \mathfrak{b} \cap I[Y_1, \dots, Y_n]$. In particular, let I be a field. It is obvious that $W_{(0)}$ is contained in the set V of zero points of \mathfrak{a} . However, it is not necessarily true that $V = W_{(0)}$. If every f_i is homogeneous in X_1, \dots, X_m and also in Y_1, \dots, Y_n , then we have $V = W_{(0)}$.

If we wish to write a system of resultants explicitly, we can proceed as follows: Regard the f_i as polynomials in X_1 with coefficients in $I[X_2, \dots, X_m, Y_1, \dots, Y_n]$, and obtain resultants $R(f_i, f_j)$ by eliminating X_1 from the pairs f_i, f_j . Then eliminate X_2 from these resultants, and so forth. To obtain $R(f_i, f_j)$, we may use **Sylvester's elimination method**. Namely, let f and g be polynomials in x with coefficients in $I: f = a_0x^m + a_1x^{m-1} + \dots + a_m, g = b_0x^n + b_1x^{n-1} + \dots + b_n$. Let $D(f, g)$ be the following determinant of degree $m + n$:

$$D(f, g) = \begin{vmatrix} a_0 & a_1 & \dots & a_m & 0 & \dots & 0 \\ 0 & a_0 & \dots & a_{m-1} & a_m & 0 & \dots & 0 \\ & & & & & & & \\ & & & & & & & \\ & & & & & & & \\ 0 & \dots & 0 & a_0 & a_1 & \dots & a_{m-1} & a_m \\ b_0 & b_1 & \dots & b_{n-1} & b_n & 0 & \dots & 0 \\ & & & & & & & \\ & & & & & & & \\ & & & & & & & \\ 0 & \dots & 0 & b_0 & b_1 & \dots & b_{n-1} & b_n \end{vmatrix}$$

Then $D(f, g) = 0$ if and only if either f and g have a common root or $a_0 = b_0 = 0$. Therefore, if I is a u.f.d. and a_0 and b_0 have no common factor, then $D(f, g)$ is the required resultant $R(f, g)$. (For other methods of elimination see B. L. van der Waerden, *Algebra*, vol. II. For criteria on whether a finitely generated ring over a field is \dagger regular \rightarrow 370 Rings of Power Series B.)

F. Syzygy Theory

(1) **Classical Case.** The notion of **syzygy** was introduced by Sylvester (*Phil. Trans.*, 143 (1853)), then generalized and clarified by Hilbert [3], whose definition can be formulated as follows: Let $R = k[X_1, \dots, X_n]$ be a polynomial ring of n variables over a field k . R has the natural gradation (i.e., R is a graded ring in which each X_i ($1 \leq i \leq n$) is of degree 1 and elements of k are of degree 0). Let M be a finitely generated graded R -module. If f_1, \dots, f_m form a minimal basis of M over R consisting of homogeneous elements, we introduce m indeterminates u_1, \dots, u_m and put $F = \sum_{1 \leq j \leq m} Ru_j$, the free R -module generated by u_1, \dots, u_m . Set $\deg(u_j) = \deg(f_j)$ ($1 \leq j \leq m$) and supply F with the structure of a graded R -module. Let φ be the graded R -homomorphism of F onto M defined by $\varphi(u_j) = f_j$. Then $N = \text{Ker}(\varphi)$ is a graded R -module uniquely determined by M up to isomorphism (of graded R -modules); N is called the **first syzygy** of M . For a positive integer r , the **r th syzygy** of M is inductively defined as the first syzygy of the $(r - 1)$ st syzygy of M . The **Hilbert syzygy theorem** states that for any finitely generated graded R -module M , the n th syzygy of M is free. In other words, M admits a **free resolution** of length $\leq n$, i.e., an exact sequence of the form

$$0 \rightarrow F^{(v)} \rightarrow \dots \rightarrow F^{(1)} \rightarrow F^{(0)} \rightarrow M \rightarrow 0,$$

where $v \leq n$ and each $F^{(i)}$ ($0 \leq i \leq v$) is a finitely generated free graded R -module. It follows that if M_d denotes the homogeneous part of degree d in M , there exists a polynomial $P(X)$ of degree $\leq n - 1$ such that $\dim_k(M_d) = P(d)$ for sufficiently large d ; $P(X)$ is called the **Hilbert polynomial** (or **characteristic function**) of the graded R -module M .

(2) **Generalization by Serre.** The syzygy theory was generalized by J.-P. Serre [2] as follows: Let R be a Noetherian ring and M a finitely generated R -module. Then we can find a finitely generated free R -module F and an R -homomorphism φ of F onto M . The kernel of φ , called a **first syzygy** of M , is not uniquely

determined by M . However, if N_1 and N_2 are first syzygies of M , then there exist finitely generated \dagger projective R -modules P_1 and P_2 such that $N_1 \oplus P_1 \cong N_2 \oplus P_2$ (\rightarrow 277 Modules K). For a positive integer r , an r th syzygy is defined inductively as in (1) of this section. An important result of Serre is that R is a \dagger regular ring of \dagger Krull dimension at most n if and only if an n th syzygy of every finitely generated R -module is \dagger projective.

(3) Serre Conjecture. D. Quillen (*Inventiones Math.*, 36 (1976)) and A. Suslin (*Dokl. Akad. Nauk SSSR* (26 Feb. 1976)) solved the Serre conjecture by proving that every projective module over a ring of polynomials over a field is free.

(4) Special Cases. In the following special cases, we can define the first syzygy of M uniquely up to isomorphism: (i) R is a Noetherian \dagger local ring and M is a finitely generated R -module; and (ii) R is a graded Noetherian ring $\sum_{d \geq 0} R_d$, where R_0 is a field and M is a finitely generated graded R -module [4].

**370 (III.14)
Rings of Power Series**

A. Rings of Formal Power Series (\rightarrow 67 Commutative Rings; 284 Noetherian Rings; 368 Rings)

Let R be a commutative ring with unity element 1. Let F_d be the module of \dagger homogeneous polynomials of degree d in X_1, \dots, X_n with coefficients in R . A formal infinite sum $\sum_{d=0}^{\infty} a_d = a_0 + a_1 + \dots + a_n + \dots +$ of elements $a_d \in F_d$ is called a **formal power series** or simply **power series** in n variables X_1, \dots, X_n with coefficients in R , and a_d is called the **homogeneous part** of

degree d of the power series. The homogeneous part a_0 of degree zero is called the **constant term**. Addition and multiplication are defined by $(\sum a_d) + (\sum b_d) = \sum (a_d + b_d)$, $(\sum a_d)(\sum b_d) = \sum_d (\sum_{i+j=d} a_i b_j)$. By these operations, the set of power series forms a commutative ring, which is called the **ring of (formal) power series** (or **(formal) power series ring**) in X_1, \dots, X_n over R and is denoted by $R[[X_1, \dots, X_n]]$ or $R\{X_1, \dots, X_n\}$. If there is a natural number N such that $a_d = 0$ for every $d > N$, then the power series $\sum a_d$ is identified with the polynomial $a_0 + a_1 + \dots + a_n$. Thus $R[X_1, \dots, X_n] \subset R[[X_1, \dots, X_n]]$. Set $\mathfrak{X} = \sum_i X_i R[[X_1, \dots, X_n]]$. Then $R[[X_1, \dots, X_n]]$ is \dagger complete under the \mathfrak{X} -adic topology (\rightarrow 284 Noetherian Rings B).

Assume that R' is a commutative ring containing R and having a unity element in common with R , \mathfrak{a}' is an ideal of R' such that R' is complete under the \mathfrak{a}' -adic topology, and x_1, \dots, x_n are elements of \mathfrak{a}' . Then an infinite sum $\sum c_{i_1, \dots, i_n} x_1^{i_1} \dots x_n^{i_n}$ (each i_j ranges over nonnegative rational integers and $c_{i_1, \dots, i_n} \in R$) has a well-defined meaning in R' (namely, if S_d is a finite sum of these terms such that $\sum i_j \leq d$, then the infinite sum is defined to be $\lim_{d \rightarrow \infty} S_d$). This element $\sum c_{i_1, \dots, i_n} x_1^{i_1} \dots x_n^{i_n}$ is also called a **power series** in x_1, \dots, x_n with coefficients in R . The set of such power series in x_1, \dots, x_n is a subring of R' , called the **power series ring** in x_1, \dots, x_n over R and denoted by $R[[x_1, \dots, x_n]]$ or $R\{x_1, \dots, x_n\}$. Defining φ by $\varphi(\sum c_{i_1, \dots, i_n} X_1^{i_1} \dots X_n^{i_n}) = \sum c_{i_1, \dots, i_n} x_1^{i_1} \dots x_n^{i_n}$, we obtain a ring homomorphism $\varphi: R[[X_1, \dots, X_n]] \rightarrow R[[x_1, \dots, x_n]]$. If φ is an isomorphism, then we say that x_1, \dots, x_n are **analytically independent** over R .

If \bar{m} is a \dagger maximal ideal of the formal power series ring $R[[X_1, \dots, X_n]]$, then $m = \bar{m} \cap R$ is a maximal ideal of R and \bar{m} is generated by m and X_1, \dots, X_n . An element f of the power series ring is \dagger invertible if and only if its constant term f_0 is an invertible element of R , and in this case $f^{-1} = \sum_{d=0}^{\infty} f_0^{-d-1} \cdot (f_0 - f)^d$. If R is one of the following, then $R[[X_1, \dots, X_n]]$ is also of the same kind: (i) \dagger Noetherian ring, (ii) \dagger local ring, (iii) \dagger semilocal ring, (iv) \dagger integral domain, (v) \dagger regular local ring, (vi) Noetherian \dagger normal ring. But even if R is a \dagger unique factorization domain (u.f.d.), $R[[X_1, \dots, X_n]]$ need not be a u.f.d. (If R is a field, or more generally, if R is a regular semilocal ring, then $R[[X_1, \dots, X_n]]$ is a u.f.d.). In particular, a formal power series ring $k[[X]]$ in one variable X over a field k is an integral domain whose field of quotients is called the **field of (formal) power series** (or **(formal) power series field**) in one variable X over k and is denoted by $k((X))$; an element of $k((X))$ is expressed uniquely in the form $\sum_{n=r}^{\infty} a_n X^n$ ($a_n \in k, r \in \mathbb{Z}$).

B. Rings of Convergent Power Series

Let K be a field with multiplicative \dagger valuation v (for instance, $K = \mathbb{C}$, the complex number field, and $v(z) = |\alpha|$ for $\alpha \in \mathbb{C}$). A formal power series $f(X_1, \dots, X_n) = \sum c_{i_1, \dots, i_n} X_1^{i_1} \dots X_n^{i_n}$ is said to be a **convergent power series** if there are positive numbers r_1, \dots, r_n, M such that $v(c_{i_1, \dots, i_n}) r_1^{i_1} \dots r_n^{i_n} \leq M$ for every (i_1, \dots, i_n) . In this case, if $a_i \in K$ and $v(a_i) < r_i$, then $\sum c_{i_1, \dots, i_n} a_1^{i_1} \dots a_n^{i_n}$ has its sum in the \dagger completion of K . The set of convergent power series is a subring of $K[[X_1, \dots, X_n]]$. It is called the **ring of convergent power series** (or **convergent power series ring**) in n variables over K and is denoted by $K\langle\langle X_1, \dots, X_n \rangle\rangle$ or $K\{X_1, \dots, X_n\}$. It is a regular local ring of \dagger Krull dimension n . Hence it is a u.f.d. and its completion is $K[[X_1, \dots, X_n]]$. If v is a \dagger trivial valuation, then $K\langle\langle X_1, \dots, X_n \rangle\rangle = K[[X_1, \dots, X_n]]$.

Weierstrass's Preparation Theorem. For an element $f = \sum c_{i_1, \dots, i_n} X_1^{i_1} \dots X_n^{i_n} \in K\langle\langle X_1, \dots, X_n \rangle\rangle$, assume that $c_{0, \dots, 0, i} = 0$ for $i = 0, 1, \dots, r-1$ and $c_{0, \dots, 0, r} \neq 0$. Then for an arbitrary element g of $K\langle\langle X_1, \dots, X_n \rangle\rangle$, there exists a unique $q \in K\langle\langle X_1, \dots, X_n \rangle\rangle$ such that $g - qf \in \sum_{i=0}^{r-1} X_n^i K\langle\langle X_1, \dots, X_{n-1} \rangle\rangle$. In particular (considering the case where $g = X_n^r$), there is an invertible element u of $K\langle\langle X_1, \dots, X_n \rangle\rangle$ such that $fu = f_0 + f_1 X_n + \dots + f_{r-1} X_n^{r-1} + X_n^r$ ($f_i \in K\langle\langle X_1, \dots, X_{n-1} \rangle\rangle$).

By this theorem, we see easily that if \mathfrak{a} is an ideal of \dagger height h of $K\langle\langle X_1, \dots, X_n \rangle\rangle$, then $K\langle\langle X_1, \dots, X_n \rangle\rangle/\mathfrak{a}$ is isomorphic to a ring that is a finite module over $K\langle\langle X_1, \dots, X_{n-h} \rangle\rangle$.

If \mathfrak{p} is a \dagger prime ideal of $K\langle\langle X_1, \dots, X_n \rangle\rangle$, then $\mathfrak{p}K[[X_1, \dots, X_n]]$ is a prime ideal.

The Jacobian Criterion. Let K be a field, and let R be the ring of polynomials $K[X_1, \dots, X_n]$, the ring of formal power series $K[[X_1, \dots, X_n]]$, or the ring of convergent power series $K\langle\langle X_1, \dots, X_n \rangle\rangle$ in n variables X_1, \dots, X_n over K . \dagger Partial derivatives $\partial/\partial X_i$ are well defined in R . For $f_1, \dots, f_r \in R$, a \dagger Jacobian matrix $J(f_1, \dots, f_r)$ is defined to be the $t \times n$ matrix whose (i, j) -entry is $\partial f_i / \partial X_j$. Let \mathfrak{p} be a \dagger prime divisor of the ideal $\sum_i f_i R$, and let \mathfrak{q} be a prime ideal containing \mathfrak{p} . If the \dagger rank of $(J(f_1, \dots, f_r))$ modulo \mathfrak{q} is equal to the height of \mathfrak{p} , then the ring $R_{\mathfrak{q}}/\sum_i f_i R_{\mathfrak{q}}$ is a regular local ring. The converse is also true if K is a \dagger perfect field (if K is not a perfect field, then, modifying $J(f_1, \dots, f_r)$, we can have a similar criterion [1]).

C. Hensel Rings

A **Hensel ring** (or **Henselian ring**) is a commutative ring with unity element satisfying the

following two conditions: (i) R has only one maximal ideal \mathfrak{m} (i.e., R is a \dagger quasilocal ring); and (ii) if f, g_0, h_0 are monic polynomials in one variable x (here, a polynomial in x is called monic if the coefficient of the term of the highest degree is 1) such that $f - g_0 h_0 \in \mathfrak{m}R[x]$, $g_0 R[x] + h_0 R[x] + \mathfrak{m}R[x] = R[x]$, then there are monic polynomials $g, h \in R[x]$ such that $f = gh$ and $g \equiv g_0, h \equiv h_0$ modulo \mathfrak{m} .

Important examples of Hensel rings are complete local rings, rings of convergent power series, and \dagger complete valuation rings. When R is a Hensel ring, a commutative ring R' with unity element such that R' is a finite R -module is the direct sum of a finite number of Hensel rings. For any quasilocal ring Q , there exists a Hensel ring \tilde{Q} , called the **Henselization** of Q (for details \rightarrow [1]), for which the following statements hold: (i) \tilde{Q} is a \dagger faithfully flat Q -module; (ii) if \mathfrak{m} is the maximal ideal of Q , then the maximal ideal of \tilde{Q} is $\mathfrak{m}\tilde{Q}$, and $\tilde{Q}/\mathfrak{m}\tilde{Q} = Q/\mathfrak{m}Q$; (iii) if R is a Hensel ring that contains Q and has a maximal ideal \mathfrak{n} , and $\mathfrak{n} \cap Q = \mathfrak{m}$, then there is one and only one Q -homomorphism φ of \tilde{Q} into R ; (iv) if Q is a \dagger normal ring, then the Q -homomorphism φ is an injection; (v) if Q is a local ring, then \tilde{Q} is also a local ring, and Q is dense in \tilde{Q} .

Robust and Nonparametric Methods**

A. General Remarks

Robust and nonparametric or distribution-free methods are statistical procedures specifically devised to deal with broad families of probability distributions.

In the theory of statistical inference it is usual to assume that the probability distribution of the population from which the observed values are chosen at random is specified exactly except for a small number of unknown parameters (\rightarrow 401 Statistical Inference). In practical applications, however, it often happens that the assumptions made for the model,

especially those about the shape of the distribution, may not hold for the actual data. In such cases robust and/or nonparametric procedures that do not require exact knowledge of the shape of the distribution and yet prove to be relatively efficient or valid are required. The term **nonparametric** or **distribution-free** is used for problems of testing hypotheses, and the term **robust** is mainly used for problems of point estimation (→ 396 Statistic; 399 Statistical Estimation; 400 Statistical Hypothesis Testing).

Although the idea of the sign test appears in the work of J. Arbuthnot (1710), the theoretical foundation for nonparametric tests was first given in the proposals for the permutation test by R. A. Fisher (1935), the rank test by F. Wilcoxon (1945), and the test based on *U*-statistics by H. B. Mann and D. R. Whitney (1947). In the years that followed two important ideas appeared: the concept of asymptotic relative efficiency by E. J. G. Pitman (1948) and the development of the theory of *U*-statistics by W. Hoeffding (1948). H. Chernoff and I. R. Savage (1958) showed, in studying the asymptotic distribution of a class of rank statistics, that the asymptotic efficiencies of nonparametric tests are incredibly high. These findings accelerated the studies of nonparametric tests; recent progress is summarized in the books by J. Hájek and Z. Šidák [1], M. L. Puri and P. K. Sen [2], R. H. Randles and D. A. Wolfe [3], and P. J. Huber [6].

On the other hand, G. E. P. Box (1953) first coined the term robustness in his sensitivity studies, in which he investigated how the standard statistical procedures obtained under certain assumptions are influenced when such assumptions are violated. Two papers by J. W. Tukey (1960, 1962) provided the initial foundation for robust estimation. J. L. Hodges and E. L. Lehmann (1963) noticed that estimators of location could be derived from nonparametric tests and that these estimators have sometimes much higher efficiency than the sample mean. A similar study for scale was made by S. Kakeshita and T. Yanagawa (1967). Huber (1964) proposed an estimator of location by generalizing the method of least squares. Along with the idea of the influence curve introduced by F. R. Hampel (1974) the estimator proposed by Huber has become a core of subsequent studies of robust estimation. K. Takeuchi (1971) proposed an adaptive estimate that is asymptotically fully efficient for a wide class of underlying distribution functions. The developments of the theory of robust estimation are reviewed by Huber [4–6] and R. V. Hogg [7]. Various proposed estimators are compared in the book by D. F. Andrews et al. [8].

B. The One-Sample Problem

Let $F(x)$ be a †distribution function of a †random variable X , (X_1, \dots, X_n) be an independent random sample of size n from $F(x)$, and (x_1, \dots, x_n) be an observed sample value. The $100p$ percentile of F is denoted by ξ_p , i.e., $F(\xi_p) = p$. For testing the †hypothesis $H: \xi_p \leq \xi^0$ against the †alternative hypothesis $A: \xi_p > \xi^0$, the following procedure is proposed. Let $i(x_1, \dots, x_n)$ be the number of x_i that are greater than ξ^0 . A test procedure by the following †test function φ is †uniformly most powerful in some neighborhood of $\xi_p = \xi^0$ for the double exponential distribution, where $\varphi(x_1, \dots, x_n)$ is defined by the equations

$$\varphi(x_1, \dots, x_n) = \begin{cases} 1 & \text{when } i(x_1, \dots, x_n) > c, \\ a & \text{when } i(x_1, \dots, x_n) = c, \\ 0 & \text{when } i(x_1, \dots, x_n) < c \end{cases}$$

($0 < a < 1, 0 \leq c \leq n$). This procedure is called the **sign test**.

Suppose that $F(x)$ is symmetric about $x = \xi_{1/2}$. Let R_i^+ be the rank of $|X_i - \xi^0|$ among $|X_1 - \xi^0|, \dots, |X_n - \xi^0|$, and let $\Psi(t) = 1, 0$ according as $t > 0, \leq 0$. Set

$$S_n(X_1, \dots, X_n) = \sum_{i=1}^n a_n(R_i^+) \Psi(X_i - \xi^0)$$

for some weights $a_n(1), \dots, a_n(n)$. The following procedure φ , called the **signed rank test**, is also used for testing the hypothesis $H: \xi_{1/2} \leq \xi^0$ against the alternative hypothesis $A: \xi_{1/2} > \xi^0$:

$$\varphi(x_1, \dots, x_n) = \begin{cases} 1 & \text{when } S_n(x_1, \dots, x_n) > c, \\ a & \text{when } S_n(x_1, \dots, x_n) = c, \\ 0 & \text{when } S_n(x_1, \dots, x_n) < c. \end{cases}$$

The procedure with $a_n(i) = i$ is frequently used and is called the **Wilcoxon signed rank test**, which is the uniformly most powerful rank test in a neighborhood of $\xi_{1/2} = \xi^0$ for $F(x) = 1/(1 + e^{-x})$, the logistic distribution.

C. The Two-Sample Problem

Let F and G be continuous distribution functions of random variables X and Y , respectively, (X_1, \dots, X_m) and (Y_1, \dots, Y_n) be the corresponding random samples, and (x_1, \dots, x_m) and (y_1, \dots, y_n) be the respective sample values. Consider the problem of testing the hypothesis $H: F(x) \equiv G(x)$ against the alternative hypothesis $A_1: F(x) \not\equiv G(x)$ or $A_2: F(x) \geq G(x)$ for all x and $F(x) \neq G(x)$. When the alternative hypothesis A_2 is true, we say that the random variable Y is **stochastically larger** than X and write $F > G$. A frequently used example of such an alternative hypothesis A_2 is $G(x) = F(x - \theta)$, θ

> 0 . Let \mathcal{K} be the family of all strictly increasing continuous functions. Then the hypothesis H and the alternative hypothesis A_2 are invariant under the group of transformations of the form $x'_i = h(x_i)$, $y'_j = h(y_j)$ ($i = 1, \dots, m$; $j = 1, \dots, n$; $h \in \mathcal{K}$). The †maximal invariant statistic in this case is the rank (R_1, \dots, R_m) of (X_1, \dots, X_m) or the rank (S_1, \dots, S_n) of (Y_1, \dots, Y_n) when the combined sample $(X_1, \dots, X_m; Y_1, \dots, Y_n)$ is ordered in an ascending order. If a test function $\varphi(x_1, \dots, x_m; y_1, \dots, y_n)$ satisfies $P_\varphi(F, F) \leq \alpha$ and $P_\varphi(F, G) \geq \alpha$ for any $F > G$, then φ is considered a desirable test, where

$$P_\varphi(F, G) = \int \dots \int \varphi(x_1, \dots, x_m; y_1, \dots, y_n) \times \prod_i dF(x_i) \prod_j dG(y_j).$$

Lehmann's Theorem. If φ satisfies the conditions stating that $y_j^* > y_j$ ($j = 1, \dots, n$) yield $\varphi(x_1, \dots, x_m; y_1^*, \dots, y_n^*) \geq \varphi(x_1, \dots, x_m; y_1, \dots, y_n)$, then $P_\varphi(F, G) \geq P_\varphi(F, F)$. If in addition φ is a †similar test, then φ is unbiased (\rightarrow 400 Statistical Hypothesis Testing C).

The **Wilcoxon test** (or the **Mann-Whitney U-test**) is described by a test function $\varphi = 1$ when $U \geq c$ and $\varphi = 0$ when $U < c$, where U is a †U-statistic defined by

$$U = \frac{1}{mn} \sum_{i=1}^m \sum_{j=1}^n \psi(x_i, y_j)$$

with $\psi(x, y) = 1$ when $x \leq y$ and $\psi(x, y) = 0$ when $x > y$. This test is similar and unbiased.

Testing the hypothesis $H: F = G$ against the alternative hypothesis $A: F \neq G = F(x/\sigma)$, $\sigma > 1$, is another two-sample problem, for which the following test was proposed by T. Tamura. The test function is given by $\varphi = 1$ for $U \geq c$ and $\varphi = 0$ for $U < c$, where $U = \binom{m}{2}^{-1} \binom{n}{2}^{-1} \sum_{i < i'} \sum_{j < j'} \psi(x_i, x_{i'}, y_j, y_{j'})$ with $\psi(u, u'; v, v') = 1$ when $v < u < v'$, $v < u' < v'$ or $v' < u < v$, $v' < u' < v$ and $\psi(u, u'; v, v') = 0$ otherwise.

The following statistic T_N is used frequently in nonparametric problems. Let $x_1, \dots, x_m; y_1, \dots, y_n$ be arranged in order of magnitude. Set $z_k = +1$ or 0 when the k th value ($k = 1, 2, \dots, n + m$) in the arrangement is an x_i or y_j , respectively. For a given set of $N = n + m$ reals $\{e_k\}$, T_N is defined by $T_N = m^{-1} \sum_{k=1}^N e_k z_k$. Set $H_N(x) = \lambda_N F_m(x) + (1 - \lambda_N) G_n(x)$, where $F_m(x)$ and $G_n(x)$ are the †empirical distribution functions based on (x_1, \dots, x_m) and (y_1, \dots, y_n) , respectively, and $0 < \lambda_0 \leq \lambda_N = m/N \leq 1 - \lambda_0 < 1$. Then T_N is represented by the integral

$$\int J_N(H_N(x)) dF_m(x)$$

with $e_k = J_N(k/N)$. Chernoff and Savage [9] proved that under some regularity conditions the asymptotic distribution of T_N is normal and that the asymptotic mean μ and the vari-

ance σ^2 of T_N are given by

$$\begin{aligned} \mu &= \int J(H(x)) dF(x), \\ N\sigma^2 &= 2(1 - \lambda) \left\{ \iint_{x < y} G(x)(1 - G(y)) \right. \\ &\quad \times J'(H(x))J'(H(y)) dF(x) dF(y) \\ &\quad + \frac{1 - \lambda}{\lambda} \iint_{x < y} F(x)(1 - F(y)) \\ &\quad \left. \times J'(H(x))J'(H(y)) dG(x) dG(y) \right\}, \end{aligned}$$

where $J(H) = \lim_{N \rightarrow \infty} J_N(H)$, $H(x) = \lambda F(x) + (1 - \lambda)G(x)$, and $\lambda = \lim \lambda_N$. When $e_k = k/N$, the statistic T_N is equivalent to the †U-statistic in the Wilcoxon test. When e_k is the mean $E(Z_k)$ of the k th order statistic Z_k in an independent sample of size N from $N(0, 1)$, then the test by T_N is called the **Fisher-Yates-Terry normal score test**. When J is the inverse function of the distribution function of $N(0, 1)$, then the test is called the **van der Waerden test**.

D. The k -Sample Problem

Let $(X_{ij}, j = 1, \dots, n_i)$ be a random sample of size n_i from the population with a distribution function $F_i(x)$ for each $i = 1, \dots, k$. The **k -sample problem** is concerned with testing the hypothesis $H: F_1(x) = \dots = F_k(x)$ against an alternative hypothesis A_1 : not all the $F_i(x)$ are equal, $A_2: F_i(x) = F(x - \theta_i)$ with $\theta_i \neq \theta$, or $A_3: F_i(x) = F(x/\sigma_i)$ with $\sigma_i \neq \sigma$. Several tests have been proposed for this problem, using quadratic forms of the vector-valued U-statistic $U = (U^1, \dots, U^k)$ whose coordinates U^i are defined by means of a function

$$\psi^i(x_{11}, \dots, x_{1n_1}; \dots; x_{k1}, \dots, x_{kn_k}), \quad i = 1, \dots, k.$$

When $N = \sum n_i \rightarrow \infty$ with $n_i = \rho_i N$, $0 < \rho_i < 1$, and $\sum \rho_i = 1$, then

$$V = (\sqrt{N}(U^1 - E(U^1)), \dots, \sqrt{N}(U^k - E(U^k)))$$

has asymptotically a †multivariate normal distribution $N(0, \Sigma)$. Let B be the projection matrix corresponding to the eigenspace for the zero eigenvalues of the matrix Σ , and let Λ be a matrix such that $\Lambda B = 0$, $\Sigma \Lambda = I - B$. The statistic $V \Lambda^t V$ has asymptotically a †noncentral chi-square distribution with degrees of freedom = rank Σ . Several kinds of test represented by a critical region of the form $V \Lambda V^t > c$ are proposed, among which the **Kruskal-Wallis test** is a particular one having

$$\psi^i(x_1; \dots; x_k) = \sum_x \frac{1}{n_i n_x} \delta(x_x, x_i), \quad i = 1, \dots, k,$$

as basic functions, where $\delta(x, y) = 1$ when $x < y$ and $\delta(x, y) = 0$ otherwise.

E. Asymptotic Relative Efficiency of Tests

If there is more than one test procedure for a given testing problem, then one may wish to compare these procedures. Let $\{\varphi_n\}$ and $\{\psi_n\}$ be two sequences of level α tests, where φ_n and ψ_n are test functions based on a sample of size n . The power functions of φ_n and ψ_n are denoted by $\beta(\theta | \varphi_n)$ and $\beta(\theta | \psi_n)$, respectively. Let θ be a real parameter and $\{\theta_i\}$ be such that $\theta_i \rightarrow \theta_0$ as $i \rightarrow \infty$. Consider a hypothesis $\theta = \theta_0$ and a sequence $\{\theta_i\}$ of alternative hypotheses. If, for any increasing sequences $\{n_i\}$ and $\{n_i^*\}$ of positive integers satisfying $\alpha < \lim \beta(\theta_i | \varphi_{n_i}) = \lim \beta(\theta_i | \psi_{n_i^*}) < 1$, $\lim n_i^*/n_i = e$ ($e = e(\{\varphi_n\}, \{\psi_n\}$), say) exists and is independent of α and $\lim \beta(\theta_i | \varphi_{n_i})$, then e is called Pitman's asymptotic relative efficiency of $\{\varphi_n\}$ against $\{\psi_n\}$. Suppose further that the tests $\{\varphi_n\}$ and $\{\psi_n\}$ are based on statistics $T_n = t_n(\mathbf{X})$ and $T_n^* = t_n^*(\mathbf{X})$, respectively, in the following manner:

$$\varphi_n(\mathbf{x}) = \begin{cases} 1 & \text{when } t_n(\mathbf{x}) > c, \\ a & \text{when } t_n(\mathbf{x}) = c, \\ 0 & \text{when } t_n(\mathbf{x}) < c, \end{cases}$$

$$\psi_n(\mathbf{x}) = \begin{cases} 1 & \text{when } t_n^*(\mathbf{x}) > c^*, \\ b & \text{when } t_n^*(\mathbf{x}) = c^*, \\ 0 & \text{when } t_n^*(\mathbf{x}) < c^*, \end{cases}$$

where $\mathbf{X} = (X_1, \dots, X_n)$ and $\mathbf{x} = (x_1, \dots, x_n)$. Put $\theta_0 = 0$ and $\theta_n = k/\sqrt{n}$ ($k = \text{constant}$) for simplicity. If T_n and T_n^* are asymptotically normal, then under some conditions e is given by the formula

$$e = \lim \frac{(dE_\theta(T_n)/d\theta|_{\theta=0})^2 \sigma_0^2(T_n^*)}{(dE_\theta(T_n^*)/d\theta|_{\theta=0})^2 \sigma_0^2(T_n)}$$

As an example, consider a two-sample problem on a location parameter. If the population distribution is normal and the Wilcoxon test is used to test the hypothesis of equality of means, then its asymptotic relative efficiency against Student's test is $3/\pi$. For the same problem, the asymptotic relative efficiencies of the Fisher-Yates-Terry normal score test and the van der Waerden test against Student's test are both unity. For the hypothesis of equality of means in the k -sample problem, the asymptotic relative efficiency of the Kruskal-Wallis test against the F -test is $3/\pi$, provided that the sample is distributed normally.

F. Kolmogorov-Smirnov Tests

Let $F_n(x)$ be the empirical distribution function based on a random sample of size n from

$F_0(x)$. Set

$$d_n = \sup |F_n(x) - F_0(x)|,$$

$$D_n = \sup (F_n(x) - F_0(x)),$$

$$s_n = \sup_{a \leq F_0(x)} \left| \frac{F_n(x) - F_0(x)}{F_0(x)} \right|,$$

$$S_n = \sup_{a \leq F_0(x)} \frac{F_n(x) - F_0(x)}{F_0(x)}.$$

Then

$$\lim_{n \rightarrow \infty} P_r(d_n < z/\sqrt{n}) = L(z) = \sum_{k=-\infty}^{\infty} (-1)^k e^{-2k^2 z^2},$$

$$\lim_{n \rightarrow \infty} P_r(D_n < z/\sqrt{n}) = K(z) = 1 - e^{-2z^2},$$

$$P_r(D_n < D) = 1 - D \sum_{j=0}^{[(1-D)]} \binom{n}{j} \times \left(1 - D - \frac{j}{n}\right)^{n-j} \left(D + \frac{j}{n}\right)^{j-1},$$

$$\lim_{n \rightarrow \infty} P_r(s_n < z/\sqrt{n}) = \frac{4}{\pi} \sum_{k=0}^{\infty} (-1)^k \times (2k+1)^{-1} e^{-((2k+1)^2 \pi^2 / 8) ((1-a)/a) z^2},$$

$$\lim_{n \rightarrow \infty} P_r(S_n < z/\sqrt{n}) = \sqrt{\frac{2}{\pi}} \int_0^{z\sqrt{a/(1-a)}} e^{-t^2/2} dt.$$

The statistics d_n, D_n, s_n, S_n are frequently used to test the hypothesis $F(x) = F_0(x)$. (This problem is called testing goodness of fit.)

In a two-sample problem, let $F_m(x)$ and $G_n(x)$ be two empirical distribution functions based on samples of sizes m and n from $F(x)$ and $G(x)$, respectively. Set

$$d_{m,n} = \sup |F_m(x) - G_n(x)|,$$

$$D_{m,n} = \sup (F_m(x) - G_n(x)).$$

If the hypothesis $F = G$ is true, we have

$$\lim P_r(d_{m,n} < z/\sqrt{N}) = L(z),$$

$$\lim P_r(D_{m,n} < z/\sqrt{N}) = K(z),$$

provided that m and n tend to ∞ so that $N = mn/(m+n) \rightarrow \infty$ and m/n is constant. Taking account of these facts, $d_{m,n}$ and $D_{m,n}$ are used to test the hypothesis $F = G$. The tests using the statistics $d_n, D_n, d_{m,n}, D_{m,n}$ are called **Kolmogorov-Smirnov tests**.

G. Interval Estimation

Let (X_1, \dots, X_n) be an independent random sample from the population with a distribution function $F(x - \theta)$, where θ is an unknown location parameter, and (x_1, \dots, x_n) be its observed value. Suppose that $F(x)$ is continuous and symmetric about the origin.

Using the statistic $S_n = S(x_1, \dots, x_n)$ for the one-sample nonparametric test for testing the hypothesis $H: \theta = 0$, a \dagger confidence interval of θ is constructed as follows. For an appropriately given γ ($0 < \gamma < 1$), select constants d_1 and d_2 in the range of $S(x_1, \dots, x_n)$ that satisfy

$$P_0\{d_1 < S(X_1, \dots, X_n) < d_2\} = 1 - \gamma,$$

where P_0 means the probability under the hypothesis $H: \theta = 0$. If there exist statistics $L_s(x_1, \dots, x_n)$ and $U_s(x_1, \dots, x_n)$ such that $L_s(x_1, \dots, x_n) \leq \theta < U_s(x_1, \dots, x_n)$ if and only if $d_1 < S(x_1 - \theta, \dots, x_n - \theta) < d_2$ for all θ , then the confidence interval of θ with $100(1 - \gamma)\%$ confidence coefficient is given by $(L_s(x_1, \dots, x_n), U_s(x_1, \dots, x_n))$. This interval is distribution-free, i.e., it holds that

$$P\{L_s(X_1, \dots, X_n) < \theta < U_s(X_1, \dots, X_n)\} = 1 - \gamma$$

for all F .

When S_n is the statistic for the Wilcoxon signed rank test, L_s and U_s are given by $L_s = W_{(M+1-d_2)}$ and $U_s = W_{(M-d_1)}$, where $M = n(n+1)/2$ and $W_{(1)} \leq \dots \leq W_{(M)}$ are ordered values for M averages $(x_i + x_j)/2$ ($i \leq j = 1, 2, \dots, n$).

H. Point Estimation

Let (X_1, \dots, X_n) be an independent random sample from the population with a distribution function $F(x - \theta)$, where θ is an unknown location parameter, and let (x_1, \dots, x_n) be its observed value.

There are four methods of constructing robust estimators of θ . Let $X_{(1)} < \dots < X_{(n)}$ be ordered values of X_1, \dots, X_n . The first method is to use $T_n = a_1 X_{(1)} + \dots + a_n X_{(n)}$ for some given constants a_1, \dots, a_n such that $\sum_{i=1}^n a_i = 1$. T_n is called the **L-estimator**. An example is

$$T_n(\alpha) = (pX_{([xn]+1)} + X_{([xn]+2)} + \dots + pX_{(n-[xn])})/n(1 - 2\alpha),$$

where $p = 1 + [xn] - xn$. This estimator is called the α -**trimmed mean**. Let J be a real-valued function such that $\int_0^1 J(t) dt = 1$, and set $a_k = \int_{(k-1)/n}^k J(t) dt$; then as $n \rightarrow \infty$, T_n converges to $T(F) = \int_0^1 J(t) F^{-1}(t) dt$ in probability. Suppose that F is a distribution function having an \dagger absolutely continuous density function f . Denote the derivative of f by f' , and let $I(F)$ be the \dagger Fisher information on θ . Set $\psi(t) = -f'(t)/f(t)$ and $J(t) = \psi(F^{-1}(t))/I(F)$. Then Chernoff, J. L. Gastwirth, and M. V. Johns [10] proved that under some regularity conditions T_n is an \dagger asymptotically efficient estimator of θ for F .

Let ρ be a real-valued (usually convex) function of a real parameter with derivative $\psi = \rho'$. The second method is to estimate θ by T_n

by minimizing $\sum_{i=1}^n \rho(x_i - T_n)$ or by satisfying

$$\sum_{i=1}^n \psi(x_i - T_n) = 0.$$

T_n is called the **M-estimator**. When $\rho(t) = t^2$, it agrees with the least squares estimator. Let $\Phi(x)$ be the distribution function of the standard normal distribution, $H(x)$ be an arbitrary continuous distribution function which is symmetric about the origin, \mathcal{F} be a class of distribution functions of the form $F(x) = (1 - \varepsilon)\Phi(x) + \varepsilon H(x)$ for a given ε ($0 < \varepsilon < 1$), and $V(\rho, F)$ be the asymptotic variance of T_n . Huber [11] proved that ρ minimizing $\sup_{F \in \mathcal{F}} V(\rho, F)$ is given by $\rho_K(t) = t^2/2$, $K|t| - K^2/2$ defined for $|t| \leq K$, $> K$, respectively, for some constant K . Under quite general conditions, the **M-estimator** converges as $n \rightarrow \infty$ to $T(F)$ in probability, which is defined by $\int \psi(x - T(F)) dF(x) = 0$. If $\psi(t) = -f'(t)/f(t)$ is chosen for $\psi(x)$, then T_n is the \dagger maximum likelihood estimator of θ for F and is asymptotically efficient under some regularity conditions. Generally, the **M-estimator** defined above is not scale invariant. A scale invariant version of the **M-estimator** is obtained by replacing the defining equation by

$$\sum_{i=1}^n \psi\left(\frac{x_i - T_n}{S_n}\right) = 0, \tag{1}$$

where S_n is any robust estimate of scale, e.g., the median of $\{|x_i - M|/0.6745\}_{i=1,2,\dots,n}$ where M is the sample median, or by solving the simultaneous equations (1) and

$$\sum_{i=1}^n \chi\left(\frac{x_i - T_n}{S_n}\right) = 0$$

with respect to T_n and S_n . In the context of the maximum likelihood estimation, χ is chosen to be $\chi(t) = t\psi(t) - 1$ (\rightarrow 399 Statistical Estimation P).

The third method employs nonparametric tests for testing the hypothesis $H: \theta = 0$ against the alternative hypothesis $A: \theta > 0$. Let J be a real-valued and nondecreasing function such that $\int_0^1 J(t) dt = 0$ and $R_k^+(\theta)$ be the rank of $|X_k - \theta|$ among $|X_1 - \theta|, \dots, |X_n - \theta|$. Set $\Psi(t) = 1, 0$ according as $t > 0, \leq 0$ and $S(X_1 - \theta, \dots, X_n - \theta) = \sum_{k=1}^n J((R_k^+(\theta) + n)/(2n + 1))\Psi(X_k - \theta)$. Let

$$\theta^* = \sup\{\theta; S(X_1 - \theta, \dots, X_n - \theta) > \mu\},$$

$$\theta^{**} = \inf\{\theta; S(X_1 - \theta, \dots, X_n - \theta) < \mu\},$$

where μ is the expected value of $S(X_1, \dots, X_n)$ under the hypothesis $H: \theta = 0$. Then an estimator of θ is defined by $T_n = (\theta^* + \theta^{**})/2$. Hodges and Lehmann [12] first proposed this technique, and this estimator is called the **R-estimator**. When $F(x)$ is symmetric about the origin and $J(t) = t - \frac{1}{2}$, S tends to be the statistic for the Wilcoxon signed rank test, and the

R-estimator reduces to the median of $n(n+1)/2$ averages $(X_i + X_j)/2$ ($1 \leq i < j \leq n$). As $n \rightarrow \infty$, the R-estimator converges in probability to $T(F)$, defined by

$$\int J\left(\frac{F(x) + 1 - F(2T(F) - x)}{2}\right) dF(x) = 0.$$

For symmetric F , the R-estimator defined by the statistic S with $J(t) = -f'(F^{-1}(t))/f(F^{-1}(t))$ is asymptotically efficient under some regularity conditions.

Although the above three methods provide robust estimators, which are seldom affected by outlying observations or contamination by gross errors, their behavior still depends on F . The last method of constructing robust estimators consists of estimating θ adaptively by utilizing information on the shape of F . Among these, a striking one is the asymptotically fully efficient estimator for a wide class of F proposed by Takeuchi [13]. The estimator is constructed by using subsamples of size K ($K < n$) drawn from the original sample, estimating the elements of the covariance matrix of the order statistics by U -statistics, and selecting the best weights of the L -estimator. L. A. Jaeckel [14] made an α -trimmed mean adaptive estimator by selecting an α that minimizes the estimated asymptotic variance.

I. The Influence Curve

Let $T(F)$ be a functional of a distribution function F , and let an estimator T_n of θ calculated from an empirical distribution function F_n converge to $T(F)$ in probability as $n \rightarrow \infty$. A real-valued function $IC(x; F, T)$ defined by

$$IC(x; F, T) = \lim_{\epsilon \rightarrow 0} \frac{T((1-\epsilon)F + \epsilon\delta_x) - T(F)}{\epsilon}$$

for all x

is called the **influence curve**, where δ_x is the distribution function of a point mass 1 at x . The curve was first introduced by Hampel [15] to study the stability aspect of estimators against a small change of F . As an example, when F is symmetric about the origin, the influence curve for the α -trimmed mean $IC(x; F, T)$ is given by

$$\begin{aligned} F^{-1}(\alpha)/(1-2\alpha) & \text{ when } x < F^{-1}(\alpha), \\ x/(1-2\alpha) & \text{ when } F^{-1}(\alpha) \leq x < F^{-1}(1-\alpha), \\ F^{-1}(1-\alpha)/(1-2\alpha) & \text{ when } x > F^{-1}(1-\alpha). \end{aligned}$$

By substituting the empirical distribution function F_n for F in $T(F)$, we can represent the robust estimators discussed in Section H, at

least approximately, by $T_n = T(F_n)$. Under some conditions, it can be proved that as $n \rightarrow \infty$,

$$n^{1/2}(T(F_n) - T(F)) - \frac{1}{n} \sum_{i=1}^n IC(X_i; F, T) \rightarrow 0$$

in probability. Thus it follows that $n^{1/2}(T_n - T(F))$ is asymptotically normally distributed with asymptotic variance $\int (IC(x; F, T))^2 dF(x)$.

J. The Regression Problem

Consider the linear regression problem (\rightarrow 403 Statistical Models D)

$$X_i = \sum_{j=1}^p \theta_j a_{ij} + \epsilon_i, \quad i = 1, 2, \dots, n,$$

where the X_i are observable variables, the θ_j are regression coefficients to be estimated, the a_{ij} are given constants, and $\epsilon_1, \epsilon_2, \dots, \epsilon_n$ are identically and independently distributed random errors whose distribution function is given by $F(x)$. The idea of the M -estimator is a direct generalization of the method of least squares; namely, to adopt $(\hat{\theta}_1, \dots, \hat{\theta}_p)$ as an estimator for $(\theta_1, \dots, \theta_p)$ that minimizes $\sum_{i=1}^n \rho(X_i - \sum_j \theta_j a_{ij})$ for some function ρ such as the one described above.

R-estimators of the regression coefficients are obtained by minimizing $\sum_{i=1}^n a_n(R_i) \Delta_i$, where $\Delta_i = X_i - \sum_j \theta_j a_{ij}$, R_i is the rank of Δ_i among $\Delta_1, \dots, \Delta_n$, and $a_n(\cdot)$ is some monotone function satisfying $\sum_{i=1}^n a_n(i) = 0$. It has been proved that minimizing $\sum_{i=1}^n a_n(R_i) \Delta_i$ is asymptotically equivalent to minimizing

$$\sum_{j=1}^p \left| \sum_{i=1}^n a_n(R_i) a_{ij} \right|,$$

the properties of which were first studied by J. Jurečková [16].

K. Dependence

Let $(X_1, Y_1), \dots, (X_n, Y_n)$ be random samples from a population with a bivariate distribution function, R_i be the rank of X_i among X_1, \dots, X_n when they are rearranged in an ascending order, and S_j be the rank of Y_j among Y_1, \dots, Y_n defined similarly as R_i . Various quantities are devised to measure the degree of dependence between X and Y .

(1) Spearman's Rank Correlation. Set $d_i = R_i - S_i$. Then $r_s = 1 - 6 \sum_i d_i^2 / (n^3 - n)$ is called **Spearman's rank correlation**. If there is no dependence between X and Y , i.e., if the X_i and Y_j are independent random variables, then $E(r_s) = 0$ and $V(r_s) = (n-1)^{-1}$.

(2) Kendall's Rank Correlation. Take pairs (R_i, S_i) and (R_j, S_j) . If $(R_j - R_i)(S_j - S_i) > 0$, set

Robust and Nonparametric Methods

$\varphi_{ij} = 1$; otherwise, $\varphi_{ij} = -1$. The statistic $r_k = \binom{n}{2}^{-1} \sum \varphi_{ij}$ is called **Kendall's rank correlation**, where \sum runs over all possible pairs chosen from $(R_1, S_1), \dots, (R_n, S_n)$.

If there is no dependence between X and Y , then $E(r_k) = 0$ and $V(r_k) = 2(2n+5)/(9n(n-1))$.

(3) **Rankit Correlation.** R_i and S_i , $i = 1, \dots, n$, are replaced by the corresponding normal scores, i.e., the means of order statistics in an independent sample of size n from $N(0, 1)$; then the usual sample correlation coefficient is calculated from these scores. This correlation coefficient r_R is called rankit correlation; and if there is no dependence between X and Y , then $E(z) = 0$, $V(z) = (n-3)^{-1}$, asymptotically, where $z = \frac{1}{2} \log \frac{1+r_R}{1-r_R}$ (Fisher's z -transformation).

These statistics are used to test the hypothesis of independence.

372 (XXI.3) Roman and Medieval Mathematics

The Romans were interested in mathematics for everyday use; their arithmetic consisted of computation (by means of the **abacus**), weights and measures, and money. For their monetary system, they developed a computational method using duodecimal fractions. Julius Caesar (102?–44 B.C.), known for his calendar reform in 46 B.C., also undertook to measure his territory, which aroused a demand for land surveying techniques. Books on practical geometry which provided this knowledge were called *gromatics* (a “groma” was a land surveying instrument). Toward the end of the Western Roman Empire (476), Greek mathematics was studied; during this period Boethius (c. 480–524) wrote his two books on arithmetic and geometry. The former was a summarized translation of Nichomachus' book, and the latter included propositions from the first three books of Euclid's *Elements* (without proof) and practical geometry.

Music, astronomy, geometry, and arithmetic, which constituted the “mathemata” of Plato's Academy (closed in 529), were treated as the “quadrivium” (the four major subjects) in the *Encyclopedia* of Martianus Capella, Cassiodorus, Isidorus, Hispalensis, and others. After the establishment of the Roman Church in the 5th century, the quadrivium was to be studied for the glory of God. Books on mathematics from this period laid emphasis on the computation of an ecclesiastical calendar and mystical interpretations of integers, as seen in books by Bede Venerabilis, Alcuin, and Maurus from the 7th through 9th centuries.

Arabian science was imported first through Spain—under Moorish influence beginning in 711, the year of the fall of the Visigoths—and then through the Crusades (1096–1270). Computation with figures, originating in India, replaced the abacus in the 12th century, when

Arabian books on arithmetic and algebra, along with Greek books on geometry and astronomy (such as books by Euclid and Ptolemy), were translated into Latin. Italian merchants, whose occupation necessitated computation, rapidly adopted the new system. Representative books of this period are *Liber abaci* (1202) and *Practica geometrica* (1220) by Leonardo da Pisa (also known as Fibonacci, c. 1170–1250). The former includes the four arithmetic operations, showing Indian influence, commercial arithmetic, and algebra. The new methods were not limited to merchants. The French bishop Nicole Oresme (c. 1323–1382), who influenced Leonardo da Vinci (1452–1519), introduced fractional exponents and conceived the graphic representation of temperature, a precursor of coordinates and functions.

From the 11th century, universities developed from theological seminaries, first in Italian cities such as Bologna and Palermo, and later in Paris, Oxford, and Cambridge. Mathematics was taught in these universities, although no remarkable creative contributions were made. However, theologians such as Albertus Magnus (c. 1193–1280) and Thomas Aquinas (1225?–1274) discussed infinity in a way that went beyond Greek thought and thus helped to lay a basis for the modern philosophy of mathematics.

S

373 (XVIII.13) Sample Survey

A. General Remarks

The sample survey is a means of getting statistical information about a certain aggregate from the observation of some but not all of it. The aggregate concerned is usually called the **finite population**, and the observed part is called the **sample**. Introducing a random mechanism, J. Neyman established a method of ascertaining objectively the reliability of such information. This method is mainly applied to demographic statistical surveys and opinion polls, but it is also applicable to random samples of physical materials. We briefly sketch the mathematical structure of this method without going into detail about technical problems that arise in the practical survey situation.

Suppose that the population consists of N units, where N is called its **size**. Each unit has some characteristic α , which is an element of some set Ω . The set of all characteristics of the units in the population is designated by $\theta = \{\alpha_1, \dots, \alpha_N\}$, which we regard as a parameter. The set of all possible θ is denoted by $\Theta \subset \Omega^N$.

Suppose that one unit is chosen and observed according to some procedure, the index number of the unit in the population is J , and the observed characteristic is X . It is assumed that the observation is without error, hence $X = \alpha_J$.

Denote the whole sample by $(\mathbf{J}, \mathbf{X}) = (J_1, \dots, J_n, X_1, \dots, X_n)$, where n is the **sample size** and $X_i = \alpha_{J_i}$. The sample size n may be a random variable, and among J_1, \dots, J_n , duplication may be allowed. The probabilistic scheme for \mathbf{J} is called the **sampling procedure**, and if it satisfies the condition

(c) $\Pr\{J_i = j\}$ is independent of α_{J_i} and of X_{i+1}, \dots, X_n (but may depend on X_1, \dots, X_{i-1}),

it is called a **random sampling procedure**. Moreover, if the joint distribution of \mathbf{J} is independent of θ , it is called **regular**. Specifically, if n is constant and $\Pr\{\mathbf{J}\}$ is symmetric in \mathbf{J} , it is called **uniform**.

The two main mathematical problems of sample surveys are to determine a random sampling procedure and to provide methods whereby statistical inferences can be made concerning θ (\rightarrow 401 Statistical Inference).

B. The Problem of Inference

Condition (c) is assumed. The probability of (\mathbf{J}, \mathbf{X}) is given by

$$\begin{aligned} \Pr\{(\mathbf{J}, \mathbf{X}) = (j_1, \dots, j_n, X_1, \dots, X_n)\} \\ = \Pr\{J_1 = j_1\} \chi_\theta(X_1) \Pr\{J_2 = j_2 | J_1, X_1\} \chi_\theta(X_2) \\ \dots \Pr\{J_n = j_n | J_1, X_1, \dots, J_{n-1}, X_{n-1}\} \chi_\theta(X_n), \end{aligned}$$

where $\chi_\theta(X_i)$ is defined as 1 if $X_i = \alpha_{j_i}$ and 0 otherwise. This formula can be shortened to the form

$$\Pr\{(\mathbf{J}, \mathbf{X})\} = P(\mathbf{J}, \mathbf{X}) \chi_\theta(\mathbf{X}, \mathbf{J}), \quad (1)$$

where

$$\chi_\theta(\mathbf{X}, \mathbf{J}) = \begin{cases} 1 & \text{if } X_i = \alpha_{J_i}, i = 1, \dots, n, \\ 0 & \text{otherwise.} \end{cases}$$

Expression (1) is the fundamental model for the sample survey problem. Note that $P(\mathbf{J}, \mathbf{X})$ is independent of the parameter θ . Therefore if we let $\mathbf{I} = (I_1, \dots, I_m)$ ($I_1 < \dots < I_m$) be the set of numbers in (J_1, \dots, J_n) after deleting duplications, and let $\mathbf{Y} = (Y_1, \dots, Y_m)$ be the corresponding X values, then the joint distribution of \mathbf{I} and \mathbf{Y} can also be expressed as

$$\Pr\{(\mathbf{I}, \mathbf{Y})\} = P(\mathbf{I}, \mathbf{Y}) \chi_\theta(\mathbf{Y}, \mathbf{I}),$$

where

$$\chi_\theta(\mathbf{Y}, \mathbf{I}) = \begin{cases} 1 & \text{if } Y_j = \alpha_{I_j}, j = 1, \dots, m, \\ 0 & \text{otherwise.} \end{cases}$$

Since $\chi_\theta(\mathbf{Y}, \mathbf{I}) = \chi_\theta(\mathbf{X}, \mathbf{J})$ for all θ , the conditional probability distribution of (\mathbf{J}, \mathbf{X}) for given (\mathbf{I}, \mathbf{Y}) is independent of $\chi_\theta(\mathbf{X}, \mathbf{J})$, and hence (\mathbf{J}, \mathbf{X}) is a \dagger sufficient statistic. According to the general theory of sufficient statistics, we can restrict ourselves to the class of procedures depending only on (\mathbf{I}, \mathbf{Y}) .

C. Estimation

Suppose that $g(\theta) = g(\alpha_1, \dots, \alpha_N)$ is a real parameter whose unbiased estimators are under discussion.

Theorem. There exists an unbiased estimator of $g(\theta)$ if and only if there exists a decomposition

$$\begin{aligned} g(\theta) = \sum h_v(\alpha_{j_1(v)}, \dots, \alpha_{j_n(v)}), \\ \Pr\{\mathbf{I} = (j_1(v), \dots, j_n(v))\} > 0, \quad v = 1, 2, \dots \quad (2) \end{aligned}$$

If the sampling procedure is regular, the second condition can be replaced by $\Pr\{\mathbf{I} \supset (j_1(v), \dots, j_n(v))\} > 0, v = 1, 2, \dots$. Hence, for example, if α_i is real and the sampling procedure is regular, $\bar{\alpha} = \sum \alpha_i / N$ is estimable if and only if $\Pr\{\mathbf{I} \ni i\} > 0$ for all i , and $\sigma_\alpha^2 = \sum (\alpha_i - \bar{\alpha})^2 / (N - 1) = \sum \sum (\alpha_i - \alpha_j)^2 / N(N - 1)$ is estimable if and only if $\Pr\{\mathbf{I} \ni i, j\} > 0$ for all i and j . Also, $\prod_{i=1}^N \alpha_i$ is not estimable unless $\Pr\{\mathbf{I} = (1, \dots, N)\} > 0$. The decomposition (2) is not unique, and corresponding to different decompositions, different unbiased estimators are derived. Also, for the case of regular sampling

procedures, for any $\theta = \theta_0$ it is always possible to construct an unbiased estimator $g(\theta)$ such that $\Pr\{\hat{g}(\theta) \equiv g(\theta_0) | \theta = \theta_0\} = 1$ if $g(\theta)$ is estimable. Hence the variance of the locally best unbiased estimator is always 0, and the uniformly minimum variance unbiased estimators exist only in the trivial case.

If some kind of symmetry exists among the population units as well as the sampling procedure and the parameter, it would be natural to require the same kind of symmetry for the estimators. Let G be a group of permutations among N numbers. Assume that for any $\theta \in \Theta$ and $\gamma \in G$, we have $\gamma\theta \in \Theta$ and $g(\gamma\theta) = g(\theta)$. If $\Pr\{\gamma\mathbf{J}\} = \Pr\{\mathbf{J}\}$ for all γ , then the sampling procedure is said to be **invariant** with respect to G . An estimator is also called invariant if its value does not change under any permutation $\gamma \in G$ of the numbers of sample units. Thus if G is the set of all permutations (i.e., the symmetric group), then the invariant estimator is a function of \mathbf{Y} (or \mathbf{X}) only. Moreover, if the dimension m of \mathbf{Y} is constant, \mathbf{Y} is complete (under some mild conditions); hence there exists a unique minimum variance invariant unbiased estimator.

When there is some additional information, it can be represented by **auxiliary variables** β_1, \dots, β_N , which are known and assumed to have some relation to $\alpha_1, \dots, \alpha_N$. Assume that the α_i are real numbers and that the parameter to be estimated is $\theta = \bar{\alpha} = (\sum \alpha_i)/N$. If we can assume that α_i and β_i are approximately proportional, we can estimate the unknown population mean $\bar{\alpha}$ by $\hat{\alpha}^* = (\bar{X}/\bar{Z}) \times \bar{\beta}$ where \bar{X} is the sample mean of the α 's and \bar{Z} the sample mean of the β 's. Although $\hat{\alpha}^*$ is not unbiased, we may expect that it has small error if the relation between two variables is close. $\hat{\alpha}^*$ is usually called the ratio estimator.

In practical research, as an estimator of the population total $A = \sum \alpha_i$, we usually use $\hat{A} = \sum X_i/P_i$, where $P_i = \Pr\{\mathbf{J} \ni i\}$. Its variance is $V(\hat{A}) = \sum \sum (P_i P_j - P_{ij})(\alpha_i/P_i - \alpha_j/P_j)^2$ and is estimated by $v(\hat{A}) = \sum \sum \{(P_i P_j - P_{ij})/P_{ij}\} (X_i/P_i - X_j/P_j)^2$, where $P_{ij} = \Pr\{\mathbf{J} \ni (i, j)\}$. When N is unknown, it can be estimated by the same procedure as \hat{A} (say \hat{N}), and the population mean $\bar{\alpha}$ can be estimated by $\hat{\alpha} = \hat{A}/\hat{N}$, which is called a ratio estimator. $\hat{\alpha}$ is biased except when N is known.

D. Asymptotic Confidence Intervals

It is usually impossible to obtain any meaningful confidence interval based on exact small-sample theory. But when the α_i are real and the sampling procedure is uniform and without replacement, the sample mean \bar{X} is asymptotically normal with mean $\bar{\alpha}$ and variance

$\frac{1}{n} \left(1 - \frac{n}{N}\right) \sigma_{\alpha}^2$, where $\sigma_{\alpha}^2 = \frac{1}{N-1} \sum (\alpha_i - \bar{\alpha})^2$, as N and $n \rightarrow \infty$, and $\limsup n/N < 1$, provided that

$$\limsup_{N \rightarrow \infty} \frac{\max_{1 < i \leq N} (\alpha_i - \bar{\alpha})^2}{\sum (\alpha_i - \bar{\alpha})^2} = 0.$$

Also, the sample variance converges to σ_{α}^2 as $n \rightarrow \infty$. From these results we can construct asymptotic confidence intervals for $\bar{\alpha}$.

E. The Problem of Sampling Procedures

In determining the sampling procedures, both the technical aspects of sampling and the accuracy of the estimators should be considered. The most commonly used methods are **multistage sampling** and **stratified sampling**, or some combination of the two. For example, the population is partitioned into several clusters. First we select some of them according to a probability scheme and then choose units from the selected clusters. This procedure is called **two-stage sampling**. The probabilities for the selection of clusters may be uniform or proportional to the size of the clusters. **Stratified sampling** is the method of dividing the population into several subpopulations, called **strata**, and selecting the sample units within each stratum. If the size of the i th stratum is N_i , the size of the sample chosen from this stratum is n_i , and the probability is uniform within each stratum, then the most common estimator for the population mean $\bar{\alpha}$ is given by

$$\hat{\alpha} = \sum N_i \bar{X}_i / N,$$

where \bar{X}_i is the mean of the sample values in the i th stratum. The variance of $\hat{\alpha}$ is given by

$$V(\hat{\alpha}) = \left(\frac{1}{N}\right)^2 \sum \frac{N_i^2}{n_i} \left(1 - \frac{n_i}{N_i}\right) \sigma_i^2,$$

where σ_i^2 is the population variance within the i th stratum.

If the cost of drawing one sample unit in the i th stratum is equal to c_i , then for fixed cost, the variance of the estimator is minimized when

$$n_i/N_i \propto \sigma_i / \sqrt{c_i},$$

which is called the condition of **optimum allocation**.

F. Replicated Sampling Plan

W. E. Deming proposed an effective method in practical sample surveys, called a replicated sampling plan, following J. W. Tukey's hint. It enables us to easily evaluate variances of esti-

mates for any estimator and any sampling procedure. Let the sample be composed of k subordinate samples which are selected by the same random sampling procedure from the same population, and let $\hat{\theta}_i(\mathbf{J}_i, X_i)$ be the estimate from the i th subordinate sample by the same estimator and $\hat{\theta}$ be the estimate from the whole sample by the same estimator. Then, provided $\hat{\theta} = \sum \hat{\theta}_i/k$ approximately, the variance of $\hat{\theta}$ can be estimated by $v(\hat{\theta}) = \sum (\hat{\theta}_i - \hat{\theta})^2/k(k-1)$. If the sample is selected by the simple random sampling procedure and is of large scale, $\hat{\theta}_i$ and $\hat{\theta}$ are approximately normal variates, and $v(\hat{\theta})$ is evaluated by using the sample range of the $\hat{\theta}_i$. In large-scale sample surveys, even when the random sampling procedure is not simple, the theory related to the normal distribution can be applied to the $\hat{\theta}_i$ and $\hat{\theta}$. It has been shown that $v(\hat{\theta})$ evaluated by the above method includes not only the sampling error but also the random part of the nonsampling errors.

G. Conceptual Problems

Although it has been established that the sample survey method is useful in large-scale social or economic surveys, there are difficult conceptual problems about the foundations of the method (especially when auxiliary information exists) that are still far from being settled.

**374 (XVIII.4)
Sampling Distributions**

A. General Remarks

To perform statistical inference, it is necessary to find the †probability distribution of a †sta-

tistic involved in the situation (→ 396 Statistic, 401 Statistical Inference). In general, the probability distribution of a statistic is called the **sampling distribution**. A set $\{X_1, X_2, \dots, X_n\}$ of †random variables that are independently and identically distributed according to a distribution F is called a **random sample** from F . A common sampling distribution described in this article is that of the statistic $Y = f(X_1, \dots, X_n)$, where the set $\{X_1, \dots, X_n\}$ is a random sample from a †normal distribution. Examples of such a statistic Y of dimension 1 are the †sample mean, †sample variance, linear or quadratic forms of $\{X_1, \dots, X_n\}$, their ratios, and †order statistic, while examples of Y of higher dimensions are the sample mean vector and the sample covariance matrix and its eigenvalues. The †normal distribution with †mean μ and †variance σ^2 is denoted by $N(\mu, \sigma^2)$, while the † p -dimensional (p -variate) normal distribution with mean vector μ and covariance matrix Σ is denoted by $N(\mu, \Sigma)$ (→ Appendix A, Table 22).

B. Samples from Univariate Normal Distributions

If random variables X_1, \dots, X_n are distributed independently according to $N(\mu_1, \sigma_1^2), \dots, N(\mu_n, \sigma_n^2)$, then a linear form $\sum_i a_i X_i$ has the distribution $N(\sum_i a_i \mu_i, \sum_i a_i^2 \sigma_i^2)$. In particular, if $\{X_1, \dots, X_n\}$ is a random sample from $N(\mu, \sigma^2)$, then the sample mean $\bar{X} = \sum_i X_i/n$ has the distribution $N(\mu, \sigma^2/n)$.

Let $\{X_1, \dots, X_n\}$ be a random sample from the distribution $N(0, 1)$. The sampling distribution of the statistic $Y = \sum_i X_i^2$ is called the **chi-square distribution** with n **degrees of freedom** and is denoted by $\chi^2(n)$. It has the †probability density

$$f_n(y) = 2^{-n/2} \left(\Gamma\left(\frac{n}{2}\right) \right)^{-1} y^{-1+n/2} e^{-y/2}$$

for $0 < y < \infty$, $f_n(y) = 0$ elsewhere, where Γ is the †gamma function. The distribution of $Y = \sum_{i=1}^n (X_i + \mu_i)^2$ depends only on n and $\lambda = \sum_i \mu_i^2$, and is called the **noncentral chi-square distribution** with n **degrees of freedom** and **noncentrality** λ and denoted by $\chi^2(n, \lambda)$. It has the probability density

$$f_{n,\lambda}(y) = \sum_{k=0}^{\infty} e^{-\lambda/2} \left(\frac{\lambda}{2}\right)^k \frac{1}{k!} f_{n+2k}(y) \\ = e^{-\lambda/2} {}_0F_1\left(\frac{n}{2}; \frac{\lambda y}{4}\right) f_n(y)$$

for $0 < y < \infty$, where f_{n+2k} and f_n are the probability densities of chi-square distributions and ${}_0F_1$ is an extended hypergeometric func-

tion. Noncentral chi-square distributions have the following †reproducing property: If Y_1, \dots, Y_k are distributed independently according to $\chi^2(n_1, \lambda_1), \dots, \chi^2(n_k, \lambda_k)$, then $\sum_i Y_i$ has the distribution $\chi^2(\sum_i n_i, \sum_i \lambda_i)$. Also, we have **Cochran's theorem** (*Proc. Cambridge Philos. Soc.*, 30 (1934)): If X_1, \dots, X_n are distributed independently according to $N(\mu_1, 1), \dots, N(\mu_n, 1)$ and if for quadratic forms $Q_m = \sum_i \sum_j a_{ij}^{(m)} X_i X_j$ for $m = 1, \dots, k$ the matrices $A_m = (a_{ij}^{(m)})$ with †rank r_m satisfy the condition $A_1 + \dots + A_k = I$ (unit matrix), then a necessary and sufficient condition for Q_1, \dots, Q_k to have independent noncentral chi-square distributions with r_1, \dots, r_k degrees of freedom, respectively, is that $r_1 + \dots + r_k = n$. In particular, when $\mu_i = 0$ for all i , they have (central) chi-square distributions, and the theorem implies their reproducing property.

Let X and Y be independent random variables having distributions $N(\delta, 1)$ and $\chi^2(n)$, respectively. Then the sampling distribution of $T = X/\sqrt{Y/n}$ is called the **noncentral t -distribution** with n degrees of freedom and noncentrality δ and is denoted by $t(n, \delta)$. Its probability density is given by

$$f_{n,\delta}(t) = \sum_{k=0}^{\infty} e^{-\delta^2/2} \delta^k \frac{2^{k/2} \Gamma((n+k+1)/2)}{k! \sqrt{\pi n} \Gamma(n/2)} \times \frac{(t/\sqrt{n})^k}{(1+t^2/n)^{(n+k+1)/2}}$$

for $-\infty < t < \infty$. In particular, when $\delta = 0$, the distribution is called the **t -distribution** with n degrees of freedom and is denoted by $t(n)$. Its probability density is simplified to

$$f_n(t) = \frac{\Gamma((n+1)/2)}{\sqrt{\pi n} \Gamma(n/2)} \left(1 + \frac{t^2}{n}\right)^{-(n+1)/2}$$

for $-\infty < t < \infty$.

Let $\{X_1, \dots, X_n\}$ be a random sample from $N(\mu, \sigma^2)$. Exact sampling distributions of the †sample variance $S^2 = \sum(X_i - \bar{X})^2/(n-1)$ and of the **t -statistic** $T = \sqrt{n}(\bar{X} - \mu_0)/\sqrt{S^2}$, where $\mu = \mu_0$ is a given number, were essentially obtained by Student [5]: $(n-1)S^2/\sigma^2$ and T are distributed according to $\chi^2(n-1)$ and $t(n-1)$, respectively. His proof was made rigorous by R. A. Fisher (*Metron*, 5 (1925)), who proved in particular that \bar{X} and S^2 are independent. If $\mu \neq \mu_0$, then T follows the distribution $t(n-1, \sqrt{n}(\mu - \mu_0)/\sigma)$.

Let X and Y be distributed independently according to $\chi^2(m, \lambda)$ and $\chi^2(n)$, respectively. The distribution of $Z = (X/m)/(Y/n)$ is called the **noncentral F -distribution** with m and n degrees of freedom and noncentrality λ . In the special case when $\lambda = 0$ it is called the **F -distribution** with m and n degrees of freedom and is denoted by $F(m, n)$. The probability

densities $f_{m,n,\lambda}$ and $f_{m,n}$ of these distributions are given by

$$f_{m,n}(z) = \frac{(m/n)^{m/2} z^{(m/2)-1}}{B(m/2, n/2) (1+mz/n)^{(m+n)/2}}$$

$$f_{m,n,\lambda}(z) = \sum_{k=0}^{\infty} e^{-\lambda/2} \left(\frac{\lambda}{2}\right)^k \frac{1}{k!} \frac{(m/n)^{(m/2)+k}}{B((m/2)+k, n/2)} \times \frac{z^{(m/2)+k-1}}{(1+mz/n)^{(m+n)/2+k}}$$

$$= e^{-\lambda/2} {}_1F_1\left(\frac{m+n}{2}; \frac{m}{2}; \frac{\lambda}{2} \frac{mz/n}{1+mz/n}\right) f_{m,n}(z)$$

for $0 < z < \infty$, where B and ${}_1F_1$ are the †beta function and the confluent hypergeometric function (\rightarrow 167 Functions of Confluent Type), respectively.

Let X be a random variable having the distribution $F(m, n)$. The distribution of $Z = \frac{1}{2} \log X$ is called the **z -distribution** with m and n degrees of freedom and is denoted by $z(m, n)$. Its probability density is given by

$$\frac{2(m/n)^{m/2} e^{mz}}{B(m/2, n/2) (1+me^{2z}/n)^{(m+n)/2}}$$

for $-\infty < z < \infty$. If $S_1^2 = \sum_{i=1}^m (X_i - \bar{X})^2/(m-1)$ and $S_2^2 = \sum_{i=1}^n (Y_i - \bar{Y})^2/(n-1)$ are sample variances based on independent samples of sizes m and n taken from $N(\mu, \sigma^2)$ and $N(v, \tau^2)$, respectively, then the statistic $z = \frac{1}{2} \log(S_1^2/S_2^2)$, which was introduced by Fisher (*Proc. Int. Math. Congress*, 1924), is distributed according to $z(m-1, n-1)$ under the hypothesis $\sigma^2 = \tau^2$. Fisher [6] tabulated percent points of $z(m, n)$.

C. Samples from Multivariate Normal Distributions

Let \mathbf{X} be a p -dimensional random vector, namely, a vector having real random variables as its components. \mathbf{X} has the p -variate normal distribution $N(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ if and only if for any real vector $\mathbf{a} = (a_1, \dots, a_p)'$, the random variable $\mathbf{a}'\mathbf{X}$ has the normal distribution $N(\mathbf{a}'\boldsymbol{\mu}, \mathbf{a}'\boldsymbol{\Sigma}\mathbf{a})$. If $\mathbf{X}_1, \dots, \mathbf{X}_n$ are independent and have p -variate normal distributions $N(\boldsymbol{\mu}_1, \boldsymbol{\Sigma}_1), \dots, N(\boldsymbol{\mu}_n, \boldsymbol{\Sigma}_n)$, respectively, and if A_1, \dots, A_n are $m \times p$ real matrices, then the random vector $A_1\mathbf{X}_1 + \dots + A_n\mathbf{X}_n$ has the m -variate normal distribution $N(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, where $\boldsymbol{\mu} = \sum_{j=1}^n A_j\boldsymbol{\mu}_j$ and $\boldsymbol{\Sigma} = \sum_{j=1}^n A_j\boldsymbol{\Sigma}_jA_j'$.

Suppose that $\{\mathbf{X}_1, \dots, \mathbf{X}_n\}$ is a random sample from the p -variate normal distribution $N(\mathbf{0}, \boldsymbol{\Sigma})$, and let $\mathbf{X} = (\mathbf{X}_1, \dots, \mathbf{X}_n)$ be a $p \times n$ matrix. Then the probability distribution of $\mathbf{W} = \mathbf{X}\mathbf{X}'$ is called the **Wishart distribution** with **scale matrix** $\boldsymbol{\Sigma}$ and **n degrees of freedom** and is denoted by $W_p(\boldsymbol{\Sigma}, n)$ or simply $W(\boldsymbol{\Sigma}, n)$. If $n > p-1$, the joint probability density function

of $p(p+1)/2$ arguments of $W=(W_{ij})$ is

$$f_{\Sigma,n}(W) = (\Gamma_p(n/2) |2\Sigma|^{n/2})^{-1} \times \text{etr}(-\Sigma^{-1}W/2) |W|^{(n-p-1)/2}$$

for $W > 0$, where $W > 0$ means that W is positive definite, $\text{etr}(A) = \exp(\text{tr } A)$, and Γ_p , a **multi-dimensional gamma function**, is defined as

$$\Gamma_p(a) = \pi^{p(p-1)/4} \prod_{i=1}^p \Gamma\left(a - \frac{1}{2}(i-1)\right)$$

for $a > (p-1)/2$. When $n \leq p-1$ the distribution is **singular** and has no probability density.

Suppose that $\mathbf{X}_1, \dots, \mathbf{X}_n$ are independent and obey normal distributions $N(\boldsymbol{\mu}_1, \Sigma), \dots, N(\boldsymbol{\mu}_n, \Sigma)$, and let $\mathbf{X} = (\mathbf{X}_1, \dots, \mathbf{X}_n)$, $\mathbf{M} = (\boldsymbol{\mu}_1, \dots, \boldsymbol{\mu}_n)$. Then the distribution of $W = \mathbf{X}\mathbf{X}'$ is called the **p -dimensional noncentral Wishart distribution with scale matrix Σ , n degrees of freedom, and noncentrality matrix $\Omega = \Sigma^{-1}\mathbf{M}\mathbf{M}'$** and is denoted by $W(\Sigma, n, \Omega)$. If $n > p-1$, the probability density function is

$$\text{etr}(-\Omega/2) {}_0F_1(n/2; \Omega \Sigma^{-1}W/4) f_{\Sigma,n}(W)$$

for $W > 0$. ${}_aF_b$ is a hypergeometric function with matrix argument, which is defined by ${}_aF_b(a_1, \dots, a_x; b_1, \dots, b_\beta; S) = {}_aF_b^{(p)}(a_1, \dots, a_x; b_1, \dots, b_\beta; S, I)$, where

$${}_aF_b^{(p)}(a_1, \dots, a_x; b_1, \dots, b_\beta; S, T)$$

$$= \sum_{k=0}^{\infty} \sum_{\kappa} \left(\frac{\prod_{i=1}^x (a_i)_{\kappa_i}}{\prod_{j=1}^{\beta} (b_j)_{\kappa_j}} \right) \frac{C_{\kappa}(S) C_{\kappa}(T)}{k! C_{\kappa}(I_p)}$$

$\kappa = (k_1, \dots, k_p)$ is an ordered set of integers such that $k_1 + \dots + k_p = k$ and $k_1 \geq \dots \geq k_p \geq 0$, and where $C_{\kappa}(S)$ is a **zonal polynomial** (\rightarrow [8]) of a symmetric matrix S . The multivariate hypergeometric coefficient $(a)_{\kappa}$ is given by

$$(a)_{\kappa} = \prod_{i=1}^p \left(a - \frac{1}{2}(i-1) \right)_{k_i}$$

$$(a)_k = a(a+1) \dots (a+k-1).$$

The noncentral Wishart distribution is singular when $n \leq p-1$. Similarly to the noncentral chi-square distribution, the noncentral Wishart distribution has the reproducing property with respect to both the number of degrees of freedom and the noncentrality matrix. Also, Cochran's theorem can be extended to the multivariate case: Let $\mathbf{X}_1, \dots, \mathbf{X}_n$ be p -variate random vectors independently distributed according to $N(\boldsymbol{\mu}_1, \Sigma), \dots, N(\boldsymbol{\mu}_n, \Sigma)$, respectively, and let $A_m = (a_{ij}^{(m)})$, $m = 1, \dots, k$, be $p \times p$ real matrices of rank r_m and such that $A_1 + A_2 + \dots + A_k = I$ (unit matrix). A necessary and sufficient condition for random matrices $\mathbf{Q}_m = \sum_{i,j} a_{ij}^{(m)} \mathbf{X}_i \mathbf{X}_j'$, $m = 1, \dots, k$, to be independently distributed according to noncentral

Wishart distributions with r_1, \dots, r_k degrees of freedom, respectively, is that $r_1 + \dots + r_k = n$. If, in particular, $\boldsymbol{\mu}_1 = \dots = \boldsymbol{\mu}_n = 0$ and if $r_m \geq p$, then \mathbf{Q}_m is distributed according to $W(\Sigma, r_m)$.

If \mathbf{W} has the distribution $W(\Sigma, n)$ with $n > p-1$, then the eigenvalues $\lambda_1, \dots, \lambda_p$ ($\lambda_1 \geq \dots \geq \lambda_p > 0$) of W have the joint probability density function $C_{p,n} |\Sigma|^{-n/2} {}_0F_0^{(p)}(-\Sigma^{-1}/2, \Lambda) |\Lambda|^{(n-p-1)/2} \prod_{i < j} (\lambda_i - \lambda_j)$, where Λ is a diagonal matrix with diagonal elements $\lambda_1, \dots, \lambda_p$ and $C_{p,n} = \pi^{p^2/2} (2^{pn/2} \Gamma_p(p/2) \Gamma_p(n/2))^{-1}$. If $\Sigma = I$, then the joint probability density function becomes

$$C_{p,n} \text{etr}(-\Lambda/2) |\Lambda|^{(n-p-1)/2} \prod_{i < j} (\lambda_i - \lambda_j).$$

Suppose that \mathbf{S}_1 and \mathbf{S}_2 have independent Wishart distributions $W(\Sigma, n_1)$ and $W(\Sigma, n_2)$, respectively. The random matrix $\mathbf{B} = (\mathbf{S}_1 + \mathbf{S}_2)^{-1/2} \mathbf{S}_1 (\mathbf{S}_1 + \mathbf{S}_2)^{-1/2}$ is called the **beta matrix**, and its distribution is denoted by $B(n_1/2, n_2/2)$. Its probability density function is

$$\left(\Gamma_p\left(\frac{n_1+n_2}{2}\right) / \Gamma_p\left(\frac{n_1}{2}\right) \Gamma_p\left(\frac{n_2}{2}\right) \right) |\mathbf{B}|^{(n_1-p-1)/2} \times |\mathbf{I} - \mathbf{B}|^{(n_2-p-1)/2}$$

for $0 < \mathbf{B} < \mathbf{I}$.

Suppose that \mathbf{S} has the distribution $W(\Sigma, n)$ and \mathbf{B} has $B(n_1/2, n_2/2)$; then, for any nonsingular symmetric matrix Ω ,

$$P\{\mathbf{S} < \Omega\} = \left\{ |2\Sigma\Omega^{-1}|^{-n/2} \Gamma_p\left(\frac{p+1}{2}\right) / \Gamma_p\left(\frac{n+p+1}{2}\right) \right\} {}_1F_1\left(\frac{n}{2}; \frac{n+p+1}{2}; -\frac{1}{2}\Sigma^{-1}\Omega\right)$$

and

$$P\{\mathbf{B} < \Omega\} = \left\{ \Gamma_p\left(\frac{n_1+n_2}{2}\right) \Gamma_p\left(\frac{p+1}{2}\right) / \Gamma_p\left(\frac{n_1+p+1}{2}\right) \Gamma_p\left(\frac{n_2}{2}\right) \right\} |\Omega|^{n_1/2} \times {}_2F_1\left(\frac{n_1}{2}, -\frac{n_2}{2} + \frac{p+1}{2}; \frac{n_1+p+1}{2}; \Omega\right).$$

If $\{\mathbf{X}_1, \dots, \mathbf{X}_n\}$ is a random sample from $N(\boldsymbol{\mu}, \Sigma)$, then the sample mean $\bar{\mathbf{X}} = \sum_{\alpha=1}^n \mathbf{X}_{\alpha}/n$ and the sample covariance matrix $\mathbf{S} = \sum_{\alpha=1}^n (\mathbf{X}_{\alpha} - \bar{\mathbf{X}})(\mathbf{X}_{\alpha} - \bar{\mathbf{X}})'/(n-1)$ are distributed independently according to the respective distributions $N(\boldsymbol{\mu}, \Sigma/n)$ and $W(\Sigma, n-1)$. If $n > p-1$, $T^2 = n(\bar{\mathbf{X}} - \boldsymbol{\mu}_0)' \mathbf{S}^{-1} (\bar{\mathbf{X}} - \boldsymbol{\mu}_0)$ is called the **noncentral Hotelling T^2 statistic with $n-1$ degrees of freedom and noncentrality $\lambda = n(\boldsymbol{\mu} - \boldsymbol{\mu}_0)' \Sigma^{-1} (\boldsymbol{\mu} - \boldsymbol{\mu}_0)$** . $(n-p)T^2/p(n-1)$ has a noncentral F -distribution with p and $n-p$ degrees of freedom and noncentrality λ .

Let $\mathbf{X} = (X_1, \dots, X_p)'$ and $\mathbf{Y} = (Y_1, \dots, Y_q)'$, $p \leq q$ denote two random vectors, Σ_{11} and Σ_{22} their respective covariance matrices, and Σ_{12} the $p \times q$ matrix of covariances between

the components of \mathbf{X} and \mathbf{Y} . Each of the nonnegative roots ρ_1, \dots, ρ_p of the equation $|\Sigma_{12}\Sigma_{22}^{-1}\Sigma_{21} - \rho^2\Sigma_{11}| = 0$ is called the **canonical correlation coefficient**. Let $(X_1, Y_1), \dots, (X_n, Y_n)$ be a random sample from the $(p+q)$ -variate normal distribution $N(\mathbf{0}, \Sigma)$, and let $S_{11} = \sum_{\alpha=1}^n X_\alpha X_\alpha/n, S_{12} = S'_{21} = \sum_{\alpha=1}^n X_\alpha Y'_\alpha/n, S_{22} = \sum_{\alpha=1}^n Y_\alpha Y'_\alpha/n$, and $\mathbf{S} = (S_{ij}), j=1, 2$. The sample canonical correlation coefficients are the nonnegative roots r_1, \dots, r_p of $|S_{12}S_{22}^{-1}S_{21} - r^2S_{11}| = 0$ and for $n \geq p+q$ the probability density function of r_1^2, \dots, r_p^2 is

$$C_{p,q,n} |I - P^2|^{n/2} |R^2|^{(q-p-1)/2} |I - R^2|^{(n-q-p-1)/2} \times \prod_{i < j} (r_i^2 - r_j^2) {}_2F_1^{(p)} \left(\begin{matrix} n & n & q \\ 2 & 2 & 2 \end{matrix}; R^2, P^2 \right),$$

where

$$C_{p,q,n} = \pi^{p^2/2} \Gamma_p \left(\frac{n}{2} \right) / \left\{ \Gamma_p \left(\frac{n-q}{2} \right) \Gamma_p \left(\frac{p}{2} \right) \Gamma_p \left(\frac{q}{2} \right) \right\},$$

and R^2 and P^2 are diagonal matrices with elements r_i^2 and ρ_j^2 , respectively. If, in particular, $p=1$, then ρ_1 and r_1 are, respectively, the population and the sample multiple correlation coefficients, and $(n-q)r_1^2/q(1-r_1^2)$ follows the distribution $F(q, n-q)$ whenever $\rho_1 = 0$.

Let $\{(X_1, Y_1), \dots, (X_n, Y_n)\}$ be a random sample from the 2-dimensional normal distribution with correlation coefficient ρ . Then the sample correlation coefficient

$$R = \frac{\sum_i (X_i - \bar{X})(Y_i - \bar{Y})}{(\sum_i (X_i - \bar{X})^2 \sum_i (Y_i - \bar{Y})^2)^{1/2}}$$

has probability density

$$f_n(r; \rho) = (2^{n-3}/\pi(n-3)!) (1 - \rho^2)^{(n-1)/2} (1 - r^2)^{(n-4)/2} \times \sum_{k=0}^{\infty} \Gamma^2 \left(\frac{1}{2}(n+k-1) \right) \frac{(2\rho r)^k}{k!}$$

for $-1 < r < 1$. For the special case $\rho=0$, the probability density becomes

$$f_n(r) = \frac{1}{\sqrt{\pi}} \frac{\Gamma \left(\frac{1}{2}(n-1) \right)}{\Gamma \left(\frac{1}{2}(n-2) \right)} (1 - r^2)^{(n-4)/2},$$

which implies that $T = \sqrt{n-2}R/\sqrt{1-R^2}$ has the t -distribution with $n-2$ degrees of freedom.

Given a random sample from a p -variate normal distribution, the probability density of the sample partial correlation coefficient $R_{12 \cdot 3 \dots p}$ between the first and the second components with the remaining components fixed is given by $f_{n-p+2}(r; \rho_{12 \cdot 3 \dots p})$, where f is

the density of R mentioned in the previous paragraph and $\rho_{12 \cdot 3 \dots p}$ is the population partial correlation.

D. Large-Sample Theory

So far we have dealt with random samples $\{X_1, \dots, X_n\}$ composed of finitely many random variables (or vectors). The theory dealing with such finite cases is called small-sample theory, which is not always suitable for numerical applications. In comparison with this, in large-sample theory, where the sample size is assumed to be sufficiently large, an approximation of the sampling distribution can often be obtained easily by means of the central limit theorem.

If for three sequences X_n, μ_n , and $\sigma_n, n=1, 2, \dots$, of random variables, real numbers, and positive numbers, respectively, the sequence $(X_n - \mu_n)/\sigma_n$ converges in distribution to $N(0, 1)$ as $n \rightarrow \infty$, then the sequence X_n is said to be **asymptotically distributed** according to $N(\mu_n, \sigma_n^2)$. The definition can be extended to higher dimensions. We write $X_n = o_p(r_n)$ for a sequence r_n of positive numbers if and only if X_n/r_n converges in probability to zero as $n \rightarrow \infty$. The following theorem is useful: If $X_n = a + o_p(r_n)$, where a is a constant and $r_n = o(1)$, and if a real-valued function $f(x)$ is of class C^s in a neighborhood of $x=a$, then

$$f(X_n) = \sum_{k=0}^s \frac{1}{k!} f^{(k)}(a)(X_n - a)^k + o_p(r_n^s).$$

If X_n is asymptotically distributed according to $N(\mu, \sigma^2/n)$ and $f(x)$ is differentiable at $x = \mu$ with the derivative $f'(\mu) \neq 0$, then $f(X_n)$ is asymptotically distributed according to $N(f(\mu), (f'(\mu))^2 \sigma^2/n)$. In higher-dimensional cases, if \mathbf{X}_n is asymptotically distributed according to $N(\mu, \Sigma/n)$ and $f(\mathbf{x})$ is continuously differentiable in a neighborhood of $\mathbf{x} = \mu$ with nonzero vector $\mathbf{c} = (\partial f/\partial x_1, \dots, \partial f/\partial x_p)_{\mathbf{x}=\mu}$, then $f(\mathbf{X}_n)$ is asymptotically distributed according to $N(f(\mu), \mathbf{c}\Sigma\mathbf{c}'/n)$.

Let $\{X_1, \dots, X_n\}$ be a random sample from a univariate distribution with finite moments $v_i = E(X^i)$ for $i=1, \dots, k$, and let $a_i = \sum_{\alpha} X_\alpha^i/n$ be its i th sample moment. Then the random vector (a_1, \dots, a_k) asymptotically follows the k -variate normal distribution as $n \rightarrow \infty$ with mean vector (v_1, \dots, v_k) and covariance matrix $n^{-1}(\sigma_{ij})$, where $\sigma_{ij} = v_{i+j} - v_i v_j$. Let $M_i = \sum_{\alpha} (X_\alpha - \bar{X})^i/n$ and $\mu_i = E(X - v_1)^i$ for $i=2, \dots, k$ be the sample central moment of order i and population central moment of order i , respectively. Then the random vector $(\bar{X}, M_2, \dots, M_k)$ obeys the k -variate normal distribution asymptotically as $n \rightarrow \infty$ with mean vector $(v_1, \mu_2, \dots, \mu_k)$

and covariance matrix $n^{-1}(\sigma_{ij})$, where $\sigma_{11} = \mu_2$, $\sigma_{ii} = \mu_{i+1} - i\mu_2\mu_{i-1}$, $\sigma_{ij} = \mu_{i+j} - i\mu_{i-1}\mu_{j+1} - j\mu_{i+1}\mu_{j-1} - \mu_i\mu_j + ij\mu_2\mu_{i-1}\mu_{j-1}$ for $i, j \geq 2$.

A random variable χ_n^2 that has a \dagger chi-square distribution with n degrees of freedom obeys the distribution $N(n, 2n)$ asymptotically as $n \rightarrow \infty$. Also, $\sqrt{2\chi_n^2} - \sqrt{2n-1}$ obeys $N(0, 1)$ asymptotically. The latter distribution approximates χ_n^2 indirectly better than $N(n, 2n)$ approximates χ_n^2 directly. The t -distribution with n degrees of freedom obeys $N(0, 1)$ asymptotically as $n \rightarrow \infty$. If X_n obeys an F -distribution with m and n degrees of freedom, then mX_n obeys asymptotically the distribution $\chi^2(m)$ as $n \rightarrow \infty$. If X_n obeys a \dagger binomial distribution $Bin(n, p)$, then X_n obeys asymptotically the distribution $N(np, np(1-p))$, and $\text{Arcsin} \sqrt{X_n/n}$ obeys asymptotically $N(\text{Arcsin} \sqrt{p}, 1/4n)$ as $n \rightarrow \infty$. This transformation is called the **arcsin** (or **angular**) **transformation**. If (X_1, X_2, \dots, X_k) obeys the multinomial distribution $Mu(n; p_1, p_2, \dots, p_k)$, then it is asymptotically distributed according to the normal distribution $N(\mu_n, \Sigma_n)$, where $\mu_n = (np_1, \dots, np_k)$, $\Sigma_n = (\sigma_{ij}^{(n)})$, $\sigma_{ii}^{(n)} = np_i(1-p_i)$, and $\sigma_{ij}^{(n)} = -np_ip_j$, ($i \neq j$), and the random variable $\sum_{j=1}^{k+1} (X_j - np_j)^2 / np_j$, where $X_{k+1} = n - (X_1 + \dots + X_k)$ and $p_{k+1} = 1 - (p_1 + \dots + p_k)$, obeys asymptotically the distribution $\chi^2(k)$ [11].

If X_n has the \dagger Poisson distribution with mean λ_n , where $\lambda_n \rightarrow \infty$ as $n \rightarrow \infty$, then X_n and $\sqrt{X_n}$ obey the respective distributions $N(\lambda_n, \lambda_n)$ and $N(\sqrt{\lambda_n}, 1/4)$ asymptotically. If R is the sample correlation coefficient based on a random sample of size n from a 2-dimensional (bivariate) normal distribution with population correlation coefficient ρ , then R is asymptotically distributed according to $N(\rho, (1-\rho^2)^2/n)$ as $n \rightarrow \infty$, and therefore $z = \frac{1}{2} \log((1+R)/(1-R))$ obeys asymptotically the distribution $N(\frac{1}{2} \log((1+\rho)/(1-\rho)), 1/n)$ asymptotically. This transformation is called **Fisher's z-transformation**. The distribution

$$N\left(\frac{1}{2} \log \frac{1+\rho}{1-\rho} + \frac{\rho}{2(n-1)}, \frac{1}{n-3}\right)$$

gives a better approximation.

E. Empirical Distribution Function

Let $\{X_1, \dots, X_n\}$ be a random sample from a distribution F . The random function

$$F_n(x) = \frac{1}{n} \{\text{number of } X\text{'s that are } \leq x\}$$

is called the **empirical distribution function**. For any collection of fixed x 's ($-\infty = x_0 < x_1 < \dots < x_k < \infty$), the random vector $(nF_n(x_1), n(F_n(x_2) - F_n(x_1)), \dots, n(F_n(x_k) - F_n(x_{k-1})))$ obeys the \dagger multinomial distribution $Mu(n; p_1, \dots, p_k)$,

where $p_j = F(x_j) - F(x_{j-1})$, $j = 1, \dots, k$, provided that the p 's are positive. In particular, the vector is asymptotically distributed according to the k -variate normal. The result is substantially strengthened as follows: the **Glivenko-Cantelli theorem** states that $\sup_x |F_n(x) - F(x)|$ converges to zero with probability 1 as n tends to infinity. If $F(x)$ is continuous, then the random function $\sqrt{n}(F_n(t) - F(t))$ converges in distribution to a \dagger Gaussian process $X(t)$ such that $E(X(t)) = 0$ and $E(X(s)X(t)) = F(s)(1 - F(t))$ for $s \leq t$. A Gaussian process $X(t)$, $0 \leq t \leq 1$, with this moment condition is called a **Brownian bridge** if $F(t) = t$, for $0 \leq t \leq 1$. If $F(x)$ is continuous, then the distributions of the random variables $C_n = \sqrt{n} \sup_x (F_n(x) - F(x))$ and $D_n = \sqrt{n} \sup_x |F_n(x) - F(x)|$ do not depend on F . Asymptotically, they have identical distributions with $\sup_t B(t)$ and $\sup_t |B(t)|$, respectively, where $B(t)$ is a Brownian bridge. We have

$$P(\sup_t B(t) \leq x) = 1 - e^{-2x^2},$$

$$P(\sup_t |B(t)| \leq x) = 1 + 2 \sum_{k=1}^{\infty} (-1)^k e^{-2k^2 x^2},$$

$x > 0$.

Let $\{X_1, \dots, X_m\}$ and $\{Y_1, \dots, Y_n\}$ be random samples from continuous distributions F and G , respectively, and let $F_m(x)$ and $G_n(x)$ be their empirical distribution functions. Under the hypothesis $H_0: F \equiv G$, the distribution of the **Kolmogorov-Smirnov test statistic**

$$D_{m,n} = \sup_x |F_m(x) - G_n(x)|$$

does not depend on F (or G), and asymptotically, as $m \rightarrow \infty$ and $m/n \rightarrow \lambda \leq 1$, the random function $\sqrt{m}(F_m(t) - G_n(t))$ converges in distribution to a Gaussian process $X(t)$ such that $E(X(t)) = 0$ and $E(X(s)X(t)) = (1 + \lambda)F(s)(1 - F(t))$, $s \leq t$.

F. Edgeworth and Cornish-Fisher Expansions

Let $\{X_1, X_2, \dots, X_n\}$ be a sample from a distribution with mean μ and variance σ^2 . The random variable $(X_1 + X_2 + \dots + X_n - n\mu) / \sqrt{n}\sigma$ is called the normalized sum of the sample. The distribution function $F_n(x)$ of the normalized sum of a sample from an absolutely continuous distribution F with higher-order moments admits the **Edgeworth expansion** [15]:

$$F_n(x) = \Phi(x) + \sum_{k=1}^{v-2} R_k(x) \left(\frac{1}{\sqrt{n}}\right)^k \phi(x) + B\left(\frac{1}{\sqrt{n}}\right)^{v-1},$$

where Φ and ϕ are the \dagger cumulative distribution and the \dagger probability density functions, respec-

tively, of $N(0, 1)$, and B is a quantity bounded by a constant depending on F and v . $R_k(x)$ is the polynomial given by

$$R_k(x) = -\sum H_{k+2l-1}(x) \prod_{j=1}^k \frac{1}{m_j!} \left(\frac{\gamma_{j+2}}{(j+2)!} \right)^{m_j},$$

where $H_k(x)$ is the Hermite polynomial of degree k , γ_k is the cumulant (†semi-invariant) of order k of the distribution of $(X_1 - \mu)/\sigma$, the summation extends over all nonnegative m 's such that $m_1 + 2m_2 + \dots + km_k = k$, and $l = m_1 + m_2 + \dots + m_k$. In particular, we have $R_1(x) = -\gamma_3(x^2 - 1)/6$ and $R_2(x) = -\gamma_4(x^3 - 3x)/24 - \gamma_3^2(x^5 - 10x^3 + 15x)/72$. For a †lattice distribution F concentrated on $0, \pm 1, \pm 2, \dots$ but not on $0, \pm \rho, \pm 2\rho, \dots$ for any $\rho > 1$, the following expansion is valid for $x = 0, \pm 1, \pm 2, \dots$:

$$F_n \left(\frac{x - n\mu}{\sqrt{n}\sigma} \right) = \Phi(z) + \sum_{k=1}^{v-2} Q_k(z) \left(\frac{1}{\sqrt{n}} \right)^k \phi(z) + B \left(\frac{1}{\sqrt{n}} \right)^{v-1},$$

where $z = (x - n\mu + 1/2)/\sqrt{n}\sigma$ and the Q 's are suitable polynomials; $Q_1(z) = R_1(z)$ and $Q_2(z) = R_2(z) + z/24\sigma^2$.

The Edgeworth expansion makes it possible to derive asymptotic formulas for the relation between those u and v such that $F_n(v) = \Phi(u)$. If F is an absolutely continuous distribution with moments of order $v (\geq 3)$, then we have the **Cornish-Fisher expansions** [16]:

$$u = v + \sum_{k=1}^{v-2} A_k(v) \left(\frac{1}{\sqrt{n}} \right)^k + O(n^{-(v-1)/2})$$

and

$$v = u + \sum_{k=1}^{v-2} B_k(u) \left(\frac{1}{\sqrt{n}} \right)^k + O(n^{-(v-1)/2}),$$

where the A 's and B 's are polynomials derived from the R 's of the Edgeworth expansion; $A_1(v) = -\gamma_3(v^2 - 1)/6$, $A_2(v) = -\gamma_4(v^3 - 3v)/24 + \gamma_3^2(4v^3 - 7v)/36$, $B_1(u) = \gamma_3(u^2 - 1)/6$, $B_2(u) = \gamma_4(u^3 - 3u)/24 - \gamma_3^2(2u^3 - 5u)/36$.

The expansions imply, in particular, that the random variable $v + \sum_{k=1}^{v-2} A_k(v) n^{-k/2}$ with $v = (X_1 + X_2 + \dots + X_n - n\mu)/\sqrt{n}\sigma$ is asymptotically distributed according to $N(0, 1)$ and that the $100\alpha\%$ point v_α of F_n is approximated by $u_\alpha + \sum_{k=1}^{v-2} B_k(u_\alpha) n^{-k/2}$, where u_α is the $100\alpha\%$ point of $N(0, 1)$. These approximations can be improved further in some cases by a suitable transformation of the sum $X_1 + X_2 + \dots + X_n$. Thus, for example, if X is distributed according to $\chi^2(n)$, then the Cornish-Fisher expansions with $v = 3$ are

$$u = v - \frac{1}{3\sqrt{n}}(v^2 - 1) + O\left(\frac{1}{n}\right)$$

and

$$v = u + \frac{1}{3\sqrt{n}}(u^2 - 1) + O\left(\frac{1}{n}\right),$$

where $v = (X - n)/\sqrt{2n}$. However, the distribution of the random variable

$$\sqrt{\frac{9n}{2}} \left\{ \left(\frac{X}{n} \right)^{1/3} - 1 + \frac{2}{9n} \right\}$$

is much better approximated by $N(0, 1)$, and

$$n \left(1 - \frac{2}{9n} + \sqrt{\frac{2}{9n}} u_\alpha \right)^3$$

gives a more accurate approximation to the $100\alpha\%$ point of the distribution $\chi^2(n)$. These are called the **Wilson-Hilferty approximations** (*Proc. Nat. Acad. Sci. US*, 17 (1931)).

The Edgeworth expansion was shown to be valid in more general situations by R. N. Bhattacharya and J. K. Ghosh [17]. In particular, they obtained the following: Let $\{X_1, X_2, \dots, X_n\}$ be a random sample from a p -variate distribution with a nonzero †absolutely continuous component w.r.t. †Lebesgue measure on \mathbf{R}^p . Let $f_0 (\equiv 1)$, f_1, \dots, f_k be linearly independent, real-valued, and continuously differentiable functions. For $i = 1, \dots, n$, put $Z_i = (f_1(X_i), f_2(X_i), \dots, f_k(X_i))$, and assume that the distribution of Z_1 has moments up to the order $v (\geq 3)$. Let H be a real-valued function on \mathbf{R}^k such that the v th order derivatives are continuous in a †neighborhood of $\mu \equiv E(Z_1)$. Let $V = (v_{ij})$, $i, j = 1, \dots, k$, be the covariance matrix of the random vector Z_1 , and put $\sigma^2 = \sum v_{ij} l_i l_j$, where $l_i = \partial H(z)/\partial z_i|_{z=\mu}$, and $z = (z_1, \dots, z_k)$. Then

$$\sup_B \left| \Pr \{ \sqrt{n}(H(\bar{Z}) - H(\mu)) \in B \} - \int_B \psi_{v,n}(x) dx \right| = O(n^{-(v-2)/2}),$$

where $\bar{Z} = \sum_{i=1}^n Z_i/n$, the supremum is taken over all Borel measurable sets B ,

$$\psi_{v,n}(x) = \left(1 + \sum_{k=1}^{v-2} \left(\frac{1}{\sqrt{n}} \right)^k P_k \left(-\frac{d}{dx} \right) \right) \phi_\sigma(x),$$

$\phi_\sigma(x)$ is the probability density function of the normal distribution $N(0, \sigma^2)$, and the P 's are polynomials whose coefficients are independent of n .

G. Order Statistics

Let $\{X_1, \dots, X_n\}$ be a random sample from a univariate distribution with continuous probability density $f(x)$ and distribution function $F(x)$, and let $X_{(1)} \leq \dots \leq X_{(n)}$ be †order statistics. The joint probability density of $Y_1 = X_{(\alpha)}$, $Y_2 =$

$X_{(p)}, \dots, Y_{p-1} = X_{(e)}$, and $Y_p = X_{(n)}$ is given by

$$\frac{n!}{(\alpha-1)(\beta-\alpha-1)! \dots (\eta-\varepsilon-1)(n-\eta)!} \times (F(y_1))^{\alpha-1} (F(y_2) - F(y_1))^{\beta-\alpha-1} \dots \times (F(y_p) - F(y_{p-1}))^{\eta-\varepsilon-1} (1 - F(y_p))^{\eta-\eta} \dots \times f(y_1)f(y_2) \dots f(y_p)$$

for $-\infty < y_1 < \dots < y_p < \infty$, where $\alpha < \beta < \dots < \varepsilon < \eta$. If for given constants $0 < \lambda_1 < \dots < \lambda_p < 1$, each of the subscripts α, \dots, η tends to infinity as $n \rightarrow \infty$ under the conditions $r_i = n\lambda_i + o(\sqrt{n})$, where $\alpha = r_1, \dots, \eta = r_p$, then the random vector (Y_1, \dots, Y_p) asymptotically obeys the p -dimensional normal distribution with mean vector (ξ_1, \dots, ξ_p) and covariance matrix $n^{-1}(\sigma_{ij})$, where $\sigma_{ij} = \sigma_{ji} = \lambda_i(1 - \lambda_j)/f(\xi_i)f(\xi_j)$ for $i \leq j$ and ξ_i is the λ_i -quantile of the population, defined by $\lambda_i = F(\xi_i)$.

Suppose that there exist two sequences a_n and b_n of real and positive numbers, respectively, such that as $n \rightarrow \infty$ the sequence $(X_{(n)} - a_n)/b_n$ converges in distribution to a nondegenerate distribution G . The underlying distribution F is said to belong to the **domain of attraction** of the limiting distribution G (DA(G), for short). Except for the change of location and scale, only the following three distributions have nonempty domains of attraction:

$$G_1(x) = \begin{cases} 0 & x < 0 \\ e^{-x^{-\gamma}} & x \geq 0 \end{cases}$$

$$G_2 = \begin{cases} e^{-(-x)^\gamma} & x < 0 \\ 1, & x \geq 0 \end{cases}$$

$$G_3(x) = e^{-e^{-x}}$$

Writing $\bar{F}(x) = 1 - F(x)$, $\alpha(F) = \inf\{x | F(x) > 0\}$ and $\omega(F) = \sup\{x | F(x) < 1\}$, we have the following theorem (B. V. Gnedenko, *Ann. Math.*, 44 (1943)):

$F \in \text{DA}(G_1)$ iff $\omega(F) = \infty$ and there exists an a such that

$$\lim_{u \rightarrow \infty} \bar{F}(a + ux)/\bar{F}(a + u) = x^{-\gamma} \quad \text{for all } x;$$

$F \in \text{DA}(G_2)$ iff $a \equiv \omega(F) < \infty$ and

$$\lim_{u \rightarrow 0} \bar{F}(a - ux)/\bar{F}(a - u) = x^\gamma \quad \text{for all } x > 0;$$

$F \in \text{DA}(G_3)$ iff there exists a positive function $R(t)$ such that

$$\lim_{t \rightarrow \omega(F)} \bar{F}(t + xR(t))/\bar{F}(t) = e^{-x} \quad \text{for all } x.$$

If $F(x)$ is twice differentiable, $f(x) = F'(x)$ is positive for sufficiently large x , and $\lim_{x \rightarrow \omega(F)} d\{(1 - F(x))/f(x)\}/dx = 0$, then $F \in \text{DA}(G_3)$. Noticing the relation $X_{(1)} = -\max\{-X_1, -X_2, \dots, -X_n\}$, we can also derive the possible limiting distributions for

the sequence $(X_{(1)} - a_n)/b_n$ and their domains of attraction. The statistics $R_n = X_{(n)} - X_{(1)}$ and $M_n = (X_{(1)} + X_{(n)})/2$ are called the range and the **midrange** of the sample, respectively. If, for some a_n, a'_n , and b_n , both sequences $(X_{(n)} - a_n)/b_n$ and $(X_{(1)} - a'_n)/b_n$ converge to nondegenerate distributions G and H , respectively, then they are asymptotically independent, and we have

$$\begin{aligned} \lim \Pr\{(R_n - a_n + a'_n)/b_n \leq x\} &= \int_{-\infty}^{\infty} (1 - H(y - x)) dG(y), \\ \lim \Pr\{(2M_n - a_n - a'_n)/b_n \leq x\} &= \int_{-\infty}^{\infty} H(x - y) dG(y). \end{aligned}$$

H. Characterization of the Distribution by means of a Property of the Sampling Distribution

A distribution or a family of distributions can be characterized by a property of the sampling distribution of a suitable statistic. Let $\{X_1, X_2, \dots, X_n\}$ be a random sample from a nondegenerate distribution F , and let $X_{(1)} \leq \dots \leq X_{(n)}$ be the \dagger order statistics. The \dagger sample mean \bar{X} is independent of the \dagger sample variance $S^2 = \sum(X_j - \bar{X})^2/(n - 1)$ iff F is normal $N(\mu, \sigma^2)$ (Kawata and Sakamoto, *J. Math. Soc. Japan*, 1 (1949)). Let $a_{ij}, i, j = 1, \dots, n$, be real numbers such that $\sum a_{ij} = 0$ and $\sum a_{ii} \neq 0$. If F has a finite second moment, then the condition $E(\sum a_{ij} X_i X_j | \bar{X}) = \text{const.}$ implies that F is normal. Two linear statistics $L_1 = a_1 X_1 + \dots + a_n X_n$ and $L_2 = b_1 X_1 + \dots + b_n X_n$ are independent only if F is normal, provided that $a_j b_j \neq 0$ for some j . In fact, the X 's need not be identically distributed: If L_1 and L_2 are independent and $a_j b_j \neq 0$, then the distribution of X_j is normal (**Skitovich-Darmois theorem**). Yu. V. Linnik [23] gave a necessary and sufficient condition for the normality of F to be equivalent to the identity of the distributions of L_1 and L_2 . The condition is stated in terms of the zeros of the entire function $\sigma(z) = |a_1|^2 + \dots + |a_n|^2 - |b_1|^2 - \dots - |b_n|^2$. The result contains as a special case the following characterization theorem for the normal distribution: If $\sum a_j^2 = 1$ and L_1 has a distribution identical to that of X_1 , then F is normal $N(\mu, \sigma^2)$ with $\mu(\sum a_j - 1) = 0$. R. Shimizu gave a complete description of the characteristic function of the distribution for which L_1 has the same distribution as X_1 . In particular, it was proved that if $\log|a_1|/\log|a_2|$ is an irrational number, α is the positive number given by $\sum |a_j|^\alpha = 1$, and if L_1 has a distribution identical to that of X_1 , then F is the \dagger stable distribution with \dagger characteristic

exponent α . The result was extended in [24] to the cases where the a 's are random variables independent of the X 's. If $E(X_i) = 0$ and $E(\bar{X} | X_1 - \bar{X}, X_2 - \bar{X}, \dots, X_n - \bar{X}) = 0$, then F is normal [26]. Let $\mu_1, \mu_2, \dots, \mu_n$ be a set of real numbers. If the sampling distribution of the statistic $\sum (X_i + \mu_i)^2$ depends on the μ 's only through $\sum \mu_i^2$, then F is normal. If X_i is positive and has finite mean, then the condition $E(\bar{X} | X_2/X_1, X_3/X_1, \dots, X_n/X_1) = \text{const.}$ implies that F is the gamma distribution. If the distribution F is not concentrated on a lattice $0, \rho, 2\rho, \dots$, then $E(X_{(k+1)} - X_{(k)} | X_{(k)}) = \text{const.}$ for some k implies that F is the exponential distribution: $F(x) = 1 - e^{-\lambda x}, x > 0$. $X_{(k+1)} - X_{(k)}$ has the identical distribution for some k with $\min\{X_1, X_2, \dots, X_{n-k}\}$ iff F is exponential. If a_1, a_2, \dots, a_n are positive numbers such that $a_1 + a_2 + \dots + a_n = 1$ and such that $\log a_1 / \log a_2$ is irrational, then the sampling distribution of $\min\{X_1/a_1, X_2/a_2, \dots, X_n/a_n\}$ is the same as that of X_1 iff F is exponential. $X_{(1)}$ is independent of $X_{(1)} - \bar{X}$ iff F is exponential.

Suppose that the distribution F has a bounded density function and that the integral $\int_{-\infty}^{\infty} e^{tx} dF(x)$ is finite on a neighborhood of $t = 0$. Let $\{X_1, X_2, \dots, X_n\}$ be a random sample from a distribution of the family $\mathcal{P} = \{F((x - \mu)/\sigma) | -\infty < \mu < \infty, \sigma > 0\}$. For $n \geq 9$, the sampling distribution of the statistics

$$\left\{ \frac{(X_3 - X_1)}{(X_9 - X_7)}, \frac{(X_2 - X_1)}{(X_8 - X_7)}, \frac{(X_6 - X_4)}{(X_9 - X_7)}, \frac{(X_5 - X_4)}{(X_8 - X_7)}, \right. \\ \left. \text{sgn}(X_3 - X_1), \text{sgn}(X_2 - X_1), \right. \\ \left. \text{sgn}(X_6 - X_4), \text{sgn}(X_5 - X_4) \right\}$$

uniquely determines the family \mathcal{P} . If F is symmetric, then for $n \geq 6$ the distribution of $\{|(X_4 - X_3)/(X_2 - X_1)|, |(X_6 - X_5)/(X_2 - X_1)|\}$ uniquely determines \mathcal{P} [25].

I. U-Statistics

Let $\{X_1, \dots, X_n\}$ be a random sample from a certain distribution, and let $\varphi(x_1, \dots, x_m)$ be a real-valued function that is symmetric with respect to the arguments x_1, \dots, x_m . The statistic

$$U = \binom{n}{m}^{-1} \sum \varphi(X_{\alpha_1}, \dots, X_{\alpha_m}),$$

where the summation extends over all combinations $(\alpha_1, \dots, \alpha_m)$ taken from $(1, 2, \dots, n)$, is called a **U-statistic**. Let $\theta = E(\varphi(X_1, \dots, X_m))$, and assume that $E(\varphi(X_1, \dots, X_m)^2)$ is finite. Then the mean and variance of U are given by

$$E(U) = \theta, V(U) = \binom{n}{m}^{-1} \sum_{i=1}^m \binom{m}{i} \binom{n-m}{m-i} \zeta_i,$$

where ζ_i is the covariance between $\varphi(X_1, \dots, X_m)$ and $\varphi(X_1, \dots, X_i, X'_{i+1}, \dots, X'_m)$, with X'_{i+1}, \dots, X'_m an additional independent random sample of size $m - i$ from the same distribution. If $\zeta_1 \neq 0$, then U obeys the distribution $N(\theta, m^2 \zeta_1/n)$ asymptotically as $n \rightarrow \infty$ (W. Hoeffding, *Ann. Math. Statist.*, 19 (1948)).

These results can be generalized to the case of several populations and samples. Let $X_{11}, \dots, X_{1n_1}; \dots; X_{c1}, \dots, X_{cn_c}$ be c independent random samples, each drawn from one of c populations. Assume that a real-valued function $\varphi(x_{11}, \dots, x_{1m_1}; \dots; x_{c1}, \dots, x_{cm_c})$ is symmetric with respect to the arguments x_{i1}, \dots, x_{im_i} for each $i = 1, \dots, c$. Then

$$U = \prod_{i=1}^c \binom{n_i}{m_i}^{-1} \cdot \sum \varphi(X_{1\alpha(11)}, \dots, X_{1\alpha(1m_1)}; \dots; X_{c\alpha(c1)}, \dots, X_{c\alpha(cm_c)}),$$

where the summation extends over all combinations $(\alpha(i1), \dots, \alpha(im_i))$ of m_i numbers taken from $(1, 2, \dots, n_i)$ for each $i = 1, \dots, c$, is called a **U-statistic**. The mean and variance of U can be obtained as before, while U is asymptotically normally distributed as the sample sizes n_1, \dots, n_c tend to infinity in fixed proportion. Furthermore, if there are given several U -statistics, their joint distribution is asymptotically normal.

J. Distributions Having Monotone Likelihood Ratio, and Pólya-Type Distributions

Let $(\mathcal{X}, \mathfrak{B})$ be a sample space and

$$\mathcal{P} = \{p_\theta(x) | \theta \in \Omega\}$$

be a family of probability densities with respect to a fixed σ -finite measure. The function $p_\theta(x)$ regarded as a function of θ with a fixed observed value of x is called the **likelihood function**, and its value at a particular point θ is called the **likelihood** of that point. The family \mathcal{P} with $\Omega \subset \mathbf{R}$ is said to have **monotone likelihood ratio** with respect to a real-valued function $T(x)$ if and only if for any $\theta < \theta'$ such that θ and θ' belong to Ω the ratio $p_{\theta'}(x)/p_\theta(x)$ is a nondecreasing function of $T(x)$. Under the assumption that $\mathcal{X} \subset \mathbf{R}$ and $\partial^2 \log p_\theta(x)/\partial x \partial \theta$ exists, a necessary and sufficient condition for \mathcal{P} to have monotone likelihood ratio with respect to $T(x) \equiv x$ is that $\partial^2 \log p_\theta(x)/\partial x \partial \theta \geq 0$ for any x and θ . If $\{X_1, \dots, X_n\}$ is a random sample from a distribution that has a monotone likelihood ratio and if a real-valued function $\psi(x_1, \dots, x_n)$ is nondecreasing in each of its arguments, then the expectation $E_\theta(\psi(X_1, \dots, X_n))$ is a nondecreasing function of θ .

The family \mathcal{P} is said to be of **Pólya type n** if and only if for any $m = 1, 2, \dots, n$ and any

real numbers $x_1 < \dots < x_m$ and $\theta_1 < \dots < \theta_m$, the determinant of the matrix $(p_{\theta_i}(x_j))$, $i, j = 1, \dots, m$, is nonnegative, and \mathcal{P} is said to be **strictly of Pólya type n** if the determinant is positive. Being of Pólya type 2 is equivalent to having a monotone likelihood ratio. If \mathcal{P} is (strictly) of Pólya type n for any positive integer n , then it is said to be (strictly) of **Pólya type**. An exponential family of distributions with probability density $p_{\theta}(x) = \exp(\theta x + \alpha(\theta) + s(x))$ for $x \in \mathcal{X} \subset \mathbf{R}$ and $\theta \in \Omega \subset \mathbf{R}$ is strictly of Pólya type. Each of the noncentral chi-square distribution, noncentral t -distribution, and noncentral F -distribution is strictly of Pólya type with respect to the noncentrality parameter.

**375 (XX.26)
Scattering Theory**

A. General Remarks

The path of a moving (incident) particle is distorted when it interacts with another (target) particle, such as an atom or a molecule. Phenomena of this sort are generally called

scattering. Scattering is called **elastic** when the internal properties of the incident particle and the target remain unchanged after the collision, and **inelastic** when the internal properties change, other particles are emitted, or the two particles form a bound state.

The extent of scattering depends on the sizes of the incident and target particles. The **scattering cross section** is defined as the probability that the incident beam will be scattered per unit time (normalized to one particle per unit time crossing unit area perpendicular to the direction of incidence). In †classical mechanics the scattering cross section is equal to the cross section of the target perpendicular to the incoming beam, hence the term “cross section.” The probability of scattering into a unit solid angle in a particular direction is called the **differential cross section**. The probability that the incoming particle is absorbed by the target, called the **absorption cross section**, is intimately connected with the scattering cross section. Analyses of scattering give information on the structure and interactions of atoms, molecules, and elementary particles. One can also study the scattering of acoustic and electromagnetic waves by inhomogeneous media and obstacles, by considering notions similar to the above.

Scattering theory may be dated back to Lord Rayleigh. Since the advent of quantum mechanics in the mid-1920s, scattering problems, mainly for central (spherically symmetric) potentials, have been investigated strenuously by physicists. It may be said, however, that a scattering theory having mathematically rigorous foundations began around the 1950s, when the pioneering work of K. Friedrichs (*Comm. Pure Appl. Math.*, 1 (1948)), A. Ya. Povzner (*Mat. Sb.*, 32 (1953)), T. Kato (*J. Math. Soc. Japan*, 9 (1957)), J. M. Cook (*J. Math. Phys.*, 36 (1957)), and J. M. Jauch (*Helv. Phys. Acta*, 31 (1958)), among others, appeared, and scattering theory has now grown into a branch of mathematical physics.

General references for mathematical scattering theory are, e.g., [1–5].

B. Wave and Scattering Operators

In †quantum mechanics the dynamics of an interacting system is given by a †one-parameter group of unitary operators e^{-itH} , where t denotes the time and H , called the Hamiltonian of the system, is a †self-adjoint operator acting in a †Hilbert space \mathcal{H} . Elements of \mathcal{H} represent (pure) states of the system. Let H_0 be the “free” Hamiltonian of the corresponding “noninteracting” system. (There are at present no generally accepted definite

criteria for “free” and “noninteracting.”) H_0 is assumed to be †absolutely continuous, which is the case in most practical situations. Then the **outgoing and incoming wave operators** $W_{\pm} = W_{\pm}(H, H_0)$ are defined, if they exist, by

$$W_{\pm} = s\text{-}\lim_{t \rightarrow \pm\infty} e^{itH} e^{-itH_0} \quad (s\text{-}\lim = \text{†strong limit}).$$

This means that given any free motion $e^{-itH_0}u$ there is an initial ($t=0$) state $u_{\pm} (= W_{\pm}u)$ such that $e^{-itH}u_{\pm}$ and $e^{-itH_0}u$ are asymptotically equal at $t = \pm\infty$. W_{\pm} are †isometric, intertwine the two dynamics: $e^{-itH}W_{\pm} = W_{\pm}e^{-itH_0}$, and map \mathcal{H} (which is nothing but the †absolutely continuous subspace $\mathcal{H}_{ac}(H_0)$ for H_0) onto a closed subspace of $\mathcal{H}_{ac}(H)$. The **scattering operator** S is defined as $S = W_{+}^{*}W_{-}$ (A^{*} is the Hilbert-space †adjoint of A). S commutes with H_0 and maps states in the remote past into states in the distant future. One of the most important problems in scattering theory is to prove the †unitarity of S , or equivalently, $\text{Ran } W_{+} = \text{Ran } W_{-}$ ($\text{Ran} = \text{†range} = \text{†image}$). W_{\pm} is called **complete** if $\text{Ran } W_{\pm} = \mathcal{H}_{ac}(H)$. The completeness of W_{\pm} implies that S is unitary.

As a typical example we consider the 1-body problem. Note that the 2-body problem reduces to the 1-body problem by separating out the center-of-mass motion, which is free. Then $H_0 = -\Delta$ (the negative †Laplacian in \mathbf{R}^3), $H = -\Delta + V$, the operator V being multiplication by a real-valued function $V(x)$, called the **potential**, and $\mathcal{H} = L_2(\mathbf{R}^3)$. If V is **short range**, i.e., if, roughly speaking, $V(x) = O(|x|^{-1-\epsilon})$ ($\epsilon > 0$) at ∞ , the wave operators are known to exist and to be complete (S. Agmon, *Ann. Scuola Norm. Sup. Pisa*, (4) 2 (1975)). If the potential $V(x)$ is **long range**, i.e., if, roughly speaking, $V(x) = O(|x|^{-\epsilon})$ ($\epsilon > 0$) at ∞ , then the foregoing definition of the wave operators has to be modified. For the Coulomb potential $V(x) = c/x$, for instance, one can adopt the following definition of **modified wave operators**:

$$\tilde{W}_{\pm} = s\text{-}\lim_{t \rightarrow \pm\infty} e^{itH} \exp(-itH_0 - i(c/2)H_0^{-1/2} \log t).$$

It can be shown that the \tilde{W}_{\pm} exist (which implies that the ordinary wave operators do not exist) and are complete: $\text{Ran } \tilde{W}_{\pm} = \mathcal{H}_{ac}(H)$ (J. D. Dollard, in [6]). The same result obtains for more general long-range potentials (H. Kitada, *J. Math. Soc. Japan*, 30 (1978); T. Ikebe and H. Isozaki, *Integral Equations and Operator Theory*, 5 (1982)).

If the wave operators exist and are complete, they give †unitary equivalence between the †absolutely continuous parts of H_0 and H (\rightarrow T. Kato [7]; 331 Perturbation of Linear Operators).

In the foregoing discussion it was tacitly assumed that in dealing with scattering phenomena we adhere to states in $\mathcal{H}_{ac}(H_0)$ and

$\mathcal{H}_{ac}(H)$. A more physically intuitive definition in the case of potential scattering ($H_0 = -\Delta$, $H = H_0 + V$) of **scattering states** $\Sigma_{\pm}(H)$ is the following: $f \in \Sigma_{\pm}(H)$ if and only if for any $r > 0$,

$$\lim_{T \rightarrow \pm\infty} \frac{1}{T} \int_0^T \|F_r e^{-itH} f\|^2 dt = 0$$

($\| \cdot \| = L_2$ -norm),

where F_r is the (projection) operator of multiplication by the characteristic function of $\{x \in \mathbb{R}^3 \mid |x| < r\}$. In general no inclusion relations between $\Sigma_{\pm}(H)$ and $\mathcal{H}_{ac}(H)$ are known. But for a wide class of potentials it is known that $\mathcal{H}_{ac}(H)$ as well as the †continuous subspace of H coincides with $\Sigma_{\pm}(H)$ (in this case there is no †singular continuous spectrum) (W. O. Amrein and V. Georgescu, *Helv. Phys. Acta*, 46 (1973); C. Wilcox, *J. Functional Anal.*, 12 (1973); Amrein, in [8]).

A purely abstract result in scattering theory may be noted. Let H_0 and H be self-adjoint operators in an abstract Hilbert space \mathcal{H} such that $V = H - H_0$ is a †trace-class (†nuclear) operator. Then the **generalized wave operators** $W_{\pm}(H, H_0) = s\text{-}\lim_{t \rightarrow \pm\infty} \exp(itH) \exp(-itH_0)$ $P_{ac}(H_0)$ exist, where $P_{ac}(H_0)$ is the †projection onto $\mathcal{H}_{ac}(H_0)$. Since this statement is symmetric in H_0 and H , the “inverse” generalized wave operators $W_{\pm}(H_0, H)$ also exist, from which one can conclude that $W_{\pm}(H, H_0)$ are complete. Moreover, the **invariance principle** holds, which means roughly the following: If ϕ is a strictly increasing function on \mathbb{R} , then $W_{\pm}(\phi(H), \phi(H_0))$ exists and is equal to $W_{\pm}(H, H_0)$. This result can be applied to potential scattering when $V(x) \in L_2(\mathbb{R}^3) \cap L_1(\mathbb{R}^3)$ (Kato [7]; D. B. Pearson, *J. Functional Anal.*, 28 (1978)).

C. Stationary (Time-Independent) Approach

We again consider the 1-body problem as in Section B. $V(x)$ is assumed to verify certain appropriate decay conditions at ∞ as the case may be. Consider the †resolvents $R_0(z) = (H_0 - z)^{-1}$ and $R(z) = (H - z)^{-1}$ for $z \in \mathbb{C} - \mathbb{R}$, which are well-defined bounded integral operators on $\mathcal{H} = L_2(\mathbb{R}^3)$. Here we note the following: $[0, \infty)$ is the †continuous spectrum of H_0 and H , $(-\infty, 0)$ is contained in the †resolvent set of H_0 , and H has possibly †discrete †eigenvalues in $[-a, 0)$ with $(-\infty, -a)$ contained in the resolvent set, where a is a positive number. When z approaches a positive real value, $R_0(z)$ and $R(z)$ do not have limits as †bounded operators on \mathcal{H} . But if we regard them as operators from $L_{2,\gamma}$ to $L_{2,-\gamma}$ ($L_{2,\alpha} = \{u \mid (1 + |x|)^{\alpha} u(x) \in L_2(\mathbb{R}^3)\}$), $\gamma > 1/2$, they can be shown to have boundary values $R_0(\lambda \pm i0)$ and

$R(\lambda \pm i0)$, $\lambda > 0$ (**limiting absorption principle**; → Agmon, *loc. cit.*, for short-range potentials; for long-range potentials → R. Lavine, *J. Functional Anal.*, 12 (1973); T. Ikebe and Y. Saitō, *J. Math. Kyoto Univ.*, 12 (1972); and Saitō, *Publ. Res. Inst. Math. Sci.*, 9 (1974). With these boundary values we can define “stationary” wave operators whose range is easily proved to coincide with $\mathcal{H}_{ac}(H)$, and show their equality to the time-dependent wave operators discussed in Section B, thus obtaining the completeness of the latter.

H_0 is known to have **generalized** (improper) **eigenfunctions** $\varphi_0(x, \xi) = e^{ix \cdot \xi}$ with **generalized** (improper) **eigenvalues** $|\xi|^2$. The associated eigenfunction expansion is nothing but the Fourier integral expansion. An eigenfunction expansion, similar to the Fourier expansion, that diagonalizes H can be obtained by using generalized eigenfunctions

$$\varphi_{\pm}(x, \xi) = \varphi_0(x, \xi) - (R(|\xi|^2 \pm i0) V \varphi_0(\cdot, \xi))(x),$$

which are the solutions to the **Lippmann-Schwinger equation**

$$\varphi_{\pm}(x, \xi) = \varphi_0(x, \xi) - \frac{1}{4\pi} \int_{\mathbb{R}^3} \frac{e^{\pm i|\xi||x-y|}}{|x-y|} V(y) \varphi_{\pm}(y, \xi) dy.$$

A rough statement of this is the following:

Let $\tilde{u}_{\pm}(\xi) = (2\pi)^{-3/2} \int \varphi_{\pm}(x, \xi) u(x) dx$. Then $\|\tilde{u}\| = \|u\|$, $(Hu)^{\sim}(\xi) = |\xi|^2 \tilde{u}(\xi)$, and $u(x) = (2\pi)^{-3/2} \int \varphi_{\pm}(x, \xi) \tilde{u}(\xi) d\xi$ (→ e.g. [4, XI.6] for a more precise statement).

In view of the fact that S commutes with H_0 , we can show that S admits the following representation: Let $\hat{u}(\xi) = (2\pi)^{-3/2} \int \varphi_0(x, \xi) u(x) dx$ be the †Fourier transform of u . Then

$$(Su)^{\sim}(\xi) \equiv (\hat{S}\hat{u})(\xi) = \hat{u}(\xi) - \pi i \int_{S^2} |\xi| T(\xi, |\xi| \omega) \hat{u}(|\xi| \omega) d\omega,$$

where

$$T(\xi, \xi') = (2\pi)^{-3} \int \varphi_0(x, \xi) V(x) \varphi(x, \xi') dx$$

is the kernel of the so-called **T-operator**, which is a †compact operator on $L_2(S^2)$ under suitable conditions on $V(x)$. $T(\xi, \xi')$ is related to the experimentally measurable total cross section (for incident momentum ξ) $\sigma(\xi)$:

$$\sigma(\xi) = 2\pi \int_{S^2} |f(|\xi|; \omega, \omega')|^2 d\omega' \quad (\omega = \xi/|\xi|),$$

$$f(\lambda; \omega, \omega') = -2\pi^2 T(\lambda\omega, \lambda\omega') \quad (\lambda > 0).$$

The quantity $f(\lambda; \omega, \omega')$ is called the **scattering amplitude** and appears in the asymptotic

expansion of $\varphi_{\pm}(x, \xi)$ as

$$\varphi_{\pm}(x, \xi) \sim \varphi_0(x, \xi) + \frac{e^{\pm i|\xi||x|}}{|x|} f(|\xi|; \hat{x}, \hat{\xi}),$$

where $a = a/|a|$ for $a \in \mathbf{R}^3$.

An abstract version of the limiting absorption principle and eigenfunction expansion is known as the Kato-Kuroda theory, for which the reader is referred to Kato and S. T. Kuroda in [6] and in *Functional analysis and related fields*, Springer, 1970, and to Kuroda (*J. Math. Soc. Japan*, 25 (1973)).

D. Time-Dependent Approach

Consider the same situation as in Section C. Since scattering is a time-dependent phenomenon, it seems natural to develop scattering theory in a time-dependent fashion. Indeed, there is an approach to the completeness of wave operators that does not resort to any eigenfunction expansion results, but instead follows the temporal development of the wave packet $e^{-itH}u$. The completeness of W_{\pm} will be established if one can show that any $u \in \mathcal{H}_{ac}(H)$ orthogonal to $\text{Ran } W_{\pm}$ is 0. A crucial step to prove this is to find a clever decomposition of a wave packet into an outgoing and an incoming one, or to find projections P_{\pm} such that $P_+ + P_- = I$ and $P_{\pm}e^{-itH_0}$ goes to 0 as $t \rightarrow \mp\infty$. Some compactness arguments are also needed.

To construct such a decomposition or projections one looks at the scalar product $x \cdot \xi$, x and ξ being the position and momentum (operators), respectively. The main idea is that if this is positive, the particle will be outgoing (to infinity), and if negative, incoming (from infinity). But since we work in the framework of quantum mechanics, this classical-mechanical intuition should be properly modified.

Besides the completeness of wave operators it can also be shown through the above approach that the singular continuous spectrum of H is absent. For details \rightarrow [4, XI.17] and V. Enss, *Comm. Math. Phys.*, 61 (1978).

E. Partial Wave Expansion

In this section we assume that the potential $V(x)$ is central, i.e., $V(x)$ is a function of $|x|$ alone. Then the scattering operator S turns out to commute not only with H_0 but also with the angular momentum operator $L = x \times i^{-1}\nabla$ (vector product). The eigenvalues of $L^2 = L \cdot L$ (scalar product) are $l(l+1)$ ($l=0, 1, 2, \dots$), and those of L_z , the third component of L , are $m = -l, -(l-1), \dots, l-1, l$ if L^2 has eigenvalue $l(l+1)$, while simultaneous eigenfunctions are given by suitably normalized \dagger spherical har-

monics $Y_{lm}(\omega)$, $\omega \in S^2$. Let E_l be the projection onto the subspace spanned by functions of the form $\sum_{m=-l}^l u_{lm}(r) Y_{lm}(\omega)$ ($r = |x| > 0, \omega = x/r$). \mathcal{H} becomes an orthogonal sum of $\mathcal{H}_l = E_l \mathcal{H}$. The aforementioned commutation property claims that $E_l S = S E_l \equiv S_l$, and the operator S_l reduces to multiplication by a scalar function $e^{2i\delta_l(\lambda)}$ in \mathcal{H}_l (\rightarrow Section C). $\delta_l(\lambda)$ is called the **phase shift**. Defining the **partial wave scattering amplitude** $f_l(\lambda) = (2i\lambda)^{-1}(e^{2i\delta_l(\lambda)} - 1)$, one obtains the **partial wave expansion** of the scattering amplitude:

$$f(\lambda; \omega, \omega') = \sum_{l=0}^{\infty} (2l+1) f_l(\lambda) P_l(\cos \theta),$$

where θ is the angle between ω and ω' , and P_l is a \dagger Legendre polynomial. The total cross section is $\sigma(\lambda) = 4\pi\lambda^{-2} \sum_{l=0}^{\infty} (2l+1) |f_l(\lambda)|^2$ [1-5, 9].

F. Many-Body Problem (Multichannel Scattering)

We consider only the 3-body case, which is complicated enough compared with the 2- (essentially 1-) body case. The complications are both kinematical and dynamical. The configuration of a 3-body system is given by a point in \mathbf{R}^9 . Once we choose the center-of-mass coordinates, there is no kinematically natural way to choose the remaining six coordinates. In the 2-body case a freely moving particle in the remote past will be freely moving in the distant future. But in the 3-body case there come into play various other dynamical processes, such as capture, breakup, rearrangement, and excitation.

The 3-body Hamiltonian is a self-adjoint operator in $L_2(\mathbf{R}^9)$ of the form

$$\tilde{H} = - \sum_{i=1}^3 \frac{1}{2m_i} \Delta_i + \sum_{i < j} V_{ij}(x_i - x_j),$$

where Δ_i is the 3-dimensional Laplacian associated with particle i , m_i is the mass of particle i , and each $V_{ij}(x) (= V_{ji}(x) = V_{ij}(-x))$ is a real-valued function decaying at ∞ in \mathbf{R}^3 (not in \mathbf{R}^9). If we remove the center-of-mass motion, \tilde{H} can be written in the form

$$\tilde{H} = H_0 \otimes I + I \otimes H \quad (\otimes = \dagger\text{tensor product}),$$

where H_0 is the center-of-mass Hamiltonian in $L_2(\mathbf{R}^3)$ representing the uniform free motion of the center of mass, and H is the Hamiltonian of relative motion in $L_2(\mathbf{R}^6)$. One should note as mentioned above that there is no unique natural way of choosing coordinates in \mathbf{R}^6 and representing H , but there are many equivalent representations. Suppose, for instance, that particles 1 and 2 and particles 1 and 3 form \dagger bound states (12) and (13) and that there are

no bound states between 2 and 3. We partition the whole system into **clusters**: (1) (2) (3), (12) (3), and (13) (2) () represents a cluster and figures in () are the particles forming the cluster). A **channel** is a partition into clusters together with a specified bound-state eigenfunction. Take, for instance, channel (12) (3), and suppose $\psi \in L_2(\mathbf{R}^3)$ is the eigenfunction in question. If we take $x = x_2 - x_1$ and $y = x_3 - (m_1 + m_2)^{-1}(m_1 x_1 + m_2 x_2)$, then

$$H = -\frac{1}{2m} \Delta_y - \frac{1}{2n} \Delta_x + V_{12}(x) + V_{23} \left(\frac{m_1 x}{m_1 m_2} - y \right) + V_{31} \left(\frac{m_2 x}{m_1 + m_2} + y \right),$$

where $m^{-1} = m_3^{-1} + (m_1 + m_2)^{-1}$, $n^{-1} = m_1^{-1} + m_2^{-1}$. Let us neglect the interactions between (12) and (3), i.e., set $V_{23} = V_{31} = 0$ to define the **cluster decomposition Hamiltonian**

$$H_{(12)(3)} = -\frac{1}{2m} \Delta_y - \frac{1}{2n} \Delta_x + V_{12}(x).$$

Let $\mathcal{H}_{(12)(3)} = L_2(\mathbf{R}^3)$ (called the **channel Hilbert space** consisting of functions of y), and define a mapping $\tau: \mathcal{H}_{(12)(3)} \rightarrow \mathcal{H} = L_2(\mathbf{R}^6)$ (functions of x and y) by $(\tau f)(x, y) = \psi(x)f(y)$. The **channel wave operators** $W_{(12)(3)\pm}$ are defined by

$$W_{(12)(3)\pm} = s\text{-}\lim_{t \rightarrow \pm\infty} e^{itH} e^{-itH_{(12)(3)}\tau}$$

as isometries from $\mathcal{H}_{(12)(3)}$ into \mathcal{H} . Their ranges are not expected to coincide as in the 2-body case. $W_{(1)(2)(3)\pm}$ and $W_{(13)(2)\pm}$ are similarly defined. Note that $\mathcal{H}_{(1)(2)(3)} = \mathcal{H}$. If α and β are distinct channels, we have $\text{Ran } W_{\alpha+} \perp \text{Ran } W_{\beta+}$ and $\text{Ran } W_{\alpha-} \perp \text{Ran } W_{\beta-}$, but no such relations exist between $\text{Ran } W_{\alpha+}$ and $\text{Ran } W_{\beta-}$ or $\text{Ran } W_{\alpha-}$ and $\text{Ran } W_{\beta+}$. Define, for channels α and β , $S_{\alpha\beta}: \mathcal{H}_\beta \rightarrow \mathcal{H}_\alpha$ by $S_{\alpha\beta} = (W_{\alpha+})^* W_{\beta-}$. Now the **scattering operator** S for the 3-body system is defined as the \dagger direct sum of $S_{\alpha\beta}$ acting in the Hilbert space $\sum_\alpha \oplus \mathcal{H}_\alpha: S = \sum_{\alpha,\beta} \oplus S_{\alpha\beta}$. Naturally the question arises: Is S unitary? The first affirmative answer was made by L. D. Faddeev (*Israel Program for Scientific Translations*, 1965 (in English; original in Russian, 1963)), and later the work of J. Ginibre and M. Moulin (*Ann. Inst. H Poincaré*, A21 (1974)) and L. Thomas (*Ann. Phys.*, 90 (1975)) came out. The method of these authors is stationary. There have also been some attempts using time-dependent methods.

G. Inverse Problem

The **inverse problem** in potential scattering may be formulated at least mathematically as follows: Given the scattering operator or scat-

tering amplitude, determine the potential(s) giving rise to the operator or amplitude. We consider here only the 2-body case (as to the many-body case, almost nothing is known). The central-potential case can be reduced to 1-dimensional problems on $(0, \infty)$. In the 1-dimensional case the celebrated Gel'fand-Levitan theory (\rightarrow 112 Differential Operators O) has long been known and has been successfully applied even to nonlinear problems such as the \dagger Korteweg-de Vries equation. In the 3-dimensional case, however, the problem becomes difficult; so far there has not been any satisfactory theory comparable to that for the 1-dimensional case. The potential $V(x)$ is a function $\mathbf{R}^3 \rightarrow \mathbf{R}$. The scattering amplitude $f(\lambda; \omega, \omega')$ is a function $f: \mathbf{R} \times S^2 \times S^2 \rightarrow \mathbf{C}$. Let M be the mapping that takes V into f . The inverse problem deals with M^{-1} . Several questions may be posed (in order of increasing difficulty): (1) Is M one-to-one? (2) When it is known that M is one-to-one and f is in the image of M , how does one (re-)construct the V that yields f ? (3) What conditions characterize the image of M ? Question (1) has been rather satisfactorily answered insofar as short-range potentials are concerned. Concerning questions (2) and (3), attempts have been and are being made to generalize the Gel'fand-Levitan theory, but it may be said that we are still at the beginning stage. References are [2, 9, 10] and R. G. Newton (*J. Math. Phys.*, 20 (1980); 21 (1981); 22 (1982)).

H. Scattering for the Wave Equation

Consider the \dagger wave equation $u_{tt} - \Delta u = 0$ in \mathbf{R}^3 . The solution $u(t) = u(t, x)$ is uniquely determined by the initial data $\{f, g\} = \{u(0), u_t(0)\}$, and $U_0(t)\{f, g\} = \{u(t), u_t(t)\}$ defines the solution operator $U_0(t)$. The set of data $\{f, g\}$ with finite energy: $\int (|\nabla f|^2 + |g|^2) dx < \infty$ forms a Hilbert space \mathcal{H}_0 . $U_0(t)$ is a unitary group on \mathcal{H}_0 . A similar description is possible for solutions of the wave equation in an exterior domain Ω outside an obstacle with zero boundary condition. Denote the resulting Hilbert space and solution operator by \mathcal{H} and $U(t)$, respectively. Let $J: \mathcal{H}_0 \rightarrow \mathcal{H}$ be the identification operator defined by $(J\{f, g\})(x) = \{f, g\}(x)$, $x \in \Omega$. The **wave operators** are defined by $W_\pm = s\text{-}\lim_{t \rightarrow \pm\infty} U(-t)J U_0(t)$. The existence of W_\pm is shown rather easily by using \dagger Huygens's principle. As in Section B, we define the **scattering operator** $S = W_+^* W_-$ and say that W_\pm is **complete** if $\text{Ran } W_\pm = \mathcal{H}_{ac}(H)$, where H is the self-adjoint \dagger infinitesimal generator of $U(t): U(t) = e^{-itH}$. The completeness of W_\pm and the unitarity of S are proved on the basis of the abstract **translation representation**

theorem: Let $U(t)$ be a unitary group on a Hilbert space \mathcal{H} . Suppose there exist subspaces D_+ and D_- , called **outgoing and incoming subspaces**, such that $U(t)D_{\pm} \subset D_{\pm}$ for $\pm t \geq 0$, $\bigcap_{t \in \mathbb{R}} U(t)D_{\pm} = \{0\}$, and $\bigcup_{t \in \mathbb{R}} U(t)D_{\pm}$ is dense in \mathcal{H} . Then we have two unitary operators $\mathcal{R}_{\pm}: \mathcal{H} \rightarrow L_2(\mathbb{R}; N)$, where N is an auxiliary Hilbert space, such that $\mathcal{R}_{\pm} U(t) \cdot \mathcal{R}_{\pm}^{-1}$ is right translation by t , and D_+ (D_-) is mapped onto $L_2(0, \infty; N)$ ($L_2(-\infty, 0; N)$) by \mathcal{R}_+ (\mathcal{R}_-).

Turning to the concrete situation, one can study the detailed properties of S . The uniqueness theorem in the inverse problem is also obtained, to the effect that S determines the obstacle uniquely. The foregoing treatment of scattering is known as the Lax-Phillips theory (P. D. Lax and R. S. Phillips, in [6, 8, 11]).

376 (XIX.15) Scheduling and Production Planning

Production planning emerges in many situations. Models of economic planning can be classified as (1) fiscal policy-oriented, (2) final demand-oriented, (3) structure-oriented, (4)

expenditure-oriented, and (5) industrialization-oriented. Types (2), (3), and (5) belong to production planning in a broad sense, as emphasis is placed on production in these models.

A typical **production planning** theory of primary importance is **activity analysis**, which has made remarkable progress since its initiation by T. C. Koopmans [1]. Its principal theoretical content consists of linear programming. Most applications of linear programming are more or less concerned with production activities. Because of the additivity and divisibility of production as well as the limitation of production intensities, problems of production planning can be formulated as problems of linear programming. The methods of linear algebra are used to obtain an optimal production plan and are very important in modern economic analysis, because these methods not only provide practical algorithms but also clarify the role of price, especially in dual linear programming problems.

The originators of general equilibrium theory (\rightarrow 128 Econometrics) failed to give an analytical demonstration of the existence of solutions of certain systems of equations of economic relevance. The existence of a determinate equilibrium was established first by A. Wald for a system of equations of the Walras-Cassel type. On the other hand, J. von Neumann [3] proved the existence of non-negative solutions α, β, x_i, y_j for a system of inequalities

$$\alpha \sum_{i=1}^m a_{ij} x_i \leq \sum_{i=1}^m b_{ij} x_i, \quad j = 1, 2, \dots, n,$$

$$\beta \sum_{j=1}^n a_{ij} y_j \geq \sum_{j=1}^n b_{ij} y_j, \quad i = 1, 2, \dots, m,$$

by reducing the problem to the proof of the existence of a saddle point (\rightarrow 292 Nonlinear Programming A) of the function

$$\Phi(X, Y) \equiv \sum_{i=1}^m \sum_{j=1}^n b_{ij} x_i y_j / \sum_{i=1}^m \sum_{j=1}^n a_{ij} x_i y_j$$

by means of Brouwer's fixed-point theorem. In this result an equilibrium is defined in the broad sense that demand for goods does not exceed their supply, rather than requiring exact balance.

A second important kind of production planning is related to both inventory control (\rightarrow 227 Inventory Control) and sales planning. An example is the minimization of

$$\int_0^T (z(t) + \beta \max(dz/dt, 0)) dt$$

subject to the condition $z(t) \geq r(t)$, where $z(t)$ and $r(t)$ are the output and demand, respectively, at time t . Stabilization of employment

and production can also be classified as a production planning problem of this kind, in which inventory holding is considered as a means for lessening the change of employment level. This is related to the problem of smoothing production by inventory control. Dynamic programming (\rightarrow 127 Dynamic Programming) is very useful in dealing with problems of smoothing production.

Production planning as a production management tool is often embodied in **scheduling**. Consider a project that consists of n indivisible tasks (jobs or activities) $J_i, i = 1, 2, \dots, n$, each requiring p_i units of time for processing, where p_i is given either deterministically or probabilistically. A precedence constraint (generally a \dagger partial ordering) partially specifying the order in which these tasks are to be processed is also imposed by technical considerations: One attempts to find a schedule (i.e., a specification of the time to process the tasks J_i) consistent with the given precedence constraint.

Well-known techniques developed for this purpose are **PERT** (program evaluation and review technique) [4] and **CPM** (critical path method) [5], in which the precedence constraint is represented by an acyclic \dagger directed graph, called an arrow diagram, a project network, or a PERT network, such that each task J_i corresponds to an arc of length equal to p_i . An arrow diagram is illustrated in Fig. 1. The longest path from the start node to the end node in the network is called the **critical path**, and gives the minimum time necessary to complete the project. Following computation of the critical path by means of dynamic programming, computations are also made for the earliest (latest) start time, the earliest (latest) finish time, and the floats (i.e., the allowances for such start and finish times) of each task to be satisfied in order to complete the project within the indicated minimum time. These are used to review and control the progress of the project. In PERT the processing time of each task is probabilistically treated on the basis of three estimates: most likely, optimistic, and pessimistic. From these data other parameters,

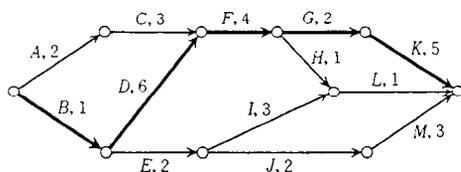

Fig. 1
 A, B, \dots, M denote tasks, while the associated integers are their processing times. Bold arrows indicate the critical path. The start node is on the left, the end node is on the right.

such as the probability of completing the project before the specified due date, are computed. In CPM, on the other hand, a minimum cost schedule to attain the given due date is obtained by utilizing \dagger network flow algorithms (J. E. Kelley [6], D. R. Fulkerson [7]), in which the processing time of a task is determined by linear interpolation between the normal time (achieved with low cost) and the crash time (high cost).

PERT and CPM are used in various areas of application, e.g., civil engineering and the construction industry, shipbuilding, production of automobiles, machines, and electric apparatus, and management of research and development programs. PERT was originally developed by the US Navy to monitor and control the development of the Polaris fleet ballistic missile program, while CPM was developed by the RAND Corporation and the Du Pont Corporation, both in the late 1950s. Computers have been essential from the beginning, to handle the large amount of associated data. A number of application program packages, each with some additional features, are currently available, e.g., PERT/TIME, PERT/COST, CPM, and RAMPS.

The **machine sequencing (scheduling) problem** arises when the resources, instruments, workers, and so forth, required to process a task are abstractly formulated as machines and if the restriction on the number of available machines is taken into consideration (i.e., the conflict between tasks competing for the same machine at the same time must be resolved). Usually one machine is assigned to each task. Such a machine is either (a) uniquely determined for each task or (b) chosen from a given set of machines; in the latter case, there might be (i) parallel machines with the same capability or (ii) machines with different capabilities. The precedence constraints are also ramified into independent (i.e., no constraint), in-tree, out-tree, series-parallel, and general partial ordering constraints. Each task has a ready time (release time) r_i such that J_i cannot be processed before it, and a due time d_i . One is asked to find a schedule satisfying the above machine constraints, precedence constraints, and ready time constraints, while considering an optimality criterion that is a function of the completion time C_i of J_i ($i = 1, 2, \dots, n$). Typical criteria for minimization are: (1) maximum completion time (makespan) $C_{\max} = \max_i C_i$; (2) flowtime (total completion time) $F = \sum C_i$; weighted flowtime $\sum w_i C_i$, where $w_i \geq 0$ are weights representing the relative importance of J_i ; (3) maximum lateness $L_{\max} = \max_i L_i, L_i = C_i - d_i$; (4) total tardiness $T = \sum T_i, T_i = \max(0, L_i)$, and weighted total

tardiness $\sum w_i T_i$; (5) number of tardy tasks $U = \sum U_i$, $U_i = 1$ (if $C_i > d_i$), 0 (otherwise), and weighted number of tardy tasks $\sum w_i U_i$.

Numerous problems can be defined by combining the above conditions. Typical ones might be: the **job-shop scheduling problem**, in which n tasks are scheduled on m machines of type (a), and where the maximum completion time is minimized; the **flow-shop scheduling problem**, which is the same as the job-shop scheduling problem except that $n = n'm$ tasks are divided into n' groups of m tasks processed on machine 1, machine 2, ..., machine m , respectively, in this order; the **multiprocessor scheduling problem**, in which the maximum completion time of n independent tasks on m parallel machines is minimized; the **one-machine sequencing problem**, assuming only one machine (with various types of precedence constraints and optimality criteria), and others [8, 9].

These machine sequencing problems are examples of the combinatorial optimization problem (\rightarrow 281 Network Flow Problems E), as the processing time p_i is usually considered to be a given constant. Their computational complexity (\rightarrow 71 Complexity of Computations) has been extensively studied with an emphasis on the classification between those problems solvable in polynomial time and those that are \dagger NP-complete, as summarized in [10]. Table 1 lists representative results for one-machine sequencing problems with $r_i = 0$ ($i = 1, 2, \dots, n$). The improvement of the algorithm efficiency is pursued for both polynomially solvable problems and NP-complete problems. \dagger Branch and bound (\rightarrow 215 Integral Programming D) is a common approach used to solve NP-complete problems such as the

job-shop and flow-shop scheduling problems [8, 9]. Many approximation algorithms to obtain good suboptimal schedules in reasonable computation time are also known, and their worst-case and average accuracies have been analyzed [10], as these are important in practical applications.

In more realistic scheduling situations, other factors, such as the set-up cost, balancing of production lines, frequent modifications and updatings of project data, capacity of factories, manpower planning including the possibility of overtime and part-time employment, should be taken into account. Both deterministic and probabilistic models have been proposed for these cases. Mathematical tools used to compute adequate schedules include \dagger mathematical programming, \dagger queuing theory, and \dagger simulation techniques.

377 (XX.27) Second Quantization

A. Fock Space

For a complex Hilbert space K with $\dim K \geq 1$, $K^{\otimes n}$ denotes the n -fold tensor product of K with itself (where the vectors $f_1 \otimes \dots \otimes f_n$ with $f_j \in K$ are total). Let $E_{\pm}^{(n)}$ be the projection operators on totally symmetric and antisymmetric parts of $K^{\otimes n}$:

$$E_{\pm}^{(n)}(f_1 \otimes \dots \otimes f_n) = (n!)^{-1} \sum \varepsilon_{\pm}(P) f_{P(1)} \otimes \dots \otimes f_{P(n)},$$

where the sum is over all permutations P , $\varepsilon_+(P) = 1$ and $\varepsilon_-(P)$ is the signature of P (+1 for even permutations and -1 for odd permutations). The following orthogonal direct sum is called a **Fock space** (symmetric for E_+ , and antisymmetric for E_-):

$$\mathcal{F}_{\pm}(K) = \sum_{n=0}^{\infty} \oplus E_{\pm}^{(n)} K^{\otimes n}.$$

Here the term for $n=0$ is the 1-dimensional space \mathbb{C} , and a vector Ω represented by $1 \in \mathbb{C}$ is called the **vacuum vector** in $\mathcal{F}_{\pm}(K)$. The subspace $\mathcal{F}_{\pm}(K)_n = E_{\pm}^{(n)} K^{\otimes n}$ is called the **n -particle subspace**. The operator $N = \sum_{n=0}^{\infty} n$, which takes the value n on $\mathcal{F}_{\pm}(K)_n$, is called the **number operator**.

On the algebraic sum

$$D_{\pm} = \bigcup_N \sum_{n=0}^N \oplus \mathcal{F}_{\pm}(K)_n \subset \mathcal{F}_{\pm}(K),$$

the **creation operator** $a^+(f)$ for $f \in K$ is defined as the unique linear operator with domain D_{\pm}

satisfying

$$a^+(f) E_{\pm}^{(n)} f_1 \otimes \dots \otimes f_n = (n+1)^{1/2} E_{\pm}^{(n+1)} f \otimes f_1 \otimes \dots \otimes f_n.$$

For $f \in K$, \bar{f} denotes the element of the dual K^* satisfying $\bar{f}(g) = (g, f)$ for $g \in K$ (the inner product is linear in the first entry). The **annihilation operator** $a(\bar{f})$ is defined by

$$a(\bar{f}) E_{\pm}^{(n)} f_1 \otimes \dots \otimes f_n = n^{-1/2} \sum_{j=1}^n \varepsilon^{j-1}(f_j, f) E_{\pm}^{(n-1)} f_1 \otimes \dots \otimes \hat{f}_j \otimes \dots \otimes f_n,$$

where the tensor product of f_k , $k \neq j$, appears in the j th term and $\varepsilon = \pm 1$ depending on which of \pm is taken in $\mathcal{F}_{\pm}(K)$. For $n=0$, $a(\bar{f})\Omega$ is defined to be 0. The adjoint of $a^+(f)$ coincides with $a(\bar{f})$ on D_{\pm} .

The creation and annihilation operators map D_{\pm} into itself and satisfy the following commutation relations on D_{\pm} :

$$[a^+(f_1), a^+(f_2)]_{\mp} = [a(\bar{f}_1), a(\bar{f}_2)]_{\mp} = 0, \\ [a(\bar{f}_1), a^+(f_2)]_{\mp} = (f_2, f_1),$$

where $[A, B]_{\mp} = AB \mp BA$ and \mp is used depending on the choice of \pm in $\mathcal{F}_{\pm}(K)$. These relations are often called **canonical commutation relations** for $[\ ,]_-$ (CCRs) and **canonical anticommutation relations** for $[\ ,]_+$ (CARs).

On $\mathcal{F}_-(K)$, $a^+(f)$ and $a(\bar{f})$ are bounded with $\|a^+(f)\| = \|a(\bar{f})\| = \|f\|$. On $\mathcal{F}_+(K)$, both $a^+(f)$ and $a(\bar{f})$ are not bounded, though $a^+(f)N^{-1/2}$ and $a(\bar{f})N^{-1/2}$ are bounded.

On $\mathcal{F}_+(K)$, $2^{-1/2}(a^+(f) + a(\bar{f}))$ is essentially self-adjoint. Let $\psi(f)$ be its closure. The operator $W(f) = e^{i\psi(f)}$ is unitary and satisfies the identity

$$W(f_1)W(f_2) = W(f_1 + f_2) \exp(-i \operatorname{Im}(f_1, f_2)/2).$$

It also satisfies $(W(f)\Omega, \Omega) = \exp(-4^{-1}\|f\|^2)$.

Let K_{ϕ} be a real subspace of K such that the inner product (f, g) in K is real for any f and g in K_{ϕ} and $K = K_{\phi} + iK_{\phi}$. (K_{ϕ} is then a real Hilbert space.) The unitary operators $U(f) = W(f)$ and $V(f) = W(if)$ for $f \in K_{\phi}$ satisfy the following **Weyl form of the CCRs**:

$$U(f_1)U(f_2) = U(f_1 + f_2), \\ V(f_1)V(f_2) = V(f_1 + f_2), \\ U(f_1)V(f_2) = V(f_2)U(f_1) \exp(-i(f_1, f_2)).$$

The infinitesimal generators of the continuous one-parameter groups of unitaries $U(tf)$ and $V(tg)$ ($t \in \mathbb{R}$) are denoted by $\varphi(f)$ and $\pi(g)$ and satisfy the following CCRs:

$$[\varphi(f_1), \varphi(f_2)]\Psi = [\pi(g_1), \pi(g_2)]\Psi = 0, \\ [\varphi(f), \pi(g)]\Psi = i(f, g)\Psi,$$

where $[A, B] = AB - BA$ and $\Psi \in D_{\pm}$.

If Q is a linear operator on K , $\Gamma(Q)$ denotes the linear operator on $\mathcal{F}_\pm(K)$ defined as the closure of $\sum_{n=0}^{\infty} Q^{\otimes n} |D_\pm$. It is bounded if $\|Q\| \leq 1$. $\Gamma(Q_1)\Gamma(Q_2) = \Gamma(Q_1 Q_2)$ on D_\pm . If H is a self-adjoint operator on K , then $\Gamma(e^{iH}) = \exp i d\Gamma(H)$ defines a self-adjoint operator $d\Gamma(H)$ on $\mathcal{F}_\pm(K)$, usually called a **bilinear Hamiltonian** and denoted (a^\pm, Ha) . More explicitly,

$$d\Gamma(H)E_\pm^{(n)}f_1 \otimes \dots \otimes f_n = \sum_{j=1}^n E_\pm^{(n)}f_1 \otimes \dots \otimes Hf_j \otimes \dots \otimes f_n.$$

If U is a unitary operator on K , then

$$\Gamma(U)W(f)\Gamma(U)^{-1} = W(Uf).$$

B. Second Quantization

A single (scalar) particle in quantum mechanics is described by a wave function $\Psi(x)$, $x \in \mathbb{R}^3$, considered as a unit vector in a Hilbert space $K = L_2(\mathbb{R}^3)$. The system consisting of n such identical particles is described by a totally symmetric function $\Psi(x_1, \dots, x_n)$, $x_j \in \mathbb{R}^3$, considered as a unit vector in the totally symmetric part $E_+^{(n)}K^{\otimes n}$ of the n -fold tensor product of the one-particle Hilbert space K , where the restriction to totally symmetric wave functions is referred to as **Bose statistics**. In a non-relativistic system, the Hamiltonian operator on a 1-particle space is

$$T = -\hbar^2(2m)^{-1}\Delta_x,$$

called the kinetic energy (Δ_x denotes the Laplacian); on an n -particle space it is typically given by

$$H_n = -\hbar^2(2m)^{-1} \sum_{j=1}^n \Delta_{x_j} + \sum_{i < j}^n V(x_i - x_j),$$

where V is a 2-body potential.

The totality of multiparticle spaces $E_\pm^{(n)}K^{\otimes n}$ can be described in terms of the Fock space $\mathcal{F}_\pm(K)$, the vacuum vector Ω (no-particle state), and the annihilation and creation operators, denoted by

$$a(\bar{f}) = \int \Psi(x)\bar{f}(x)d^3x,$$

$$a^*(f) = \int \Psi^+(x)f(x)d^3x.$$

Since the CCRs (for operator-valued distributions)

$$[\Psi(x), \Psi(y)]_- = [\Psi^+(x), \Psi^+(y)]_- = 0,$$

$$[\Psi(x), \Psi^+(y)]_- = \delta^3(x - y)$$

are a continuous generalization of CCRs for canonical variables in quantum mechanics and since $\Psi(x)$ comes from the wave function by way of quantization, the above formalism is

called **second quantization**. The Hamiltonians H_n for all n can now be combined into the expression

$$H = \int \Psi^+(x)T\Psi(x)d^3x + \frac{1}{2} \int \Psi^+(x)\Psi^+(y)V(x-y) \times \Psi(x)\Psi(y)d^3x d^3y,$$

where the first term is $d\Gamma(T)$.

For particles such as electrons the system of n identical particles is described by a totally antisymmetric wave function, the total antisymmetry being referred to as **Fermi statistics**. Then the antisymmetric Fock space $\mathcal{F}_-(K)$ can be used in exactly the same manner as $\mathcal{F}_+(K)$ in the preceding case.

The method of second quantization was introduced by P. Dirac [2] for the case of bosons and extended by P. Jordan and E. Wigner [3] to fermions. Electromagnetic waves, when quantized in this way, represent a system of **photons**, and the quantization of electron waves leads to the particle picture of the **electron**. The method of second quantization is intimately connected with the notion of fields, as shown below for free fields, and is the basis of the perturbation approach in field theory (\rightarrow 150 Field Theory).

C. Free Fields

Let σ_j ($j = 1, 2, 3$) be \dagger Pauli spin matrices and $\sigma_0 = \begin{pmatrix} 1 & \\ & -1 \end{pmatrix}$. Let $\tilde{p} = \sum_{\mu=0}^3 \sigma_\mu p^\mu$ for a 4-vector $p = (p^0, \mathbf{p})$ with $\mathbf{p} = (p^1, p^2, p^3)$ and $p^0 = (m^2 + \mathbf{p}^2)^{1/2}$. Let $u_j(a, A)$ be the irreducible unitary representation $[m_+, j]$ of \mathcal{B}_+^\dagger on a Hilbert space $K_j = L_2(\mathbb{R}^3, \mathbb{C}^{2j}, (2p^0)^{-1}(m/\tilde{p})^{\otimes 2j} d^3\mathbf{p})$ (\rightarrow 258 Lorentz Group C (3)).

Consider first the symmetric Fock space $\mathcal{F}_+(K_0)$. For any complex-valued rapidly decreasing C^∞ -function f ($f \in \mathcal{S}(\mathbb{R}^4)$), let

$$\tilde{f}(\mathbf{p}) = (2\pi)^{-3/2} \int e^{i\mathbf{p} \cdot \mathbf{x}} f(x) d^4x \quad (p = (p^0, \mathbf{p}), \quad p^0 = (\mathbf{p}^2 + m^2)^{1/2}),$$

$$A(f) = a^+(\tilde{f}) + a(\bar{\tilde{f}}) \quad \left(= \int A(x)f(x)d^4x \right),$$

where $\mathbf{p} \cdot \mathbf{x} = p^0 x^0 - \sum_{j=1}^3 p^j x^j$ and the bar denotes the complex conjugate. Then $A(x)$ as an operator-valued distribution satisfies the \dagger Wightman axiom and is called the **free scalar field** of mass m . It satisfies the **Klein-Gordon equation**

$$(\square_x + m^2)A(x)\Psi = 0 \quad \left(\square_x = (\partial/\partial x^0)^2 - \sum_{j=1}^3 (\partial/\partial x^j)^2 \right),$$

it has the 4-dimensional scalar commutator

$$i[A(x), A(y)]_- \Psi = \Delta_m(x-y)\Psi,$$

and it has the two-point function

$$i(A(x)A(y)\Omega, \Omega) = \Delta_m^+(x-y).$$

Here Ψ is any vector in D_+ ; for example, Ω is the vacuum vector, and the **invariant distributions** Δ_m and Δ_m^+ are defined by

$$\Delta_m^+(x) = i(2\pi)^{-3} \int e^{-ip \cdot x} (2p^0)^{-1} d^3 p,$$

$$\Delta_m(x) = (2\pi)^{-3} \int (\sin p \cdot x) (p^0)^{-1} d^3 p.$$

If we define $U(a, \Lambda(A)) = \Gamma(u_0(a, A))$, then

$$U(a, \Lambda)A(x)U(a, \Lambda)^* = A(\Lambda x + a).$$

If $g \in \mathcal{S}(\mathbf{R}^3)$ and $h \in \mathcal{S}(\mathbf{R}^3)$, $\tilde{g}(\mathbf{p})$ and $\tilde{h}(\mathbf{p})$ obtained by substituting $g(\mathbf{x})\delta(x^0)$ and $-h(\mathbf{x})\delta'(x^0)$ into f in the defining equation of \tilde{f} above are in K_0 . We then define

$$\varphi(g) = a^+(\tilde{g}) + a(\tilde{\tilde{g}}) \quad \left(= \int \varphi(\mathbf{x})g(\mathbf{x})d^3 \mathbf{x} \right),$$

$$\pi(h) = a^+(\tilde{h}) + a(\tilde{\tilde{h}}) \quad \left(= \int \pi(\mathbf{x})h(\mathbf{x})d^3 \mathbf{x} \right).$$

The operator-valued distributions $\varphi(\mathbf{x})$ and $\pi(\mathbf{x})$ are the **canonical field** and its **conjugate field** at time 0 for the free scalar field and satisfy the following **canonical commutation relations**:

$$[\varphi(\mathbf{x}), \varphi(\mathbf{y})]_- \Psi = [\pi(\mathbf{x}), \pi(\mathbf{y})]_- \Psi = 0,$$

$$[\varphi(\mathbf{x}), \pi(\mathbf{y})]_- \Psi = i\delta^3(\mathbf{x} - \mathbf{y})\Psi.$$

If we set $T(t) \equiv U(te_0, 1)$ for $e_0 = (1, 0, 0, 0)$ and $(\alpha \otimes g)(x) = \alpha(x^0)g(\mathbf{x})$ for $\alpha \in \mathcal{S}(\mathbf{R})$ and $g \in \mathcal{S}(\mathbf{R}^3)$, then for $\Psi \in D_+$

$$A(\alpha \otimes g)\Psi = \int_{-\infty}^{\infty} T(t)\varphi(g)T(t)^*\Psi\alpha(t)dt,$$

$$-A(\alpha' \otimes g)\Psi = \int_{-\infty}^{\infty} T(t)\pi(g)T(t)^*\Psi\alpha(t)dt,$$

or, equivalently,

$$A(x) = T(x^0)\varphi(x)T(x^0)^*,$$

$$\partial A(x)/\partial x^0 = T(x^0)\pi(x)T(x^0)^*.$$

If $A(x)$ is a classical field, then $\varphi(\mathbf{x})$ and $\pi(\mathbf{x})$ are the value of $A(x)$ and its time derivative at $x^0 = 0$, and they serve as initial data for the Klein-Gordon equation

$$(\square_x + m^2)A(x) = 0.$$

Consider next the antisymmetric Fock space $\mathcal{F}_-(K_{1/2} \otimes K_{1/2})$. For $f_{\pm} \in \mathcal{S}(\mathbf{R}^4, \mathbf{C}^2)$ (\mathbf{C}^2 -valued rapidly decreasing \mathbf{C}^∞ -functions), write $f = (f_+, f_-)$, $f_+ = (f_1, f_2)$, $f_- = (f_3, f_4)$, define \tilde{f}_{\pm}

as before, and let

$$\begin{aligned} \psi(f) &= m^{1/2} \{ a(\tilde{f}_- + (\tilde{p}/m)\tilde{f}_+) \oplus 0 \\ &\quad + a^+(0 \oplus (\sigma_2 \tilde{f}_+ - (\tilde{p}/m)\sigma_2 \tilde{f}_-)) \} \\ &= \sum_{\alpha=1}^4 \int \psi_{\alpha}(x) f_{\alpha}(x) d^4 x, \end{aligned}$$

where $\sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} = -i\epsilon$. Then $\psi_{\alpha}(x)$ as an operator-valued distribution satisfies the $^+$ Wightman axiom and is called the **free Dirac field** of mass m . In the present formulation, $\{\psi_1, \psi_2\}$ is a contravariant spinor of rank (1, 0) and $\{\psi_3, \psi_4\}$ is a covariant spinor of rank (0, 1). This field satisfies the **Dirac equation**

$$\left(\sum_{\mu} \gamma^{\mu} (\partial/\partial x^{\mu}) + im \right) \psi(x) = 0,$$

as well as the relations

$$[\psi_{\alpha}(x), \psi_{\beta}(y)]_+ \Psi = 0,$$

$$[\psi_{\alpha}(x), \psi_{\beta}(y)^*]_+ \Psi$$

$$= \left\{ \left(\sum_{\mu} \gamma^{\mu} (\partial/\partial x^{\mu}) - im \right) \gamma^0 \right\}_{\alpha\beta} \Delta_m(x-y),$$

$$(\psi_{\alpha}(x)\psi_{\beta}(y)^*\Omega, \Omega)$$

$$= \left\{ \left(\sum_{\mu} \gamma^{\mu} (\partial/\partial x^{\mu}) - im \right) \gamma^0 \right\}_{\alpha\beta} \Delta_m^+(x-y).$$

Here $\Psi \in D_+$, Δ_m and Δ_m^+ are as described above, and the γ 's are **Dirac matrices** in the following form (somewhat different from but equivalent to the usual form; \rightarrow 351 Quantum Mechanics):

$$\gamma^0 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \gamma^j = \begin{pmatrix} 0 & -\sigma_j \\ \sigma_j & 0 \end{pmatrix},$$

and the σ 's are $^+$ Pauli spin matrices.

D. Coherent Vectors and Exponential Hilbert Space

In the symmetric Fock space $\mathcal{F}_+(K)$, a vector of the form

$$\exp f \equiv \Omega \oplus \sum_{n=1}^{\infty} (n!)^{-1/2} f^{\otimes n} \in \mathcal{F}_+(K)$$

for $f \in K$ is called a **coherent vector**. The set of $\exp f$ is linearly independent (in the algebraic sense) and total. The inner product is given by

$$(\exp f_1, \exp f_2) = \exp(f_1, f_2).$$

Conversely, we can define $\mathcal{F}_+(K)$ abstractly by introducing this inner product into the formal linear combinations of $\exp f$, $f \in K$, and by completion. In this sense, $\mathcal{F}_+(K)$ is also denoted as $\exp K$ and is called an **exponential Hilbert space** [5]. Then

$$\exp \sum^{\oplus} K_j = \otimes \exp K_j,$$

where $\exp \sum^{\oplus} f_j$ is identified with $\otimes \exp f_j$. If the number of indices is infinite, the right-hand side is the incomplete infinite tensor product containing the product of the vacuum vector Ω .

If $K = \int_{\Xi} K_{\lambda} d\mu(\lambda)$ and the measure μ is nonatomic, then for any measurable set S in Ξ , there corresponds a decomposition $\exp K = (\exp K(S)) \otimes (\exp K(S^c))$, where $K(S) = \int_S K_{\lambda} d\mu(\lambda)$ and S^c is the complement of S in Ξ , and an associated von Neumann algebra $R(S) = B(K(S)) \otimes 1$, where $B(K(S))$ is the set of all bounded linear operators on $K(S)$. The system $\{R(S)\}$ forms a complete Boolean lattice of type I factors on $\exp K$. Coherent vectors are characterized by the property of being a product vector for $\{R(S)\}$ in the sense that for any $S, A \in R(S)$ and $A' \in R(S^c)$, the vector $\Psi = \exp f$ satisfies

$$(AA'\Psi, \Psi) \|\Psi\|^2 = (A\Psi, \Psi)(A'\Psi, \Psi).$$

In this sense, we can interpret $\exp K$ as a **continuous tensor product** of $\exp K_{\lambda}$ and also, if $\Psi = \int \Psi_{\lambda} d\mu(\lambda)$, $\exp \Psi$ as a continuous tensor product of $\exp \Psi_{\lambda}$ [5].

378 (XII.14) Semigroups of Operators and Evolution Equations

A. Introduction

The analytical theory of semigroups was inaugurated around 1948 in order to define exponential functions in infinite-dimensional

function spaces. Then it was generalized to the theory of evolution equations as ordinary differential equations in infinite-dimensional linear spaces.

B. The Hille-Yosida Theorem

Let X be a locally convex topological linear space, and denote by $L(X)$ the totality of continuous linear operators defined on X with values in X . A family $\{T_t | t \geq 0\}$ of operators $T_t \in L(X)$ is called a **(one-parameter) semigroup of class (C^0)** or a **strongly continuous semigroup** if it satisfies the following two conditions: (i) $T_t T_s = T_{t+s}$ (the semigroup property), $T_0 = I$ (the identity operator); and (ii) $\lim_{t \rightarrow t_0} T_t x = T_{t_0} x$ ($\forall x \in X, \forall t_0 \geq 0$). When X is a Banach space, (ii) is implied by $w\text{-}\lim_{t \downarrow 0} T_t x = x$ ($\forall x \in X$), as proved by N. Dunford in 1938. In this case there exist constants $M > 0$ and $\beta \geq 0$ such that (iii) $\|T_t\| \leq M e^{\beta t}$ ($\forall t \geq 0$). Hence, considering $e^{-\beta t} T_t$ in place of T_t , we can assume the equicontinuity: (iii) For any continuous seminorm p on X , there exists a continuous seminorm q on X such that $p(T_t x) \leq q(x)$ ($\forall x \in X, \forall t \geq 0$). Such semigroups are called **equicontinuous semigroups of class (C^0)** (abbreviated e.c.s.g. (C^0)).

Example 1. $X = L_p(0, \infty)$ with $\infty > p \geq 1$.

$$(T_t x)(s) = x(t + s).$$

Example 2. $X = L_p(-\infty, \infty)$ with $\infty > p \geq 1$.

$$(T_t x)(s) = (2\pi t)^{-1/2} \int_{-\infty}^{\infty} \exp\left(\frac{(s-u)^2}{2t}\right) x(u) du, \quad t > 0,$$

$$= x(s), \quad t = 0.$$

Example 3. $X = BC(-\infty, \infty)$.

$$(T_t x)(s) = e^{-\lambda t} \sum_{k=0}^{\infty} \frac{(\lambda t)^k}{k!} x(s - k\mu), \quad t \geq 0.$$

Here λ and μ are positive constants. (For these examples, we have $\|T_t\| \leq 1$; hence (iii) is satisfied.) For L_p and $BC \rightarrow$ 168 Function Spaces.

We assume in the remainder of the article that X is sequentially complete, that is, if a sequence $\{x_n\}$ of X satisfies $\lim_{n, m \rightarrow \infty} p(x_n - x_m) = 0$ for every continuous seminorm p on X , then there exists a unique $x \in X$ such that $\lim_{n \rightarrow \infty} p(x - x_n) = 0$.

The **infinitesimal generator** A of an e.c.s.g. (C^0) $\{T_t | t \geq 0\}$ is defined by

$$Ax = \lim_{t \downarrow 0} t^{-1} (T_t - I)x. \tag{1}$$

(This is also called the **generator** of T_t .) Then we have the following results.

(I) Differentiability theorem. For every complex number λ with $\text{Re } \lambda > 0$, the resolvent $(\lambda I - A)^{-1} \in L(X)$ exists and

$$(\lambda I - A)^{-1}x = \int_0^\infty e^{-\lambda t} T_t x dt \quad (\forall x \in X), \quad (2)$$

where the integration is Riemannian. Hence the domain $D(A)$ of A is dense in X and coincides with the range $R((\lambda I - A)^{-1})$, and A is a closed linear operator such that the family

$$\{(\lambda(\lambda I - A)^{-1})^n | \lambda > 0, n = 0, 1, 2, \dots\} \quad (3)$$

is equicontinuous.

(II) Representation theorem. Let $J_n = (I - n^{-1}A)^{-1}$ and consider the approximations to T_t :

$$T_t^{(n)}x = e^{-nt} \sum_{m=0}^\infty (m!)^{-1} (nt J_n)^m x,$$

$$\hat{T}_t^{(n)}x = (J_{nt})^n x.$$

Then

$$T_t x = \lim_{n \rightarrow \infty} T_t^{(n)}x = \lim_{n \rightarrow \infty} \hat{T}_t^{(n)}x \quad (5)$$

uniformly on every compact set of t .

(III) Converse theorem. Let a linear operator A with both dense domain $D(A)$ and range $R(A)$ in X satisfy the condition $(nI - A)^{-1} \in L(X)$ for $n = 1, 2, \dots$. Then a necessary and sufficient condition for A to be the infinitesimal generator of an e.c.s.g. (C^0) is that the family of operators

$$\{(I - n^{-1}A)^{-m} | n = 1, 2, \dots; m = 0, 1, \dots\} \quad (3')$$

be equicontinuous. Since such a semigroup $\{T_t | t \geq 0\}$ is uniquely determined by A , we can write $T_t = \exp(tA)$.

These three theorems together are called the **Hille-Yosida theorem** or the Hille-Yosida-Feller-Phillips-Miyadera theorem.

Examples of Infinitesimal Generators. $A = d/ds$ for example 1 above, $A = 2^{-1}d^2/ds^2$ for example 2, and $(Ax)(s) = \lambda(x(s - \mu) - x(s))$ for example 3.

C. Groups

An operator A in a Hilbert space X generates a group $\{T_t | -\infty < t < \infty\}$ of unitary operators of class (C^0) satisfying $T_t T_s = T_{t+s}$ for $-\infty < t, s < \infty$ if and only if A is equal to iH for some self-adjoint operator H (M. H. Stone's theorem, 1932). In a locally convex space, a necessary and sufficient condition for a given e.c.s.g. (C^0) $\{T_t | t \geq 0\}$ to be extended to an equicontinuous group of class (C^0) $\{T_t | -\infty < t < \infty\}$ is that the family (3') be equicontinuous also for $n = \pm 1, \pm 2, \dots$

D. Holomorphic Semigroups

For an e.c.s.g. (C^0) $\{T_t | t \geq 0\}$, the following three conditions are equivalent (K. Yosida, 1963; the equivalence between (ii) and (iii) for Banach spaces was proved earlier by E. Hille, 1948): (i) When $t > 0$,

$$T_t' x = \lim_{h \rightarrow 0} h^{-1} (T_{t+h} - T_t)x$$

exists for all $x \in X$ and $\{(CtI_t^n) | n = 1, 2, \dots$ and $0 < t \leq 1\}$ is equicontinuous for a certain constant $C > 0$. (ii) When $t > 0$, T_t admits a convergent expansion T_λ given locally by $T_\lambda x = \sum_{n=0}^\infty (\lambda - t)^n T_t^{(n)}x/n!$. The extension exists for $|\arg \lambda| \leq \arctan(Ce^{-1})$, and the family of operators $\{e^{-\lambda} T_\lambda\}$ is equicontinuous in λ for $|\arg \lambda| \leq \arctan(2^{-k}Ce^{-1})$ with some positive constant k . (iii) For the infinitesimal generator A of T_t , there exists a positive constant C_1 such that $\{(C_1 \lambda(\lambda I - A)^{-1})^n\}$ is equicontinuous in $n = 1, 2, \dots$ and in λ with $\text{Re}(\lambda) \geq 1 + \epsilon$, $\epsilon > 0$. An e.c.s.g. (C^0) $\{T_t\}$ satisfying the above conditions is called a **holomorphic semigroup**.

For example, introduce

$$f_{t,\alpha}(\lambda) = (2\pi i)^{-1} \int_{\sigma-i\infty}^{\sigma+i\infty} e^{z\lambda - tz^\alpha} dz, \\ \lambda \geq 0, \quad t > 0, \quad \sigma > 0, \quad 0 < \alpha < 1, \\ = 0, \quad \lambda < 0, \quad (6)$$

where the branch of z^α is taken so that $\text{Re } z^\alpha > 0$ for $\text{Re } z > 0$. Following S. Bochner (1949), we define

$$\hat{T}_{t,\alpha}x = \hat{T}_t x = \int_0^\infty f_{t,\alpha}(s) T_s x ds, \quad t > 0, \\ = x, \quad t = 0, \quad (7)$$

from a given e.c.s.g. (C^0) $\{T_t | t \geq 0\}$. Then $\{\hat{T}_{t,\alpha} | t \geq 0\}$ is a holomorphic semigroup (Yosida, T. Kato, and A. V. Balakrishnan, 1960). Its infinitesimal generator \hat{A}_α can be considered as the **fractional power** $(-A)^\alpha$ of $-A$, multiplied by -1 .

Fractional powers $(-A)^\alpha$, $\alpha \in \mathbb{C}$, of operators have also been defined for operators A satisfying the weaker condition than (3') that $\{\lambda(\lambda - A)^{-1} | \lambda > 0\}$ is equicontinuous (Balakrishnan, H. Komatsu). If A is such an operator, $-\sqrt{-A}$ generates a holomorphic semigroup and the unique uniformly bounded solution of the "elliptic" equation

$$x_t'' = -Ax_t, \quad t > 0, \quad \lim_{t \rightarrow 0} x_t = x_0 \quad (8)$$

is the solution of

$$x_t' = -\sqrt{-A} x_t, \quad t > 0, \quad \lim_{t \rightarrow 0} x_t = x_0,$$

and therefore $x_t = \exp(-t\sqrt{-A})x_0$ (Balakrishnan). Equation (8) has also been discussed by

M. Sova and H. O. Fattorini from a different point of view.

E. Convergence of Semigroups

Let a sequence $\{\exp(tA_n) | n = 1, 2, \dots\}$ of e.c.s.g. (C^0) be equicontinuous as a family of operators $\in L(X)$. Then a necessary and sufficient condition for there to exist an e.c.s.g. (C^0) $\exp(tA)$ such that $\lim_{n \rightarrow \infty} (\exp(tA_n))x = (\exp(tA))x$ uniformly on every compact interval of t is that $\lim_{n \rightarrow \infty} (\lambda_0 I - A_n)^{-1} x = J_{\lambda_0} x$ exist (for some λ_0 with $\text{Re } \lambda_0 > 0$ and for all $x \in X$) and be such that $R(J_{\lambda_0})$ is dense in X (H. F. Trotter, Kato).

F. Miscellaneous Semigroups

(i) **Distribution semigroups.** The semigroup of translations $(T_t x)(s) = x(t+s)$ in $X = L_\infty(-\infty, \infty)$ is not continuous and hence not measurable in t . However, $T_t x$ is an X -valued distribution. For semigroups $\{T_t\}$ such that $T_t x$ is an X -valued distribution for $x \in X$, an analog of the Hille-Yosida theorem is known (J.-L. Lions, 1960). It has been generalized to ultradistribution semigroups by J. Chazarain and to hyperfunction semigroups by S. Ōuchi.

(ii) **Dual semigroups.** The above semigroup $\{T_t\}$ of translations in $L_\infty(-\infty, \infty)$ is obtained as $T_t = S_t^*$ from the e.c.s.g. (C^0) $\{S_t\}$ defined by $(S_t x)(s) = x(s-t)$ in $L_1(-\infty, \infty)$. Let $B = d/ds$ be the infinitesimal generator of $\{S_t\}$. The restriction of $\{S_t^*\}$ to the space of uniformly continuous functions, which is the closure of the domain $D(B^*)$ of the dual B^* in $L_\infty(-\infty, \infty)$, is an e.c.s.g. (C^0) . This fact holds for the semigroup $\{S_t^*\}$ of an e.c.s.g. (C^0) $\{S_t\}$ in a Banach space X in general (R. Phillips, 1955) and also in a locally convex space.

(iii) **Locally equicontinuous semigroups.** The infinitesimal generator A of the semigroup of translations $(T_t x)(s) = x(t+s)$ in $X = C(-\infty, \infty)$ is d/ds . A has no resolvent since all complex numbers are eigenvalues of A . $\{T_t\}$ is not equicontinuous but locally equicontinuous, i.e., $\{T_t | 0 \leq t \leq t_1\}$ is equicontinuous for any $t_1 > 0$. For locally equicontinuous (C^0) semigroups an analog of the Hille-Yosida theorem is obtained by using the notion of generalized resolvents (T. Kōmura, 1968; Ōuchi, 1973).

(iv) **Differentiable semigroups.** The notion of the holomorphy of semigroups in Section D is weakened to the differentiability. A characterization of a semigroup $\{T_t\}$ such that $T_t x$ is infinitely differentiable in $t > 0$ is given by using the resolvent of the infinitesimal generator (A. Pazy, 1968).

(v) **Nonlinear semigroups.** For a (C^0) semigroup $\{T_t\}$ of contractions (i.e., $\|T_t x - T_t y\| \leq$

$\|x - y\|$ for $x, y \in X$) in a Hilbert space X , an analog of the Hille-Yosida theorem is known (Y. Kōmura, 1969). This result has been partially extended to Banach spaces (\rightarrow 286 Non-linear Functional Analysis X).

G. The Evolution Equation

Let $T_t = \exp(tA)$ be an e.c.s.g. (C^0) . Then for $x \in D(A)$,

$$T_t' x = AT_t x (= T_t Ax). \tag{9}$$

Considered in suitable function spaces, the †equation of heat conduction ($A = \Delta =$ the †Laplacian), the †Schrödinger equation ($A = \sqrt{-1}(\Delta - V(x))$), and the †wave equation given in matrix form

$$\begin{pmatrix} u \\ v \end{pmatrix}' = \begin{pmatrix} u' \\ v' \end{pmatrix} = \begin{pmatrix} 0 & I \\ \Delta & 0 \end{pmatrix} \begin{pmatrix} u \\ v \end{pmatrix}$$

are all of the form (9). For a linear operator A_t in X depending on t , the ordinary differential equation in X

$$x_t' = A_t x_t + f(t), \quad t \geq 0, \tag{10}$$

is called the **evolution equation**. A family of operators $\{V(r, s) | r \geq s \geq 0\}$ in X which gives general solutions to the homogeneous evolution equation

$$x_t' = A_t x_t \tag{11}$$

(i.e., for any $s \geq 0, a \in D(A_s), x_t = V(t, s)a$ is a solution to (11) for $x_s = a$) is called the **evolution operator** associated with the generators $\{A_t\}$. An evolution operator $\{V(r, s)\}$ satisfies (i) $V(r, r) = I$, (ii) $V(r, s)V(s, t) = V(r, t)$. The solution to (10) is formally expressed by

$$x_t = V(t, 0)x_0 + \int_0^t V(t, s)f(s)ds. \tag{12}$$

H. Integration of the Evolution Equation

For equation (11) we have the following result (Kato, 1953; Yosida, 1966). Assume the following four conditions: (i) $D(A_t)$ is independent of t and dense in the Banach space X , and for all $\alpha > 0, (I - \alpha A_t)^{-1} \in L(X)$ with the estimate $\|(I - \alpha A_t)^{-1}\| \leq 1$; (ii) $B_{t,s} = (I - A_t)(I - A_s)^{-1}$ is uniformly bounded in the norm for $0 \leq s, t \leq l$; (iii) $\sum_{j=0}^{n-1} \|B_{t_{j+1}, t_0} - B_{t_j, t_0}\| \leq N$, where N is independent of the partition $(0 = t_0 < t_1 < \dots < t_n = l)$; (iv) $B_{t,0}$ is weakly differentiable with respect to t such that the differentiated operator $\partial B_{t,0} / \partial t$ is strongly continuous in t . Under these assumptions, we can prove that for $x_0 \in D(A_0)$, the limit $V(t, 0)x_0 = s\text{-}\lim_{k \rightarrow \infty} V_k(t, 0)x_0$,

with

$$V_k(t, s) = \left(I - \left(t - \frac{[kt]}{k} \right) A \left(\frac{[kt]}{k} \right) \right)^{-1} \\ \times \left(I - \frac{1}{k} A \left(\frac{[kt] - 1}{k} \right) \right)^{-1} \\ \times \dots \times \left(I - \frac{1}{k} A \left(\frac{[ks] + 1}{k} \right) \right)^{-1} \\ \times \left(I - \left(\frac{[ks] + 1}{k} - s \right) A \left(\frac{[ks]}{k} \right) \right)^{-1}$$

($0 \leq s \leq t \leq l$), exists and gives the unique solution of (11). If $f(t)$ is continuously differentiable, the right-hand side of (12) exists and gives a unique solution to the inhomogeneous equation (10).

I. The Evolution Equation of Parabolic Type

Equation (10), for which every A_t is the infinitesimal generator of a holomorphic semigroup, is said to be of **parabolic type** by analogy to parabolic partial differential equations. Under weaker conditions, especially without the condition that $D(A_t)$ is independent of t , the existence of solutions of an equation of this type is obtained. Moreover, differentiability or analyticity of solutions follow from some natural assumptions.

(i) Existence of weak solutions. Let X be a Hilbert space. For $t \in [0, l]$, let V_t be a subspace and at the same time a Hilbert space with respect to a norm $\|\cdot\|_t$, stronger than $\|\cdot\|$. Since the form $(A_t x, y)$ is sesquilinear (linear in x and antilinear in y), we get a sesquilinear functional $a(t, \cdot, \cdot)$ on $V_t \times V_t$ such that

$$a(t, x, y) = -(A_t x, y), \quad x, y \in D(A_t),$$

if $D(A_t)$ is dense in V_t with respect to $\|\cdot\|_t$ and if

$$|a(t, x, y)| \leq C \|x\|_t \|y\|_t, \quad x, y \in D(A_t).$$

$V_t, a(t, \cdot, \cdot)$ should be measurable in a certain sense. A solution x_t of the equation (10) in $[0, l]$ satisfies

$$\int_0^t a(t, x_t, v_t) dt - \int_0^t (x_t, v_t) dt \\ = \int_0^t (f(t), v_t) dt + (x_0, v_0) \quad (13)$$

for any differentiable X -valued function v_t such that $v_t \in V_t, v_t = 0, \int_0^t \|v_t\|^2 dt < \infty$, and $\int_0^t \|v_t'\|^2 dt < \infty$. A solution x_t of (13) is called a **weak solution** of equation (10), though it does not necessarily satisfy (10). If the relation

$$a(t, x, x) + \lambda \|x\|^2 \geq \alpha \|x\|_t, \quad x \in V_t,$$

holds for some $\lambda, \alpha > 0$, a weak solution of (10) in the sense of (13) exists for a given $x_0 \in X$

(Lions, 1961). In order to obtain the uniqueness or the differentiability of weak solutions, we need some additional conditions.

(ii) Some properties of strong solutions. Let X be a Banach space. Let every semigroup $\{T_t^\alpha\}$ generated by A_t be holomorphic in a complex sector $|\arg \lambda| \leq \theta, \theta > 0$, independent of t . Suppose one of the following conditions holds: (1) For some $\alpha, 0 < \alpha < 1, D(A_t^\alpha)$ is independent of t and for $1 - \alpha < \beta < 1$,

$$\|(A_t^\alpha - A_s^\alpha) A_0^{-\alpha}\| \leq C |t - s|^\beta, \quad t, s \in [0, 1]$$

(P. E. Sobolevskii, 1958–1961; Kato, 1961);

(2) A_t^{-1} is differentiable in t ,

$$\|dA_t^{-1}/dt - dA_s^{-1}/ds\| \leq C |t - s|^\beta$$

for some $C' > 0, 0 < \beta \leq 1$, and

$$\left\| \frac{\partial}{\partial t} (A_t - \lambda)^{-1} \right\| \leq \frac{N}{|\lambda|^\alpha}$$

for every $\lambda: |\arg \lambda| \geq \pi/2 - \theta$ for some $N, 0 < \alpha < 1$ (Kato and H. Tanabe, 1962). Then a differentiable evolution operator $\{V(t, s)\}$ associated with (11) exists.

The most interesting property of evolution equations of parabolic type is the analyticity of solutions. If A_t is holomorphic in t in a certain sense, then the solutions are holomorphic (Tanabe, 1967; first noted by Komatsu, 1961). Furthermore, a characterization of evolution operators $\{V(t, s)\}$ holomorphic in some complex neighborhood of $[0, l]$ (called **holomorphic evolution operators**) is obtained by using the resolvent of A_t (Kato and Tanabe, 1967; K. Masuda, 1972; → [8]).

J. Application to Semilinear Evolution Equations

The evolution equation with a nonlinear additive term $f(t, x_t): x_t' = A_t x_t + f(t, x_t)$ can be written as an inhomogeneous integral equation $x_t = V(t, 0)x_0 + \int_0^t V(t, s)f(s, x_s) ds$ in the Banach space X , by means of the evolution operator $\{V(t, s)\}$ introduced in Section G. The existence, differentiability (Kato, H. Fujita, and Sobolevskii, 1963–1966), and analyticity (Masuda, 1967) of solutions of the Navier-Stokes equation has been obtained by reducing it to an integral equation of this type.

Concerning quasilinear equations in which A_t depends on x_t , the existence, differentiability, and analyticity of their solutions have been discussed.

379 (X.18) Series

A. Convergence and Divergence of Infinite Series

Let $\{a_n\}$ ($n=1, 2, 3, \dots$) be a sequence of real or complex numbers. Then the formal infinite sum $a_1 + a_2 + \dots$ is called an **infinite series** (or **series**) and is denoted by $\sum_{n=1}^{\infty} a_n$ or $\sum a_n$. The number a_n is the n th **term** of the series $\sum a_n$, and $s_n = a_1 + a_2 + \dots + a_n$ is the n th **partial sum** of $\sum a_n$. Also, for a finite sequence a_1, a_2, \dots, a_n , the sum $a_1 + a_2 + \dots + a_n$ is called a series. To distinguish these two series, the latter is called a **finite series**. In this article, *series* means an infinite series. If the sequence of partial sums $\{s_n\}$ †converges to s , we say that the series $\sum a_n$ **converges** or is **convergent** to the **sum** s and write $\sum_{n=1}^{\infty} a_n = s$ or $\sum a_n = s$. If the sequence $\{s_n\}$ is not convergent, we say that the series **diverges** or is **divergent**. In particular, if $\{s_n\}$ is divergent to $+\infty$ ($-\infty$) or †oscillating, we say that the series is **properly divergent** to $+\infty$ ($-\infty$) or **oscillating**, respectively.

The notation $\sum a_n$ is customarily used for both the sum s of the convergent series and the formal series, which may or may not be convergent. When the series is convergent, the sum is sometimes called the **Cauchy sum** in contrast to the “summations” of series, which are not necessarily convergent (\rightarrow Sections K ff.).

Applying the †Cauchy criterion for the convergence of a sequence, we see that a necessary and sufficient condition for $\sum a_n$ to be convergent is that for any given $\varepsilon > 0$, we can take N sufficiently large so that

$$|s_m - s_n| = |a_{n+1} + \dots + a_m| < \varepsilon$$

for all m, n such that $m > n > N$. Hence if $\sum a_n$

converges, the $a_n \rightarrow 0$ as $n \rightarrow \infty$, but the converse is not always true.

Elementary properties of the convergence of series are: (1) If $\sum a_n$ and $\sum b_n$ converge to a, b , respectively, then $\sum (a_n + b_n)$ converges to $a + b$. (2) If $\sum a_n$ converges to a , then $\sum ca_n$ converges to ca for any constant c . (3) Suppose that $\{b_m\}$ is a subsequence of $\{a_n\}$ obtained by deleting a finite number of terms a_n from $\{a_n\}$. Then $\sum b_m$ is convergent if and only if $\sum a_n$ is convergent. (4) When a series $\sum a_n$ converges to a and $\{b_m\}$ is a sequence such that $b_1 = a_1 + a_2 + \dots + a_{r_1}$, $b_2 = a_{r_1+1} + a_{r_1+2} + \dots + a_{r_2}$, $b_3 = a_{r_2+1} + \dots + a_{r_3}$, \dots , then $\sum b_m$ also converges to a . The converse, however, is not always true. For example, $1 - 1 + 1 - 1 + \dots$ is oscillating, but $(1 - 1) + (1 - 1) + \dots = 0$.

B. Series of Positive Terms

Suppose that $\sum a_n$ is a **series of positive** (or **nonnegative**) terms. Since its partial sums s_n form a †monotonically increasing sequence, the series is convergent if and only if $\{s_n\}$ is bounded. For example, the series $\sum_{n=1}^{\infty} n^{-p}$ ($p > 0$) converges if $p > 1$ because $s_n < 2^{p-1} / (2^{p-1} - 1)$, whereas it diverges if $p \leq 1$ because $s_{2^{m+1}} > 1 + (m+1)/2$. The **geometric series** $\sum_{n=1}^{\infty} a^{n-1}$ ($a > 0$) converges for $a < 1$ because $s_n = (1 - a^n) / (1 - a)$, and diverges for $a \geq 1$ because $s_n \geq n$.

Some criteria for the convergence of a series $\sum a_n$ of nonnegative terms are: (1) If $\{a_n\}$ is monotone decreasing, then the series $\sum a_n$ and $\sum 2^n a_{2^n}$ have the same convergence behavior (**Cauchy's condensation test**). (2) Suppose that $f(x)$ is a positive monotone decreasing function defined for $x \geq 1$ such that $f(n) = a_n$ ($n = 1, 2, \dots$). Then the series $\sum a_n$ and the integral $\int_1^{\infty} f(x) dx$ have the same convergence behavior (**Cauchy's integral test**), for example, $\sum n^{-p}$ ($p > 0$) and $\int_1^{\infty} x^{-p} dx$. (3) If for any positive constant k we have $a_n \leq kb_n$ except for a finite number of n , then the convergence of $\sum b_n$ implies the convergence of $\sum a_n$. If $kb_n \leq a_n$ and $\sum b_n$ diverges, then $\sum a_n$ also diverges (**comparison test**). (4) Let $a_n > 0$ and $b_n > 0$. If $a_{n+1}/a_n \leq b_{n+1}/b_n$ except for a finite number of values of n and $\sum b_n$ converges, then $\sum a_n$ also converges; if $a_{n+1}/a_n \geq b_{n+1}/b_n$ and $\sum b_n$ diverges, then $\sum a_n$ also diverges (\rightarrow Appendix A, Table 10).

C. Absolute Convergence and Conditional Convergence

A series $\sum a_n$ (with real or complex terms a_n) is called **absolutely convergent** if the series $\sum |a_n|$ is convergent. If a convergent series is not

absolutely convergent, then it is called **conditionally convergent**. An absolutely convergent series is convergent. A real series $\sum a_n$ whose terms have alternating signs is called an **alternating series**. An alternating series $\sum a_n$ is convergent if the absolute values of terms $|a_n|$ form a monotone decreasing sequence which converges to zero (**Leibniz's test**). An absolutely convergent series remains absolutely convergent under every rearrangement of terms and retains its sum under the rearrangement (**Dirichlet's theorem**). If a series with real terms is conditionally convergent, then it is possible to rearrange its terms so that the rearranged series converges to any given number, diverges to $+\infty$ (or $-\infty$), or is oscillating (**Riemann's theorem**). A convergent series whose convergence behavior is unaffected by rearrangement and whose sum remains unchanged is called **unconditionally convergent** (or **commutatively convergent**). A real or complex series is unconditionally convergent if and only if it is absolutely convergent. The notion of infinite series can be extended to any complete normed linear space, and absolute convergence can be defined by replacing the absolute values of the terms by the norm of the terms. However, in general, unconditional convergence is not always equivalent to absolute convergence.

D. Abel's Partial Summation

Let $\{a_0, a_1, a_2, \dots\}$ and $\{b_0, b_1, b_2, \dots\}$ be arbitrary sequences, and put $A_n = a_0 + a_1 + \dots + a_n$ for $n \geq 0$. Then the following formula of **Abel's partial summation** holds:

$$\sum_{v=n+1}^{n+k} a_v b_v = \sum_{v=n+1}^{n+k} A_v (b_v - b_{v+1}) - A_n b_{n+1} + A_{n+k} b_{n+k-1}$$

for any $n \geq 0$ and any $k \geq 1$; this formula also holds for $n = -1$ if we put $A_{-1} = 0$.

Abel's partial summation enables us to deduce a number of tests of convergence for series of the form $\sum a_n b_n$. In particular, the following criteria are easy to apply:

- (1) $\sum a_n b_n$ is convergent if $\sum a_n$ is convergent and if the sequence $\{b_n\}$ is monotone and bounded (**Abel's test**).
- (2) $\sum a_n b_n$ is convergent if the sequence $\{s_n\}$ of partial sums of $\sum a_n$ is bounded and if $\{b_n\}$ is monotone and converges to zero (**Dirichlet's test**).
- (3) $\sum a_n b_n$ is convergent if $\sum (b_n - b_{n+1})$ is absolutely convergent and if $\sum a_n$ is (at least conditionally) convergent (**test of du Bois-Reymond and Dedekind**).

For example, criterion (2) implies that if $\{b_n\}$

is monotone and converges to zero, then the power series $\sum b_n z^n$ of a complex variable z is convergent on the unit circle $|z| = 1$ except at most for $z = 1$; the case $z = -1$ gives Leibniz's test for alternating series (\rightarrow Section C).

E. Double Series

A sequence with two indices, i.e., a mapping from the Cartesian product $\mathbb{N} \times \mathbb{N}$ of two copies of the set of natural numbers \mathbb{N} to a subset of the real or complex numbers, is called a **double sequence** and is denoted by $\{a_{mn}\}$ or $\{a_{m,n}\}$. If there exists a number l such that for any positive ϵ there is a natural number $N(\epsilon)$ satisfying $|a_{mn} - l| < \epsilon$ for all $m > N(\epsilon)$ and $n > N(\epsilon)$, then we say that the sequence $\{a_{mn}\}$ has a limit l and write $\lim_{m \rightarrow \infty, n \rightarrow \infty} a_{mn} = l$. This limit should not be confused with repeated limits such as $\lim_{n \rightarrow \infty} (\lim_{m \rightarrow \infty} a_{mn})$. If $\lim_{m \rightarrow \infty} a_{mn} = \alpha_n$ uniformly in n and $\lim_{n \rightarrow \infty} \alpha_n = l$, then $\lim_{m \rightarrow \infty, n \rightarrow \infty} a_{mn} = l$. For a given double sequence $\{a_{mn}\}$, the formal series $\sum_{m,n=1}^{\infty} a_{mn}$ is called a **double series** and is sometimes denoted by $\sum a_{mn}$. In contrast with double series, the ordinary series discussed previously is called a **simple series**.

Given a double series $\sum a_{mn}$, when the double sequence of partial sums $s_{mn} = \sum_{k=1}^m \sum_{l=1}^n a_{kl}$ is convergent to s , then $\sum a_{mn}$ is said to be **convergent** to the **sum** s . On the other hand, if s_{mn} is not convergent, $\sum a_{mn}$ is said to be **divergent**. If $\sum_{n=1}^{\infty} a_{mn}$ converges to b_m for each m , then $\sum_{m=1}^{\infty} b_m = \sum_{m=1}^{\infty} (\sum_{n=1}^{\infty} a_{mn})$ is called the **repeated** (or **iterated**) **series by rows**. If $\sum_{m=1}^{\infty} a_{mn}$ converges to c_n for each n , then $\sum_{n=1}^{\infty} c_n = \sum_{n=1}^{\infty} (\sum_{m=1}^{\infty} a_{mn})$ is called the **repeated** (or **iterated**) **series by columns**. Even if two repeated series by rows and columns are convergent, the two sums are not always identical, and $\sum a_{mn}$ is not always convergent. However, if the double series $\sum a_{mn}$ is convergent and $\sum_n a_{mn}$ is convergent for each m , then the repeated series by rows is convergent to the same sum. A similar statement is valid for the repeated series by columns.

Suppose that we are given a double series $\sum a_{mn}$ of nonnegative terms. If any one of $\sum_{m,n} a_{mn}$, $\sum_m \sum_n a_{mn}$, and $\sum_n \sum_m a_{mn}$ is convergent, the other two converge to the same sum. If the **diagonal partial sum** $s_{mm} = \sum_{k=1}^m \sum_{l=1}^m a_{kl}$ converges to a , then the double series $\sum a_{mn}$ also converges to a .

If $\sum |a_{mn}|$ converges, the double series $\sum a_{mn}$ is called **absolutely convergent**, whereas if $\sum a_{mn}$ converges but not absolutely, then $\sum a_{mn}$ is called **conditionally convergent**. If $\sum a_{mn}$ is absolutely convergent, then any series obtained from $\sum a_{mn}$ by arranging the terms in an arbitrary order is convergent to the same sum.

F. Multiplication of Series

The series $\sum_{n=1}^{\infty} c_n$, where $c_n = a_1 b_n + a_2 b_{n-1} + \dots + a_n b_1$, is called the **Cauchy product** of two series $\sum_{n=1}^{\infty} a_n$ and $\sum_{n=1}^{\infty} b_n$. (1) Let $\sum a_n$ and $\sum b_n$ be two convergent series and A, B be the sums of these series. If their Cauchy product $\sum c_n$ is also convergent, then it has the sum $C = AB$ (**Abel's theorem**). (2) If at least one of the two convergent series $\sum a_n$ and $\sum b_n$ with the sums A, B , respectively, is absolutely convergent, then their Cauchy product $\sum c_n$ is also convergent and has the sum $C = AB$ (**Mertens's theorem**). (3) If $\sum a_n$ and $\sum b_n$ are absolutely convergent, then their Cauchy product $\sum c_n$ is absolutely convergent (**Cauchy's theorem**). (4) Let $\sum a_n$ and $\sum b_n$ be two convergent series with the sums A, B , respectively. If $\{na_n\}$ and $\{nb_n\}$ are bounded from below, then $\sum c_n$ is convergent and has the sum $C = AB$ (**Hardy's theorem**).

G. Infinite Product

Let $\{a_n\}$ be a given sequence with terms $a_n \neq 0$ ($n = 1, 2, \dots$). The formal **infinite product** $a_1 \cdot a_2 \cdot a_3 \cdot \dots$ is denoted by $\prod_{n=1}^{\infty} a_n$. We call $p_n = a_1 \cdot a_2 \cdot \dots \cdot a_n$ its n th **partial product**. If the sequence $\{p_n\}$ is convergent to a nonzero limit p , then this infinite product is said to **converge** to p , and p is called the **value** of the infinite product. We write $\prod a_n = p$. If $\{p_n\}$ is not convergent or is convergent to 0, then the infinite product is called **divergent**. Sometimes we consider the infinite product $\prod a_n$ with $a_n = 0$ for a finite number of n 's; and then by convergence or divergence of $\prod a_n$ we mean that of the infinite product $\prod a'_n$, where the sequence $\{a'_n\}$ is obtained by deleting zero terms from $\{a_n\}$. Usually we do not treat an infinite product with $a_n = 0$ for an infinite number of n 's.

A necessary and sufficient condition for $\prod_{n=1}^{\infty} a_n$ to be convergent is that for any positive ε there is a number N such that $|p_m/p_n - 1| < \varepsilon$ for all $n, m > N$. If $\prod a_n$ converges, then $a_n \rightarrow 1$, but the converse is not always true.

It is often convenient to write an infinite product as $\prod(1 + a_n)$. Then $\prod(1 + a_n)$ and $\sum \log(1 + a_n)$ have the same convergence behavior, where the imaginary part $i\theta$ of the logarithm is assumed to satisfy $0 \leq |\theta| < \pi$. If $a_n \geq 0$, convergence of $\prod(1 + a_n)$ implies convergence of $\sum a_n$, and vice versa.

If $\prod(1 + |a_n|)$ converges, then $\prod(1 + a_n)$ is said to be **absolutely convergent**. An absolutely convergent infinite product is also convergent, and the value of the infinite product is unchanged by the alteration of the order of terms.

H. Termwise Differentiation of Infinite Series with Function Terms

Uniform convergence of an infinite series $\sum f_n(x)$ is defined by uniform convergence of the sequence of the partial sums $\sum_{k=1}^n f_k(x)$ (\rightarrow 435 Uniform Convergence). If the infinite series $\sum f_n(x)$ defined on an interval I of the real line is convergent at least at one point of I and $\sum f'_n(x)$ is convergent uniformly in I when the derivatives $f'_n(x)$ exist, then $\sum f_n(x)$ is convergent to $f(x)$ uniformly in I , and $\sum f_n(x)$ is **termwise differentiable**, that is, $f'(x) = \sum f'_n(x)$. If the $\varphi_n(z)$ are holomorphic in a complex domain D and $\sum \varphi_n(z)$ converges to $\varphi(z)$ uniformly on every compact subset of D , then $\sum \varphi'_n(z)$ also converges to $\varphi'(z)$ uniformly on every compact subset of D (**Weierstrass's theorem of double series**). (For termwise integration \rightarrow 216 Integral Calculus.)

I. Numerical Evaluation of Series

In some special cases, we can express the n th partial sum s_n of a series $\sum a_n$ as a well-known function of n . Specifically, if $\sum a_n$ is an **arithmetic progression** $\sum_{k=1}^n (a + (k-1)d)$ or a **geometric progression** $\sum_{k=1}^n aq^{k-1}$, we have

$$s_n = \frac{n}{2}(2a + (n-1)d), \quad s_n = \frac{a(q^n - 1)}{q - 1},$$

respectively. If $|q| < 1$, then $\sum_{n=0}^{\infty} aq^n$ converges to $a/(1 - q)$. If $B_{r+1}(x)$ is the $(r+1)$ st \dagger Bernoulli polynomial, then $s_n = 1^r + 2^r + \dots + n^r = [B_{r+1}(x)]_1^{n+1}/(r+1)$. This sum was studied by J. Bernoulli, who gave formulas up to $r = 10$ in his *Ars conjectandi*.

In the series $\sum u_n$, if we can find another sequence $\{v_n\}$ such that $u_n = v_n - v_{n-1}$, then $s_n = u_1 + u_2 + \dots + u_n = v_n - v_0$. For example, if $u_n = n(n+1)(n+2)$, then $v_n = n(n+1)(n+2)(n+3)/4$ and $s_n = v_n$ because $v_0 = 0$ (\rightarrow 104 Difference Equations). Series with trigonometric function terms are calculated analogously.

There are cases where the sum $\sum a_n$ itself can be expressed in a satisfactory form although we cannot find an appropriately simple expression for each partial sum s_n . For example, $\zeta(r) = \sum_{m=1}^{\infty} 1/m^r$ can be represented by \dagger Bernoulli numbers if r is even. In particular, $\zeta(2) = \pi^2/6$, $\zeta(4) = \pi^4/90$ (\rightarrow Appendix A, Table 10).

If an infinite series converges rapidly, we can get a good approximation by taking a suitable partial sum. On the other hand, if the series converges less rapidly, an effective means for evaluating series is afforded by transformation of series. If the k th \dagger difference is exactly zero, then

$$s_n = \sum_{i=1}^k \binom{n+1}{i} \Delta^{i-1} u_1.$$

Since the absolute value of finite differences often decreases rapidly, it is sometimes convenient to consider the series whose terms are the differences of the original series. One finite difference method is **Euler's transformation** of infinite series. In particular, the formula

$$\sum_{k=0}^{\infty} (-1)^k a_k = \sum_{n=0}^{\infty} \frac{\Delta^n a_0}{2^{n+1}}$$

is useful for numerical calculation of sums of slowly converging alternating series. In numerical calculation of the series, we usually start calculating the numerical values of the first few terms; we then apply such transformations as Euler's to the remainder, and calculate the partial sums of the transformed series.

When we calculate the sum of an infinite series approximately, we must estimate the error, i.e., the remainder that must be added to yield the sum of the series itself. We can estimate the maximum error by derivatives or differences of higher orders. We also have the transformations of Markov and Kummer. In the former, every term of the series is represented by convergent series, and in the latter, the given series is reduced by subtracting another convergent series, which has a known sum and similar terms [1].

J. Infinite Series and Integrals

In numerical calculation of functions, we sometimes use the **Euler-Maclaurin formula** [5]:

$$f(x + \xi\omega) = \frac{1}{\omega} \int_x^{x+\omega} f(z) dz + \sum_{r=1}^m \left(\frac{\omega^r}{r!} B_r(\xi) \Delta_{\omega} f^{(r-1)}(x) \right) + R_m,$$

$$R_m = -\omega \int_0^1 \frac{\bar{B}_m(\xi - z)}{m!} f^{(m)}(x + \omega z) dz,$$

where

$$\bar{B}_m(\xi - z) = \begin{cases} B_m(\xi - z + 1), & \xi < z, \\ B_m(\xi - z), & \xi \geq z. \end{cases}$$

The speed of the convergence for this formula is greater than that for Taylor's expansion when $\xi\omega$ is large, since the terms of the formula are \dagger Bernoulli polynomials $B_r(\xi)$ in $0 \leq \xi \leq 1$. We also have Boole's formula, with \dagger Euler polynomials as its terms [4]. The formulas discussed in this section are also used to calculate approximately the partial sums of infinite series.

Another method of evaluating sums of infinite series analytically entails transforming infinite series to definite integrals using the \dagger residue theorem. If an analytic function $f(z)$ is

holomorphic except at poles a_n ($n = 1, 2, \dots, k$) in a domain bounded by the closed curve C and containing the points $z = m$ ($m = 1, 2, \dots, N$), then

$$\sum_{m=1}^N f(m) = \frac{1}{2\pi i} \int_C \pi(\cot \pi z) f(z) dz - \sum_{n=1}^k \text{Res}[\pi(\cot \pi z) f(z)]_{z=a_n}.$$

When the left-hand side of this equation is replaced by

$$\sum_{m=1}^N (-1)^m f(m),$$

we replace $\cot \pi z$ by $\text{cosec } \pi z$. $\text{Res}[F(z)]_{z=a}$ is the \dagger residue of $F(z)$ at $z = a$. The line integral along C is often calculated easily by choosing a suitable deformation of C . Sometimes it can be shown immediately that the integral along C is zero, or its asymptotic value can be evaluated by the \dagger method of steepest descent.

K. History of the Study of Divergent Series

Mathematicians in the 18th century did not concern themselves with the question of whether \dagger series were \dagger convergent or \dagger divergent. This indiscriminateness led to various contradictions. In 1821 an exact definition of the notion of convergence of series (Section A) was given by A. L. Cauchy; since then, mathematicians have mostly concerned themselves with convergent series. However, since divergent series appeared in many problems in analysis, the study of such series could not be neglected, and it became desirable to give a suitable definition of their sum. Although some results were given by L. Euler, N. Abel, and others, it was during the latter part of the 19th century that methods of summation of divergent series were studied systematically. This study constituted a new branch of mathematics.

In the following sections, some important methods of summation of divergent series are mentioned. Cesàro's method (\dashv Section M) was the forerunner of the theory whose general foundation is now the theory of linear transformations.

L. Linear Transformations

For a sequence $\{s_n\}$ ($n = 0, 1, 2, \dots$) of real or complex numbers, assume that $\sigma_n = \sum_{i=0}^n a_{ni} s_i$ converges for $n = 0, 1, 2, \dots$, where (a_{ik}) is a given matrix ($i, k = 0, 1, 2, \dots$). The mapping $T: \{s_n\} \rightarrow \{\sigma_n\}$ is called a **linear transformation**, and $\{\sigma_n\}$ is called the **transform** of $\{s_n\}$ under T . If the matrix satisfies $a_{ik} = 0$ ($k > i$), then T is defined for any sequence $\{s_n\}$ and T is said to

be **triangular**. If the transform $\{\sigma_n\}$ under T is defined and convergent whenever $\{s_n\}$ converges, then T is called a **semiregular transformation**. If in addition $\{\sigma_n\}$ has the same limit as $\{s_n\}$, then T is called a **regular transformation**. If for any bounded sequence $\{s_n\}$ the transform $\{\sigma_n\}$ is defined and convergent, then T is called a **normal transformation**. If T is triangular and the transform $\{\sigma_n\}$ of $\{s_n\}$ under T is divergent to ∞ whenever $s_n \rightarrow \infty$, then T is called a **totally regular transformation**.

Let T be a regular transformation. If for at least one divergent sequence $\{s_n\}$ the transform $\{\sigma_n\}$ of $\{s_n\}$ under T converges, then T is called a **method of summation**. The limit s of $\{\sigma_n\}$ is called the **sum** of $\{s_n\}$ under the method T of summation, and $\{s_n\}$ is said to be **T -summable** to s . For a given method of summation T_1 , let $D(T_1)$ be the set of sequences that are T_1 -summable. If $D(T_1) = D(T_2)$, then the methods T_1 and T_2 are called **equivalent**. If $D(T_1) \subset D(T_2)$, then we say that T_1 is **weaker** than T_2 and T_2 is **stronger** than T_1 . If $D(T_1) \not\subset D(T_2)$ and $D(T_2) \not\subset D(T_1)$, then T_1 and T_2 are called **mutually noncomparable**. The following theorems on linear transformations of sequences are important:

(1) **Kojima-Schur theorem**. In order that T be semiregular it is necessary and sufficient that (i) $\lim_{n \rightarrow \infty} a_{nk}$ exist for each k ; (ii) $t_n = \sum_{k=0}^{\infty} |a_{nk}|$ exist and $\{t_n\}$ be bounded; and (iii) $\lim_{n \rightarrow \infty} \sum_{k=0}^{\infty} a_{nk}$ exist. In that case, we have

$$\sum_{k=0}^{\infty} \lim_{n \rightarrow \infty} |a_{nk}| < \infty$$

and

$$\begin{aligned} \lim_{n \rightarrow \infty} \sigma_n &= \lim_{n \rightarrow \infty} \sum_{k=0}^{\infty} a_{nk} s_k \\ &= \left(\lim_{n \rightarrow \infty} s_n \right) \left(\lim_{n \rightarrow \infty} \sum_{k=0}^{\infty} a_{nk} \right) \\ &\quad + \sum_{k=0}^{\infty} \left(\lim_{n \rightarrow \infty} a_{nk} \right) \left(s_k - \lim_{n \rightarrow \infty} s_n \right). \end{aligned}$$

In particular, in order that $\{\sigma_n\}$ converge whenever $s_n \rightarrow 0$ it is necessary and sufficient that conditions (i) and (ii) be satisfied. In that case,

$$\begin{aligned} \lim_{n \rightarrow \infty} \sigma_n &= \lim_{n \rightarrow \infty} \sum_{k=0}^{\infty} a_{nk} s_k \\ &= \sum_{k=0}^{\infty} \left(\lim_{n \rightarrow \infty} a_{nk} \right) s_k \end{aligned}$$

(I. Schur, *J. Reine Angew. Math.*, 151 (1921); T. Kojima, *Tôhoku Math. J.*, 12 (1917)).

(2) **Toeplitz's theorem**. In order that T be regular it is necessary and sufficient that (i') $\lim_{n \rightarrow \infty} a_{nk} = 0$ for each k ; (ii); and (iii') $\lim_{n \rightarrow \infty} \sum_{k=0}^{\infty} a_{nk} = 1$ (O. Toeplitz, *Prace Mat.-Fiz.*, 22 (1914)). In particular, (ii) and (i')

$\lim_{n \rightarrow \infty} \sum_{k=K}^{\infty} a_{nk} = 1$ for each K imply that T is regular (**Perron's theorem**).

(3) **Schur's theorem**. In order that T be normal it is necessary and sufficient that (i); (ii); (iii); and (iv) for any $\varepsilon > 0$ there exist a $K > 0$ such that $\sum_{k=K+1}^{\infty} |a_{nk}| < \varepsilon$ for each n .

(4) In order that the regular triangular transformation T be totally regular, it is necessary and sufficient that $a_{nk} \geq 0$ except for a finite number of k .

M. Cesàro's Method of Summation

We write

$$(1-x)^{-\alpha-1} = \sum_{n=0}^{\infty} A_n^\alpha x^n,$$

$$A_n^\alpha = \binom{n+\alpha}{n} \sim \frac{n^\alpha}{\Gamma(\alpha+1)},$$

$$\begin{aligned} (1-x)^{-\alpha-1} \sum_{n=0}^{\infty} u_n x^n &= (1-x)^{-\alpha} \sum_{n=0}^{\infty} s_n x^n \\ &= \sum_{n=0}^{\infty} s_n^\alpha x^n, \end{aligned}$$

where $s_n = \sum_{i=0}^n u_i$. Thus the series $\sum u_i$ is associated with the sequence $\{s_n^\alpha\}$. If $\sigma_n^{(\alpha)} = s_n^\alpha / A_n^\alpha$ converges to s as $n \rightarrow \infty$, then we say that $\sum u_n$ is **summable by Cesàro's method of order α** (or simply **(C, α)-summable**) to s and write $\sum_{n=0}^{\infty} u_n = s$ (C, α). This method of summation is called **Cesàro's method of summation of order α** (or simply **(C, α)-summation**).

It is natural to consider (C, α)-summation for $\alpha > -1$. We say that $\sum u_n$ is (C, -1)-summable if $\sum u_n$ converges and $nu_n = o(1)$. Here $\sum_{n=0}^{\infty} u_n = s$ (C, 0) means $\lim_{n \rightarrow \infty} s_n = s$, and $\sum_{n=1}^{\infty} u_n = s$ (C, 1) means $s = \lim_{n \rightarrow \infty} (s_0 + s_1 + \dots + s_{n-1})/n$. Generally, we have the following results:

(1) A_n^α is increasing if $\alpha > 0$ and decreasing if $0 > \alpha > -1$. $A_n^0 = 1$ and $A_n^\alpha > 0$ if $\alpha > -1$.

(2) $s_n^{\alpha+\beta+1} = \sum_{k=0}^n A_{n-k}^\beta s_k^\alpha$, $A_n^\alpha - A_{n-1}^\alpha = A_n^{\alpha-1}$, $s_n^\alpha - s_{n-1}^\alpha = s_n^{\alpha-1}$.

(3) (C, α) ($\alpha \geq 0$) is regular, and $D(C, \alpha) \supset D(C, \beta)$ if $\alpha > \beta > -1$.

(4) If $\sum u_n = s$ (C, α), then $u_n = o(n^\alpha)$. Moreover, if $\sum u'_n = s'$ (C, α), then $\sum (u_n + u'_n) = s + s'$ (C, α) and $\sum \lambda u_n = \lambda s$ (C, α) for any number λ .

(5) If $\sum u_n = s$ (C, α) and $\sum u'_n = s'$ (C, β), then their \dagger Cauchy product $\sum v_n = ss'$ (C, $\alpha + \beta + 1$) (**Chapman's theorem**). Moreover, if $\sum_{k=0}^n A_k^\alpha |s_{n-k}^{\beta-\alpha-1} (u'_{n-k})| / A_n^\beta = O(1)$, then $\sum v_n = ss'$ (C, β) (T. Kojima). If $\alpha', \beta' > -1$, $s_n^{(\alpha')}(u_n) = O(n^{\alpha'})$, and $s_n^{(\beta')}(u'_n) = O(n^{\beta'})$, then $\sum v_n = ss'$ (C, $\alpha' + \beta' + 2$) (G. Doetsch).

(6) For any integer $\alpha > 0$, in order that $\sum u_n = s$ (C, α) it is necessary and sufficient that there exist $\{v_n\}$ such that $u_n = (n+1)(v_n - v_{n+1})$ and $\sum v_n = s$ (C, $\alpha - 1$) (G. H. Hardy, *Proc. London Math. Soc.*, (2) 8 (1910)). This condi-

tion is equivalent to (i)–(iii) together: (i) the series $\sum_{k=n}^{\infty} s_n^{x-2}/(k+1) \dots (k+\alpha)$ converges to the limit b_n ; (ii) $b_n = o(1)$ as $n \rightarrow \infty$; and (iii) $(s_n^{x-1}/A_n^{x-1}) + (n+\alpha)\Gamma(\alpha)b_{n+1} \rightarrow s$ as $n \rightarrow \infty$.

(7) If $\sum u_n = s$ (C, α) ($\alpha > 0$), one of the following five conditions is sufficient for the convergence of $\sum u_n$ (this is a kind of †Tauberian theorem): (i) $nu_n = o(1)$; (ii) $t_n = \sum_{v=1}^n v u_v = o(n)$; (iii) $\sum n^p |u_n|^{p+1} < \infty$ ($p \geq 0$); (iv) $nu_n > -K$ (K is independent of n); (v) $\liminf(s_m - s_n) \geq 0$ as $m > n \rightarrow \infty$, $m/n \rightarrow 1$ (**R. Schmidt's condition**).

(8) If $\alpha' > \alpha > -1$ and $\sum u_n = s(C, \alpha')$, then $\sum u_n = s(C, \alpha + \epsilon)$ for any $\epsilon > 0$.

For a given series $\sum u_n$, we write H_n^0 for s_n , H_n^1 for the arithmetic mean of $\{H_n^0\}$, and H_n^2 for the arithmetic mean of $\{H_n^1\}$. Similarly, we can define $\{H_n^p\}$ for any integer p . If $H_n^p \rightarrow s$ as $n \rightarrow \infty$, then $\sum u_n$ is said to be **summable by Hölder's method of order p** (or (H, p) -summable) to s , and we write $\sum u_n = s(H, p)$. For any integer $p \geq 0$, (H, p) -summability is equivalent to (C, p) -summability (**Knopp-Schnee theorem**).

N. Abel's Method of Summation

If the radius of convergence of the power series $\sum_{n=0}^{\infty} u_n r^n$ is ≥ 1 and $\sum_{n=0}^{\infty} u_n r^n \rightarrow s$ as $r \rightarrow 1$, then $\sum u_n$ is said to be **summable by Abel's method** (or **A-summable**) to s , and we write $\sum u_n = s(A)$. The transformation matrix is denoted by A , and the transformation is called **Abel's method of summation**.

(1) If $\sum u_n = s(A)$, then $\limsup_{n \rightarrow \infty} |u_n|^{1/n} \leq 1$. (2) If $\sum u_n = s(A)$ and $\sum u'_n = s'(A)$, then $\sum(u_n + u'_n) = s + s'(A)$ and $\sum \lambda u_n = \lambda s(A)$ for any constant λ . Moreover, $\sum_{n=k+1}^{\infty} u_n = s - u_0 - u_1 - \dots - u_k(A)$. (3) If $\sum u_n = s(A)$ and $\sum u'_n = s'(A)$, then the Cauchy product is $\sum u_n = ss'(A)$. (4) If $\sum u_n = s(A)$ and one of the following five conditions is satisfied, then $\sum u_n = s$: (i) $nu_n = o(1)$; (ii) $t_n = \sum_{v=1}^n v u_v = o(n)$; (iii) $nu_n = O(1)$; (iv) $nu_n > -M$; (v) $\liminf(s_m - s_n) \geq 0$ as $m > n \rightarrow \infty$ and $m/n \rightarrow 1$. These theorems are †Tauberian, in the original form proved by Tauber (*Monatsh. Math.*, 8 (1897)). (5) The matrix A is regular, and $D(C, \alpha) \subset D(A)$ for any $\alpha > -1$. (6) If $\sum u_n = s(A)$ and $s_n \geq 0$, then $\sum u_n = s(C, 1)$. Moreover, if $\sigma_n^{(\alpha)} = O(1)$, then $\sum u_n = s(C, \alpha + \epsilon)$ for $\alpha > -1$ and $\epsilon > 0$.

O. Borel's Method of Summation

If for a given series $\sum u_n$,

$$u(x) = \sum_{n=0}^{\infty} \frac{s_n x^n}{n!}$$

is convergent for all x , and $u(x)/e^x \rightarrow s$ as $x \rightarrow \infty$, then $\sum u_n$ is said to be **summable by**

Borel's exponential method to the sum s , and we write $\sum u_n = s(B)$. The transformation thus determined is denoted by B and is called **Borel's method of summation**. If

$$\int_0^{\infty} u(x)e^{-x} dx = s,$$

then $\sum u_n$ is said to be **summable by Borel's integral method** (or **B-summable**) to s , and we write $\sum u_n = s(\mathfrak{B})$. Then we have: (1) B is regular and $D(C, \alpha) \subset D(B)$ ($\alpha > -1$), while $D(C, \alpha)$ and $D(\mathfrak{B})$ are noncomparable. (2) If the radius of convergence of $\sum_{n=0}^{\infty} u_n x^n$ is ≥ 1 and $\sum u_n = s(B)$, then $\sum u_n = s(A)$. (3) If $\sum_{n=k+1}^{\infty} u_n = s(B)$ (resp. (\mathfrak{B})), then $\sum u_n = s + u_0 + u_1 + \dots + u_k(B)$ (resp. (\mathfrak{B})), but the converse is not always true. (4) $\sum u_n = s(B)$ implies $|u_n|^{1/n} = o(n)$. (5) If $\sum u_n = s(B)$ and $\sum u'_n = s'(B)$, then $\sum(u_n + u'_n) = s + s'(B)$, and $\sum \lambda u_n = \lambda s(B)$ for any constant λ . The same is true for summation (\mathfrak{B}) . (6) If $\sum u_n = s(B)$ and if one of the following two conditions is satisfied, then $\sum u_n = s$: (i) $\sqrt{n} u_n = o(1)$; (ii) $\liminf(s_m - s_n) \geq 0$ as $m > n \rightarrow \infty$ and $(m - n)\sqrt{n} \rightarrow 0$. (7) If $\sum u_n = s(B)$ and $s_{n-1}^{\alpha} = o(n^{\alpha-1/2})$, then $\sum u_n = s(C, \alpha)$ ($\alpha \geq 0$). (8) If $\sum u_n = s(A)$ and $u(t) > -Mt^{-1} \exp t$, then $\sum u_n = s(B)$. (9) If the sequences $\{n_k\}$ and $\{n'_k\}$ satisfy $n_{k+1} > n_k$, $n'_k/n_k > 1 + \epsilon$ ($k = 1, 2, \dots$; $\epsilon > 0$), $u_v = 0$ ($n_k < v \leq n'_k$), and $\sum u_n = s(B)$, then $s_{n_k} \rightarrow s$ as $k \rightarrow \infty$.

If $\sum u_n = s(\mathfrak{B})$ and

$$\int_0^{\infty} \left| \frac{d^{\lambda} u(x)}{dx^{\lambda}} \right| e^{-x} dx$$

converges for all $\lambda = 0, 1, 2, \dots$, then $\sum u_n$ is said to be **absolute Borel summable** (or **|\mathfrak{B}|-summable**). Concerning this we have: (1) If $\sum |u_n|$ converges, then $\sum u_n$ is $|\mathfrak{B}|$ -summable, but even if $\sum u_n$ converges, $\sum u_n$ is not always $|\mathfrak{B}|$ -summable. If $\sum u_n$ is $|\mathfrak{B}|$ -summable, then $\sum u_n$ is \mathfrak{B} -summable to s . In this case, we write $\sum u_n = s(|\mathfrak{B}|)$. (2) $\sum_{n=0}^{\infty} u_n = s(|\mathfrak{B}|)$ implies $\sum_{n=k+1}^{\infty} u_n = s - (u_0 + u_1 + \dots + u_k)(|\mathfrak{B}|)$. (3) If $\sum u_n = s(B)$, $\sum u'_n = s'(B)$, and if at least one of them is $|\mathfrak{B}|$ -summable, then their Cauchy product is $\sum v_n = ss'(|\mathfrak{B}|)$.

P. Euler's Method of Summation

In the series $\sum u_n$, if

$$\left\{ \binom{k+1}{1} s_0 + \binom{k+1}{2} s_1 + \dots + \binom{k+1}{k+1} s_k \right\} 2^{-(k+1)}$$

($s_n = \sum_{k=0}^n u_k$) converges to s as $k \rightarrow \infty$, then $\sum u_n$ is said to be **summable by Euler's method**, and we write $\sum u_n = s(E)$. The transformation thus obtained is called **Euler's method of summation**. A necessary and sufficient condition

for $\sum u_n = s$ (E) is that $\sum v_n = s$, where $v_n = 2^{-(n+1)} \sum_{k=0}^n \binom{n}{k} u_k$. This summation method is regular. We have $\sum u_n = s$ if $\sum u_n = s$ (E) and if one of the following two conditions is satisfied: (i) $\sqrt{n} u_n = O(1)$; (ii) $\liminf (s_m - s_n) \geq 0$ for $m > n \rightarrow \infty$, $(m - n)/\sqrt{n} \rightarrow 1$. Cesàro and Euler summations are noncomparable. As an extension of Euler's method, the Euler method of summation of p th order is also defined (e.g., → [6]).

Q. Nörlund's Method of Summation

For a positive sequence $\{p_n\}$, let $P_n = \sum_{v=0}^n p_v \rightarrow \infty$ as $n \rightarrow \infty$ and $p_n/P_n \rightarrow 0$ as $n \rightarrow \infty$. If

$$\left(\sum_{k=0}^n s_k p_{n-k} \right) / P_n = \left(\sum_{k=0}^n u_k P_{n-k} \right) / P_n$$

converges to s as $n \rightarrow \infty$, then $\sum u_n$ is said to be **summable by Nörlund's method** of type $\{p_n\}$, and we write $\sum u_n = s$ (N, $\{p_n\}$). The transformation thus obtained is also regular and is called **Nörlund's method of summation**. If $\sum u_n = s$ (C, 1) and $0 \leq p_0 \leq p_1 \leq \dots$, then $\sum u_n = s$ (N, $\{p_n\}$). Cesàro's method is actually a special case of this method.

R. M. Riesz's Method of Summation

Let $\{\lambda_n\}$ be a sequence with increasing terms and tending to $+\infty$ as $n \rightarrow \infty$. If

$$R(\lambda_n, k, \tau) = \left(\sum_{\lambda_n < \tau} (\tau - \lambda_n)^k u_n \right) / \tau^k$$

converges to s as $\tau \rightarrow \infty$, then $\sum u_n$ is said to be **summable by Riesz's method of order k** and type λ_n , and we write $\sum u_n = s$ (R, λ_n, k). The transformation thus obtained is regular and is called **Riesz's method of summation of the k th order**. In particular, if $\lambda_n = n$, then $D(R, \lambda_n, k) = D(C, k)$.

S. Riemann's Method of Summation

If

$$\sum_{n=1}^{\infty} u_n \left(\frac{\sin nh}{nh} \right)^k, \quad u_0 = 0,$$

converges for $h > 0$ and tends to s as $h \rightarrow 0$, then $\sum u_n$ is said to be **(R, k)-summable to s** . When $k = 1$, this method, often called **Lebesgue's method of summation**, is not regular. When $k = 2$, it is ordinarily called **Riemann's method of summation** and is regular. Corresponding to these cases, if

$$\frac{2}{\pi} \sum s_n \frac{\sin nh}{n} \rightarrow s \quad \text{or} \quad \frac{2}{\pi h} \sum s_n \left(\frac{\sin nh}{n} \right)^2 \rightarrow s$$

as $h \rightarrow 0$, then $\sum u_n$ is called **(R₁)-summable** or **(R₂)-summable to s** , respectively. The summation method (R₁) is not regular, while (R₂) is regular. If $\sum u_n$ is (R₁)-summable, then it is also (R₂)-summable, but (R, 2) and (R₂) are noncomparable.

Other methods of summation were developed by G. H. Hardy and J. E. Littlewood, E. Le Roy, C. J. de La Vallée Poussin, and others (e.g., → [6]).

380 (X.15)
Set Functions

A. General Remarks

A †function whose domain is a †family of sets is called a **set function**. Usually we consider set functions that take real values or $\pm\infty$. For example, if $f(x)$ is a real-valued function

defined on a set X , and if we assign to each subset A of X values such as $\sup_A f$, $\inf_A f$, or $\sup_A f - \inf_A f$, then we obtain a corresponding set function. In particular, a set function whose domain is the family of left open intervals in \mathbf{R}^m is called an **interval function**. To distinguish between set functions and ordinary functions defined at each point of a set, we call the latter **point functions**. For example, if $f(x)$ is an integrable (point) function with \mathbf{R} ($=\mathbf{R}^1$) as its domain and we put $F(I) = \int_a^b f(x) dx$ for $I = (a, b]$, then we obtain an interval function F on \mathbf{R} .

B. Finitely Additive Set Functions

Let $\Phi(E)$ be a real-valued set function defined on a finitely additive class \mathfrak{B} in a space X . If Φ satisfies the finite additivity condition:

$$E_1, E_2 \in \mathfrak{B}, \quad E_1 \cap E_2 = \emptyset \quad \text{imply}$$

$$\Phi(E_1 \cup E_2) = \Phi(E_1) + \Phi(E_2),$$

then $\Phi(E)$ is called a **finitely additive set function** on \mathfrak{B} . For each $E \in \mathfrak{B}$ we denote $\sup\{\Phi(A) \mid A \subset E, A \in \mathfrak{B}\}$ ($\inf\{\Phi(A) \mid A \subset E, A \in \mathfrak{B}\}$) by $\bar{V}(\Phi; E)$ ($\underline{V}(\Phi; E)$), the **upper (lower) variation** of Φ . Since $\Phi(\emptyset) = 0$, we have $\underline{V}(\Phi; E) \leq 0 \leq \bar{V}(\Phi; E)$. $V(\Phi; E) = \bar{V}(\Phi; E) + |\underline{V}(\Phi; E)|$ is called the **total variation** of Φ on E . When we deal with a fixed Φ , instead of $\bar{V}(\Phi; E)$, $\underline{V}(\Phi; E)$, $V(\Phi; E)$ we write simply $\bar{V}(E)$, $\underline{V}(E)$, $V(E)$. If $V(\Phi; E)$ is bounded, then Φ is said to be **of bounded variation**. If $\Phi(E) \geq 0$ (≤ 0) for every $E \in \mathfrak{B}$, i.e., $E \subset E'$ implies $\Phi(E) \leq \Phi(E')$ ($\Phi(E) \geq \Phi(E')$), then Φ is said to be **monotone increasing (decreasing)**. Every finitely additive set function of bounded variation can be represented as the difference of two monotone increasing finitely additive set functions.

Let I_0 be a fixed interval in \mathbf{R}^m and $F(I)$ be an interval function defined for left open intervals $I \subset I_0$, where \emptyset is considered as a degenerate left open interval. If, for any two left open intervals I_1, I_2 such that $I_1 \cup I_2$ is an interval and $I_1 \cap I_2 = \emptyset$, we have $F(I_1 \cup I_2) = F(I_1) + F(I_2)$, then we call $F(I)$ an **additive interval function** in I_0 . Specifically, if $f(x)$ is a real-valued bounded function on \mathbf{R} and D is an interval function determined by $D(I) = f(b) - f(a)$, where $I = [a, b)$ (i.e., $D(I)$ is the increment of $f(x)$), then D is an additive interval function on \mathbf{R} , called the **increment function** of f . For a given f the increment function is determined uniquely. Conversely, for a given D , a function f such that D is its increment function is determined uniquely up to an additive constant. In this sense an additive interval function in \mathbf{R} may be identified with the corresponding point function on \mathbf{R} .

Let $\mathfrak{R}(I_0)$ be the finitely additive class of all

finite unions R of left open intervals in I_0 . Then any additive interval function $F(I)$ can be extended to a finitely additive set function $F(R)$ defined on $\mathfrak{R}(I_0)$. For the rest of this article, it is understood that an additive interval function means this extended set function. If for any $\varepsilon > 0$ there exists a $\delta > 0$ such that $|I| < \delta$ implies $F(I) < \varepsilon$ (where $|I|$ is the volume of the interval I), then we say that F is **continuous**.

C. Completely Additive Set Functions

Let $\Phi(E)$ be a real-valued set function defined on a completely additive class \mathfrak{B} in a space X . If Φ satisfies the complete additivity condition:

$$E_j, E_k \in \mathfrak{B}, \quad E_j \cap E_k = \emptyset \quad (j \neq k)$$

$$\text{imply} \quad \Phi\left(\sum_{j=1}^{\infty} E_j\right) = \sum_{j=1}^{\infty} \Phi(E_j),$$

then $\Phi(E)$ is called a **completely additive set function** (or simply **additive set function**) on \mathfrak{B} . In this case the corresponding upper variation $\bar{V}(E)$, lower variation $\underline{V}(E)$, and total variation $V(E)$ are all completely additive set functions, and for every $E \in \mathfrak{B}$ we have $\Phi(E) = \bar{V}(E) + \underline{V}(E)$ (**Jordan decomposition**). Furthermore, $V(E) = \sup \sum_{j=1}^n |\Phi(E_j)|$, where the supremum is taken over all decompositions of E such that $E = \bigcup_{j=1}^n E_j$ ($E_j \in \mathfrak{B}$, $E_j \cap E_k = \emptyset$, $j \neq k$). The completely additive nonnegative set functions are the same as the finite measures. Hence the Jordan decomposition implies that every completely additive set function is represented as the difference of two finite measures. A completely additive set function is also called a **signed measure**.

Any continuous additive interval function of bounded variation can be extended to a completely additive set function. The notion of additive interval function of bounded variation is a generalization of that of function of bounded variation (\rightarrow 166 Functions of Bounded Variation).

Let Φ be a completely additive set function and μ a finite or σ -finite measure, both defined on \mathfrak{B} . If $\mu(E) = 0$ implies $\Phi(E) = 0$, then Φ is said to be **absolutely continuous** with respect to μ or μ -**absolutely continuous**. Then Φ is μ -absolutely continuous if and only if for any $\varepsilon > 0$, there exists a $\delta > 0$ such that $\mu(E) < \delta$ implies $|\Phi(E)| < \varepsilon$. If for given Φ and μ there exists an $E_0 \in \mathfrak{B}$ such that $\mu(E_0) = 0$ and $\Phi(E) = \Phi(E \cap E_0)$ for every $E \in \mathfrak{B}$, then Φ is said to be **singular** with respect to μ or μ -**singular**.

In a σ -finite measure space (X, \mathfrak{B}, μ) , every completely additive set function $\Phi(E)$ defined on \mathfrak{B} can be represented uniquely as the sum of a μ -absolutely continuous set function and a

μ -singular set function (**Lebesgue decomposition theorem**). Also, $\Phi(E)$ is μ -absolutely continuous if and only if $\Phi(E)$ can be represented as the indefinite integral $\int_E f(x) d\mu$ of a function f that is integrable on X with respect to μ (**Radon-Nikodym theorem**). This function $f(x)$ is called the **Radon-Nikodym derivative**, $d\Phi/d\mu$, of Φ with respect to μ (\rightarrow 270 Measure Theory L (iii)).

D. Differentiation of Set Functions

Let m be the Lebesgue measure in \mathbf{R}^m and E a Lebesgue measurable set. We denote $\sup(m(E)/m(Q))$ for all cubes Q such that $E \subset Q$ by $r(E)$ and call it the **parameter of regularity** of E . If for a sequence of sets $\{E_n\}$ there exists an α such that $r(E_n) > \alpha > 0$, then $\{E_n\}$ is called a **regular sequence**. If all the E_n contain a point P and the diameter of E_n tends to 0 as $n \rightarrow \infty$, then we say that $\{E_n\}$ converges to the point P . Let Φ be a set function in \mathbf{R}^m . For a regular sequence $\{E_n\}$ of closed sets converging to a point P , we put $l = \limsup(\Phi(E_n)/m(E_n))$ and define the **general upper derivative** of Φ at P to be the least upper bound of l for all such sequences $\{E_n\}$, denoted by $\bar{D}\Phi(P)$. Similarly, the **general lower derivative** $\underline{D}\Phi(P)$ of Φ at P is defined to be the greatest lower bound of $\liminf(\Phi(E_n)/m(E_n))$ for all regular sequences $\{E_n\}$ of closed sets converging to P . The **ordinary upper (lower) derivative**, denoted by $\bar{\Phi}(E)(\Phi(E))$, is defined in the same way by taking regular sequences of closed intervals instead of closed sets. $\bar{D}\Phi, \underline{D}\Phi, \bar{\Phi}, \Phi$ are point functions derived from Φ . Clearly, $\underline{D}\Phi(P) \leq \Phi(P) \leq \bar{D}\Phi(P)$. If $\bar{D}\Phi(P) = \underline{D}\Phi(P)$, then we write it simply as $D\Phi(P)$. If $D\Phi(P)$ is finite, then we call it the **general derivative** of Φ at P and say that Φ is **derivable in the general sense** at P . If $\bar{\Phi}(P) = \Phi(P)$, then we write it as $\Phi(P)$. If $\Phi(P)$ is finite, then we call it the **ordinary derivative** of Φ at P and say that Φ is **derivable in the ordinary sense**. We have the following theorems: (1) A completely additive set function is derivable in the general sense almost everywhere (Lebesgue). The Radon-Nikodym derivative of a set function absolutely continuous with respect to the Lebesgue measure is equal almost everywhere to the generalized derivative of the set function. (2) An additive interval function of bounded variation is derivable in the ordinary sense almost everywhere (Lebesgue). (3) An additive interval function Φ is derivable in the ordinary sense at almost all points such that $\bar{\Phi}(P) < +\infty$ or $\underline{\Phi}(P) > -\infty$.

For the proof of these theorems, **Vitali's covering theorem** is essential: Let A be a given set and \mathfrak{F} a family of measurable sets in Euclidean space. If for each $x \in A$ there is a

regular sequence of sets belonging to \mathfrak{F} that converges to x , then there exists a finite or countable set of disjoint $E_n \in \mathfrak{F}$ such that $m(A \setminus \bigcup_{j=1}^{\infty} E_j) = 0$.

Sets**

A. Definitions and Symbols

G. Cantor defined a **set** as a collection of objects of our intuition or thought, within a certain realm, taken as a whole. Each object in the collection is called an **element** (or **member**) of the set. The notation $a \in A$ ($A \ni a$) means that a is an element of the set A . In this case we say that a is a member of A or a **belongs** to A . The negation of $a \in A$ ($A \ni a$) is written $a \notin A$ or $a \bar{\in} A$ ($A \not\ni a$ or $A \bar{\ni} a$). The set having no element, namely the set A such that $a \notin A$ for every object a , is called the **empty set** (or **null set**) and is usually denoted by \emptyset . Two sets A and B are identical, i.e., $A = B$, if every element of A belongs to B , and vice versa. The set containing a, b, c, \dots as its elements is said to consist of a, b, c, \dots and is denoted by $\{a, b, c, \dots\}$. The symbol $\{x | C(x)\}$ (or $\{x; C(x)\}$, sometimes $E_x[C(x)]$) denotes the set of all objects that have the property $C(x)$. Thus $\{a\}$ is the set whose only element is a , and $\{a, b\}$ is the set with two elements a and b , provided that $a \neq b$. A set is called a **finite set** or an **infinite set** according as the number of its elements is finite or infinite.

A set A is a **subset** of a set B if each element of A is an element of B . In this case we also say that A is contained in B or that B **contains** A , and we write $A \subset B$ and $B \supset A$. The negation of $A \subset B$ ($B \supset A$) is $A \not\subset B$ ($B \not\supset A$). For every set A , $\emptyset \subset A$. $A \subset B$ and $B \subset C$ imply $A \subset C$. If $A \subset B$ and $B \subset A$, then $A = B$. A is a **proper subset** of B (in symbols: $A \subsetneq B$, $B \supsetneq A$) if $A \subset B$ and $A \neq B$. Some authors use \subsetneq (\supsetneq) for \subset (\supset), and \subset (\supset) for \subsetneq (\supsetneq).

B. Algebra of Sets

The **union** (**join** or **sum**) of sets A and B , written $A \cup B$, is the set of all elements which belong either to A or to B or to both. The **intersection** (**meet** or **product**) of sets A and B , written $A \cap B$, is the set of all elements which belong to both A and B . In other words, $x \in A \cup B$ if and only if $x \in A$ or $x \in B$ or both, and $x \in A \cap B$ if and only if $x \in A$ and $x \in B$. Given sets A , B , and C , $A \cup B = B \cup A$, $A \cap B = B \cap A$ (**commutative law**); $(A \cup B) \cup C = A \cup (B \cup C)$, $(A \cap B) \cap C = A \cap (B \cap C)$ (**associative law**); $A \cup (B \cap C) = (A \cup B) \cap (A \cup C)$, $A \cap (B \cup C) = (A \cap B) \cup (A \cap C)$ (**distributive law**); $A \cup (A \cap B) = A$, $A \cap (A \cup B) = A$ (**absorption law**).

Two sets A and B are **disjoint** if $A \cap B = \emptyset$. In this case the set $C = A \cup B$ is said to be the **disjoint union** (or **sum**) of A and B , and is written sometimes as $C = A + B$. The set of elements of A which are not members of B is denoted by $A - B$, and is called the **difference** of A and B (or **relative complement** of B in A). If $A \supset B$, $A - B$ is called the **complement** (or **complementary set**) of B with respect to A .

We often consider a theory in which we restrict our attention to elements and subsets of a certain fixed set Ω , and call it the **universal set** of the theory. In geometric terms, Ω is also called the **space** or the **abstract space**, elements of Ω are called **points**, and subsets of Ω **point sets**. If A is a subset of Ω , $\Omega - A$ is simply called the **complement** of A and is denoted A^c . For $A \subset \Omega$ and $B \subset \Omega$, $A \supset B$ and $A^c \subset B^c$ are equivalent. Furthermore, we have $A \cup A^c = \Omega$, $A \cap A^c = \emptyset$, $A^{cc} = A$; and $(A \cap B)^c = A^c \cup B^c$, $(A \cup B)^c = A^c \cap B^c$ (**de Morgan's law**).

The **power set** of a set X , written $\mathfrak{P}(X)$, is the set of all subsets of X . A set whose elements are sets is often called a **family of sets**.

The **pair** consisting of objects a and b is denoted by (a, b) . Two pairs (a, b) , (c, d) are defined to be equal if and only if $a = c$ and $b = d$. A pair (a, b) is called an **ordered pair**, while the set $\{a, b\}$ is sometimes called an **unordered pair**. Generally the **n -tuple** (a, b, c, \dots, d) of n given objects a, b, c, \dots, d is defined to be $((\dots((a, b), c), \dots), d)$, so that $(a, b, c, \dots, d) = (a', b', c', \dots, d')$ if and only if $a = a'$, $b = b'$, $c = c'$, \dots , $d = d'$. The **Cartesian product** (or **direct product**) of sets A and B , written $A \times B$, is the set of all pairs (a, b) such that $a \in A$ and $b \in B$. $A \times B = \emptyset$ if and only if either $A = \emptyset$ or $B = \emptyset$; $A \times B \subset C \times D$ if and only if $A \subset C$ and $B \subset D$, provided that neither A nor B is empty. Furthermore,

$$(A \times B) \cup (A' \times B) = (A \cup A') \times B,$$

$$(A \times B) \cap (C \times D) = (A \cap C) \times (B \cap D).$$

The subset $\{(a, a) | a \in A\}$ of $A \times A$ is called the **diagonal** of $A \times A$ and is denoted by Δ_A .

Generally the **Cartesian product** (or **direct product**) of sets A, B, \dots, D , written $A \times B \times \dots \times D$, is defined as the set $\{(a, b, \dots, d) | a \in A, b \in B, \dots, d \in D\}$.

C. Mappings

If there exists a rule which assigns to each element of a set A an element of a set B , this rule is said to define a **mapping** (or simply **map**), **function**, or **transformation** from A into B . The term *transformation* is sometimes restricted to the case where $A = B$. Usually letters f, g, ϕ, ψ, \dots stand for mappings. The expression $f: A \rightarrow B$ ($A \xrightarrow{f} B$) means that f is a function which maps A into B . If $f: A \rightarrow B$ and $a \in A$, then $f(a)$ denotes the element of B which is assigned to a by f . We call $f(a)$ the **image** of a under f . The notation $f: a \mapsto b$ (or $f: a \rightarrow b$) is often used to mean $f(a) = b$ (but not in the present volumes). The **domain** of a mapping $f: A \rightarrow B$ is the set A , and its **range** (or **codomain**), written $f(A)$, is the subset $\{f(a) | a \in A\}$ of B . Two functions f and g are equal ($f = g$) if their domains coincide and $f(a) = g(a)$ for each a in the common domain.

For a mapping $f: A \rightarrow B$ and a set $C \in \mathfrak{P}(A)$, $f(C)$ is defined to be the set $\{f(x) | x \in C\}$. This definition induces the mapping from $\mathfrak{P}(A)$ to $\mathfrak{P}(B)$ which is usually also denoted by f . If $A_i \in \mathfrak{P}(A)$ ($i = 1, 2$), then $f(A_1 \cup A_2) = f(A_1) \cup f(A_2)$ and $f(A_1 \cap A_2) \subset f(A_1) \cap f(A_2)$. The **inverse image** of $D \in \mathfrak{P}(B)$, denoted by $f^{-1}(D)$, is defined to be the set $\{x | x \in A, f(x) \in D\}$; thus the mapping $f^{-1}: \mathfrak{P}(B) \rightarrow \mathfrak{P}(A)$ is defined. If $B_i \in \mathfrak{P}(B)$ ($i = 1, 2$), then $f^{-1}(B_1 \cup B_2) = f^{-1}(B_1) \cup f^{-1}(B_2)$; $f^{-1}(B_1 \cap B_2) = f^{-1}(B_1) \cap f^{-1}(B_2)$; $f^{-1}(B - B_1) = A - f^{-1}(B_1)$. Furthermore, $A_1 \subset f^{-1} \circ f(A_1)$ and $f \circ f^{-1}(B_1) \subset B_1$.

A mapping g is an **extension** of a mapping f to a set A' if A' is the domain of g and contains the domain A of f , and if $g(a) = f(a)$ for each a in A . In this case f is called a **contraction** (or **restriction**) of g to A or simply a **partial mapping** of g , and is denoted by $g|A$. A mapping f is the **constant mapping** (or **constant function**) with the value b_0 if $f(a) = b_0$ for every a in the domain of f . The **identity mapping** (or **identity function**) on A , often denoted by 1_A , is the mapping with the domain A such that $f(a) = a$ for every a in A . Given two mappings $f: A \rightarrow B$ and $g: B \rightarrow C$, the mapping from A to C which assigns $g(f(a))$ to each $a \in A$ is called the **composite** of f and g and is denoted by $g \circ f$. If $f: A \rightarrow B$, $g: B \rightarrow C$, and $h: C \rightarrow D$, then $(h \circ g) \circ f = h \circ (g \circ f)$ (associative law for composition of mappings).

A mapping $f: A \rightarrow B$ is from A **onto** B if $f(A) = B$. In this case f is also called a **surjection** (or a **surjective mapping**). A mapping $f: A \rightarrow B$

is **one-to-one (1-1, or injective)** if $a \neq a'$ implies $f(a) \neq f(a')$ for every pair of elements a and a' in A , that is, if for each b in the range of A , there exists only one element a of A such that $f(a) = b$. Such an f is also called an **injection**. In particular, given a subset B of a set A , the injection $f: B \rightarrow A$ defined by the condition $f(b) = b$ for each $b \in B$ is called the **inclusion mapping (inclusion or canonical injection)**. A necessary and sufficient condition for $f: A \rightarrow B$ to be a surjection is that $g \circ f = h \circ f$ imply $g = h$ for every pair of mappings $g: B \rightarrow C$ and $h: B \rightarrow C$. For $f: A \rightarrow B$ to be an injection it is necessary and sufficient that $f \circ g = f \circ h$ imply $g = h$ for every pair of mappings $g: C \rightarrow A$ and $h: C \rightarrow A$. A mapping which is both a surjection and an injection is called a **bijection (or bijective mapping)**. If $f: A \rightarrow B$ is a bijection, then the mapping from B to A which assigns to each element b of B the unique element a of A such that $f(a) = b$ is called the **inverse mapping (inverse function or simply inverse)** of f , and is denoted by f^{-1} . We have $f \circ f^{-1} = 1_B$ and $f^{-1} \circ f = 1_A$ for every bijection $f: A \rightarrow B$.

If the domain A of a mapping $f: A \rightarrow B$ is the Cartesian product of A_1 and A_2 , $f(a) = b$ (where $a = (a_1, a_2)$) is written as $f(a_1, a_2) = b$. Given $A = A_1 \times A_2$, $B = B_1 \times B_2$, and $f_i: A_i \rightarrow B_i$ ($i = 1, 2$), the mapping $f: A \rightarrow B$ defined by the condition $f(a_1, a_2) = (f_1(a_1), f_2(a_2))$ is called the **Cartesian product (or direct product)** of the mappings of f_1 and f_2 , and is denoted by $f_1 \times f_2$.

For a mapping $f: A \rightarrow B$, the subset $G = \{(a, f(a)) | a \in A\}$ of $A \times B$ is called the **graph** of f . The basic properties of the graph G of f are: (1) For every $a \in A$ there exists a $b \in B$ such that $(a, b) \in G$. (2) $(a, b) \in G$ and $(a, b') \in G$ imply $b = b'$. Conversely, a subset G of $A \times B$ with these two properties determines a mapping $f: A \rightarrow B$ such that $(a, b) \in G$ if and only if $f(a) = b$. All notions concerning a mapping $f: A \rightarrow B$ can be transferred by means of its graph to those concerning a subset of a Cartesian product $A \times B$.

Given sets A and B , we denote by B^A the set of mappings from A to B . If a mapping is identified with its graph, B^A is considered to be a subset of $\mathfrak{P}(A \times B)$. For $X \in \mathfrak{P}(A)$, the mapping $c_X: A \rightarrow \{0, 1\}$ such that $c_X(x) = 1$ if $x \in X$ and $c_X(x) = 0$ if $x \notin X$ is called the **characteristic function (or representing function)** of X . By assigning to each $X \in \mathfrak{P}(A)$ its characteristic function $c_X \in \{0, 1\}^A$, we obtain a one-to-one correspondence between $\mathfrak{P}(A)$ and $\{0, 1\}^A$; hence $\mathfrak{P}(A)$ is sometimes denoted by 2^A .

D. Families of Sets

A mapping from a set Λ to a set A is also called a family of elements of A indexed by Λ . Λ is its **index set (or indexing set)**. In this case,

the image $f(\lambda)$ of $\lambda \in \Lambda$ is denoted by a_λ , and the mapping itself is denoted by $\{a_\lambda\}_{\lambda \in \Lambda}$ ($\{a_\lambda\}$), or simply $\{a_\lambda\}$. In particular, if the set A is the power set of a set, the family $\{a_\lambda\}_{\lambda \in \Lambda}$ is called a **family of sets indexed by Λ** , or simply a **family of sets**. (Moreover, if Λ is chosen to be a subset of the power set $\mathfrak{P}(X)$ of a set X and f to be the identity mapping on Λ , then the family of sets resulting from f can be identified with the set of subsets Λ itself.)

The union $\bigcup_{\lambda \in \Lambda} A_\lambda$ of a family of sets $\{A_\lambda\}_{\lambda \in \Lambda}$ is the set of all elements a such that $a \in A_\lambda$ for at least one λ in Λ . Their intersection $\bigcap_{\lambda \in \Lambda} A_\lambda$ is the set of all elements a such that $a \in A$ for all λ in Λ . A family of sets $\{A_\lambda\}_{\lambda \in \Lambda}$ is **mutually disjoint** if $\lambda \neq \mu$ implies $A_\lambda \cap A_\mu = \emptyset$. In this case $A = \bigcup_{\lambda \in \Lambda} A_\lambda$ is called the **disjoint union (or direct sum)** of the sets of the family, and $\{A_\lambda\}_{\lambda \in \Lambda}$ is called a **partition (or decomposition)** of A . For families of sets, the following hold: $\bigcup_{\lambda \in \Lambda} \bigcap_{\mu \in M_\lambda} A_{\lambda\mu} = \bigcap_{\lambda \in \Lambda} \bigcup_{\mu \in M_\lambda} A_{\lambda\mu}$ (associative law); $(\bigcup_{\lambda \in \Lambda} A_\lambda) \cap (\bigcap_{\mu \in M} B_\mu) = \bigcap_{(\lambda, \mu) \in \Lambda \times M} (A_\lambda \cap B_\mu)$, $(\bigcap_{\lambda \in \Lambda} A_\lambda) \cup (\bigcap_{\mu \in M} B_\mu) = \bigcap_{(\lambda, \mu) \in \Lambda \times M} (A_\lambda \cup B_\mu)$ (distributive law); $(\bigcup_{\lambda \in \Lambda} A_\lambda)^c = \bigcap_{\lambda \in \Lambda} A_\lambda^c$, $(\bigcap_{\lambda \in \Lambda} A_\lambda)^c = \bigcup_{\lambda \in \Lambda} A_\lambda^c$ (de Morgan's law).

A family $\{A_\lambda\}_{\lambda \in \Lambda}$ of sets is a **covering** of a set A , or **covers A** , if $A \subset \bigcup_{\lambda \in \Lambda} A_\lambda$.

Given $f: X \rightarrow Y$, $\{A_\lambda\}_{\lambda \in \Lambda}$ and $\{B_\lambda\}_{\lambda \in \Lambda}$ (where $A_\lambda \subset X$ and $B_\lambda \subset Y$), then $f(\bigcup_{\lambda \in \Lambda} A_\lambda) = \bigcup_{\lambda \in \Lambda} f(A_\lambda)$, $f(\bigcap_{\lambda \in \Lambda} A_\lambda) \subset \bigcap_{\lambda \in \Lambda} f(A_\lambda)$; and $f^{-1}(\bigcup_{\lambda \in \Lambda} B_\lambda) = \bigcup_{\lambda \in \Lambda} f^{-1}(B_\lambda)$, $f^{-1}(\bigcap_{\lambda \in \Lambda} B_\lambda) = \bigcap_{\lambda \in \Lambda} f^{-1}(B_\lambda)$.

E. Direct Sum and Direct Product of Families of Sets

Given a family $\{A_\lambda\}_{\lambda \in \Lambda}$ of sets indexed by Λ , a set S , and a family of injections $\{i_\lambda: A_\lambda \rightarrow S\}_{\lambda \in \Lambda}$, then the pair $(S, \{i_\lambda\}_{\lambda \in \Lambda})$ is called the **direct sum** of $\{A_\lambda\}_{\lambda \in \Lambda}$ if $\{i_\lambda(A_\lambda)\}_{\lambda \in \Lambda}$ is a partition of S . In this case, S is written $\sum_{\lambda \in \Lambda} A_\lambda$ (or $\sum_\lambda A_\lambda$ or $\coprod_\lambda A_\lambda$). Each A_λ is called a **direct summand** of S , and each i_λ is called a **canonical injection**.

The **Cartesian product (or direct product)** $\prod_{\lambda \in \Lambda} A_\lambda$ ($\prod_\lambda A_\lambda$) of $\{A_\lambda\}_{\lambda \in \Lambda}$ (where $A_\lambda \subset X$) is the set of all mappings from Λ to X such that $f(\lambda) \in A_\lambda$ for every $\lambda \in \Lambda$. The sets A_λ are the **direct factors** of $\prod_{\lambda \in \Lambda} A_\lambda$. Each element f of $\prod_{\lambda \in \Lambda} A_\lambda$ is denoted by $\{x_\lambda\}_{\lambda \in \Lambda}$ or $(\dots, x_\lambda, \dots)$ (where $x_\lambda = f(\lambda)$). The element x_λ is the λ th **component (or coordinate)** of f . The mapping $\text{pr}_\lambda: \prod_{\lambda \in \Lambda} A_\lambda \rightarrow A_\lambda$ which assigns x_λ to each $\{x_\lambda\}_{\lambda \in \Lambda} \in \prod_{\lambda \in \Lambda} A_\lambda$ is called the **projection** of $\prod_{\lambda \in \Lambda} A_\lambda$ onto its λ th component. If $\Lambda = \{1, 2\}$, $\prod_{\lambda \in \Lambda} A_\lambda$ can be identified with $A_1 \times A_2$.

F. Set Theory

It was G. †Cantor who introduced the concept of the set as an object of mathematical study.

Cantor stated: "A set is a collection of definite, well-distinguished objects of our intuition or thought. These objects are called the elements of the set" (G. Cantor, *Math. Ann.*, 46 (1895)). Cantor introduced the notions of †cardinal number and †ordinal number and developed what is now known as **set theory**. He proved that the cardinal number of the set of transcendental numbers is greater than that of algebraic numbers, and that all Euclidean spaces have the same cardinal number regardless of their dimension. He stated the †continuum hypothesis and also conjectured the †well-ordering theorem (G. Cantor, *Math. Ann.*, 21 (1883)), which was proved by E. Zermelo [2]. In this proof Zermelo stated the †axiom of choice explicitly for the first time, and used it in an essential way.

Meanwhile it was pointed out that Cantor's naive set concept leads to various logical †paradoxes (\rightarrow 319 Paradoxes). Since the set concept plays a fundamental role in every branch of mathematics, the discovery of the paradoxes had a serious impact upon mathematics, and led to a systematic investigation of the †foundations of mathematics. In the course of attempts to avoid paradoxes, set theory was reconstructed as †axiomatic set theory (\rightarrow 33 Axiomatic Set Theory), in which Cantor's theory of cardinal numbers and ordinal numbers was restored. Also, the theory of the algebra of sets, which forms a basis for various branches of mathematics, was reconstructed. Axiomatic set theory is considered to be free from paradoxes.

G. Classes

A set in the naive sense is a collection $\{x | C(x)\}$ of all x which satisfy a certain condition $C(x)$. The only principle for generating sets in naive set theory is the **axiom of comprehension**, which asserts the existence of the set $\{x | C(x)\}$ for any condition $C(x)$. However, this principle leads to paradoxes if the notion of an **arbitrary set** is considered to be well defined; for example, the †Russell paradox is caused by the set $\{x | x \notin x\}$. This situation necessitates some restrictions on the axiom of comprehension. The simplest way to overcome the paradoxes is to adopt Zermelo's **axiom of subsets**: Given a set M and a condition $C(x)$, there exists a set $\{x | x \in M, C(x)\}$. But this axiom cannot produce any sets other than subsets of sets whose existence is preassumed. Hence further generating principles of sets had to be introduced. The following axioms are usually chosen as generating principles.

Axiom of pairing: For any two objects (possibly sets) a and b , there exists a set $\{a, b\}$.

Axiom of power set: Given a set A , its power set $\mathfrak{P}(A)$ exists.

Axiom of union: For any family of sets the union exists.

Axiom of substitution (or replacement): For any set A and any mapping f from A , there exists a set of all images $f(x)$ with $x \in A$.

In ordinary theories of mathematics the set of natural numbers, the set of real numbers, etc., are assumed to exist, in addition to sets generated by the axioms in this section. In pure set theory the **axiom of infinity** is needed to secure the existence of infinite sets.

The concept of the "set" $\{x | x \notin x\}$ does not automatically lead to Russell's paradox. The trouble arises when this "set" is regarded as a member of a collection represented by x . This leads to a narrower concept of sets. Consider a fixed collection V consisting of sets in the naive sense and closed under the set-theoretic operations mentioned in the axioms. Call a member of V a set in the narrow sense. Then set theory becomes free from the known paradoxes if the qualification for being a set is restricted in this narrow sense. When sets in the narrow sense are called simply sets, sets in the naive sense are called **classes**. The object $\{x | x \notin x\}$ (where x ranges over sets in the narrow sense) is a class which is not a set. Those classes which are not sets are called **proper classes**; for example, the class V of all sets and the class of all ordinal numbers are both proper classes. For classes, unrestricted use of the comprehension axiom again leads to paradoxes, but other set-theoretic operations are justifiably applicable to classes.

The notion of classes was first introduced in connection with the construction of an axiomatic set theory. The term *class* was used originally to denote certain subclasses of the class V of all sets. In these volumes the term *set* is mostly used to mean a set in the naive sense, and most of the notions defined for sets are applicable to classes.

382 (IX.23) Shape Theory

A. General Remarks

In 1968 K. Borsuk introduced the notion of shape as a modification of the notion of homotopy type. His idea was to take into account the global properties of topological spaces and neglect the local ones. It is a classification of spaces that is coarser than the homotopy type but that coincides with it on ANR-spaces.

Let \mathcal{P} be the category whose objects are all polyhedra and whose morphisms are homotopy classes of continuous mappings between them. For spaces X and Y , denote the set of all homotopy classes of continuous mappings of X to Y by $[X, Y]$ and the homotopy class of a mapping f by $[f]$. For a space X , let Π_X be the functor from \mathcal{P} to the category of sets and functions that assigns to a polyhedron P the set $\Pi_X(P) = [X, P]$. A morphism $\varphi: P \rightarrow Q$ of \mathcal{P} induces the function $\varphi_*: [X, P] \rightarrow [X, Q]$ defined by $\varphi_*([f]) = \varphi \circ [f]$ for $[f]: X \rightarrow P$. A natural transformation from Π_Y to Π_X is a **shape morphism** from X to Y . A continuous mapping $f: X \rightarrow Y$ defines the shape morphism $f^\#$ of X to Y as follows: For $[g]: Y \rightarrow P$ in $\Pi_Y(P)$, the composition $[g \circ f]$ is an element of $\Pi_X(P)$. The correspondence: $[g] \rightarrow [g \circ f]$ defines a natural transformation from Π_Y to Π_X and hence determines the shape morphism $f^\#: X \rightarrow Y$. The identity mapping 1_X on X defines the identity shape morphism $1_X^\#$ on X . Given spaces X and Y , X **shape dominates** Y if there are shape morphisms $\xi: Y \rightarrow X$ and $\eta: X \rightarrow Y$ such that $\xi\eta = 1_Y^\#$, and we write $\text{Sh}(X) \leq \text{Sh}(Y)$. If, in addition, $\eta\xi = 1_X^\#$, then X and Y are of the **same shape**, and we write $\text{Sh}(X) = \text{Sh}(Y)$. A **shape category** \mathcal{S} is the category whose objects are all topological spaces and whose morphisms are shape morphisms between them. If we replace topological spaces by pointed ones, the **pointed shape category** is obtained. In what follows,

382 C Shape Theory

for simplicity, we assume that all spaces are metrizable and the mappings are continuous. General references are Borsuk [1], J. Dydak and J. Segal [3], R. H. Fox [4], S. Mardešić [7].

B. Chapman's Complement Theorem

Let X be a compactum. A closed set A of X is a **Z-set** in X if for any $\varepsilon > 0$ there is a mapping $f: X \rightarrow X - A$ such that $d(x, f(x)) < \varepsilon$ for $x \in X$, where d is a metric on X . The **Hilbert cube** Q is the countable product $\prod_{i=1}^{\infty} I_i$, where I_i is the closed interval $[0, 1]$. The subset $s = \prod_{i=1}^{\infty} I_i^0$ ($I_i^0 = (0, 1)$) is called the **pseudointerior** of Q . The following facts are known: (1) If a compact metric space X is contained in s or $Q - s$, then X is a Z-set in Q . (2) For any continuous mapping f of a compact metric space X into Q , there exists an embedding g of X into Q such that g is arbitrarily close to f and the image $g(X)$ in Q is a Z-set. The **complement theorem** (T. A. Chapman [2]) states: Let X and Y be Z-sets in Q . Then $\text{Sh}(X) = \text{Sh}(Y)$ iff $Q - X$ and $Q - Y$ are homeomorphic.

C. FAR, FANR, Movability, and Shape Group: Shape Invariants

A closed set A of a compactum X is a **fundamental retract** of X if there is a shape morphism $r: X \rightarrow A$ such that $r \circ i^\# = 1_A^\#$, where i is the inclusion of A into X . A compactum X is a **fundamental absolute retract (FAR)** (resp. **fundamental absolute neighborhood retract (FANR)**) if for any compactum Y containing X , X is a fundamental retract of Y (resp. of some closed neighborhood of X in Y). A compactum X is **movable** if for any embedding $X \subset Q$ and for any neighborhood U of X in Q there is a neighborhood V of X satisfying the following condition: For any mapping f of a compactum Y to V and for any neighborhood W of X , there is a homotopy $H: Y \times I \rightarrow U$ such that $H(y, 0) = f(y)$ and $H(y, 1) \in W$ for $y \in Y$. In this definition, if Y is replaced by a compactum with dimension $\leq k$, then X is said to be **k-movable**. Pointed FAR, FANR, movability, and k -movability are defined similarly in the pointed shape category. The following facts are known (Borsuk [1], Dydak and Segal [3], J. Keeslings [5], J. Krasinkiewicz [8]). A compactum X is a FAR if and only if X is a pointed FAR iff $\text{Sh}(X) = \text{Sh}(\text{point})$, i.e., X has the same shape as a one-point space. A pointed compactum (X, x) is a pointed FANR iff $\text{Sh}(X, x) \leq \text{Sh}(K, k)$ for some pointed polyhedron (K, k) . An FANR is movable. A compact connected Abelian topological group is movable if and only if it is locally connected.

A continuous image of a pointed 1-movable compactum is pointed 1-movable. It is unknown whether (i) an FANR is a pointed FANR and (ii) movability means pointed movability. For a pointed compactum (X, x) , let $\{(K_i, k_i) \mid i = 1, 2, \dots\}$ be a countable inverse system consisting of pointed finite polyhedra whose limit is (X, x) . The limit group $\varprojlim \pi_n(K_i, k_i)$ is the k th **shape group** of (X, x) , where $\pi_n(K, k)$ is the k th homotopy group of (K, k) . It is known that the shape groups for movable compacta behave like homotopy groups for ANR. A property P of spaces is a **shape invariant** if whenever X has P and $\text{Sh}(X) = \text{Sh}(Y)$, then Y has P . FAR, FANR, movability, k -movability, and shape groups are shape invariants.

D. CE Mappings

A mapping f of a space X onto a space Y is a **cell-like (CE) mapping** if it is proper and $\text{Sh}(f^{-1}(y)) = \text{Sh}(\text{point})$ for each point y of Y . It is known (R. B. Sher [9], Y. Kodama [6]) that if there is a CE mapping of X to Y with finite dimension, then $\text{Sh}(X) = \text{Sh}(Y)$. Here the finite-dimensionality of Y is essential. A **Q -manifold** is a space, each point of which has a closed neighborhood homeomorphic to Q . The following are known (Chapman [2], J. E. West [10]): (1) If f is a CE mapping of a Q -manifold M to an ANR X , then the mapping $g: M \times Q \rightarrow X \times Q$ defined by $g(m, x) = (f(m), x)$ for $(m, x) \in M \times Q$ is approximated by homeomorphisms. As a consequence, if X is a locally compact ANR, then $X \times Q$ is a Q -manifold. (2) Every compact ANR is a CE image of a compact Q -manifold. (3) Every compact ANR has the same homotopy type as that of a compact polyhedron. The following problem raised by R. H. Bing is open: Is a CE image of a finite-dimensional compactum finite-dimensional?

383 (II.26) Sheaves

A. Presheaves

Let X be a topological space. Suppose that the following conditions are satisfied: (i) There exists an (additive) Abelian group $\mathcal{F}(U)$ for each open set U of X , and $\mathcal{F}(\emptyset) = \{0\}$; and (ii) there exists a homomorphism $r_{UV}: \mathcal{F}(V) \rightarrow \mathcal{F}(U)$ for each pair $U \subset V$, such that $r_{UU} = 1$ (identity) and $r_{UV} = r_{UV} \circ r_{VW}$ for $U \subset V \subset W$. We call \mathcal{F} , consisting of a family $\{\mathcal{F}(U)\}$ of Abelian groups and a family of mappings $\{r_{UV}\}$, a **presheaf** (of Abelian groups) on X . If $a \in \mathcal{F}(V)$ and $U \subset V$, we write $r_{UV}(a) = a|U$ and call it the **restriction** of a to U . A **homomorphism** φ between two presheaves \mathcal{F} and \mathcal{G} on X is a family $\{\varphi(U)\}$ of group homomorphisms $\varphi(U): \mathcal{F}(U) \rightarrow \mathcal{G}(U)$ satisfying $r_{UV} \circ \varphi(V) = \varphi(U) \circ r_{UV}$ whenever $U \subset V$. The presheaves on X and their homomorphisms form a †category.

B. Axioms for Sheaves

A presheaf \mathcal{F} is called a **sheaf** (of Abelian groups) if it satisfies the following condition: If U is open in X and $(U_i)_{i \in I}$ is an †open covering of U , and if for each $i \in I$ an element s_i of $\mathcal{F}(U_i)$ is given such that $s_i|U_i \cap U_j = s_j|U_i \cap U_j$ for all i and j , then there exists a unique $s \in \mathcal{F}(U)$ such that $s|U_i = s_i$ for all i . By definition, a **homomorphism** between two sheaves is a homomorphism of the presheaves. The sheaves on X also form a category.

Let \mathcal{F} be a presheaf, x a point of X , and \mathfrak{R}_x the †directed set of open neighborhoods of x , with the order opposite to that of inclusion. Then $\{\mathcal{F}(U) \mid U \in \mathfrak{R}_x\}$ is an inductive system of groups. The †inductive limit $\varinjlim_{U \in \mathfrak{R}_x} \mathcal{F}(U)$ of groups $\{\mathcal{F}(U)\}$ is denoted by \mathcal{F}_x and called the **stalk** of \mathcal{F} over x . The image of $s \in \mathcal{F}(U)$ in \mathcal{F}_x is called the **germ** of s at x and is written s_x .

A homomorphism $\varphi: \mathcal{F} \rightarrow \mathcal{G}$ of presheaves induces a homomorphism $\varphi_x: \mathcal{F}_x \rightarrow \mathcal{G}_x$ of stalks.

C. Sheaf Spaces

We introduce a topology on the †direct sum $\mathcal{F}' = \coprod_{x \in X} \mathcal{F}_x$ in the following way: For each open set U of X and each $s \in \mathcal{F}(U)$, consider the set $M_{U,s} = \{s_x | x \in U\}$ of the germs defined by s at the points of U , and take the set of all such $M_{U,s}$ as a †base of open sets of the topology. If $p: \mathcal{F}' \rightarrow X$ is the mapping that maps the points of \mathcal{F}'_x to x , then p is continuous, and each $p^{-1}(x)$ ($= \mathcal{F}'_x$) has the structure of an Abelian group. Moreover, the following conditions are satisfied: (i) p is a †local homeomorphism, and (ii) the group operations on $p^{-1}(x)$ are continuous in the sense that $(a, b) \rightarrow a + b$ is a continuous mapping from the †fiber product $\mathcal{F}' \times_X \mathcal{F}'$ (i.e., the subspace $\{(a, b) | p(a) = p(b)\}$ of the product space $\mathcal{F}' \times \mathcal{F}'$) to \mathcal{F}' and $a \rightarrow -a$ is a continuous mapping from \mathcal{F}' to itself. In general, a topological space \mathcal{F}' with a structure satisfying these conditions is called a **sheaf space** over X .

When \mathcal{F}' is a sheaf space, a continuous mapping s from a subspace A of X to \mathcal{F}' such that $p \circ s = 1_A$ is called a **section** of \mathcal{F}' over A . The **set of sections** over A , denoted by $\Gamma(A, \mathcal{F}')$, is an Abelian group in the obvious way. If we associate $\Gamma(U, \mathcal{F}')$ with each open set U and define r_{UV} by the restriction of sections ($r_{UV}(s) = s|U$), then we get a sheaf \mathcal{F}'' on X . If we start from a presheaf \mathcal{F} and get \mathcal{F}'' via \mathcal{F}' , the correspondence $\mathcal{F} \rightarrow \mathcal{F}''$ is a †covariant functor from the category of presheaves to the category of sheaves, and \mathcal{F}'' is called the **sheaf associated with the presheaf \mathcal{F}** . If \mathcal{F} is a sheaf, we can prove $\mathcal{F}'' \cong \mathcal{F}$. Conversely, if we start from a sheaf space \mathcal{F}' and construct the sheaf \mathcal{F}'' and then the sheaf space \mathcal{F}''' , then \mathcal{F}''' is canonically isomorphic to \mathcal{F}' . Since we can identify a sheaf and the corresponding sheaf space, both are usually denoted by the same letter. In particular, when \mathcal{F} is a sheaf, $\mathcal{F}(U)$ is usually written $\Gamma(U, \mathcal{F})$.

Given a section $s \in \Gamma(X, \mathcal{F})$ of a sheaf, the points $x \in X$ for which $s_x \neq 0$ in \mathcal{F}_x form a closed set (the sheaf space \mathcal{F} is not necessarily Hausdorff even if X is so). This set is called the **support** of s and is denoted by $\text{supp } s$.

In the theory of this and the previous two sections, we can replace Abelian groups by groups, rings, etc. Then $\mathcal{F}(U)$ is a group or ring accordingly, and $\mathcal{F}(\emptyset)$ the group consisting of the identity element or the ring consisting of the zero element, respectively. We thus obtain the theories of **sheaves of groups**, **sheaves of rings**, etc. In general, a presheaf \mathcal{F} on X with values in a category \mathcal{C} is a †con-

travariant functor from the category of open sets of X to \mathcal{C} , and a homomorphism between presheaves \mathcal{F} and \mathcal{G} on X is a †natural transformation between the functors \mathcal{F} and \mathcal{G} .

The presheaves (sheaves) of Abelian groups on a space X form an †Abelian category, denoted by \mathcal{P}^X (\mathcal{C}^X). For a homomorphism $f: \mathcal{F} \rightarrow \mathcal{G}$ of presheaves, the **image**, **coimage**, **kernel**, and **cokernel** of f in \mathcal{P}^X are given by

$$(\text{Im } f)(U) = \text{Im } f(U),$$

$$(\text{Coim } f)(U) = \text{Coim } f(U),$$

$$(\text{Ker } f)(U) = \text{Ker } f(U),$$

$$(\text{Coker } f)(U) = \text{Coker } f(U).$$

When \mathcal{F} and \mathcal{G} are sheaves, the kernel of f in \mathcal{C}^X coincides with the kernel in \mathcal{P}^X , while the image and cokernel of f in \mathcal{C}^X are the associated sheaves of the image and the cokernel in \mathcal{P}^X , respectively. Thus, $f: \mathcal{F} \rightarrow \mathcal{G}$ induces $f_x: \mathcal{F}_x \rightarrow \mathcal{G}_x$ at each $x \in X$, $(\text{Ker } f)_x = \text{Ker } f_x$, $(\text{Im } f)_x = \text{Im } f_x$, $(\text{Coker } f)_x = \text{Coker } f_x$, and a sequence of sheaves $0 \rightarrow \mathcal{F} \xrightarrow{f} \mathcal{G} \xrightarrow{g} \mathcal{H} \rightarrow 0$ is **exact** if and only if $0 \rightarrow \mathcal{F}_x \xrightarrow{f_x} \mathcal{G}_x \xrightarrow{g_x} \mathcal{H}_x \rightarrow 0$ is exact at each $x \in X$.

D. Examples

(1) Let G be an Abelian group (or some other †algebraic system) with †discrete topology. The Cartesian product $X \times G$ gives rise to a sheaf on X , called a **constant sheaf** (or **trivial sheaf**).

(2) Let X be a topological space and Y be a topological Abelian group (e.g., the real or complex numbers). We obtain a sheaf \mathcal{F} on X by putting $\mathcal{F}(U) =$ the set of all continuous mappings $U \rightarrow Y$ and $r_{UV} =$ the natural restriction. The stalk over $x \in X$ is the set of germs at x of continuous functions into Y . This sheaf is called the **sheaf of germs of continuous functions** with values in Y .

(3) When X is an †analytic manifold and Y is a commutative †Lie group, we define the **sheaf of germs of analytic mappings** with values in Y in the same way. If Y is the complex number field \mathbb{C} , this sheaf is the **sheaf \mathcal{O} of germs of analytic** (or **holomorphic**) **functions**. A †connected component of the sheaf space \mathcal{O} can be identified with the †analytic function determined by the function element corresponding to a point on that component. The **sheaf of germs of functions of class C^r** on a C^s -manifold ($r \leq s$) is similarly defined.

(4) Given a †vector bundle B over a topological space X , we define a sheaf on X by $\mathcal{F}(U) = \Gamma(U)$ ($=$ the module of sections of B over U) and $r_{UV} =$ the natural restriction. Here the stalk over $x \in X$ consists of the germs at x of sections of B , and is called the **sheaf of germs of sec-**

tions of the vector bundle B . We have similar definition for the **sheaf of germs of differentiable (analytic) sections** when X is a †differentiable (complex) manifold. The case where B is a †tensor bundle (e.g., the †cotangent bundle $\mathfrak{T}^*(X)$) is important. The sheaf $\mathfrak{U}^r(X)$ of germs of C^∞ -sections of the r -fold †exterior power of $\mathfrak{T}^*(X)$ is called the **sheaf of germs of differential forms of degree r** ($0 \leq r \leq \dim X$).

E. Sheaf Cohomology

The category \mathcal{C}^X of sheaves of Abelian groups on X has sufficiently many †injective objects. A sheaf \mathcal{F} with the property that $r_{U,X}: \Gamma(U, \mathcal{F}) \rightarrow \Gamma(U, \mathcal{F})$ is surjective for any open set U is said to be **flabby** (or **scattered**). An injective sheaf is flabby.

Fix a nonempty family Φ of closed subsets of X satisfying the following two conditions: (i) $A, B \in \Phi \Rightarrow A \cup B \in \Phi$; (ii) any closed set contained in an element of Φ belongs to Φ . Putting $\Gamma_\Phi(\mathcal{F}) = \{s \mid s \in \Gamma(X, \mathcal{F}), \text{supp } s \in \Phi\}$ for each $\mathcal{F} \in \mathcal{C}^X$, we obtain a †left-exact †covariant functor Γ_Φ from \mathcal{C}^X to the category (Ab) of Abelian groups. Therefore, by the general theory of homological algebra, we can define the †right derived functors $R^q \Gamma_\Phi: \mathcal{C}^X \rightarrow (\text{Ab})$ ($q = 0, 1, 2, \dots$). We put $R^q \Gamma_\Phi(\mathcal{F}) = H_\Phi^q(X, \mathcal{F})$ and call the $H_\Phi^q(X, \mathcal{F})$ ($q = 0, 1, \dots$) the **cohomology groups with coefficient sheaf \mathcal{F}** and family of supports Φ (\rightarrow 200 Homological Algebra I). When Φ is the family of all closed subsets of X , we write $H^q(X, \mathcal{F})$ instead of $H_\Phi^q(X, \mathcal{F})$.

Thus the cohomology group $H_\Phi^q(X, \mathcal{F})$ is the q th cohomology of the complex $\Gamma_\Phi(\mathcal{Q}^0) \xrightarrow{d^0} \Gamma_\Phi(\mathcal{Q}^1) \xrightarrow{d^1} \Gamma_\Phi(\mathcal{Q}^2) \xrightarrow{d^2} \dots$ induced by an †injective resolution $0 \rightarrow \mathcal{F} \rightarrow \mathcal{Q}^0 \rightarrow \mathcal{Q}^1 \rightarrow \dots$ of the sheaf $\mathcal{F}: H_\Phi^q(X, \mathcal{F}) = \text{Ker } d^q / \text{Im } d^{q-1}$ ($q = 0, 1, \dots; d^{-1} = 0$).

$H_\Phi^0(X, \mathcal{F}) = \Gamma_\Phi(\mathcal{F})$, and from an exact sequence of sheaves $0 \rightarrow \mathcal{F} \rightarrow \mathcal{G} \rightarrow \mathcal{H} \rightarrow 0$ we get an exact sequence $0 \rightarrow H_\Phi^0(X, \mathcal{F}) \rightarrow H_\Phi^0(X, \mathcal{G}) \rightarrow H_\Phi^0(X, \mathcal{H}) \rightarrow H_\Phi^1(X, \mathcal{F}) \rightarrow H_\Phi^1(X, \mathcal{G}) \rightarrow H_\Phi^1(X, \mathcal{H}) \rightarrow H_\Phi^2(X, \mathcal{F}) \rightarrow \dots$

Similarly, the cohomology groups $H_\Phi^q(X, \mathcal{F})$ can also be calculated with an exact sequence $0 \rightarrow \mathcal{F} \rightarrow \mathcal{Q}^0 \rightarrow \mathcal{Q}^1 \rightarrow \dots$, where each \mathcal{Q}^i is assumed to be Γ_Φ -acyclic (i.e., $H_\Phi^q(X, \mathcal{Q}^i) = 0$ for $q > 0$) instead of injective. The flabby sheaves, for instance, are Γ_Φ -acyclic, so we can compute $H_\Phi^q(X, \mathcal{F})$ by a flabby resolution of \mathcal{F} (R. Godement). For example, let X be an n -dimensional †paracompact C^∞ -manifold and $\mathcal{F} = \mathbf{R}$. Then $0 \rightarrow \mathbf{R} \rightarrow \mathfrak{U}^0(X) \xrightarrow{d^0} \mathfrak{U}^1(X) \xrightarrow{d^1} \dots$ is exact, where $\mathfrak{U}^q(X)$ is the †sheaf of germs of C^∞ -differential forms of degree q , d^q is †exterior differentiation (**Poincaré's theorem**), and we have $H^p(X, \mathfrak{U}^q) = 0$ for $p > 0$. Therefore

$H^q(X, \mathbf{R})$ is the q th cohomology of the complex $0 \rightarrow D^0(X) \xrightarrow{d^0} D^1(X) \xrightarrow{d^1} \dots$, where $D^i(X) = \Gamma(X, \mathfrak{U}^i(X)) =$ the group of C^∞ -differential forms of degree i on X . This proves the de Rham theorem, which says that the †de Rham cohomology group is isomorphic to the †(singular) cohomology group of X with real coefficients (\rightarrow 105 Differentiable Manifolds R). For a sheaf \mathcal{F} of noncommutative groups, we can define the first cohomology $H^1(X, \mathcal{F})$ [2].

F. The Čech Cohomology Group

Let $\mathfrak{U} = \{U_i\}$ be an open covering of X , and write $U_i \cap U_j = U_{ij}$, etc. Put

$$C^p(\mathcal{F}) = \prod_{i_0, \dots, i_p} \Gamma(U_{i_0 \dots i_p}, \mathcal{F}), \quad p = 0, 1, 2, \dots$$

An element of $C^p(\mathcal{F})$ is called a cochain of degree p . Define $d: C^p(\mathcal{F}) \rightarrow C^{p+1}(\mathcal{F})$ by $(df)_{i_0 \dots i_{p+1}} = \sum_{r=0}^{p+1} (-1)^r (f_{i_0 \dots \hat{i}_r \dots i_{p+1}} | U_{i_0 \dots i_{p+1}})$, and denote the q th cohomology of the complex $(C^p(\mathcal{F}), d)$ thus obtained by $H^q(\mathfrak{U}, \mathcal{F})$. When an open covering \mathfrak{B} is a refinement of \mathfrak{U} , there is a canonical homomorphism $H^q(\mathfrak{U}, \mathcal{F}) \rightarrow H^q(\mathfrak{B}, \mathcal{F})$. So we can take the inductive limit of the groups $H^q(\mathfrak{U}, \mathcal{F})$ with respect to the refinement of open coverings. This limit group is denoted by $\check{H}^q(X, \mathcal{F})$ and is called the **Čech cohomology group with coefficient sheaf \mathcal{F}** . It coincides with $H^q(X, \mathcal{F})$ for $q \leq 1$, and if X is paracompact, for all q .

G. Relation to Continuous Mappings

Let X and Y be topological spaces and $f: X \rightarrow Y$ be a continuous mapping. If \mathcal{F} is a sheaf on Y , the fiber product $X \times_Y \mathcal{F}$ (where \mathcal{F} is viewed as a sheaf space over Y) is a sheaf on X . It is denoted by $f^*(\mathcal{F})$ or $f^{-1}(\mathcal{F})$ and is called the **inverse image** of \mathcal{F} . The correspondence $\mathcal{F} \rightarrow f^*(\mathcal{F})$ is an exact functor from \mathcal{C}^Y to \mathcal{C}^X . Next, let \mathcal{G} be a sheaf on X . Associating $\Gamma(f^{-1}(U), \mathcal{G})$ with each open set U of Y , we obtain a sheaf on Y , which we denote by $f_*(\mathcal{G})$ and call the **direct image** of \mathcal{G} . The correspondence f_* is a left-exact functor $\mathcal{C}^X \rightarrow \mathcal{C}^Y$, and we can consider its right derived functors $R^q f_*$. The sheaf $R^q f_*(\mathcal{G})$ is the sheaf associated with the presheaf that associates $H^q(f^{-1}(U), \mathcal{G})$ with each open set U .

A homomorphism ψ from \mathcal{F} to $f_*(\mathcal{G})$ is also called an f -homomorphism from \mathcal{F} to \mathcal{G} . To give such a ψ is equivalent to giving a family of homomorphisms of the stalks $\psi_x: \mathcal{F}_{f(x)} \rightarrow \mathcal{G}_x$ ($x \in X$) satisfying the continuity condition: For any open set U of Y and any section $s \in \Gamma(U, \mathcal{G})$ over U , the mapping φ from $f^{-1}(U)$ to \mathcal{G} defined by $\varphi(x) = \psi_x(s(f(x)))$ is continuous.

The functors f^* and f_* are related by

$\text{Hom}(f^*(\mathcal{F}), \mathcal{G}) \cong \text{Hom}(\mathcal{F}, f_*(\mathcal{G}))$. The Leray spectral sequence

$$E_2^{p,q} = H^p(Y, R^q f_*(\mathcal{G})) \Rightarrow H^n(X, \mathcal{G})$$

exists and connects the cohomologies of X and of Y .

H. Ringed Spaces

Let X be a topological space and \mathcal{O} be a sheaf on X of commutative rings with unity element such that $\mathcal{O}_x \neq \{0\}$ for any $x \in X$. Then the pair (X, \mathcal{O}) is called a **ringed space**, and \mathcal{O} is called its **structure sheaf**. A morphism $(X, \mathcal{O}) \rightarrow (X', \mathcal{O}')$ is by definition a pair (f, θ) consisting of a continuous mapping $f: X \rightarrow X'$ and an f -homomorphism $\theta: \mathcal{O} \rightarrow \mathcal{O}'$. When each \mathcal{O}_x is a local ring, (X, \mathcal{O}) is called a **local ringed space**. A morphism of local ringed spaces is defined to be a pair $(f, \theta): (X, \mathcal{O}) \rightarrow (X', \mathcal{O}')$ as before, satisfying the additional condition that θ is local (i.e., $\theta_x: \mathcal{O}'_{f(x)} \rightarrow \mathcal{O}_x$ maps the maximal ideal into the maximal ideal for each $x \in X$). These concepts are important in algebraic geometry and the theory of functions of several complex variables.

I. Direct Products and Tensor Products

Let \mathcal{F}_λ ($\lambda \in \Lambda$) be sheaves of Abelian groups on a topological space X . The sheaf \mathcal{F} on X defined by $\mathcal{F}(U) = \prod_\lambda \mathcal{F}_\lambda(U)$ and $r_{UV} = \prod_\lambda r_{UV}^\lambda$ is denoted by $\mathcal{F} = \prod_\lambda \mathcal{F}_\lambda$ and called the **direct product** of sheaves $\{\mathcal{F}_\lambda\}$. For each $x \in X$ there is a natural mapping $\mathcal{F}_x \rightarrow \prod_\lambda (\mathcal{F}_\lambda)_x$, which is in general neither injective nor surjective. When Λ is a finite set, $\prod \mathcal{F}_i$ is also written $\mathcal{F} = \mathcal{F}_1 + \dots + \mathcal{F}_n$ and is called the **direct sum** of the sheaves. The **inductive limit** $\mathcal{F} = \text{ind lim } \mathcal{F}_\lambda$ of an inductive system of sheaves on X also exists, and $\mathcal{F}_x = \text{ind lim } \mathcal{F}_{\lambda,x}$.

Let (X, \mathcal{O}) be a ringed space. A sheaf of Abelian groups \mathcal{F} on X is called a **sheaf of \mathcal{O} -modules** (or simply an **\mathcal{O} -module**) if $\mathcal{F}(U)$ is an $\mathcal{O}(U)$ -module for each U and $r_{UV}: \mathcal{F}(V) \rightarrow \mathcal{F}(U)$ is a module homomorphism compatible with $\mathcal{O}(V) \rightarrow \mathcal{O}(U)$ for each $U \subset V$. Then \mathcal{F}_x is an \mathcal{O}_x -module for each $x \in X$. For a fixed (X, \mathcal{O}) , the \mathcal{O} -modules form an Abelian category. When \mathcal{F} and \mathcal{G} are \mathcal{O} -modules, the **tensor product** $\mathcal{H} = \mathcal{F} \otimes_{\mathcal{O}} \mathcal{G}$ of \mathcal{F} and \mathcal{G} as sheaves over \mathcal{O} is defined as follows: Define a presheaf by $U \rightarrow \mathcal{F}(U) \otimes_{\mathcal{O}(U)} \mathcal{G}(U)$ and $r_{UV} = r_{UV}^\mathcal{F} \otimes r_{UV}^\mathcal{G}$, and let \mathcal{H} be the associated sheaf of this presheaf. Then we have $\mathcal{H}_x = \mathcal{F}_x \otimes_{\mathcal{O}_x} \mathcal{G}_x$.

The notion of coherent sheaves is important in the theory of \mathcal{O} -modules (\rightarrow 16 Algebraic Varieties E).

J. History

About 1945, J. Leray established the theory of sheaf coefficient cohomology groups (in a form slightly different from that in Sections E and F) and the theory of spectral sequences to study the relation between the local properties of a continuous mapping and the global cohomologies. In the theory of functions of several complex variables, K. Oka conceived the idea of "ideals of indefinite domain." These two ideas were unified by H. Cartan into the present form of sheaf theory. As a link between local properties and global properties, sheaf theory has been applied in many branches of mathematics (\rightarrow 16 Algebraic Varieties; 21 Analytic Functions of Several Complex Variables; 23 Analytic Spaces; 72 Complex Manifolds).

384 (VII.20) Siegel Domains

A. Siegel Domains

Let D be a bounded domain in \mathbb{C}^n and $G_n(D)$ the full holomorphic automorphism group of

D , which is a \dagger Lie transformation group with respect to the \dagger compact-open topology. If $G_h(D)$ acts transitively on D , then D is called a **homogeneous bounded domain**. The study of homogeneous bounded domains was initiated systematically by E. Cartan in 1936, while the notion of **Siegel domains**, which was introduced by I. I. Pyatetskiĭ-Shapiro, has made remarkable contributions to the study of homogeneous bounded domains.

Let V be a convex domain in an n -dimensional real vector space R . V is called a **regular cone** if for every $x \in V$ and $\lambda > 0$, $\lambda x \in V$ and if V contains no entirely straight lines. Let W be a complex vector space. A mapping $F: W \times W \rightarrow R^C$ (the \dagger complexification of R) is a **V -Hermitian form** if the following conditions are satisfied: (Fi) $F(u, v)$ is C -linear in u , (Fii) $\overline{F(u, v)} = F(v, u)$, where the bar denotes the \dagger conjugation with respect to R , (Fiii) $F(u, u) \in \overline{V}$ (the closure of V), and (Fiv) $F(u, u) = 0$ implies $u = 0$. Given a regular cone $V \subset R$ and a V -Hermitian form F on W , one can define a **Siegel domain $D(V, F)$ (of the second kind)** by putting $D(V, F) = \{(x + iy, u) \in R^C \times W \mid y - F(u, u) \in V\}$, which is holomorphically equivalent to a bounded domain in $R^C \times W$. When $W = (0)$, $D(V, F)$ is reduced to $D(V) = \{x + iy \in R^C \mid y \in V\}$, which is called a **Siegel domain of the first kind**. A mapping $L: W \times W \rightarrow R^C$ is a nondegenerate semi-Hermitian form if L can be written as $L = L_1 + L_2$, where L_1 and L_2 are R^C -valued functions satisfying the conditions: (Li) L_1 satisfies (Fi) and (Fii); (Lii) L_2 is a symmetric C -bilinear form; (Liii) $L(u, v) = 0$ for all $u \in W$ implies $v = 0$. Let B be a bounded domain in a complex vector space X and L_p ($p \in B$) an R^C -valued nondegenerate semi-Hermitian form on W depending differentiably on $p \in B$. Consider a domain $D(V, L, B)$ in $R^C \times W \times X$ defined by putting $D(V, L, B) = \{(x + iy, u, p) \in R^C \times W \times X \mid y - \text{Re} L_p(u, u) \in V, p \in B\}$. The domain $D(V, L, B)$ is called a **Siegel domain of the third kind** over B if it is holomorphically equivalent to a bounded domain. $D(V, L, B)$ is a fiber space over B .

By the affine automorphism group G_a of a Siegel domain $D(V, F) \subset R^C \times W$ we mean the group consisting of all elements in the complex affine transformation group of $R^C \times W$ leaving $D(V, F)$ stable. The full holomorphic automorphism group G_h of $D(V, F)$ contains G_a as a closed subgroup. If G_h acts transitively on $D(V, F)$, then $D(V, F)$ is said to be homogeneous. A homogeneous Siegel domain is necessarily affinely homogeneous, i.e., G_a acts transitively on $D(V, F)$ [2]. The \dagger Bergman metric of $D(V, F)$ which is a G_h -invariant \dagger Kähler metric, is \dagger complete [3], and so $D(V, F)$ is a \dagger domain of holomorphy.

Examples. $H(n, R)$ denotes the vector space of all real symmetric matrices of degree n , and $H^+(n, R)$ the regular cone consisting of all positive definite matrices in $H(n, R)$.

(i) The Siegel domain of the first kind $D(H^+(n, R)) = \{X + iY \mid X \in H(n, R), Y \in H^+(n, R)\}$ is called the \dagger Siegel upper half-plane, which is holomorphically equivalent to the classical \dagger symmetric domain of type III.

(ii) Let $u, v \in C$ and $F(u, v)$ be the 2×2 diagonal matrix $\text{diag}(u\bar{v}, 0)$, which is an $H^+(2, R)$ -Hermitian form on C . The resulting Siegel domain is

$$D(H^+(2, R), F) = \left\{ (z_1, z_2, z_3, u) \in C^4 \mid \begin{pmatrix} \text{Im } z_1 - |u|^2 & \text{Im } z_3 \\ & \text{Im } z_3 & \text{Im } z_2 \end{pmatrix} \in H^+(2, R) \right\}.$$

(iii) Let $B = \{t \in C \mid |t| < 1\}$, and let $u, v \in C$. Put $L_t(u, v) = (1 - |t|^2)^{-1}(u\bar{v} + t\bar{u}v)$. Then $L_t(u, v)$ is a nondegenerate semi-Hermitian form, and we have $D(H^+(2, R), L, B) = \{(z, u, t) \in C^3 \mid \text{Im } z - (1 - |t|^2)^{-1} \text{Re}(|u|^2 + \bar{t}u^2) > 0, |t| < 1\}$, which is a Siegel domain of the third kind and is holomorphically equivalent to the Siegel upper half-plane of dimension 3.

The domains in (i) and (ii) are both affinely homogeneous; the latter was originally found by Pyatetskiĭ-Shapiro in 1959 [1] and provides the least-dimensional example of non-symmetric homogeneous bounded domains, which answered affirmatively Cartan's conjecture (1936): Are there non- \dagger symmetric homogeneous bounded domains in C^n ($n \geq 4$)?

B. Infinitesimal Automorphisms of Siegel Domains

For a Siegel domain $D(V, F) \subset R^C \times W$, the Lie algebra \mathfrak{g}_h of G_h can be identified with the Lie algebra of infinitesimal automorphisms, i.e., all complete holomorphic vector fields on $D(V, F)$. Let $G(V)$ be the group consisting of all the linear automorphisms of R leaving V stable. Let us fix a base in R , and let (z_1, z_2, \dots, z_n) be the complex linear coordinate system in R^C corresponding to it. Choose a complex linear coordinate system (u_1, u_2, \dots, u_m) in W . We write $F(u, v)$ as $F(u, v) = (F_1(u, v), \dots, F_n(u, v))$. Consider the following two vector fields in the Lie algebra \mathfrak{g}_a of G_a :

$$E = 2 \sum_k z_k \frac{\partial}{\partial z_k} + \sum_x u_x \frac{\partial}{\partial u_x}, \quad I = \sum_x i u_x \frac{\partial}{\partial u_x},$$

and put $\mathfrak{g}_a^\lambda = \{X \in \mathfrak{g}_a \mid [E, X] = \lambda X\}$, $\lambda \in Z$. Then \mathfrak{g}_a can be written as a \dagger graded Lie algebra in the following way: $\mathfrak{g}_a = \mathfrak{g}_a^{-2} + \mathfrak{g}_a^{-1} + \mathfrak{g}_a^0$. Here

we have

$$g_a^{-2} = \left\{ \sum_k a_k \frac{\partial}{\partial z_k} \mid a_k \in \mathbf{R} \right\},$$

$$g_a^{-1} = \left\{ 2i \sum_k F_k(u, c) \frac{\partial}{\partial z_k} + \sum_a c_a \frac{\partial}{\partial u_a} \mid \right.$$

$$\left. c = (c_a), \quad c_a \in \mathbf{C} \right\},$$

and g_a^0 consists of all vector fields $X_{(A, B)}$ of the form

$$\sum_{k, j} a_{kj} z_j \frac{\partial}{\partial z_k} + \sum_{\alpha, \beta} b_{\alpha\beta} u_\beta \frac{\partial}{\partial u_\alpha},$$

where the matrices $A = (a_{kj}), B = (b_{\alpha\beta})$ satisfy the conditions: $\exp tA \in G(V), t \in \mathbf{R}; AF(u, v) = F(Bu, v) + F(u, Bv)$. For $X_{(A, B)} \in g_a^0$ we define $\text{tr } X_{(A, B)}$ to be the sum of the trace of A and that of B . Let g^λ be the λ -eigenspace of $\text{ad } E$ in g_h ($\lambda \in \mathbf{Z}$). Then g_h can be written also in the form of a graded Lie algebra: $g_h = g^{-2} + g^{-1} + g^0 + g^1 + g^2$, and $g^\lambda = g_a^\lambda$ is valid for $\lambda = -2, -1, 0$. Furthermore g_h can be nicely determined by g_a in the following manner. $p_{\mu\lambda}$ denotes a polynomial on $R^C \times W$ homogeneous of degree μ in z_1, \dots, z_n , and homogeneous of degree λ in u_1, \dots, u_m . Let \hat{g}^1 (resp. \hat{g}^2) be the set of all polynomial vector fields of the form

$$\sum_k p_{1,1}^k \frac{\partial}{\partial z_k} + \sum_a (p_{1,0}^a + p_{0,2}^a) \frac{\partial}{\partial u_a}$$

$$\left(\text{resp. } \sum_k p_{2,0}^k \frac{\partial}{\partial z_k} + \sum_a p_{1,1}^a \frac{\partial}{\partial u_a} \right).$$

Then we have $g^1 = \{X \in \hat{g}^1 \mid [X, g^{-1}] \subset g^0\}$, and $g^2 = \{X \in \hat{g}^2 \mid [X, g^{-2}] \subset g^0, [X, g^{-1}] \subset g^1, \text{Im Tr } [X, Y] = 0 \text{ for } Y \in g^{-2}\}$. Another description of g^1 and g^2 has been given in terms of Jordan triple systems [4]. The explicit descriptions of g^1 and g^2 have been given for most homogeneous Siegel domains $D(V, F)$ over irreducible self-dual cones V (\rightarrow Section D; T. Tsuji, *Nagoya Math. J.*, 55 (1974)). $g_h = g_a$ is valid for the Siegel domains which are irreducible quasisymmetric but not symmetric (\rightarrow Section D). Main references for this section are [2-6].

C. *j*-Algebras and Homogeneous Bounded Domains

The notion of *j*-algebra was introduced by Pyatetskii-Shapiro [1], which reduces the study of homogeneous bounded domains to purely algebraic problems. Let g be a Lie algebra over \mathbf{R} , and \mathfrak{f} a subalgebra of g , (j) a collection of linear endomorphisms of g , and ω be a linear form on g . Then the quadruple

$\{g, \mathfrak{f}, (j), \omega\}$ (sometimes abbreviated g) is called a *j*-algebra if the following conditions are satisfied: (i) $j\mathfrak{f} \subset \mathfrak{f}$ for $j \in (j)$ and $j \equiv j' \pmod{\mathfrak{f}}$ for $j, j' \in (j)$; (ii) $j^2 \equiv -id \pmod{\mathfrak{f}}$; (iii) $j[k, x] \equiv [k, jx] \pmod{\mathfrak{f}}$ for $k \in \mathfrak{f}, x \in g$; (iv) $[jx, jy] \equiv j[jx, y] + j[x, jy] + [x, y] \pmod{\mathfrak{f}}$ for $x, y \in g$; (v) $\omega([k, x]) = 0$ for $k \in \mathfrak{f}$; (vi) $\omega([jx, jy]) = \omega([x, y])$; (vii) $\omega([jx, x]) > 0$ for $x \notin \mathfrak{f}$. Let g' be a subalgebra of g such that $jg' \subset g' + \mathfrak{f}$. Then, putting $\mathfrak{f}' = g' \cap \mathfrak{f}$, one can naturally induce a *j*-algebra structure on the pair $\{g', \mathfrak{f}'\}$. The *j*-algebra thus obtained is called a *j*-subalgebra of $\{g, \mathfrak{f}, (j), \omega\}$. A *j*-algebra $\{g, \mathfrak{f}, (j), \omega\}$ is called proper (resp. effective), if, for any *j*-subalgebra $\{g', \mathfrak{f}'\}$ with g' compact semisimple, g' is contained in \mathfrak{f} (resp. if $\{g, \mathfrak{f}\}$ is an effective pair).

Now let D be a homogeneous bounded domain in \mathbf{C}^n , G a connected \dagger Lie subgroup of $G_h(D)$ acting \dagger transitively on D , and K the \dagger isotropy subgroup at a point in D . The Lie algebras of G and K are denoted by g and \mathfrak{f} , respectively. Then the pair $\{g, \mathfrak{f}\}$ becomes an effective proper *j*-algebra. Conversely, to every effective proper *j*-algebra there corresponds a homogeneous bounded domain. The identity component of $G_h(D)$ is isomorphic to the identity component of a \dagger real algebraic group via the \dagger adjoint representation. Let $\{g, \mathfrak{f}, (j), \omega\}$ be a *j*-algebra. Suppose that g satisfies the following conditions: (i) $g = g^{-2} + g^{-1} + g^0$ as a graded Lie algebra; (ii) $g^0 = \mathfrak{f} + jg^{-2}$; (iii) there exists a $j \in (j)$ such that $jg^{-1} = g^{-1}$; and (iv) there exists an $r \in g^{-2}$ such that $[jx, r] = x$ for $x \in g^{-2}$. Such a decomposition is called a Siegel decomposition of g . To an effective *j*-algebra admitting a Siegel decomposition there corresponds a unique Siegel domain up to affine equivalence. Vinberg, Gindikin, and Pyatetskii-Shapiro (Appendix in [1] or *Trans. Moscow Math. Soc.*, 12 (1963)) proved that the Lie algebra $g_h(D)$ of $G_h(D)$ contains a *j*-subalgebra admitting a Siegel decomposition and corresponding to the same domain D , and obtained the realization theorem: Every homogeneous bounded domain D is holomorphically equivalent to a Siegel domain. In consequence, D is diffeomorphic to a Euclidean space, and the isotropy subgroup $K_h(D)$ is a maximal compact subgroup of $G_h(D)$. We have the decomposition $G_h(D) = K_h(D) \cdot T$ (semi-direct), where T is an \mathbf{R} -splittable solvable subgroup of $G_h(D)$ acting simply transitively on D . T is uniquely determined up to conjugacy in $G_h^0(D)$ (= the identity component of $G_h(D)$), and is called the **Iwasawa group** of D .

The *j*-algebra structure of the Lie algebra \mathfrak{t} of the Iwasawa group T is characterized by the following properties: (i) for every $t \in \mathfrak{t}$, the eigenvalues of $\text{ad } t$ are all real; (ii) there exists a \dagger complex structure j such that $[jx, jy] =$

$j[jx, y] + j[x, jy] + [x, y]$ for $x, y \in \mathfrak{t}$; and (iii) there exists a linear form ω on \mathfrak{t} such that $\omega([jx, jy]) = \omega([x, y])$ and that $\omega([jx, x]) > 0$ for $x \neq 0$. A Lie algebra satisfying (i)–(iii) is called a **normal j -algebra**. There exists a one-to-one correspondence between the set of holomorphic equivalence classes of homogeneous bounded domains and the set of j -isomorphism classes of normal j -algebras; by a j -isomorphism here we mean an isomorphism which commutes with j . Let $\{\mathfrak{g}, j, \omega\}$ be a normal j -algebra and define an inner product $\langle \cdot, \cdot \rangle$ on \mathfrak{g} by $\langle x, y \rangle = \omega([jx, y])$. The orthogonal complement \mathfrak{h} with respect to $\langle \cdot, \cdot \rangle$ of the \dagger commutator subalgebra \mathfrak{g}_1 of \mathfrak{g} is an Abelian subalgebra of \mathfrak{g} , and the adjoint representation of \mathfrak{h} on \mathfrak{g}_1 is fully reducible. One has $\mathfrak{g} = \sum_{\alpha} \mathfrak{k}_{\alpha}$, $\mathfrak{h} = \mathfrak{k}_0$, and $\mathfrak{g}_1 = \sum_{\alpha \neq 0} \mathfrak{k}_{\alpha}$, where $\mathfrak{k}_{\alpha} = \{x \in \mathfrak{g} \mid [h, x] = \alpha(h)x, h \in \mathfrak{h}\}$. The linear form α on \mathfrak{h} is called a root of \mathfrak{g} . There exist l roots $\alpha_1, \dots, \alpha_l$ ($l = \dim \mathfrak{h}$) such that \mathfrak{h} can be written in the form $\mathfrak{h} = j\mathfrak{k}_{\alpha_1} + \dots + j\mathfrak{k}_{\alpha_l}$, l being the **rank** of \mathfrak{g} . Then, after a suitable change of the numbering of the α_i 's, any root α will be seen to be of the form $(\alpha_i + \alpha_k)/2$, $(\alpha_i - \alpha_k)/2$ or $\alpha_i/2$, where $1 \leq i \leq k \leq l$. A normal j -algebra admits a unique Siegel decomposition which can be constructed by using root spaces.

D. Equivariant Holomorphic Embedding

We retain the notation of Section B. Let $D(V, F) \subset R^C \times W$ be a Siegel domain and \mathfrak{g}_C be the \dagger complexification of the Lie algebra \mathfrak{g}_h . \mathfrak{g}^{-1} has the complex structure defined by the endomorphism $\text{ad } I$. Let \mathfrak{g}_{\pm}^{-1} be the $\pm i$ -eigenspaces in the complexification \mathfrak{g}_C^{-1} of \mathfrak{g}^{-1} under $\text{ad } I$. Let us consider the complex subalgebras $\mathfrak{b} = \mathfrak{g}^{-1} + \mathfrak{g}_C^0 + \mathfrak{g}_C^1 + \mathfrak{g}_C^2$ and $\mathfrak{n} = \mathfrak{g}_C^{-2} + \mathfrak{g}_C^{-1}$ of \mathfrak{g}_C , where the subscripts C denote the complexification of the respective space. Let G_C be the connected \dagger complex Lie group generated by \mathfrak{g}_C and containing G_h^0 (= the identity component of G_h) as a subgroup. The Lie algebra of the normalizer B of \mathfrak{b} in G_C coincides with \mathfrak{b} . Identifying $R^C \times W$ with \mathfrak{n} as a complex vector space, and denoting by π the natural projection of G_C onto the complex coset space G_C/B , the composite mapping $\tau = \pi \exp$ is a holomorphic embedding of \mathfrak{n} into G_C/B , which induces a holomorphic G_h^0 - \dagger equivariant embedding of $D(V, F)$ into G_C/B as an open submanifold. This embedding is called the **Tanaka embedding**. By the **(Shilov) boundary S** of $D(V, F)$ we mean the real submanifold $S = \{(x + iy, u) \in R^C \times W \mid y = F(u, u)\}$ of $R^C \times W$, which is a subset of the boundary of $D(V, F)$. S has the natural \dagger CR-structure induced from the complex structure of $R^C \times W$. Every element of \mathfrak{g}_h can be extended to a unique holomorphic

vector field on $R^C \times W$ which is tangent to S , and its restriction to S is an infinitesimal \dagger CR-automorphism on S , i.e., a complete vector field generating a 1-parameter group of \dagger CR-equivalences of S onto itself. Conversely, every infinitesimal CR-automorphism on S can be extended uniquely to a holomorphic vector field on $R^C \times W$, and an element of \mathfrak{g}_h is characterized as an infinitesimal CR-automorphism on S whose extension leaves the \dagger Bergman kernel form of $D(V, F)$ invariant [6]. Let $n = \dim_C \mathfrak{g}_C$, $m = \dim_C \mathfrak{b}$, and let $k = \binom{n}{m} - 1$. Then G_C/B , and consequently $D(V, F)$, is embedded holomorphically into the complex \dagger Grassmann manifold of m -dimensional subspaces in \mathfrak{g}_C and so into the \dagger complex projective space $P_k(\mathbb{C})$. Any element of G_h^0 is induced from a projective transformation and hence is a birational transformation on $D(V, F)$.

Let D be a homogeneous bounded domain in \mathbb{C}^n , \mathfrak{g}_h the Lie algebra of $G_h(D)$, and \mathfrak{k}_h the isotropy subalgebra of \mathfrak{g}_h ; and let \mathfrak{g}_C be the complexification of \mathfrak{g}_h . \mathfrak{g}_h is a j -algebra. Let us define the complex subalgebra \mathfrak{g}_- of \mathfrak{g}_C by putting $\mathfrak{g}_- = \{x + ijx \mid x \in \mathfrak{g}_h, j \in (j)\}$. Then we have $\mathfrak{g}_C = \mathfrak{g}_h + \mathfrak{g}_-$, $\mathfrak{g}_h \cap \mathfrak{g}_- = \mathfrak{k}_h$. Let G_C be the connected Lie group generated by \mathfrak{g}_C and containing $G_h^0(D)$ as a subgroup. Let G_- be the connected (closed) Lie subgroup of G_C generated by \mathfrak{g}_- . Then D can be holomorphically embedded in G_C/G_- as the open $G_h^0(D)$ -orbit of the origin of G_C/G_- [8]. This embedding is called the **generalized Borel embedding**. G_C/G_- is compact if and only if D is symmetric, and in this case G_C/G_- coincides with the compact dual [9].

Let $\{\mathfrak{t}_0, j, \omega\}$ be a normal j -algebra of rank l corresponding to a homogeneous bounded domain D_0 , and define the Hermitian inner product h by $h(x, y) = \omega([jx, y]) + i\omega([x, y])$ for $x, y \in \mathfrak{t}_0$. \mathfrak{t}_0 has $l-1$ (normal) nontrivial j -ideals (i.e., j -invariant ideals) up to j -isomorphisms. Take a j -ideal \mathfrak{t}_1 of \mathfrak{t}_0 . Then we have $\mathfrak{t}_0 = \mathfrak{t}_1 + \mathfrak{t}_2$, \mathfrak{t}_2 being a (normal) j -subalgebra of \mathfrak{t}_0 defined as the orthogonal complement of \mathfrak{t}_1 in \mathfrak{t}_0 with respect to h . The geometric version of this is that D_0 is represented as a holomorphic fiber space over the homogeneous bounded domain D_2 corresponding to \mathfrak{t}_2 , with fibers holomorphically equivalent to the homogeneous bounded domain D_1 corresponding to \mathfrak{t}_1 . For this fibering there exists a universal fiber space D over the product \hat{D}_2 of certain classical symmetric domains, with the same fibers, which plays the same role as that of a \dagger universal fiber bundle in topology. Here, D is again a homogeneous bounded domain. The fiber space $D_0 \rightarrow D_2$ is induced from the fiber space $D \rightarrow \hat{D}_2$ by the classifying mapping λ of D_2 to \hat{D}_2 . Let β be the generalized Borel embedding of D into G_C/G_- . Then there exists a

complex Abelian subalgebra m of g_C satisfying $g_C = g_- + m$ (semidirect), and one can construct a biholomorphic mapping f of $\beta(D)$ onto a certain Siegel domain of the third kind over D_2 in the vector space m [8]. The fiber space $D_0 \rightarrow D_2$ coincides with the one induced from the aforementioned Siegel domain of the third kind by the composite mapping of λ and $f \cdot \beta$. Every realization of a homogeneous bounded domain as a Siegel domain of the third kind is obtained by this method.

E. Classification of Homogeneous Bounded Domains

The main concern is to classify all homogeneous bounded domains in C^n up to holomorphic equivalence. Since the realization as Siegel domains has been set up, the second step is to get the uniqueness theorem: The holomorphic equivalence of two homogeneous Siegel domains implies that they are linearly equivalent, that is, there exists a (complex) linear isomorphism between the ambient vector spaces which carries the one domain to the other. The uniqueness theorem was first stated in 1963 (Appendix in [1]), rigorously proved in 1967 [10], and in 1970 the homogeneity assumption was removed [2]. A homogeneous Siegel domain is called **irreducible** if it is not holomorphically equivalent to a product of two homogeneous Siegel domains. Every homogeneous Siegel domain is linearly equivalent to a product of irreducible homogeneous Siegel domains [3, 10]. A homogeneous Siegel domain $D(V, F)$ is irreducible if and only if the regular cone V is irreducible, i.e., if V cannot be written as a direct sum of two regular cones. So the problem is to classify irreducible homogeneous Siegel domains up to linear equivalence. This reduces to classifying two kinds of nonassociative algebras with bigradation, called T -algebras and S -algebras [11]. Nonsymmetric homogeneous Siegel domains appear in dimension 4. The numbers of such domains are finite up to dimension 6, but in every dimension ≥ 7 there is at least one continuous family of nonsymmetric irreducible homogeneous Siegel domains, which are not mutually holomorphically equivalent.

There is a remarkable class of homogeneous Siegel domains, called **quasisymmetric** [12], which contains the class of symmetric bounded domains. A regular cone $V \subset R$ is called **self-dual** if there exists an inner product $(,)$ on R such that $V = \{x \in R \mid (x, y) > 0 \text{ for } y \in \bar{V} - (0)\}$, \bar{V} denoting the closure of V . V is called homogeneous if the group $G(V)$ is transitive on V . Suppose that V is homogeneous self-dual. Then the group $G(V)$ is †self-adjoint

with respect to the inner product $(,)$ on R . Let $g(V)$ be the Lie algebra of $G(V)$. Then the totality $\mathfrak{k}(V)$ of skew-symmetric operators in $g(V)$ with respect to $(,)$ is a †maximal compact subalgebra of $g(V)$ and is the isotropy subalgebra of $g(V)$ at a point $e \in V$. Consider the associated †Cartan decomposition $g(V) = \mathfrak{k}(V) + \mathfrak{p}(V)$. For each $x \in R$ there exists a unique element $T(x) \in \mathfrak{p}(V)$ such that $T(x)e = x$. Let F be a V -Hermitian form on a complex vector space W . Define a Hermitian inner product \langle , \rangle on W by $\langle u, v \rangle = (e, F(u, v))$ for $u, v \in W$, and let $H(W)$ be the set of Hermitian operators on W with respect to \langle , \rangle . A (homogeneous) Siegel domain $D(V, F) \subset R^C \times W$ is called quasisymmetric if V is homogeneous self-dual and if for each $x \in R$ there exists $R(x) \in H(W)$ such that $F(R(x)u, v) + F(u, R(x)v) = T(x)F(u, v)$ for $u, v \in W$. The normal j -algebra \mathfrak{t} of an irreducible quasisymmetric Siegel domain is characterized by the following conditions: $\dim \mathfrak{k}_{(\alpha_i + \alpha_k)/2} = a$ ($1 \leq i \leq k \leq l$); and $\dim \mathfrak{k}_{\alpha_i/2} = b$ ($1 \leq i \leq l$), where a, b are some constants and l is the rank of \mathfrak{t} (D'Atri and de Miatello). Quasisymmetric Siegel domains have been completely classified (M. Takeuchi, *Nagoya Math. J.*, 59 (1975), also [12]).

F. Generalized Siegel Domains and Further Results

Let Ω be a domain in $C^n \times C^m$ ($n, m \geq 0$) which is holomorphically equivalent to a bounded domain and contains a point of the form $(z, 0)$, $z \in C^n$. Ω is called a **generalized Siegel domain** with exponent c ($c \in R$), if Ω is invariant under holomorphic transformations of $C^n \times C^m$ of the types

$$\begin{aligned} (z, u) &\mapsto (z + a, u) && \text{for all } a \in R^n, \\ (z, u) &\mapsto (z, e^{tu}) && \text{for all } t \in R, \\ (z, u) &\mapsto (e^t z, e^{ct} u) && \text{for all } t \in R. \end{aligned}$$

Let D be a bounded domain in C^n , and Γ a subgroup of $G_n(D)$. Γ is said to **sweep** D if there exists a compact set $K \subset D$ such that $\Gamma K = D$. Γ is said to **divide** D if Γ , provided with discrete topology, acts properly on D and sweeps D . D is called **sweepable** (resp. **divisible**) if there exists a subgroup Γ of $G_n(D)$ which sweeps (resp. divides) D . A divisible generalized Siegel domain is symmetric. A sweepable generalized Siegel domain with exponent $c \neq 0$ (resp. $c = 0$) is a Siegel domain (resp. a product of a Siegel domain of the first kind and of a homogeneous bounded circular domain) ([13]; also A. Kodama, *J. Math. Soc. Japan*, 33 (1981)).

Some results have been obtained concerning geometry of bounded domains, homogeneous bounded domains, and Siegel domains in

complex Banach spaces [14], and also concerning the unitary representations of the generalized Heisenberg group on the square-integrable cohomology spaces of $\bar{\partial}_b$ -complexes on the Shilov boundary of a Siegel domain [15].

385 (XVI.6) Simulation

A. General Remarks

Simulation, in its widest sense, is a method of utilizing models to study the nature of certain phenomena. This method is employed when experimentation with the actual phenomena in question is difficult because of high cost in time or money. Also, it is sometimes almost impossible to carry out observations when the behavior of the objects can be influenced by their surroundings.

We can classify simulation techniques into the following four types, although simulations in practical use are usually a mixture of them.

The first type is **model experimentation**, which includes model basins and wind tunnels in hydrodynamics and pilot plants in the chemical industry. In advance of construction in a real situation, we perform experiments on a small scale and verify or modify those theories upon which the construction is based.

The second type is **analog simulation** or **experimental analysis**. We investigate the properties of real objects by experiments on alternative phenomena satisfying the same differential equations as those known for or assumed to be satisfied by the real objects. For example, we use an equivalent electric network to study dynamic vibration, and dynamic systems to study heat conduction problems. When theoretical analysis of the actual phenomenon is difficult, we look for other phenomena with similar properties and study them in order to construct mathematical models for them. This type of simulation has come into practical use mainly in engineering problems, but recently it has been utilized for the study of economic phenomena, nervous systems, the circulating system of an artificial heart, etc. Analog simulation was in the past often performed by means of [†]analog computers. Nowadays, analog simulation is more frequently performed by digital computers than by analog ones. And with the progress of electronics it has become easier to make special-purpose simulators.

The third method of simulation, **simulation in the narrow sense**, has become more important as [†]digital computers have been developed. In general this method is applied to problems that are more complicated and of larger scale than problems treated by analog simulation. When the mathematical expressions of the phenomenon and the algorithms of its dynamic structure are known, it is easy to simulate it by means of a computer program. In

particular, when these techniques are used to study systems such as sets of machines, equipment at factories, or management organization, we call them **system simulations**. Major fields where system simulation techniques have been used are traffic control on highways or at airports, arrangement or operation of machines at factories, balancing problems in chemical processes, production scheduling in connection with demands and stocks, overall management problems, and design of information systems. The method has also been applied in designing plants and highways and in the study of social or biological phenomena. Also, when we investigate instruction systems of computers that are yet to be completed or develop programming systems for such computers, existing computers can be used to simulate the new ones. †Random numbers play an important role where the simulation must include random fluctuations (→ 354 Random Numbers). In such instances, the method is often called the Monte Carlo method (→ Section C).

The fourth method of simulation deals with systems containing human beings. Among them are war games for training in military-operation planning, business games for training in business enterprises, and simulators for training pilots and operators of atomic power plants. The contribution of human decision to simulation processes is characteristic of these cases. For example, the participants in a business game are divided into several enterprise groups. Each group discusses and decides how to invest in plants, equipment, research, and advertising and how to schedule production for each quarter. On the basis of the decisions, a computer outputs the records of sales, stocks, and cash for each quarter, according to hidden rules. From the results, each group decides on the next steps. In this way, the groups compete for development. This type of simulation is important not only for training but also for investigating the mechanism of human decision. Slightly different from this type of simulation, the "perceptron" and EPAM (Elementary Perceiver and Memorizer) are related to artificial intelligence and have been used extensively in the cognitive sciences and in research into the structure and function of the human brain.

The third type of simulation has attracted attention in particular and has been used both in theoretical problems, such as the explication of various phenomena, and in practical problems, such as design or optimum operation of systems or prediction of their behavior. For school education and training of technicians, this is put to use together with simulations of

the fourth type. But their use has also induced heated discussions and controversies on the validity of results.

B. Programming Languages for Simulation

We usually describe models by using general purpose language: such as FORTRAN, or list processing languages such as LISP to simulate situations on computers. For system simulation, a number of programming languages have been developed and put to practical use. They can be divided roughly into two categories: those for which systems change continuously and those describing discrete changes. CSMP (Continuous System Modeling Program), CSSI (Continuous System Simulation Language), and DDS (Digital Dynamics Simulator) belong to the former, and hence all involve integration mechanisms; but each has a different way of describing a model. DYNAMO, which has been implemented, or J. W. Forrester's Industrial Dynamics and World Dynamics, are used extensively. To control simulation time, one may use GPSS (General Purpose Simulation System), SIMULA (Simulation Language), or SIMSCRIPT (Simulation Scriptor), each employing a different method to describe state transitions.

C. The Monte Carlo Method

The **Monte Carlo method** was introduced by J. von Neumann and S. M. Ulam around 1945. They defined this as a method of solving deterministic mathematical problems using †random numbers. L. de Buffon's needle experiment, in which the approximate value of π is obtained by dropping needles at random many times, is a classical example of this method.

Another example is the problem of evaluating a definite integral $I = \int_a^b f(x) dx$ ($B \geq f(x) \geq A \geq 0$). First we generate many pairs of (uniform) random numbers (x, y) , where $a \leq x \leq b$ and $A \leq y \leq B$. The proportion (p) of pairs satisfying $y \leq f(x)$ gives an estimate of the integral, i.e., $I \approx p(B - A)(b - a)$. The techniques for inverting matrices, solving †boundary value problems of partial differential equations, and so on, are also examples of the Monte Carlo method in this sense. However, direct numerical calculation seems to be more useful in dealing with this sort of problem. At present, *Monte Carlo methods* are usually used when it is difficult to construct (or solve) mathematical equations describing the phenomena in question, for example, when the phenomena involve †stochastic processes such as †random

walks. Some methods have been devised so as to get precise results efficiently.

**386 (XX.29)
S-Matrices**

A. Basic Notion

It is often useful to focus attention on the relation between a physical system's input and output, without worrying about intermediate processes (the black box), which may be insufficiently understood or too complicated to analyze. For the scattering of particles, this leads to the notion of an **S-matrix** that directly relates the state of incoming particles (before scattering processes take place) to that of outgoing (scattered) particles.

In typical cases, the incoming and outgoing particles are described as mutually noninteracting (these are called free particles). This implies particle motions along straight lines at constant speeds (asymptotic to the actual motion at infinite past for incoming particles and at infinite future for outgoing particles) in classical mechanics, and wave functions (or vectors in a Hilbert space) obeying the Schrödinger equation with a free Hamiltonian H_0 in quantum mechanics and more or less the same in quantum field theory.

A wave function for n particles is an L_2 -function of their momenta p_1, \dots, p_n (each p_j being a 3-dimensional vector) with respect to an appropriate measure (normally the Lebesgue measure $d\mu(p) = \prod d^3 p_j$ in quantum mechanics and the Lorentz-invariant measure $d\mu(p) = \prod \{(m^2 + p_j^2)^{-1/2} d^3 p_j\}$ in quantum field

theory, where m is the mass of the particle), and the S -matrix S is described in terms of the S -matrix elements $(p_1, \dots, p_n | S | p'_1, \dots, p'_n)$ (which is a distribution) as

$$(\Phi, S\Psi) = \int \overline{\Phi(p)} (p | S | p') \Psi(p') d\mu(p) d\mu(p')$$

where Φ and Ψ are wave functions for n and n' particles, $p = (p_1, \dots, p_n)$, and similarly for p' . $(p | S | p')$ gives quantities measured in scattering experiments, as will be explained in Section B (2).

In quantum mechanics, the free and actual (interacting) motion of particles is described in the same Hilbert space with free and interacting Hamiltonians H_0 and H . A vector Φ in interacting motion behaves like a vector φ in free motion at infinite past if

$$\|(\exp[-iHt])\Phi - (\exp[-iH_0t])\varphi\| \rightarrow 0$$

as $t \rightarrow -\infty$

and hence

$$\Phi = W_-(H; H_0)\varphi,$$

$$W_-(H; H_0) = \lim_{t \rightarrow -\infty} e^{iHt} e^{-iH_0t}.$$

Such a Φ is often written as

$$\Phi = \Phi^{in}(\varphi) = \int \Phi^{in}(p)\varphi(p) d\mu(p),$$

and is called an **in-state**. A definition for an **out-state** Φ^{out} is obtained by changing $t \rightarrow -\infty$ to $t \rightarrow +\infty$ and W_- to W_+ . The S -matrix element is defined (as a distribution) by

$$(p | S | p') = (\Phi^{out}(p), \Phi^{in}(p')).$$

The existence and properties of W_{\pm} (called †wave operators) are central subjects in scattering theory (\rightarrow 375 Scattering Theory).

In quantum field theory, the asymptotic description is given in terms of vectors in †Fock space, and the in- and out-states are constructed in terms of †asymptotic fields (\rightarrow 150 Field Theory).

The foregoing description actually applies only to a system of one-component particles of the same kind. More generally, additional (discrete) variables, say α , are needed to distinguish different kinds of particles and different spin components of each kind of particle, and the p 's appearing in the above formulas should be replaced by (p, α) 's, along with related changes in the measure.

Even in a quantum mechanics of many identical particles a bound state, if it exists, is to be treated as another particle (different from the original one) and should be distinguished by α 's in the asymptotic description φ .

If the interaction is of long range (e.g.,

Coulomb interaction), the classical path of a particle does not have an asymptote in general, and correspondingly the wave operators W_{\pm} do not exist for the usual free Hamiltonian. Still, an asymptotic description of scattering is possible in some cases.

In the presence of massless particles, such as photons in quantum field theory, another difficulty, called the infrared problem, can arise in the asymptotic description of scattering because the scattered particle may be accompanied by an infinite number of massless particles (with very small energy). In such a situation, a representation of a free massless field not equivalent to the standard Fock representation is believed to be a possible candidate for the asymptotic description of scattering.

B. Basic Properties

(1) Invariance. Let \mathcal{H}_0 be the Hilbert space for the asymptotic description of scattering, such as the space of L_2 -functions $\varphi(p_1, \dots, p_n)$ relative to the measure $d\mu(p)$. The S -matrix is an operator on \mathcal{H}_0 whose matrix element is as described above. (The corresponding operator S in the Hilbert space \mathcal{H} describing the interacting states is defined by $S\Phi^{\text{out}}(\varphi) = \Phi^{\text{in}}(\varphi)$ and is sometimes called an **S-operator**.)

S is said to be **invariant** under a group G of transformations of the p 's (and possibly the α 's) if $(U(g)\varphi)(p) = \varphi(g^{-1}p)$ defines a continuous unitary representation $U(g)$ and if $U(g)S = SU(g)$ for all $g \in G$. First, S is usually invariant under time translation. In the quantum mechanics of a particle scattered by a rotationally invariant potential, S is invariant under the group of rotations of 3-dimensional vectors p ; in the quantum mechanics of many particles (mutually interacting through central potentials), S is invariant under the 3-dimensional Euclidean group of transformations $p \rightarrow Rp + a$ with rotation R ; in relativistic field theory, S is assumed to be invariant under the inhomogeneous Lorentz group of transformations $p \rightarrow \Lambda p + a$ with $p = (p^0, \mathbf{p})$ and homogeneous Lorentz transformation Λ .

In all these examples, G is of type I, i.e., there is a direct integral decomposition

$$\mathcal{H}_0 = \int \mathcal{H}(k) \otimes \mathcal{L}(k) dv(k),$$

$$U(g) = \int U_k(g) \otimes 1_{\mathcal{L}(k)} dv(k),$$

into irreducible representations U_k on $\mathcal{H}(k)$, which are mutually inequivalent, where $\mathcal{L}(k)$ is some Hilbert space for each k . The S -matrix is

invariant under G if and only if

$$S = \int 1_{\mathcal{H}(k)} \otimes S(k) dv(k).$$

When a (scalar) particle is scattered by a central potential, irreducible representations are labeled by the energy $E(p) = p^2/(2m)$ (for time translation) and the angular momentum l (for rotations) with $\dim \mathcal{L}(E(p), l) = 1$. Therefore each $S(k) = S_l(|p|)$ is a number. For any given energy, $l = 0, 1, 2, \dots$ are referred to as the S -wave, P -wave, D -wave, ... or generally as **partial waves**.

For relativistic scalar particles, irreducible representations (with positive energy and nonzero real mass) are labeled by the center-of-mass energy squared $s = (\sum(m^2 + p_i^2))^{1/2})^2 - (\sum p_i)^2$ and the total angular momentum l . If s is below the threshold $(3m)^2$ of 3-particle scattering, $\dim \mathcal{L}(k) = 1$ and $S(k) = S_l(s)$ is a number.

(2) Unitarity. $S\varphi$ is supposed to represent the $t = +\infty$ asymptotic (free) behavior of the state that initially (i.e., at $t = -\infty$) behaves like a free state φ . If there is no loss of probability in the description of scattering, the S -matrix is isometric. If all asymptotic configurations are realized as a result of scattering, the S -matrix must also be unitary. The mappings $\Phi^{\text{in}} : \varphi \in \mathcal{H}_0 \rightarrow \Phi^{\text{in}}(\varphi) \in \mathcal{H}$ (W_{\pm} in quantum mechanics) are proved to be isometric under a general assumption. The unitarity is then proved in potential scattering (under some conditions on the potential) by showing that the two wave operators W_{\pm} have the same range. In fact, a somewhat stronger result—that this range is the same as the absolutely continuous spectral subspace for the interacting Hamiltonian H —is usually proved and is called **completeness (of scattering states)** in the absolutely continuous spectral subspace of H . If the mappings Φ^{out} and Φ^{in} (or W_{\pm}) are isometric and have the same range, then $\Phi^{\text{in}}(\varphi) = \Phi^{\text{out}}(S\varphi)$, which shows that the state behaving like φ at $t = -\infty$ behaves like $S\varphi$ at $t = +\infty$.

In the simple multiplicity cases such as $S_l(|p|)$ and $S_l(s)$ above (which correspond to the physical situation of purely elastic scattering without any production or change of particles), these numbers must be of the form $e^{2i\delta_l}$ due to unitarity, where the real number δ_l is called the **phase shift**. In terms of the phase shift, the **differential cross section** $d\sigma/d\Omega$, which is the average number of particles scattered per unit time per unit solid angle around the direction forming an angle θ with the incident uniform parallel beam of unit intensity (one particle per unit time per unit area) when

viewed in the center-of-mass system, and the **total elastic cross section** $\sigma_{el} = \int (d\sigma/d\Omega)d\Omega$ are given by the following formulas, called the **partial wave expansion**:

$$d\sigma/d\Omega = |f(s, \theta)|^2,$$

$$f(s, \theta) = k^{-1} \sum_{l=0}^{\infty} (2l+1) f_l P_l(\cos \theta), \quad f_l = \sin \delta_l e^{i\delta_l},$$

$$\sigma_{el} = 4\pi k^{-2} \sum_l (2l+1) \sin^2 \delta_l,$$

where $d\Omega = \sin \theta d\theta d\varphi$ (invariant measure on a 2-dimensional sphere S^2) and k is the wave number of the particle in the center-of-mass system ($k = \hbar^{-1}|p| = \hbar^{-1}[(s/4) - m^2]^{1/2}$). The function f is called the **scattering amplitude**. The forward scattering amplitude $f(s, 0)$ is related to the total cross section σ_{tot} by the **optical theorem**:

$$\sigma_{tot} = 4\pi k^{-1} \text{Im} f(s, 0),$$

which follows from the unitarity of the S -matrix. Here the **total cross section** is expressed as the area of the transverse cross section of a classical (impenetrable) scatterer that would scatter the same amount of particles. In a purely elastic region, $\sigma_{tot} = \sigma_{el}$, and the optical theorem is the same as the assertion $\text{Im} f_l = |f_l|^2$.

Even for values of s above the threshold of inelastic scattering, the restriction of S_0 to the subspace of two particles is again described by numbers $e^{2i\delta_l}$, where δ_l is now complex, and the same formulas for the differential and total elastic cross sections hold, except that unitarity of S_0 now implies $\text{Im} f_l \geq |f_l|^2$.

(3) TCP Symmetry. In the framework of either \dagger axiomatic quantum field theory or the \dagger theory of local observables, the TCP theorem (or PCT theorem) shows [1] that to every particle there corresponds another particle with the same mass and spin, which is called the **antiparticle** and can be the original particle itself, such that any particle is the antiparticle of its antiparticle, and the following relation, called **TCP invariance** (or **PCT invariance** [2]) holds for S -matrix elements:

$$\begin{aligned} & \langle p, \alpha | S | p', \alpha' \rangle \\ &= \eta(\alpha)\eta(\alpha') i^{F(\alpha) - F(\alpha')} \langle p', 0_0 \alpha' | S | p, 0_0 \alpha \rangle. \end{aligned}$$

Here $F(\alpha)$ and $F(\alpha')$ are the number of particles with half odd integer spin amongst the incoming and outgoing particles (i.e., in α and α'), $\eta(\alpha)$ and $\eta(\alpha')$ are the product of ± 1 assigned to each particle in α and α' , respectively, with the assignment to a particle and its antiparticle the same for bosons and opposite for fermions, (p, α) is an abbreviation for an ordered n -tuple of energy-momentum 4-vectors p_i and other indices α_i (for spin components and particle

species), $i = 1, \dots, n$, and similarly for (p', α') , and θ_0 is the mapping from particles to their antiparticles (without changing spin indices). We may view the mapping $|p, \alpha\rangle \rightarrow \eta(\alpha) i^{F(\alpha)} |p, \theta_0 \alpha\rangle$ as an antiunitary operator Θ_0 on \mathcal{H}_0 satisfying $\Theta_0 S \Theta_0^{-1} = S^*$ so that

$$(\varphi_1, S_0 \varphi_2) = (\Theta_0 \varphi_2, S_0 \Theta_0 \varphi_1).$$

This is related to the \dagger TCP operator Θ in quantum field theory by $\Theta \Psi^{\text{out}}(\varphi) = \Psi^{\text{in}}(\Theta_0 \varphi)$ and $\Theta \Psi^{\text{in}}(\varphi) = \Psi^{\text{out}}(\Theta_0 \varphi)$. The name TCP comes from the combination of T for time reversal (incoming \rightleftharpoons outgoing, $v \equiv p/m \rightarrow -v$), C for charge conjugation (particle \rightleftharpoons antiparticle), and P for parity, which is a quantum number for space inversion ($p \rightarrow -p$).

TCP symmetry was suggested to G. Lüders (*Dansk. Mat. Fys. Medd.*, 1954) by B. Zumino in the form that P-invariance implies TC symmetry. W. Pauli (*Niels Bohr and the development of physics*, Pergamon 1955, 30) realized that TCP is a symmetry. R. Jost (*Helv. Phys. Acta*, 1957) gave its proof in the framework of axiomatic quantum field theory.

(4) Crossing Symmetry. In the framework of either axiomatic quantum field theory or the theory of local observables, it has been shown by J. Bros, H. Epstein, and V. Glaser (*Comm. Math. Phys.*, 1 (1965); also [3]) that there exist analytic functions $H(k, \alpha)$ of complex variables $k = (k_1, \dots, k_4)$ in a certain domain D such that each k_j is a complex 4-vector, the variables are on the mass-shell manifold defined by $k_j^2 = m_j^2$ (k_j^2 is in the Minkowski metric) and $\sum k_j = 0$, and the boundary value of $H(k, \alpha)$ as k_j approaches $\varepsilon_j p_j$ from $\text{Im} s > 0$ (s being the square of the sum of two k 's for incoming particles) in D is the scattering amplitude for the following processes involving the particles A_j and their antiparticles \bar{A}_j ($j = 1, \dots, 4$) with 4-momenta p_j , $\varepsilon_j = 1$ for A_j and -1 for \bar{A}_j (some of the A 's and \bar{A} 's may coincide):

- (i) $A_1 + A_2 \rightarrow \bar{A}_3 + \bar{A}_4$,
- (i') $A_3 + A_4 \rightarrow \bar{A}_1 + \bar{A}_2$,
- (ii) $A_1 + A_3 \rightarrow \bar{A}_2 + \bar{A}_4$,
- (ii') $A_2 + A_4 \rightarrow \bar{A}_1 + \bar{A}_3$,
- (iii) $A_1 + A_4 \rightarrow \bar{A}_2 + \bar{A}_3$,
- (iii') $A_2 + A_3 \rightarrow \bar{A}_1 + \bar{A}_4$.

Any pair of relations taken from (i)–(iii) constitutes a **crossing symmetry**.

(5) High Energy Theorems. M. Froissart (*Phys. Rev.*, 123 (1961)) obtained from the Mandelstam representation the following bound for the forward scattering amplitude (called the

Froissart bound) at large s :

$$|F(s, 0)| < (\text{const})s(\log s)^2,$$

$$F(s, t) = kf(s, \theta), \quad t = 2k^2(\cos \theta - 1).$$

A. Martin has obtained such a bound in the axiomatic framework. As a consequence we have the **Froissart-Martin bound**:

$$\sigma_{\text{tot}} < 4\pi R^{-1}(1 + \varepsilon)^2(\log(s/s_0))^2,$$

where $\varepsilon > 0$ is arbitrary, R can be taken to be $4m_\pi^2$ (m_π is the mass of a pion) for many cases, such as $\pi\pi$, πK , πN , and $\pi\Lambda$ scattering, and s_0 is an unknown constant.

Many other upper and lower bounds for scattering amplitudes have been obtained under other assumptions [4, 5].

I. Ya. Pomeranchuk (*Sov. Phys. JETP*, 7 (1958)) suggested the asymptotic coincidence of total cross sections at high energy for scattering of AB and $A\bar{B}$, where \bar{B} is the antiparticle of B . This **Pomeranchuk theorem** has been shown to hold by Martin (*Nuovo Cimento*, 39 (1965)) by using the analyticity derived in the axiomatic framework under the following sufficient condition: The existence of $\lim_{s \rightarrow \infty} [\sigma(AB) - \sigma(A\bar{B})]$ and $\lim_{s \rightarrow \infty} (s \log s)^{-1} f(s, 0) = 0$.

C. S-Matrix Approach

(1) **History.** All the information needed to understand the experimental elementary-particle scattering data seems to be expressible by S -matrix elements. It was therefore natural to try to develop a foundation (and practical methods of calculation) for the theory of elementary particles on the basis of some general properties of the S -matrix, especially when other approaches, such as quantum field theory, faced difficulties. W. Heisenberg (*Z. Phys.*, 120 (1943)) first pointed out the possibility of such an approach soon after the introduction of the S -matrix by J. A. Wheeler (*Phys. Rev.*, 52 (1937)). Unfortunately, in the early 1940s not much dynamical content could be given to such an S -matrix-theoretic approach because only unitarity and some invariance properties, such as \dagger Lorentz invariance, were used to characterize the S -matrix. In the late 1950s, through the study of the analyticity of the S -matrix in connection with dispersion relations in quantum field theory, it became evident that causality is another important determinant of S -matrix structure. In practice, causality in position space is used in the form of the analyticity of the S -matrix elements in the energy-momentum space (variables dual to space-time positions in the Fourier transform). Subsequently it was realized that analyticity combined with unitarity gives surprisingly

strong control over the structure of the S -matrix (G. F. Chew [6]; H. P. Stapp, *Phys. Rev.*, 125 (1962); J. C. Polkinghorne, *Nuovo Cimento*, 23 and 25 (1962); J. Gunson, *J. Math. Phys.*, 6 (1965); D. I. Olive, *Phys. Rev.*, 135B (1964); Chew [7]; R. J. Eden et al. [8]). The study of the S -matrix based on its general properties, such as invariance, unitarity, and analyticity, is called **S -matrix theory**. In the present form, it is adapted only to massive particles with short-range interactions, and its applicability is believed to be limited to strongly interacting systems.

(2) **Landau-Nakanishi Variety.** C. Chandler and Stapp (*J. Math. Phys.*, 10 (1969)) and D. Iagolnitzer and Stapp (*Comm. Math. Phys.*, 14 (1969)) clarified the analytic structure of the S -matrix in terms of Landau equations (\rightarrow 146 Feynman Integrals) based on the important physical idea of **macroscopic causality**, which gives much more precise information in the physical region than a superficial application of \dagger locality (also called microcausality) in axiomatic quantum field theory, though it is possible that a detailed study starting from microcausality and incorporating \dagger asymptotic completeness (the so-called nonlinear program in axiomatic quantum field theory) might eventually entail the macroscopic causality condition (e.g., J. Bros, in [9]; Iagolnitzer [10, ch. IV]; also K. Symanzik, *J. Math. Phys.*, 1 (1960)).

(3) **Microlocal Analysis.** An important fact is that the **normal analytic structure** of the S -matrix discussed by Iagolnitzer and Stapp essentially coincides with the notion of analyticity in microlocal analysis, i.e., with microanalyticity (\rightarrow 274 Microlocal Analysis; F. Pham and Iagolnitzer, *Lecture notes in math.* 449, Springer, 1975; M. Sato, *Lecture notes in phys.* 39, Springer, 1975)). In a word, the \dagger Landau equations have acquired a new interpretation in the description of the microanalytic structure of the S -matrix. In the new developments, the Landau equations define a variety in the cotangent bundle (over the mass-shell manifold in momentum space), and the \dagger singularity spectrum of S -matrix elements is assumed to be confined to $\bigcup_G \mathcal{L}^+(G)$ (except for the so-called \mathcal{M}_0 -points), where G ranges over all possible **Feynman graphs** and $\mathcal{L}^+(G)$ denotes the positive- α Landau-Nakanishi variety associated with G (\rightarrow 146 Feynman Integrals). The union $\bigcup_G \mathcal{L}^+(G)$ is known to be locally finite and hence makes sense (Stapp, *J. Math. Phys.*, 8 (1967)). The old interpretation of Landau equations, as defining a variety in energy-momentum space, corresponds now to considering the variety $L^+(G)$

obtained by projecting $\mathcal{L}^+(G)$ from the cotangent bundle to the base manifold (i.e., the mass shell manifold). The new interpretation of Landau equations led Sato (*Lecture notes in phys.* 39, Springer, 1975) to make a further intriguing conjecture that the S-matrix would satisfy a special overdetermined system (a holonomic system) of (micro-) differential equations whose characteristic variety is given by the complexification of Landau-Nakanishi varieties. This conjecture is closely related to the monodromy-theoretic approach by T. Regge (*Publ. Res. Inst. Math. Sci.*, 12 suppl. (1977) and the references cited therein) and his co-workers.

(4) Discontinuity Formula. It has turned out that the above approach is closely related to the so-called **discontinuity formula** obtained by combining the unitarity and the analyticity of the S-matrix. Actually T. Kawai and Stapp (*Publ. Res. Inst. Math. Sci.*, 12 suppl. (1977)) have shown that Sato's conjecture can be verified at several physically important points on the basis of the discontinuity formula. The discontinuity formula was first found by R. E. Cutkosky (*J. Math. Phys.*, 1 (1960)) for Feynman integrals. It describes the ramification property of the integral around its singularities (\rightarrow 146 Feynman Integrals). An analogous formula has been shown to be valid also for the S-matrix, and it demonstrates how strict are the constraints derived from unitarity and analyticity (Eden et al. [8, ch. 4]; M. J. D. Bloxham et al., *J. Math. Phys.*, 10 (1969); J. Coster and Stapp, *J. Math. Phys.*, 10 (1969); also Stapp in [11] and Iagolnitzer [10]). Note, however, that the derivation of the hitherto-known discontinuity uses either some *ad hoc* assumptions or some heuristic reasoning which is not rigorous or sometimes is even erroneous from the mathematical viewpoint. Efforts to give a rigorous proof are still being made, and these present several mathematically interesting problems (e.g., Iagolnitzer in [9] and M. Kashiwara and Kawai in [9]).

(5) Regge Poles. The results stated so far concerning the analyticity of the S-matrix have been primarily derived in the low-energy region. It is commonly hoped that these results can be related to its high-energy behavior through the inner consistency of S-matrix theory, even though it is still unclear to what extent such a relationship can be developed. Such a hope was advocated by Chew, who had been inspired by the results of Regge (*Nuovo Cimento*, 14 (1959); 18 (1960)) for potential scattering. After being adapted to the relativistic case, Regge's idea took the following form: Consider the scattering of two incoming

and two outgoing scalar particles with equal mass $m > 0$. Let $f_l(s)$ be the partial scattering amplitude defined earlier. Regge introduced the idea of extending the function $f_l(s)$ to an analytic function $f(l, s)$ ($l \in \mathbb{C}$) and of applying the Sommerfeld-Watson transformation in order to replace the partial wave expansion by the integral

$$\sqrt{-1/2} \int_C (2l+1) f(l, s) P_l(-\cos \theta) dl / \sin \pi l$$

$$= F(s, t)$$

for a certain contour C in the complex l -plane which encircles $\{0, 1, 2, \dots\}$. If $f(l, s)$ is meromorphic in $\text{Re } l > -1/2$ and if it tends to zero sufficiently rapidly at infinity, then one can change the contour C so that, with the help of Cauchy's integral formula, $F \sim \text{constant} \cdot t^{\alpha(s)}$, $\alpha(s) = \max \text{Re } l(s)$, where the maximum is taken over all the poles of $f(l, s)$. Thus the poles of the extended function $f(l, s)$ determine the asymptotic behavior of F as $t \rightarrow \infty$ (**Regge behavior**) under the assumption that $f(l, s)$ can be chosen to satisfy suitable analyticity and growth order conditions. These poles are called **Regge poles**. Even though meromorphy conditions are found to be satisfied for scattering by a (Yukawa) potential, they do not seem to be satisfied for the full S-matrix in the relativistic case. More general cases than those discussed here, i.e., the cases where more variables are considered, are also being studied but without full success at the moment. For details and references \rightarrow [7, 12, 13].

(6) Veneziano Model. In connection with Regge-pole theory, we note an interesting observation by G. Veneziano (*Nuovo Cimento*, 57A (1968)) to the effect that $\Gamma(1 - \alpha(s))\Gamma(1 - \alpha(t))/\Gamma(1 - \alpha(s) - \alpha(t))$, with $\alpha(s)$ being linear in s , satisfies a crossing symmetry (in s and t) and shows an exact Regge-pole behavior. Although the many results that have been obtained give rise to a hope of constructing a realistic model of the S-matrix starting from the aforementioned function, no one has yet succeeded [14]. A more promising approach is the topological expansion procedure in which the first term of the expansion apparently shares with the potential-scattering functions the property of having only poles in the complex l -plane, along with several other physically important properties of Veneziano's function.

387 (XX.34) Solitons

A. General Remarks

Solitons are nonlinear waves that preserve their shape under interaction. Mathematically, the theory of solitons continues to develop as a theory of completely integrable mechanical systems. Typical examples are the **Korteweg-de Vries equation** (\rightarrow Section B), the **Toda lattice** (\rightarrow 287 *Nonlinear Lattice Dynamics*), and the **Sine-Gordon equation**

$$u_{tt} - u_{xx} = \sin u,$$

studied classically in connection with transformations of surfaces of constant negative curvature.

B. The KdV Equation

In the late 19th century J. Boussinesq and then D. Korteweg and G. de Vries obtained equa-

tions describing water waves having traveling-wave solutions. The equation

$$u_t - 6uu_x + u_{xx} = 0, \quad u = u(x, t), \quad (1)$$

derived by de Vries is called the **KdV equation** for short. Putting $u(x, t) = s(x - ct - \delta)$, we find that s is an elliptic function, and we obtain

$$s = -\frac{c}{2} \operatorname{sech}^2\left(\frac{\sqrt{c}}{2}x\right)$$

as its degenerate form. This solution is called a **solitary wave**.

Around 1965, M. Kruskal and N. Zabusky solved the KdV equation numerically, taking several separated solitary waves as the initial data. They found that the waves interact in a complicated way but that eventually the initial solitary waves reappear. Noting the particle-like character of the waves, they called each of these waves a **soliton**. Subsequently, the KdV equation was found to have an infinite number of constants of motion.

C. Gardner, J. Greene, Kruskal, and R. Miura associated the 1-dimensional \dagger Schrödinger operator $-d^2/dx^2 + u(x, t)$ to each solution $u(x, t)$ of the KdV equation and showed that its \dagger eigenvalues are preserved in time. Moreover, they applied inverse scattering theory (\rightarrow Section D) and obtained explicit formulas for the solutions.

C. Lax Representation

Let

$$L = -D^2 + u(x), \quad D = d/dx.$$

For

$$M = -4D^3 + 6uD + 3u_x,$$

the commutator $[M, L] = ML - LM$ is the operator of multiplication by the function $6uu_x - u_{xxx}$. So $u = u(x, t)$ is a solution of the KdV equation if and only if

$$L_t = [M, L]. \quad (2)$$

Equation (2) is also the condition that all $L = L(t)$ are \dagger unitarily equivalent to each other and the \dagger spectrum of L is preserved through time.

Most equations having soliton solutions can be represented in the form of (2) for a suitable pair of L and M . This representation is called the **Lax representation**. One sometimes says that an **isospectral deformation** of L is given by (2).

On the other hand, isomonodromic deformations (\rightarrow 253 *Linear Ordinary Differential Equations (Global Theory)*) have been studied extensively by M. Sato and his co-workers, and relations to soliton theory have been

discovered (Sato, T. Miwa, and M. Jimbo, *Publ. Res. Inst. Math. Sci.*, 14 (1978), 15 (1979)).

In the present case, the requirement that the commutator $[M, L]$ be a multiplication by a function determines an essentially unique $(2n + 1)$ th-order ordinary differential operator $M = A_n$, the differential operator part of the \dagger fractional power $L^{n+1/2}$. $[A_n, L]$ is a polynomial in u and its derivatives, denoted by $K_n[u]$. The equation $u_t = K_n[u]$ is called the n th KdV equation. The transformation taking the initial data $u(x)$ to the solution $u_n(x, t)$ of the n th KdV equation is denoted by $T_n(t)$. Then $T_n(t)T_m(s) = T_m(s)T_n(t)$, i.e., the flows defined by these higher-order KdV equations commute. This property and the existence of infinite number of invariant integrals are consequences of the complete integrability of the higher-order KdV equations considered as infinite-dimensional Hamiltonian systems. The KdV equations can be studied group-theoretically as Hamiltonian systems on a certain coadjoint orbit in the \dagger dual space of the \dagger Lie algebra of a certain class of \dagger pseudo-differential operators (M. Adler, *Inventiones Math.*, 50 (1979); also \rightarrow B. Kostant, *Advances in Math.*, 34 (1979) for the analogous facts for the Toda lattice).

The ordinary differential equation $K_n[u] = 0$ is called a stationary KdV equation. By the commutativity of the flows $T_n(t)$, each KdV flow leaves invariant the space of solutions of $K_n[u] = 0$. The flows restricted to this space form a completely integrable Hamiltonian system with finitely many degrees of freedom (S. P. Novikov, *Functional Anal. Appl.*, 8 (1974)).

$K_n[u] = 0$ is also the condition that there exist an ordinary differential operator M which commutes with L . J. Burchnal and T. Chaundy (*Proc. London Math. Soc.*, (2) 21 (1922)) studied this problem and showed that such L and M are connected by the relation $M^2 = P(L)$, where P is a certain polynomial of degree $2n + 1$ and that the potential u is expressed by the \dagger theta function associated with the \dagger hyperelliptic curve $w^2 = P(z)$.

D. Inverse Scattering Method

Let $u(x)$ be a potential such that $u(x) \rightarrow 0$ as $x \rightarrow \pm\infty$. The equation $Lf = \zeta^2 f$ ($\text{Im } \zeta \geq 0$) has solutions $f_{\pm}(x, \zeta)$ that can be represented as

$$f_{\pm}(x, \zeta) = e^{\pm i\zeta x} (1 + \int_0^{\infty} K_{\pm}(x, t) e^{\pm 2i\zeta t} dt).$$

Putting $\zeta = \xi + i\eta$ and noting that $f_{+}(x, \xi)$ and $f_{-}(x, -\xi)$ are independent solutions of $Lf = \xi^2 f$, one can express f_{-} as

$$f_{-}(x, \xi) = a(\xi)f_{+}(x, -\xi) + b(\xi)f_{+}(x, \xi).$$

The coefficient $a(\xi)$ can be continued analytically to the upper half-plane, where it has only a finite number of zeros, all of which are simple and lie on the imaginary axis. Denote them by $i\eta_j$ ($j = 1, \dots, n$). The \dagger point spectrum of the operator L consists of the numbers $-\eta_j^2$, and the associated eigenfunctions are $f_{+}(x, i\eta_j)$, which are real-valued. Put

$$c_j = (\int f_{+}(x, i\eta_j)^2 dx)^{-1},$$

and call $t(\xi) = a(\xi)^{-1}$ and $r(\xi) = b(\xi)/a(\xi)$ the **transmission coefficient** and the **reflection coefficient**, respectively. The triplet $r(\xi), \eta_j, c_j$ ($j = 1, \dots, n$) is called the **scattering data**. It is connected with the kernel $K = K_{+}$ by the **Gel'fand-Levitan-Marchenko equation**

$$K(x, t) + F(x+t) + \int_0^{\infty} F(x+t+s)K(x, s) ds = 0 \quad (t > 0),$$

$$F(x) = \pi^{-1} \int_{-\infty}^{\infty} r(\xi) e^{2i\xi x} d\xi + 2 \sum_{j=1}^n c_j e^{-2\eta_j x}.$$

The potential is given by

$$u(x) = -(\partial K / \partial x)(x, 0).$$

When the reflection coefficient $r(\xi)$ vanishes identically, the potential is called a **reflectionless potential**. The kernel K then becomes a \dagger degenerate kernel and the potential is expressed by

$$u(x) = -2 \frac{d^2}{dx^2} \log D(x),$$

where $D(x)$ is the determinant of the $n \times n$ matrix whose j, k entry is $\delta_{jk} + c_j \exp\{-(\eta_j + \eta_k)x\}$.

The authors of [1] showed that if $u(x, t)$ is a solution of the KdV equation and if $u(x, t) \rightarrow 0$ ($x \rightarrow \pm\infty$), then the time development of the scattering data of the potential $u(x, t)$ is as follows: n and η_j do not depend on t , and

$$c_j(t) = c_j e^{8\eta_j^3 t}, \quad r(\xi, t) = r(\xi) e^{8i\xi^3 t}.$$

The solution associated with the reflectionless potentials are obtained by replacing c_j by $c_j(t)$ in the formula for $D(x)$. These are soliton solutions of the KdV equation.

R. Hirota developed a method of treating functions like $D(x)$ directly for most of the equations in the soliton theory (*Lecture notes in math.* 515, Springer, 1976).

A certain geometric method that enables one to obtain solutions of the Sine-Gordon equation from a known solution has been studied in the transformation theory of surfaces of constant negative curvature (G. Darboux, *Leçons sur la théorie générale des surfaces*, Chelsea, 1972, vol. 3, ch. 12), and its generalizations are called Bäcklund transfor-

mations. Soliton solutions of the KdV equation can also be constructed by this method. Relations to the inverse scattering method, differential systems, and transformation groups have also been studied (*Lecture notes in math.* 515, Springer, 1976).

E. Periodic Problem

Let the potential $u(x)$ be of period l , and consider Hill's equation (\rightarrow 268 Mathieu Functions E) $Lf = \lambda f$. The real (λ -) axis is divided into intervals of unstable solutions (u -intervals) alternating with intervals of stable solutions. One of the u -intervals is of the form $(-\infty, \lambda_0]$ and the others are finite, possibly degenerating to points. The special potentials that have only a finite number of nondegenerate u -intervals are the periodic analog of the reflectionless potentials, and are called the **finite-gap** (or **-band**) potentials.

Consider the eigenvalue problem $Lf = \lambda f$, $f(\tau) = f(\tau + l) = 0$ for a fixed real parameter τ . Exactly one of its eigenvalues belongs to each finite u -interval. These eigenvalues move with τ , but those in degenerate intervals cannot move.

Let u be a finite-gap potential, $I_j = [\lambda_{2j-1}, \lambda_{2j}]$ ($j = 1, \dots, g$) be the nondegenerate (finite) u -intervals, and $\mu_j(\tau)$ be the associated eigenvalues in I_j . The potential is recovered by the formula

$$u(x) = \sum_{j=0}^{2g} \lambda_j - 2 \sum_{j=1}^g \mu_j(x).$$

Put $P(\lambda) = \prod_{j=0}^{2g} (\lambda - \lambda_j)$, realize the \dagger Riemann surface S of the hyperelliptic curve $w^2 = P(z)$ as a two-sheeted cover of the \dagger Riemann sphere, and consider the $\mu_j(\tau)$ as points on S . Let ω_j ($j = 1, \dots, g$) be a basis for the space of the \dagger differentials of the first kind on S . Fix a point P_0 in S and put

$$w_j(\tau) = \sum_{k=1}^g \int_{P_0}^{\mu_k(\tau)} \omega_j \quad (j = 1, \dots, g)$$

(\rightarrow 3 Abelian Varieties L). Then the locus $(w_1(\tau), \dots, w_g(\tau))$ ($-\infty < \tau < \infty$) on the \dagger Jacobian variety turns out to be a straight line, the direction v_x being determined by the \dagger periods of certain \dagger differentials of the second kind on S . Employing the solution of \dagger Jacobi's inverse problem, we can write the potential in terms of the \dagger Riemann theta function as

$$u(x) = -2 \frac{d^2}{dx^2} \log \theta(xv_x + c) + C, \tag{3}$$

where c is a certain constant vector and C is a constant.

Suppose now that $u(x, t)$ is a solution of the KdV equation which is a finite-gap potential

for each t . Then g and λ_j are preserved in time. The determination of the direction v_t on the Jacobian variety is similar to that of v_x , and the solutions of the KdV equation are obtained by replacing the vector c by $tv_t + c'$ in (3). The case $g = 1$ is the elliptic traveling wave solution (\rightarrow Section B). Most of these results have been extended to the general periodic problem (H. P. McKean and E. Trubowitz, *Comm. Pure Appl. Math.*, 29 (1976)).

F. Two-Dimensional KdV Equation

Let S be a compact \dagger Riemann surface of \dagger genus g , and let p_∞ be a fixed point on S . Put $F(\kappa) = a_n \kappa^n + \dots + a_0$ and $G(\kappa) = b_m \kappa^m + \dots + b_0$. A function $\psi(x, y, t, p)$ of $p \in S$ and of x, y, t is uniquely determined by the following conditions: (a) it is meromorphic on $S - \{p_\infty\}$, and its pole \dagger divisor is a general divisor of degree g and does not depend on x, y, t ; (b) for a \dagger local parameter z at p_∞ ($z(p_\infty) = 0$) and $\kappa = z^{-1}$, $\psi_0 = \psi \exp(-\kappa x - F(\kappa)y - G(\kappa)t)$ is holomorphic near p_∞ , and $\psi_0(p_\infty) = 1$.

Moreover, there is a differential operator $L = a_n D^n + a_{n-1} D^{n-1} + \sum_{j=0}^{n-2} u_j(x, y, t) D^j$ such that $\psi_y = L\psi$. Expanding ψ_0 at p_∞ as $1 + \sum_{j=1}^{\infty} \zeta_j(x, y, t) z^j$, one can express the coefficients u_j by ζ_1, ζ_2, \dots . Analogously, there is an $M = b_m D^m + b_{m-1} D^{m-1} + \sum_{j=0}^{m-2} v_j D^j$ such that $\psi_t = M\psi$. The operators L and M satisfy the relation

$$L_t - M_y = [L, M], \tag{4}$$

which is a generalization of the Lax representation. The coefficients of L and M satisfy a certain system of nonlinear differential equations (V. E. Zakharov and A. B. Shabat, *Functional Anal. Appl.*, 8 (1974); I. M. Krichever, *Functional Anal. Appl.*, 11 (1977)).

Example. Let $F(\kappa) = \kappa^2$ and $G(\kappa) = \kappa^3 + c\kappa$. Then one finds

$$L = D^2 + u, \quad M = D^3 + (3u/2 + c)D + v,$$

where $u = -2\zeta_1'$ and $v = 3\zeta_1 \zeta_1' - 3\zeta_1'' - 3\zeta_2'$. Eliminating v from (4), one has

$$3u_{yy} + (-4u_t + 4cu_x + u_{xxx} + 6uu_x)_x = 0,$$

the so-called **two-dimensional KdV equation** (**Kadomtsev-Petvyashvili equation**). If $u(x, y, t)$ does not depend on y , the equation reduces to the KdV equation, and if u does not depend on t , to the **Boussinesq equation**.

The condition for reduction to these special cases can be described in terms of the meromorphic functions admitted by S . Suppose that there is a meromorphic function $E_F(p)$ holomorphic for $p \neq p_\infty$ and of \dagger principal part $F(\kappa)$ at $p = p_\infty$. Then ψ is written as $\varphi(x, t, p) \exp\{E_F(p)y\}$, and the coeffi-

icients of L and M do not depend on y . φ satisfies $L\varphi = E\varphi$, and (4) reduces to the Lax representation.

If such an E_F exists, S is hyperelliptic, and p_∞ is one of its \dagger branch points over the Riemann sphere. Thus the result of the previous section is recovered.

G. Solvable Models in Field Theory

The Sine-Gordon equation has been studied extensively as a solvable model in \dagger field theory. It is a special case of a field in two space-time dimensions with values in a \dagger symmetric space; this can also be treated by a variant of the inverse scattering method (V. E. Zakharov and A. V. Mikhailov, *Sov. Phys. JETP*, 47 (1978)).

Much work has been done on the semiclassical \dagger quantization of equations encountered in soliton theory. Recently, a method of exact quantization (called quantum inverse scattering) was developed (see, for example, L. A. Takhtadzhyan and L. D. Faddeev, *Russian Math. Surveys*, 34 (5) (1979)).

**388 (XIII.32)
Special Functional Equations**

A. General Remarks

The term **special functional equations** usually means functional equations that do not involve limit operations. Such functional equations appear in various fields, but there is no systematic method for solving them. Usually

they are solved by reduction to functional equations of some standard type. In this article functions are all real-valued functions of real variables unless otherwise specified.

B. Additive Functional Equations and Related Equations

Suppose that we are given an equation

$$f(x + y) = f(x) + f(y). \tag{1}$$

Clearly, $f(x) = cx$ (c a constant) is a solution. If $f(x)$ is continuous, (1) has no other solution (Cauchy). The same conclusion holds under any one of the following weaker conditions: (i) $f(x)$ is continuous at a point; (ii) $f(x)$ is bounded in a neighborhood of a point; (iii) $f(x)$ is \dagger measurable in a neighborhood of a point. However, it was shown by G. Hamel and H. Lebesgue by means of \dagger transfinite induction that equation (1) has infinitely many nonmeasurable solutions. On the other hand, it was proved by A. Ostrowski [2] that if a solution $f(x)$ of equation (1) does not take any value between two distinct numbers for x on a set of positive measure, then $f(x)$ is continuous. This result can be extended to the case where x is a point (x_1, \dots, x_n) of an n -dimensional Euclidean space. In this case, any continuous solution is of the form

$$f(x) = \sum_{j=1}^n C_j x_j$$

(C_j constant).

Next, we consider the equation

$$f\left(\frac{x + y}{2}\right) = \frac{f(x) + f(y)}{2}. \tag{2}$$

Any solution of equation (1) satisfies this equation. When x is a point (x_1, \dots, x_n) of an n -dimensional Euclidean space, any continuous solution of (2) is of the form $f(x) = \sum_{j=1}^n C_j x_j + C_0$ (C_j constant). If a solution $f(x)$ of (2) defined on a \dagger convex set K does not take any value between two distinct numbers for x on a set of positive measure, then $f(x)$ is continuous (M. Hukuhara).

Consider the equation

$$g(x + y) = g(x)g(y). \tag{3}$$

If a solution $g(x)$ vanishes at some point ξ , then $g(x) \equiv 0$. Excluding this trivial case, we assume that $g(x)$ never vanishes. Then, putting $y = x$, we see that $g(x) > 0$ for all x . The substitution $f(x) = \log g(x)$ then reduces equation (3) to equation (1). Thus we see that any continuous solution of (3) is of the form $g(x) = \exp(cx)$.

Next, we consider the equation

$$g(uv) = g(u)g(v). \tag{4}$$

If a solution $g(u)$ vanishes at some $\xi \neq 0$, then $g(u) \equiv 0$. Excluding this case, we assume that $g(u) \neq 0$ for $u \neq 0$. For $u, v > 0$, by the substitution $x = \log u, y = \log v$, we have an equation of the form (3). On the other hand, putting $v = -1$, we have $g(-u) = g(-1)g(u)$. Since $g^2(-1) = g(1) = 1$, we see that any continuous solution of (4) is of the form $|u|^c$ or $(\text{sgn } u)|u|^c$ according as $g(-1) = 1$ or -1 .

C. The General Addition Theorem and Related Functional Equations

The **general addition theorem** is: If the equation $f(x + y) = F(f(x), f(y))$ (5)

has a continuous nonconstant solution $f(x)$ on $-\infty < x < +\infty$, then $f(x)$ is strictly monotone, and $F(u, v)$ is strictly monotone increasing and continuous with respect to u and v for $\alpha < u, v < \beta$ and satisfies $\alpha < F(u, v) < \beta$ for $\alpha < u, v < \beta$. There is also a constant c satisfying $F(c, c) = c$, and the identity $F(F(u, v), w) = F(u, F(v, w))$ holds for any u, v, w in the interval (α, β) . Conversely, if $F(u, v)$ is such a function, then (5) has a continuous nonconstant solution on $-\infty < x < +\infty$. Let $f(x)$ be such a solution. Then any other continuous solution is given by $f(cx)$. When $F(u, v)$ is continuously differentiable, a continuous solution $f(x)$ of (5) can be obtained as a solution of the differential equation

$$f'(x) = F_v(f(x), a)c, \quad c = f'(0),$$

satisfying the initial condition $f(0) = a$.

Consider the equation

$$F(f(x), f(y), f(x + y)) = 0.$$

Suppose that $F(u, v, w)$ is a polynomial in u, v , and w . If this equation has a meromorphic solution $f(x)$, then $f(x)$ must be a rational function, a rational function of $\exp cx$, or an elliptic function [1, p. 64].

Next, consider the equation

$$f(x + y) + f(x - y) = 2(f(x) + f(y)). \quad (6)$$

Any solution continuous on $-\infty < x < \infty$ is of the form $f(x) = cx^2$. When x is a point (x_1, \dots, x_n) of an n -dimensional Euclidean space, any continuous solution of (6) is given by a quadratic form $f(x) = \sum_{i,j}^n c_{ij}x_i x_j$.

Consider the equation

$$f(x + y) + f(x - y) = 2f(x)f(y). \quad (7)$$

Any solution continuous on $-\infty < x < \infty$ is of the form $f(x) = \cosh cx = (e^{cx} + e^{-cx})/2$ or $f(x) = \cos cx$. If $f(x)$ is allowed to take complex values, then any continuous solution can be written in the form $f(x) = (e^{bx} + e^{-bx})/2$ in terms of a complex number b . A special case

is $\cos x$, since b may take purely imaginary values.

D. Schröder's Functional Equation

Schröder's functional equation is

$$f(\theta(x)) = cf(x), \quad (8)$$

where $\theta(x)$ is a given function and c is a constant. A general solution of (8) can be written as $f(x) = f_1(x)\varphi(x)$, where $f_1(x) \neq 0$ is a particular solution of (8) and $\varphi(x)$ is a general solution of the equation $\varphi(\theta(x)) = \varphi(x)$. Suppose that there is a point a such that $\theta(a) = a$, and $\theta(x)$ and $f(x)$ are both differentiable in a neighborhood of $x = a$. Then we have $f'(a) = 0$ or $\theta'(a) = c$. Consider the case where $\theta'(a) = c$, and suppose that $\theta(x)$ is twice differentiable at $x = a$. When $|c| = |\theta'(a)| < 1$, define $\theta_n(x)$ ($n = 0, 1, 2, \dots$) by $\theta_0(x) = x$ and $\theta_n(x) = \theta(\theta_{n-1}(x))$. Then the sequence $\{(\theta_n(x - a)c^{-n})\}$ ($n = 0, 1, 2, \dots$) converges uniformly in a neighborhood of $x = a$, and its limit function $f(x)$ is a solution of (8). When $|c| = |\theta'(a)| > 1$, put $\theta(x) = u$. Then we have the equation $f(\theta^{-1}(u)) = c^{-1}f(u)$, and the problem reduces to the previous case. The results obtained for equation (8) can be extended to the following system of equations:

$$f_j(\theta_1(x), \theta_2(x), \dots, \theta_n(x)) = \lambda_j f_j(x) + \delta_j f_{j-1}(x) + g_j(x), \quad j = 1, 2, \dots, n, \quad (9)$$

where the $\theta_j(x)$ are given functions holomorphic in a neighborhood of $x = 0$, $\theta_j(0) = 0$, the coefficients of f in the right-hand side of (9) are numbers such that the matrix $A = (a_{ij})$ ($a_{ij} = 0$ except for $a_{ij} = \lambda_j, a_{j-1,j} = \delta_j$) is the \dagger Jordan canonical form of the matrix formed by $\{(\partial\theta_j/\partial x_k)_{x=0}\}$, and the $g_j(x)$ are polynomials consisting of terms of the form constant $\times x_1^{m_1} x_2^{m_2} \dots x_n^{m_n}$ with exponents m_1, m_2, \dots, m_n for which $\lambda_j = \lambda_1^{m_1} \dots \lambda_n^{m_n}$. If $0 < |\lambda_j| < 1$ ($j = 1, 2, \dots, n$), then we can always choose the coefficients of the polynomials $g_j(x)$ so that equation (9) has a solution $\{f_j(x)\}$ holomorphic in a neighborhood of $x = 0$. The same conclusion can be obtained for $|\lambda_j| > 1$ ($j = 1, \dots, n$).

Consider **Abel's functional equation**

$$f(\theta(x)) = f(x) + 1. \quad (10)$$

If we put $\exp f(x) = \varphi(x)$, then we have Schröder's functional equation

$$\varphi(\theta(x)) = e\varphi(x).$$

Consider the equation

$$f(x + 1) = A(x)f(x). \quad (11)$$

If we put $\varphi(x) = \log f(x)$, then we have a linear difference equation of the form

$$\varphi(x + 1) - \varphi(x) = \log A(x).$$

389 (XIV.1) Special Functions

A. Special Functions

The term **special functions** usually refers to the classes of functions listed in (1)–(4) (other terms, such as **higher transcendental functions**, are sometimes used). (1) The \dagger gamma function and related functions (\rightarrow 174 Gamma Function); (2) \dagger Fresnel's integral, the \dagger error function, the \dagger logarithmic integral, and other functions that can be expressed as indefinite integrals of elementary functions (\rightarrow 167 Functions of Confluent Type D); (3) \dagger elliptic functions (\rightarrow 134 Elliptic Functions); (4) solutions of \dagger linear ordinary differential equations of the second order derived by the method of separation of variables in certain partial differential equations, e.g., \dagger Laplace's equation, in various \dagger curvilinear coordinates. Recently, new types of special functions, such as \dagger Painlevé's, have been introduced as the solutions of special differential equations.

In this article we discuss class (4); for the other classes, see the articles quoted. Class (4) is further divided into the following three types, according to the character of the \dagger singular points of the differential equations of which the functions are solutions. Equations with a smaller number of singular points than those indicated in (1)–(3) below can be integrated in terms of elementary functions.

(1) **Special functions of hypergeometric type** are solutions of differential equations with three \dagger regular singular points on the Riemann sphere. Examples are the \dagger hypergeometric function and the \dagger Legendre function. Any function of this type reduces to a hypergeometric function through a simple transformation (\rightarrow 206 Hypergeometric Functions; 393 Spherical Functions).

(2) **Special functions of confluent type** are solutions of differential equations that are derived from \dagger hypergeometric differential equations by the confluence of two regular singular points, that is, by making one of the regular singular points tend to the other one so that the resulting singularity is an \dagger irregular singular point of class 1 (\rightarrow 167 Functions of Confluent Type). Any function of this type can be expressed by means of \dagger Whittaker functions, of which many important special functions, such as \dagger Bessel functions, are special cases (\rightarrow 39 Bessel Functions). Also, one can reduce to this type the \dagger parabolic cylindrical functions, that is, the solutions of differential equations with only one singular point which is at infinity and is irregular of class 2.

(3) **Special functions of ellipsoidal type** are solutions of differential equations with four or five regular singular points, some of which may be confluent to become irregular singular points. Examples are \dagger Lamé functions, \dagger Mathieu functions, and \dagger spheroidal wave functions (\rightarrow 133 Ellipsoidal Harmonics; 268 Mathieu Functions). In contrast to types (1) and (2), functions of type (3) are difficult to characterize by means of \dagger difference-differential equations and have not been fully explored. Sometimes the term *special function* in the strict sense is not applied to them. To specify the special functions of types (1) and (2), the term *classical special functions* has been proposed.

B. Unified Theories of Special Functions

Though many special functions were introduced separately to solve practical problems, several unified theories have been proposed. The classification in Section A based on differential equations may be regarded also as a kind of unified theory. Other examples are:

(1) Expression by \dagger Barnes's extended hypergeometric function or its extension to the case of several variables by means of a definite integral of the form

$$\int (\zeta - a_1)^{b_1} (\zeta - a_2)^{b_2} \dots (\zeta - a_m)^{b_m} (\zeta - z)^c d\zeta$$

(\rightarrow 206 Hypergeometric Functions).

(2) A unified theory [14] that includes the gamma function and is based upon Truesdell's difference-differential equation

$$\partial F(z, \alpha) / \partial z = F(z, \alpha + 1).$$

(3) Unification from the standpoint of expansions in terms of \dagger zonal spherical functions of a differential operator (the Laplacian) invariant under a transitive group of motions on a \dagger symmetric Riemannian manifold (\rightarrow 437

Unitary Representations). With this approach a great variety of formulas can be derived in a unified way [3, 4].

390 (XII.12) Spectral Analysis of Operators

A. General Remarks

Throughout this article, X stands for a \dagger complex linear space and A for a \dagger linear operator in X . Except when X is finite-dimensional, A need not be defined over all X . A linear operator A in X is by definition a linear mapping whose \dagger domain $D(A)$ and \dagger range $R(A)$ are linear subspaces of X . A complex number λ is said to be an **eigenvalue (proper value or characteristic value)** of A if there exists an $x \in D(A)$ such that $Ax = \lambda x$, $x \neq 0$. Any such x is called an **eigenvector (eigenelement, proper vector, characteristic vector)** associated with λ . When X is a \dagger function space, the word **eigenfunction** is also used. For an eigenvalue λ of A , the subspace $M(\lambda)$ of X given by

$$M(\lambda) = M(\lambda; A) = \{x \mid Ax = \lambda x\},$$

i.e., the subspace consisting of 0 and all eigenvectors associated with λ , is called the **eigenspace** associated with λ , and the number $m(\lambda) = \dim M(\lambda)$ is called the **geometric multiplicity** of λ . The eigenvalue λ is said to be (**geometrically**) **simple** or **degenerate** according as $m(\lambda) = 1$ or $m(\lambda) \geq 2$. The problem of seeking eigenvalues and eigenvectors is referred to as the **eigenvalue problem**.

When X is a \dagger topological linear space, the notion of eigenvalues leads to a more general object called the spectrum of A . Let λ be a complex number and put $A_\lambda = \lambda I - A$, where I is the \dagger identity operator in X . Furthermore, put $R_\lambda = (A_\lambda)^{-1} = (\lambda I - A)^{-1}$, if the inverse exists. Then the **resolvent set** $\rho(A)$ of A is defined to be the set of all λ such that R_λ exists, has domain \dagger dense in X , and is continuous. The **spectrum** $\sigma(A)$ of A is, by definition, the complement of $\rho(A)$ in the complex plane, and it is divided into three mutually disjoint sets: the **point spectrum** $\sigma_p(A)$, the **continuous spectrum** $\sigma_c(A)$, and the **residual spectrum** $\sigma_R(A)$. These are defined as follows: $\sigma_p(A) = \{\lambda \mid R_\lambda \text{ does not exist}\} = \{\lambda \mid \lambda \text{ is an eigenvalue of } A\}$; $\sigma_c(A) = \{\lambda \mid R_\lambda \text{ exists and has domain dense in } X, \text{ but is not continuous}\}$; $\sigma_R(A) = \{\lambda \mid R_\lambda \text{ exists, but its domain is not dense in } X\}$.

Let X be a \dagger Banach space and $\mathbf{B}(X)$ the set of all \dagger bounded linear operators with domain X . If A is a \dagger closed operator in X , then $\lambda \in \rho(A)$ if and only if $R_\lambda \in \mathbf{B}(X)$. Moreover, $\sigma(A)$ is a closed set. In particular, if $A \in \mathbf{B}(X)$, then $\sigma(A)$ is a nonempty compact set. In this case the **spectral radius** $r_\sigma(A)$ is defined as $r_\sigma(A) = \sup_{\lambda \in \sigma(A)} |\lambda|$. Then $r_\sigma(A) \leq \|A^n\|^{1/n}$, $n = 1, 2, \dots$, and $\|A^n\|^{1/n} \rightarrow r_\sigma(A)$, $n \rightarrow \infty$.

In many problems of analysis crucial roles have been played by methods involving the spectrum and other related concepts. This branch of analysis is called **spectral analysis**. For an infinite-dimensional X the theory is well developed when X is a †Hilbert space and A is †self-adjoint or †normal.

B. Eigenvalue Problems for Matrices

Throughout this section let X be an N -dimensional complex linear space ($N < \infty$) and A a linear operator in X . (We assume that A is defined over all X .) With respect to a fixed basis (ψ_1, \dots, ψ_N) of X , the operator A is represented by an $N \times N$ matrix, also denoted by A . Then the eigenvalues of A coincide with the roots of the †characteristic equation $\det(\lambda I - A) = 0$. There are no points of the spectrum other than eigenvalues, that is $\sigma(A) = \sigma_p(A)$. Let $\lambda \in \sigma(A)$. The multiplicity $\tilde{m}(\lambda)$ of λ as a root of the characteristic equation is called the **(algebraic) multiplicity** of the eigenvalue λ . The sum of $\tilde{m}(\lambda)$ over all the eigenvalues of A is equal to N . The eigenvalue λ is said to be **(algebraically) simple** or **degenerate** according as $\tilde{m}(\lambda) = 1$ or $\tilde{m}(\lambda) \geq 2$. Let $v = 1, 2, \dots$, and $N_v(\lambda) = \{x | (\lambda I - A)^v x = 0\}$. Then $\{N_v(\lambda)\}$ forms a nondecreasing chain of subspaces $M(\lambda) = N_1(\lambda) \subset N_2(\lambda) \subset \dots$, which ceases to increase after a finite number of steps. When $v \geq \tilde{m}(\lambda)$, the space $N_v(\lambda)$ is equal to a fixed subspace $\tilde{M}(\lambda)$, sometimes called the **root subspace** (or **generalized eigenspace** or **principal subspace**) of A associated with λ . A vector in the root subspace is called a **root vector** (or a **generalized eigenvector**). Then $\dim \tilde{M}(\lambda) = \tilde{m}(\lambda)$ and hence $m(\lambda) \leq \tilde{m}(\lambda)$. When A is a †normal matrix, $M(\lambda) = \tilde{M}(\lambda)$ and $m(\lambda) = \tilde{m}(\lambda)$.

If two matrices A and B are †similar, i.e., if there exists an invertible matrix P such that $B = P^{-1}AP$, then A and B have the same eigenvalues with the same algebraic (and geometric) multiplicities. The same conclusion holds for A and A' , where A' is the †transpose of A . For the adjoint matrix A^* we have $\sigma(A^*) = \overline{\sigma(A)} \equiv \{\bar{\lambda} | \lambda \in \sigma(A)\}$. For an arbitrary polynomial f the relation $\sigma(f(A)) = f(\sigma(A)) \equiv \{f(\lambda) | \lambda \in \sigma(A)\}$ holds (**Frobenius's theorem**). These relations can be extended to operators in a Banach space. In particular, $\sigma(f(A)) = f(\sigma(A))$ if A is a bounded operator and f is a function holomorphic in a neighborhood of $\sigma(A)$ (for the †spectral mapping theorem — 251 Linear Operators).

In the next four paragraphs, in which the spectral properties of †normal or †Hermitian matrices is discussed, we introduce into X the Euclidean †inner product (\cdot, \cdot) , regarding X as a space of N -tuples of scalars. Let A be an

$N \times N$ normal matrix. Then the eigenspaces associated with different eigenvalues of A are mutually orthogonal. Moreover, the eigenspaces of A as a whole span the entire space X . One can therefore choose a †basis of X formed by a †complete orthonormal set of eigenvectors of A . Specifically, there exists a basis $\{\varphi_j | j = 1, \dots, N\}$ of X such that $A\varphi_j = \mu_j\varphi_j$ and $(\varphi_i, \varphi_j) = \delta_{ij}$, where δ_{ij} is the †Kronecker delta. Moreover, μ_1, \dots, μ_N exhaust all the eigenvalues of A . In terms of the basis $\{\varphi_j\}$, an arbitrary $x \in X$ can be expanded as

$$Ax = \sum_{j=1}^N \mu_j(x, \varphi_j)\varphi_j = \sum_{\lambda \in \sigma(A)} \lambda P_\lambda x, \tag{1}$$

where P_λ is the orthogonal †projection on the eigenspace associated with the eigenvalue λ .

Of particular importance among normal matrices are Hermitian matrices and †unitary matrices. The eigenvalues of a Hermitian matrix are real, and those of a unitary matrix have the absolute value 1.

Solving the eigenvalue problem of a normal matrix A leads immediately to the diagonalization of A . For instance, let U be the $N \times N$ matrix whose j th column is equal to φ_j . Here the basis $\{\varphi_j\}$ is as before, and each φ_j is regarded as a column vector. Then U is unitary, and the transform U^*AU of A by U is the diagonal matrix whose diagonal entries are the μ_j . The problem of transforming a †Hermitian form to its canonical form can also be solved by means of U . In fact, a Hermitian form $Q = Q(x)$ on X is expressed as $Q(x) = (Ax, x)$ with a Hermitian matrix A . For this A , construct U as before. Then by the transformation $x = Uy$ of the coordinates of X , the form Q is converted to its canonical form $Q = \mu_1|y_1|^2 + \dots + \mu_N|y_N|^2$. When X is a real linear space and A is a real symmetric matrix, U is an orthogonal matrix. By means of the orthogonal transformation $x = Uy$, the surface of the second order $Q(x) = 1$ in \mathbf{R}^N is converted to the form $\mu_1 y_1^2 + \dots + \mu_N y_N^2 = 1$. The orthogonal transformation $x = Uy$ is called the **transformation to principal axes** of the surface $Q(x) = 1$.

When A is not normal, it can be transformed into †Jordan's canonical form by a basis φ_j taken from the root subspaces $\tilde{M}(\lambda)$. However, φ_j need not be orthonormal even when A is diagonalizable.

C. Spectral Analysis in Hilbert Spaces

Throughout the rest of this article except for the last section, X is assumed to be a Hilbert space with inner product (\cdot, \cdot) . Furthermore, the most complete discussions will be confined to †normal or †self-adjoint operators. A funda-

mental theorem in spectral analysis for such operators is the spectral theorem, which asserts that a representation such as (1) holds in a generalized form. When the operator is \dagger compact, we have only to replace the sum by an infinite sum (\rightarrow 68 Compact and Nuclear Operators). In the general case we need a kind of integral. This is discussed in detail in Sections D and E. The general theory of spectral analysis for nonnormal operators, however, is rather involved even in Hilbert spaces, but two important developments can be noted. One is the theory of Volterra operators, and the other is the theory of essentially normal operators. The former is discussed in Section H and the latter and its related results in Sections I and J.

D. Spectral Measure

Let \mathcal{B} be a \dagger completely additive class of subsets of a set Ω , that is, (Ω, \mathcal{B}) is a \dagger measurable space. An operator-valued set function $E = E(\cdot)$ defined on \mathcal{B} is said to be a (self-adjoint) **spectral measure** if (i) $E(M)$, $M \in \mathcal{B}$, is an \dagger orthogonal projection in X ; (ii) $E(\Omega) = I$; and (iii) E is \dagger countably additive, that is,

$$E\left(\bigcup_{n=1}^{\infty} M_n\right) = \sum_{n=1}^{\infty} E(M_n)$$

(\dagger strong convergence) for a disjoint sequence $\{M_n\}$ of subsets in \mathcal{B} . A spectral measure E satisfies $E(M \cap N) = E(M)E(N) = E(N)E(M)$, $M, N \in \mathcal{B}$. Spectral measures which are frequently used in spectral analysis are those defined on the family $\mathcal{B}_r(\mathcal{B}_c)$ of all \dagger Borel sets in the field of real (complex) numbers \mathbf{R} (\mathbf{C}). A spectral measure on $\mathcal{B}_r(\mathcal{B}_c)$ is sometimes referred to as a **real (complex) spectral measure**. For such a spectral measure E the **support** (or the **spectrum**) of E , denoted by $\Lambda(E)$, is defined to be the complement of the largest open set G for which $E(G) = 0$. A complex spectral measure such that $\Lambda(E) \subset \mathbf{R}$ can be identified with a real spectral measure.

Let E be a spectral measure on \mathcal{B}_r , and put

$$E_\lambda = E((-\infty, \lambda]), \quad -\infty < \lambda < \infty. \tag{2}$$

Then E_λ satisfies the relations

$$\begin{aligned} E_\lambda E_\mu &= E_{\min(\lambda, \mu)}, & \text{s-lim}_{\lambda \rightarrow \mu+0} E_\lambda &= E_\mu, \\ \text{s-lim}_{\lambda \rightarrow -\infty} E_\lambda &= 0, & \text{s-lim}_{\lambda \rightarrow +\infty} E_\lambda &= I, \end{aligned} \tag{3}$$

where s-lim stands for strong convergence. A family $\{E_\lambda\}_{\lambda \in \mathbf{R}}$ of orthogonal projections satisfying the relation (3) is called a **resolution of the identity**. Relation (2) gives a one-to-one correspondence between the resolutions of the identity and the spectral measures on \mathcal{B}_r .

Let E be a spectral measure on \mathcal{B}_r , and let $x, y \in X$. Then the set function $M \rightarrow (E(M)x, x) =$

$\|E(M)x\|^2$ is a bounded regular \dagger measure in the ordinary sense, and the set function $M \rightarrow (E(M)x, y)$ is a complex-valued regular \dagger completely additive set function. For every complex Borel \dagger measurable function f on \mathbf{R} , the operator $S(f)$ in X is defined by the relations

$$\begin{aligned} D(S(f)) &= \left\{ x \mid \int_{-\infty}^{\infty} |f(\lambda)|^2 (E(d\lambda)x, x) < \infty \right\}, \\ (S(f)x, y) &= \int_{-\infty}^{\infty} f(\lambda) (E(d\lambda)x, y), \end{aligned} \tag{4}$$

$x \in D(S(f)), \quad y \in X.$

$S(f)$ is a densely defined closed operator and is denoted by $S(f) = \int_{-\infty}^{\infty} f(\lambda) E(d\lambda)$. The correspondence $f \mapsto S(f)$ satisfies formulas of the so-called operational calculus (\rightarrow 251 Linear Operators). In particular, $S(\bar{f}) = S(f)^*$, and hence $S(f)$ is self-adjoint if f is real-valued. If f is bounded on the support of E , then $S(f)$ is everywhere defined in X and is bounded. $S(f)$ is sometimes called the **spectral integral** of f with respect to E . The operator $S(f)$ can be defined in a similar way for a spectral measure on \mathcal{B}_c (and for a more general spectral measure).

E. Spectral Theorems

For every self-adjoint operator H in a Hilbert space X , there exists a unique real spectral measure E such that

$$H = \int_{-\infty}^{\infty} \lambda E(d\lambda). \tag{5}$$

In other words, H and E correspond to each other by the relations

$$\begin{aligned} D(H) &= \left\{ x \mid \int_{-\infty}^{\infty} \lambda^2 (E(d\lambda)x, x) < +\infty \right\}, \\ (Hx, y) &= \int_{-\infty}^{\infty} \lambda (E(d\lambda)x, y), \end{aligned} \tag{6}$$

$x \in D(H), \quad y \in X.$

This is the **spectral theorem** for self-adjoint operators. The support of E is equal to the spectrum $\sigma(H)$, so that we can write

$$H = \int_{\sigma(H)} \lambda E(d\lambda) = \int_{-\infty}^{\infty} \lambda \chi_{\sigma(H)}(\lambda) E(d\lambda),$$

where χ_M stands for the \dagger characteristic function of M . Formulas (5) and (6) are called the **spectral resolution** (or **spectral representation**) of the **self-adjoint operator** H . We call E the spectral measure for H , and the $\{E_\lambda\}$ corresponding to E by formula (2) (or sometimes E itself) the resolution of the identity for H .

Let λ be a real number. Then $\lambda \in \sigma_p(H)$ if and only if $E(\{\lambda\}) \neq 0$. Also, $\lambda \in \sigma_c(H)$ if and only if $E(\{\lambda\}) = 0$ and $E(V) \neq 0$ for any neighborhood

V of λ . The spectral measure E can be represented in terms of the resolvent $R(\alpha; H) = (\alpha I - H)^{-1}$ of H by the formula

$$E((a, b)) = \lim_{\delta \downarrow 0} \lim_{\varepsilon \downarrow 0} \frac{1}{2\pi i} \int_{a+\delta}^{b-\delta} \{R(\mu - \varepsilon i; H) - R(\mu + \varepsilon i; H)\} d\mu$$

(strong convergence).

For every normal operator A in X , there exists a unique spectral measure E on the family of all complex Borel sets \mathcal{B}_c such that

$$A = \int_C zE(dz).$$

This is called the **complex spectral resolution** (or **complex spectral representation**) of the **normal operator** A . The support $\Lambda(E)$ is equal to $\sigma(A)$. There are characterizations of point and continuous spectra similar to the case of self-adjoint operators. Normal operators have no residual spectra. For a unitary operator U , the support of the associated spectral measure is contained in the unit circle Γ , so that U can be represented as

$$U = \int_{\Gamma} e^{i\theta} F(d\theta) \tag{7}$$

with a spectral measure F defined on Γ . Formula (7) is the **spectral resolution** of the **unitary operator** U .

For a self-adjoint operator $H = \int_{-\infty}^{\infty} \lambda E(d\lambda)$ the following two types of classification of $\sigma(H)$ are often useful.

(i) The **essential spectrum** $\sigma_e(H)$ is by definition the set $\sigma(H)$ minus all the isolated eigenvalues of H with finite multiplicity. When H is bounded this definition of the essential spectrum coincides with that to be given in Section I for a general $A \in B(X)$. $\sigma(H) \setminus \sigma_e(H)$ is called the **discrete spectrum** of H .

(ii) The set $X_{ac}(H)$ (resp. $X_s(H)$) (called the **space of absolute continuity** (resp. **singularity**) with respect to H) of all $u \in X$ such that the measure $(E(d\lambda)u, u)$ is absolutely continuous (resp. singular) with respect to the \dagger Lebesgue measure is a closed subspace of X that reduces H . The restriction of H to X_{ac} (resp. $X_s(H)$) is called the absolutely continuous (resp. singular) part of H , and its spectrum, denoted by $\sigma_{ac}(H)$ (resp. $\sigma_s(H)$), is called the **absolutely continuous** (resp. **singular**) **spectrum** of H . Note that $\sigma_{ac}(H)$ and $\sigma_s(H)$ may not be disjoint.

F. Functions of a Self-Adjoint Operator

Let $H = \int_{-\infty}^{\infty} \lambda E(d\lambda)$ be a self-adjoint operator in X . For a complex-valued Borel measurable function f on \mathbf{R} , we define $f(H)$ to be the operator $S(f)$ determined by (4) in reference to the

resolution of the identity E associated with H :

$$f(H) = \int_{-\infty}^{\infty} f(\lambda) E(d\lambda).$$

For an arbitrary $a \in X$, let $L_2(a)$ be the L_2 -space over the measure $\mu_a = \mu_a(\cdot) = (E(\cdot)a, a)$. In other words, $f \in L_2(a)$ if and only if $a \in D(f(H))$. The correspondence $f \mapsto f(H)a$ gives an isometric isomorphism between $L_2(a)$ and the subspace $M(a) = \{f(H)a \mid f \in L_2(a)\}$ of X . (In particular, $M(a)$ is closed.) H is reduced by $M(a)$, and the part of H in $M(a)$ corresponds to the multiplication $f(\lambda) \rightarrow \lambda f(\lambda)$ in $L_2(a)$.

For a given self-adjoint operator H there exists a (not necessarily countable) family $\{a_\theta\}_{\theta \in \Theta}$ of elements a_θ of X such that

$$X = \sum_{\theta \in \Theta} M(a_\theta), \tag{8}$$

where \sum stands for the \dagger direct sum of mutually orthogonal closed subspaces. Consequently, X is represented by the direct sum $\sum_{\theta \in \Theta} L_2(a_\theta)$ of L_2 -spaces. If $x \in D(H)$ is represented by $\{f_\theta\}_{\theta \in \Theta}$ in this representation, Hx is represented by $\{\lambda f_\theta\}_{\theta \in \Theta}$.

G. Unitary Equivalence and Spectral Multiplicity

In this section X is assumed to be a \dagger separable Hilbert space. Then (8) can be made more precise. Namely, for a self-adjoint operator H , we can find a countable family $\{a_n\}_{n=1}^{\infty}$ of elements of X such that

$$X = \sum_{n=1}^{\infty} M(a_n) \cong \sum_{n=1}^{\infty} L_2(a_n), \tag{9}$$

$\mu_{a_{n+1}}$ is \dagger absolutely continuous

$$\text{with respect to } \mu_{a_n}, \quad n = 1, 2, \dots \tag{10}$$

Furthermore, if $\{a'_n\}$ is another family satisfying (9) and (10), then μ_{a_n} and $\mu_{a'_n}$ are absolutely continuous with respect to each other (**Hellinger-Hahn theorem**). μ_{a_1} is said to be the **maximum spectral measure**.

Two operators H_1 and H_2 are said to be **unitarily equivalent** if there exists a unitary operator U such that $H_2 = U^*H_1U$. A criterion for unitary equivalence of self-adjoint operators can be given in terms of the spectral representation given previously. Namely, let $\{a_n^{(i)}\}$, $i = 1, 2$, be a sequence satisfying (9) and (10) with respect to H_i . Then H_1 and H_2 are unitarily equivalent if and only if $\mu_{a_n^{(1)}}$ and $\mu_{a_n^{(2)}}$ are absolutely continuous with respect to each other for all $n = 1, 2, \dots$

A self-adjoint operator H is said to have a **simple spectrum** if there exists an $a \in X$ such that $M(a) = X$. Such an $a \in X$ is called a **generating element** of X with respect to H .

Self-adjoint operators with simple spectra are closely related to Jacobi matrices. Let H be such an operator with a generating element $a \in X$. Take a complete orthonormal set $\{g_n\}_{n=1}^\infty$ in $L_2(a)$ such that $G_n = G_n(\lambda)$ is a polynomial of degree $n-1$ and $\lambda G_n(\lambda) \in L_2(a)$. Then $\{g_n\}_{n=1}^\infty, g_n = G_n(H)a$, is a complete orthonormal set in X . The matrix representation $\{a_{mn}\}, a_{mn} = (Hg_n, g_m)$ of H with respect to the basis $\{g_n\}$ has the following properties: (i) $a_{mn} = 0$ if $|m-n| \geq 2$; (ii) $a_{n,n+1} = \overline{a_{n+1,n}} \neq 0$; (iii) a_{nn} is real. Any infinite matrix $\{a_{mn}\}$ satisfying (i), (ii), and (iii) is called a **Jacobi matrix**. A Jacobi matrix determines a \dagger -symmetric operator whose \dagger -deficiency index is either $(0, 0)$ or $(1, 1)$. Any self-adjoint extension has a simple spectrum. (For more details about Jacobi matrices and their applications \rightarrow [8].)

H. Triangular Representation of Volterra Operators

A linear operator A in a Hilbert space X is called a \dagger -Volterra operator if it is \dagger -compact and \dagger -quasinilpotent (i.e., 0 is the only spectrum). The name is justified because under very general assumptions such an operator is unitarily equivalent to the integral operator of Volterra type in the vector-valued L_2 space on $[0, 1]$. Let \mathfrak{P} be a maximal \dagger -totally ordered family of orthogonal projections in X such that PX is an \dagger -invariant subspace of a Volterra operator A for every $P \in \mathfrak{P}$. Such a family \mathfrak{P} always exists and is called a maximal **eigenchain** of A . Then generalizing the triangular representation of nilpotent matrices, we have the integral representation

$$A = 2i \int_{\mathfrak{P}} P A_I dP,$$

where $A_I = (A - A^*)/(2i)$ is the imaginary part of A and the integral is the limit in norm of approximating sums of the form $\sum Q_i A_I (P_i - P_{i-1})$ for finite partitions $0 = P_0 < P_1 < \dots < P_n = I$ of \mathfrak{P} in which Q_i is an arbitrary projection in \mathfrak{P} such that $P_{i-1} \leq Q_i \leq P_i$ (M. S. Brodskii). Conversely, let \mathfrak{P} be a totally ordered family of orthogonal projections that contains 0 and the identity. If the integral $A = \int_{\mathfrak{P}} P B dP$ converges in norm for a compact linear operator B , then A is a Volterra operator and \mathfrak{P} is an eigenchain of A . If, moreover, B is self-adjoint, we have $B = A_I$ (I. C. Gokhberg and M. G. Krein; Brodskii). Furthermore, assume for simplicity that \mathfrak{P} is continuous in the sense that for every $P_1 < P_2$ in \mathfrak{P} there exists an element P in \mathfrak{P} such that $P_1 < P < P_2$. If B is a \dagger -Hilbert-Schmidt operator, then the integral $A = \int_{\mathfrak{P}} P B dP$ converges in the \dagger -Hilbert-Schmidt norm and the mapping $B \mapsto A$ is an orthogonal

projection to the set of all Volterra operators of Hilbert-Schmidt class possessing \mathfrak{P} as an eigenchain (Gokhberg and Krein). Volterra operators with the imaginary part of the \dagger -trace class are especially important for applications. In this case we have the following fundamental theorem on the density of the spectrum of the real part A_R of the Volterra operator A : Let $n_+(r; A_R)$ and $n_-(r; A_R)$ be the numbers of eigenvalues of A_R in the intervals $[1/r, \infty)$ and $(-\infty, -1/r]$, respectively.

$$\text{Then } \lim_{r \rightarrow \infty} n_+(r; A_R)/r = \lim_{r \rightarrow \infty} n_-(r; A_R) = h/\pi.$$

The number h is given by

$$h = \int_{\mathfrak{P}} \|dP A_I dP\|_1 = \inf \sum \| (P_i - P_{i-1}) A_I (P_i - P_{i-1}) \|_1,$$

where the norm is the \dagger -trace norm and the infimum is taken over all finite partitions P_i of a maximal eigenchain \mathfrak{P} for A . We refer for further details and applications to the books by Gokhberg and Krein [9, 10].

I. Fredholm Operators and Essential Spectra of Operators

Throughout Sections I and J we assume that X is a separable infinite-dimensional complex Hilbert space, and we consider only bounded linear operators in X . The set $\mathbf{B}^{(c)}(X)$ of all \dagger -compact linear operators in X is a \dagger -maximal two-sided ideal of the \dagger - C^* -algebra $\mathbf{B}(X)$ of all bounded linear operators. The simple quotient C^* -algebra $\mathbf{A}(X) = \mathbf{B}(X)/\mathbf{B}^{(c)}(X)$ is called the **Calkin algebra**. We denote the quotient mapping by $\pi: \mathbf{B}(X) \rightarrow \mathbf{A}(X)$. Then an operator $A \in \mathbf{B}(X)$ is a \dagger -Fredholm operator if and only if its image $\pi(A)$ is an invertible element of $\mathbf{A}(X)$. Let $\mathbf{F}(X)$ be the set of all Fredholm operators in X , and let $\mathbf{F}_n(X)$, $n \in \mathbf{Z}$, be its subset of all operators of \dagger -index n . $\mathbf{F}_n(X)$ is a connected set in $\mathbf{B}(X)$, and in particular, $\mathbf{F}_0(X)$ is the inverse image of the connected component of the identity in the multiplicative topological group $\pi(\mathbf{F}(X))$ of all invertible elements in $\mathbf{A}(X)$. The index gives the group isomorphisms $\mathbf{F}(X)/\mathbf{F}_0(X) \cong \pi(\mathbf{F}(X))/\pi(\mathbf{F}_0(X)) \cong \mathbf{Z}$. More generally, we have for any compact topological space Y the group isomorphisms $[Y, \mathbf{F}(X)] \cong [Y, \pi(\mathbf{F}(X))] \cong K(Y)$ of the groups of \dagger -homotopy classes of continuous mappings and the K -group in the \dagger - K -theory (M. F. Atiyah [12]).

If N is a \dagger -normal operator, its **essential spectrum** $\sigma_e(N)$ is defined to be the set of all $\lambda \in \sigma(N)$ that is not an isolated eigenvalue of finite multiplicity. Let H_1 and H_2 be self-adjoint operators. Then $\sigma_e(H_1) = \sigma_e(H_2)$ if and

only if $U^*H_1U = H_2 + K$ for a unitary operator U and a compact operator K (Weyl-von Neumann theorem).

I. D. Berg and W. Sikonja (1971) extended this result to normal operators N_1 and N_2 . Moreover, for any compact subset Y of \mathbb{C} there exists a normal operator N such that $\sigma_e(N) = Y$. Hence it follows that the essential spectrum $\sigma_e(N)$ of a normal operator N coincides with the \dagger spectrum $\sigma(\pi(N))$ of the image in $\mathbf{A}(X)$. Thus we define the **essential spectrum** $\sigma_e(A)$ of an arbitrary operator A to be the spectrum $\sigma(\pi(A))$ in $\mathbf{A}(X)$. An operator $A \in \mathbf{B}(X)$ is said to be **essentially normal** (resp. **essentially self-adjoint**, **essentially unitary**) if $\pi(A)$ is normal (resp. self-adjoint, unitary) in $\mathbf{A}(X)$. (Note that this definition of essentially self-adjoint operators is completely different from that in 251 Linear Operators E.) Since an essentially self-adjoint operator is the sum of a self-adjoint operator and a compact operator, the Weyl-von Neumann theorem classifies essentially self-adjoint operators up to \dagger unitary equivalence modulo $\mathbf{B}^{(c)}(X)$. An operator A is essentially normal if and only if the commutator $[A, A^*]$ is compact, but it need not be the sum of a normal operator and a compact operator. For example, let V be the **unilateral shift operator** that maps the orthonormal basis e_i of X into e_{i+1} for every $i = 1, 2, \dots$. Then V is essentially unitary, but it cannot be written as the sum of a normal operator and a compact operator. The essential spectrum $\sigma_e(V)$ is the unit circle, whereas the spectrum $\sigma(V)$ is the unit disk and $\text{ind}(V - \lambda) = -1$ for $|\lambda| < 1$.

J. The Brown-Douglas-Fillmore (BDF) Theory

The following is the main theorem for essentially normal operators, due to L. G. Brown, R. G. Douglas, and P. A. Fillmore [14]. Let A_1 and A_2 be essentially normal operators. There are a unitary operator U and a compact operator K such that $U^*A_1U = A_2 + K$ if and only if $\sigma_e(A_1) = \sigma_e(A_2)$ and $\text{ind}(A_1 - \lambda) = \text{ind}(A_2 - \lambda)$ for every λ in the complement of the essential spectrum. An essentially normal operator A is the sum of a normal operator and a compact operator if and only if $\text{ind}(A - \lambda) = 0$ for every λ in the complement of $\sigma_e(A)$.

To prove this and many other facts, they developed the theory of extension of $\mathbf{B}^{(c)}(X)$ by the C^* -algebra $C(Y)$ of continuous complex-valued functions on a compact metrizable space Y [14–16]. This revealed deep relations between the theory of operator algebras on Hilbert spaces (\rightarrow 36 Banach Algebras, 308 Operator Algebras) and algebraic topology (in particular, K -theory; \rightarrow 237 K -Theory). Extension theory also gives a natural setting for the \dagger index theory of elliptic differential operators due to Atiyah and I. M. Singer [13, 16].

An **extension** of $\mathbf{B}^{(c)}(X)$ by $C(Y)$ is a \dagger short exact sequence

$$0 \rightarrow \mathbf{B}^{(c)}(X) \xrightarrow{\varphi} E \xrightarrow{\psi} C(Y) \rightarrow 0 \tag{11}$$

of a C^* -subalgebra E of $\mathbf{B}(X)$ and $\dagger*$ -homomorphisms, i.e., E is a C^* -subalgebra of $\mathbf{B}(X)$ containing the identity I and including $\mathbf{B}^{(c)}(X)$ as a C^* -subalgebra, and φ is a $*$ -homomorphism onto $C(Y)$ whose kernel is equal to $\mathbf{B}^{(c)}(X)$. Or equivalently, an extension is a unital (identity preserving) $*$ -monomorphism $\tau: C(Y) \rightarrow \mathbf{A}(X)$ defined by $\tau = \pi \circ \varphi^{-1}$. (For general extension of C^* -algebras \rightarrow 36 Banach Algebras.) Two extensions (E_1, φ_1) and (E_2, φ_2) (or τ_1 and τ_2) are said to be equivalent if there exists a $*$ -isomorphism $\psi: E_1 \rightarrow E_2$ such that $\varphi_2 \circ \psi = \varphi_1$ (or equivalently there exists a unitary operator U such that $\pi(U^*)\tau_1(f)\pi(U) = \tau_2(f)$ for every $f \in C(Y)$). We denote by $\text{Ext}(Y)$ the set of all equivalence classes of extensions of $\mathbf{B}^{(c)}(X)$ by $C(Y)$.

Let A be an essentially normal operator in X with the essential spectrum $\sigma_e(A) = Y$. Then the C^* -algebra E_A generated by $\mathbf{B}^{(c)}(X)$, A and the identity I , and the $*$ -homomorphism φ_A of E_A onto $C(Y)$ which sends A to the function $\chi(z) = z$ define an extension (E_A, φ_A) . It is easy to see that two essentially normal operators A_1 and A_2 are unitarily equivalent modulo $\mathbf{B}^{(c)}(X)$ if and only if $\sigma_e(A_1) = \sigma_e(A_2)$ and the extensions (E_{A_1}, φ_{A_1}) and (E_{A_2}, φ_{A_2}) are equivalent. Conversely, if Y is a compact subset of \mathbb{C} and (11) is an extension, then (E, φ) is equivalent to (E_A, φ_A) , where A is an essentially normal operator in E such that $\varphi(A) = \chi$.

Extensions of $\mathbf{B}^{(c)}(X)$ by $C(Y)$ appear also in different parts of analysis. Let X be the Hilbert space $L_2(M)$ on a compact differentiable manifold M relative to a fixed smooth measure and let E be the C^* -subalgebra of $\mathbf{B}(X)$ generated by all zeroth-order \dagger pseudodifferential operators together with $\mathbf{B}^{(c)}(X)$. Then E and the \dagger symbol mapping $\varphi: E \rightarrow C(S^*(M))$ define an extension of $\mathbf{B}^{(c)}(X)$ by $C(S^*(M))$, where $S^*(M)$ is the \dagger cosphere bundle of M . This extension is closely related to the \dagger Atiyah-Singer index theorem. Let Ω be a \dagger strongly pseudoconvex domain in \mathbb{C}^n . Then the C^* -algebra generated by \dagger Toeplitz operators with continuous symbol gives rise to an extension of $\mathbf{B}^{(c)}(H_2(\partial\Omega))$ by $C(\partial\Omega)$.

Let τ_1 and τ_2 be $*$ -monomorphisms from $C(Y)$ into $\mathbf{A}(X)$ and $a_1 = [\tau_1]$ and $a_2 = [\tau_2]$ be corresponding elements in $\text{Ext}(Y)$. Then the sum $a_1 + a_2 \in \text{Ext}(Y)$ is defined to be the equivalence class of $\tau: C(Y) \rightarrow \mathbf{A}(X)$ which sends f to $\tau_1(f) \oplus \tau_2(f) \in \mathbf{A}(X) \oplus \mathbf{A}(X) \subset \mathbf{A}(X \oplus X) \cong \mathbf{A}(X)$. It does not depend on the

choice of τ_1, τ_2 and the unitary $X \oplus X \cong X$. An extension $\tau: C(Y) \rightarrow A(X)$ is said to be **trivial** if there exists a unital $*$ -monomorphism $\sigma: C(Y) \rightarrow B(X)$ such that $\tau = \pi \circ \sigma$. For each compact metrizable space Y there exists a unique equivalence class of trivial extensions in $\text{Ext}(Y)$. $\text{Ext}(Y)$ is an Abelian group in which the class of trivial extensions is the identity element. The extension (E_A, φ_A) for an essentially normal operator A is trivial if and only if $A = N + K$ with N normal and K compact. Hence follows the Weyl-von Neumann-Berg-Sikonia theorem. The BDF theorem for essentially normal operators is proved by the pairing $\text{Ext}(Y) \times K^1(Y) \rightarrow \mathbf{Z}$ defined by the index, where $K^1(Y) = \tilde{K}(SY^+) = \lim_{n \rightarrow \infty} [Y, GL(n, \mathbf{C})]$ (\rightarrow 237 *K-Theory*; [13]). The induced homomorphism $\gamma_\infty: \text{Ext}(Y) \rightarrow \text{Hom}(K^1(Y), \mathbf{Z})$ is always surjective, and it is an isomorphism for $Y \subset \mathbf{R}^3$ or $Y = S^n$ but not for $Y \subset \mathbf{R}^4$.

Ext is a \dagger covariant functor from the category of compact metrizable spaces to the category of Abelian groups. It is \dagger homotopy invariant. Define for $n = 0, 1, \dots$ the group $\text{Ext}_{1 \rightarrow n}(Y)$ by $\text{Ext}(S^n Y)$, where $S^n Y$ is the n -fold \dagger suspension. Then we have the **periodicity** $\text{Ext}_{n+2}(Y) \cong \text{Ext}_n(Y)$. Moreover, for each pair of compact metrizable spaces $Y \supset Z$ we have the long exact sequence

$$\text{Ext}_n(Z) \xrightarrow{i_*} \text{Ext}_n(Y) \xrightarrow{p_*} \text{Ext}_n(Y/Z) \xrightarrow{\partial} \text{Ext}_{n-1}(Z) \xrightarrow{i_*} \dots,$$

where Y/Z is the space obtained from Y by collapsing Z to a point and ∂ is $q_* r_*^{-1}$: $\text{Ext}_n(Y/Z) \rightarrow \text{Ext}_n(SZ)$ defined by $q: Y \cup CZ \rightarrow (Y \cup CZ)/Y = SZ$ and $r: Y \cup CZ \rightarrow (Y \cup CZ)/CZ = Y/Z$, CZ being the \dagger cone over Z . Ext_* satisfies the \dagger Eilenberg-Steenrod axioms for homology theory except for the dimension axiom, which is replaced by $\text{Ext}_n(S^0) = \text{Ext}(S^{n-1}) = \mathbf{Z}$ for n even and $= 0$ for n odd.

The von Neumann algebra $\mathbf{B}(X)$ is classified as a \dagger factor of type I_∞ . In the case of a factor M of type II_∞ another index theory has been developed by H. Breuer [17] and others replacing $\mathbf{B}^{(c)}(X)$ by the closed ideal of M generated by finite projections and using the \dagger semifinite trace on M for the dimensions of kernels and cokernels of operators in M .

K. Spectral Analysis in Banach Spaces

Spectral analysis becomes rather involved for general operators in a Banach space as well as for nonnormal operators in Hilbert space.

For a \dagger compact operator A , the nature of the spectrum $\sigma(A)$ and the structure of A in the root subspace associated with a nonzero eigenvalue are well known (\rightarrow 68 *Compact and*

390 Ref. Spectral Analysis of Operators

Nuclear Operators). However, a full spectral analysis may not be possible without further assumptions.

For a \dagger closed operator with nonempty resolvent set $\rho(A)$, an \dagger operational calculus can be developed by means of a function-theoretic method based on the fact that the resolvent $R_\lambda = (\lambda I - A)^{-1}$ is a $\mathbf{B}(X)$ -valued holomorphic function of λ in $\rho(A)$. In particular, the \dagger spectral mapping theorem holds (\rightarrow 251 *Linear Operators G*).

A general class of operators having associated spectral resolution was introduced by N. Dunford. Let X be a Banach space. An operator $E \in \mathbf{B}(X)$ is called a projection if $E^2 = E$. As before we can define a (projection-valued countably additive) **spectral measure** on \mathcal{B}_c . An operator $A \in \mathbf{B}(X)$ is said to be a **spectral operator** if there exists a **spectral measure** E on \mathcal{B}_c satisfying the following properties: (i) $E(M)A = AE(M)$, $M \in \mathcal{B}_c$; (ii) $\sigma(A|_{E(M)X}) \subset \bar{M}$, $M \in \mathcal{B}_c$, where $A|_Y$ is the restriction of A to Y and \bar{M} is the closure of M ; (iii) there exists a $k \geq 0$ such that $\|E(M)\| \leq k$ for all $M \in \mathcal{B}_c$. E is unique. A spectral operator A is expressed as $A = S + N$, where $S = \int_C z E(dz)$ and N is \dagger quasinilpotent. A is said to be a **scalar operator** if $N = 0$. Unbounded spectral operators are defined similarly, with (i') $E(M)A \subset AE(M)$ in place of (i). However, for unbounded spectral operators A we no longer have the decomposition $A = S + N$. (For more details about spectral operators \rightarrow [3]. For other topics related to the material discussed in this section \rightarrow 68 *Compact and Nuclear Operators*; 251 *Linear Operators*; and 287 *Numerical Computation of Eigenvalues*.)

391 (VII.21) Spectral Geometry

A. General Remarks

Let E^3 be a Euclidean 3-space with a standard coordinate system (x_1, x_2, x_3) and E^2 be the $x_1 x_2$ -plane. Consider a domain D in E^2 as a vibrating membrane with the fixed boundary ∂D . Then the height $x_3 = F(x_1, x_2, t)$ obeys the differential equation of hyperbolic type, $\partial^2 F(x_1, x_2, t)/\partial t^2 = c^2 \Delta F(x_1, x_2, t)$, where $\Delta = \partial^2/\partial x_1^2 + \partial^2/\partial x_2^2$ denotes the \dagger Laplacian in E^2 and c is a constant (we put $c = 1$ in the following). For solutions of the form $F(x_1, x_2, t) = U(x_1, x_2)V(t)$, U is a solution of the \dagger Dirichlet problem in $D \subset E^2$; $\Delta U + \lambda U = 0$, where λ is a positive constant called an \dagger eigenvalue of Δ . Solutions of the form $F(x_1, x_2, t) = U(x_1, x_2)\sin\sqrt{\lambda}t$ represent the pure tones that the membrane produces as normal modes. That is, the shape of D is related to the possible sounds or vibrations (i.e., to the eigenvalues of Δ) through the Dirichlet problem.

The set of eigenvalues of Δ is called the **spectrum of D** and is denoted by $\text{Spec}(D)$. There arises the question of how much information $\text{Spec}(D)$ can impart about the geometric properties (i.e., the shape, extent, and connectedness) of D . Generally, **spectral geometry** is the study of the relations between the spectrum of domains D of \dagger Riemannian manifolds or compact Riemannian manifolds (M, g) and the geometric properties of D or (M, g) .

B. Spectra

Let $\mathcal{D}^p(M)$ denote the space of smooth $\dagger p$ -forms on a compact m -dimensional C^∞ -Riemannian manifold (M, g) . Then eigenvalues of the \dagger Laplacian (Laplace-Beltrami operator) Δ acting on $\mathcal{D}^p(M)$ are discretely distributed in $[0, \infty)$, and each multiplicity is finite (\rightarrow 68 Compact and Nuclear Operators, 323 Partial Differential Equations of Elliptic Type). The **spectrum for p -forms** $\text{Spec}^p(M, g)$ is $\{\lambda_{p,1} \leq \lambda_{p,2} \leq \dots\}$, where each eigenvalue is repeated as many times as its multiplicity indicates. If 0 is an eigenvalue, its multiplicity is equal to the p th \dagger Betti number of M .

In the following, mainly the case $p = 0$ is explained. $\text{Spec}^0(M, g)$ is denoted by $\text{Spec}(M, g)$. 0 is always in $\text{Spec}(M, g)$ and its multiplicity is 1. So we put $\lambda_0 = 0$, and λ_1 is the first nonzero eigenvalue. A geometric meaning of Δf at x for a function f is as follows: If $\{\gamma_h\}_{h=1}^m$ are m geodesics mutually orthogonal at x and parametrized by arc length, then $(\Delta f)(x) = \sum_h (f \circ \gamma_h)''(0)$.

Let $\{\varphi_i\}_{i=0}^\infty$ be an orthonormal basis of $\mathcal{D}^0(M)$ consisting of eigenfunctions: $\Delta\varphi_i + \lambda_i\varphi_i = 0$, $\langle\varphi_i, \varphi_j\rangle = \int_M \varphi_i\varphi_j = \delta_{ij}$. Then the \dagger fundamental solution $E(x, y, t)$ of the heat equation $\Delta - \partial/\partial t = 0$ is given by $E(x, y, t) = \sum_i e^{-\lambda_i t} \varphi_i(x) \otimes \varphi_i(y)$ as a function on $M \times M \times (0, \infty)$. We put $Z(t) = \int_M E(x, x, t) = \sum_i e^{-\lambda_i t}$. $Z(t)$ and $\text{Spec}(M, g)$ are equivalent. The Minakshisundaram-Pleijel **asymptotic expansion of $Z(t)$** ,

$$Z(t) \sim (1/4\pi t)^{m/2} (a_0 + a_1 t + a_2 t^2 + \dots), \quad t \downarrow 0,$$

is the bridge connecting $\text{Spec}(M, g)$ and geometric properties of (M, g) , because a_0, a_1, \dots can be expressed as the integrals of functions over M defined by $g = (g_{ij})$, the components R_{jki}^i of the \dagger Riemannian curvature tensor, and their derivatives of finite order [1]. a_0 is the volume of (M, g) and $a_1 = (1/6) \int_M S$, where S is the \dagger scalar curvature. a_2 was calculated by H. P. McKean, I. M. Singer, and M. Berger, and a_3 by T. Sakai.

Let D be a bounded domain in E^2 or, more generally, a bounded domain in a Riemannian manifold, and assume that the boundary ∂D is piecewise smooth. For smooth functions which

take the value 0 on ∂D , eigenvalues of the Laplacian Δ are discretely distributed in $(0, \infty)$, and each multiplicity is finite. We denote the spectrum of D by $\text{Spec}(D) = \{\lambda_1 < \lambda_2 \leq \dots\}$. The multiplicity of λ_1 is 1, and an eigenfunction f corresponding to λ_1 takes the same sign in D . The behavior of $Z(t) = \sum_i e^{-\lambda_i t}$ for D is different from that for (M, g) since $Z(t)$ reflects the geometric situation of ∂D in this case.

(M, g) and (N, h) , or D_1 and D_2 are called **isospectral** if they have the same spectra.

Examples for which the spectrum is explicitly calculable are as follows: spheres $(S^m, g_0 = \text{canonical})$, real projective spaces (RP^m, g_0) , complex projective spaces (CP^n, J_0, g_0) , $(S^{2n+1}, g_s = \text{suitably deformed from } g_0)$, flat tori, (and for domains D) unit disks, rectangles, equilateral triangles, etc.

C. Congruence and Characterization

Let D_1 and D_2 be bounded domains in E^2 . An open question is whether isospectral D_1, D_2 are congruent. Concerning this, there is M. Kac's paper with the famous title "Can one hear the shape of a drum?" Let D be a bounded domain in E^2 with smooth boundary ∂D . If D has r holes, then

$$Z(t) \sim A(D)/4\pi t - L(\partial D)/4\sqrt{4\pi t + (1-r)/12}, \quad t \downarrow 0,$$

holds (A. Pleijel, Kac, P. McKean, I. M. Singer; \rightarrow [7]), where $A(D)$ denotes the area of D and $L(\partial D)$ denotes the length of ∂D . This theorem implies that the area, the length of ∂D , and the number of holes are determined by $\text{Spec}(D)$. In particular, if D_2 is a unit disk, $\text{Spec}(D_1) = \text{Spec}(D_2)$ implies that D_1 and D_2 are congruent. There are some other results on $Z(t)$ for domains D of surfaces in E^m or for domains D in Riemannian manifolds (M, g) .

Two isometric $(M, g), (N, h)$ are isospectral. Concerning the question of whether isospectral $(M, g), (N, h)$ are isometric, there are some counterexamples. The first is the case of two flat tori T^{16} , given by J. Milnor. Examples with nonflat metrics were given by N. Ejiri using warped products and by M. F. Vigneras for surfaces of constant negative curvature. In those examples, M and N are homeomorphic. A. Ikeda showed that there are lens spaces that are isospectral but not homotopy equivalent.

Examples of affirmative cases are as follows: $\text{Spec}(M, g) = \text{Spec}(S^m, g_0), m \leq 6$, implies that (M, g) is isometric to (S^m, g_0) (M. Berger, S. Tanno). The result is the same for $(RP^m, g_0), m \leq 6$. For $n \leq 6, (CP^n, J_0, g_0)$ is characterized by a spectrum among \ast Kählerian manifolds (M, J, g) .

The number of nonisometric flat tori (or more generally, compact flat Riemannian manifolds) with the same spectrum is finite (M. Kneser, T. Sunada).

If one considers spectra for two types of forms, then the situation turns out to be simpler. For example, if $\text{Spec}^p(M, g) = \text{Spec}^p(N, h)$ for $p = 0, 1$, then (M, g) is of constant curvature K if and only if (N, h) is also and $K' = K$ (V. K. Patodi [9]).

D. The First Eigenvalue

The first eigenvalue λ_1 for (M, g) or for a domain D in (M, g) reflects the geometric situation of (M, g) or D . A lower bound of λ_1 given by J. Cheeger is $\lambda_1 \geq h(M)^2/4$, where $h(M)$ is the **isoperimetric constant**, defined by

$$h(M) = \inf\{\text{vol}(S)/\min[\text{vol}(M_1), \text{vol}(M_2)]\},$$

where the inf is taken over all smoothly embedded hypersurfaces S dividing M into two open submanifolds $M_1, M_2, \partial M_1 = \partial M_2 = S$, and vol means the volume. $1/4$ is the best possible estimate.

Let ρ denote the maximum radius of a disk included in a simply connected $D \subset E^2$. Then $\lambda_1 \geq 1/(4\rho^2)$ (W. K. Hayman, R. Osserman).

If (M, g) has Ricci curvature $\geq k > 0$, then $\lambda_1 \geq mk/(m-1)$ holds, and the equality holds if and only if (M, g) is isometric to $(S^m, (1/k)g_0)$ (A. Lichnerowicz, M. Obata). λ_1 can also be estimated from k and the diameter $d(M)$ of M (P. Li, S. T. Yau).

To obtain upper bounds of λ_1 the **minimum principle of λ_1** is useful. We state it only for (M, g) :

$$\lambda_1 = \inf\left\{\frac{\int_M (\nabla f, \nabla f)}{\int_M f^2}\right\},$$

where inf is taken over all piecewise smooth functions f satisfying $\int_M f = 0, f \neq 0$, and $(\ , \)$ denotes the local inner product with respect to g . An upper bound of λ_1 for (M, g) of nonnegative curvature is $\lambda_1 \leq c(m)/d(M)^2$, where $c(m)$ is some constant depending on m (Cheeger).

For (M, g) or D a submanifold of another Riemannian manifold, there exist some estimates of λ_1 in terms of second fundamental forms, etc.

$\lambda_1 \geq j^2/(A(D))$ holds for $D \subset E^2$, and the equality holds if and only if ∂D is a circle (C. Faber, E. Krahn), where j denotes the first zero of the \ast Bessel function J_0 . This estimate is generalized in many directions; for example, for $D \subset (M^2, g)$ in terms of the integral of the Gauss curvature, etc. It is very useful to note that the estimate of λ_1 for D is deeply related to the isoperimetric inequality (\rightarrow 228 Isoperimetric Problems).

E. Hersch Type Theorem

With respect to the first eigenvalue $\lambda_1(g)$ and the volume $\text{Vol}(M, g)$ of (M, g) , $\lambda_1(g) \cdot \text{vol}(M, g)^{2/m}$ is invariant under a change of metric $g \rightarrow c^2g$ (c is a constant). **Hersch's problem** is stated as follows: Is there a constant $k(M)$ depending on M so that for any Riemannian metric g on M , $\lambda_1(g) \cdot \text{vol}(M, g)^{2/m} \leq k(M)$? J. Hersch proved this for a 2-sphere $M = S^2$ with $k(S^2) = 8\pi$, and in this case the equality holds if and only if g is proportional to the canonical metric g_0 .

The Hersch type theorem holds for an oriented Riemann surface M of genus q with $k(M) = 8\pi(q + 1)$ (P. C. Yang, S. T. Yau). There is no such constant $k(S^m)$ for an m -sphere S^m , $m \geq 3$ (H. Urakawa, H. Muto, S. Tanno).

F. The Multiplicity of λ_i

By a theorem of K. Uhlenbeck each eigenvalue for a Riemannian manifold (M, g) is simple. However, for (S^m, g_0) the first eigenvalue λ_1 is m and its multiplicity is $m + 1$. Furthermore, for some g_s deformed from g_0 , $\lambda_1(g_s)$ of (S^{2n+1}, g_s) has multiplicity $n^2 + 4n + 2$, which is larger than $m + 1$ ($= 2n + 2$).

The multiplicity $m(\lambda_i)$ of the i th eigenvalue λ_i for a Riemann surface of genus q satisfies $m(\lambda_i) \leq 4q + 2i + 1$ (S. Y. Cheng, G. Besson).

G. k th Eigenvalue

The **minimum principle** for λ_k of $\text{Spec}(M, g)$ is stated as follows: Let f_i be an eigenfunction corresponding to λ_i , $0 \leq i \leq k - 1$. Define H_{k-1} to be the set of piecewise smooth functions $f \neq 0$ orthogonal to each f_i , i.e., $\int_M f f_i = 0$. Then

$$\lambda_k = \inf \left\{ \int_M (\nabla f, \nabla f) / \int_M f^2 \right\},$$

where \inf is taken over $f \in H_{k-1}$. We have the **minimax principle** for λ_k of the first and second type. We state the second type only:

$$\lambda_k = \inf_{L_{k+1}} \sup_{0 \neq f \in L_{k+1}} \left\{ \int_M (\nabla f, \nabla f) / \int_M f^2 \right\},$$

where L_k denotes a k -dimensional linear subspace of $\mathcal{D}^0(M)$. From this, for 1-parameter metrics g_u ($a < u < b$) on M , the continuity of $\lambda_k(g_u)$ with respect to u follows.

H. Courant-Cheng Nodal Domain Theorem

Let f be an eigenfunction on (M, g) or D . The set of all zero points of f is called the **nodal set** of f (or the **nodal curve** of f if $m = 2$). Each connected component of the complement of

the nodal set in (M, g) or D is called a **nodal domain** of f . The nodal set of f is a smooth submanifold of (M, g) or D except for a set of lower dimension. The number of nodal domains of an eigenfunction corresponding to the i th eigenvalue is $\leq i + 1$ for (M, g) and $\leq i$ for D (**Courant-Cheng nodal domain theorem**).

I. Estimate of $N(\lambda)$

$N(\lambda)$ is defined as the number of eigenvalues of (M, g) or D which are less than or equal to λ . For $D \subset E^2$, H. A. Lorentz conjectured that the behavior of $N(\lambda)$ for $\lambda \rightarrow \infty$ does not depend on the shape of D but only on the area $A(D)$ of D , i.e., $\lim_{\lambda \rightarrow \infty} N(\lambda)/\lambda = A(D)/4\pi$. This was proved by H. Weyl. Generally, for D or (M, g) , the behavior of $N(\lambda)$ for $\lambda \rightarrow \infty$ is $\text{vol}(D)\lambda^{m/2} / (4\pi)^{m/2} \Gamma(m/2 + 1)$, and this is related to the first term $\text{vol}(D)/(4\pi t)^{m/2}$ of the asymptotic expansion of $Z(t)$ by \dagger Tauberian and \dagger Abelian theorems.

J. $\text{Spec}(M, g)$ and Geodesics

Let $T^m = E^m/\Gamma$ be a flat torus, Γ being the lattice for T^m . Let Γ^* be the lattice dual to Γ . Then **Poisson's formula**,

$$\sum_{y \in \Gamma^*} e^{-4\pi^2|y|^2 t} = (\text{vol}(T^m)/(4\pi t)^{m/2}) \sum_{x \in \Gamma} e^{-|x|^2/4t},$$

gives a clear relation between $\text{Spec}(T^m) = \{4\pi^2|y|^2, y \in \Gamma^*\}$ and the set $\{|x|, x \in \Gamma\}$ of lengths of closed geodesics on T^m .

If (M, g) satisfies some conditions, then $\text{Spec}(M, g)$ determines the set of lengths of periodic geodesics (Y. Colin de Verdiere), and the spectrum characterizes those Riemannian manifolds whose geodesics are all periodic (J. J. Duistermaat, V. W. Guillemin).

K. $\text{Spec}^p(M, g)$ and the Euler-Poincaré Characteristic

Let (M, g) be oriented and even dimensional. Let $E^p(x, y, t)$ be the \dagger fundamental solution of the \dagger heat equation for p -forms. Corresponding to $Z(t)$ for $\text{Spec}(M, g)$, we get $Z^p(t) = \int_M E^p = \sum_i e^{-\lambda_{p,i} t}$. Then

$$\sum_{p=0}^m (-1)^p Z^p(t) = \sum_{p=0}^m (-1)^p \int_M \text{tr } E^p = \chi(M),$$

where $\chi(M)$ denotes the \dagger Euler-Poincaré characteristic of M (McKean, Singer). On the other hand, the \dagger Gauss-Bonnet theorem is $\chi(M) = \int_M C$, where C is a function on M expressed as a homogeneous polynomial of components of the Riemannian curvature tensor. Then

Patodi proved

$$\sum_{p=0}^m (-1)^p \text{tr } E^p = C + O(t), \quad t \downarrow 0.$$

L. η -Function

Let (X, g) be a compact oriented $4k$ -dimensional Riemannian manifold with boundary $\partial X = Y$ and assume that some neighborhood of Y in (X, g) is isometric to a Riemannian product $Y \times [0, \epsilon]$. Define an operator B acting on forms of even degree on Y by

$$Bw = (-1)^{k+r+1} (*d - d*)w, \quad w \in \mathcal{D}^{2r}(Y),$$

where $*$ denotes the \dagger Hodge star operator and d denotes exterior differentiation on Y . Then $B^2 = \Delta$ holds. Using the spectrum $\{\mu\}$ of B , we define the η -function by

$$\eta(s) = \sum_{\mu \neq 0} (\text{sgn } \mu) |\mu|^{-s}.$$

$\eta(s)$ is a spectral invariant, and

$$\text{sgn}(X) = \int_X L_k(p_1, \dots, p_k) - \eta(0)$$

holds (Atiyah, Patodi, and Singer [2]), where $\text{sgn}(X)$ is the \dagger signature of the quadratic form defined by the \dagger cup product on the image of $H^{2k}(X, Y)$ in $H^{2k}(X)$, L_k is the k th \dagger Hirzebruch L -polynomial, and p_1, \dots, p_k are the Pontryagin forms of (X, g) .

M. Analytic Torsion

Let χ be a representation of the fundamental group $\pi_1(M)$ of (M, g) by the orthogonal group and E_χ be the associated vector bundle. Let Δ^χ be the Laplacian acting on E_χ -valued p -forms on M and $\{\lambda_{p,i}^\chi\}$ be its spectrum. Then

$$\log T(M, \chi) = \sum_{p=0}^m (-1)^p p \log \frac{d}{ds} \left(\sum_i (\lambda_{p,i}^\chi)^{-s} \right) \Big|_{s=0}$$

is independent of the choice of g . $T(M, \chi)$ is called the **analytic torsion** of M . $T(M, \chi)$ is equal to the $\dagger R$ -torsion $\tau(M, \chi)$ (W. Müller, Cheeger).

N. Concluding Remarks

An \dagger isometry ψ of (M, g) commutes with the Laplacian and induces a linear transformation $\psi_\lambda^\#$ of each eigenspace V_λ . Using the asymptotic expansion of $\sum \text{tr}(\psi_\lambda^\#) e^{-\lambda t}$, the Atiyah-Singer $\dagger G$ -signature theorem has been proved (H. Donnelly, Patodi).

The Atiyah-Singer \dagger index theorem has been proved by using Gilkey's theory and the heat equation (Atiyah, R. Bott, Patodi).

Let (N, h) be a complete Riemannian manifold of negative curvature. Then Δ is extended

to an unbounded self-adjoint operator for $L_2(N)$. Generally Δ has a continuous spectrum. Some conditions for (N, h) to have pure point spectrum were given in terms of curvature (Donnelly, P. Li).

If D is a minimal submanifold of another Riemannian manifold, estimates of λ_1 are related to the stability of D (\rightarrow 275 Minimal Submanifolds).

On the nonexistence of the 1-parameter isospectral deformation $(M, g_0) \rightarrow (M, g_t)$, there are results for (i) $m = 2$ and g_0 of negative curvature, $m \geq 3$ and negatively pinched g_0 (V. Guillemin, D. Kazhdan); (ii) flat metrics g_0 (R. Kuwabara); and (iii) g_0 of constant positive curvature (Tanno).

As for spectral geometry for complex Laplacian on Hermitian manifolds, there are results by P. Gilkey, Tsukada, and others.

**392 (XX.5)
Spherical Astronomy**

Spherical astronomy is concerned with the apparent positions of celestial bodies and their

motions on a celestial sphere with center at an observer on the Earth, while celestial mechanics is concerned with computing heliocentric true positions of planets and comets and geocentric true positions of satellites. The purpose of spherical astronomy is to find all possible causes of displacement of the apparent positions of celestial bodies on the celestial sphere from their geocentric positions and to study their effects. Atmospheric refraction, geocentric parallax, aberration, annual parallax, precession, nutation, and proper motion are examples of these causes.

When light from a celestial body passes through the Earth's atmosphere, it is refracted since air densities at different heights are different. This phenomenon is called **atmospheric refraction**. The effect of refraction on the apparent direction of the celestial body is a minimum when the body is at its culmination, and vanishes when this coincides with the observer's zenith, while the maximum refraction of 34.5 occurs when the body is at the horizon.

Topocentric positions differ appreciably from geocentric positions for the Moon and planets, since their geocentric distances are not large compared with the radius of the Earth. The difference is largest when the observer is on the equator and the celestial body is at the horizon, and this largest value is called the **geocentric parallax**. The geocentric parallax of the Moon is between 53.9 and 60.2; those of the Sun, Mercury, Venus, Mars, Jupiter, and Saturn are, respectively, 8".64–8".94, 6"–16".5, 5"–32", 3".5–23".5, 1".4–2".1, and 0".8–1".1. For fixed stars geocentric parallaxes can be regarded as zero since the stars are far from the Earth.

The Earth moves in an orbit around the Sun with period of one year (365.2564 days) and rotates around the polar axis, which is inclined at 66.5 to the orbital plane (the **ecliptic**), with period of one day (23 hours, 56 minutes, 4.091 seconds). Therefore the observer on the Earth moves with a speed depending on the latitude (0.465 km/sec on the equator) due to the rotation and moves with an average speed of 29.785 km/sec on the ecliptic. Due to these motions of the observer, apparent directions of celestial bodies are displaced from their geometric directions. Displacement due to the rotation is called **diurnal aberration**, and that due to the orbital motion, **annual aberration**. The effect of diurnal aberration is between 0" and 0".32 and varies with a period of one day, while that of the annual aberration is between 0" and 20".496 and varies with a period of one year. Moreover, to compute the positions of celestial bodies, the travel time of light to the observer should be taken into account.

Annual parallax for a fixed star is half the difference of its apparent directions, which are measured at the ends of a diameter perpendicular to the direction of the star from the orbit of the Earth. The effect of the annual parallax varies with a period of one year. However, except for nearby stars, it is not necessary to take this effect into account when computing apparent positions.

The pole of the Earth on the celestial sphere moves on a circle around the pole of the ecliptic due to the gravitational attraction of the Moon, Sun, and planets, and therefore the equinox moves clockwise on the ecliptic. Because the resultant of the attractive force of the Moon, Sun, and planets changes periodically, the motion of the equinox is not uniform. Therefore the motion is expressed as the sum of secular motion, called **precession**, and periodic motion, called **nutation**. Since the positions of fixed stars on the celestial sphere are measured with respect to the equator and the equinox, their right ascensions and declinations are continuously changing because of precession and nutation.

Since the stars are not fixed in space but themselves have **proper motions**, their positions on the celestial sphere are continuously changing.

Spherical astronomy also includes predictions of solar and lunar eclipses, the theory of orbit determination to compute apparent positions of celestial bodies in the solar system by use of orbital elements, and the computation of ephemerides for the Sun, Moon, planets, and fixed stars. Practical astronomy, which develops theories and methods of observation by use of meridian circles, transit instruments, zenith telescopes, sextants, theodolites, telescopes with equatorial mountings, and astronomical clocks, and navigational astronomy, which deals with methods for determining the positions of ships and aircraft, are closely connected to spherical astronomy.

It should be noted that recently radar has been used to measure distances to the Moon and planets accurately, a contribution to determining the size of the solar system with precision.

393 (XIV.6) Spherical Functions

A. Spherical Functions

The term *spherical functions* in modern terminology means a certain family of functions on †symmetric Riemannian spaces obtained as simultaneous †eigenfunctions of certain integral operations (→ 437 Unitary Representations). In this article, however, we explain only the classical theory of **Laplace's spherical functions** with respect to the rotation group in 3-dimensional space.

Solutions of †Laplace's equation $\Delta V=0$ that are homogeneous polynomials of degree n with respect to the orthogonal coordinates x, y, z are called **solid harmonics** of degree n . If n is a positive integer, there are $2n+1$ linearly independent solid harmonics of degree n . In †polar coordinates (r, θ, φ) they are of the form $r^n Y_n(\theta, \varphi)$, where $Y_n(\theta, \varphi)$, the **surface harmonic** of degree n , satisfies the differential equation

$$\frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial Y_n}{\partial \theta} \right) + \frac{1}{\sin^2 \theta} \frac{\partial^2 Y_n}{\partial \varphi^2} + n(n+1) Y_n = 0.$$

Here, if we apply †separation of variables to θ and φ and put $z = \cos \theta$, then the component in φ is represented by trigonometric functions, and the other component in θ reduces to a solution of **Legendre's associated differential equation**

$$(1-z^2) \frac{d^2 w}{dz^2} - 2z \frac{dw}{dz} + \left(n(n+1) - \frac{m^2}{1-z^2} \right) w = 0. \quad (1)$$

B. Legendre Functions

With $m=0$ in (1) and n replaced by an arbitrary complex number ν , the equation is reduced to **Legendre's differential equation**

$$(1-z^2) \frac{d^2 w}{dz^2} - 2z \frac{dw}{dz} + \nu(\nu+1)w = 0, \quad (2)$$

whose fundamental solutions are represented by

$$P_\nu(z) = \frac{1}{2\pi i} \oint^{(1+, z+)} \frac{(\zeta^2 - 1)^\nu}{2^\nu (z - \zeta)^{\nu+1}} d\zeta, \quad (3)$$

$$Q_\nu(z) = \frac{1}{4i \sin \nu \pi} \oint^{(1+, -1+)} \frac{(\zeta^2 - 1)^\nu}{2^\nu (z - \zeta)^{\nu+1}} d\zeta, \quad (4)$$

where the contour of integration in (3) is a closed curve with positive direction on the ζ -plane, avoiding the half-line $(-\infty, -1)$, and admitting 1 and z as inner points of the domain it bounds, whereas the contour in (4) is a closed ∞ -shaped curve encircling the point 1 once in the negative direction and the point -1 once in the positive direction. The functions $P_\nu(z)$ and $Q_\nu(z)$ are called **Legendre functions of the first and second kind**, respectively. The integral representation (3) is **Schl\"afli's integral representation**. If $\text{Re}(\nu+1) > 0$, we can deform the contour of integration and obtain

$$Q_\nu(z) = \frac{1}{2^{\nu+1}} \int_{-1}^1 \frac{(1-\zeta^2)^\nu}{(z-\zeta)^{\nu+1}} d\zeta. \quad (5)$$

If ν is an integer, it is convenient to use the representation (5).

From (3)–(5), we can obtain the recurrence formulas for Legendre functions of distinct degrees. The recurrence formulas for $P_\nu(z)$ and $Q_\nu(z)$ have exactly the same form (→ Appendix A, Table 18.II). Expanding the integrand in (3) and (4) with respect to $z-1$ and ζ/z , the following identities are obtained:

$$P_\nu(z) = F\left(\nu+1, -\nu, 1, \frac{1-z}{2}\right), \quad |1-z| < 2,$$

$$Q_\nu(z) = \frac{\sqrt{\pi} \Gamma(\nu+1)}{(2z)^{\nu+1} \Gamma(\nu+3/2)} \times F\left(\frac{\nu+1}{2}, \frac{\nu+2}{2}, \nu+2, \frac{1}{z^2}\right),$$

$|z| > 1, |\arg z| < \pi,$

where $F(\alpha, \beta, \gamma, z)$ is the †hypergeometric function. These expansions are the solutions in series of Legendre's differential equation in the neighborhood of the †regular singular points $z=1$ and ∞ , respectively (→ Appendix A, Table 18.II).

If ν is a positive integer, since $\zeta=1$ is not a †branch point in (3), $P_n(z)$ is represented by **Rodrigues's formula**

$$P_n(z) = \frac{1}{2\pi i} \oint \frac{(\zeta^2 - 1)^n}{2^n (z - \zeta)^{n+1}} d\zeta = \frac{1}{2^n n!} \frac{d^n}{dz^n} (z^2 - 1)^n. \quad (6)$$

In this case, $P_n(z)$ is a polynomial of degree n such that

$$P_n(z) = \sum_{r=0}^{[n/2]} (-1)^r \frac{(2n-2r)!}{2^n r!(n-r)!(n-2r)!} z^{n-2r},$$

$$P_0(z) = 1,$$

which is called the **Legendre polynomial** (Legendre, 1784). The †generating function for the

Legendre polynomials is $(1 - 2\rho \cos \theta + \rho^2)^{-1/2}$, whose expansion with respect to ρ is of the form $\sum_{n=0}^{\infty} P_n(z) \rho^n$, $z = \cos \theta$. Here the †generating function $(1 - 2\rho \cos \theta + \rho^2)^{-1/2}$ is the inverse of the distance between two points (ρ, θ) and $(1, 0)$ in polar coordinates. Hence $P_n(z)$ is also called the **Legendre coefficient**. If z is real, $\{((2n + 1)/2)^{1/2} P_n(z)\}_{n=0}^{\infty}$ constitutes an orthonormal system on $[-1, 1]$ (\rightarrow 317 Orthogonal Functions). The n zeros of $P_n(z)$ are all real, simple, and lie in $(-1, 1)$. For sufficiently large n , we have

$$P_n(\cos \theta) = \sqrt{\frac{2}{n\pi \sin \theta}} \sin\left(\left(n + \frac{1}{2}\right)\theta + \frac{\pi}{4}\right) + O(1/n^{3/2}),$$

$$Q_n(\cos \theta) = \sqrt{\frac{\pi}{2\pi \sin \theta}} \cos\left(\left(n + \frac{1}{2}\right)\theta + \frac{\pi}{4}\right) + O(1/n^{3/2})$$

as $n \rightarrow \infty$.

C. Associated Legendre Functions

For any positive integer m , the functions

$$P_v^m(z) = (1 - z^2)^{m/2} d^m P_v(z)/dz^m,$$

$$Q_v^m(z) = (1 - z^2)^{m/2} d^m Q_v(z)/dz^m$$

are called the **associated Legendre functions of the first and second kind**, respectively. This definition, due to N. M. Ferrers, is convenient for the case $-1 < z < 1$. For arbitrary complex z in a domain G obtained by deleting the segment $[-1, 1]$ from the complex plane, the following definition, due to H. E. Heine and E. W. Hobson, is used:

$$P_v^m(z) = (z^2 - 1)^{m/2} d^m P_v(z)/dz^m,$$

$$Q_v^m(z) = (z^2 - 1)^{m/2} d^m Q_v(z)/dz^m.$$

The associated Legendre functions satisfy the associated Legendre differential equation (1). In particular, for $v = n$ (a positive integer) and $z = x$ (real),

$$\{(2n + 1)(n - m)!/2(n + m)!\}^{1/2} P_n^m(z),$$

$n = 0, 1, \dots, m = \text{constant},$

constitute an orthonormal system on $[-1, 1]$.

The **addition theorem** for the Legendre functions is

$$P_n\left(z_1 z_2 \pm \sqrt{\pm(1 - z_1^2)} \sqrt{\pm(1 - z_2^2)} \cos \varphi\right) = P_n(z_1)P_n(z_2) + 2 \sum_{m=1}^n \frac{(n - m)!}{(n + m)!} P_n^m(z_1) \times P_n^m(z_2) \cos m\varphi,$$

where the equality with the plus sign was

obtained by Ferrers and that with the minus sign by Heine and Hobson.

D. Surface Harmonics

From the considerations so far for the surface harmonics $Y_n(\theta, \varphi)$, $2n + 1$ independent solutions

$$P_n(\cos \theta), \quad P_n^m(\cos \theta) \sin m\varphi, \\ q P_n^m(\cos \theta) \cos m\varphi, \quad 1 \leq m \leq n,$$

are obtained. Since $P_n(\cos \theta)$ vanishes on n latitudes of the unit sphere, and $P_n^m(\cos \theta) \cdot \cos m\varphi$ and $P_n^m(\cos \theta) \sin m\varphi$ vanish on $n - m$ latitudes and m longitudes of the unit sphere, respectively, the former functions are called **zonal harmonics** and the latter, **tesseral harmonics**. The general form of surface harmonics Y_n of order n is given by a linear combination of zonal and tesseral harmonics:

$$Y_n(\theta, \varphi) = A_{n,0} P_n(\cos \theta) + \sum_{m=1}^n (A_{n,m} \cos m\varphi + B_{n,m} \sin m\varphi) P_n^m(\cos \theta). \quad (7)$$

Expressing two surface harmonics $Y_n^{(1)}$ and $Y_n^{(2)}$ in linear combinations such as (7), the following orthogonality relations hold:

$$\int_{-\pi}^{\pi} \int_0^{\pi} Y_n^{(1)}(\theta, \varphi) Y_n^{(2)}(\theta, \varphi) \sin \theta d\theta d\varphi = \delta_{n,l} \frac{4\pi}{2n + 1} \left(A_{n,0}^{(1)} A_{n,0}^{(2)} + \frac{1}{2} \sum_{m=1}^n \frac{(n + m)!}{(n - m)!} (A_{n,m}^{(1)} A_{n,m}^{(2)} + B_{n,m}^{(1)} B_{n,m}^{(2)}) \right).$$

Since the family of all zonal and tesseral harmonics constitutes a †complete orthogonal system, it is possible to expand a function $f(\theta, \varphi)$ on the sphere into an orthogonal series:

$$f(\theta, \varphi) = \sum_{n=0}^{\infty} Y_n(\theta, \varphi) = \sum_{n=0}^{\infty} \left(A_{n,0} P_n(\cos \theta) + \sum_{m=1}^n (A_{n,m} \cos m\varphi + B_{n,m} \sin m\varphi) P_n^m(\cos \theta) \right).$$

To obtain surface harmonics, the following method is effective. Let v be a direction proportional to the direction cosines l, m, n . Then a function

$$\left(l \frac{\partial}{\partial x} + m \frac{\partial}{\partial y} + n \frac{\partial}{\partial z} \right) \frac{1}{r} = \alpha \frac{\partial}{\partial v} \left(\frac{1}{r} \right),$$

$$\alpha = \sqrt{l^2 + m^2 + n^2}$$

is a solution of Laplace's equation. Physically, this corresponds to a †potential of double pole with moment α and direction v . A more gen-

eral multipole potential

$$V = c \left(\prod_{i=1}^n \alpha_i \frac{\partial}{\partial v_i} \right) \left(\frac{1}{r} \right)$$

also satisfies Laplace's equation. If we put $V = U_n(x, y, z)r^{-2n-1}$, U_n is a spherical function of order n (**Maxwell's theorem**). Various spherical functions correspond to particular directions v_i . For example, if every v_i is equal to z , we have zonal harmonics; and if $n - m$ of the v_i are equal to z and m of the v_i are symmetric on the xy -plane, we obtain tesseral harmonics. Let γ be an angle between two segments connecting the origin to the points (r, θ, φ) and (r', θ', φ') in polar coordinates. Then $\cos \gamma = \cos \theta \cos \theta' + \sin \theta \sin \theta' \cos(\varphi - \varphi')$, and if we choose the line connecting the origin to a point (r', θ', φ') as the axis defining P_n , we have

$$P_n(\cos \gamma) = (-1)^n \frac{r^{n+1}}{n!} \left(\frac{x'}{r'} \frac{\partial}{\partial x} + \frac{y'}{r'} \frac{\partial}{\partial y} + \frac{z'}{r'} \frac{\partial}{\partial z} \right)^n \left(\frac{1}{r} \right).$$

These are called **biaxial spherical harmonics**, which can also be represented (by the addition theorem) by means of spherical harmonics with respect to each axis.

E. Extension of the Legendre Functions

We extend the associated functions with positive integer m to any number m . First, if m is a negative integer, we put

$$P_v^{-m}(z) = (1 - z^2)^{-m/2} \int_1^z d\zeta_m \int_1^{\zeta_m} d\zeta_{m-1} \dots \times \int_1^{\zeta_3} d\zeta_2 \int_1^{\zeta_2} P_v(\zeta_1) d\zeta_1,$$

$$Q_v^{-m}(z) = (1 - z^2)^{-m/2} \int_\infty^z d\zeta_m \int_\infty^{\zeta_m} d\zeta_{m-1} \dots \times \int_\infty^{\zeta_3} d\zeta_2 \int_\infty^{\zeta_2} Q_v(\zeta_1) d\zeta_1,$$

a definition due to Ferrers. Then

$$P_v^{-m}(z) = (-1)^m \frac{\Gamma(v - m + 1)}{\Gamma(v + m + 1)} P_v^m(z),$$

$$Q_v^{-m}(z) = (-1)^m \frac{\Gamma(v - m + 1)}{\Gamma(v + m + 1)} Q_v^m(z).$$

When we use the definition due to Heine and Hobson, the factor $(-1)^m$ in these formulas is excluded. Two fundamental solutions, called **hypergeometric functions of the hyperspherical differential equation**

$$(1 - z^2)d^2w/dz^2 - 2(\mu + 1)z dw/dz + (v - \mu)(v + \mu + 1)w = 0,$$

are

$$P_{v-\mu}^{(\mu, \mu)}(z) = \frac{e^{-v\pi i}}{2^{v-\mu} 4\pi \sin v\pi} \times \oint_{(z+, 1+, z-, 1-)} \frac{(\zeta^2 - 1)^v}{(\zeta - 2)^{v+\mu+1}} d\zeta,$$

$$Q_{v-\mu}^{(\mu, \mu)}(z) = \frac{e^{(1+v)\pi i}}{2^{v-\mu} 4i \sin v\pi} \oint_{(-1+, 1-)} \frac{(\zeta^2 - 1)^v}{(\zeta - z)^{v+\mu+1}} d\zeta,$$

where the contour of integration for the latter integral is a curve encircling the point -1 once in the positive direction and the point 1 once in the negative direction. Then the associated Legendre functions for an arbitrary number μ are defined as follows:

$$P_v^\mu(z) = \frac{\Gamma(v + \mu + 1)}{2^\mu \Gamma(v + 1)} (z^2 - 1)^{\mu/2} P_{v-\mu}^{(\mu, \mu)}(z),$$

$$Q_v^\mu(z) = \frac{\Gamma(v + \mu + 1)}{2^\mu \Gamma(v + 1)} (z^2 - 1)^{\mu/2} Q_{v-\mu}^{(\mu, \mu)}(z).$$

If $v - \mu$ is a positive integer, $P_{v-\mu}^{(\mu, \mu)}$ is called the **Gegenbauer polynomial**, also denoted by $C_{v-\mu}(z)$. The $C_{v-\mu}(z)$ are obtained as coefficients of the expansion of the generating function $(1 - 2hz + z^2)^{-(2\mu+1)/2}$ (\rightarrow Appendix A, Table 20.1).

For spherical functions of several variables there is an investigation by P. Appell and J. Kempé de Fériet [2] (\rightarrow 206 Hypergeometric Functions D).

**394 (XIII.13)
Stability**

A. General Remarks

Stability was originally a concept concerned with stationary physical states. When a state is affected by a small disturbance, this state is said to be **stable** if the disturbance subsequently remains small, and **unstable** if the dis-

turbance gradually increases. For instance, consider a rod placed in the Earth's gravitational field with one end fixed at a point around which the rod can rotate freely. When the rod is placed vertically, this state is stationary. It is stable if the rod is hanging down from the fixed end, and unstable if it is standing on the fixed end. In physical systems only the stable state is practically realizable, so this distinction is important.

The concept of stability is used not only in relation to physical states but also in many other fields of science. We shall restrict ourselves to stability of solutions of differential equations. There, the term *stability* is used in the sense that a small change in the initial values results in a small change in the solution. As long as the solution is considered within a finite interval of the independent variable, this stability is naturally guaranteed by the continuity of the solution with respect to its initial values (\rightarrow 316 Ordinary Differential Equations (Initial Value Problems)). The problem arises when an independent variable moves over an unbounded interval.

Let $(x_1, \dots, x_n) = \mathbf{x}$, $(x_1(t), \dots, x_n(t)) = \mathbf{x}(t)$, $(x'_1(t), \dots, x'_n(t)) = \mathbf{x}'(t)$ (the symbol ' means differentiation by t), and $|\mathbf{x}| = \sum_{j=1}^n |x_j|$. Consider the differential equation

$$\mathbf{x}' = \mathbf{f}(t, \mathbf{x}), \tag{1}$$

for which the existence and uniqueness of the solution of the initial value problem is assumed for $|t| < \infty$, $|\mathbf{x}| < \infty$. Let $\mathbf{x} = \varphi(t)$ be a solution of (1). If for any $\varepsilon > 0$ and t_0 , a $\delta > 0$ can be chosen so that $|\mathbf{x}(t_0) - \varphi(t_0)| < \delta$ implies $|\mathbf{x}(t) - \varphi(t)| < \varepsilon$ for $t_0 \leq t < \infty$ ($-\infty < t \leq t_0$), where $\mathbf{x}(t)$ is any solution of (1), then $\mathbf{x} = \varphi(t)$ is said to be **(Lyapunov) stable in the positive (negative) direction**. If it is stable both in the positive and negative directions, it is said to be **stable in both directions**. In the remainder of this article we will consider stability in the positive direction only. Corresponding assertions for stability in the negative direction can be obtained by reversing the sign of t .

B. Classification

We denote by $\mathbf{x} = \mathbf{x}(t, t_0, \mathbf{x}_0)$ a solution of (1) such that $\mathbf{x} = \mathbf{x}_0$ at $t = t_0$.

Suppose a solution $\mathbf{x} = \varphi(t)$ is stable. If for any t_0 there exists a $\zeta > 0$ such that $|\mathbf{x}(t, t_0, \mathbf{x}_0) - \varphi(t)| \rightarrow 0$ as $t \rightarrow \infty$ for any $\mathbf{x}(t, t_0, \mathbf{x}_0)$ with $|\mathbf{x}_0 - \varphi(t_0)| < \zeta$, $\varphi(t)$ is said to be **asymptotically stable**.

If a constant δ in the definition of stability can be chosen independently of t_0 , $\varphi(t)$ is said to be **uniformly stable**. When equation (1)

is \dagger autonomous, stability implies uniform stability.

If (1) $\varphi(t)$ is uniformly stable and (2) for any t_0 and $\eta > 0$, there exist a $\zeta > 0$ independent of t_0 and a $T > 0$ independent of t_0 such that $|\mathbf{x}_0 - \varphi(t_0)| < \zeta$ and $t > t_0 + T$ imply $|\mathbf{x}(t, t_0, \mathbf{x}_0) - \varphi(t)| < \eta$, then $\varphi(t)$ is said to be **uniformly asymptotically stable**.

Suppose that there exists a positive number λ with the following property: For any t_0 and $\varepsilon > 0$ one can take a $\delta(\varepsilon) > 0$ such that $|\mathbf{x}_0 - \varphi(t_0)| < \delta(\varepsilon)$ implies $|\mathbf{x}(t, t_0, \mathbf{x}_0) - \varphi(t)| < \varepsilon e^{-\lambda(t-t_0)}$ for $t \geq t_0$. Then $\varphi(t)$ is said to be **exponentially stable**. Exponential stability implies uniform asymptotic stability.

C. Criteria

To deal with the stability of $\mathbf{x} = \varphi(t)$, we need consider only the case $\varphi(t) \equiv \mathbf{0}$, since the transformation $\mathbf{x} = \mathbf{y} + \varphi(t)$ reduces equation (1) to

$$\mathbf{y}' = \mathbf{f}(t, \mathbf{y} + \varphi(t)) - \mathbf{f}(t, \varphi(t)) = \mathbf{F}(t, \mathbf{y}),$$

$$\mathbf{F}(t, \mathbf{0}) \equiv \mathbf{0}, \tag{2}$$

and thus $\mathbf{x} = \varphi(t)$ is transformed into $\mathbf{y} \equiv \mathbf{0}$. If \mathbf{F} is continuously differentiable with respect to \mathbf{y} , (2) can be written in the form

$$\mathbf{y}' = \mathbf{F}_y(t, \mathbf{0})\mathbf{y} + \mathbf{g}(t, \mathbf{y}), \quad \mathbf{g}(t, \mathbf{y}) = o(|\mathbf{y}|).$$

The linear part of this equation,

$$\mathbf{y}' = \mathbf{F}_y(t, \mathbf{0})\mathbf{y},$$

is called the **variational equation** for (1). So, in this section, we can state several criteria for stability of the null solution $\mathbf{y} \equiv \mathbf{0}$ of the equation

$$\mathbf{y}' = P(t)\mathbf{y} + \mathbf{g}(t, \mathbf{y}), \quad |\mathbf{g}(t, \mathbf{y})| = o(|\mathbf{y}|). \tag{3}$$

(I) If (3) is linear (i.e., $\mathbf{g}(t, \mathbf{y}) \equiv \mathbf{0}$), then $\mathbf{y} \equiv \mathbf{0}$ is stable if and only if every solution of (3) is bounded as $t \rightarrow \infty$.

(II) If (3) is linear, uniform asymptotic stability implies exponential stability.

Let $f(t, \mathbf{y})$ be a function defined for $|\mathbf{y}| < \rho$, $t > \alpha$. If there exists a continuous function $w(\mathbf{y})$ such that $w(\mathbf{0}) = 0$, $w(\mathbf{y}) > 0$ ($\mathbf{y} \neq \mathbf{0}$), $f(t, \mathbf{y}) \geq w(\mathbf{y})$ ($|\mathbf{y}| < \rho, t > \alpha$), then $f(t, \mathbf{y})$ is said to be **positive definite**. If $-f(t, \mathbf{y})$ is positive definite, then $f(t, \mathbf{y})$ is said to be **negative definite**.

(III) The existence of a **Lyapunov function** $V(t, \mathbf{y})$ with the following properties implies the stability of $\mathbf{y} \equiv \mathbf{0}$: (i) $V(t, \mathbf{y})$ is positive definite and differentiable, (ii) $V(t, \mathbf{0}) = 0$, (iii) $\dot{V}(t, \mathbf{y}) = V_t + V_y \cdot (P(t)\mathbf{y} + \mathbf{g}(t, \mathbf{y})) \leq 0$.

The existence of $V(t, \mathbf{y})$ with the following properties implies the uniform asymptotic stability of $\mathbf{y} \equiv \mathbf{0}$: (i) same as (i) above, (ii) there exists a continuous function $v(\mathbf{y})$ such that

$v(\mathbf{0})=0$, $v(\mathbf{y})>0$ ($\mathbf{y}\neq\mathbf{0}$), $V(t, \mathbf{y})\leq v(\mathbf{y})$, (iii) $\dot{V}(t, \mathbf{y})$ is negative definite.

Hereafter we shall assume that $|\mathbf{g}(t, \mathbf{y})|=o(|\mathbf{y}|)$ as $\mathbf{y}\rightarrow\mathbf{0}$ uniformly with respect to t .

(IV) If $P(t)$ is a constant matrix all of whose eigenvalues have negative real parts, then $\mathbf{y}\equiv\mathbf{0}$ is asymptotically stable [3, 4].

(V) Let $P(t)$ be continuous and periodic with period T and Z be a fundamental system of solutions of the variational equation

$$\mathbf{z}' = P(t)\mathbf{z}. \quad (4)$$

Then there exists a constant matrix C such that $Z(t+T)=Z(t)C$. Let $\lambda_1, \dots, \lambda_n$ be the eigenvalues of C . Then the numbers $\mu_k = (\log \lambda_k)/T$ ($k=1, \dots, n$) are called the **characteristic exponents** of (4). Obviously they are determined up to integral multiples of $2\pi i/T$. If the real parts of the characteristic exponents are all negative, then $\mathbf{y}\equiv\mathbf{0}$ is asymptotically stable [3, 4].

(VI) If $\mathbf{f}(t, \mathbf{x})$ in (1) is periodic in t with period T and (1) admits a periodic solution $\mathbf{x}=\varphi(t)$ with period T , then (1) can be reduced to (3) by putting $\mathbf{x}=\mathbf{y}+\varphi(t)$, and $P(t)$, $\mathbf{g}(t, \mathbf{y})$ are both periodic in t with period T . Thus criterion (V) can be applied as a stability criterion for the periodic solution of (1). There are many other criteria for various particular forms of the equation (\rightarrow 290 Nonlinear Oscillation). For the autonomous case where $\mathbf{f}(t, \mathbf{x})$ is of the form $\mathbf{p}(\mathbf{x})$ or $\mathbf{p}(\mathbf{x})+\mathbf{q}(t)$ with $\mathbf{q}(t+T)=\mathbf{q}(t)$, many results have been found.

(VII) If the solution $\mathbf{z}\equiv\mathbf{0}$ of

$$\mathbf{z}' = P(t)\mathbf{z}$$

is uniformly asymptotically stable, then the solution $\mathbf{y}\equiv\mathbf{0}$ of (3) is also uniformly asymptotically stable [4].

D. Conditional Stability

Let $\varphi(t)$ be a solution and \mathfrak{F} a family of solutions of (1). If for any $\varepsilon>0$, a $\delta>0$ can be determined so that $|\mathbf{x}(t_0)-\varphi(t_0)|<\delta$ implies $|\mathbf{x}(t)-\varphi(t)|<\varepsilon$ for $t_0\leq t<\infty$ for any solution $\mathbf{x}(t)$ in \mathfrak{F} , then $\varphi(t)$ is said to be stable with respect to the family \mathfrak{F} . If a family \mathfrak{F} can be found so that a solution is stable with respect to \mathfrak{F} , the solution is said to be **conditionally stable**. For instance, in equation (3), if $P(t)$ is a constant matrix some of whose eigenvalues have negative real parts, $\mathbf{g}(t, \mathbf{y})$ is differentiable with respect to \mathbf{y} , and $\mathbf{g}_y(t, \mathbf{y})=o(1)$ uniformly in t as $\mathbf{y}\rightarrow\mathbf{0}$, then $\mathbf{y}\equiv\mathbf{0}$ is conditionally stable.

We now mention a weaker kind of stability called orbital stability. Let $\varphi(t)$ be a solution and ε any positive number. If there can be found a positive number δ such that for

394 Ref. Stability

any solution $\mathbf{x}(t)$ with $|\mathbf{x}(t_1)-\varphi(t_0)|<\delta$ for some t_0 and $t_1, \bigcup_{t_0\leq t<\infty}\mathbf{x}(t)$ belongs to the ε -neighborhood of $\bigcup_{t_0\leq t<\infty}\varphi(t)$, then $\varphi(t)$ is said to have **orbital stability**.

When $\mathbf{f}(t, \mathbf{x})$ in equation (1) is independent of t , (1) is often called a dynamical system. In the theory of dynamical systems, not merely the stability of a solution itself but also the stability of a closed invariant set is of importance (\rightarrow 126 Dynamical Systems).

It is also of importance to investigate the change in solution caused by a small change in the right-hand member of the equation. Suppose, for instance, that the right-hand member of the equation depends continuously on a parameter ε . Then the question arises as to how the solution changes if ε changes. The theory of such problems is called perturbation theory. Suppose that the equation

$$\mathbf{x}' = \mathbf{f}(t, \mathbf{x}, \varepsilon)$$

admits a periodic solution $\varphi(t)$ for $\varepsilon=0$. Then $\varphi(t)$ is said to be stable under perturbation if for $\varepsilon\neq 0$ the same equation admits a periodic solution lying near $\varphi(t)$. In celestial mechanics and nonlinear oscillation theory this concept plays an important role.

395 (XVII.12) Stationary Processes

A. Definitions

Stationary process is a general name given to all †stochastic processes (→ 407 Stochastic Processes) that have the property of being stationary (to be defined in the next paragraph) under a shift of a time parameter t that extends over T , which is either the set of all real numbers \mathbf{R} (a continuous parameter) or the set of all integers \mathbf{Z} (a discrete parameter).

Let $(\Omega, \mathfrak{B}, P)$ be a †probability space and $\{X_t(\omega)\}$ ($t \in T, \omega \in \Omega$) a complex-valued †stochastic process. If for every n , every $t_1, t_2, \dots, t_n \in T$, and every †Borel subset E_n of complex n -dimensional space C^n , the equality

$$\begin{aligned} P((X_{t_1+t}, \dots, X_{t_n+t}) \in E_n) \\ = P((X_{t_1}, \dots, X_{t_n}) \in E_n) \end{aligned} \quad (1)$$

holds, then $\{X_t\}$ is called a **strongly** (or **strictly stationary process**); while if $E(|X_t|^2)$ is finite for every t , and if the †moments up to the second order are stationary, i.e., if

$$\begin{aligned} E(X_{t+h}) &= E(X_t), \\ E(X_{t+h}\bar{X}_{s+h}) &= E(X_t\bar{X}_s), \end{aligned} \quad (2)$$

then $\{X_t\}$ is called a **weakly stationary process** or a **stationary process in the wider sense**. The “stationary” in the latter sense obviously includes the former if $E(|X_t|^2) < \infty$. Condition (2) is equivalent to

$$\begin{aligned} E(X_t) &= m \quad (\text{a constant independent of } t), \\ E((X_t - m)\overline{(X_s - m)}) &= \rho(t - s) \\ &\quad (\text{a function of } t - s). \end{aligned} \quad (3)$$

We call m and $\rho(t)$ the **mean** and the **covariance function** of $\{X_t\}$.

In the continuous parameter case, we assume †continuity in probability,

$$\lim_{h \rightarrow 0} P(|X_{t+h} - X_t| > \varepsilon) = 0, \quad \varepsilon > 0,$$

for a strongly stationary process, and continuity in mean square,

$$\lim_{h \rightarrow 0} E(|X_{t+h} - X_t|^2) = 0,$$

for a weakly stationary process. The latter assumption is equivalent to continuity of the covariance function $\rho(t)$.

A †Gaussian process is strongly stationary if and only if it is weakly stationary; and so it is simply called a †stationary Gaussian process. Such processes constitute a typical class of stationary processes (→ 176 Gaussian Processes C).

B. Spectral Decomposition of Weakly Stationary Processes

The covariance function $\rho(t)$ is obviously †positive definite and continuous. Therefore, by †Bochner’s theorem, we have the †spectral decomposition of $\rho(t)$:

$$\rho(t) = \int_{T'} e^{i\lambda t} F(d\lambda), \quad (4)$$

where T' is either \mathbf{R} (when $T = \mathbf{R}$) or $[-\pi, \pi]$ (when $T = \mathbf{Z}$) and F is a bounded measure on T' . The decomposition (4) is called the **Khinchin decomposition** of $\rho(t)$, and $F(d\lambda)$ is called the **spectral measure**. If the process $\{X_t\}$ is real-valued, then the spectral measure $F(d\lambda)$ is symmetric with respect to the origin.

To obtain the spectral decomposition of a weakly stationary process X_t itself, we introduce the †Hilbert space $L_2(\Omega)$ (where $\Omega = (\Omega, \mathfrak{B}, P)$ is the basic probability space on which each X_t is regarded as a †square integrable function). Let $\mathfrak{M}(X)$ be the subspace of $L_2(\Omega)$ spanned by the X_t ($t \in T$) and the constant function 1. Since $\{X_t\}$ is weakly stationary, we can define a one-parameter group of †unitary operators U_t ($t \in T$) determined by $U_t X_s = X_{t+s}$ and $U_t 1 = 1$. By †Stone’s theorem we have the spectral decomposition of U_t :

$$U_t = \int_{T'} e^{i\lambda t} E(d\lambda). \quad (5)$$

Setting $M(\Lambda) = E(\Lambda)(X_0 - m)$, we obtain the **spectral decomposition** of X_t :

$$X_t = U_t X_0 = m + \int_{T'} e^{i\lambda t} M(d\lambda). \quad (6)$$

We also have

$$\begin{aligned} (M(\Lambda), 1) &= 0, \\ (M(\Lambda_1), M(\Lambda_2)) &= F(\Lambda_1 \cap \Lambda_2). \end{aligned} \quad (7)$$

The study of weakly stationary processes is based on the decomposition (6). For example, the **weak law of large numbers** for $\{X_t\}$,

$$\text{l.i.m.}_{B \rightarrow A \rightarrow \infty} \frac{1}{B - A} \int_A^B X_t dt = m + M(\{0\}), \quad (8)$$

is an immediate consequence of (6). In the discrete parameter case a similar result is obtained by replacing the integral sign in expression (8) by the summation sign. In particular, if F is continuous at the origin, we have $M(\{0\}) = 0$, and only the constant m remains in the right-hand side of (8) [1, 2].

C. Weakly Stationary Random Distributions

Just as we introduce †distributions as generalizations of ordinary functions, we define

weakly stationary random distributions as generalizations of weakly stationary processes. Let \mathcal{D} be the space of all functions of class C^∞ on $T = \mathbf{R}$ with compact support. We introduce the same topology on \mathcal{D} as in the theory of distributions. If a random variable $X_\varphi \in L_2(\Omega)$ is defined for every $\varphi \in \mathcal{D}$ and the mapping $\varphi \rightarrow X_\varphi$ is continuous in the L_2 -sense and linear, then the family $\{X_\varphi\}$ of random variables is called a **random distribution in the wider sense** (\rightarrow 407 Stochastic Processes). Furthermore, if

$$\begin{aligned} (X_{\tau_h \varphi}, 1) &= (X_\varphi, 1), \\ (X_{\tau_h \varphi}, X_{\tau_h \psi}) &= (X_\varphi, X_\psi) \end{aligned} \tag{9}$$

for every $h \in \mathbf{R}^1$, where (\cdot, \cdot) stands for the inner product in $L_2(\Omega)$ and

$$\tau_h \varphi(t) = \varphi(t - h),$$

then $\{X_\varphi\}$ is said to be a **weakly stationary random distribution**. With a weakly stationary process we can associate a weakly stationary random distribution by the relation

$$X_\varphi = \int_T X_t \varphi(t) dt. \tag{10}$$

This correspondence is one-to-one, and therefore we can identify $\{X_t\}$ with $\{X_\varphi\}$ as we identify an ordinary function with a distribution. From equations (9) it follows that there exist a constant m and a distribution ρ such that $E(X_\varphi) = m \int \varphi(t) dt$ and $E(X_\varphi - E(X_\varphi))(X_\psi - E(X_\psi)) = \rho(\varphi * \check{\psi})$, where $*$ denotes convolution, and $\check{\psi}(t) = \overline{\psi(-t)}$. We call m and ρ the **mean value** and **covariance distribution** of $\{X_\varphi\}$, respectively. By the generalized Bochner theorem ρ can be expressed in the form

$$\rho(\varphi) = \int \hat{\varphi}(\lambda) F(d\lambda), \quad \hat{\varphi}(\lambda) = \int e^{i\lambda t} \varphi(t) dt,$$

where $F(d\lambda)$ is a slowly increasing measure, i.e.,

$$\int (1 + \lambda^2)^{-k} F(d\lambda) < \infty \tag{11}$$

for some positive integer k . $F(d\lambda)$ is called the **spectral measure**. This expression is the generalization of the Khinchin decomposition. The spectral decomposition corresponding to (6) and the "law of large numbers for X_φ can be discussed in a manner similar to that for weakly stationary processes (K. Itô [3]).

D. Prediction Theory

Let $\{X_t\}$ be a weakly stationary process. Suppose that its values $X_s (s \leq t)$ up to time t are observed. **Prediction theory** deals with the problem of forecasting the future value $X_{t+\tau}$

($\tau > 0$) from the known values $X_s (s \leq t)$. If the domain of the admissible predictors is limited to linear functions of $X_s (s \leq t)$, the theory is called **linear prediction theory**. We can assume without loss of generality that the mean value m of X_t is zero and that the spectral measure $F(d\lambda)$ of $\{X_t\}$ is not a zero measure.

Let $\mathcal{M}_t(X)$ be the subspace of $L_2(\Omega)$ spanned by the $X_s (s \leq t)$, then $\mathcal{M}(X) = \bigvee_t \mathcal{M}_t(X)$. A **linear predictor** for $X_{t+\tau}$ from $X_s (s \leq t)$ is an element Y of $\mathcal{M}_t(X)$. If a linear predictor minimizes the prediction error $\sigma^2(\tau) = E(|X_{t+\tau} - Y|^2)$ in $\mathcal{M}_t(X)$, it is called an **optimum linear predictor**, which turns out to be the (orthogonal) projection of $X_{t+\tau}$ on $\mathcal{M}_t(X)$ and which is denoted by $\hat{X}_{t,\tau}$. Since $\{X_t\}$ is stationary, the error $\sigma^2(\tau)$ does not depend on t for such a predictor. Corresponding to the spectral decomposition (6) of X_t , the optimum linear predictor is expressed in the form

$$\hat{X}_{t,\tau} = \int_{T'} e^{i\lambda t} \hat{\varphi}_\tau(\lambda) M(d\lambda), \tag{12}$$

where $\hat{\varphi}_\tau(\cdot)$ is square integrable with respect to the spectral measure $F(d\lambda)$.

The subspace $\mathcal{M}_t(X)$ is nondecreasing in t . If $\mathcal{M}_t(X)$ is independent of t , i.e., $\mathcal{M}_t(X) = \mathcal{M}(X)$ for every t , then $\{X_t\}$ is said to be **deterministic**. In this case we have $\hat{X}_{t,\tau} = X_{t+\tau}$ for every t and $\tau > 0$, since $X_{t+\tau} \in \mathcal{M}_t(X)$. This means that the linear predictor enables us to determine the unknown quantities without error, and therefore such a process is of no probabilistic interest. On the other hand, if $\bigcap_t \mathcal{M}_t(X) = \{0\}$, then $\{X_t\}$ is said to be **purely nondeterministic**. A general $\{X_t\}$ is expressed as the sum of the deterministic part $\{X_t^d\}$ and the purely nondeterministic part $\{X_t^n\}$ (**Wold decomposition**). Furthermore, we have $\mathcal{M}(X^d) = \bigcap_t \mathcal{M}_t(X)$, and $\mathcal{M}_t(X) = \mathcal{M}(X^d) + \mathcal{M}_t(X^n)$ (direct sum). Thus $\{X_t^d\}$ and $\{X_t^n\}$ can be dealt with separately.

A weakly stationary process $\{X_t\}$ is purely nondeterministic if and only if the spectral measure $F(d\lambda)$ is absolutely continuous with respect to the Lebesgue measure, and the density $f(\lambda)$ is positive almost everywhere and satisfies

$$\int_{-\pi}^{\pi} \log f(\lambda) d\lambda > -\infty$$

(discrete parameter case),

$$\int_{-\infty}^{\infty} \frac{\log f(\lambda)}{1 + \lambda^2} d\lambda > -\infty$$

(continuous parameter case).

By using $f(\lambda)$ the optimum linear predictor can be obtained.

First, we explain the discrete parameter case. There exists a function $\gamma(z) = \sum_{t=0}^{\infty} a_t z^t$ in the "Hardy class H_2 relative to the unit disk

such that its boundary value satisfies

$$f(\lambda) = (1/2\pi)|\gamma(e^{-i\lambda})|^2.$$

Then we can find a sequence of mutually orthogonal random variables $\{\xi_t\}$ ($t \in \mathbf{Z}$) such that $\{X_t\}$ admits a **backward moving average representation**

$$X_t = \sum_{s=-\infty}^t a_{t-s} \xi_s. \quad (13)$$

There are many pairs $\{a_t\}$ and $\{\xi_t\}$ which give the representation (13), but if $\gamma(z)$ is maximal (optimal), namely, if $\gamma(z)$ is expressed as

$$\gamma(z) = \sqrt{2\pi} \exp\left(\frac{1}{4\pi} \int_{-\pi}^{\pi} \log f(\lambda) \frac{e^{-i\lambda} + z}{e^{-i\lambda} - z} d\lambda\right), \quad (14)$$

then the representation (13) is **canonical** in the sense that $\mathcal{M}_t(X) = \mathcal{M}_t(\xi)$ for every t . Hence the optimum predictor $\hat{X}_{t,\tau}$ for $X_{t+\tau}$ is given by

$$\hat{X}_{t,\tau} = \sum_{s=-\infty}^t a_{t+\tau-s} \xi_s = \int_{-\pi}^{\pi} e^{i\lambda t} \hat{\phi}_t(\lambda) M(d\lambda), \quad (15)$$

where

$$\hat{\phi}_t(\lambda) = \frac{e^{i\lambda t}}{\gamma(e^{-i\lambda})} \left(\gamma(e^{-i\lambda}) - \sum_{s=0}^{\tau-1} a_s e^{-i\lambda s} \right).$$

The prediction error $\sigma^2(\tau)$ of this predictor is given by

$$\sigma^2(\tau) = \sum_{s=0}^{\tau-1} |a_s|^2.$$

Example. Let the covariance function of a weakly stationary process $\{X_t\}$ be $e^{-\alpha|t|}$ ($\alpha > 0$). Then we have

$$f(\lambda) = (1/2\pi)(1 - \beta^2) |1 - \beta e^{-i\lambda}|^{-2},$$

$$\beta = e^{-\alpha}.$$

The maximal $\gamma(z)$ is expressed as $\sqrt{1 - \beta^2} (1 - \beta z)^{-1}$, and

$$\hat{X}_{t,\tau} = \int_{-\pi}^{\pi} e^{i\lambda t} \frac{e^{i\lambda \tau}}{1 - \beta e^{-i\lambda}} \sum_{s=\tau}^{\infty} \beta^s e^{-i\lambda s} M(d\lambda)$$

$$= \beta^\tau X_t,$$

$$\sigma^2(\tau) = 1 - 2\beta^\tau e^{-\alpha\tau} + \beta^{2\tau} = 1 - e^{-2\alpha\tau}.$$

We now come to the continuous parameter case. By replacing the holomorphic function $\gamma(z)$ on the unit disk with the one on the half-plane, we see that almost all results obtained in the discrete parameter case hold similarly in this case. The maximal $\gamma(z)$ is expressed as

$$\gamma(z) = \sqrt{\pi} \exp\left(\frac{1}{2\pi i} \int_{-\infty}^{\infty} \log f(\lambda) \frac{1 + \lambda z}{z - \lambda} \frac{d\lambda}{1 + \lambda^2}\right).$$

Using the Fourier transform a_t of the boundary function of $\gamma(z)$ and a process $\{\xi_t\}$ with orthogonal increments, we have the **canonical backward moving average representation** for

the process $\{X_t\}$:

$$X_t = \int_{-\infty}^t a_{t-s} d\xi_s,$$

which enables us to obtain the optimum predictor and the prediction error in a manner similar to the discrete parameter case [4]. In particular, if the optimal $\gamma(z)$ is of the form $\gamma(z) = c/P(iz)$, where c is a constant and $P(z)$ is a polynomial of degree p , then X_t is $p - 1$ times differentiable and $P(d/dt)X_t = (d/dt)\xi_t$ up to a multiplicative constant; therefore $\hat{X}_{t,\tau}$ is obtained explicitly. To obtain the optimum linear predictor for $Y \in \mathcal{M}(X)$, we first establish the expression

$$Y = \sum_{s=-\infty}^{\infty} f(s)\xi_s \quad \text{or} \quad \int_{-\infty}^{\infty} f(s)d\xi_s,$$

and then take $\sum_{s=-\infty}^0 f(s)\xi_s$ or $\int_{-\infty}^0 f(s)d\xi_s$ for the optimum linear predictor.

The results stated above can be generalized to multivariate (n -dimensional) stationary processes [6, 7] and to the case where the parameter space T is multidimensional.

N. Wiener observed the individual sample process $X(t, \omega)$ and discussed a method of finding the optimum predictor for $X(t + \tau, \omega)$ by using a linear functional

$$\int_0^{\infty} X(t-s, \omega) dK(s)$$

(K is of bounded variation) of the values X_s ($s \leq t$) [8]. The spectral measure played an important role in his observation. Calculations in this case are analogous to those mentioned above.

For a weakly stationary random distribution $\{X(\varphi)\}$ ($\varphi \in \mathcal{D}$), the prediction theory is reduced to that for ordinary stationary processes. Assume that the spectral measure $F(d\lambda)$ of $\{X(\varphi)\}$ satisfies (11). Set $e(t) = \exp(it)$ ($t \leq 0$), $= 0$ ($t > 0$), and let $e_k(t)$ be the k -times convolution of $e(t)$ with itself. Set $Y(\varphi) = X(e_k * \varphi)$. Then $\{Y(\varphi)\}$ is equivalent to a weakly stationary process. It is obvious that $\mathcal{M}_t(X) = \mathcal{M}_t(Y)$ for every t , where $\mathcal{M}_t(X)$ is the linear subspace spanned by $\{X(\varphi) | \text{support of } \varphi \subset (-\infty, t]\}$. This consideration allows us to reduce the prediction problem for $\{X(\varphi)\}$ to that for the stationary process corresponding to $\{Y(\varphi)\}$.

Nonlinear prediction theory is formulated as follows. Let \mathfrak{B}_t be the smallest σ -algebra with respect to which every X_s ($s \leq t$) is measurable and $H_t(X)$ be the subspace of $L_2(\Omega)$ consisting of all \mathfrak{B}_t -measurable elements. The problem is to forecast $X_{t+\tau}$ ($\tau > 0$) by using an element of $H_t(X)$. The optimum predictor is obviously equal to $E(X_{t+\tau} | \mathfrak{B}_t)$. For a stationary Gaussian process it has been proved that

the optimum predictor found in $H_t(X)$ belongs to $\mathcal{M}_t(X)$. Therefore the optimum nonlinear predictor coincides with the optimum linear predictor. However, except for stationary Gaussian processes, no systematic approach for nonlinear prediction theory has been established so far. (For a typical case that arises from a stationary Gaussian process → 176 Gaussian Processes H.)

E. Interpolation and Filtering

Interpolation and filtering of stationary processes have many similarities with prediction theory, both in the formulation of the problems and in their method of solution.

Let $\{X_t\}$ be a weakly stationary process, all of whose values $\{X_t | t \notin T_1\}$. T_1 some interval, are known with the exception of those at $t \in T_1$. The problem of linear interpolation of the unknown value X_t ($t \in T_1$) is to find the best approximation of this random variable by the limit of linear combinations of the known values. The following example illustrates the problem in the discrete parameter case.

Example. Let $T_1 = \{t_0\}$ and $f(\lambda)d\lambda$ be the spectral measure of $\{X_t\}$. The interpolation of X_{t_0} has an error if and only if

$$\int_{-\pi}^{\pi} \frac{1}{f(\lambda)} d\lambda < \infty.$$

Expressing X_t in the form (6) with $m=0$, the best (linear) interpolation \hat{X}_{t_0} of X_{t_0} is given by

$$\int_{-\pi}^{\pi} e^{i\lambda t_0} \left(1 - 2\pi \left(f(\lambda) \int_{-\pi}^{\pi} \frac{1}{f(\mu)} d\mu \right)^{-1} \right) M(d\lambda),$$

and the error of the interpolation is expressed by

$$E(|X_{t_0} - \hat{X}_{t_0}|^2) = 4\pi^2 \left(\int_{-\pi}^{\pi} \frac{1}{f(\lambda)} d\lambda \right)^{-1}.$$

The problem of interpolation for multivariate stationary processes has also been discussed [7].

The filtering problem originated in communication theory as a technique to extract the relevant component from a received signal with noise [8, 13]. Suppose that a complex-valued stationary process $\{X_t\}$ with continuous parameter is expressed in the form

$$X_t = \int_{-\infty}^{\infty} e^{i\lambda t} M(d\lambda) = S_t + N_t,$$

where (S_t, N_t) is a (2-dimensional) weakly stationary process with mean vector 0. Here, S_t and N_t indicate the signal and noise, respectively. The filtering problem is to find the element of $\mathcal{M}_t(X)$ that approximates $S_{t+\tau}$ as

Stationary Processes

closely (relative to the $\mathcal{M}(X)$ -norm) as possible. The best approximation is the projection of $S_{t+\tau}$ on $\mathcal{M}_t(X)$, but its expression in terms of the spectral measure becomes extremely complicated [8]. This problem is usually discussed under the assumption that S_t and N_t are orthogonal. Let us further assume that their spectral measures are absolutely continuous. The density functions are denoted by $f_S(\lambda)$ and $f_N(\lambda)$, respectively. If $\{X_t | t \in T\}$ is observed, then the best (linear) approximation \hat{S}_t of S_t is given by

$$\hat{S}_t = \int_{-\infty}^{\infty} e^{i\lambda t} \varphi_0(\lambda) M(d\lambda),$$

where $\varphi_0(\lambda) = f_S(\lambda)/(f_S(\lambda) + f_N(\lambda))$. The mean square error $E(|S_t - \hat{S}_t|^2)$ of this filtering is

$$\int_{-\infty}^{\infty} f_S(\lambda)f_N(\lambda)/(f_S(\lambda) + f_N(\lambda)) d\lambda.$$

F. Strongly Stationary Processes and Flows

Let $\{X_t(\omega)\}$ ($t \in T, \omega \in \Omega(\mathfrak{B}, P)$) be a strongly stationary process. To study it we take the coordinate representation of $\{X_t\}$ as follows. Let Ω be the complex vector space \mathbb{C}^T , \mathfrak{B} the σ -algebra generated by the Borel cylinder sets, $X_t(\omega)$ the t th coordinate of the function $\omega \in \mathbb{C}^T$, and P the probability distribution of the process $\{X_t\}$ defined on (Ω, \mathfrak{B}) . Define the shift transformation S_t of Ω onto itself by $(S_t\omega)(s) = \omega(s+t)$. Then $\{S_t\}$ forms a group of measure-preserving transformations on $\Omega(\mathfrak{B}, P)$ (→ 136 Ergodic Theory) since $\{X_t\}$ is strongly stationary. Thus we are given a (measure-preserving) flow $\{S_t\}$ ($t \in T$) on $\Omega(\mathfrak{B}, P)$. Conversely, if $\{S_t\}$ ($t \in T$) is a (measure-preserving) flow on a probability space $\Omega(\mathfrak{B}, P)$, then $\{X_t\}$, given by $X_t(\omega) = f(S_t\omega)$, is a strongly stationary process, provided that f is measurable. Many properties of a strongly stationary process are closely related to those of the corresponding flow. For example, the strong law of large numbers for a strongly stationary process follows from Birkhoff's individual ergodic theorem for flows. Ergodicity, several kinds of mixing properties, and the spectral properties of a strongly stationary process are defined in accordance with the respective notions for the corresponding flow. Now we give some examples of flows corresponding to strongly stationary processes.

(1) If X_t ($t \in \mathbb{Z}$) are mutually independent and have the same probability distribution, then the process $\{X_t\}$ ($t \in \mathbb{Z}$) is strongly stationary and $\bigcap_t \mathfrak{B}_t$ is trivial (the definition of $\mathfrak{B}_t \rightarrow \mathcal{D}$). Hence the corresponding flow is a Kolmogorov flow.

(2) Similarly to (1), the flow corresponding to †Gaussian white noise (→ 176 Gaussian Process) is also a Kolmogorov flow.

(3) The mixing properties of the flow corresponding to a stationary Gaussian process is determined by the smoothness of its spectral measure $F(d\lambda)$. The flow is ergodic if and only if F is continuous (i.e., F has no point mass). In this case, the flow is also †weakly mixing. For the flow to be †strongly mixing, it is necessary and sufficient that the covariance function $\rho(t)$ of the process tend to zero as $|t| \rightarrow \infty$. In this case the flow is †mixing of all orders (→ 136 Ergodic Theory) [14–16].

G. Analytic Properties of Sample Functions of Stationary Processes

In the continuous parameter case, we always assume that †continuity in probability holds for strongly stationary processes and †mean square continuity holds for weakly stationary processes. Hence the processes discussed here are all continuous in probability, and without loss of generality we can assume that the stationary processes are †separable and †measurable (→ 407 Stochastic Processes).

Let $\{X_t\}$ be a weakly stationary process. Assume that the moments up to order $2n$ of the spectral measure $F(d\lambda)$ are all finite. Then almost all †sample functions of $\{X_t\}$ are $n - 1$ times continuously differentiable, and almost all sample functions of $\{X_t^{(n-1)}\}$ are absolutely continuous. Define the spectral distribution function $F(\lambda) = F((-\infty, \lambda])$ for the spectral measure $F(d\lambda)$ of $\{X_t\}$. If F satisfies

$$\sum_{n=-\infty}^{\infty} |n|^r (F(n+1) - F(n))^{1/2} < \infty \tag{16}$$

for a nonnegative integer r , then almost all sample functions of $\{X_t\}$ have continuous r th derivatives. In particular, if the condition (16) is satisfied for $r=0$, then almost all sample functions are continuous. Conditions for Hölder continuity of almost all sample functions of a weakly stationary process have also been obtained [17, 18]. (For sample functions of stationary Gaussian processes → 176 Gaussian Processes F.)

For a strongly stationary process $\{X_t\}$ with $E(X_0) = 0$ and finite $E(X_0^2)$, the **sample covariance function**

$$R(t) = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T X_{t+s}(\omega) \overline{X_s(\omega)} ds$$

is determined with probability 1. We can therefore apply the theory of †generalized harmonic analysis, due to Wiener [9]. (Further results on sample function properties are found in [19].)

H. Strongly Stationary Random Distributions

Let \mathcal{D} be the space of all C^∞ -functions with compact support and \mathcal{D}' be the space of †distributions. If $X_\varphi(\omega)$ is defined for $\omega \in \Omega(\mathfrak{B}, P)$ and $\varphi \in \mathcal{D}$, and if for almost all ω , $X_\varphi(\omega)$ belongs to \mathcal{D}' as a linear functional of φ , then $\{X_\varphi\}$ is called a **random distribution**. Suppose that the joint distribution of the random variables $X_{\tau_h \varphi_1}, X_{\tau_h \varphi_2}, \dots, X_{\tau_h \varphi_n}$ ($\tau_h \varphi(t) = \varphi(t - h)$) is independent of h . Then we call $\{X_\varphi(\omega)\}$ a **strongly (or strictly) stationary random distribution**. If we identify random distributions that have the same probability law, then $\{X_\varphi\}$ is determined by the characteristic functional

$$C(\varphi) = E(e^{iX_\varphi}).$$

For $\{X_\varphi\}$ to be strictly stationary it is necessary and sufficient that the equality $C(\tau_h \varphi) = C(\varphi)$ hold. The simplest example of a strictly stationary random distribution is the Gaussian white noise (→ 176 Gaussian Processes, 341 Probability Measures) [20].

I. Generalizations of Stationary Processes

The concept of stationary processes is generalized in many directions.

(1) Let T be a set different from \mathbf{R} or \mathbf{Z} , and suppose that there is given a group G of transformations that map T onto itself. If a family $\{X_t\}$ of random variables with parameter $t \in T$ has the property that for every choice of random variables $X_{t_1}, X_{t_2}, \dots, X_{t_n}$, the joint distribution of $(X_{gt_1}, \dots, X_{gt_n})$ is always independent of $g \in G$, then $\{X_t\}$ ($t \in T$) is said to be a **strictly G -stationary** system of random variables. Similarly, a **weakly G -stationary** system of random variables can be defined [21, 22].

(2) Let T be a Riemannian space, and let G be the group of all isometric transformations on T or one of its subgroups. Suppose that a †tensor field $\mathbf{X}_t(\omega)$ of constant rank is associated with any $\omega \in \Omega(\mathfrak{B}, P)$ at every point t . Then $\mathbf{X}(\omega) \equiv \{\mathbf{X}_t(\omega) | t \in T\}$ is called a **random tensor field** over the Riemannian space T . Any $g \in G$ induces an isometric transformation of the tangent vector space at t to that at gt . Hence g maps a tensor field $\mathbf{X}(\omega)$ to another tensor field $g\mathbf{X}(\omega)$ for every ω . If $\mathbf{X}(\omega)$ and $g\mathbf{X}(\omega)$ have the same probability law, then $\mathbf{X}(\omega)$ is said to be **strictly G -stationary**. $X(\omega)$ is defined to be **weakly G -stationary** in a similar way [21, 22].

(3) In the same way as we extended stochastic processes to random distributions, we can generalize random tensor fields to **random currents** and discuss stationary random currents [21].

(4) **Stochastic process with stationary incre-**

ments of order n . Assume that $\{X_t\}$ ($t \in \mathbf{R}$) is not necessarily a stationary process but that the n th-order increment of X_t is stationary. Then by taking the n th derivative $D^n X_t$ in the sense of random distributions, we obtain a stationary random distribution. From the properties of $D^n X_t$, we can investigate the original process itself. Brownian motion is an example of a stochastic process with stationary increments of order 1.

(5) Weakly stationary processes of degree k .

A weakly stationary process is a process whose moments up to order 2 are stationary. Generalizing this, we can define a weakly stationary process of degree k by requiring the moments up to order k to be stationary. We can obtain more detailed properties of such processes than those of weakly stationary processes [23].

396 (XVIII.3) Statistic

A. General Remarks

A statistic is a function of a value (i.e., a sample value) observed in the process of statistical inference (\rightarrow 401 Statistical Inference). A statistic is used for two purposes: (a) to characterize the set of observed values or sample values, and (b) to summarize the information contained in the sample about the unknown parameters of the population from which it is assumed to have been drawn.

B. Samples and Statistics

The basic concepts in statistical inference are \dagger population and \dagger sample. Let (Ω, \mathcal{B}, P) be a \dagger probability space, where P is a \dagger probability measure on \mathcal{B} . A \dagger random variable X defines a 1-dimensional probability distribution $\Phi(A) = P\{\omega \mid X(\omega) \in A\}$, where A is a 1-dimensional \dagger Borel set, which gives rise to a 1-dimensional probability space $(\mathbf{R}, \mathcal{B}^1, \Phi)$. Here \mathcal{B}^1 is the

family of all 1-dimensional \dagger Borel sets. Let X_1, X_2, \dots, X_n be \dagger independent random variables with identical 1-dimensional distributions. The $\dagger n$ -dimensional random variable $X = (X_1, X_2, \dots, X_n)$ is called a **random sample of size n** from the population (Ω, \mathcal{B}, P) . In particular, when each of X_1, \dots, X_n takes only two values (usually 0 and 1), the sample is called a **Bernoulli sample** or a **sequence of Bernoulli trials**. Generally, if Φ_n is the $\dagger n$ -dimensional probability distribution determined by X (i.e., the direct product of n copies of the 1-dimensional probability distribution Φ), then the n -dimensional probability space $(\mathbf{R}^n, \mathcal{B}^n, \Phi_n)$, where \mathcal{B}^n is the family of n -dimensional Borel sets, is called an **n -dimensional sample space**. A point belonging to the set of actually observed values of the sample X , which is a random variable by definition, is called a **sample value** and is denoted by x . Thus the sample value can be expressed as $x = X(\omega)$ ($\omega \in \Omega$) and regarded as a point in the sample space (**sample point**). The basic underlying structure which determines the probability distribution is the set Ω , which we can view as describing the physical structure of the observed phenomena, but statistical procedures are always carried out through the observations of samples, and Ω itself is often disregarded. The 1-dimensional probability distribution Φ (the n -dimensional probability distribution Φ_n determined by X) is called the **population distribution** in the 1-dimensional (n -dimensional) sample space, since it is induced from the probability measure on (Ω, \mathcal{B}) .

A **statistic** Y is a random variable expressed as $Y = f(X)$, where f is a \dagger measurable function from the sample space $(\mathbf{R}^n, \mathcal{B}^n, \Phi_n)$ into a measurable space $(\mathbf{R}, \mathcal{B}^1)$. The value of the statistic Y corresponding to a sample value x of the sample X is denoted by $y = f(x)$.

When we deal with a statistical problem we often have no exact knowledge of the population distribution $\Phi(\Phi_n)$ except that it belongs to a family $\mathcal{P} = \{P_\theta | \theta \in \Theta\}$ of probability measures on $\mathcal{B}^1(\mathcal{B}^n)$. We call θ the **parameter** of the probability distribution and Θ the **parameter space**. The typical cases described in this section can be extended as follows: (1) The distribution Φ may be an r -dimensional probability distribution. In this case a sample of size n induces an nr -dimensional sample space. (2) Random variables X_1, \dots, X_n , being mutually independent, may not have identical distributions. (3) Random variables X_1, \dots, X_n may not be mutually independent. In both cases (2) and (3) the sample space is of the form $(\mathbf{R}^n, \mathcal{B}^n, \Phi_n)$, but n may not be the sample size itself, nor Φ_n be the direct product of n copies of identical 1-dimensional components. (4) The most general sample space is expressed as a

certain measurable space $(\mathcal{X}, \mathcal{A})$ and a family $\mathcal{P} = \{P_\theta | \theta \in \Theta\}$ of probability measures on \mathcal{A} .

A **statistic**, in general, is a random variable expressed as $Y = f(X)$ by a measurable function f defined on a sample space $(\mathcal{X}, \mathcal{A})$ taking values in another measurable space $(\mathcal{Y}, \mathcal{C})$. When $(\mathcal{Y}, \mathcal{C})$ is $(\mathbf{R}, \mathcal{B}^1)$ or $(\mathbf{R}^n, \mathcal{B}^n)$, $Y = f(X)$ is accordingly called a **1-dimensional** or **n -dimensional statistic**.

C. Population and Sample Characteristics in the 1-Dimensional Case

In a 1-dimensional probability space $(\mathbf{R}, \mathcal{B}^1, P_0)$ the following quantities, called **population characteristics**, are used to characterize the population distribution P_0 : Letting $F(z) = P_0((-\infty, z])$ be the \dagger distribution function of P_0 , we use the **population mean** $\mu = \int z dF(z)$; the **population variance** $\sigma^2 = \int (z - \mu)^2 dF(z)$; the **population standard deviation** $\sigma (\geq 0)$; the **population moment of order k** $\mu'_k = \int z^k dF(z)$ ($\mu'_1 = \mu$); the **kurtosis** μ_4/σ^4 ; the **coefficient of excess** $(\mu_4/\sigma^4) - 3$; the **skewness** μ_3/σ^3 ; the **α -quantile** or **100 α %-point m** satisfying $F(m-0) \leq \alpha \leq F(m+0)$; the **median**, which is the 50%-point; the **first and third quartiles**, which are the 25%-point and 75%-point, respectively; the **range**, which is the third quartile minus the first quartile; and the **mode**, which is the value or values of z for which $dF(z)/dz$ attains its maximum.

Sometimes the kurtosis and others are called **population kurtosis**, etc. Here the word "population" is used when it is desirable to distinguish population characteristics from the sample characteristics defined in 341 Probability Measures.

Let $x = (x_1, \dots, x_n)$ be a point of an n -dimensional sample space (a sample value). Corresponding to each 1-dimensional Borel set A , the number of components of x that belong to A is called the **frequency** of A in the sample value $x = (x_1, \dots, x_n)$, and (frequency)/ n is called the **relative frequency** of A . If we take $A = (-\infty, z]$ and regard its relative frequency $F_x(z)$ as a function of z , it becomes a \dagger distribution function for every $x \in \mathbf{R}^n$, called the **empirical distribution function** based on x .

Various characteristics can be defined from the empirical distribution function in exactly the same way as population characteristics are derived from a population distribution function. These are called **sample characteristic values** and can be expressed as functions of x_1, \dots, x_n .

Assuming that $x = (x_1, \dots, x_n)$ is a sample value of a sample $X = (X_1, \dots, X_n)$, the statistic obtained by substituting X for x in the function denoting a sample characteristic value is

called a **sample characteristic** and given the same name as the corresponding population characteristic, except that the word "population" is replaced by the word "sample." A sample characteristic is a function of random variables. Hence it is also a random variable, and the problem of deriving its probability distribution from the assumed population distribution is called that of sampling distribution (→ 374 Sampling Distributions). Thus we define the **sample mean** $\bar{X} = \sum_{i=1}^n X_i/n$; the **sample variance** $\sum_{i=1}^n (X_i - \bar{X})^2/n$ (sometimes $\sum_{i=1}^n (X_i - \bar{X})^2/(n-1)$ is taken as the sample variance); the **sample standard deviation**

$$\sqrt{\sum_{i=1}^n (X_i - \bar{X})^2/n},$$

which is the positive square root of the sample variance; the **sample mode**, which is the value taken by the largest number of X_i ; and the **sample moment of order k** $\sum_{i=1}^n (X_i - \bar{X})^k/n$.

Among other statistics of frequent use are the **order statistic**, i.e., the set of values of X_1, \dots, X_n arranged in order of magnitude and usually denoted by $X_{(1)} < X_{(2)} < \dots < X_{(n)}$. Various other statistics are defined in terms of order statistics: the **sample median** $X_{med} = X_{((n+1)/2)}$ for odd n and $=(X_{(n/2)} + X_{((n/2)+1)})/2$ for even n , the **sample range** $R = \max X_i - \min X_i = X_{(n)} - X_{(1)}$, and so on. The empirical distribution function $F_x(z)$ or its standardized form $S_x(z) = \sqrt{n}\{F_x(z) - F(z)\}$ can also be considered to be a function of the order statistics, and hence is a statistic taking values in the space of functions of a real variable. So is the **empirical characteristic function**

$$\phi_x(t) = \int \exp(itz) dF_x(z) = \sum_j \exp(itx_{(j)})/n.$$

In a sequence of Bernoulli trials, a set of successive components with an identical value is called a **run**. For example, (01100010) has a run of 0 of the length 3 and a run of 1 of the length 2.

Among the statistics listed in the previous paragraphs, the order statistic is an n -dimensional statistic and all others are 1-dimensional.

D. Other Cases

Let $(\mathbf{R}^2, \mathcal{B}^2, P_0)$ be a 2-dimensional probability space with a 2-dimensional population distribution P_0 , and let (X_1, \dots, X_n) ($X_i = (U_i, V_i)$) be a random sample of size n from P_0 . In this case also, the population characteristics for the marginal distributions of U_i and V_i and sample characteristics for (U_1, \dots, U_n) and (V_1, \dots, V_n) are defined as in Section C.

As an index for association between U_i and

V_i the **population covariance** $\int (u - \mu_{(1)})(v - \mu_{(2)}) dF(u, v)$ of U_i and V_i and the **population correlation coefficient**, which is equal to (population covariance)/ $\sigma_{(1)}\sigma_{(2)}$, are defined. Here $F(u, v)$ is the joint distribution function of U_i and V_i , $\mu_{(1)}$ and $\mu_{(2)}$ are the respective population means of U_i and V_i , and $\sigma_{(1)}$ and $\sigma_{(2)}$ are the respective standard deviations. As corresponding sample characteristics, we have the **sample covariance** $\sum_{i=1}^n (U_i - \bar{U})(V_i - \bar{V})/n$ of (U_1, \dots, U_n) and (V_1, \dots, V_n) and the **sample correlation coefficient**

$$\frac{\sum_{i=1}^n (U_i - \bar{U})(V_i - \bar{V})}{\left(\sum_{i=1}^n (U_i - \bar{U})^2\right)^{1/2} \left(\sum_{i=1}^n (V_i - \bar{V})^2\right)^{1/2}},$$

where $\bar{U} = \sum_{i=1}^n U_i/n$ and $\bar{V} = \sum_{i=1}^n V_i/n$.

Similarly, statistics of the samples from a population of k -dimensional distribution ($k \geq 3$) can be defined (→ 280 Multivariate Analysis). More generally, in statistical inference we encounter samples where observed values may not be mutually independent or identically distributed, but have more complicated probability structures. Statistics as functions of such samples are also considered.

E. General Properties of Statistics

The general theory of statistics has been studied in a measure-theoretic framework. $(\mathcal{X}, \mathcal{A}, \mathcal{P})$ is called a **statistical structure**, where $(\mathcal{X}, \mathcal{A})$ is a measurable space and \mathcal{P} is a family of probability measures on $(\mathcal{X}, \mathcal{A})$. A σ -subfield \mathcal{B} of \mathcal{A} (hereafter abbreviated σ -field) is called **sufficient** for \mathcal{P} if for any $A \in \mathcal{A}$ there exists a \mathcal{B} -measurable conditional probability of A independent of $P_\theta \in \mathcal{P}$, that is, a \mathcal{B} -measurable function $\phi_A(x)$ satisfying

$$P_\theta(A \cap B) = \int_B \phi_A(x) dP_\theta(x)$$

for all $P_\theta \in \mathcal{P}$ and $B \in \mathcal{B}$.

For any two σ -fields \mathcal{B}_1 and \mathcal{B}_2 , the notation $\mathcal{B}_1 \subset \mathcal{B}_2[\mathcal{P}]$ means that to each set A_1 in \mathcal{B}_1 there corresponds an A_2 in \mathcal{B}_2 satisfying $P_\theta((A_1 - A_2) \cup (A_2 - A_1)) = 0$ for all $P_\theta \in \mathcal{P}$. When the reverse relation $\mathcal{B}_2 \subset \mathcal{B}_1[\mathcal{P}]$ also holds, we write $\mathcal{B}_1 = \mathcal{B}_2[\mathcal{P}]$.

For a statistic t which is a measurable function from $(\mathcal{X}, \mathcal{A})$ to $(\mathcal{Y}, \mathcal{C})$, $\mathcal{B}(t) = \{B \mid B \in \mathcal{A}, t(B) \in \mathcal{C}\}$ is a σ -field and is called the σ -field induced by t . If $\mathcal{B}(t)$ is sufficient for \mathcal{P} , t is said to be sufficient for \mathcal{P} . Since sufficiency of a statistic means that of a σ -field, we consider only sufficiency of a σ -field.

\mathcal{B} is called **necessary** if for any sufficient \mathcal{B}_0 we have $\mathcal{B} \subset \mathcal{B}_0[\mathcal{P}]$. A necessary and sufficient σ -field is called a **minimal sufficient σ -field**. A

necessary and sufficient statistic is also called a **minimal sufficient statistic**. Such a statistic does not always exist; \mathcal{B}_2 containing a sufficient \mathcal{B}_1 is not always sufficient.

\mathcal{B} is said to be **complete** if for every \mathcal{B} -measurable integrable function φ , $\int_X \varphi(x) dP_\theta(x) = 0$ for all $P_\theta \in \mathcal{P}$ implies $P_\theta(\{x | \varphi(x) \neq 0\}) = 0$ for all $P_\theta \in \mathcal{P}$. \mathcal{B} is said to be **boundedly complete** if for every bounded \mathcal{B} -measurable φ , $\int_X \varphi(x) dP_\theta(x) = 0$ for all $P_\theta \in \mathcal{P}$ implies $P_\theta(\{x | \varphi(x) \neq 0\}) = 0$ for all $P_\theta \in \mathcal{P}$. When $\mathcal{B}(t)$ is (boundedly) complete, t is called (boundedly) complete. If $\mathcal{B}_1 \subset \mathcal{B}_2$ and \mathcal{B}_2 is (boundedly) complete, \mathcal{B}_1 is also (boundedly) complete. If \mathcal{B}_1 is (boundedly) complete and sufficient and \mathcal{B}_2 is minimal sufficient, we have $\mathcal{B}_1 = \mathcal{B}_2[\mathcal{P}]$.

F. Dominated Statistical Structure

When all $P_\theta \in \mathcal{P}$ are absolutely continuous with respect to a σ -finite measure λ on \mathcal{A} , then $(\mathcal{X}, \mathcal{A}, \mathcal{P})$ is said to be a **dominated** statistical structure and \mathcal{P} is said to be a dominated family of probability distributions. In this case, P_θ has the density $f_\theta(x) = dP_\theta/d\lambda$ with respect to λ by the Radon-Nikodym theorem. If \mathcal{A} is separable, \mathcal{P} is a separable metric space with respect to the metric $\rho(P_{\theta_1}, P_{\theta_2}) = \sup_{B \in \mathcal{A}} |P_{\theta_1}(B) - P_{\theta_2}(B)|$. There exists a countable subset $\mathcal{P}' = \{P_{\theta_1}, P_{\theta_2}, \dots\}$ of \mathcal{P} such that $P_\theta(N) = 0$ for all $P_\theta \in \mathcal{P}'$ implies $P_\theta(N) = 0$ for all $P_\theta \in \mathcal{P}$. If we put $\lambda_0 = \sum_i c_i P_{\theta_i}$, $c_i > 0$, $\sum_i c_i = 1$, λ_0 dominates \mathcal{P} , and if \mathcal{B} is sufficient for \mathcal{P} we can choose a \mathcal{B} -measurable version of $dP_\theta/d\lambda_0$. Conversely, if there exists a σ -finite measure λ such that we can choose a \mathcal{B} -measurable version of $dP_\theta/d\lambda$ for all $P_\theta \in \mathcal{P}$, then \mathcal{B} is sufficient.

If \mathcal{P} is dominated by a σ -finite λ , \mathcal{B} is sufficient if and only if there exist a \mathcal{B} -measurable g_θ and an \mathcal{A} -measurable h independent of θ satisfying

$$\frac{dP_\theta}{d\lambda} = g_\theta h \text{ a.e. } (\mathcal{A}, \lambda) \text{ for all } P_\theta \in \mathcal{P}.$$

This is called **Neyman's factorization theorem**.

With a dominated statistical structure, there exists a minimal sufficient σ -field, and a σ -field containing a sufficient σ -field is also sufficient.

We say that a σ -field \mathcal{B} is **pairwise sufficient** for \mathcal{P} if it is sufficient for every pair $\{P_{\theta_1}, P_{\theta_2}\}$ of measures in \mathcal{P} . A necessary and sufficient condition for \mathcal{B} to be sufficient for a dominated set \mathcal{P} is that \mathcal{B} be pairwise sufficient for \mathcal{P} .

Recently, a more general statistical structure has been studied. Put $\mathcal{A}_e(\mu) = \{A | A \in \mathcal{A}, \mu(A) < \infty\}$. A measure μ on \mathcal{A} is said to be a localizable measure if there exists $\text{ess-sup } \mathcal{F}(\mu)$ for any subfamily $\mathcal{F} \subset \mathcal{A}_e(\mu)$, that is, if there exists a set $E \in \mathcal{A}$ such that $\mu(A - E) = 0$ holds

for all $A \in \mathcal{F}$, and $\mu(A - S) = 0$ for all $A \in \mathcal{F}$ implies $\mu(E - S) = 0$. A σ -finite measure is localizable. A measure μ is said to have the **finite subset property** if for any A satisfying $0 < \mu(A) < \infty$, there exists a $B \subset A$ satisfying $0 < \mu(B) < \infty$. A statistical structure $(\mathcal{X}, \mathcal{A}, \mathcal{P})$ is said to be **weakly dominated** if \mathcal{P} is dominated by a localizable measure μ with the finite subset property and a density $dP_\theta/d\mu$ exists for all $P_\theta \in \mathcal{P}$. In this case a minimal sufficient σ -field exists, and a pairwise sufficient σ -field is sufficient. For example, let $\mathcal{A} = 2^{\mathcal{X}}$ and \mathcal{P} be the set of all discrete probability measures on \mathcal{A} . \mathcal{P} is weakly dominated by the counting measure μ which is localizable on \mathcal{A} .

The order statistic is sufficient if \mathcal{P} is dominated, X_1, \dots, X_n are mutually independent and identically distributed random variables with $\mathcal{X} = \mathbf{R}^n$, and each $P_\theta \in \mathcal{P}$ is invariant under every permutation of the components of the points $x = (x_1, \dots, x_n)$ in \mathcal{X} . Moreover, the order statistic is complete if \mathcal{P} is large enough. For example, we have the following theorem: The order statistic is complete if every P_θ^0 (the component of P_θ on $\mathcal{B}_0 \subset \mathcal{B}^1$, $\theta \in \Theta$) is absolutely continuous with respect to the Lebesgue measure l on \mathbf{R} and $\{P_\theta^0 | \theta \in \Theta\}$ contains all P_θ^0 for which $g(z) = dP_\theta^0/dl$ is constant on some finite disjoint intervals in $\mathcal{X}_0 \subset \mathbf{R}$. A similar result holds for discrete distributions.

We call θ a **selection parameter** when $f_\theta(x) = c(\theta)\chi_{E_\theta}(x)h(x)$, where $h(x)$ is a positive \mathcal{B} -measurable function, $\chi_{E_\theta}(x)$ is the indicator function of a set $E_\theta \in \mathcal{B}$, and $c(\theta)$ is a constant depending on θ . Here θ determines the carrier E_θ of $f_\theta(x)$ but does not essentially affect the functional form of $f_\theta(x)$. A necessary and sufficient statistic is given by $t^*(x) = \bigcap \{E_\theta | E_\theta \ni x, P_\theta \in \mathcal{P}\}$. Here the class of sets of the form given in the right-hand side of this expression is taken as \mathcal{C} , and we set $\mathcal{C} = \{C | C \subset \mathcal{Y}, t^{*-1}(C) \in \mathcal{B}\}$. We call $t^*(x)$ the **selection statistic**. Two examples follow.

(I) [†]Uniform distributions. Let $\Theta = \{(\alpha, \beta) | -\infty < \alpha < \beta < \infty\}$, $\mathcal{X}_0 = \mathbf{R}$, P_θ^0 be the uniform distribution on (α, β) , and $X = (X_1, \dots, X_n)$ be a random sample of size n having P_θ^0 as its population distribution. Then $E_\theta = \{x | \alpha \leq \min_i x_i \leq \max_i x_i \leq \beta\}$ and $f_\theta(x) = (\beta - \alpha)^{-n} \chi_{E_\theta}(x)$. If we put $t(x) = (\min_i x_i, \max_i x_i)$, $\mathcal{Y} = \mathbf{R}^2$, and $\mathcal{C} =$ the set of all Borel sets of \mathbf{R}^2 , it follows that $t(x) = t^*(x)[\mathcal{P}]$, where $t^*(x)$ is the selection statistic. Hence $t(x)$ itself is necessary and sufficient.

(II) [†]Exponential distributions. Put $\Theta = (-\infty, \infty)$, $\mathcal{X}_0 = \mathbf{R}$, and

$$g_\theta(z) = \begin{cases} \alpha e^{-\alpha(z-\theta)}, & z \geq \theta, \\ 0, & z < \theta, \end{cases}$$

where α is a known constant, and let $X = (X_1, \dots, X_n)$ be a random sample of size n

having a population distribution with density function $g_\theta(z)$. Then

$$E_\theta = \left\{ x \mid \theta \leq \min_i x_i \right\},$$

$$f_\theta(x) = \alpha^n e^{n\alpha\theta} \chi_{E_\theta}(x) \exp\left(-\alpha \sum_{i=1}^n x_i\right).$$

If we put $t(x) = \min_i x_i$ and let $t^*(x)$ be the selection statistic, it follows that $t(x) = t^*(x) [\mathcal{P}]$, and $t(x)$ is necessary and sufficient. If $\Theta = \{(\alpha, \theta) \mid 0 < \alpha < \infty, -\infty < \theta < \infty\}$, then $t(x) = \{\min_i x_i, \sum_i x_i\}$ is a necessary and sufficient statistic.

G. Exponential Families of Distributions

A dominated \mathcal{P} is called an **exponential family of distributions** if and only if $f_\theta(x) = dP_\theta/d\lambda$ can be expressed in the form

$$f_\theta(x) = \exp\left(\sum_{j=1}^k s_j(x)\alpha_j(\theta) + \alpha_0(\theta) + s_0(x)\right), \quad x \in \mathcal{X}, \theta \in \Theta, \quad (1)$$

where the $s_j(x)$ ($j = 0, 1, \dots, k$) are real-valued \mathcal{B} -measurable functions and the $\alpha_j(\theta)$ ($j = 0, 1, \dots, k$) are constants depending on θ . If there exists a sufficient statistic for \mathcal{P} that is not equivalent to but is in a certain sense simpler than the sample itself or the order statistics, then it can be shown under some regularity conditions that \mathcal{P} must be an exponential family. The following theorem provides an instance of the hypotheses that guarantee such a conclusion: Let X be a sample from a 1-dimensional probability space $(\mathcal{X}_0, \mathcal{B}_0, P_\theta^0)$ with P_θ^0 the population distribution, where \mathcal{X}_0 is a finite or infinite interval in \mathbf{R} and \mathcal{B}_0 is the class of all Borel sets. Let l denote the Lebesgue measure. Assume that $\{P_\theta^0\}$ is dominated by l and $g_\theta(z) = dP_\theta^0/dl$ is greater than a positive constant and continuously differentiable in z on \mathcal{X}_0 . Assume further that there exists a sufficient statistic $t(x)$ with the property that for each open subset B of \mathcal{X} ($\subset \mathbf{R}^n$) and λ -null set N there are two points $x \notin x'$ in $B - N$ such that $t(x) \neq t(x')$. Then \mathcal{P} is an exponential family, and the k given in (1) is less than n . Similar results are known also for cases where X_1, \dots, X_n are not identically distributed.

It is evident from the construction of a necessary and sufficient statistic that the statistic $t(x) = (s_1(x), \dots, s_k(x))$, where the $s_j(x)$ are those appearing in (1), is sufficient for an exponential family and necessary if $\alpha_1(\theta), \dots, \alpha_k(\theta)$ are linearly independent. If $\{(\alpha_1(\theta), \dots, \alpha_k(\theta)) \mid \theta \in \Theta\}$ contains a k -dimensional interval, $t(x)$ is complete. The distribution of $t(x)$ is of exponential type. When X_1, \dots, X_n are mutu-

ally independent with a common distribution of exponential type, the distribution of $X = (X_1, \dots, X_n)$ is of exponential type, and vice versa. The family (1) of distributions is a special form of * Pólya-type distributions, and various distributions given in (III)–(VII) below are written in this form. In the following examples, for a sample of size n from the specified distribution, $f_\theta(x)$ is the density with respect to Lebesgue measure in (III), (IV), and (V) and to counting measure in (VI) and (VII) (\rightarrow Appendix A, Table 22).

(III) * Normal distributions $N(\mu, \sigma^2)$, $\mathcal{X}_0 = (-\infty, \infty)$.

$$f_\theta(x) = \exp\left(-\left(\sum_{i=1}^n x_i^2\right) \frac{1}{2\sigma^2} + \left(\sum_{i=1}^n x_i\right) \frac{\mu}{\sigma^2} - \frac{n\mu^2}{2} - n \log \sigma - \frac{n}{2} \log 2\pi\right).$$

(IV) * Γ -distributions $\Gamma(p, \sigma)$, $\mathcal{X}_0 = (0, \infty)$.

$$f_\theta(x) = \exp\left(\left(p-1\right) \sum_{i=1}^n \log x_i - \frac{1}{\sigma} \sum_{i=1}^n x_i - np \log \sigma - n \log \Gamma(p)\right).$$

(V) * Exponential distributions $e(\mu, \sigma)$, $\mathcal{X}_0 = (\mu, \infty)$.

$$f_\theta(x) = \exp\left(-\left(\sum_{i=1}^n x_i\right) \frac{1}{\sigma} - n \log \sigma + n \frac{\mu}{\sigma}\right).$$

(VI) * Binomial distributions $Bin(N, p)$, $\mathcal{X}_0 = \{0, 1, \dots, N\}$.

$$f_\theta(x) = \exp\left(\left(\sum_{i=1}^n x_i\right) \log \frac{p}{1-p} + nN \log(1-p) - \sum_{i=1}^n \log \binom{N}{x_i}\right).$$

(VII) * Poisson distributions $P(\lambda)$, $\mathcal{X}_0 = \{0, 1, 2, 3, \dots\}$.

$$f_\theta(x) = \exp\left(\left(\sum_{i=1}^n x_i\right) \log \lambda - \sum_{i=1}^n \log(x_i!) - n\lambda\right).$$

H. Ancillary Statistics

A statistic $t(x)$ is called an **ancillary statistic** when for every element A in $\mathcal{A}(t)$, $P_\theta(A)$ is independent of θ , or in other words, when the distribution of $t(x)$ is independent of θ . A sufficient condition for a statistic to be ancillary is that it is independent of some sufficient statistic. Conversely, an ancillary statistic is independent of all boundedly complete sufficient statistics.

I. Invariant Statistics

Suppose that we are given groups of one-to-one measurable transformations G and \bar{G} on

\mathcal{X} and Θ , respectively. Suppose also that we are given a homomorphism $g \rightarrow \bar{g}$ from G to \bar{G} satisfying $P_{\theta}(g^{-1}B) = P_{\bar{g}\theta}(B)$. In this case $\mathcal{P} = \{P_{\theta} | \theta \in \Theta\}$ is called **G-invariant**. If \bar{G} is transitive, there exists a fixed element θ_0 of Θ that is sent to an arbitrary θ by an element g of G . In this case, θ is called a **transformation parameter**. In particular, if $\Theta = \mathbf{R}$, X is a random sample from a population distribution, and $P_{\theta}(B) = P_{\theta_0}(B - \theta)$, where $B - \theta = \{x | (x_1 + \theta, \dots, x_n + \theta) \in B\}$, then θ is called a **location parameter**. When $\Theta = (0, \infty)$ and $P_{\theta}(B) = P_1(B/\theta)$, where $B/\theta = \{x | (\theta x_1, \dots, \theta x_n) \in B\}$, θ is called a **scale parameter**. Now assume that θ is a combination of these two kinds of parameters such that $\theta = (\alpha, \beta)$ ($-\infty < \alpha < \infty, 0 < \beta < \infty$) and $P_{\theta}(B) = P_{\theta_0}((B - \alpha)/\beta)$, where $\theta_0 = (0, 1)$. Then if \mathcal{P} is an exponential family, (1) of Section G can be written as

$$g_{\alpha}(z) = \frac{dP_{\theta}^0}{d\alpha} = \frac{1}{\beta} \exp\left(\sum_{j=0}^m k_j \left(\frac{z - \alpha}{\beta}\right)^j\right),$$

where the k_j ($j=0, 1, \dots, m$) are constants.

We call $t(x)$ an **invariant statistic** with respect to a general transformation group G when $t(gx) = t(x)$ for all $g \in G$ and $x \in \mathcal{X}$. An invariant statistic is said to be **maximal invariant** with respect to G if, for $t(x) = t(x')$, there exists a $g \in G$ such that $x = gx'$. If t_0 is maximal invariant with respect to G , a statistic t is invariant under G if and only if $t_0(x) = t_0(x')$ implies $t(x) = t(x')$.

When \mathcal{P} is G -invariant, a set A ($\in \mathcal{A}$) is called G -invariant if $gA = A$ for all $g \in G$. We denote by \mathcal{A}^0 the set of all G -invariant sets in \mathcal{A} . \mathcal{A}^0 is clearly a σ -field. A set A ($\in \mathcal{A}$) is called **almost G -invariant** if $gA = A$ (\mathcal{A}, \mathcal{P}) for all $g \in G$. We denote by \mathcal{A}^* the σ -field consisting of all almost G -invariant sets. If \mathcal{P} is G -invariant, \mathcal{B} is sufficient for \mathcal{P} , $g\mathcal{B} = \mathcal{B}$ for all $g \in G$, and moreover, $\mathcal{B}^0 = \mathcal{B}^*$ (\mathcal{A}, \mathcal{P}), then \mathcal{B}^0 is a sufficient σ -subfield of \mathcal{A}^0 , where $\mathcal{B}^0 = \mathcal{B} \cap \mathcal{A}^0$ and $\mathcal{B}^* = \mathcal{B} \cap \mathcal{A}^*$.

J. Various Definitions of Sufficiency

There are many different definitions of sufficiency, and the relations among them have been investigated. A σ -field \mathcal{B} is called **decision-theoretically sufficient** or **D-sufficient** if for a given \mathcal{A} -measurable decision function δ there exists a \mathcal{B} -measurable decision function δ' such that

$$\int_x \delta(x, E) dP_{\theta}(x) = \int_x \delta'(x, E) dP_{\theta}(x)$$

for all $E \in \mathcal{D}$, $P_{\theta} \in \mathcal{P}$, where a decision space (D, \mathcal{D}) is quite arbitrary. \mathcal{B} is called **test sufficient** if for any given \mathcal{A} -measurable test function φ , there exists a \mathcal{B} -measurable test func-

tion φ' satisfying $E_{\theta}(\varphi) = E_{\theta}(\varphi')$ for all $P_{\theta} \in \mathcal{P}$. Let (Θ, \mathcal{C}) be a measurable space of parameter θ and $\hat{\Theta}$ be the set of all probability measures on \mathcal{C} . Moreover we assume that $P_{\theta}(B)$ is \mathcal{C} -measurable as a function of θ for any fixed $B \in \mathcal{A}$. For any $\xi \in \hat{\Theta}$, we define λ_{ξ} by

$$\lambda_{\xi}(A \times C) = \int_C P_{\theta}(A) d\xi(\theta), \quad A \in \mathcal{A}, C \in \mathcal{C}.$$

We denote by $\tilde{\lambda}_{\xi}$ the extension of λ_{ξ} to $\mathcal{A} \times \mathcal{C}$. \mathcal{B} is said to be **Bayes sufficient** if

$$E_{\tilde{\lambda}_{\xi}}(I_{\mathcal{X} \times \mathcal{C}} | \mathcal{A} \times \mathcal{C}) = E_{\tilde{\lambda}_{\xi}}(I_{\mathcal{X} \times \mathcal{C}} | \mathcal{B} \times \mathcal{C})$$

for all $\xi \in \hat{\Theta}$, $C \in \mathcal{C}$, that is, the a posteriori distribution on Θ given \mathcal{A} coincides with that given \mathcal{B} for any a priori ξ . When \mathcal{P} is dominated, these definitions coincide with the classical definition of sufficiency. Generally, a D-sufficient σ -field contains at least one sufficient σ -field. A σ -field containing a sufficient σ -field is Bayes sufficient. Hence Bayes sufficiency follows from D-sufficiency and from classical sufficiency. If a D-sufficient σ -field is separable it is sufficient.

The notion of **prediction sufficiency** or **adequacy** was defined by Skibinsky [10]. Let (X, Y) be a pair of random variables defined over the probability space $(\mathcal{X} \times \mathcal{Y}, \mathcal{A} \times \mathcal{B}, P_{\theta})$. We suppose that X is the sample to be observed, and Y is (are) the value(s) of future observation(s) about which we are to make prediction(s) based on X . X and Y have joint probability distribution with an unknown parameter. A statistic $T = T(X)$ or a subfield \mathcal{C} of \mathcal{A} is said to be prediction sufficient or adequate if (a) given T , X and Y are conditionally independent (or given \mathcal{C} , \mathcal{A} and \mathcal{B} are conditionally independent or Markov) and (b) T is sufficient for X (\mathcal{C} is sufficient for \mathcal{A}). It was proved that in any form of prediction on Y , we may restrict ourselves to the class of procedures that are functions of T (or are \mathcal{C} -measurable).

397 (XVIII.1) Statistical Data Analysis

A. Statistical Data

Statistical data analysis is comprised of a collection of mathematical methods whereby we can deal with numerical data obtained through observations, measurements, surveys, or experiments on the “objective” world. The purpose of statistical analysis is to extract the relevant information from that numerical data pertinent to the subject under consideration. The nature and the properties of the subject and also the purpose of the analysis may vary greatly. The subject may be physical, biological, chemical, sociological, psychological, economic, etc. in nature, and the purpose of the analysis can be purely scientific, as well as technological, medical, or managerial. Because of the great diversity of statistical data, the methods of statistical data analysis and the manner of application should differ greatly from situation to situation; we cannot expect a single unified system of methods to be applicable to all cases. Nevertheless, we have several formal methods of statistical analysis that are more or less mutually related and have been successfully applied to most, if not all, statistical data.

Statistical data can be classified into several types according to a few criteria: according to the property of each observation or measurement, they can be either **quantitative** or **qualitative**; according to whether only one observation is made on each object under investigation or many observations on the same object, they can be either **univariate** or **multivariate**; and according to whether the observations are made at one time or consecutively in the course of time, they may be either

cross sectional or **time series**. Each different type of statistical data requires a different type of procedure (→ 280 Multivariate Analysis, 421 Time Series Analysis).

B. Frequency Distributions and Histograms

Statistical data have the simplest structure when they consist of a collection of observations made on an aggregate of objects supposedly of the same kind. Such an aggregate is usually called a **population**, and the number of its members (its size) is denoted by N . When the data are qualitative or **categorical**, each member of the population is classified into several types according to some criteria, the data consist of the numbers of the members of the population classified into each of the categories. Such numbers are usually called **frequencies**, and the set of frequencies is called the **frequency distribution**.

When the data are quantitative and univariate, one quantitative attribute of each member of the population is observed, and the results are given as a set of N real numbers (x_1, x_2, \dots, x_N) . When N is large, as is usually expected, it is necessary to summarize these results in some manner. One common method is to tabulate the frequency distribution: We define a certain number of intervals $(a_{i-1}, a_i]$, $i = 1, \dots, K$, $a_0 < a_1 < \dots < a_K$, $a_0 \leq \min x_i$, $\max x_i \leq a_K$; and we count the numbers of those x 's falling within each of the intervals and tabulate those numbers or frequencies f_i , $i = 1, 2, \dots, K$. Frequency distribution is often represented in the form of a **histogram**, where the endpoints of the intervals are marked on the horizontal axis, and above each interval a rectangle of area proportional to the frequency for the interval is drawn. It is usually recommended that the widths of the intervals in the frequency distribution be equal, especially when it is to be represented by a histogram. It is, however, often impossible or impractical to do so, and sometimes a logarithmic or other functional scale is used in the abscissa of the histogram; then it is desirable that the intervals of the transformed values are approximately of equal lengths. The number K of the intervals should also be of an appropriate magnitude, neither too large nor too small; K is often constrained by the size N of the population, the shape of the distribution, or other factors. Usually, K is chosen to be between 6 and 20.

From the frequency distribution, we obtain the **cumulative distribution** by associating with each endpoint a_i of the intervals the number F_i of x 's not greater than a_i , namely, $F_i = \sum_{j \leq i} f_j$. The curve obtained by connecting $K + 1$ points

of coordinates (a_i, F_i) , $i = 0, 1, \dots, K$, by linear segments is called the **cumulative distribution curve** (or **polygon**).

C. Characteristics of the Distribution

In order to summarize univariate quantitative data, various values are calculated from the values x_1, \dots, x_N . Such values are called **statistics** (singular, †statistic) and are used to characterize the distribution of the values. Various types of statistics characterize different aspects of the distribution:

(a) **Representative value or measure of location**: a value which is supposed to give the “representative,” “typical,” or “most common” value in the population. By far the most commonly used measure is the **mean** $\bar{x} = \sum_{i=1}^N x_i / N$. \bar{x} is sometimes called the **arithmetic mean**, and some other “means” are also calculated: especially when all the values are positive, the **geometrical mean** $\bar{x}_G = (\prod_i x_i^{1/N})$ or **harmonic mean** $\bar{x}_H = (\sum_i (1/x_i) / N)^{-1}$ may be calculated; more generally, for some monotone function $f(x)$ we can calculate the f -mean by $\bar{x}_f = f^{-1}(\sum_i f(x_i) / N)$, of which the geometric and the harmonic means are special cases. Another measure of location is the **median**, which is the value in the population located exactly in the middle of the ordering of the magnitudes; more precisely, if $x_{(1)} < x_{(2)} < \dots < x_{(N)}$ are the values in the population arranged according to their magnitudes, the median $x_{med} = x_{((N+1)/2)}$ for odd N , and $= \frac{1}{2}(x_{(N/2)} + x_{(N/2+1)})$ for even N . The **mode** is also sometimes used; this is defined as the value (usually the center) corresponding to the highest frequency.

(b) **The measure of variability or dispersion** shows how widely the values in the population vary. The most common measure is the **standard deviation**, which is defined by $s_x = \sqrt{\sum_i (x_i - \bar{x})^2 / N}$, and its square is called the **variance** V_x^2 . A similar measure is the **mean absolute deviation** $D_x = \sum_i |x_i - \bar{x}| / N$. Another type of a measure of dispersion is the **range** $R_x = \max x_i - \min x_i$, and the **interquartile range** $Q_x = x_{(3N/4)} - x_{(N/4)}$ and more generally the interquartile range $x_{(\alpha N)} - x_{((1-\alpha)N)}$ for some α . The ratio of the standard deviation to the mean is called the **coefficient of variation** (C. V. for short) and is used as a measure of relative variability when all the values in the population are positive.

(c) Characteristics often used to characterize the “shape” of distributions are the **moments** (around the origin) $m_k = N^{-1} \sum_i x_i^k$ and the **central moments** (moments around the mean) $M_k = N^{-1} \sum_i (x_i - \bar{x})^k$ for a positive integer k ; for a specific k these are called the k th moments. Central k th moments with odd k are equal to zero when the distribution is symmetric, i.e.,

when the histogram is symmetrically shaped. Hence the third moment or its ratio to the third power of the standard deviation s_x^3 is used as a measure of the asymmetry of a distribution; this is called the **skewness**. The fourth moment is large if there are some values which are far off from others and small when all values are concentrated; hence it tends to be large when the histogram has a rather sharp peak in the center and has a long tail in either direction or both, and tends to be small when the histogram is flat in the center and drops off sharply at both ends. Accordingly, the ratio M_4/V_x^2 is used as a measure of long-tailedness of the distribution; this ratio minus 3 is called the **kurtosis**.

D. Theoretical Frequency Distribution

When the observed values can be any real number (sometimes in an interval), the size of the population N is increased indefinitely, and the widths of the intervals are decreased to 0, the histogram is expected to approach a smooth curve. And in the limit when N is infinity, we can assume that the distribution is represented by a mathematically well-behaved function $f(x)$ and that the ratio of the numbers of those values in the population within the interval (a, b) to the size of the population approaches $\int_a^b f(x) dx$. Such a function $f(x)$ is called the **frequency function** or **density function**. Various types of functions have been proposed and used as “theoretical” frequency functions to approximate the actually observed frequency distributions. The most important is the **normal density function**

$$\varphi(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left\{-\frac{1}{2\sigma^2}(x-\mu)^2\right\}.$$

The following density functions most commonly appear in applications: the **gamma density**, $f(x) = x^{p-1} \exp(-x/a) / a^p \Gamma(p)$ for $x > 0$ and $= 0$ for $x \leq 0$; the **beta density**, $f(x) = x^{p-1} (1-x)^{q-1} / B(p, q)$ for $0 < x < 1$ and $= 0$ otherwise.

We can conceive of a population of infinite size with some density function; the term **theoretical distribution** is used to mean such a population with its density function, and more specifically the †normal distribution, etc. Such a population and associated density is often called a continuous distribution. For a theoretical distribution, the mean, variance, and moments are naturally defined by

$$\mu = \int x f(x) dx, \quad \sigma^2 = \int (x - \mu)^2 f(x) dx,$$

$$\mu_k = \int (x - \mu)^k f(x) dx, \quad \mu'_k = \int x^k f(x) dx.$$

It should, however, be noted that the mean, the variance, or the moments may not exist for particular distributions.

K. Pearson introduced a system of density functions defined as solutions of the differential equation

$$d \ln f(x)/dx = (A + Bx)/(C + Dx + Ex^2),$$

where A, B, \dots, E are constants. A distribution thus obtained is called a **Pearson distribution**. The normal, gamma, and beta distributions together with some other commonly used distributions, such as the t - and F -distributions, are Pearson distributions.

E. Measure of Concentration

When all the observed values are nonnegative in nature, we may sometimes require some measure of inequality or concentration of the distribution. For such a purpose we order the observed values according to their magnitudes and obtain $x_{(1)} \leq x_{(2)} \leq \dots \leq x_{(N)}$; we define $S_i = \sum_{j \leq i} x_{(j)}$ for $i = 1, \dots, N$, and $S_0 = 0$, plot $N + 1$ points $(S_i/S_N, i/N)$, $i = 0, 1, \dots, N$, and connect them by line segments. The graph thus obtained is called the **Lorentz curve** or the curve of concentration, and it connects the origin and the point $(1, 1)$. It lies below the 45° line, and if all the values are nearly equal the curve comes close to the 45° line, but if values are widely unequal, the curve comes close to the horizontal axis and suddenly jumps to the point $(1, 1)$. The area between the curve and the 45° line is called the **area of concentration**, and it is equal to one-fourth of the mean difference δ divided by the mean, where δ is defined by

$$\delta = \frac{1}{N^2} \sum_i \sum_j |x_i - x_j|.$$

$G = \delta/\bar{x}$ is called the **Gini coefficient of concentration** and is used as a measure of concentration or inequality of distribution. Other measures, including the coefficient of variation, are also used to represent the concentration.

F. Discrete Distributions

There are cases where the observed values are taken only from the nonnegative integers, e.g., the number of individual animals of a specific species in an area, of accidents during a specified time, etc. In such cases, when we increase the number of observations, the distribution does not approach one with a continuous density function but rather one with a certain theoretical discrete distribution. Among theoretical discrete distributions, the most commonly used are the **binomial distri-**

bution: $f_j = {}_n C_j p^j (1-p)^{n-j}$ for $0 \leq j \leq n$, and the **Poisson distribution:** $f_j = e^{-\lambda} \lambda^j / j!$ for $j = 0, 1, \dots$. The **hypergeometric distribution:** $f_j = {}_M C_j \cdot {}_{N-M} C_{n-j} / {}_N C_n$, for $\max(0, M + n - N) \leq j \leq \min(n, M)$, and the **negative binomial distribution:** $f_j = {}_{j+r-1} C_{r-1} p^r (1-p)^j$, $j = 0, 1, \dots$, are also often used.

For discrete distributions we can define moments by $\mu = \sum_j j f_j$ and $\mu_k = \sum_j (j - \mu)^k f_j$, and $\mu'_k = \sum_j j^k f_j$, $k = 2, 3, \dots$

G. Generating Functions and Cumulants

For a theoretical distribution with the density function $f(x)$, the **moment generating function** $M(\theta)$ is defined by $M(\theta) = \int e^{\theta x} f(x) dx$. When $M(\theta)$ is well defined in an open interval including the origin, the distribution has all k th moments, and it can be expanded as

$$M(\theta) = 1 + \mu'_1 \theta + \frac{1}{2!} \mu'_2 \theta^2 + \dots + \frac{1}{k!} \mu'_k \theta^k,$$

from which the term "moment generating function" is derived. When θ is replaced by it with real t , we have the **characteristic function** $\phi(t) = M(it)$, which can be expanded as

$$\phi(t) = 1 + \mu'_1(it) + \frac{1}{2!} \mu'_2(it)^2 + \dots + \frac{1}{k!} \mu'_k(it)^k + o(|t|^k)$$

if the distribution has moments up to the k th. The function $K(\theta) = \ln M(\theta)$ is called the **cumulant generating function**, and the coefficients κ_j in the expansion

$$K(\theta) = \kappa_1 \theta + \frac{\kappa_2}{2} \theta^2 + \dots$$

are called the **cumulants**. The k th cumulant κ_k is expressed as a polynomial of the moments of order not exceeding k ; thus

$$\kappa_1 = \mu'_1, \quad \kappa_2 = \mu'_2 - \mu_1^2, \quad \kappa_3 = \mu'_3 - 3\mu'_2 \mu'_1 + 2\mu_1^3, \quad \text{etc.}$$

For the normal distribution,

$$M(\theta) = \exp \left\{ \mu\theta + \frac{\sigma^2 \theta^2}{2} \right\};$$

hence

$$K(\theta) = \mu\theta + \frac{\sigma^2 \theta^2}{2},$$

and the k th cumulant for $k \geq 3$ is equal to 0. Cumulants are used as measures indicating whether the distribution is close to or different from the normal.

For discrete distributions, the moment generating function is defined as $M(\theta) = \sum e^{\theta j} f_j$, but the **probability generating func-**

tion $P(t) = \sum f_j t^j = M(\ln t)$, the **factorial moment generating function** $\tilde{M}(\theta) = P(\theta + 1)$, and the **factorial cumulant generating functions** $\tilde{K}(t) = \ln \tilde{M}(t)$ are also of use. The coefficient of t^j in the Maclaurin expansion of $\tilde{M}(t)$ is expressed as $\mu_{[k]}$ and called the **k th factorial moment**; it is equal to $\mu_{[k]} = \sum_j j(j-1)\dots(j-k+1)f_j$. That in the expansion of $\tilde{K}(t)$ is the **factorial cumulant**. The factorial cumulant $\kappa_{[k]}$ is expressed by the same polynomial in $\mu_{[k]}$ as κ_k is expressed in μ'_k . For the Poisson distribution, $M(\theta) = \exp \lambda(e^\theta - 1)$; hence $\tilde{K}(t) = \lambda t$ and it follows that the factorial cumulants $\kappa_{[k]}$ for $k \geq 2$ are all equal to zero if and only if the distribution is Poisson.

H. Bivariate Distribution

When two quantitative observations are obtained for each member of a population of size N , the results are given as N pairs of real numbers (x_i, y_i) , $i = 1, 2, \dots, N$. Such data are called **bivariate data** and the distribution, **bivariate distribution**. Those data can be illustrated as N points in a plane with coordinates (x_i, y_i) , and such an illustration is called a **scatter diagram**. In order to characterize a bivariate distribution, we often use **bivariate moments**

$$M_{k,l} = \frac{1}{N} \sum (x_i - \bar{x})^k (y_i - \bar{y})^l,$$

where \bar{x} and \bar{y} are the means of x and y , respectively; especially, the (1,1) moment $M_{1,1}$ is called the **covariance** and is denoted as $\text{Cov}(x, y)$. The most often used measure of the strength of the relation between x and y values is the **correlation coefficient** $r_{x,y} = \text{Cov}(x, y) / s_x s_y$, where s_x and s_y are the standard deviations of x and y . It is easily shown that $-1 \leq r_{x,y} \leq 1$, and when there exists a nearly linear relationship between x and y values, $r_{x,y}$ is close to either $+1$ or -1 according to whether the x and y values change in the same direction or in opposite directions. When there is no clear relationship between x and y , the correlation coefficient is close to zero, but it may not be a good measure of the relationship when x and y values are related nonlinearly.

A linear function $y = a + bx$ is called the **linear regression function** of y on x , for which the sum of the square distances $\sum_i (y_i - a - bx_i)^2$ is minimized. For the linear regression function the coefficients a and b are determined by $b = \text{Cov}(x, y) / s_x^2$ and $a = \bar{y} - b\bar{x}$, and b is called the **regression coefficient**. We have that $\sum_i (y_i - a - bx_i)^2 / \sum_i (y_i - \bar{y})^2 = 1 - r_{xy}^2$, i.e., that the square of the correlation coefficient is

equal to 1 minus the ratio of the variance of the residual $y_i - a - bx_i$ to that of y ; hence it is sometimes called the **coefficient of determination**. Similarly, the linear regression function of x on y is defined by $x = c + dy$, where $d = \text{Cov}(x, y) / s_y^2$ and $c = \bar{x} - d\bar{y}$. We have $bd = r_{xy}^2$, and $|1/d| = |b/r_{xy}^2| \geq |b|$.

We can tabulate the bivariate frequency distribution by splitting the range of x values into K intervals $(a_{i-1}, a_i]$, $i = 1, \dots, K$, and the range of y values into L intervals $(b_{j-1}, b_j]$, $j = 1, \dots, L$, and counting the number f_{ij} of cases for which $a_{i-1} < x \leq a_i$ and $b_{j-1} < y \leq b_j$. In contrast to the bivariate frequency distribution, the distributions of x and y values are called the **marginal distributions**.

I. Bivariate Density Function

As we did for the univariate distribution, we can consider the limiting shape of the bivariate frequency distribution when the size N of the population tends to infinity and define a continuous bivariate distribution with density function $f(x, y)$, with which the ratio of those members in the population with values (x, y) in a set S in a plane is given by $\iint_S f(x, y) dx dy$. The bivariate density function is also called the **joint density**, and then the density functions of x and y are called the **marginal density functions** and are given by $f_1(x) = \int f(x, y) dy$ and $f_2(y) = \int f(x, y) dx$. The joint moments of a continuous bivariate distribution are defined by $\mu_{k,l} = \iint (x - \mu_1)^k (y - \mu_2)^l f(x, y) dx dy$, where μ_1 and μ_2 are the means of x and y , respectively. The **joint moment generating function** is defined by $M(t_1, t_2) = \iint e^{t_1 x + t_2 y} f(x, y) dx dy$, and the cumulant generating function by $K(t_1, t_2) = \log M(t_1, t_2)$, from which the **joint cumulants**

$$\kappa_{k,l} = \frac{\partial^{k+l}}{\partial t_1^k \partial t_2^l} K(t_1, t_2) \Big|_{t_1=0, t_2=0}$$

are derived.

The **conditional density** of y given x is defined by $f(y|x) = f(x, y) / f_1(x)$, and the distribution with this density function is the **conditional distribution** of y given x ; this latter can be interpreted as the distribution of y of those members in the population with x values in the interval $(x, x + dx]$, where dx is small. The conditional density and the conditional distribution of x given y are similarly defined. The mean and the moments of the conditional distribution are called the **conditional mean** and the **conditional moments**. The conditional mean of y given x , considered as a function of x , is called the **regression function** of y on x .

By far the most important theoretical bivariate density is the **bivariate normal density**,

which is given by

$$f(x, y) = (2\pi\sigma_1\sigma_2\sqrt{1-\rho^2})^{-1} \times \exp \left\{ \frac{1}{2(1-\rho^2)} \left[\frac{(x-\mu_1)^2}{\sigma_1^2} + \frac{(y-\mu_2)^2}{\sigma_2^2} - 2\rho \frac{(x-\mu_1)(y-\mu_2)}{\sigma_1\sigma_2} \right] \right\},$$

for which the mean of x is μ_1 and that of y is μ_2 , the variances of x and y are σ_1^2 and σ_2^2 , respectively, and the covariance of x and y is equal to $\rho\sigma_1\sigma_2$. The bivariate normal distribution has several remarkable properties: All the k, l joint cumulants are equal to zero for $k + l \geq 3$; the marginal distributions of x and y are normal; the regression functions of y on x and x on y are both linear; the conditional distribution of y given x (and x given y) is normal and the conditional variance is constant; and the contours $f(x, y) = c$ for different values of c are equicentric ellipsoids.

J. Higher-Dimensional Data

When the data are of more than two dimensions, i.e., more than two observations are made on each of the objects, we designate the data by Nk -tuples of real numbers $(x_{i1}, x_{i2}, \dots, x_{ik}), i = 1, \dots, N (k \geq 3)$. Then we can calculate the moments of each of the variates and the joint moments, which are defined by

$$M_{k_1, k_2, \dots, k_k} = \frac{1}{N} \sum (x_{i1} - \bar{x}_1)^{k_1} (x_{i2} - \bar{x}_2)^{k_2} \dots (x_{ik} - \bar{x}_k)^{k_k}.$$

Also, we can arrange the variances and covariances in a symmetric matrix of order k , and we call it the **(variance-) covariance matrix**. A covariance matrix is easily shown to be non-negative definite. The determinant of the covariance matrix is called the **generalized variance**. The matrix with the (i, j) element equal to the correlation coefficient of the i th and the j th variates r_{ij} (r_{ii} is set equal to 1) is called the **correlation matrix** and is denoted by R . R is also nonnegative definite. If we denote the (i, j) cofactor of R by R_{ij} , the quantity defined by

$$R_{i|1, \dots, (i), \dots, k} = \sqrt{1 - |R|/R_{ii}}$$

is called the **multiple correlation coefficient** of the i th variate and all other variates; and

$$r_{ij|1, \dots, (i), \dots, (j), \dots, k} = -R_{ij}/\sqrt{R_{ii}R_{jj}}$$

is called the **partial correlation coefficient** of the i th and the j th variates given all other variates. The meaning of these coefficients will be elucidated below. A linear function $a_0 + a_1x_1 + a_2x_2 + \dots + a_{k-1}x_{k-1}$ is called the **linear**

regression function of x_k on x_1, \dots, x_{k-1} , when the coefficients a_1, \dots, a_{k-1} are so determined that the sum $Q = \sum_i (x_{ik} - a_0 - a_1x_{i1} - \dots - a_{k-1}x_{ik-1})^2$ is minimized. They are determined from the equation

$$C_{i1}a_1 + C_{i2}a_2 + \dots + C_{ik-1}a_{k-1} = C_{ik}, \quad (*)$$

$$i = 1, \dots, k-1,$$

with $a_0 = \bar{x}_k - a_1\bar{x}_1 - \dots - a_{k-1}\bar{x}_{k-1}$, where C_{ij} are the covariances. a_1, \dots, a_{k-1} thus determined are called the **regression coefficients** of x_k on x_1, \dots, x_{k-1} , and such a procedure is called the **method of least squares**. The equation (*) is called the **normal equation**. If we write $\hat{x}_{ik} = a_0 + a_1x_{i1} + \dots + a_{k-1}x_{ik-1}$, we have $Q = \sum (x_{ik} - \hat{x}_{ik})^2 = \sum (x_{ik} - \bar{x}_k)^2 - \sum (\hat{x}_{ik} - \bar{x}_k)^2 = \sum (x_{ik} - \bar{x}_k)^2 \times (1 - R_{k|1, \dots, k-1}^2)$, where $R_{k|1, \dots, k-1}$ is the multiple correlation coefficient of x_k and x_1, \dots, x_{k-1} , which is also equal to the correlation coefficient of x_k and \hat{x}_k . The square of the multiple correlation coefficient is also called the **coefficient of determination**. The quantities $x_{ik} - \hat{x}_{ik}$ are called the residuals. Let \hat{x}_{ik-1} and \hat{x}_{ik} be the values of regression functions of x_{k-1} and x_k , respectively, on x_1, \dots, x_{k-2} , and let $y_{ik-1} = x_{ik-1} - \hat{x}_{ik-1}$ and $y_{ik} = x_{ik} - \hat{x}_{ik}$ be the residuals; then the correlation coefficient of y_{k-1} and y_k is equal to the partial correlation coefficient of x_{k-1} and x_k given x_1, \dots, x_{k-2} . We have the following relation between the multiple and the partial correlation coefficients:

$$1 - R_{k|1, \dots, k-1}^2 = (1 - R_{k|1, \dots, k-2}^2)(1 - r_{k-1, k|1, \dots, k-2}^2).$$

Multiple and partial correlation coefficients are also expressed in terms of the correlation coefficients of the variates. For example, it can be shown that

$$R_{3|12}^2 = (r_{13}^2 + r_{23}^2 - 2r_{12}r_{13}r_{23})/(1 - r_{12}^2)$$

and that

$$r_{23|1} = (r_{23} - r_{12}r_{13})/\sqrt{(1 - r_{12}^2)(1 - r_{13}^2)}.$$

For higher dimensions, we can also define the **(joint) density function** $f(x_1, x_2, \dots, x_k)$ and the **(joint) moment generating function**

$$M(t_1, t_2, \dots, t_k) = \int \dots \int \exp(t_1x_1 + t_2x_2 + \dots + t_kx_k) \times f(x_1, x_2, \dots, x_k) dx_1 \dots dx_k.$$

The most important multivariate joint density is that of the **multivariate normal distribution**, which is expressed by

$$f(x_1, \dots, x_k) = (2\pi)^{-R/2} |\Sigma| \exp \left\{ \frac{1}{2} \sum \sum \sigma^{ij}(x_i - \mu_i)(x_j - \mu_j) \right\},$$

where Σ is the covariance matrix with elements σ_{ij} , $\Sigma^{-1} = (\sigma^{ij})$, and μ_i is the mean of the i th variate. For the multivariate normal distribution the moment generating function is given by

$$M(t_1, \dots, t_k) = \exp\left(\sum \mu_i t_i + \frac{1}{2} \sum \sigma_{ij} t_i t_j\right).$$

K. Contingency Tables

When several qualitative observations are made on N objects, each object is classified according to the combination of the categories, and the data are summarized by the numbers $N(i_1, i_2, \dots, i_k)$ of the objects that fall in the i_1 th category according to the first observation, i_2 th category in the second observation, etc. A table that shows the results of such observations is called a (*k*-way) **contingency table**. If there are m_1 categories in the first criterion, m_2 categories in the second, etc., the contingency table is also called an m_1 by m_2 by ... by m_k table. The numbers $\tilde{N}(j, i_j)$ of the objects which are classified into the i_j th category according to the j th criterion are called marginal frequencies. If we have

$$N(i_1, i_2, \dots, i_k) / N = \tilde{N}(1, i_1) \tilde{N}(2, i_2) \dots \tilde{N}(k, i_k) / N^k$$

for all i_1, i_2, \dots, i_k ,

then the k observations or criteria are independent.

The simplest contingency table is a 2 by 2 table, where several measures for the relation of two observations or criteria have been proposed, among which the most commonly used are the **measure of association** defined by

$$Q = \frac{N(1, 1)N(2, 2) - N(1, 2)N(2, 1)}{N(1, 1)N(2, 2) + N(1, 2)N(2, 1)}$$

and the **odds ratio**

$$\delta = \frac{N(1, 1)N(2, 2)}{N(1, 2)N(2, 1)}$$

and also

$$V = \frac{N(1, 1)N(2, 2) - N(1, 2)N(2, 1)}{\sqrt{\tilde{N}(1, 1)\tilde{N}(1, 2)\tilde{N}(2, 1)\tilde{N}(2, 2)}}$$

where $N(i, j_i)$ are marginal frequencies. The two observations are independent if and only if $Q=0$ or $\sigma=1$ and $V=0$. V is equal to the correlation coefficient of the variables x_1 and x_2 , for which $x_i=0$ if the object is classified into the first category according to the i th criterion and $x_i=1$ if it is classified into the second category. In a two-way m_1 by m_2 table a measure of association is defined by

$$\frac{X^2}{N} = \sum \sum \left(\frac{N(i_1, i_2)N}{\tilde{N}(1, i_1)\tilde{N}(2, i_2)} - 1 \right)^2;$$

it can be shown that $X^2/N=0$ if and only if the two criteria are independent, and that $0 \leq X^2/N \leq \min(m_1 - 1, m_2 - 1)$. When we take $x_i=1$ if the object is classified into the i th category according to the first criterion and $x_i=0$ otherwise and take $y_j=1$ if it belongs to the j th category in the second criterion and $y_j=0$ otherwise, it is shown that the sum of squares of the multiple correlation coefficients of x_i and y_1, \dots, y_{m_2-1} is equal to X^2/N .

L. Decomposition of the Variance

When one observation is qualitative while another is quantitative the objects are classified into several categories according to the first observation, while for each object the value of the second observation is also given. Let x_{ij} be the observed value of the j th object in the group of the i th category; then for each i we can obtain frequency distributions of x_{ij} , and compare these distributions. Let N_i be the number of objects in the i th category, and $\bar{x}_i = \sum x_{ij} / N_i$ be the mean in the i th category. Then the weighted variance of the \bar{x}_i defined by $v_B = \sum N_i(\bar{x}_i - \bar{x})^2 / N$, where \bar{x} is the mean of all the observations, i.e., $\bar{x} = \sum N_i \bar{x}_i / N$, is called the **between-group variance**, and the weighted mean of the variances of each of the groups defined by $v_W = \sum N_i(x_{ij} - \bar{x}_i)^2 / N$ is called the **within-group variance**. It can be shown that $V_B + V_W = V = \sum \sum (x_{ij} - \bar{x})^2 / N$, i.e., the variance of all the observations is decomposed as a sum of the between-group and the within-group variances. The ratio V_B/V is called the **correlation ratio**, which is equal to the square of the multiple correlation coefficient of x and y_1, \dots, y_m , where $y_i=1$ if the object is in the i th category and $y_i=0$ otherwise.

M. Ordinal Data

When the observation is not quantitative but there exists a natural ordering among the categories into which the objects are classified, the observation is said to be in an **ordinal scale**, or simply ordinal.

When two ordinal observations are made on the same set of N objects, we can define several measures of association between the two ordinal scales. For each pair of objects we define a variable c_{ij} , $i, j = 1, \dots, N$, $i \neq j$, as $c_{ij} = 1$ if the i th object is classified as "better" (or "superior") than the j th object according to both of the measurements, $c_{ij} = -1$ if the orderings are different in the two scales, or $c_{ij} = 0$ if they are in the same category according to either or both of the scales. A measure of association is then given by $S = \sum \sum c_{ij} / N(N - 1)$,

which takes a value between -1 and $+1$ but usually cannot attain ± 1 . Other ways of normalizing the sum $\sum \sum c_{ij}$ have been proposed.

Another method of calculating the association is the **scoring method**, i.e., giving a set of ordered real numbers to the categories of each of the scales and calculating the correlation coefficient between the scores. The simplest scores are $0, 1, \dots, m-1$ when there are m categories, but other methods of scoring are also used. Scores that give the largest possible correlation are called **canonical scores**, which are obtained as the characteristic vectors of the matrices NN' and $N'N$, where N is the matrix of the contingency table.

N. Time Series Data

Time series data can be recorded in a continuous time scale, but usually measurements are made at discrete times, which are most commonly equally spaced. Hence we here denote them as $x(t)$, $t = 1, 2, \dots, T$. First we consider the quantitative univariate case. The intertemporal change of $x(t)$ is often decomposed into three parts:

$$x(t) = m(t) + c(t) + e(t),$$

where $m(t)$ is called the **trend**, and represents the secular, systematic change of x ; $c(t)$ is called the **cycle**, and represents the recurrent pattern of the change; and $e(t)$ is called the error or random fluctuation, and represents the irregular changes. Such a decomposition cannot be defined rigorously without assuming some probabilistic or stochastic model for $x(t)$, but it is intuitively clear and practically useful in many applications.

There are two ways to estimate the trend. One is to calculate the **moving average** $\hat{x}(t) = (x(t-k) + x(t-k+1) + \dots + x(t) + \dots + x(t+k))/(2k+1)$ and use it as an estimate of the trend of $x(t)$; here k should be chosen to substantially eliminate the cyclic and random parts. More generally we can use the weighted moving average defined as $x(t) = \sum_{j=-k}^k w(j)x(t+j)$, where $w(-j) = w(j)$ and $\sum w(j) = 1$. The second method is to assume some functional form, usually a polynomial in t , for the trend: $m(t) = a_0 + a_1 t + \dots + a_k t^k$, and to determine the coefficient by least squares, i.e., to calculate the values of a_0, a_1, \dots, a_k which minimize $\sum_i (x(t) - a_0 - a_1 t - \dots - a_k t^k)^2$.

There are two cases of cyclical changes. One is the case when there is a clearly defined relevant external time period, such as the seasons of the year or the days of the week. In such cases the effects of such external periodical cycles must be eliminated, and the process which does that is called **seasonal adjustment**

of the time series data. Various methods of seasonal adjustment have been proposed and applied, but none is definitive. The other case is where the cyclical changes are produced from the observed process itself; here, the length of the period and the pattern of the cyclical change must be estimated.

Now assume that the data do not contain any trend, or that the trend has been effectively eliminated. First we calculate the correlation coefficient between $x(t)$ and $x(t+s)$ by

$$r(s) = \frac{\sum (x(t) - \bar{x}'_s)(x(t+s) - \bar{x}''_s)}{\sqrt{\sum (x(t) - \bar{x}'_s)^2 \sum (x(t+s) - \bar{x}''_s)^2}},$$

where

$$\bar{x}'_s = \sum_{t=1}^{T-s} x(t)/(T-s), \quad \bar{x}''_s = \sum_{t=s+1}^T x(t)/(T-s),$$

or more simply by

$$r(s) = T \sum (x(t) - \bar{x})(x(t+s) - \bar{x}) / ((T-s) \sqrt{\sum (x(t) - \bar{x})^2}),$$

where $\bar{x} = \sum x(t)/T$. $r(s)$ is called the **serial correlation coefficient** or the **autocorrelation coefficient** of lag s . When there exists a clear and definite cyclical change of period s in the data, $r(s)$ is close to 1. The diagram in which the serial correlation coefficient $r(s)$ is plotted against s is called the **correlogram**. In order to see the cyclical properties of the data more clearly, we calculate the **power spectral density**

$$w(\lambda) = 1 + 2 \sum_s r(s) \cos \lambda s.$$

The graph of $w(\lambda)$ is called the **power spectrum**, or simply the **spectrum**. $w(\lambda)$ represents the square of the width of the sine curve of frequency $\lambda/2\pi$ or of period $2\pi/\lambda$ contained in the data. The spectral density is closely related to the intensity, defined by

$$I(\lambda) = \frac{1}{T} \left(\left(\sum_t x(t) \cos \lambda t \right)^2 + \left(\sum_t x(t) \sin \lambda t \right)^2 \right),$$

which is proportional to the square of the multiple correlation coefficient of $x(t)$ and the functions $\cos \lambda t$ and $\sin \lambda t$ and is large if the data contains a sine curve of frequency $\lambda/2\pi$. It can be shown that $I(\lambda)$ is approximately equal to $w(\lambda)V(x)/\pi$. The spectral density thus obtained usually oscillates irregularly and far from smoothly; hence smoothing by use of a "spectral window" is often applied (\rightarrow 421 Times Series Analysis).

When several observations are made in time series data, we speak of multivariate time series. Let $x_i(t)$ be the i th observation in the t th period. The correlation coefficient between $x_i(t)$ and $x_j(t+s)$ is called the **serial cross-correlation coefficient** and is denoted by $r_{ij}(s)$ ($s = 0, \pm 1, \pm 2, \dots$). Analogously to the univari-

ate case we define

$$w_{ij}(\lambda) = \sum_s r_{ij}(s) \cos \lambda s + i \sum_s r_{ij}(s) \sin \lambda s \\
 = p_{ij}(\lambda) + i q_{ij}(\lambda),$$

and we call $p_{ij}(\lambda)$ the **cospectral density** between the i th and the j th variables, and $q_{ij}(\lambda)$ the **quadrature spectral density**. $p_{ij}^2 + q_{ij}^2$ is called the **amplitude**, and

$$C_{ij}(\lambda) = \frac{p_{ij}^2(\lambda) + q_{ij}^2(\lambda)}{\sqrt{w_i(\lambda)w_j(\lambda)}},$$

where w_i and w_j are the spectral densities of the i th and the j th variables, is called the **coherence**.

O. Events in Time Scale

Some data give us the time points at which a specific event occurs. Let T_i be the time when the event occurs for the i th time. Then usually the most important information we want to obtain is about the time intervals $d_i = T_{i+1} - T_i$. If there is a periodicity in the occurrences of the event, the d_i will be approximately equal. On the other hand, if the event tends to occur repeatedly after its first appearance, some d_i will be small while others will be large. When there is no periodicity, no tendency to repetition, and no increasing or decreasing trend in the occurrences, we can suppose that the event occurs simply by chance, and this is good reason to suppose that the density function of the distribution of the intervals is exponential, i.e., it can be expressed by $f(d) = (\exp(-d/\alpha))/\alpha$ for $d > 0$. Also in such a case the number of occurrences in fixed time intervals are distributed according to the Poisson distribution. Such a sequence of occurrences of an event is called a **Poisson process**. More generally, let $f(d)$ be the density function of the time intervals; then

$$h(d) = \frac{f(d)}{1 - \int_0^d f(c) dc}$$

is called the **hazard rate** or **hazard function**. The hazard function is constant if and only if the process is Poisson.

P. Probabilistic Models

In many applications of statistical data analysis, the data exhibit variabilities and fluctuations that are due to fortuitous or hazardous causes or chance effects and that obscure the information contained in the data. In such cases we assume that the chance variabilities and fluctuations are random variables distributed according to some probability distribu-

tion, and the information we require is represented by a set of unknown constants that characterize the probability distribution of the data as unknown parameters. Suppose, to take the simplest case, that we have repeated observations of results of some experiment under a fixed condition and that we obtain the values x_1, x_2, \dots, x_n . Since the experimental condition is fixed, the variations among the x_i values can be considered to be due to chance causes, such as variations in materials, uncontrolled small fluctuations in experimental conditions or instruments, and various other variations usually called the errors. Whatever the true causes of the variations, we can consider them to be random, and we can regard the values x_1, x_2, \dots, x_n as the results of random experiments or the realizations of random variables X_1, X_2, \dots, X_n independently and identically distributed according to some probability distribution. Or we may think of a **hypothetical infinite population** of the results of supposedly infinite replications of the experiment under the same fixed condition, and regard the actual observations as n values chosen from this population at random. We may also consider that in this hypothetical infinite population, the frequency distribution is represented by a density function f , which in turn determines the probability distribution of each observation. We may be interested in the "average" values of the result of the experiment as well as the magnitude of the variability; then those values are represented by the mean and the variance of the population distribution. If the form of the population distribution is assumed to be completely specified except for the mean μ and the variance σ^2 , the density function f is determined without these two parameters, and is expressed as $f(x; \mu, \sigma)$. The joint density for n repeated observations is $\prod_i f(x_i; \mu, \sigma)$. The set of assumptions that determines the probability distributions of the observations in terms of the unknown parameters is called the **probabilistic model**, and its determination is called the **problem of specification**.

Once the probabilistic model is given, the purpose of statistical data analysis can be formulated as making judgments on the values of the parameters, which may sometimes go wrong but can be relied on with some margin of probability of error that can be mathematically rigorously ascertained. The formal procedure of making such judgments is called **statistical inference**, and its mathematical theory has been well established over the last hundred years (\rightarrow 401 Statistical Inference).

In most cases of statistical inference, the joint density function of the data plays an important role, and when it is regarded as a function of the unknown parameters for given

values of observations it is called the †likelihood function.

Q. Exploratory Procedures

In many applications of statistical data analysis, we are not quite sure of the validity of the probabilistic model assumed, or we admit that the models are, at best, approximations to reality and hence cannot be exactly correct; the approximation may not be precise enough for the conclusions drawn from the assumptions to be practically reliable. Therefore we have to check whether the model assumed is at least approximately valid for the data, and if not, we have to look for a better model that reflects more accurately the structure of the actual data. Thus in many practical applications of data analysis, we have to scrutinize the structure of the data and try various models before settling on a model and drawing final conclusions (which are still susceptible to further revisions when more data are obtained). Methods used in such a process are called **exploratory procedures**, which depend partly on the formal procedure of testing hypotheses and partly on intuitive reasoning sometimes combined with graphical presentations of the data, and also on scientific and empirical understanding of the subject matter.

Suppose in the simplest case that n observations X_1, \dots, X_n are assumed to be independently and identically distributed. Under the condition that all those values are observed under the same well-controlled situation, this assumption is reasonable. But in reality some of the observations may be subject to some unexpected effect due to either a fortuitous outside cause or some “gross error” in the measurement procedure, the process of reporting, etc., and may show much greater variation than others. Such observations can be detected by certain **outlier tests** or simply by looking at the data carefully, and if it is established that some observations are definitely outside of the possible random variability or are subject to some hazardous external effect, those data could be omitted from consideration. Further, the assumed probability density $f(x, \theta)$ may not well approximate the distribution of the actual data even after the “outliers” are omitted. Some test for **goodness of fit** should be applied, and if the hypothesis is rejected, we have to modify our model. Also, if we are provided with several candidates for the model to be adopted, we have to apply some procedure of model selection (\rightarrow 400 Statistical Hypothesis Testing, 403 Statistical Models). It could also happen that the supposedly uniform conditions of

observation, measurement, or experimentation did not actually prevail but that there has been some heterogeneity among the observations. Bimodality or multimodality of the histogram, i.e., existence of two or more peaks in the histogram, usually strongly suggests such heterogeneity. In such cases, grouping or stratification of the observations is required to make the conditions of observation within each group nearly uniform.

398 (XVIII.6) Statistical Decision Functions

A. General Remarks

The theory of statistical decision functions was established by A. Wald as a mathematically unified theory of statistics (\rightarrow 401 Statistical Inference). In this theory, the problems of mathematical statistics, for example, statistical hypothesis testing and †statistical estimation, are formulated in a unified way [1].

A †measurable space $(\mathcal{X}, \mathfrak{B})$ with a fixed †probability measure is called a **sample space**, and an element $x \in \mathcal{X}$ is called a **sample point**. Suppose that we are given a family $\mathcal{P} = \{P_\theta \mid \theta \in \Omega\}$ of probability measures on $(\mathcal{X}, \mathfrak{B})$, where Ω is called the **parameter space**, and a †random variable X takes values in \mathcal{X} according to a true probability distribution P assumed to belong to \mathcal{P} . This article deals with the problems involved in making a decision about the parameter θ , called determining the **true value of the parameter**, such that $P = P_\theta$. To describe the procedure for such a decision based on the observation of the behavior of X , we need a triple $(\mathcal{A}, \mathfrak{C}; D)$ consisting of a set \mathcal{A} , a † σ -algebra \mathfrak{C} of subsets of \mathcal{A} , and a set D of mappings δ from \mathcal{X} into the set of probability measures on $(\mathcal{A}, \mathfrak{C})$, $\delta: x \rightarrow \delta(\cdot | x)$, such that for a fixed $C \in \mathfrak{C}$, the function $\delta(C | x)$ is \mathfrak{B} -measurable. We call \mathcal{A} an **action space** or **decision space**, δ a **statistical decision function** (or simply a **decision function**) or **statistical deci-**

sion procedure, and D a **space of decision functions**. In actual decision procedures, $\delta(C|x)$ is the probability that an action belonging to C is taken, based on the observation of sample point x . We further consider a nonnegative function $w: \Omega \times \mathcal{A} \rightarrow \mathbf{R}$, called a **loss function**, such that for a fixed θ , $w(\theta, a)$ is \mathbb{C} -measurable. By averaging the loss, we obtain the **risk function**:

$$r(\theta, \delta) = \int_{\mathcal{X}} \int_{\mathcal{A}} w(\theta, a) \delta(da|x) P_{\theta}(dx).$$

Two decision functions δ and δ' are identified if $\delta(C|x) = \delta'(C|x)$ for almost every x with respect to P_{θ} , for all $\theta \in \Omega$ and all $C \in \mathbb{C}$. When to each $x \in \mathcal{X}$ there corresponds a unique action a_x such that $\delta(\{a_x\}|x) = 1$, the decision function δ is said to be **nonrandomized**; otherwise, **randomized**. The system $(\mathcal{X}, \mathfrak{B}, \mathcal{P}, \Omega, \mathcal{A}, \mathbb{C}, W, D)$ is called a **statistical decision problem**.

From the point of view of this theory, †point estimation, †interval estimation, and statistical hypothesis testing (\rightarrow 400 Statistical Hypothesis Testing) are described as follows.

(1) In point estimation we assume that the action space \mathcal{A} is a subset of \mathbf{R} and that we are given functions $\varphi: \mathcal{X} \rightarrow \mathcal{A}$ and $l: \mathcal{P} \rightarrow \mathbf{R}$. The problem is to estimate the value of $l(P)$ by using the real value $\varphi(x)$ at an observed sample point $x \in \mathcal{X}$. As the loss function, we often set $w(\theta, a) = C(\theta)(a - l(P_{\theta}))^2$, where $C(\theta)$ is a function of θ , and call it a **quadratic loss function** (\rightarrow 399 Statistical Estimation).

(2) In interval estimation we assume that each action is represented as an interval in \mathbf{R} . Each interval $[u, v]$ can be represented by a point (u, v) of the half-space $\mathbf{R}^2 = \{z = (z_1, z_2) | z_1 \leq z_2\}$, which may be taken as the action space. A weighted sum $\alpha w_1(\theta, z) + \beta w_2(\theta, z)$ ($\alpha, \beta \geq 0$) of two functions,

$$w_1(\theta, z) = \begin{cases} 1 & (\theta \notin [z_1, z_2]), \\ 0 & (\theta \in [z_1, z_2]), \end{cases}$$

$$w_2(\theta, z) = z_2 - z_1,$$

often supplies the loss function (\rightarrow 399 Statistical Estimation).

(3) In testing a hypothesis $\mathbf{H}: \theta \in \omega_0$ versus an †alternative $\mathbf{A}: \theta \in \omega_1$ ($\omega_0 \cap \omega_1 = \emptyset$, $\omega_0 \cup \omega_1 = \Omega$), the action space can be expressed by the set consisting of two points a_1, a_2 , where a_1 denotes the decision to reject \mathbf{H} and a_2 the decision to accept \mathbf{H} . The loss function is defined as follows:

$$w(\theta, a_1) = \begin{cases} 1 & (\theta \in \omega_0), \\ 0 & (\theta \in \omega_1), \end{cases}$$

$$w(\theta, a_2) = \begin{cases} 0 & (\theta \in \omega_0), \\ 1 & (\theta \in \omega_1). \end{cases}$$

This is called a **simple loss function**. Whatever

testing procedure δ is adopted, the probabilities of the †errors of the first or second kind coincide with the values of $r(\theta, \delta)$ for $\theta \in \omega_0$ or $\theta \in \omega_1$, respectively (\rightarrow 400 Statistical Hypothesis Testing).

When Ω is the union of mutually disjoint nonempty sets $\omega_1, \omega_2, \dots, \omega_n$, $\mathcal{A} = \{a_1, a_2, \dots, a_n\}$, and $w(\theta, a_j) = c_{ij}$ ($\theta \in \omega_i$) with $c_{ij} \geq 0$ ($i \neq j$), $c_{ii} = 0$, the decision problem is called an **n -decision problem**.

B. Optimality of Statistical Decision Functions

Consider the problem of choosing the best decision function δ . When $r(\theta, \delta_1) \leq r(\theta, \delta_2)$ for all θ and there exists at least one θ_0 such that $r(\theta_0, \delta_1) < r(\theta_0, \delta_2)$, the decision function δ_1 is said to be **uniformly better** than δ_2 . If there exists a decision function δ_0 in D that is uniformly better than any other δ in D , it is the **best** decision function. However, such a function δ_0 does not always exist. A decision function $\tilde{\delta}$ in D is said to be **admissible** if there exists no other decision function δ in D that is uniformly better than $\tilde{\delta}$. In other words, $\tilde{\delta}$ is admissible if and only if the validity of the inequality $r(\theta, \delta) \leq r(\theta, \tilde{\delta})$ for some $\delta \in D$ and all $\theta \in \Omega$ implies $r(\theta, \delta) = r(\theta, \tilde{\delta})$ for all $\theta \in \Omega$. When there is no information about P except that it is a member of \mathcal{P} , we follow the **minimax principle** and choose a function δ^* for which we have $\inf_{\delta \in D} \sup_{\theta \in \Omega} r(\theta, \delta) = \sup_{\theta \in \Omega} r(\theta, \delta^*)$. This decision function δ^* is called a **minimax decision function** or **minimax solution**.

Let \mathfrak{F} be a σ -algebra of subsets of Ω , and suppose that $r(\theta, \delta)$ is \mathfrak{F} -measurable for any fixed δ . If, furthermore, we are given a probability measure ξ , called an **a priori distribution**, on (Ω, \mathfrak{F}) , we choose a $\hat{\delta}$ that satisfies

$$\inf_{\delta \in D} \int_{\Omega} r(\theta, \delta) d\xi(\theta) = \int_{\Omega} r(\theta, \hat{\delta}) d\xi(\theta).$$

Such a $\hat{\delta}$ and the integral of $r(\theta, \hat{\delta})$ are called a **Bayes solution** and the **Bayes risk** relative to ξ , respectively. Let F be a family of a priori distributions on (Ω, \mathfrak{F}) . If $\hat{\delta}$ satisfies

$$\inf_{\xi \in F} \left(\int_{\Omega} r(\theta, \hat{\delta}) d\xi(\theta) - \inf_{\delta \in D} \int_{\Omega} r(\theta, \delta) d\xi(\theta) \right) = 0,$$

$\hat{\delta}$ is called a **Bayes solution in the wider sense** relative to F . If \mathcal{P} is †dominated by λ with a $\mathfrak{B} \times \mathfrak{F}$ -measurable $f(x, \theta) = dP_{\theta}/d\lambda$, $w(\theta, a)$ is $\mathfrak{F} \times \mathbb{C}$ -measurable, and

$$A_x = \left\{ \tilde{a} \in \mathcal{A} \mid \int_{\Omega} w(\theta, \tilde{a}) f(x, \theta) d\xi(\theta) = \inf_{a \in \mathcal{A}} \int_{\Omega} w(\theta, a) f(x, \theta) d\xi(\theta) \right\}$$

is nonempty and \mathbb{C} -measurable for λ -almost

every x , then a Bayes solution δ with respect to ξ satisfies $\delta(A_x|x) = 1$ for λ -almost every x . For a sample point x with $\int_{\Omega} f(x, \theta) d\xi(\theta) \neq 0$, a probability measure $\eta(\cdot|x, \xi)$ on (Ω, \mathfrak{F}) defined by

$$\eta(B|x, \xi) = \frac{\int_B f(x, \theta) d\xi(\theta)}{\int_{\Omega} f(x, \theta) d\xi(\theta)}$$

is called an a **posteriori distribution**. To get a Bayes solution it is enough to minimize the value of $\int_{\Omega} w(\theta, a) d\eta(\theta|x, \xi)$ for every observed x .

If ξ in the definition of A_x defined above is a σ -finite measure on (Ω, \mathfrak{F}) , a decision function δ satisfying $\delta(A_x|x) = 1$ for λ -almost every x is called a **generalized Bayes solution** with respect to ξ .

Let D' be a subset of the space D . If for any $\delta \in D - D'$ there exists a $\delta' \in D'$ that is uniformly better than δ , then D' is called a **complete class**. If for any $\delta \in D$ there exists a $\delta' \in D'$ that is either uniformly better than δ or has the same risk function as δ , then D' is called an **essentially complete class**. If D' is complete and any proper subset of D' is not complete, then D' is called a **minimal complete class**. If a minimal complete class exists, it is unique and coincides with the set of all admissible decision functions.

C. n -Decision Problems

In an n -decision problem where $\mathcal{A} = \{a_1, \dots, a_n\}$, we set $\delta_i(x) = \delta(a_i|x)$ for a decision function δ , where $\delta_i(x)$ is \mathfrak{B} -measurable and satisfies $\delta_i(x) \geq 0$, $\delta_1(x) + \dots + \delta_n(x) = 1$. We consider the set \mathcal{D} of vector-valued functions $\Delta(x) = (\delta_1(x), \dots, \delta_n(x))$ whose components $\delta_i(x)$ satisfy the conditions just given. Such a vector-valued function $\Delta(x)$ can be identified with $\delta(x)$; we write $\delta(x)$ instead of $\Delta(x)$ also. If in addition the parameter space Ω is a finite set $\{\theta_1, \theta_2, \dots, \theta_k\}$, we can consider a mapping $\psi: \mathcal{D} \rightarrow \mathbf{R}^k$ defined by $\psi(\delta) = (r(\theta_1, \delta), \dots, r(\theta_k, \delta))$, and then $S = \psi(\mathcal{D}) = \{\psi(\delta) | \delta \in \mathcal{D}\}$ is convex and closed in \mathbf{R}^k . If δ is nonrandomized, then for each x , one and only one of the $\delta_i(x)$ is 1, and all others are 0. Hence, in this case, \mathcal{X} is the disjoint union of \mathfrak{B} -measurable subsets B_i ($i = 1, \dots, n$) such that $\delta(a_i|x) = 1$ if and only if $x \in B_i$. A probability measure m on $(\mathcal{X}, \mathfrak{B})$ is said to be **atomless** if for any set $A \in \mathfrak{B}$ with $m(A) > 0$ and any b with $0 < b < m(A)$, there exists a subset $B \in \mathfrak{B}$ of A such that $m(B) = b$. If Ω is finite and every member of \mathcal{D} is atomless, the image $\psi(\mathcal{D}^0)$ of the set \mathcal{D}^0 of all nonrandomized decision functions coincides with $\psi(\mathcal{D})$. This shows that \mathcal{D}^0 is an essentially complete

class in \mathcal{D} . However, when some members of \mathcal{D} are not atomless, $\psi(\mathcal{D})$ is not always equal to $\psi(\mathcal{D}^0)$, but $\psi(\mathcal{D}^0)$ is a closed subset of \mathbf{R}^k . In particular, when $n = 2$ for given probability measures P_1, \dots, P_k over $(\mathcal{X}, \mathfrak{B})$, the set S of all points $(P_1(B), \dots, P_k(B))$ ($B \in \mathfrak{B}$) in \mathbf{R}^k is a closed set. If in addition P_1, \dots, P_k are all atomless, S is convex. These results are known as the **Lyapunov theorem**.

A two-decision problem with $\omega_1 = \{1\}$, $\omega_2 = \{2\}$, and $c_{ij} = 1$ ($i \neq j$), $= 0$ ($i = j$) is called a **dichotomy**. We discuss this problem in some detail in order to explain the concept of optimality of decision functions. For a dichotomy, $S = \psi(\mathcal{D})$ is a set in \mathbf{R}^2 that (i) is convex, (ii) is closed, (iii) is symmetric about $(1/2, 1/2)$, (iv) contains the points $(0, 1)$, $(1, 0)$, and (v) is a subset of interval $[0, 1] \times [0, 1]$ (Fig. 1). The set of decision functions δ that is mapped under ψ onto the curve $ACDB$ in Fig. 1 constitutes the minimal complete class, and a decision function δ mapped onto the point D is a minimax solution. Let ξ be an a priori distribution such that

$$\xi(1) = \alpha, \quad \xi(2) = \beta \quad (\alpha + \beta = 1, \alpha \geq 0, \beta \geq 0).$$

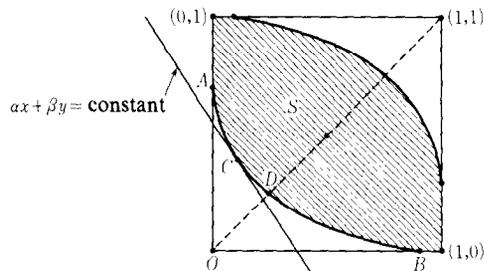

Fig. 1

Then a Bayes solution relative to ξ is mapped under ψ onto a supporting point c with direction ratio $-\alpha/\beta$ and is obtained as the characteristic function of the set $E = \{x | \alpha f(x) < \beta g(x)\}$, where f and g are \dagger Radon-Nikodym derivatives $dP_1/d\lambda$ and $dP_2/d\lambda$ with respect to $\lambda = P_1 + P_2$, that is, f, g are measurable functions on \mathcal{X} such that for any measurable set E , we have

$$P_1(E) = \int_E f d\lambda, \quad P_2(E) = \int_E g d\lambda.$$

This fact implies that the most powerful test constructed in the Neyman-Pearson fundamental lemma (\rightarrow 400 Statistical Hypothesis Testing B) is precisely a Bayes solution.

D. Complete Class Theorems

Suppose that \mathcal{D} is \dagger dominated by a σ -finite measure λ , and let $f(x, \theta)$ be the Radon-Nikodym derivative of P_θ with respect to λ .

Statistical Decision Functions

Consider a subspace L of $L_1(\mathcal{X}, \lambda)$ containing $\{f(x, \theta) | \theta \in \Omega\}$, and the following equivalence relation between bounded \mathfrak{B} -measurable functions on \mathcal{X} : φ_1 and φ_2 are defined to be equivalent if and only if $\int \varphi_1 f d\lambda = \int \varphi_2 f d\lambda$ holds for every $f \in L$. We further assume that the dual space of L is the linear space \mathfrak{M} of the equivalence classes of bounded measurable functions just defined. Let $C_0(\mathcal{A})$ be the set of all continuous functions on \mathcal{A} with compact support, $\pi \circ \alpha$ the integral of $\alpha \in C_0(\mathcal{A})$ with respect to a probability measure π over \mathcal{A} , and $g \circ \delta$ the integral

$$\int \delta(\cdot | x) g(x) d\lambda$$

for $g \in L, \delta \in D$. As a base for neighborhoods of the space of decision functions around $\delta_0 \in D$, we consider $V(\delta_0; \alpha_1, \dots, \alpha_n, g_1, \dots, g_n, \epsilon) = \{\delta | |g_i \circ \delta_0 \circ \alpha_i - g_i \circ \delta \circ \alpha_i| < \epsilon, i = 1, \dots, n\}$, where $\alpha_i \in C_0(\mathcal{A}), g_i \in L, \epsilon > 0$.

Let F be the set of all a priori distributions ξ on (Ω, \mathfrak{F}) each of which assigns the total mass 1 to a finite subset of Ω , B the set of all Bayes solutions relative to some $\xi \in F$, and W the set of all Bayes solutions in the wide sense relative to F . Suppose that \mathcal{A} is a locally compact, separable metric space and $w(\theta, a)$ is lower semicontinuous with respect to a for every fixed θ . Then if D is compact and convex, the intersection of W and the closure \bar{B} of B constitutes an essentially complete class [2]. Moreover, if Ω is compact with respect to the metric $d(\theta_1, \theta_2) = \sup_{B \in \mathfrak{B}} |P_{\theta_1}(B) - P_{\theta_2}(B)|$ and $\{w(\cdot, a) | a \in \mathcal{A}\}$ is a uniformly bounded and equicontinuous family on Ω , then the class of Bayes solutions relative to some a priori distribution is a complete class [1]. These propositions are called **complete class theorems** (for complete classes in specified problems and admissibility of individual procedures → 399 Statistical Estimation; 400 Statistical Hypothesis Testing; and Appendix A, Table 23).

Two measurable spaces (S, \mathcal{S}) and (R, \mathcal{R}) are said to be **isomorphic** if there exists a correspondence ρ of S and R ($E \in \mathcal{S}$ implies $\rho(E) \in \mathcal{R}$ and, conversely, $\rho(E) \in \mathcal{R}$ implies $E \in \mathcal{S}$) where ρ is one-to-one onto. Let \mathcal{D} be the set of all decision functions associated with a sample space $(\mathcal{X}, \mathfrak{B})$ and an action space $(\mathcal{A}, \mathfrak{C})$, T be a statistic on $(\mathcal{X}, \mathfrak{B})$ taking values in a measurable space $(\mathcal{Y}, \mathfrak{E})$, and \mathcal{D}^* be the set of all decision functions having sample space $(\mathcal{Y}, \mathfrak{E})$ and action space $(\mathcal{A}, \mathfrak{C})$. The set of all $\delta \in \mathcal{D}$ for which there exists a $\delta^* \in \mathcal{D}^*$ satisfying $\delta(C | x) = \delta^*(C | T(x))$ ($C \in \mathfrak{C}$) is denoted by \mathcal{D}_T . If (i) T is a sufficient statistic and if (ii) $(\mathcal{A}, \mathfrak{C})$ is isomorphic to the measurable space \mathbf{R}^k associated with the σ -algebra of its Borel subsets, then \mathcal{D}_T is essentially complete in \mathcal{D} . Conversely, if (i) \mathcal{P} is a dominated family, (ii) $f(x, \theta) > 0$ always

holds on \mathcal{X} , and (iii) for any pair $\theta_1, \theta_2 \in \Omega$, there exists a $\theta_3 \in \Omega$ such that no element a in \mathcal{A} makes two of the $w(\theta_i, a)$ ($i = 1, 2, 3$) attain their minimum simultaneously, then essential completeness of \mathcal{D}_T in \mathcal{D} implies that T is sufficient [3] (→ 399 Statistical Estimation).

E. Invariance

Suppose that there exist one-to-one transformation groups G, \bar{G} , and \tilde{G} of X, Ω , and \mathcal{A} , respectively, onto themselves (transformations belonging to G, \bar{G} , and \tilde{G} are measurable with respect to $\mathfrak{B}, \mathfrak{F}$, and \mathfrak{C} , respectively) and that there exist homomorphisms $g \rightarrow \bar{g}, g \rightarrow \tilde{g}$ of G to \bar{G} and \tilde{G} , respectively, such that for $B \in \mathfrak{B}$ we have $P_\theta(g^{-1}B) = P_{\bar{\theta}}(B)$ and $w(\bar{g}\theta, \bar{g}a) = w(\theta, a)$. Then a decision problem $(\mathcal{X}, \mathfrak{B}, \mathcal{P}, \Omega, \mathcal{A}, \mathfrak{C}, w, D)$ is said to be **invariant** under (G, \bar{G}, \tilde{G}) . In a decision problem invariant under (G, \bar{G}, \tilde{G}) , a decision function satisfying $\delta(\bar{g}C | g x) = \delta(C | x)$ is called an **invariant decision function**.

Suppose that the transformation group G is locally compact and is the union of a countable family $\{K_n\}$ of compact subsets. Let Γ be the σ -algebra of Borel subsets of G such that the mapping $(g, x) \rightarrow (g, gx)$ is measurable in the sense that the inverse image of any set in $\Gamma \times \mathfrak{B}$ is also a set in $\Gamma \times \mathfrak{B}$. For such a Γ the orbit $G(x)$ of G through x is Γ -measurable. We assume that following conditions: (1) \mathcal{P} is dominated; (2) G operates effectively on \mathcal{X} ; (3) \bar{G} operates transitively on Ω ; (4) for any compact subset J of G ,

$$\lim_{n \rightarrow \infty} \{ \mu^r(K_n) / \mu^r(K_n \cdot J^{-1}) \} = 1,$$

where μ^r is a right-invariant Haar measure (→ 225 Invariant Measures C) on G and $K_n \cdot J^{-1} = \{gh^{-1} | g \in K_n, h \in J\}$; (5) there is a conditional probability distribution $P_\theta(\cdot : z)$, given $z \in G(x)$, on \mathcal{X} ; (6) the integral $\int_{G(x)} w(\theta, \bar{g}a) P_\theta(dgx : z)$ attains its minimum value $b(\theta, z)$ for any θ and $z \in G(x)$; and (7)

$$\lim_{n \rightarrow \infty} \left\{ \int_{K_n x} w(\theta, \bar{g}a) P_\theta(dgx : z) - b(\theta, z) \right\} \geq 0$$

uniformly in a , where $K_n x = \{gx | g \in K_n\}$. Then the best invariant decision function exists which is also minimax in \mathcal{D} [4] (→ 400 Statistical Hypothesis Testing). It is shown in [9] that some invariant minimax decision functions are not admissible.

F. Sequential Decision Problems

In the general framework of statistical decision theory, not only the decisions to be taken but the number of samples to be observed

may be determined based on the previous observations.

A simple formulation is illustrated for the sequential decision problem given below. Suppose that X_1, X_2, \dots, X_n are independently and identically distributed random variables with probability measure P_θ . We assume that the X 's are to be observed one by one, and at the i th stage, when we have observed X_1, \dots, X_i , we are to decide whether to continue sampling and observe X_{i+1} or to stop observation and choose an action or decision in \mathcal{D} , utilizing all the observations thus far obtained. Then a decision rule is defined by a sequence of pairs $(\delta_n, s_n), n = 0, 1, \dots$, where δ_n is a mapping from the space X^n to \mathcal{D} (for the sake of simplicity we here exclude randomized decisions), and $s_n = s_n(x_1, \dots, x_n)$ is a measurable function from X^n to the interval $[0, 1]$. s_n gives the probability of stopping the sampling when the first n of the X 's are observed, and δ_n defines the decision taken when the observations are stopped. We include s_0 and δ_0 to denote the probability of taking a decision without making any observation and the decision to be taken then. We call δ_n the **terminal decision rule** and s_n the **stopping rule**. Then for such a decision rule $\tilde{\delta}$ the total expected loss or the risk is given by

$$r(\theta, \tilde{\delta}) = \sum_{n=0}^{\infty} \int \prod_{j=0}^{n-1} (1 - s_j(x_1, \dots, x_j)) \times \{s_n(x_1, \dots, x_n)w(\theta, \delta_n(x_1, \dots, x_n)) + c_n(x_n | x_1, \dots, x_{n-1})\} \prod_{j=1}^n dP_\theta(x_j),$$

where $c_n(x_n | x_1, \dots, x_{n-1})$ is the **cost of observation** of $X_n = x_n$ when $X_1 = x_1, \dots, X_{n-1} = x_{n-1}$. The rule $\tilde{\delta}$ is called a **sequential decision rule** or a **sequential decision function**, and the whole setup a **sequential decision problem**. In most of the sequential decision problems the cost of observation is assumed to be equal to a constant c per observation, and then the Bayes risk $r^*(\xi_\theta)$ for the prior distribution ξ_θ satisfies the relation

$$r^*(\xi_\theta) = \min \left\{ \inf_d \int w(\theta, d) d\xi_\theta, \int \int r^*(\pi_\theta(x_1, \xi_\theta)) dP_\theta(x_1) d\xi_\theta + c \right\},$$

where $\pi_\theta(x_1, \xi_\theta)$ denotes the posterior distribution when $X_1 = x_1$ is observed under the prior distribution ξ_θ ; and the Bayes decision rule satisfies the condition

$$s_n(x_1, \dots, x_n) = 1 \text{ if } r^*(\pi_\theta(x_1, \dots, x_n; \xi_\theta)) = \inf \int w(\theta, d) d\pi_\theta(x_1, \dots, x_n; \xi_\theta), \\ = 0 \text{ otherwise,}$$

and $\delta_n(x_1, \dots, x_n) = d^*$ if $\int w(\theta, d^*) d\pi_\theta(x_1, \dots, x_n; \xi_\theta) = \inf_d \int w(\theta, d) d\pi_\theta(x_1, \dots, x_n; \xi_\theta)$, where $\pi_\theta(x_1, \dots, x_n; \xi_\theta)$ is the posterior distribution given $X_1 = x_1, \dots, X_n = x_n$ under the prior ξ_θ .

For the dichotomy problem with the simple loss function discussed above, the Bayes decision rule has the form

$$s_n(x_1, \dots, x_n) = 1 \text{ if } \pi_0(x_1, \dots, x_n) \leq \pi_1 \text{ or } \geq \pi_2, \\ = 0 \text{ otherwise,}$$

and

$$\delta_n(x_1, \dots, x_n) = d_1 \text{ if } \pi_0(x_1, \dots, x_n) \leq \pi_1, \\ = d_0 \text{ if } \pi_0(x_1, \dots, x_n) \geq \pi_2,$$

where $\pi_0(x_1, \dots, x_n)$ is the posterior probability that $\theta = \theta_0$, given $X_1 = x_1, X_n = x_n$. This amounts to the following rule: Continue sampling as long as

$$\gamma_1 < \lambda(x_1, \dots, x_n) = \prod_1 P_{\theta_0}(x_i) / \prod_1 P_{\theta_1}(x_i) < \gamma_2,$$

and decide on d_0 as soon as $\lambda(x_1, \dots, x_n) \geq \gamma_2$ and on d_1 as soon as $\lambda(x_1, \dots, x_n) \leq \gamma_1$, which is actually equivalent to a sequential probability ratio test (\rightarrow 400 Statistical Hypothesis Testing).

G. Information in Statistical Experiments

The part $\mathcal{E} = (\mathcal{X}, \mathfrak{B}, \mathcal{P}, \Omega)$ of a decision problem $\Delta = (\mathcal{X}, \mathfrak{B}, \mathcal{P}, \Omega, \mathcal{A}, \mathfrak{C}, w, D)$ is called a **statistical experiment**. In this section, we consider n -decision problems, i.e., those wherein Ω consists of a finite number $\{1, 2, \dots, n\}$ of states, and we denote the set $S = \{r(1, \delta), r(2, \delta), \dots, r(n, \delta) | \delta \in \mathcal{D}\}$ by $L(\Delta)$. Let \mathcal{E}_1 and \mathcal{E}_2 be two experiments having a common parameter space Ω , and let Δ_1 and Δ_2 be two decision problems composed of \mathcal{E}_1 and \mathcal{E}_2 , respectively, and a common $(\mathcal{A}, \mathfrak{C}, w)$. We say that the experiment \mathcal{E}_1 is **more informative** than the experiment \mathcal{E}_2 if $L(\Delta_1) \supseteq L(\Delta_2)$ for any action space $(\mathcal{A}, \mathfrak{C})$ and any loss function w [6]; that is, whatever the actions proposed and the loss incurred, the experiment \mathcal{E}_1 can offer a decision procedure at least as efficient as the experiment \mathcal{E}_2 . Thus the set $L(\Delta)$ with $\Delta = (\mathcal{E}, \mathcal{A}, \mathfrak{C}, w, D)$ represents some feature of information that \mathcal{E} can provide about the states Ω . However, comparison of $L(\Delta)$ is not easy to carry out. S. Kullback and R. A. Leibler defined the concept of information for the case of a dichotomy Δ [5]. If the probability distribution induced by a random variable X has a Radon-Nikodym derivative $f_1(x) (> 0)$ or $f_2(x) (> 0)$ with respect to λ , we define

$$I(X; 1, 2) = I(f_1, f_2) = \int_x \log \frac{f_1(x)}{f_2(x)} f_1(x) d\lambda,$$

calling this the **Kullback-Leibler information number** (or **K-L information number**). This number is uniquely determined by the set $S = L(\Delta)$ in Fig. 1, and the larger S becomes, the larger $I(f_1, f_2)$ becomes. If α, β ($\alpha + \beta = 1$) are a priori probabilities and $\eta(1|x)$ and $\eta(2|x)$ are a posteriori probabilities of 1 and 2, respectively, we have, from the Bayes theorem,

$$\log \frac{f_1(x)}{f_2(x)} = \log \frac{\eta(1|x)}{\eta(2|x)} - \log \frac{\alpha}{\beta}.$$

Here the right-hand side stands for the change in the probability of the occurrence of the state after an observation of x , and the expectation of the left-hand side under f_1 is $I(f_1, f_2)$. The K-L information number has the following properties: (i) $I(X:1,2) \geq 0$, and $I(X:1,2) = 0 \Leftrightarrow f = g$; (ii) independence of X and Y implies $I(X:1,2) + I(Y:1,2) = I(X, Y:1,2)$; (iii) for a statistic $T = t(x)$, $I(X:1,2) \leq I(T:1,2)$, where the equality holds if and only if T is sufficient for $\mathcal{P} = \{P_1, P_2\}$, in which $dP_1/d\lambda = f_1$ and $dP_2/d\lambda = f_2$; and, as a result of (ii), (iv) if X_1, \dots, X_n are distributed independently with the same distribution, $I(X_1, \dots, X_n:1,2) = nI(X_1:1,2)$.

Suppose next that Ω is the real line and that the Radon-Nikodym derivative $g(t:\theta)$ of the distribution of a statistic T with respect to a measure λ has the following properties: (i) the set of all t at which $g(t:\theta) > 0$ is independent of θ ; (ii) $g(t:\theta)$ is continuously twice differentiable; and (iii) the order of differentiation with respect to θ and integration with respect to t can be interchanged. Then $I(T:\theta, \theta + d\theta) = I(T:\theta)d\theta^2$ for an infinitesimal displacement $d\theta$ of θ , where

$$I(T:\theta) = \int_x \left(\frac{\partial \log g(t:\theta)}{\partial \theta} \right)^2 g(t:\theta) d\lambda.$$

Here $I(T:\theta)$ coincides with the Fisher information (\rightarrow 399 Statistical Estimation).

Suppose that we are given a sequence (X_1, X_2, \dots) of independent random variables whose distributions have as their density either (f_1, f_2, \dots) or (g_1, g_2, \dots) , that is, f_i and g_i are candidates for the density of distribution of X_i ($i = 1, 2, \dots$). A method to determine which of the sequences $(f_i), (g_i)$ actually corresponds to (X_i) is given by the **Kakutani theorem**. Let F be the distribution of (X_1, X_2, \dots) when each X_i is distributed according to f_i , and let G be that of (X_1, X_2, \dots) when each X_i is distributed according to g_i . To see how X_1, X_2, \dots are actually distributed, we assume that the loss incurred by an incorrect decision is 1 and the loss incurred by a correct decision is 0. Denote such a decision problem (dichotomy) by Δ . Then we generally have $L(\Delta) \subset I$, where $I = \{(x, y) | 0 \leq x, y \leq 1\}$. A necessary and sufficient condition for

$L(\Delta) = I$ is that $\prod_{n=1}^{\infty} \rho(f_n, g_n) = 0$, where

$$\rho(f_n, g_n) = \int_x \sqrt{f_n(x)g_n(x)} dx.$$

Consequently, if the X_n ($n = 1, 2, \dots$) have the same distribution, we have $L(\Delta) = I$, and the correct decision can be made with no error based on infinitely many independent observations of X_1, X_2, \dots .

H. Relation to Game Theory

The theory of statistical decision functions is closely related to game theory. From the game-theoretic viewpoint, a statistical decision problem is considered to be a zero-sum two-person game played by the statistician against nature. A strategy of nature is the true distribution P of the variable X or the true value of θ , and a strategy of the statistician is a decision δ . In this setup, the risk function $r(\theta, \delta)$ can be regarded as a payoff function paid by the statistician to nature. An a priori distribution ξ is a mixed strategy of nature. A randomized decision function is a mixed strategy of the statistician. A minimax decision function corresponds to a minimax strategy of the statistician. A minimax strategy of nature is called a **least favorable a priori distribution**. If a decision problem is strictly determined as a game, a minimax solution is a Bayes solution in the wide sense.

If δ_0 is a Bayes solution with respect to ξ_0 and $r(\theta, \delta_0) \leq R(\xi_0, \delta_0)$ for all θ , the decision problem is strictly determined, and δ_0 is minimax and ξ_0 is a least favorable a priori distribution, where $R(\xi_0, \delta_0) = \int_{\Omega} r(\theta, \delta_0) d\xi_0(\theta)$. If δ_0 is a Bayes solution in the wide sense and $r(\theta, \delta_0)$ is constant as a function of θ , the decision problem is strictly determined, and δ_0 is minimax. If δ_0 is admissible and $r(\theta, \delta_0) \equiv c < \infty$, δ_0 is minimax. If Ω is a finite set and $\inf_{\delta} \sup_{\theta} r(\theta, \delta) < \infty$, the decision problem is strictly determined and there exists a least favorable a priori distribution. We have few general results about generalized Bayes solutions (\rightarrow 173 Game Theory; [6]).

399 (XVIII.7) Statistical Estimation

A. General Remarks

Statistical estimation is one of the most important methods of statistical inference (→ 401 Statistical Inference). Its purpose is to estimate the values of \dagger parameters (or their functions) involved in a distribution of a statistical \dagger population by using observations on the population (→ 396 Statistic). Let $\mathcal{P} = \{P_\theta \mid \theta \in \Theta\}$ be a family of \dagger probability distributions, indexed by a parameter θ and defined over a \dagger measurable space (i.e., sample space) $(\mathcal{X}, \mathfrak{B})$. Let X be a \dagger random variable taking values in \mathcal{X} and distributed according to a probability distribution P that is a member of \mathcal{P} . **Statistical estimation** is a method of estimating the \dagger true value of the parameter θ (i.e., the parameter θ such that $P = P_\theta$) or the (true) value $g(\theta)$ of a given **parametric function** g (i.e., a function defined over Θ) or both, at θ , based on the observed value x of the random variable X . The function g maps the parameter values into \mathbf{R} , \mathbf{R}^k , or some function space. Statistical estimation methods are classified into two types: point estimation, which deals with individual values of $g(\theta)$, and interval (or region) estimation, by means of which regions that may contain the value $g(\theta)$ are considered. We can also

399 C Statistical Estimation

include in statistical estimation the problem of predicting the tolerance region in which the value of a yet unobserved random variable may come out.

B. Point Estimation

In the method of **point estimation** for a given parametric function g , we choose a measurable mapping φ from the sample space $(\mathcal{X}, \mathfrak{B})$ into a measurable space $(\mathcal{A}, \mathfrak{C})$ and state that “the value of $g(\theta)$ is $\varphi(x)$ ” for an observed value x , where \mathcal{A} is a set containing the range of g and \mathfrak{C} is a \dagger complete additive class of subsets in \mathcal{A} . The mapping φ , or the random variable $\varphi(X)$ taking values in the space \mathcal{A} , is called an **estimator** of $g(\theta)$, while the value $\varphi(x)$ determined by the observed value x is called an **estimate** of $g(\theta)$. This estimate is sometimes termed a **nonrandomized estimate** in contrast to the following generalized notion of estimator. A mapping from \mathcal{X} to a set of probability distributions defined over $(\mathcal{A}, \mathfrak{C})$ is called a **randomized estimator**, which reduces to a nonrandomized estimator when each image distribution degenerates to a single point. We assume that $\mathcal{A} = \mathbf{R}$ and $\mathfrak{C} =$ the class \mathfrak{B} of all \dagger Borel sets in \mathbf{R} , unless stated otherwise. We denote the \dagger expectation and \dagger variance with respect to P_θ by E_θ and V_θ , respectively.

C. Unbiasedness

An estimator $\varphi(X)$ of $g(\theta)$ may not be exactly equal to $g(\theta)$ for any $\theta \in \Theta$ except for trivial cases, but could instead be stochastically distributed around it. An estimator $\varphi(X)$ is said to have **unbiasedness** if it is stochastically balanced around $g(\theta)$ in some sense, such as mean, median, or mode. A statistic $\varphi(X)$ is called a (mean) **unbiased estimator** of $g(\theta)$ if

$$E_\theta(\varphi(X)) = g(\theta)$$

for any $\theta \in \Theta$. A parametric function g is said to be **estimable** if it has an unbiased estimator. For example, the sample mean is unbiased for the population mean: $E_\theta(\bar{X}) = E_\theta(X)$ for any $\theta \in \Theta$. Unbiasedness usually implies mean unbiasedness, and we assume this unless stated otherwise. The function

$$b(\theta) = E_\theta(\varphi(X)) - g(\theta)$$

is called the **bias** of the estimator $\varphi(X)$. If we restrict ourselves to unbiased estimators $\varphi(X)$ only, it is best to choose, if possible, a $\varphi(X)$ whose variance $V_\theta(\varphi(X))$ is minimum uniformly for every $\theta \in \Theta$.

Theorem (Rao-Blackwell). If $T = t(X)$ is a \dagger sufficient statistic, then for any unbiased

estimator $\varphi(X)$ of g the †conditional expectation $\psi(t) = E(\varphi(X) | T = t)$ yields another unbiased estimator $\varphi^*(X) = \psi(t(X))$ of g , which satisfies $V_\theta(\varphi^*) \leq V_\theta(\varphi)$ for all $\theta \in \Theta$, with the equality holding if and only if $\varphi(x) = \varphi^*(x)$ (a.e. \mathcal{P}). The notation a.e. \mathcal{P} means that the statement concerned holds with probability 1 with respect to P_θ for each $\theta \in \Theta$. An estimator φ of $g(\theta)$ is called a **uniformly minimum variance (or UMV) unbiased estimator** if φ is unbiased for $g(\theta)$ and has a minimum variance uniformly in Θ among the class of unbiased estimators for $g(\theta)$.

Theorem (Lehmann-Scheffé). If T is a sufficient and †complete statistic, then for any estimable parametric function $g(\theta)$, there exists a unique UMV unbiased estimator of $g(\theta)$ that is a function of T . For example, suppose that $X = (X_1, X_2, \dots, X_n)$ is a random sample from a population with exponential type distribution P_θ with density $p_\theta(x) = \beta(\theta)u(x)\exp(\sum_{i=1}^k \alpha_i(\theta)t_i(x))$ with respect to Lebesgue measure and that the set $\{\alpha_1(\theta), \dots, \alpha_k(\theta) | \theta \in \Theta\}$ contains some open set of \mathbf{R}^k . In this case, $T = (t_1(X), \dots, t_k(X))$ is a sufficient and complete statistic, and hence every real-valued measurable function $\psi(T)$ is the unique UMV unbiased estimator of the parametric function $E_\theta(\psi(T))$. If for any $\theta \in \Theta$ the †median of the distribution of an estimator $\varphi(X)$ equals a real parametric function $g(\theta)$ when X is distributed as P_θ , i.e., if

$$P_\theta\{\varphi(X) < g(\theta)\} \leq \frac{1}{2} \leq P_\theta\{\varphi(X) \leq g(\theta)\},$$

then $\varphi(X)$ is called a **median unbiased estimator**. For example, a sample median (suitably defined for the case of an even number of samples) is median unbiased for the population median. If $\varphi(X)$ is a median unbiased estimator of g , then for any real-valued monotone function h , an estimator $h(\varphi(X))$ for $h(g(\theta))$ is median unbiased, that is, median unbiasedness is preserved under monotone transformations, which is not the case with mean unbiasedness.

Restricting our consideration to the class of all median unbiased estimators, we can use the function

$$a(u, \theta, \varphi) = \begin{cases} P_\theta\{\varphi(X) \leq u\} & \text{for } u < \theta \\ P_\theta\{\varphi(X) \geq u\} & \text{for } u > \theta \end{cases}$$

as an indicator of the behavior pattern of an estimator φ . The estimator φ that minimizes $a(u, \theta, \varphi)$ for all values of u and θ ($u \neq \theta$) is said to be **uniformly best**. This property is also preserved under monotone transformations.

Theorem (Birnbaum). If a family of distributions $\{P_\theta | \theta \in \Theta \subset \mathbf{R}\}$ has a monotone †likelihood ratio with respect to a statistic $t(x)$ and the distribution function $F(t, \theta)$ of $T = t(X)$ is continuous both in t for any θ and in θ for any

t , then there exists a uniformly best median unbiased estimator of θ . Actually, if $\theta = \hat{\theta}(t)$ is a solution of $F(t, \theta) = 1/2$, then $\varphi(X) = \hat{\theta}(t(X))$ is such an estimator.

If for any $\theta \in \Theta$ the †mode of the density function or the probability mass function of an estimator $\varphi(X)$ is equal to $g(\theta)$, then $\varphi(X)$ is called a **modal unbiased estimator** of $g(\theta)$.

D. Lower Bounded of the Variance of an Unbiased Estimator

When there does not exist a sufficient and complete statistic, we can still seek to minimize the variance of the (mean) unbiased estimator at every fixed point $\theta = \theta_0$. In the remainder of this section, \mathcal{P} is assumed to be dominated by a measure μ , and $p_\theta(x)$ denotes the density function of P_θ with respect to μ and $\pi_\theta(x) = p_\theta(x)/p_{\theta_0}(x)$. The following theorem guarantees the existence of the locally best unbiased estimator.

Theorem (Barankin). Let \mathcal{M} be the set of all unbiased estimators of a parametric function $g(\theta)$ with finite variance at $\theta = \theta_0$. Assume that \mathcal{M} is not empty and $E_{\theta_0}((\pi_\theta(X))^2) < \infty$. Then there exists an estimator φ_0 in \mathcal{M} that minimizes the variance at θ_0 within \mathcal{M} . Actually, $\{\varphi_0\} = \mathcal{M} \cap \mathcal{P}_0$, where \mathcal{P}_0 is the linear space generated by $\{\pi_\theta(x) | \theta \in \Theta\}$. The minimum variance is given as follows:

$$\begin{aligned} &V_{\theta_0}(\varphi_0) \\ &= \inf\{V_{\theta_0}(\varphi(X)); \varphi \in \mathcal{M}\} \\ &= \sup_I \left\{ \left(\sum_{i=1}^n a_i h(\theta_i) \right)^2 / E_{\theta_0} \left(\sum_{i=1}^n a_i \pi_{\theta_i}(X) \right)^2 \right\} \\ &= \sup_{II} \left\{ \sum_{i=1}^n \sum_{j=1}^n h(\theta_i) h(\theta_j) \lambda^{ij} \right\}, \end{aligned}$$

where $h(\theta) = g(\theta) - g(\theta_0)$ and λ^{ij} is the (i, j) -component of the inverse of the $n \times n$ matrix (λ_{ij}) with $\lambda_{ij} = E_{\theta_0}(\pi_{\theta_i}(X)\pi_{\theta_j}(X))$ and where the supremum \sup_I is taken over all positive integers n , $\theta_1, \dots, \theta_n \in \Theta$ and $a_1, \dots, a_n \in \mathbf{R}$, and becomes \sup_{II} when the supremum is taken over n and the θ_j . This theorem leads to the following three theorems with respect to the lower bound of the variance of an unbiased estimator. The first is immediate and the last two are obtained by replacing some order differences of π_θ with the corresponding differentials.

Theorem. For any unbiased estimator $\varphi(X)$ of g and $\theta_0 \in \Theta$, we have

$$V_{\theta_0}(\varphi(X)) \geq \sup_{\theta \in \Theta} \left\{ (g(\theta) - g(\theta_0))^2 / E_{\theta_0}(\pi_\theta(X) - \pi_{\theta_0}(X))^2 \right\}$$

(Chapman-Robbins-Kiefer inequality).

Theorem. Suppose $\Theta \subset \mathbf{R}$. For any unbiased estimator $\varphi(X)$ of g and under certain regularity conditions, we have

$$V_{\theta_0}(\varphi(X)) \geq \frac{(g'(\theta_0))^2}{E_{\theta_0}((\partial \log p_{\theta}(X)/\partial \theta|_{\theta=\theta_0})^2)}$$

(**Cramér-Rao inequality**), where the equality holds only for the exponential type distribution $p_{\theta}(x) = \beta(\theta)u(x)\exp(\alpha(\theta)\varphi(x))$. An example of such regularity conditions is (i)–(iii): (i) $E_{\theta_0}((\pi_{\theta}(X))^2) < \infty$ for all $\theta \in \Theta$; (ii) $p_{\theta}(x)$ has a partial derivative $p'_{\theta}(x)$ at $\theta = \theta_0$ (a.e. P_{θ_0}); and (iii)

$$\lim_{\Delta\theta \rightarrow 0} E_{\theta_0} \left[\left(\frac{p_{\theta_0+\Delta\theta}(X) - p_{\theta_0}(X)}{p_{\theta_0}(X)\Delta\theta} - \frac{p'_{\theta_0}(X)}{p_{\theta_0}(X)} \right)^2 \right] = 0.$$

Corollary. Let $X = (X_1, \dots, X_n)$ be a random sample from a distribution with density $f(x, \theta)$ and let

$$I(\theta) = E_{\theta}((\partial \log f(X_1, \theta)/\partial \theta)^2).$$

Since $E_{\theta}((\partial \log p_{\theta}(X)/\partial \theta)^2) = nI(\theta)$, the Cramér-Rao inequality implies

$$V_{\theta_0}(\varphi(X)) \geq (g'(\theta_0))^2/nI(\theta_0).$$

The number $I(\theta_0)$ is called the **Fisher information** of the distribution $f(x, \theta)$. When the equality holds for an unbiased estimator $\varphi(X)$, $\varphi(X)$ is called an **efficient estimator** of $g(\theta)$. In general, the **efficiency** of an unbiased estimator φ at $\theta = \theta_0$ is defined by

$$\text{Eff}(\varphi) = (g'(\theta_0))^2/(nI(\theta_0)V_{\theta_0}(\varphi)).$$

Theorem. For any unbiased estimator $\varphi(X)$ of $g(\theta)$ and under certain regularity conditions, we have

$$V_{\theta_0}(\varphi(X)) \geq \sum_{i=1}^k \sum_{j=1}^k g^{(i)}(\theta_0)g^{(j)}(\theta_0)K^{ij}$$

(**Bhattacharyya inequality**), where $g^{(i)}(\theta_0) = d^i g(\theta)/d\theta^i|_{\theta=\theta_0}$ and K^{ij} is the (i, j) -component of the inverse of the matrix (K_{ij}) with

$$K_{ij} = E_{\theta_0} \left(\frac{p_{\theta_0}^{(i)}(X)p_{\theta_0}^{(j)}(X)}{p_{\theta_0}(X)p_{\theta_0}(X)} \right), \quad i, j = 1, \dots, k.$$

An example of such regularity conditions is (i)–(iii): (i) $E_{\theta_0}((\pi_{\theta}(X))^2) < \infty$; (ii) $p_{\theta}(x)$ is k -times differentiable with respect to θ at $\theta = \theta_0$; (iii) the i th partial derivative $p_{\theta_0}^{(i)}(x)$, $i \leq k$, satisfies

$$\lim_{\Delta\theta \rightarrow 0} E_{\theta_0} \left[\left(\frac{\Delta^i p_{\theta}(X)|_{\theta=\theta_0}}{p_{\theta_0}(X)(\Delta\theta)^i} - \frac{p_{\theta_0}^{(i)}(X)}{p_{\theta_0}(X)} \right)^2 \right] = 0,$$

where $\Delta p_{\theta}(X)|_{\theta=\theta_0} = P_{\theta_0+\Delta\theta}(X) - P_{\theta_0}(X)$ and $\Delta^i p_{\theta}(X) = \Delta(\Delta^{i-1} p_{\theta}(X))$ for $i \geq 2$. For $k=1$ the Bhattacharyya lower bound is the same as the Cramér-Rao lower bound. In general, the former gives a sharper lower bound than the latter.

If the parameter is multidimensional, $\theta = (\theta_1, \dots, \theta_k)'$, then for any unbiased estimator

399 E
Statistical Estimation

$\varphi(X)$ of $g(\theta)$ and under similar conditions to those for the 1-dimensional case, we have

$$V_{\theta_0}(\varphi(X)) \geq \sum_{i=1}^k \sum_{j=1}^k g'_i(\theta_0)g'_j(\theta_0)J^{ij},$$

where $g'_i(\theta_0) = \partial g(\theta)/\partial \theta_i|_{\theta=\theta_0}$ and J^{ij} is the (i, j) -component of the inverse of the matrix (J_{ij}) with

$$J_{ij} = E_{\theta_0}(\partial \log p_{\theta}(X)/\partial \theta_i|_{\theta=\theta_0} \partial \log p_{\theta}(X)/\partial \theta_j|_{\theta=\theta_0}).$$

If $\theta^*(X) = (\theta_1^*(X), \dots, \theta_k^*(X))'$ is an unbiased estimator of $\theta = (\theta_1, \dots, \theta_k)$ (i.e., $E_{\theta}(\theta_i^*(X)) = \theta_i$ for $i = 1, 2, \dots, k$), then the covariance matrix $V_{\theta_0}(\theta^*(X))$ of $\theta^*(X)$ at θ_0 satisfies $V_{\theta_0}(\theta^*(X)) \geq J^{-1}$, that is, the difference $V_{\theta_0}(\theta^*(X)) - J^{-1}$ is a nonnegative definite matrix. If $X = (X_1, \dots, X_n)$ is a random sample from a distribution having density $f(x_1, \theta)$, then by setting

$$I_{ij} = E_{\theta_0}(\partial \log f(X_1, \theta)/\partial \theta_i|_{\theta=\theta_0} \times \partial \log f(X_1, \theta)/\partial \theta_j|_{\theta=\theta_0}),$$

we have $J_{ij} = nI_{ij}$. The matrix $I = (I_{ij})$ is called the **Fisher information matrix** of the distribution $f(x_1, \theta)$.

E. Decision-Theoretic Formulation
(→ 398 Statistical Decision Functions)

Let $W(\theta, a)$ (≥ 0) be the loss incurred from an estimate (or action) a of the parameter when the true value of the parameter is θ . The risk function of an estimator $\varphi(X)$ of the parametric function $g(\theta)$ is then defined as

$$r(\theta, \varphi) = E_{\theta}(W(\theta, \varphi(X))).$$

Statistical decision theory deals with the problem of minimizing, in an appropriate manner, the risk function by a suitable choice of φ . The notions of complete class, Bayes estimator, admissibility, minimax estimator, and invariant estimator, explained here and in Sections F–I, are the most important of the theory. The unbiased estimator explained in Section C may also be considered an important concept of the theory.

A class C of estimators is said to be essentially complete if for any estimator φ there exists an estimator φ_0 in C such that

$$r(\theta, \varphi_0) \leq r(\theta, \varphi)$$

for any $\theta \in \Theta$. The following two theorems hold, provided that the action space \mathcal{A} is \mathbf{R} and the loss function $W(\theta, a)$ is convex with respect to $a \in \mathcal{A}$ for any $\theta \in \Theta$.

Theorem (Hodges-Lehmann). If $W(\theta, a) \rightarrow \infty$ as $|a| \rightarrow \infty$, then the class of all nonrandomized estimators is essentially complete.

Theorem. If $T = t(X)$ is a sufficient statistic, then the class of all functions of T is essentially

complete. Actually, given any estimator $\varphi(X)$ of $g(\theta)$, the conditional expectation $\psi(t) = E(\varphi(X) | T = t)$ yields an estimator $\varphi_0(X) = \psi(t(X))$ satisfying $r(\theta, \varphi_0) \leq r(\theta, \varphi)$ for any θ , where the equality holds when and only when $\varphi \equiv \varphi_0$, provided that W is convex in the strict sense.

A loss function of the form

$$W(\theta, a) = \lambda(\theta)(a - g(\theta))^2, \quad \lambda(\theta) > 0,$$

is called a **quadratic loss functions**. If, in particular, $\lambda(\theta) \equiv 1$, then

$$r(\theta, \varphi) = E_\theta((\varphi(X) - g(\theta))^2)$$

is called the **mean square error** of the estimator $\varphi(X)$ of $g(\theta)$. This error coincides with the variance when the estimator is unbiased.

F. Bayes Estimators

Let ξ be an a priori distribution over the parameter space Θ associated with a certain σ -algebra \mathfrak{F} , and assume that $r(\theta, \varphi)$ is \mathfrak{F} -measurable for every φ . Denote by E^ξ the average operator relative to ξ . The infimum of the average risk $r(\xi, \varphi) = E^\xi(r(\theta, \varphi)) = E^\xi E_\theta(W(\theta, \varphi(X)))$ for φ running over its range is called the **Bayes risk** relative to ξ , while an estimator $\varphi(X)$ of $g(\theta)$ at which the average risk $r(\xi, \varphi)$ attains the infimum is called a **Bayes estimator** relative to ξ . A Bayes estimator is obtained as follows: Assume that \mathfrak{P} is dominated by a measure μ with $\mathfrak{B} \times \mathfrak{F}$ -measurable density $p_\theta(x)$, the loss function $W(\theta, a)$ is $\mathfrak{F} \times \mathfrak{C}$ -measurable, and

$$\int_{\Theta} p_\theta(x) d\xi(\theta) < \infty.$$

For each observed value of x , the Bayes estimator $\varphi(x)$ takes the value a that minimizes

$$r(a | x) = E^\xi(W(\theta, a) | x)$$

$$= \int_{\Theta} W(\theta, a) p(\theta | x) d\xi(\theta),$$

where $p(\theta | x)$ is the probability density, with given x , of θ . We call $r(a | x)$ the **posterior risk**.

Theorem (Girshick-Savage). Suppose that the loss function is quadratic. For any x the value of the posterior risk is either ∞ (for every value of a) or finite (for all or only one value of a). If the Bayes risk relative to ξ is finite, then a Bayes estimator $\varphi^*(X)$ relative to ξ is determined uniquely as follows: $\varphi^*(x) = a_0$ if $r(a_0 | x) < \infty$ for only one value a_0 , whereas $\varphi^*(x) = E^\xi(g(\theta)\lambda(\theta) | x) / E^\xi(\lambda(\theta) | x)$ if $r(a | x) < \infty$ for every a . If $E^\xi(\lambda(\theta)) < \infty$, then a Bayes estimator is either biased or has average risk zero.

G. Admissibility of Estimators

An estimator $\varphi_0(X)$ of a parametric function $g(\theta)$ is said to be **admissible** if and only if for any estimator $\varphi(X)$ of $g(\theta)$ the inequality $r(\theta, \varphi) \leq r(\theta, \varphi_0)$ for all $\theta \in \Theta$ implies that

$$r(\theta, \varphi) = r(\theta, \varphi_0)$$

for all $\theta \in \Theta$. If an estimator is the unique Bayes estimator relative to some a priori distribution, then it is admissible. For example, let X_1, \dots, X_n be a random sample from $N(\theta, 1)$, and let $W(\theta, a) = (a - \theta)^2$. Then $\varphi(X) = (c + n\sigma^2 \bar{X}) / (1 + n\sigma^2)$ is the unique Bayes estimator relative to the prior distribution $N(c, \sigma^2)$ of θ , where \bar{X} is the sample mean. Hence any estimator of the form $\varphi(X) = a\bar{X} + b$ is admissible when $0 < a < 1$ and $-\infty < b < \infty$.

In the rest of this section and the next section, we restrict ourselves to quadratic loss functions. If a statistic of the form $c\varphi(X)$ with real c is an admissible estimator of $g(\theta)$, then

$$\inf_{\theta} \left(g(\theta) \frac{E_\theta(\varphi)}{E_\theta(\varphi^2)} \right) \leq c \leq \sup_{\theta} \left(g(\theta) \frac{E_\theta(\varphi)}{E_\theta(\varphi^2)} \right).$$

Theorem (Karlin). Let X be a random variable having a 1-dimensional exponential type distribution $dP_\theta(x) = \beta(\theta)e^{\theta x} d\mu(x)$ with a parameter space $\Theta = I(\underline{\theta}, \bar{\theta}) = \{\theta | \int_{-\infty}^{\infty} e^{\theta x} d\mu(x) < \infty\}$ a closed or open interval, and let $g(\theta) = E_\theta(X) = -\beta'(\theta)/\beta(\theta)$ be a parametric function to be estimated. Then the estimator $\varphi_\lambda(X) = X/(\lambda + 1)$ for real λ is admissible provided that $\int_{\underline{\theta}}^{\bar{\theta}} (\beta(\theta))^{-\lambda} d\theta \rightarrow \infty$ as $\bar{\theta} \rightarrow \bar{\theta}$ and $\int_a^c (\beta(\theta))^{-\lambda} d\theta \rightarrow \infty$ as $a \rightarrow \underline{\theta}$ for any $c \in (\underline{\theta}, \bar{\theta})$.

Corollary. When $\Theta = (-\infty, \infty)$ the estimator $\varphi_0(X) = X$ is admissible.

Corollary. Let $\Theta = (-\infty, \infty)$, and assume that both intervals $(-\infty, 0]$ and $[0, \infty)$ have positive measure with respect to μ . Then every estimator of the form $\varphi(X) = aX$ with $0 < a \leq 1$ is admissible. This theorem can be applied to a random sample X_1, \dots, X_n drawn from an exponential type distribution because the sufficient statistic $\bar{X} = \sum X_i/n$ has an exponential type distribution and $E_\theta(\bar{X}) = E_\theta(X_1)$.

Theorem (Karlin). Let X be a random variable having a distribution $dP_\theta(x) = q(\theta) \cdot r(x) dx$ for $0 \leq x \leq \theta$ and $= 0$ otherwise, with the parameter space $\Theta = (0, \infty)$, where $\int_0^\theta r(x) dx < +\infty$ and $\int_0^\infty r(x) dx = \infty$. Among the estimators of the type $\varphi_c(X) = c(q(X))^{-\alpha}$ for $g(\theta) = (q(\theta))^{-\alpha}$ with $\alpha > 0$, only one estimator with the value $c = (2\alpha + 1)/(\alpha + 1)$ is admissible. This theorem is applicable also when the size of the random sample is larger than 1.

Theorem (Stein). Let X_1, \dots, X_n be a random sample from a univariate distribution $dP_\theta(x) = f(x - \theta) dx$ with a location parameter θ . Define

$$A_k = A_k(x_1, \dots, x_n) = \int_{-\infty}^{\infty} \theta^k \left(\prod_{i=1}^n f(x_i - \theta) \right) d\theta$$

for $k=0, 1, 2$. If

$$\int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} \left(\frac{A_2}{A_0} - \left(\frac{A_1}{A_0} \right)^2 \right)^{3/2} \prod_{i=1}^n f(x_i) \times \prod_{i=1}^n dx_i < \infty,$$

then the **Pitman estimator** $\varphi_0(X_1, \dots, X_n) = A_1(X_1, \dots, X_n)/A_0(X_1, \dots, X_n)$ of the parameter θ is admissible.

Inadmissibility of the Usual Estimator for Three or More Location Parameters. Let $X = (X_1, \dots, X_k)'$ be a k -variate normal random variable with mean $\theta = (\theta_1, \dots, \theta_k)'$ and covariance matrix I , the identity. Then the Pitman estimator of θ is $\hat{\theta} = X$. However, Stein showed that X is inadmissible. It is strictly dominated by the estimator $\theta^*(X) = (1 - (k-2)/|X|^2)X$, where $|\cdot|$ denotes the Euclidean norm $|X|^2 = \sum_{i=1}^k X_i^2$. That is, if $k \geq 3$, $E|\theta^*(X) - \theta|^2 < E|X - \theta|^2$ for any θ .

An estimator such as $\theta^*(X)$ is called **Stein's shrinkage estimator** (James and Stein, *Proc. 4th Berkeley Symp.*, 1 (1960)).

H. Minimax Estimation

An estimator $\varphi^*(X)$ is said to be **minimax** if and only if

$$\sup_{\theta} r(\theta, \varphi^*) = \inf_{\varphi} \sup_{\theta} r(\theta, \varphi).$$

If an estimator φ^* is admissible and the risk $r(\theta, \varphi^*)$ is constant with respect to θ , then φ^* is minimax.

Theorem (Hodges-Lehmann). A Bayes estimator φ^* relative to an a priori distribution ζ is minimax if ζ assigns the whole probability to a subset $\omega \subset \Theta$, $r(\theta, \varphi^*)$ is constant (say, c) for $\theta \in \omega$, and $r(\theta, \varphi^*) \leq c$ for $\theta \in \Theta$. Let X have a binomial distribution $B(n, \theta)$, $0 < \theta < 1$; θ is unknown. If the prior distribution of θ is a beta distribution $\beta(\sqrt{n}/2, \sqrt{n}/2)$, then the Bayes estimator is $T^*(X) = (X + \sqrt{n}/2)/(n + \sqrt{n})$, which has constant risk $E_{\theta}(T^*(X) - \theta)^2 = (2(1 + \sqrt{n}))^{-2}$ for all θ , $0 < \theta < 1$. Thus, according to this theorem, $T^*(X)$ is minimax. It is interesting to compare the mean square error of $T^*(X)$ to that of minimum variance unbiased estimator $\hat{\theta} = X/n$, $\theta(1 - \theta)/n$.

Theorem (Wald). If there exists a sequence of prior distributions $\{\zeta_n\}$ such that

$$\liminf_{n \rightarrow \infty} \left(r(\theta, \varphi^*) - \inf_{\varphi} \int_{\Theta} r(\theta, \varphi) d\zeta_n(\theta) \right) \leq 0$$

for any $\theta \in \Theta$, then φ^* is minimax. For example, the last theorem led to the proof of the fact that the Pitman estimator of a location parameter is minimax [4]. In the discussion of robust estimation, Huber (*Ann. Math. Statist.*,

35 (1964)) proved that Huber's minimax robust location estimator minimizes the maximum asymptotic variance over some family of symmetric distributions in a neighborhood of the normal distribution (\rightarrow 371 Robust and Non-parametric Methods).

I. Invariant Estimator

For simplicity, assume that the range A of a parametric function $g(\theta)$ coincides with the parameter space, and consider the point estimation of $g(\theta) \equiv 0$ (θ is not necessarily real). Suppose that there exist two groups $G = \{\tau\}$ and $\bar{G} = \{\bar{\tau}\}$ of one-to-one measurable transformations of \mathcal{X} and Θ , respectively, onto themselves such that (i) there exists a homeomorphic mapping $\tau \rightarrow \bar{\tau}$ from G to \bar{G} ; (ii) if X has a distribution P_{θ} , then τX has the distribution $P_{\bar{\tau}\theta}$; and (iii) $W(\tau\theta, \bar{\tau}a) = W(\theta, a)$ for any θ, a , and τ . An estimator φ is said to be **invariant** if it satisfies $\varphi(\tau x) = \bar{\tau}\varphi(x)$ for any $\tau \in G$, a.e. \mathcal{P} . An estimator φ is called a **best invariant estimator** if the risk function $r(\theta, \varphi')$, where φ' is an invariant estimator, takes its minimum value when $\varphi' = \varphi$.

If the group \bar{G} is \dagger transitive on Θ , then the risk function of any invariant estimator is independent of the value of θ , and hence any admissible invariant estimator is best invariant. For example, in the point estimation of a location parameter with a quadratic loss function, the Pitman estimator is best invariant.

Theorem. If Θ is a compact topological space, \bar{G} is a group of homeomorphisms of Θ onto itself, and \bar{G} is homeomorphic to Θ under $g \in \bar{G} \rightarrow \bar{g}\theta_0 \in \Theta$ with a fixed $\theta_0 \in \Theta$, then any Bayes estimator relative to the \dagger right-invariant Haar measure over \bar{G} is best invariant. This result can be generalized to a locally compact Θ (\rightarrow 398 Statistical Decision Functions).

J. Sequential Estimation

Estimation methods based on sequential sampling are not as popular as \dagger sequential tests, because their efficiency is not very large compared to that of nonsequential estimation. A generalization of the Cramér-Rao inequality to any sequential unbiased estimator $\varphi(X)$ of a parametric function $g(\theta)$ is the **Wolfowitz inequality**,

$$V_{\theta}(\varphi(X)) \geq (g'(\theta))^2 / (E_{\theta}(N)I(\theta))$$

for every $\theta \in \Theta$, under regularity conditions similar to those for the fixed-size sample problem, where N is the sample size and $I(\theta)$ the Fisher information.

K. Asymptotic Theory

In practical problems of statistical inference the sample size n is often large enough to give sharp estimates of the parameters involved; then the sample distributions of estimators can be approximated closely by their asymptotic distributions, which are of a simpler nature. Assume that $X = (X_1, X_2, \dots)$ is a sequence of independent and identically distributed (i.i.d.) random variables with the common distribution $P_\theta, \theta \in \Theta$. For each n , let $\varphi_n = \varphi_n(X_1, \dots, X_n)$ be an estimator of $g(\theta)$ that is a function of θ to $\mathcal{A} (\subset \mathbf{R}^p)$. Thus φ_n is a measurable mapping from $(\mathcal{X}^n, \mathfrak{B}^n)$ to $(\mathcal{A}, \mathcal{C})$. Let us denote the distribution of φ_n by $\mathcal{L}(\varphi_n), \mathcal{L}(\varphi_n|\theta)$ or $\mathcal{L}(\varphi_n|P_\theta)$, the last two emphasizing that the underlying probability distribution is P_θ . For example, if the mean vector $E_\theta(\varphi_n) = m_n(\theta)$ and the covariance matrix $v_n(\theta) = V_\theta(\varphi_n)$ exist for every n , and if $\mathcal{L}[v_n(\theta)^{-1/2}(\varphi_n(X) - m_n(\theta))|\theta] \rightarrow N_p(0, I)$ as $n \rightarrow \infty$, then $\mathcal{L}(\varphi_n|\theta)$ is approximated by a p -variate normal distribution $N_p(m_n(\theta), v_n(\theta))$ (\rightarrow 341 Probability Measures D). φ_n is said to be **asymptotically (mean) unbiased** for $g(\theta)$ if $m_n(\theta) \rightarrow g(\theta)$ for any $\theta \in \Theta$ as $n \rightarrow \infty$. But we often calculate the asymptotic distribution without obtaining the exact mean and covariance matrix of the estimator φ_n for each n . In the asymptotic theory it may be reasonable to regard the sequence of estimators $\{\varphi_n\}$ rather than each estimator φ_n as an "estimator," but we do not bother with the difference between these definitions of an estimator.

Consistency. $\{\varphi_n\}$ is called a **consistent estimator** of $g(\theta)$ if φ_n converges to $g(\theta)$ in probability as $n \rightarrow \infty$:

$$\lim P_\theta\{|\varphi_n - g(\theta)| > \varepsilon\} = 0 \text{ for any } \varepsilon > 0 \text{ and every } \theta \in \Theta.$$

If the convergence is almost sure, it is called **a.s. consistent**. For example, if φ_n is asymptotically unbiased with the covariance matrix $v_n(\theta)$ such that $|v_n(\theta)| \rightarrow 0$ as $n \rightarrow \infty$, then φ_n is a consistent estimator of $g(\theta)$. A sufficient condition for existence of a consistent estimator is given by the following result.

Theorem (LeCam). Let \mathcal{X} be a Euclidean space and \mathfrak{B} the σ -algebra of all Borel sets in \mathcal{X} . If the parameter space Θ is a locally compact subset of $\mathbf{R}^k, P_\theta \neq P_{\theta'}$ for any $\theta \neq \theta'$ (identifiability condition), and $P_{\theta_n} \rightarrow P_\theta$ whenever $\theta_n \rightarrow \theta$, then there exists a consistent estimator of θ . $\varphi_n = g(T_n)$ is a consistent estimator of $g(\theta)$ if $\{T_n\}$ is a consistent estimator of θ and $g(\theta)$ is a continuous function of θ .

Asymptotic Normality. The class of estimators is restricted to what are called consistent esti-

matoms. An estimator $\{\varphi_n\}$ is said to be **asymptotically normally distributed** if the asymptotic distribution of $n^{1/2}(\varphi_n - g(\theta))$ is normal:

$$\mathcal{L}[n^{1/2}(\varphi_n - g(\theta))|\theta] \rightarrow N_p(\mu(\theta), v(\theta)) \text{ as } n \rightarrow \infty.$$

$\mu(\theta)$ and $v(\theta)$ are called the **asymptotic bias** and **asymptotic covariance matrix**, respectively. They are not always equal to the limits, if any, of the mean and covariance matrix of $n^{1/2}(\varphi_n - g(\theta))$. $\{\varphi_n\}$ is usually called a **consistent and asymptotically normal (CAN) estimator** if the asymptotic distribution of $n^{1/2}(\varphi_n - g(\theta))$ is normal with the asymptotic bias zero. Then the distribution $\mathcal{L}(\varphi_n|\theta)$ is approximated by $N_p(0, v(\theta)/n)$. For example, the †moment method estimator is a CAN estimator.

Theorem. Let $\{\varphi_n\}$ be a CAN estimator of $g(\theta) \in \mathbf{R}^1$ with asymptotic variance $v(\theta)$. Then $\liminf_{n \rightarrow \infty} E_\theta\{n|\varphi_n - g(\theta)|^2\} \geq v(\theta)$ for every $\theta \in \Theta$.

Theorem. Suppose that $g(\theta)$ is a continuously differentiable function from $\Theta (\subset \mathbf{R}^k)$ to $\mathbf{R}^p (p \leq k)$. Let $G(\theta) = (\partial g_i(\theta)/\partial \theta_j)$, the †Jacobian matrix. If $\{T_n\}$ is a CAN estimator of θ with asymptotic covariance matrix $v(\theta)$, then $\{g(T_n)\}$ is a CAN estimator of $g(\theta)$:

$$\mathcal{L}[n^{1/2}(g(T_n) - g(\theta))|\theta] \rightarrow N_p(0, G(\theta)v(\theta)G(\theta)').$$

An estimator $\{T_n\}$ is said to be a **best asymptotically normal (BAN) estimator** of θ if $\{T_n\}$ is a CAN estimator of θ with asymptotic variance $I^{-1}(\theta)$, where $I(\theta)$ is the †Fisher information matrix on θ in a single observation. We can see that the maximum likelihood (ML) estimator (\rightarrow Section M) is a BAN estimator.

Functional on Distribution Functions. Let $\varphi(F)$ be a functional on distribution functions to \mathbf{R}^1 . Let us consider the class of estimators that are defined by $\varphi_n = \varphi(\hat{F}_n)$, where \hat{F}_n is the †empirical distribution function of n samples X_1, \dots, X_n . An estimator $\{\varphi_n\}$ with $\varphi_n = \varphi(\hat{F}_n)$ for each n is said to be **Fisher consistent** for $g(\theta)$ if $\varphi(F_\theta) = g(\theta)$ for every $\theta \in \Theta$ when F_θ is the true distribution function. $\{\varphi_n\}$ is also a.s. consistent for $g(\theta)$ if $\{\varphi_n\}$ is a Fisher consistent estimator of $g(\theta)$ and if φ is a continuous functional. Furthermore, if φ is differentiable, we can see that $\{\varphi_n\}$ is also a CAN estimator by using the fact that $n^{1/2}(\hat{F}_n(F_\theta^{-1}(t)) - t), 0 \leq t \leq 1$, converges weakly to the †Brownian bridge. Let S be a set of distribution functions. S is said to be a star-shaped set of F if $H \in S$ implies $F^{(t)} = (1-t)F + tH \in S$ for any $t \in [0, 1]$.

Theorem (Von Mises). Assume that (F1) there exists a star-shaped set S_θ at F such that $\lim_n P_\theta\{\hat{F}_n \in S_\theta\} = 1$; (F2) for any $t \in [0, 1]$ and $H \in S_\theta$, there exist derivatives $(d^i/dt^i)\varphi[(1-t)F + tH], i = 1, 2$; (F3) there exists $\psi_\theta(y)$ from \mathbf{R}^1 to \mathbf{R}^1 such that

$\frac{d}{dt} \varphi[(1-t)F_\theta + tH]|_{t=0} = \int_{-\infty}^{\infty} \psi_\theta(y) d(H(y) - F_\theta(y))$ for all $H \in \mathcal{S}_\theta$; and

$$(F4) \lim_{n \rightarrow \infty} P_\theta \left\{ n^{1-\delta} \sup_{t \in [0,1]} \left| \frac{d^2}{dt^2} \varphi[F_{\theta n}^{(t)}] \right| > c \right\} = 0$$

for any δ and $\varepsilon > 0$, where $F_{\theta n}^{(t)} = (1-t)F_\theta + t\hat{F}_n$. Then if φ_n with $\varphi_n = \varphi(\hat{F}_n)$ is Fisher consistent for $g(\theta)$, we have

$$\mathcal{L}[n^{1/2}(\varphi_n - g(\theta))|\theta] \rightarrow N(0, v(\theta)),$$

where

$$v(\theta) = \int_{-\infty}^{\infty} \psi_\theta(y)^2 dF_\theta(y) - \left\{ \int_{-\infty}^{\infty} \psi_\theta(y) dF_\theta(y) \right\}^2.$$

$\{c_n\}$ -Consistency. For a sequence of positive numbers c_n tending to infinity as $n \rightarrow \infty$, an estimator T_n is called **consistent for $\theta \in \Theta$ with order c_n** (or **$\{c_n\}$ -consistent** for short) if for every $\varepsilon > 0$ and every $\theta \in \Theta$ there exist a sufficiently small positive number δ and a sufficiently large number K satisfying

$$\limsup_{n \rightarrow \infty} \sup [P_\tau \{c_n | T_n - \tau| \geq K\}; |\tau - \theta| < \delta] < \varepsilon.$$

Let $\{c_n\}$ be a maximal order of consistency. This notion was introduced by Takeuchi and Akahira. They studied consistent estimators of location parameters with various orders. Let $\mathcal{X} = \Theta = \mathbf{R}^1$. Suppose that for every $\theta \in \Theta$, P_θ has a density function $f(x - \theta)$ with respect to the Lebesgue measure.

Theorem. Assume that

- (OC1) $f(x) > 0$ if $a < x < b$ and $f(x) = 0$ if $x \leq a$ or $x \geq b$;
- (OC2) there exist positive numbers $0 < \alpha \leq \beta < \infty$ and $0 < A', B' < \infty$ such that

$$\lim_{x \rightarrow a+0} (x-a)^{1-\alpha} f(x) = A',$$

$$\lim_{x \rightarrow b-0} (b-x)^{1-\beta} f(x) = B';$$

- (OC3) $f(x)$ is twice continuously differentiable in the interval (a, b) and there exist positive numbers $0 < A'', B'' < \infty$ such that

$$\lim_{x \rightarrow a+0} (x-a)^{2-\alpha} |f'(x)| = A'',$$

$$\lim_{x \rightarrow b-0} (b-x)^{2-\beta} |f'(x)| = B''.$$

Assume further that $f''(x)$ is bounded if $\alpha \geq 2$. Then for each α there exists a consistent estimator with the order given in Table 1.

Table 1

α	order c_n	$\{c_n\}$ -consistent estimator
$0 < \alpha < 2$	$n^{1/\alpha}$	$\{\min X_i + \max X_i - (a+b)\}/2$
$\alpha = 2$	$(n \log n)^{1/2}$	ML estimator
$\alpha > 2$	$n^{1/2}$	ML estimator

L. Moment Method

The moment method is also utilized to obtain estimators. Suppose that $\mathcal{X} \subset \mathbf{R}^1$ and $\Theta \subset \mathbf{R}^k$. Denote the \dagger population distribution function by F_θ and the \dagger empirical distribution function of n samples X_1, \dots, X_n by \hat{F}_n . The following system of simultaneous equations is derived from letting the j th \dagger population moment

$$\mu_j(\theta) = E_\theta(X^j) = \int x^j F_\theta(dx)$$

be equal to the j th \dagger sample moment

$$m_{nj} = n^{-1} \sum_{i=1}^n X_i^j = \int x^j \hat{F}_n(dx).$$

For example, for $j = 1, \dots, k$,

$$\mu(\theta) = (\mu_1(\theta), \dots, \mu_k(\theta))' = (m_{n1}, \dots, m_{nk})' = m_n.$$

A **moment method estimator** is determined as a solution $\theta = \tilde{\theta}_n(x) \in \Theta$ of k numbers of simultaneous equations.

Theorem. Assume that the function $\mu(\theta)$ from Θ to \mathbf{R}^k is continuously differentiable and that the Jacobian matrix $M(\theta) = \partial\mu(\theta)/\partial\theta = (\partial\mu_i(\theta)/\partial\theta_j)$, $i, j = 1, \dots, k$, is nonsingular in a neighborhood of the true parameter. Then the moment method estimator exists and is a CAN estimator:

$$\mathcal{L}[n^{1/2}(\tilde{\theta}_n - \theta)|\theta] \rightarrow N_k(0, M(\theta)^{-1} v(\theta) M(\theta)^{-1}),$$

where $v(\theta) = (\text{cov}_\theta(X^i, X^j))$, $i, j = 1, \dots, k$. In general, a moment method estimator is not a BAN estimator. However, in view of its simple form, a moment method estimator is important and often utilized as a first-step estimator in order to determine the maximum likelihood estimator by the iteration method.

M. Maximum Likelihood Method

Suppose that a distribution P_θ has the density function $f(x, \theta)$, $\theta \in \Theta \subset \mathbf{R}^k$, with respect to a $\dagger\sigma$ -finite measure μ , and let x_1, \dots, x_n be observed values of random samples X_1, \dots, X_n from the population $f(x, \theta)$. Then the function L_n of θ defined by

$$L_n(\theta; x_1, \dots, x_n) = \prod_{i=1}^n f(x_i, \theta)$$

is called the **likelihood function**. If $\theta = \hat{\theta}_n(x_1, \dots, x_n)$ maximizes the value of $L_n(\theta)$ for fixed x_1, \dots, x_n and if it is a measurable mapping from $(\mathcal{X}^n, \mathfrak{B}^n)$ to (Θ, \mathcal{C}) with \mathcal{C} a $\dagger\sigma$ -algebra of subsets of Θ , then $\hat{\theta}_n(X) = \hat{\theta}_n(X_1, \dots, X_n)$ is called the **maximum likelihood (ML) estimator of θ** . This method of finding estimators is called the **maximum likelihood method**. If the parameter is transformed into a new parameter $\eta = h(\theta)$ by means of a known one-to-

one bimeasurable transformation h and if there exists a unique ML estimator $\hat{\theta}_n$ of θ , then $\hat{\eta}_n(X) = h(\hat{\theta}_n(X))$ is a unique ML estimator of η . In other words, the ML estimator is invariant for every one-to-one transformation.

Many statisticians have investigated and improved known adequate regularity conditions under which the ML estimator exists and is a BAN estimator.

Theorem (Wald). Assume that

(C1) Θ is a closed subset of \mathbf{R}^k with nonempty interior Θ^0 ;

(C2) for any $x \in \mathcal{X}$, $f(x, \theta)$ is continuous with respect to θ and $\lim_{|\theta| \rightarrow \infty} f(x, \theta) = 0$ if Θ is not bounded;

(C3) if $\theta_1 \neq \theta_2$, then $P_{\theta_1} \neq P_{\theta_2}$ and $\int |f(x, \theta_1) - f(x, \theta_2)| d\mu(x) > 0$;

(C4) $E_{\theta_0}(|\log f(X, \theta_0)|) < \infty$; and

(C5) $E_{\theta_0}(\log^+ f(X, \theta, \rho)) < \infty$ and $E_{\theta_0}(\log^+ \varphi(X, r)) < \infty$, where $f(x, \theta, \rho) = \sup\{f(x, \theta') : |\theta' - \theta| \leq \rho\}$ and $\varphi(x, r) = \sup\{f(x, \theta) : |\theta| > r\}$. (The last two functions are measurable according to assumption (C2).)

Then if a sequence of measurable functions, $\{\bar{\theta}_n(x_1, \dots, x_n)\}$, satisfies

$$\liminf_{n \rightarrow \infty} \left\{ \frac{L_n(\bar{\theta}_n; x_1, \dots, x_n)}{L_n(\theta_0; x_1, \dots, x_n)} \right\} \geq C > 0 \quad (\text{a.s. } P_{\theta_0}),$$

then as $n \rightarrow \infty$, $\bar{\theta}_n(X_1, \dots, X_n)$ converges a.s. to the true value θ_0 of the parameter. Hence if the ML estimator exists, it is a.s. consistent. Pfanzagl (*Metrika*, 14 (1969)) and Fu and Gleser (*Ann. Inst. Statist. Math.*, 27 (1975)) gave rigorous proofs for the existence of the ML estimator.

Theorem. Under assumptions (C1) and (C2), there exists a maximum likelihood estimator $\hat{\theta}_n$ for any positive integer n . That is, $\hat{\theta}_n = \hat{\theta}_n(x_1, \dots, x_n)$ is a measurable function from $(\mathcal{X}^n, \mathfrak{B}^n)$ to (Θ, \mathcal{C}) and satisfies $L(\hat{\theta}_n; x_1, \dots, x_n) = \sup_{\theta} L(\theta; x_1, \dots, x_n)$.

In the remainder of this section we suppose that assumptions (C1)–(C5) are satisfied. We use the notation

$$\frac{\partial f}{\partial \theta} = \left(\frac{\partial}{\partial \theta_i} f(x, \theta) \right), \text{ a } k\text{-column vector,}$$

$$\frac{\partial^2 f}{\partial \theta^2} = \left(\frac{\partial^2}{\partial \theta_i \partial \theta_j} f(x, \theta) \right), \text{ a } k \times k \text{ matrix,}$$

$$\frac{\partial^3 \log f}{\partial \theta^3} = \left(\frac{\partial^3 \log f(x, \theta)}{\partial \theta_h \partial \theta_i \partial \theta_j} \right), \quad h, i, j = 1, \dots, k.$$

Theorem (Cramér). Assume that

(AN1) for a.s. $[\mu]x$, $f(x, \theta)$ is three-times continuously differentiable with respect to each component of $\theta = (\theta_1, \dots, \theta_k) \in \Theta^0$;

(AN2) for $\theta \in \Theta^0$, $\int_x \frac{\partial f(x, \theta)}{\partial \theta} d\mu = 0$

and $\int_x \frac{\partial^2 f(x, \theta)}{\partial \theta^2} d\mu = 0$;

(AN3) $E_{\theta} \left(\left| \frac{\partial}{\partial \theta} \log f(x, \theta) \right|^3 \right) < \infty$ for $\theta \in \Theta^0$;

(AN4) the Fisher information matrix $I(\theta) = E_{\theta} \left[\left(\frac{\partial}{\partial \theta} \log f(x, \theta) \right) \left(\frac{\partial}{\partial \theta} \log f(x, \theta) \right)' \right]$ exists and is positive definite for $\theta \in \Theta^0$; and

(AN5) there exists an $H(x)$ such that

$$\left| \frac{\partial^3}{\partial \theta^3} \log f(x, \theta) \right| < H(x) \text{ and } E_{\theta}(H(X)) < C, \text{ a constant for } \theta \in \Theta^0.$$

Then the maximum likelihood estimator is a BAN estimator: $\mathcal{L}[n^{1/2}(\hat{\theta}_n - \theta) | \theta] \rightarrow N(0, I(\theta)^{-1})$ as $n \rightarrow \infty$ for $\theta \in \Theta^0$. Note that under assumption (AN1) the likelihood function attains the maximum in Θ^0 with probability tending to 1 as $n \rightarrow \infty$ if the true value of the parameter exists in Θ^0 . Hence the ML estimator is determined as a root $\theta = \hat{\theta}_n(x_1, \dots, x_n)$ of the **likelihood equation** with the same probability as above:

$$\frac{\partial}{\partial \theta} \log L_n(\theta) = \left(\sum_{i=1}^n \frac{\partial}{\partial \theta_j} \log f(x_i, \theta) \right)_{j=1, \dots, k} = 0.$$

We also call $n^{-1} \partial \log L_n(\theta) / \partial \theta$ the **likelihood estimating function**. The essential fact used in the proof of the above theorem is the asymptotic equivalence of the ML estimator and the likelihood estimating function:

$$\Delta_n(\theta) - I(\theta)n^{1/2}(\hat{\theta}_n - \theta) \rightarrow 0 \text{ in } P_{\theta} \text{ as } n \rightarrow \infty,$$

where $\Delta_n(\theta) = n^{-1/2} \partial \log L_n(\theta) / \partial \theta$. Note the fact that

$$\mathcal{L}[\Delta_n(\theta) | \theta] \rightarrow N_k(0, I(\theta)) \text{ as } n \rightarrow \infty$$

holds according to the central limit theorem (\rightarrow 250 Limit Theorems in Probability Theory B (1)).

Contiguity. We now turn to the situation where we need asymptotic distributions under the alternative distribution $P_{\theta + n^{-1/2}h}$ with $\theta + n^{-1/2}h \in \Theta$ in estimation as we do in testing hypotheses (\rightarrow 400 Statistical Hypothesis Testing). The notion of contiguity, due to LeCam (1960), is basic for the asymptotic methods of estimation theory. We consider sequences $\{P_n\}$ and $\{P'_n\}$ of probability measures on $(\mathcal{X}^n, \mathfrak{B}^n)$ with the \dagger Radon-Nikodym derivatives p_n and p'_n with respect to a σ -finite measure, such as $P_n + P'_n$. Denote by $\chi_n = \Lambda[P'_n; P_n]$ a generalized log-likelihood ratio that is defined by $\log p'_n/p_n$ on the set $\{p_n p'_n > 0\}$ and is an arbitrary measurable function on the set $\{p_n p'_n = 0\}$. Let $\{B_n\}$ be any sequence of $\{\mathfrak{B}^n\}$ -measurable sets, and let $\{T_n\}$ be any sequence of $\{\mathfrak{B}^n\}$ -measurable functions. A sequence of distributions $\{\mathcal{L}[T_n | P_n]\}$ is said to be **relatively compact** if every subsequence $\{n'\} \subset \{n\}$ contains a further subsequence $\{m\} \subset \{n'\}$ along which it converges to a prob-

ability distribution. In the Euclidean space relative compactness is equivalent to **tightness**: that is, for every $\epsilon > 0$ there is a $b(\epsilon)$ such that $P_n\{|T_n| > b(\epsilon)\} < \epsilon$ for every n .

Theorem. The following statements are all equivalent.

- (1) For any $\{T_n\}$, $T_n \rightarrow 0$ in P_n if and only if $T_n \rightarrow 0$ in P'_n .
- (2) For any $\{T_n\}$, $\{\mathcal{L}[T_n|P_n]\}$ is relatively compact if and only if $\{\mathcal{L}[T_n|P'_n]\}$ is relatively compact.
- (3) For any $\{B_n\}$, $P_n\{B_n\} \rightarrow 0$ if and only if $P'_n\{B_n\} \rightarrow 0$.
- (4) Whatever the choice of χ_n , $\{\mathcal{L}[\chi_n|P_n]\}$ and $\{\mathcal{L}[\chi_n|P'_n]\}$ are relatively compact.
- (5) Whatever the choice of χ_n , $\{\mathcal{L}[\chi_n|P_n]\}$ is relatively compact. Furthermore, if $\{m\} \subset \{n\}$ is a subsequence of $\{n\}$ such that $\mathcal{L}[\chi_m|P_m]$ converges to $\mathcal{L}[\chi]$, then $E\{e^{\chi}\} = 1$.

Two sequences $\{P_n\}$ and $\{P'_n\}$ satisfying requirements (1)–(5) of the above theorem are said to be **contiguous**.

Theorem. Suppose that $\{P_n\}$ and $\{P'_n\}$ are contiguous. Let $\{m\} \subset \{n\}$ be a subsequence such that $\mathcal{L}[\chi_m, T_m|P_m]$ converges to a limit $\mathcal{L}[\chi, T]$. Then $\mathcal{L}[\chi_m, T_m|P'_m]$ converges to $e^{\chi} \mathcal{L}[\chi, T]$, where $v = e^{\chi} \mathcal{L}[\chi, T]$ is given by $v(A) = \int_A e^{\chi} d\mathcal{L}[\chi, T]$.

Now, set $P_n = P_{\theta}^n$ and $P'_n = P_{\theta+n^{-1/2}h}^n$ for each n . Under suitable regularity conditions, such as assumptions (C1)–(C5) and (AN1)–(AN5), it is easy to see that $\{P_{\theta}^n\}$ and $\{P_{\theta+n^{-1/2}h}^n\}$ are contiguous. At the same time, we can see that the asymptotic linearity of $\Lambda_n(\theta + n^{-1/2}h; \theta) = \Lambda[P_{\theta+n^{-1/2}h}^n; P_{\theta}^n]$ holds (say) in the vicinity of the true parameter as follows:

$$\Lambda_n(\theta + n^{-1/2}h; \theta) - h' \Delta_n(\theta) + \frac{1}{2} h' I(\theta) h \rightarrow 0 \text{ in } P_{\theta}.$$

The asymptotic equivalence of the ML estimator and $\Delta_n(\theta)$, and the asymptotic linearity of the log-likelihood function and $\Delta_n(\theta)$, leads to the regularity (\rightarrow Section N) of the ML estimator.

Theorem. Under suitable regularity conditions as above, the ML estimator is regular:

$$\mathcal{L}[n^{1/2}(\hat{\theta}_n - \theta) - h | \theta + n^{-1/2}h] \rightarrow N_k(0, I(\theta)^{-1}),$$

for any $h \in \mathbf{R}^k$ with $\theta + n^{-1/2}h \in \Theta$.

N. Asymptotic Efficiency

In Section D we discussed lower bounds of variances of unbiased estimators for finite sample size and defined the efficiency of an unbiased estimator with variance $v_n(\theta)$ by $(v_n(\theta)nI(\theta))^{-1}$. In this section we first discuss the asymptotic efficiency of a CAN estimator in the same vein as in the case of finite sample size. Second, we see a specific approach to the large-sample theory of estimation. Throughout

this section we assume (C1)–(C5) and (AN1)–(AN5) stated in Section M.

BAN Estimators. We suppose that the parameter space Θ is a subset of \mathbf{R}^1 in this paragraph. We restrict our attention to the class of CAN estimators $\{T_n\}$ of the real-valued parameter θ for which $\mathcal{L}[n^{1/2}(T_n - \theta) | \theta] \rightarrow N(0, v(\theta))$ as $n \rightarrow \infty$. Fisher's conjecture concerning the lower bound to asymptotic variance $v(\theta)$ of any CAN estimator is

$$v(\theta) \geq I(\theta)^{-1},$$

where $I(\theta)$ is the Fisher information on θ in a single observation. The **asymptotic efficiency** of a CAN estimator with asymptotic variance $v(\theta)$ is defined by $(v(\theta)I(\theta))^{-1}$. A CAN estimator with asymptotic variance $I(\theta)^{-1}$ is called a **BAN estimator** or an **asymptotically efficient estimator**. Note that under suitable regularity conditions there always exists an asymptotic efficient estimator, for example a ML estimator, although for a sample of finite size there exists an efficient estimator if and only if the family of density functions is of the exponential type.

Unfortunately, Fisher's conjecture is not true without further conditions on the competing estimators. A counterexample was provided by Hodges and reported by LeCam (1953). Let $\{T_n\}$ be any CAN estimator with the asymptotic variance $v(\theta)$. Consider the estimator

$$T'_n = \begin{cases} \alpha T_n & \text{if } |T_n| < n^{-1/4}, \\ T_n & \text{if } |T_n| \geq n^{-1/4}, \end{cases}$$

where $0 < \alpha < 1$ is a constant. $\{T'_n\}$ is also a CAN estimator with asymptotic variance $v'(\theta)$ such that

$$v'(\theta) = \begin{cases} \alpha^2 v(\theta) & \text{if } \theta = 0, \\ v(\theta) & \text{otherwise.} \end{cases}$$

Let $\{T_n\}$ be a BAN estimator; then T'_n is an estimator with asymptotic variance less than $I(\theta)^{-1}$ and is called a **superefficient estimator**.

Theorem (LeCam). The set of points θ for which the inequality due to Fisher fails is of Lebesgue measure zero. A condition due to Bahadur leads to the continuity of asymptotic variance which implies the validity of the above inequality.

Theorem (Bahadur). Suppose that $\{T_n\}$ is a CAN estimator with asymptotic variance $v(\theta)$ satisfying the condition

$$\liminf_{n \rightarrow \infty} P_{\theta_0 + n^{-1/2}\{T_n < \theta_0 + n^{-1/2}\}} \leq \frac{1}{2}$$

or

$$\liminf_{n \rightarrow \infty} P_{\theta_0 + n^{-1/2}\{T_n > \theta_0 + n^{-1/2}\}} \leq \frac{1}{2}.$$

Then the following inequality, due to Fisher, holds at $\theta = \theta_0$:

$$v(\theta_0) \geq I(\theta_0)^{-1}.$$

Regular Estimators. Wolfowitz and Kaufman considered an operationally more justifiable restriction on competing estimators, called the **uniformity property**, stating that, for an estimator $\{T_n\}$ of θ , $\mathcal{L}[n^{1/2}(T_n - \theta) | \theta](y)$ converges to any limit $L_\theta(y)$ uniformly in $(y, \theta) \in \mathbf{R}^k \times C$, where C is any compact subset of the interior Θ^0 of $\Theta \subset \mathbf{R}^k$. The ML estimator $\{\hat{\theta}_n\}$ also has this uniformity property under suitable regularity conditions, such as (C1)–(C5) and (AN1)–(AN5) to which some uniformity properties are added [29]. We note that asymptotic variance is not a good measurement of asymptotic efficiency unless an estimator is a CAN estimator, and that **asymptotic concentration** is in general a more pertinent measurement.

Theorem. For an estimator $\{T_n\}$ with uniformity property above, it holds that the limit $L_\theta(y)$ is a probability distribution function and continuous for either one of the variables y or θ if the other is fixed and furthermore that the probability measure L_θ is absolutely continuous with respect to the Lebesgue measure on \mathbf{R}^k .

Theorem. The asymptotic concentration of the ML estimator $\{\hat{\theta}_n\}$ about θ is not less than that of any estimator $\{T_n\}$ with uniformity property: For any convex and symmetric set $S \subset \mathbf{R}^k$ about the origin,

$$\lim_{n \rightarrow \infty} P_\theta \{n^{1/2}(\hat{\theta}_n - \theta) \in S\} \geq \lim_{n \rightarrow \infty} P_\theta \{n^{1/2}(T_n - \theta) \in S\}.$$

Schmetterer (*Research papers in statistics*, F. N. David (ed.), 1966) provided the notion of the continuous convergence of distributions of estimators of θ which is weaker than uniform convergence. An estimator $\{T_n\}$ is said to be **regular** if

$$\mathcal{L}[n^{1/2}(T_n - \theta) - h | \theta + n^{-1/2}h] \rightarrow L_\theta \text{ as } n \rightarrow \infty,$$

where L_θ is a probability distribution independent of h with $\theta + n^{-1/2}h \in \Theta$. It was shown that the ML estimator $\{\hat{\theta}_n\}$ is regular under ordinary regularity conditions. Hájek obtained the following characterization of the asymptotic distribution of any regular estimator and, independently Inagaki (*Ann. Inst. Statist. Math.*, 22 (1970); 25 (1973)) obtained a similar result.

Theorem. The asymptotic distribution L_θ of any regular estimator $\{T_n\}$ is represented as the \ast convolution of a normal distribution N_θ and some residual distribution G_θ :

$$L_\theta = N_\theta \ast G_\theta,$$

where $N_\theta = N_k(0, I(\theta)^{-1})$, the asymptotic distri-

bution of the ML estimator $\{\hat{\theta}_n\}$ in the ordinary regular case. It follows from the characterization $L_\theta = N_\theta \ast G_\theta$, that the first two theorems in this section hold also for regular estimators. (\rightarrow LeCam, *Proc. 6th Berkeley Symp.*, 1972, and Roussas and Soms, *Ann. Inst. Statist. Math.*, 25 (1973).)

O. Higher-Order Asymptotic Efficiency

In Section N it was shown that the ML estimator is a BAN estimator. In general, however, there exist many BAN estimators. For example, consider the case of a \ast multinomial distribution where probabilities of events are parametrized. That is, let $X = (n_1, \dots, n_m)'$, $n = n_1 + \dots + n_m$, be distributed as a multinomial distribution $M(n; \pi_1, \dots, \pi_m)$, $\pi_1 + \dots + \pi_m = 1$, and let Π_Θ be a subset of m -vectors, $\Pi_\Theta = \{\pi(\theta) = (\pi_1(\theta), \dots, \pi_m(\theta))'; \theta \in \Theta\}$, $\Theta \subset \mathbf{R}^1$. Define $\hat{p} = (\hat{p}_1, \dots, \hat{p}_m)' = (n_1/n, \dots, n_m/n)'$. Then we consider (i) the ML estimator, (ii) the minimum-chi-square estimator, (iii) the minimum modified chi-square estimator, (iv) the minimum Haldane discrepancy (D_k) estimator, (v) the minimum Hellinger distance (HD) estimator, and (vi) the minimum Kullback-Leibler (K-L) information estimator. These are defined as the values of the parameter θ that minimize the following quantities, respectively: (i) $ML = -\log L_n = -n \sum_{i=1}^m \hat{p}_i \log \pi_i(\theta)$; (ii) $\chi^2 = \sum_{i=1}^m (n\hat{p}_i - n\pi_i(\theta))^2 / (n\pi_i(\theta))$; (iii) $\text{mod } \chi^2 = \sum_{i=1}^m (n\hat{p}_i - n\pi_i(\theta))^2 / (n\hat{p}_i)$; (iv) $D_k = \sum_{i=1}^m \pi_i(\theta)^{k+1} / \hat{p}_i^k$; (v) $HD = \cos^{-1} \sum_{i=1}^m (\hat{p}_i \pi_i(\theta))^{1/2}$; and (vi) $K-L = \sum_{i=1}^m \pi_i(\theta) \log(\pi_i(\theta) / \hat{p}_i)$. Rao [32] showed that under suitable regularity conditions these estimators are Fisher consistent and BAN estimators.

Fisher-Rao Approach to Second-Order Asymptotic Efficiency. For $\theta \in \Theta \subset \mathbf{R}^1$, let $p_{\theta n}$ be the density for n i.i.d. observations $x := (x_1, \dots, x_n)$, and let $q_{\theta n}$ be the density of estimator T_n . The \ast Fisher information contained in X and in T_n are defined by $nI(\theta) = E(d \log p_{\theta n} / d\theta)^2$ and $nI_{T_n}(\theta) = E(d \log q_{\theta n} / d\theta)^2$, respectively. Rao defined the **first-order (asymptotic) efficient estimator** T_n satisfying one of the following conditions: (1) $n^{1/2} |d \log p_{\theta n} / d\theta - d \log q_{\theta n} / d\theta| \rightarrow 0$ in probability; (2) $I(\theta) - I_{T_n}(\theta) \rightarrow 0$ as $n \rightarrow \infty$; (3) the asymptotic correlation between $n^{1/2}(T_n - \theta)$ and $n^{1/2} d \log p_{\theta n} / d\theta$ is unity; (4) $|n^{1/2} d \log p_{\theta n} / d\theta - \alpha - \beta n^{1/2}(T_n - \theta)| \rightarrow 0$ in probability. We note that the larger the condition number (j), the stronger the condition. A first-order efficient estimator is a BAN estimator. Fisher proposed

$$E'_2 = \lim_{n \rightarrow \infty} (nI(\theta) - nI_{T_n}(\theta)) = \lim_{n \rightarrow \infty} V_\theta(d \log p_{\theta n} / d\theta - d \log q_{\theta n} / d\theta)$$

as a measure of **second-order (asymptotic) efficiency** to distinguish different BAN estimators. Fisher stated without any sort of proof that the maximum likelihood estimator minimizes E'_2 , i.e., maximizes second-order efficiency. Rao proposed

$$E_2 = \min_{\lambda} V_{\theta}(d \log p_{\theta n} / d\theta - \lambda n^{1/2} - \beta n(T_n - \theta) - \lambda n(T_n - \theta)^2)$$

as a measure of second-order efficiency for first-order efficient estimators $\{T_n\}$ satisfying condition (4). He showed that the estimators mentioned above for multinomial distribution are first-order efficient estimators satisfying condition (4) and furthermore calculated second-order efficiencies of these estimators measured in terms of E_2 : (i) $E_2(\text{ML}) = \gamma^2(\theta)I(\theta)$; (ii) $E_2(\chi^2) = \Delta(\theta) + E_2(\text{ML})$; (iii) $E_2(\text{mod } \chi^2) = 4\Delta(\theta) + E_2(\text{ML})$; (iv) $E_2(D_k) = (k + 1)^2 \Delta(\theta) + E_2(\text{ML})$; (v) $E_2(\text{HD}) = \Delta(\theta)/4 + E_2(\text{ML})$; (vi) $E_2(\text{K-L}) = \Delta(\theta) + E_2(\text{ML})$ with

$$\begin{aligned} \gamma^2(\theta) &= (\mu_{02} - 2\mu_{21} + \mu_{40})/I^2(\theta) - 1 \\ &\quad - (\mu_{11}^2 + \mu_{30}^2 - 2\mu_{11}\mu_{30})/I^3(\theta), \\ \Delta(\theta) &= \sum_{i=1}^m (\pi'_i(\theta)/\pi_i(\theta))^2/2 - \mu_{40}/I(\theta) \\ &\quad + \mu_{30}^2/(2I^2(\theta)), \end{aligned}$$

where

$$\begin{aligned} \mu_{rs} &= \mu_{rs}(\theta) = E_{\theta} \{ ((df(X, \theta)/d\theta)/f(X, \theta))^r \\ &\quad \times ((d^2f(X, \theta)/d\theta^2)/f(X, \theta))^s \} \\ &= \sum_{i=1}^m \pi_i(\theta) (\pi'_i(\theta)/\pi_i(\theta))^r (\pi''_i(\theta)/\pi_i(\theta))^s. \end{aligned}$$

Rao [33] gave another definition of second-order efficiency based on the expansion of the variance of T_n after correcting for bias: $V_{\theta}(T_n) = (nI(\theta))^{-1} + \psi(\theta)n^{-2} + o(n^{-2})$. The quantity $\psi(\theta)$ is considered to be a measure of second-order efficiency. The results of Fisher and Rao were confined to multinomial distributions. Efron (*Ann. Statist.*, 3 (1975)) and Ghosh and Subramanyan (*Sankhyā*, sec. A, 36 (1974)) extended the results to the so-called curved exponential family of distributions. Efron gave a geometric interpretation to the effect that second-order efficiency is related to the curvature of a statistical problem corresponding to $\gamma(\theta)$ above, and S. Amari recently extended this differential-geometric approach to the discussion of higher-order efficiency of estimators. Rao suggested that E'_2 is equal to E_2 . Ghosh and Subramanyan gave a sufficient condition for the equality to hold, whereas Efron provided a counterexample to show that $E'_2 \neq E_2$ in general.

Pfanzagl and Takeuchi-Akahira Approaches to Higher-Order Asymptotic Efficiency. For each

$k = 1, 2, \dots$, a $\{c_n\}$ -consistent estimator $\{T_n\}$ is said to be the **k th-order asymptotically median unbiased (AMU) estimator** if for any $\theta \in \Theta$ ($\subset \mathbf{R}^1$) there exists a positive number δ such that

$$\limsup_{n \rightarrow \infty} \sup_{|\tau - \theta| < \delta} c_n^{k-1} \left| P_{\tau} \{ T_n \leq \tau \} - \frac{1}{2} \right| = 0$$

or

$$\limsup_{n \rightarrow \infty} \sup_{|\tau - \theta| < \delta} c_n^{k-1} \left| P_{\tau} \{ T_n \geq \tau \} - \frac{1}{2} \right| = 0.$$

This notion, which is an extension of the condition due to Bahadur for the asymptotic efficiency, was introduced by Takeuchi and Akahira. For a k th-order AMU estimator $\{T_n\}$, $G_0(t, \theta) + c_n^{-1}G_1(t, \theta) + \dots + c_n^{-k+1}G_{k-1}(t, \theta)$ is called the **k th-order asymptotic distribution** of $c_n(T_n - \theta)$ if

$$\lim_{n \rightarrow \infty} c_n^{k-1} | P_{\theta} \{ c_n(T_n - \theta) \leq t \} - G_0(t, \theta) - c_n^{-1}G_1(t, \theta) - \dots - c_n^{-k+1}G_{k-1}(t, \theta) | = 0.$$

Pfanzagl and Takeuchi and Akahira obtained the concrete form of the second- or third-order asymptotic distribution of the ML estimator. A k th-order AMU estimator is said to be **k th-order asymptotic efficient** if the k th-order asymptotic distribution of it attains uniformly the bound for the k th-order asymptotic distributions of the k th-order AMU estimators. Takeuchi and Akahira showed that under suitable regularity conditions, T_n is second-order asymptotic efficient if

$$\begin{aligned} P_{\theta} \{ (nI(\theta))^{1/2} (T_n - \theta) \leq t \} &= \Phi(t) + n^{-1/2} (3\mu_{11}(\theta) \\ &\quad + 2\mu_{30}(\theta)) / (6I(\theta)^{3/2}) \\ &\quad \times t^2 \varphi(t) + o(n^{-1/2}), \end{aligned}$$

where $\Phi(t)$ is the standard normal distribution function and $\varphi(t)$ is its density function, and further that the modified ML estimator

$$\hat{\theta}_n^* = \hat{\theta}_n + n^{-1} \mu_{30}(\hat{\theta}_n) / (6I(\hat{\theta}_n)^2)$$

for the ML estimator $\hat{\theta}_n$ is second-order asymptotic efficient. Pfanzagl (*Ann. Statist.*, 1 (1973)) obtained a similar result. The formulation due to Takeuchi and Akahira is more extensive since it can be applied to the so-called non-regular cases.

P. Estimating Equations

We often determine an estimator as a solution $\theta = T_n(x_1, \dots, x_n)$ of an equation $\Psi_n(x_1, \dots, x_n; \theta) = 0$; for example, the ML estimator as a solution of the likelihood equation. In such case, such an equation is called an **estimating equation** and $\Psi_n(\theta) = \Psi_n(X_1, \dots, X_n; \theta)$, a random function, is called an **estimating function** [3].

Call T_n an estimator based on an estimating function $\Psi_n(\theta)$. The following result is a modification of a theorem due to Hodges and Lehmann (*Ann. Math. Statist.*, 34 (1963)).

Theorem. Let Θ be an interval of \mathbf{R}^1 . Suppose that a real-valued estimating function $\Psi_n(\theta)$ satisfies the following three conditions: (M1) $\Psi_n(\theta)$ is a nonincreasing function of the real parameter θ ;

(M2) for any real number h , $n^{1/2}\Psi_n(\theta_0 + n^{-1/2}h) - n^{1/2}\Psi_n(\theta_0) + \gamma h \rightarrow 0$ in probability, where γ is a positive constant; and

(M3) $\mathcal{L}[n^{1/2}\Psi_n(\theta_0)](y) \rightarrow \Phi(y/\sigma)$, where Φ is a continuous distribution function with zero mean and unit variance.

Define an estimator based on Ψ_n by $T_n = (\theta_n^* + \theta_n^{**})/2$, where $\theta_n^* = \sup\{\theta | \Psi_n(\theta) > 0\}$ and $\theta_n^{**} = \inf\{\theta | \Psi_n(\theta) < 0\}$. Then we have $\mathcal{L}[n^{1/2}(T_n - \theta_0)](y) \rightarrow \Phi(y\gamma/\sigma)$ as $n \rightarrow \infty$. Huber considered a formulation that guarantees the asymptotic normality of an *M-estimator*. An *M-estimator* T_n is defined by a minimum problem of the form $\sum_{i=1}^n \rho(X_i, T_n) = \min_{\theta} \sum_{i=1}^n \rho(X_i, \theta)$ or by an implicit equation $\sum_{i=1}^n \psi(X_i, T_n) = 0$, where ρ is an arbitrary function and $\psi(x, \theta) = \partial \rho(x, \theta) / \partial \theta$. Note that $\rho(x, \theta) = -\log f(x, \theta)$ gives the ordinary ML estimator. Let Θ be a closed subset of \mathbf{R}^k , let $(\mathcal{X}, \mathfrak{B}, P)$ be a probability space, and let $\psi(x, \theta)$ be some function on $\mathcal{X} \times \Theta$ with value in \mathbf{R}^k . Assume that X_1, X_2, \dots are independent random variables with values in \mathcal{X} having the common probability distribution P that need not be a member of the parametric family. Consider an estimating function

$$\Psi_n(\theta) = \frac{1}{n} \sum_{i=1}^n \psi(X_i, \theta).$$

Assume that

- (N1) for each fixed $\theta \in \Theta$, $\psi(x, \theta)$ is \mathfrak{B} -measurable and $\psi(x, \theta)$ is †separable;
- (N2) the expected value $\lambda(\theta) = E\{\psi(X, \theta)\}$ exists for all $\theta \in \Theta$, and has a unique zero at $\theta = \theta_0 \in \Theta^0$;
- (N3) there exists a continuous function that is bounded away from zero, $b(\theta) \geq b_0 > 0$, such that $E(\sup_{\theta} \{|\psi(X, \theta)|/b(\theta)\}) < \infty$, $\liminf_{\theta \rightarrow \infty} \{|\lambda(\theta)|/b(\theta)\} \geq 1$, and $E(\limsup_{\theta \rightarrow \infty} \{|\psi(X, \theta) - \lambda(\theta)|/b(\theta)\}) < 1$;
- (N4) for $u(x, \theta, d) = \sup\{|\psi(x, \tau) - \psi(x, \theta)| | |\tau - \theta| \leq d\}$,
 - (i) as $d \rightarrow 0$, $E(u(X, \theta, d)) \rightarrow 0$,
 - (ii) there exist positive numbers d_0, b_1 , and b_2 such that $E(u(X, \theta, d)) \leq b_1 d$ and $E(u(X, \theta, d)^2) \leq b_2 d$ for θ and d satisfying $0 < |\theta - \theta_0| + d \leq d_0$;
- (N5) in some neighborhood of θ_0 , $\lambda(\theta)$ is continuously differentiable and the Jacobian matrix at $\theta = \theta_0$, $\Lambda = (\partial \lambda_i(\theta_0) / \partial \theta_j)$, is nonsingular; and
- (N6) the covariance matrix $\Sigma = E\{\psi(X, \theta_0) \cdot \psi(X, \theta_0)'\}$ exists and is positive definite.

Theorem. Suppose that an estimator $\{T_n\}$ satisfies $\Psi_n(T_n) \rightarrow 0$ a.s. (or in probability) as $n \rightarrow \infty$. Then, under (N1)–(N4) (i), $T_n \rightarrow \theta_0$ a.s. (or in probability) as $n \rightarrow \infty$.

Lemma. Under (N1)–(N5),

$$\sup\{|\Psi_n(\tau) - \Psi_n(\theta_0) - \lambda(\tau)|/(n^{-1/2} + |\lambda(\tau)|); |\tau - \theta_0| \leq d_0\} \rightarrow 0$$

in probability as $n \rightarrow \infty$.

Suppose that $\{\mathcal{L}[n^{1/2}\Psi_n(T_n)]\}$ is †tight. It implies that $\Psi_n(T_n) \rightarrow 0$ in probability, and hence from the above theorem $T_n \rightarrow \theta_0$ in probability. Thus letting $\tau = T_n$ we have

$$|\Psi_n(T_n) - \Psi_n(\theta_0) - \lambda(T_n)|/(n^{-1/2} + |\lambda(T_n)|) \rightarrow 0$$

in probability. That is, for any $\varepsilon > 0$ there exists an n_0 such that for $n \geq n_0$, $P\{n^{1/2}|\lambda(T_n)| < \varepsilon + |n^{1/2}\Psi_n(T_n) - n^{1/2}\Psi_n(\theta_0)|\} > 1 - \varepsilon$. This and the tightness of $\{\mathcal{L}[n^{1/2}\Psi_n(T_n)]\}$ and $\{\mathcal{L}[n^{1/2}\Psi_n(\theta_0)]\}$ lead to the tightness of $\{\mathcal{L}[n^{1/2}(T_n - \theta_0)]\}$, and the converse is also true. At the same time we have $n^{1/2}\Psi_n(T_n) - n^{1/2}\Psi_n(\theta_0) - \Lambda n^{1/2}(T_n - \theta_0) \rightarrow 0$ in probability. The following theorem is a straightforward consequence.

Theorem. Suppose that an estimator $\hat{\theta}_n$ satisfies $n^{1/2}\Psi_n(\hat{\theta}_n) \rightarrow 0$ as $n \rightarrow \infty$. Then, under (N1)–(N6), $\mathcal{L}[n^{1/2}(\hat{\theta}_n - \theta_0) | P] \rightarrow N_k(0, \Lambda^{-1} \Sigma \Lambda^{-1})$ as $n \rightarrow \infty$.

Q. Interval Estimation

Interval estimation or **region estimation** is a method of statistical inference utilized to estimate the true value $g(\theta)$ of the given parametric function by stating that $g(\theta)$ belongs to a subset $S(x)$ of \mathcal{A} , based on the observed value x of the random variable X . If

$$P_{\theta}\{g(\theta) \in S(X)\} \geq 1 - \alpha \quad \text{for any } \theta \in \Theta$$

for a constant α ($0 < \alpha < 1$), then the random region $S(X)$ is called a **confidence region** of $g(\theta)$ of **confidence level** $1 - \alpha$, and the infimum of the left-hand side with respect to $\theta \in \Theta$ is called the **confidence coefficient**. In particular, if $\Theta \subset \mathbf{R}$ and a confidence region is an interval, as is often the case, then the region is called a **confidence interval**, and two boundaries of the interval are called **confidence limits**. If a particular subset $S(X)$ among the set of confidence regions of $g(\theta)$ of confidence level $1 - \alpha$ minimizes $P_{\theta}\{g(\theta') \in S(X)\}$ for all pairs θ and $\theta' (\neq \theta)$, $S(X)$ is said to be **uniformly most powerful**. If a confidence region $S(X)$ of $g(\theta)$ of confidence level $1 - \alpha$ satisfies $P_{\theta}\{g(\theta') \in S(X)\} \leq 1 - \alpha$ for all pairs θ and $\theta' (\neq \theta)$, then it is said to be **unbiased**. The notion of **invariance of a confidence region** can be defined similarly, and the definition for $S(X)$ being **uniformly most powerful unbiased (UMPBU)** or **uniformly most**

powerful invariant (UMPI) can be formulated in an obvious manner.

For each $\theta_0 \in \Theta$ let $A(\theta_0)$ be an acceptance region of a test of level α of the hypothesis $\theta = \theta_0$. For each $x \in \mathcal{X}$ let $S(x) = \{\theta \mid x \in A(\theta), \theta \in \Theta\}$. Then $S(X)$ is a confidence region of θ of confidence level $1 - \alpha$. If $A(\theta_0)$ is an acceptance region of a UMP test of the hypothesis $\theta = \theta_0$ for each θ_0 , then $S(X)$ is a UMP confidence region of θ of confidence level $1 - \alpha$. Furthermore, corresponding to an acceptance region $A(\theta_0)$ of a UMP unbiased (invariant) test, a UMP unbiased (invariant) confidence region can be constructed in a similar manner.

R. Tolerance Regions

Let X and Y be distributed according to probability distributions P_θ^X and P_θ^Y labeled by a common $\theta \in \Theta$ over measurable spaces $(\mathcal{X}, \mathfrak{B})$ and $(\mathcal{Y}, \mathfrak{C})$, respectively, and consider the problem of predicting a future value of the random variable Y using the observed value x of the random variable X . If a mapping $S(x)$ sending a point x to a set belonging to \mathfrak{C} is used to predict that the value of Y will lie in the set $S(x)$, then the random region is called a **tolerance region** of Y . In particular, if a tolerance region of a real random variable is an interval, it is called a **tolerance interval** and its boundaries **tolerance limits**.

For simplicity, suppose that X and Y are independent. There are several kinds of tolerance regions. First, if $P_\theta^X(P_\theta^Y\{Y \in S(X)\} \geq \beta) \geq \gamma$ for any $\theta \in \Theta$, then $S(X)$ is called a tolerance region of Y of **content** β and **level** γ . Second, if $E_\theta^X(P_\theta^Y\{Y \in S(X)\}) \geq \beta$ for any $\theta \in \Theta$, then $S(X)$ is called a tolerance region of Y of **mean content** β . Suppose that the random variable $X = (X_1, \dots, X_n)'$ is a random sample and that both X_1 and Y obey the same distribution. If further the set $\{P_\theta^Y \mid \theta \in \Theta\}$ forms the totality of 1-dimensional continuous distributions and the distribution of $P_\theta^Y\{Y \in S(X)\}$ does not depend on the choice of θ , then $S(X)$ is called a distribution-free tolerance region. For example, if $X_{(1)} \leq X_{(2)} \leq \dots \leq X_{(n)}$ is an order statistic, then the interval $[X_{(r)}, X_{(s)}]$ (for $r < s$) is a distribution-free tolerance interval for a random variable Y , independent of X_1, \dots, X_n , which has the same distribution as X_1 .

400 (XVIII.8) Statistical Hypothesis Testing

A. General Remarks

A **statistical hypothesis** is a proposition about the †probability distribution of a †sample X . If it is known that the †distribution of X belongs to a family of distributions $\mathcal{P} = \{P_\theta | \theta \in \Omega\}$ with a parameter space Ω , the hypothesis can be stated as follows: The value of the parameter θ belongs to ω_H , where ω_H is a nonempty subset of the parameter space Ω . This hypothesis is also written simply as $\mathbf{H}: \theta \in \omega_H$. When ω_H

consists of one point, it is called a **simple hypothesis**, otherwise a **composite hypothesis**.

Let \mathcal{X} be a †sample space associated with a † σ -algebra \mathfrak{B} of subsets of \mathcal{X} . To test a hypothesis \mathbf{H} is to decide whether \mathbf{H} is false, based on the observation of a sample $X (\in \mathcal{X})$. The assertion that \mathbf{H} is not false does not necessarily imply the validity of \mathbf{H} . Such an assertion is called the **acceptance** of \mathbf{H} , while the opposite assertion, that \mathbf{H} is false, is called the **rejection** of \mathbf{H} . In this framework for the testing problem, \mathbf{H} is often called a **null hypothesis** (\rightarrow 401 Statistical Inference).

Consider a testing procedure in which \mathbf{H} is rejected with probability $\varphi(x)$ ($0 \leq \varphi(x) \leq 1$) and accepted with probability $1 - \varphi(x)$, when $x \in \mathcal{X}$ is observed. This testing procedure is characterized by the function φ on \mathcal{X} with range in $[0, 1]$. Here $\varphi(x)$ is taken as \mathfrak{B} -measurable on \mathcal{X} , and is called a **test function** or **test**. If $\varphi(x)$ is the indicator function $\chi_B(x)$ of a set $B (\in \mathfrak{B})$, then the test is rejecting \mathbf{H} when x belongs to B and accepting \mathbf{H} otherwise. The set B is called a **critical region**, and its complementary set an **acceptance region**. A test is called a **nonrandomized test** if it is the indicator function of a set. Other tests are called **randomized tests**.

Suppose that the †distribution of the sample X is a probability measure P_θ on $(\mathcal{X}, \mathfrak{B})$. The probability of rejecting \mathbf{H} when θ is the true value of the parameter is calculated from

$$E_\theta(\varphi) = \int_{\mathcal{X}} \varphi(x) P_\theta(dx).$$

Let α be a given constant in $(0, 1)$. If a test $\varphi(x)$ satisfies $E_\theta(\varphi) \leq \alpha$ for all $\theta \in \omega_H$, or, in other words, if the probability of rejecting \mathbf{H} when \mathbf{H} is true is not greater than α , α is called the **level** of φ and such a test is called a **level α test**. We denote the set of all level α tests by $\Phi(\alpha)$, and $\sup_{\theta \in \omega_H} E_\theta(\varphi)$ is called the **size** of φ . To judge the merit of tests, we introduce a different hypothesis \mathbf{A} : The true value of θ belongs to $\omega_A \subset \Omega - \omega_H$. This is called an **alternative hypothesis**, or, for simplicity, an **alternative**. The errors of a test are divided into two kinds: errors owing to the rejection of the hypothesis \mathbf{H} when it is true, and errors owing to the acceptance of \mathbf{H} when it is false. The former are called **errors of the first kind**, and the latter, **errors of the second kind**. The probability $E_\theta(\varphi)$ of rejecting \mathbf{H} when $\theta \in \omega_A$, that is, the probability of the correct decision being made for $\theta \in \omega_A$, is called the **power** of a test or the **power function**. The probability of committing an error of the second kind is $1 - E_\theta(\varphi)$ for $\theta \in \omega_A$. A testing problem is indicated by the notation $(\mathcal{X}, \mathfrak{B}, \mathcal{P}, \omega_H, \omega_A)$. A test φ in a class $\Phi(\alpha)$ of tests is said to be **uniformly most powerful** in $\Phi(\alpha)$ (or **UMP** in $\Phi(\alpha)$) if for any

$\psi \in \Phi(x)$, $E_\theta(\varphi) \geq E_\theta(\psi)$ for all $\theta \in \omega_A$. When ω_A consist of a single point, it is said to be **most powerful**.

B. The Neyman-Pearson Fundamental Lemma

Let μ be a σ -finite measure over $(\mathcal{X}, \mathfrak{B})$ and f_1, \dots, f_{n+1} be μ -integrable real-valued functions. If c_1, \dots, c_n are constants such that the set $\Phi(c_1, \dots, c_n)$ of test functions φ satisfying

$$\int \varphi f_i d\mu \leq c_i, \quad i = 1, 2, \dots, n,$$

is not empty, then there exists at least one test φ_0 in $\Phi(c_1, \dots, c_n)$ that maximizes $\int \varphi f_{n+1} d\mu$ among all φ in $\Phi(c_1, \dots, c_n)$. A test $\tilde{\varphi}$ is one of these tests if it satisfies the following two conditions:

(1) For appropriate constants $k_1, \dots, k_n \geq 0$,

$$\tilde{\varphi}(x) = \begin{cases} 1 & \text{when } f_{n+1}(x) > \sum_{i=1}^n k_i f_i(x), \\ 0 & \text{when } f_{n+1}(x) < \sum_{i=1}^n k_i f_i(x) \end{cases}$$

almost everywhere with respect to μ , and (2) the equation

$$\int \tilde{\varphi} f_i d\mu = c_i, \quad i = 1, 2, \dots, n,$$

holds.

If (c_1, \dots, c_n) is an interior point of the subset

$$\mathbf{M} = \left\{ \left(\int \varphi f_1 d\mu, \dots, \int \varphi f_n d\mu \right) \mid \varphi \text{ is a test} \right\}$$

of the n -space \mathbf{R}^n and $\tilde{\varphi}$ satisfies (2) and maximizes $\int \varphi f_{n+1} d\mu$ among all φ in $\Phi(c_1, \dots, c_n)$, then $\tilde{\varphi}$ satisfies (1). These statements are called the **Neyman-Pearson lemma**.

As an illustration, suppose that $\Omega = (1, 2, \dots, n, n+1)$ and that $\{P_\theta \mid \theta \in \Omega\}$ is dominated by a σ -finite measure μ . Let $f_i(x)$ be the density of P_i with respect to μ . When ω_H is a finite set $\{1, \dots, n\}$ and ω_A consists of a single point $n+1$, then $\tilde{\varphi}$ satisfying (1) and (2) with $c_1 = \dots = c_n = \alpha$ is a uniformly most powerful level α test.

If \mathfrak{B} is generated by a countable number of sets, then there exists a most powerful level α test for any hypothesis against a simple alternative $\mathbf{A}: \theta = \tilde{\theta}$. A method of obtaining such a most powerful test is given in the **Lehman-Stein theorem**: Denote by f_θ the density function of P_θ with respect to a σ -finite measure μ , and define

$$h_\lambda(x) = \int_{\omega_H} f_\theta(x) d\lambda(\theta)$$

for a probability measure λ on ω_H . Consider testing the simple hypotheses \mathbf{H}_λ : The density

of distribution of the sample is h_λ , against the alternative $\mathbf{A}: \theta = \tilde{\theta}$, and let φ_λ be a most powerful level α test for this problem ($\mathbf{H}_\lambda: \mathbf{A}$). If $\sup_{\theta \in \omega_H} E_\theta(\varphi_\lambda) \leq \alpha$, φ_λ is a most powerful level α test for testing $\mathbf{H}: \theta \in \omega_H$ against $\mathbf{A}: \theta = \tilde{\theta}$. The measure λ satisfies $E_\theta(\varphi_\lambda) \geq E_\theta(\varphi_\lambda')$ for any probability measure λ' on ω_H and is called a **least favorable distribution**.

When the alternative hypothesis ω_A consists of more than one point, a uniformly most powerful test does not generally exist. However, if $\Omega = \mathbf{R}$, $\omega_H = (-\infty, \theta_0]$, $\omega_A = (\theta_0, \infty)$, and $f_\theta(x)$ is a density function with \dagger monotone likelihood ratio with respect to a statistic $T(x)$, then a UMP level α test $\varphi(x)$ exists and is defined by $\varphi(x) = 1$ if $T(x) > c$; = a constant if $T(x) = c$; and = 0 if $T(x) < c$. For a one-parameter exponential family of distributions, there exists a UMP level α test for testing $\mathbf{H}: \omega_H = (-\infty, \theta_1] \cup [\theta_2, \infty)$ against $\mathbf{A}: \omega_A = (\theta_1, \theta_2)$ ($\theta_1 < \theta_2$). However, a UMP test does not exist for the problem obtained by interchanging the positions of ω_H and ω_A .

Since hypothesis-testing problems admitting UMP tests are rather rare, alternative ways for judging the merit of tests are needed, and two have been devised. The first is to restrict the class Φ of tests and to find a UMP test in this restricted class. The second is to introduce an alternative criterion of optimality and to select a test accordingly. The first is discussed in detail in Sections C, D, and E, and the second in Section F.

C. Unbiased Tests

The unbiasedness criterion is based on the idea that the probability of rejecting the hypothesis \mathbf{H} when it is true (the probability of an error of the first kind) should preferably be no larger than that of rejecting \mathbf{H} when it is false (the power). If a level α test φ satisfies $E_\theta(\varphi) \geq \alpha$ for $\theta \in \omega_A$, then φ is called an **unbiased level α test**. Let $\Phi_u(\alpha)$ be the set of all unbiased level α tests. A UMP test in $\Phi_u(\alpha)$ is called a **uniformly most powerful (or UMP) unbiased level α test**.

If P_θ is of the \dagger exponential family whose parameter space Ω is a finite or an infinite open interval of \mathbf{R}^k , then there exists a UMP unbiased level α test for the following two problems: (1) $\mathbf{H}: \theta_1 \leq a$, $\mathbf{A}: \theta_1 > a$, where θ_1 is the first coordinate of $\theta = (\theta_1, \dots, \theta_k)$; and (2) $\mathbf{H}: \theta_1 = a$, $\mathbf{A}: \theta_1 \neq a$. For example, when the sample is normally distributed with unknown mean μ and unknown variance σ^2 , the Student test (defined in Section G) for a hypothesis $\mathbf{H}: \mu = \mu_0$ against an alternative $\mathbf{A}: \mu \neq \mu_0$ is a UMP unbiased test.

D. Similar Tests and Neyman Structure

If $E_{\theta}(\varphi)$ is constant for all $\theta \in \omega$ ($\subset \Omega$), φ is called a **similar test** with respect to ω . If $E_{\theta}(\varphi)$ is a continuous function of θ , an unbiased test φ is similar with respect to the common boundary $\tilde{\omega}$ of ω_H and ω_A , provided that Ω is a topological space and the density function is continuous in ω . Therefore, in this case, unbiased tests are found in the class of all tests similar with respect to $\tilde{\omega}$. Let a statistic $y = T(x)$ be †sufficient for $\mathcal{P}_{\omega} = \{P_{\theta} | \theta \in \omega\}$. A test φ is said to have **Neyman structure** with respect to T if the conditional expectation $E(\varphi | T(x) = y)$ of φ equals a constant $[\mathcal{P}_{\omega}]$. (For the notation $[\mathcal{P}_{\omega}] \rightarrow$ 396 Statistic.) A test φ having Neyman structure with respect to the statistic $T(x)$ is similar with respect to ω . A test φ similar with respect to ω has Neyman structure with respect to $T(x)$ if and only if the family $\mathcal{Q} = \{Q_{\theta} = P_{\theta} T^{-1} | \theta \in \omega\}$ of †marginal distributions of T is †boundedly complete.

E. Invariant Tests

Consider groups G and \bar{G} of one-to-one transformations on \mathcal{X} and Ω , respectively. Suppose that each element of G is a measurable transformation of \mathcal{X} onto itself (i.e., $gB \in \mathfrak{B}$ for any $B \in \mathfrak{B}$) and that a homomorphism $g \rightarrow \bar{g}$ of G into \bar{G} is defined so that $P_{\theta}(g^{-1}B) = P_{\bar{g}\theta}(B)$. The hypothesis $H: \theta \in \omega_H$ and the alternative $A: \theta \in \omega_A$ are said to be **invariant** under G if $\bar{g}\omega_H = \omega_H$ and $\bar{g}\omega_A = \omega_A$ for all $g \in G$, and in this case the testing problem $(\mathcal{X}, \mathfrak{B}, \mathcal{P}, \omega_H, \omega_A)$ is said to be **invariant** under G . A test is called an **invariant test** if $\varphi(gx) = \varphi(x)$ for every $g \in G$, and $E_{\bar{g}\theta}(\varphi) = E_{\theta}(\varphi)$ holds for any invariant φ . Accordingly, if \bar{G} is †transitive on ω_H , and invariant test is similar with respect to ω_H . If the sample space \mathcal{X} is a subset of \mathbf{R}^n that is invariant under the translation $(x_1, \dots, x_n) \rightarrow (x_1 + a, \dots, x_n + a)$ with a real a and if there exists a $\theta' = \bar{a} \cdot \theta \in \Omega$ such that $P_{\theta'}(B) = P_{\theta}(\{(x_1 - a, \dots, x_n - a) | (x_1, \dots, x_n) \in B\})$ for any $\theta \in \Omega$, then \bar{a} is a transformation on Ω . In this case the real number a is called a **location parameter**. Furthermore, if the sample space \mathcal{X} is a subset invariant under the similarity transformation $(x_1, \dots, x_n) \rightarrow (ax_1, \dots, ax_n)$ ($a > 0$) and if there exists a $\theta' = \bar{a} \cdot \theta \in \Omega$ such that $P_{\theta'}(B) = P_{\theta}(\{(x_1/a, \dots, x_n/a) | (x_1, \dots, x_n) \in B\})$ for any $\theta \in \Omega$, then the real number a is called a **scale parameter**. The **invariance principle** states that a test for a testing problem invariant under G should preferably be invariant under G . A test $\varphi(x)$ is called an **almost invariant test** if $\varphi(gx) = \varphi(x) [\mathcal{P}]$ for all $g \in G$.

Suppose that the testing problem of a hypothesis under consideration is invariant under a

transformation group G on the sample space \mathcal{X} . Denote the set of all invariant level α tests by $\Phi_I(\alpha)$. A test that is uniformly most powerful in $\Phi_I(\alpha)$ is called a **uniformly most powerful (in short, UMP) invariant level α test**. If there exists a unique UMP unbiased level α test φ^* , then a UMP invariant level α test (if it exists) coincides with $\varphi^*[\mathcal{P}]$. When $T(x)$ is †maximal invariant under G , a necessary and sufficient condition for $\varphi(x)$ to be invariant is that φ be a function of $T(x)$.

For example, suppose that the sample $X = (X_1, \dots, X_n)$ is taken from $N(\mu, \sigma^2)$ with unknown μ and σ^2 . In this situation, $Y = (\bar{X}, S)$ is a sufficient statistic, where $\bar{X} = \sum_i X_i/n$ and $S = \sqrt{\sum (X_i - \bar{X})^2}$. Let G be the group of transformations $(\bar{x}, s) \rightarrow (c\bar{x}, cs)$ ($c > 0$) on the range \mathcal{Y} of Y and \bar{G} be the group of transformations $(\mu, \sigma^2) \rightarrow (c\mu, c\sigma^2)$ ($c > 0$) on the parameter space. Both the hypotheses $H_1: \mu/\sigma^2 \leq 0$ and $H_2: \mu/\sigma^2 = 0$ are invariant under G . Since $t = \sqrt{n} \cdot \bar{x}/(s/\sqrt{n-1})$ is maximal invariant, any invariant level α test is in the class of functions of t . The Student test, defined in Section G, is UMP invariant under G .

F. Minimax Tests and Most Stringent Tests

Minimax tests and most stringent tests are sometimes used as alternatives to UMP tests. Suppose that $\mathcal{P} = \{P_{\theta} | \theta \in \Omega\}$ is a †dominated family and \mathfrak{B} is generated by a countable number of sets. A level α test φ^* is called a **minimax level α test** if for any level α test φ ,

$$\inf_{\theta \in \omega_A} E_{\theta}(\varphi^*) \geq \inf_{\theta \in \omega_A} E_{\theta}(\varphi).$$

Such a test exists for any $\alpha \in (0, 1)$. If a group G of measurable transformations on \mathcal{X} leaves a testing problem invariant, then an intimate relation exists between the minimax property and invariance. Concerning this relation, we have the following theorem: For each $\alpha \in (0, 1)$ there is an almost invariant level α test that is minimax if there exists a σ -field \mathfrak{A} of subsets of G and a sequence $\{v_n\}$ of probability measures on (G, \mathfrak{A}) such that (i) $B \in \mathfrak{B}$ implies $\{(x, g) | gx \in B\} \in \mathfrak{B} \times \mathfrak{A}$; (ii) $A \in \mathfrak{A}$, $g \in G$ implies $Ag \in \mathfrak{A}$; and (iii) $\lim_{n \rightarrow \infty} |v_n(Ag) - v_n(A)| = 0$ for any $A \in \mathfrak{A}$ and $g \in G$. Fundamental in the invariant testing problem is the **Hunt-Stein lemma**: Under the condition just stated, for any φ there exists an almost invariant test ψ such that

$$\inf_{\bar{g} \in \bar{G}} E_{\bar{g}\theta}(\varphi) \leq E_{\theta}(\psi) \leq \sup_{\bar{g} \in \bar{G}} E_{\bar{g}\theta}(\varphi).$$

The following six types of transformation groups satisfy the condition of the theorem: (1) the group of translations on \mathbf{R}^n , (2) the group of similarity transformations on \mathbf{R}^n , (3) the

group of transformations $g=(a,b):(x_1, \dots, x_n) \in \mathbf{R}^n \rightarrow (ax_1 + b, \dots, ax_n + b) \in \mathbf{R}^n$ ($0 < a < \infty, -\infty < b < \infty$), (4) finite groups, (5) the group of orthogonal transformations on \mathbf{R}^n , and (6) the direct product of a finite number of the groups mentioned in (1)–(5).

We call $\beta_x^*(\theta) = \sup_{\varphi \in \Phi(x)} E_\theta(\varphi)$ an **envelope power function**, and $\varphi^* (\in \Phi(x))$ is called a **most stringent level α test** if

$$\sup_{\theta \in \omega_A} (\beta_x^*(\theta) - E_\theta(\varphi^*)) \leq \sup_{\theta \in \omega_A} (\beta_x^*(\theta) - E_\theta(\varphi))$$

for any $\varphi \in \Phi(x)$. There exists a most stringent level α test for each $\alpha \in (0, 1)$. If a testing problem is invariant under a transformation group G on X and G satisfies the condition in the Hunt-Stein lemma, then a uniformly most powerful invariant level α test is most stringent among the level α tests (\rightarrow 398 Statistical Decision Functions).

Admissibility of a test and completeness of a class of tests are defined with respect to the probability of an error of the second kind (\rightarrow 398 Statistical Decision Functions). The uniformly most powerful level α test and the uniformly most powerful unbiased level α test are admissible.

G. Useful Tests Concerning Normal Distributions (\rightarrow Appendix A, Table 23)

In this section, we treat the rejection regions S that are commonly used in testing problems related to normal distributions. Let α be the level of S , and let $c(\alpha)$ and $d(\alpha)$ be positive numbers determined by α . In (1)–(5) below, the sample consists of n mutually independent random variables X_1, \dots, X_n each of which is assumed to be normally distributed with mean μ and variance σ^2 . For any sample point $x=(x_1, \dots, x_n)$, denote $\sum_{i=1}^n x_i/n$ by \bar{x} and $\sum_{i=1}^n (x_i - \bar{x})^2$ by s^2 . (1) To test the hypothesis $\mu \leq \mu_0$ against an alternative $\mu > \mu_0$, we can use as a critical region $S = \{x | t(x) > c(\alpha)\}$, where the test statistic $t(x)$ is given by $\sqrt{n}(\bar{x} - \mu_0) / \sqrt{s^2/(n-1)}$. (2) To test the hypothesis $\mu = \mu_0$ against an alternative $\mu \neq \mu_0$, we can use $S = \{x | |t(x)| \geq c(\alpha)\}$ with the same test statistic $t(x)$ as in (1). These tests based on the statistic $t(x)$ are generally called **Student tests** or ***t*-tests**. (3) To test the hypothesis $\sigma^2 = \sigma_0^2$ against the alternative $\sigma^2 > \sigma_0^2$ with $\sigma_0^2 > 0$, we can use $S = \{x | \chi^2(x) \geq c(\alpha)\}$, where $\chi^2 = s^2/\sigma_0^2$. (4) To test the hypothesis $\sigma^2 > \sigma_0^2$ against the alternative $\sigma^2 < \sigma_0^2$, we can use $S = \{x | \chi^2(x) \leq c(\alpha)\}$, where χ^2 is the same as in (3). (5) To test the hypothesis $\sigma^2 = \sigma_0^2$ against $\sigma^2 \neq \sigma_0^2$, we can use $S = \{x | \chi^2(x) \leq c(\alpha) \text{ or } \geq d(\alpha)\}$, where χ^2 is the same as in (3). Each of these tests based on the statistic χ^2 is called a **chi-square test**. Among

these tests, (3) is UMP and (1) is UMP when $\alpha \geq 1/2$. All tests (1)–(5) are UMP unbiased, and (3)–(5) are UMP invariant under the translations $(x_1, \dots, x_n) \rightarrow (x_1 + a, \dots, x_n + a)$ ($-\infty < a < \infty$). Since (1) and (2) are also UMP invariant under the transformations $(x_1, \dots, x_n) \rightarrow (ax_1, \dots, ax_n)$ ($0 < a < \infty$), they are most stringent tests.

Suppose that X_1, \dots, X_m are independently distributed according to $N(\mu_1, \sigma_1^2)$ and that Y_1, \dots, Y_n are independently distributed according to $N(\mu_2, \sigma_2^2)$, where μ_1, μ_2, σ_1 , and σ_2 are assumed unknown unless otherwise stated. Here we give the important tests for $\mu_1, \mu_2, \sigma_1^2, \sigma_2^2$. Let $x=(x_1, \dots, x_m)$ and $y=(y_1, \dots, y_n)$ be sample points in \mathbf{R}^m and \mathbf{R}^n , respectively, and denote $\sum_{i=1}^m x_i/m, \sum_{i=1}^n y_i/n, \sum_{i=1}^m (x_i - \bar{x})^2$, and $\sum_{i=1}^n (y_i - \bar{y})^2$ by \bar{x}, \bar{y}, s_x^2 , and s_y^2 , respectively. (6) Assume that σ_1 and σ_2 are known, and consider a hypothesis $\mu_1 = \mu_2$. When an alternative $\mu_1 > \mu_2$ ($\mu_1 \neq \mu_2$) is taken, we can use as a critical region $S = \{(x, y) | T(x, y) \geq c(\alpha)\}$ ($S = \{(x, y) | |T(x, y)| \geq c(\alpha)\}$), where $T(x, y) = (\bar{x} - \bar{y}) / \sqrt{\sigma_1^2/m + \sigma_2^2/n}$. These tests are both UMP unbiased and invariant under the translations $(x_1, \dots, x_m, y_1, \dots, y_n) \rightarrow (x_1 + a, \dots, x_m + a, y_1 + a, \dots, y_n + a)$. (7) Assume that $\sigma_1 = \sigma_2$, and consider a hypothesis $\mu_1 = \mu_2$. When $\mu_1 \neq \mu_2$ ($\mu_1 > \mu_2$) is the alternative, $S = \{(x, y) | |T(x, y)| \geq c(\alpha)\}$ ($S = \{(x, y) | T(x, y) > c(\alpha)\}$) can be used as a critical region, where $T(x, y) = (\bar{x} - \bar{y}) \sqrt{m+n-2} / (\sqrt{1/m+1/n} \sqrt{s_x^2 + s_y^2})$. Both tests are UMP unbiased and are invariant under $(x_1, \dots, x_m, y_1, \dots, y_n) \rightarrow (ax_1 + b, \dots, ax_m + b, ay_1 + b, \dots, ay_n + b)$ ($-\infty < b < \infty, 0 < a < \infty$). (8) Testing the hypothesis $\mathbf{H}: \mu_1 = \mu_2$ is called the **Behrens-Fisher problem**. Note that nothing is assumed about the relation of the variances σ_1^2 and σ_2^2 of the two samples X and Y , in contrast to (7). It is difficult to construct a statistic whose distribution is independent of σ_1^2 and σ_2^2 when \mathbf{H} is true. Compare this with (1)–(7), where the proposed statistics have this property and are used to construct similar critical regions S . The critical region

$$\{(x, y) | (\bar{x} - \bar{y}) / \sqrt{s_x^2/m(m-1) + s_y^2/n(n-1)} \geq f(s_y^2/s_x^2)\},$$

with an appropriately chosen f , is similar to such a region S . This test is called **Welch's test**. (9) For a hypothesis $\sigma_1 = \sigma_2$, we can use as a critical region $S = \{(x, y) | F(x, y) \leq c(\alpha)\}$, $S = \{(x, y) | F(x, y) \geq c(\alpha)\}$, or $S = \{(x, y) | F(x, y) \geq d(\alpha) \text{ or } < c(\alpha)\}$, when $\sigma_1 < \sigma_2, \sigma_2 < \sigma_1$, or $\sigma_1 \neq \sigma_2$, respectively, is taken as alternative, where $F(x, y) = (n-1)s_x^2 / (m-1)s_y^2$. All these tests are UMP unbiased and are invariant under the transformations $(x_1, \dots, x_m, y_1, \dots, y_n) \rightarrow (ax_1 + b, \dots, ax_m + b, ay_1 + b, \dots, ay_n + b)$ ($-\infty <$

$b < \infty, 0 < a < \infty$). A test based on $F(x, y)$ is called an F -test.

H. Linear Hypotheses

Let X_1, \dots, X_n be independent and distributed according to $N(\mu_i, \sigma^2)$ ($i = 1, 2, \dots, n$), where $\mu_1, \mu_2, \dots, \mu_s$ ($s < n$), σ are assumed to be unknown and $\mu_i = 0$ ($s < i \leq n$). The hypothesis is $\mathbf{H}: \mu_1 = \mu_2 = \dots = \mu_r = 0$ ($r \leq s$), and the alternative hypothesis is that at least one $\mu_i, 1 \leq i \leq r$, does not vanish. The critical region $S = \{(x_1, \dots, x_n) | F(x_1, \dots, x_r; x_{s+1}, \dots, x_n) = \sum_{i=1}^r x_i^2 / \sum_{i=s+1}^n x_i^2 \geq c(\alpha)\}$ is a UMP unbiased test for this problem, and S is invariant under the group g_1 of translations

$$(x_1, \dots, x_r, x_{r+1}, \dots, x_s, x_{s+1}, \dots, x_n) \rightarrow (x_1, \dots, x_r, x_{r+1} + a, \dots, x_s + a, x_{s+1}, \dots, x_n),$$

the group g_2 of similarity transformations $(x_1, \dots, x_n) \rightarrow (cx_1, \dots, cx_n)$, the group $g_3 = O(r)$ of orthogonal transformations in $\mathbf{R}^r = \{(x_1, \dots, x_r)\}$, the group $g_4 = O(n-s)$ of orthogonal transformations in $\mathbf{R}^{n-s} = \{(x_{s+1}, \dots, x_n)\}$, and finite products of elements of the groups g_1, g_2, g_3 , and g_4 . This test is also a kind of F -test. More generally, let us denote $\mathbf{X} = (X_1, X_2, \dots, X_n)'$ and assume that it is expressed as

$$\mathbf{X} = A\xi + \mathbf{W}, \quad \mathbf{W} = (W_1, W_2, \dots, W_n)', \quad (1)$$

where $\xi = (\xi_1, \xi_2, \dots, \xi_s)'$, $s \leq n$ is a vector of unknown parameters and A a matrix of known constants, and W_1, W_2, \dots, W_n are distributed independently according to the normal distribution with mean θ and variance σ^2 . Then a **general linear hypothesis** is a hypothesis stating that the vector ξ lies within a linear subspace M of \mathbf{R}^s . The set of points $A\xi$ with ξ satisfying a linear hypothesis \mathbf{H} is the linear subspace $L(B)$ of $L(A)$ spanned by the column vectors of an $n \times k_1$ matrix B . Assume, for example, that the dimension of $L(B)$ (=the rank of B) is $s-r$. Let C be an $n \times k_2$ matrix whose column vectors span the orthocomplement $L_A^\perp(B)$ of the space $L(B)$ with respect to the space $L(A)$. Then the model (1) can be written as

$$\mathbf{X} = B\boldsymbol{\eta} + C\boldsymbol{\zeta} + \mathbf{W}, \quad E(\mathbf{W}) = \mathbf{0}, \quad (2)$$

with a k_1 -vector $\boldsymbol{\eta}$ and a k_2 -vector $\boldsymbol{\zeta}$, and hence the hypothesis \mathbf{H} is represented by $\boldsymbol{\zeta} = \mathbf{0}$. We denote by $\mathbf{Y} = P_A \mathbf{X}$ the projection of \mathbf{X} onto the space $L(A)$ and by \mathbf{Z} the projection $P_B \mathbf{X}$ of \mathbf{X} onto the space $L(B)$. The quantity $Q_H = \mathbf{X}'(P_A - P_B)\mathbf{X}$ equals the square of the length of the vector $\mathbf{Y} - \mathbf{Z}$ and represents the sum of squares of residuals for the hypothesis \mathbf{H} . The error mean square $\hat{\sigma}^2 = \mathbf{X}'(I - P_A)\mathbf{X}/(n-s) = Q_e/(n-s)$ and also $\hat{\sigma}_H^2 = Q_H/r$ under \mathbf{H} are unbiased estimators of σ^2 .

Assume that $B'C = 0$. Let U be an orthogonal transformation in \mathbf{R}^n such that the first, \dots, r th, $(s+1)$ st, \dots, n th rows of UB and the $(s+1)$ st, \dots, n th rows of UC are all equal to zero vectors. Using the notation $\tilde{\mathbf{X}} = U\mathbf{X}$, $\tilde{\boldsymbol{\eta}} = UB\boldsymbol{\eta}$, $\tilde{\boldsymbol{\zeta}} = UC\boldsymbol{\zeta}$, and $\tilde{\mathbf{W}} = U\mathbf{W}$, we obtain the **canonical form** $\tilde{\mathbf{X}} = \tilde{\boldsymbol{\eta}} + \tilde{\boldsymbol{\zeta}} + \tilde{\mathbf{W}}$ of the model (2). $\tilde{\mathbf{W}}$ is also a vector of independently and identically distributed normal random variables. The hypothesis \mathbf{H} is expressed as $\tilde{\boldsymbol{\zeta}} = \mathbf{0}$. In this model, we have $E(\tilde{X}_i) = 0$ for $i = s+1, \dots, n$, and moreover, $E(\tilde{X}_i) = 0$ for $i = 1, \dots, r, s+1, \dots, n$ if and only if \mathbf{H} is true.

The least squares estimator \mathbf{Y} of $A\xi$ is the †maximum likelihood estimator, and $\mathbf{X} - \mathbf{Y}$, $\mathbf{Y} - \mathbf{Z}$, \mathbf{Z} are distributed independently according to the n -variate normal distributions $N(\mathbf{0}, \sigma^2(I - P_A))$, $N((P_A - P_B)C\boldsymbol{\zeta}, \sigma^2(P_A - P_B))$, and $N(B\boldsymbol{\eta} + P_B C\boldsymbol{\zeta}, \sigma^2 P_B)$, respectively. Hence Q/σ^2 , Q_H/σ^2 , and $\mathbf{X}'P_B\mathbf{X}/\sigma^2$ are distributed independently according to the †noncentral χ^2 -distributions with $n-s, r$, and $s-r$ degrees of freedom and †noncentrality parameters 0 , $\boldsymbol{\zeta}'C'(P_A - P_B)C\boldsymbol{\zeta}/\sigma^2$, and $(B\boldsymbol{\eta} + P_B C\boldsymbol{\zeta})'(B\boldsymbol{\eta} + P_B C\boldsymbol{\zeta})/\sigma^2$, respectively. The †likelihood ratio test of the hypothesis \mathbf{H} has a critical region $\hat{\sigma}_H^2/\hat{\sigma}^2 > c$, is a †uniformly most powerful invariant test with respect to the group of linear transformations leaving the hypothesis \mathbf{H} invariant, and is the †most stringent test. This test is also uniformly most powerful among the tests whose †power function has a single variable $\boldsymbol{\zeta}'C'(P_A - P_B)C\boldsymbol{\zeta}/\sigma^2$. Furthermore, for $s-r=1$, this test is a †uniformly most powerful unbiased test. In the decomposition $\mathbf{X}'\mathbf{X} = \mathbf{X}'(P_A - P_B)\mathbf{X} + \mathbf{X}'P_B\mathbf{X} + \mathbf{X}'(I - P_A)\mathbf{X} = Q_H + Q_B + Q_e$ the terms Q_H and Q_e are called the sum of squares due to the hypothesis and due to the error, respectively. Such a process of decomposition is called the analysis of variance and its result is summarized in the analysis of variance table (Table 1).

I. The Likelihood Ratio Test

The likelihood ratio test is comparatively easy to construct. Let $L(x_1, \dots, x_n; \theta)$ be the †likelihood function. Then

$$\Lambda(x_1, \dots, x_n) = \frac{\sup_{\theta \in \omega_H} L(x_1, \dots, x_n; \theta)}{\sup_{\theta \in \omega_H \cup \omega_A} L(x_1, \dots, x_n; \theta)}$$

is called the **likelihood ratio**, and the test corresponding to the critical region $S = \{(x_1, \dots, x_n) | \Lambda(x_1, \dots, x_n) \leq c_\alpha\}$ is called the **likelihood ratio test**, where c_α is a positive constant determined by the level α . Let $\hat{\theta}_H(x_1, \dots, x_n)$ and $\hat{\theta}_{H \vee A}(x_1, \dots, x_n)$ be the †maximum likelihood estimators for θ in ω_H and in $\omega_H \cup \omega_A$, respectively; that is, $L(x; \hat{\theta}_H(x)) = \sup_{\theta \in \omega_H} L(x; \theta)$ and $L(x; \hat{\theta}_{H \vee A}(x)) = \sup_{\theta \in \omega_H \cup \omega_A} L(x; \theta)$. Then

Table 1

Factor	Sum of Squares	Degrees of Freedom	Mean Square	Ratio of Variances
H	$Q_H = \mathbf{X}'(P_A - P_B)\mathbf{X}$	r	$\hat{\sigma}_H^2 = Q_H/r$	$\hat{\sigma}_H^2/\hat{\sigma}^2$
B	$Q_B = \mathbf{X}'P_B\mathbf{X}$	$s-r$	$\hat{\sigma}_B^2/(s-r)$	
Error	$Q_e = \mathbf{X}'(I - P_A)\mathbf{X}$	$n-s$	$\hat{\sigma}^2 = Q_e/(n-s)$	
Total	$\mathbf{X}'\mathbf{X}$	n		

$$\Lambda(x) = \frac{L(x; \hat{\theta}_H)}{L(x; \hat{\theta}_{H \vee A})}$$

The F -test for a linear hypothesis is a likelihood ratio test, and other examples of the likelihood ratio test are shown in Appendix A, Table 23. However, the likelihood ratio test does not necessarily have the desirable properties stated in the preceding sections.

J. Complete Classes

The set of critical regions of the type $\{x | T(x) > c\}$ for the problems $\mathbf{H}: \theta \leq \theta_0$ and $\mathbf{A}: \theta > \theta_0$, where the distribution family \mathcal{P} of the statistic T is of $^+P\acute{o}lya$ type 2 in the strict sense, and the set of regions of the type $\{x | c < T(x) < d\}$ for the problem $\mathbf{H}: \theta_1 \leq \theta \leq \theta_2$ and $\mathbf{A}: \theta < \theta_1$ or $\theta_2 < \theta$, where the distribution family \mathcal{P} of the statistic T is of $^+P\acute{o}lya$ type 3 in the strict sense, are examples of minimal complete classes [6]. It has been proved under a mild condition that the set of all tests with convex critical regions is essentially complete when the underlying distributions are of exponential type and the null hypothesis is simple.

Let $P_{\theta_i} \in \mathcal{P}$ ($i = 0, 1$) and let \mathfrak{B}_0 be a σ -subalgebra of \mathfrak{B} . \mathfrak{B}_0 is sufficient for \mathfrak{B} w.r.t. $\{P_{\theta_0}, P_{\theta_1}\}$ if and only if the class of all \mathfrak{B}_0 -measurable test functions is essentially complete, i.e. iff for every critical region $B \in \mathfrak{B}$ there exists a \mathfrak{B}_0 -measurable test function φ_0 such that $E_{\theta_0}(\varphi_0) \leq E_{\theta_0}(\chi_B)$ and $E_{\theta_1}(\varphi_0) \geq E_{\theta_1}(\chi_B)$. Assume that $\mathcal{P} = \{P_\theta | \theta \in \Theta\}$ is dominated; if for every \mathfrak{B} -measurable test function φ there exists a \mathfrak{B}_0 -measurable test function ψ such that $E_\theta(\psi) = E_\theta(\varphi)$ for all $\theta \in \Theta$, then \mathfrak{B}_0 is sufficient for \mathfrak{B} w.r.t. \mathcal{P} [9, 10] (\rightarrow 398 Statistical Decision Functions D, 399 Statistical Estimation E).

K. Asymptotic Theory

Let $(\mathcal{X}_v, \mathfrak{B}_v, P_{v\theta})$ ($v = 1, 2, \dots, n$) be a sequence of probability spaces, where the parameter space Ω is common to all v . Let $(\mathcal{X}^{(n)}, \mathfrak{B}^{(n)}, P_\theta^{(n)})$ be the direct product probability space of $(\mathcal{X}_v, \mathfrak{B}_v, P_{v\theta})$ for $v = 1, 2, \dots, n$. For each sample space $(\mathcal{X}^{(n)}, \mathfrak{B}^{(n)}, P_\theta^{(n)})$, denote a test function for $\mathbf{H}: \theta \in \omega_H (\subset \Omega)$ and $\mathbf{A}: \theta \in \omega_A (\subset \Omega - \omega_H)$ by $\varphi_n(x_1, \dots, x_n)$. A sequence $\{\varphi_n\}$ ($n = 1, 2, \dots$) is often

called a test. For example, a likelihood ratio test is frequently understood as a sequence of tests $S_n = \{(x_1, \dots, x_n) | \Lambda_n(x_1, \dots, x_n) \leq \lambda_n\}$, where $\{\lambda_n\}$ is a sequence of constants and $\Lambda_n(x_1, \dots, x_n)$ is the likelihood ratio defined by $(\mathcal{X}^{(n)}, \mathfrak{B}^{(n)}, P_\theta^{(n)})$ and ω_H . If a test $\{\varphi_n\}$ satisfies $E_\theta(\varphi_n) \rightarrow 0$ ($\theta \in \omega_H$) and $E_\theta(\varphi_n) \rightarrow 1$ ($\theta \in \omega_A$) as $n \rightarrow \infty$, $\{\varphi_n\}$ is said to be a **consistent test**. If these convergences are uniform with respect to θ , $\{\varphi_n\}$ is said to be a **uniformly consistent test**. When a uniformly consistent test exists, ω_H and ω_A are said to be **finitely distinguishable**. Suppose that the observed values are identically distributed (that is, $(\mathcal{X}_v, \mathfrak{B}_v, P_{v\theta})$ is a copy of a probability space $(\mathcal{X}, \mathfrak{B}, P_\theta)$) and ω_H and ω_A are both compact with respect to the metric $\rho(\theta, \theta') = \sup_{B \in \mathfrak{B}} |P_\theta(B) - P_{\theta'}(B)|$. In this case, ω_H and ω_A are finitely distinguishable if $E_\theta(\varphi)$ is a continuous function of θ for any φ [4]. Kakutani's theorem (\rightarrow 398 Statistical Decision Functions) is regarded as a proposition concerning distinguishability when the null hypothesis and the alternative are both simple.

The following result about the limit distribution of a likelihood ratio is due to H. Chernoff [3]: Let $\mathcal{X}^{(n)}$ be an n -space and Ω be an open subset of \mathbf{R}^k containing the origin 0. Suppose that the observed random variables are independent and distributed according to a density $f(x, \theta)$; that is, the likelihood function $L(x; \theta)$ is $\prod_{i=1}^n f(x_i, \theta)$. Moreover, assume the following regularity conditions:
 (1) $\log f(x, \theta)$ is three-times differentiable with respect to θ at every point of the closure of some neighborhood N of $\theta = 0$.
 (2) There exist an integrable function F and a measurable function H such that (i) $|\partial f / \partial \theta_i| < F(x)$ for every $\theta \in N$; (ii) $|\partial^2 f / \partial \theta_i \partial \theta_j| < F(x)$ for every $\theta \in N$; (iii) $|\partial^3 \log f / \partial \theta_i \partial \theta_j \partial \theta_m| < H(x)$; and (iv) $\sup_\theta E_\theta(H(x)) < \infty$.
 (3) For every $i, j = 1, 2, \dots, k$, we have $J_\theta^{ij} = E_\theta[(\partial \log f / \partial \theta_i)(\partial \log f / \partial \theta_j)] < \infty$, and the matrix $J_\theta = (J_\theta^{ij})$ is positive definite for all $\theta \in N$.
 Let $P(x_1, \dots, x_n; \omega) = \sup_{\theta \in \omega} L(x_1, \dots, x_n; \theta)$ for a subset ω of Ω . Consider testing a hypothesis $\theta \in \omega_H$ against an alternative $\theta \in \omega_A$, where 0 is an accumulation point of ω_H . If $\lambda^*(x_1, \dots, x_n) = P(x_1, \dots, x_n; \omega_H) / P(x_1, \dots, x_n; \omega_A)$, λ^* plays essentially the same role as the likelihood ratio λ and hence can be used in its place. We call a subset C of Ω a cone if $\theta \in C$ implies $a\theta \in C$ for

any $a > 0$. A subset ω of Ω is said to be approximated by C if ω satisfies $\inf_{y \in C} \|x - y\| = o(\|x\|)$ for all $y \in \omega$ and $\inf_{y \in \omega} \|x - y\| = o(\|x\|)$ for all $x \in C$ around the origin, where $\|x\|^2 = \sum_{i=1}^n x_i^2$. Suppose that ω_H and ω_A are approximated by two cones C_H and C_A , respectively. Then, setting $z_n = \sqrt{n} J_0^{-1} A(x)$ with

$$A(x) = \left[\frac{1}{n} \sum_{\alpha=1}^n \frac{\partial \log f(x_\alpha, 0)}{\partial \theta_1}, \dots, \frac{1}{n} \sum_{\alpha=1}^n \frac{\partial \log f(x_\alpha, 0)}{\partial \theta_k} \right]^T,$$

the limit distribution of $-2 \log \lambda^*$, when $\theta = 0$, coincides with that of $\inf_{\theta \in C_H} (z_n - \theta)^T J_0(z_n - \theta) - \inf_{\theta \in C_A} (z_n - \theta)^T J_0(z_n - \theta)$. In particular, when $\Omega = \mathbf{R}^k$ and $\omega_H = \{(\theta_1^0, \dots, \theta_s^0, \theta_{s+1}, \dots, \theta_k) \mid -\infty < \theta_i < \infty, i = s + 1, \dots, k\}$ and some regularity conditions are assumed, the limit distribution of $-2 \log \lambda^*$ is the χ^2 -distribution with s degrees of freedom if the hypothesis is true.

The asymptotic behavior of the chi-square test of goodness of fit is also very important. Suppose that (X_1, \dots, X_k) has a multinomial distribution $n!(x_1! \dots x_k!)^{-1} p_1^{x_1} \dots p_k^{x_k} (\sum_{i=1}^k x_i = n, x_i \geq 0)$, and consider testing $\mathbf{H}: p_1 = p_1^0, \dots, p_k = p_k^0$. The **chi-square test of goodness of fit** has a critical region of the type $\{x \mid \chi^2(x_1, \dots, x_k) \geq c\}$, where $\chi^2(x_1, \dots, x_k)$ is $\sum_{i=1}^k ((x_i - np_i^0)^2 / np_i^0)$, i.e., the weighted sum of the squares of the differences between the value p_i^0 of p_i and the maximum likelihood estimator x_i/n of p_i . The limit distribution of $\chi^2(x_1, \dots, x_k)$ when $p_i = p_i^0, i = 1, 2, \dots, k$, is the chi-square distribution with $k - 1$ degrees of freedom.

Suppose moreover that k functions $p_i(\theta)$ ($i = 1, \dots, k; s < k$) of $\theta \in \mathbf{R}^s$ are given and that the hypothesis to be tested is that the sample has been drawn from a population having a distribution determined by $\mathbf{H}: p_i = p_i(\theta)$ ($i = 1, \dots, k; s < k$) for some value of θ . In this case the chi-square test of goodness of fit could be applied after replacing the parameter θ in $p_i = p_i(\theta)$ ($i = 1, 2, \dots, k$) by the solutions $\tilde{\theta}_n(x_1, \dots, x_k)$ of the system of equations of the **modified minimum chi-square method**,

$$\sum_{i=1}^k \frac{x_i - np_i}{p_i} \frac{\partial p_i}{\partial \theta_j} = 0$$

($j = 1, \dots, s$). Suppose that (1) $p_i(\theta) > c^2 > 0$ ($i = 1, \dots, k$) and $\sum_{i=1}^k p_i(\theta) = 1$; (2) $p_i(\theta)$ is twice continuously differentiable with respect to the coordinates of θ ; and (3) the rank of the matrix $(\partial p_i / \partial \theta_j)$ is k . Then the system of equations above has a unique solution $\theta = \tilde{\theta}_n(x_1, \dots, x_k)$, and $\tilde{\theta}_n$ converges in probability to θ_0 when $\theta = \theta_0$. The asymptotic distribution of $\chi^2(x) = \sum_{i=1}^k ((x_i - np_i(\tilde{\theta}_n))^2 / np_i(\tilde{\theta}_n))$ is the chi-square distribution with $n - s - 1$ degrees of freedom

[5]. For the test of goodness of fit, the empirical distribution function may also be used (\rightarrow 371 Robust and Nonparametric Methods).

A test of independence by contingency tables is one application of the chi-square test of goodness of fit. We suppose that n individuals are classified according to two categories A and B , where A has r ranks A_1, A_2, \dots, A_r and B has s ranks B_1, B_2, \dots, B_s . Let p_i, p_j, p_{ij} be the probabilities that the observed value of an individual belongs to $A_i, B_j, A_i \cap B_j$, respectively. Let x_i, x_j, x_{ij} be the numbers of individuals belonging to A_i, B_j , and $A_i \cap B_j$, respectively. Table 2 is called a **contingency table**. To test the null hypothesis \mathbf{H} that the divisions of A and B into their ranks are independent, that is, $\mathbf{H}: p_{ij} = p_i p_j$, the statistic $\chi^2 = \sum_{i=1}^r \sum_{j=1}^s (x_{ij} - x_i x_j / n)^2 / (x_i x_j / n)$ is applied. When \mathbf{H} is true, χ^2 is asymptotically distributed according to the chi-square distribution with $(r - 1)(s - 1)$ degrees of freedom as $n \rightarrow \infty$.

Likelihood ratio tests and chi-square tests of goodness of fit are consistent tests under conditions stated in their respective descriptions. In general, there are many consistent tests for a problem. Therefore it is necessary to consider another criterion that has to be satisfied by the best test among consistent tests. Pitman's asymptotic relative efficiency is such a criterion. Other notions of efficiency have also been introduced.

A completely specified form of distribution is rather exceptional in applications. More often we encounter cases where distribution of the sample belongs in a large domain. Various tests independent of the functional form of distribution have been proposed, and the asymptotic theory plays an important role in those cases (\rightarrow 371 Robust and Nonparametric Methods).

The following concept of asymptotic efficiency is due to R. R. Bahadur [11]: Let $\{T_n\}$ be a sequence of real-valued statistics defined on $\mathcal{X}^{(n)}$. $\{T_n\}$ is said to be a standard sequence (for testing \mathbf{H}) if the following three conditions are satisfied.

(I) There exists a continuous probability distribution function F such that for each $\theta \in \omega_H, \lim_{n \rightarrow \infty} P_\theta^{(n)}\{T_n < t\} = F(t)$ for every $t \in \mathbf{R}^1$.

Table 2. Contingency Table

	B_1	B_2	\dots	B_s	Total
A_1	x_{11}	x_{12}	\dots	x_{1s}	$x_{1\cdot}$
A_2	x_{21}	x_{22}	\dots	x_{2s}	$x_{2\cdot}$
\vdots	\vdots	\vdots	\dots	\vdots	\vdots
A_r	x_{r1}	x_{r2}	\dots	x_{rs}	$x_{r\cdot}$
Total	$x_{\cdot 1}$	$x_{\cdot 2}$	\dots	$x_{\cdot s}$	n

(II) There exists a constant a , $0 < a < \infty$, such that $\log\{1 - F(t)\} = -(at^2/2)\{1 + o(1)\}$ as $t \rightarrow \infty$.

(III) There exists a function $b(\theta)$ on $\Omega - \omega_H$ with $0 < b(\theta) < \infty$ such that for each $\theta \in \Omega - \omega_H$,

$$\lim_{n \rightarrow \infty} P_{\theta}^{(n)}\{|(T_n/n^{1/2}) - b(\theta)| > t\} = 0$$

for every $t > 0$.

Suppose that $\{T_n\}$ is a standard sequence. Then T_n has the asymptotic distribution F if \mathbf{H} is satisfied, but otherwise $T_n \rightarrow \infty$ in probability. Consequently, large values of T_n are significant when T_n is regarded as a test statistic for \mathbf{H} . Accordingly, for any given $x \in \mathcal{X}^{(n)}$, $1 - F(T_n(x))$ is called the critical level in terms of T_n , and is regarded as a random variable defined on $\mathcal{X}^{(n)}$ [1]. It is convenient to describe the behavior of this random variable as $n \rightarrow \infty$ in terms of K_n , where $K_n(x) = -2 \log[1 - F(T_n(x))]$. Then for each $\theta \in \omega_H$, K_n is asymptotically distributed as a chi-square variable χ_2^2 with 2 degrees of freedom and for $\theta \in \Omega - \omega_H$, $K_n/n \rightarrow ab^2(\theta)$ in probability as $n \rightarrow \infty$. The asymptotic slope of the test based on $\{T_n\}$ (or simply the slope of $\{T_n\}$) is defined to be $c(\theta) = ab^2(\theta)$. Note that the statistic $K_n^{1/2}$ is equivalent to T_n in the following technical sense: (i) $\{K_n^{1/2}\}$ is a standard sequence; (ii) for each $\theta \in \Omega$, the slope of $\{K_n^{1/2}\}$ equals that of $\{T_n\}$; and (iii) for any given n and x , the critical level in terms of $K_n^{1/2}$ equals the critical level in terms of T_n . Since the critical level of $K_n^{1/2}$ is found by substituting $K_n^{1/2}$ into the function representing the upper tail of a fixed distribution independent of F , $\{K_n^{1/2}\}$ is a normalized version of $\{T_n\}$. Suppose that $\{T_n^{(1)}\}$ and $\{T_n^{(2)}\}$ are two standard sequences defined on $\mathcal{X}^{(n)}$, and let $F^{(i)}(x)$, a_i , and $b_i(\theta)$ be the functions and constants prescribed by conditions (I)–(III) for $i = 1, 2$. Consider an arbitrary but fixed θ in $\Omega - \omega_H$, and suppose that x is distributed according to P_{θ} . The asymptotic efficiency of $\{T_n^{(1)}\}$ relative to $\{T_n^{(2)}\}$ is defined to be $\varphi_{12}(\theta) = c_1(\theta)/c_2(\theta)$, where $c_i(\theta) = a_i b_i^2(\theta)$ is the slope of $\{T_n^{(i)}\}$, $i = 1, 2$. The asymptotic efficiency is called **Bahadur efficiency**.

Several comparisons of standard sequences are given in [11]. The relationship between Bahadur efficiency and Pitman efficiency for hypothesis-testing problems has also been studied. Under suitable conditions the two efficiencies coincide.

L. Sequential Tests

Let X_1, X_2, \dots be a given sequence of random variables. To test a hypothesis concerning the distributions of these variables (sample sizes are not predetermined), we observe first X_1 ,

400 Ref.

Statistical Hypothesis Testing

then X_2 , etc. At each stage a decision is made on the basis of the previously obtained data whether the observation should be stopped and a judgment made on the acceptability of the hypothesis. Such a test is called a **sequential test**. Let X_1, X_2, \dots be independent and identically distributed by $f_{\theta}(x)$. For testing a simple hypothesis $\mathbf{H}: \theta = 0$ against a simple alternative $\mathbf{A}: \theta = 1$, we have the **sequential probability ratio test**: Let $G_n(x_1, x_2, \dots, x_n) = \prod_{i=1}^n f_1(x_i) / \prod_{i=1}^n f_0(x_i)$, and preassign two constants $a_0 < a_1$. After the observations of X_1, \dots, X_n are performed, the next random variable X_{n+1} is observed if $a_0 < G_n(x_1, \dots, x_n) < a_1$. Otherwise the experiment is stopped, and we accept \mathbf{H} when $G_n \leq a_0$ or accept \mathbf{A} when $a_1 \leq G_n$. The constants a_0 and a_1 are determined by the desired probabilities α_1 and α_2 of errors of the first and second kind, respectively. It is known that, among the class of sequential tests in which the probability of error of the first (second) kind is not greater than α_0 (α_1), the sequential probability ratio test minimizes the expected number of observations when either \mathbf{H} or \mathbf{A} is true (\rightarrow 398 Statistical Decision Functions; 404 Statistical Quality Control).

401 (XVIII.2) Statistical Inference

A. The Statistical Model

Broadly and loosely speaking, the term “statistical inference” may imply any procedure for drawing conclusions from statistical data. But now it is usually understood more rigorously to mean those procedures based upon a †probabilistic model of the data to obtain conclusions concerning the unknown parameters of the population that represents the probabilistic model by viewing the observed data as a †random sample extracted from the population.

As the simplest example, suppose that, for some system, we have a number of observations from repeated measurements or experiments under a supposedly uniform condition. If we can assume that there are no systematic trends or tendencies involved, we can suppose that the variations among repeated observations are due to random causes and assume that the observed values X_1, X_2, \dots are independently and identically distributed random variables. Our purpose in making observations is to draw some information from the data, that is, to make some judgment on an unknown system quantity θ , which together with some other quantity (quantities) η characterizing the measurement or the experiment, determines the distribution of the X_i . We assume that the distribution has a density function $f(x; \theta, \eta)$. This amounts to assuming that the observed values X_1, X_2, \dots are a sample randomly drawn from a hypothetical population of the results of the measurements or experiments supposedly continued indefinitely. Then the problem of statistical inference is one of making some judgment based on the random sample. The set of hypotheses postulating the distribution of the observed values is called the probabilistic model of the observations, and the problem of determining a model in a specific situation is called that of **specification**.

B. Bayesian and Non-Bayesian Approaches

There are two different ways to make inferences on the population parameters: the **Bayesian approach** and the **non-Bayesian approach**.

In the Bayesian approach it is assumed that we have some probability density $\pi(\theta, \eta)$ for

the parameters θ and η . Then, given the observations $X_1 = x_1, X_2 = x_2, \dots$, the conditional probability density for θ and η is given by

$$\bar{P}(\theta, \eta | x_1, x_2, \dots) = \frac{\prod f(x_i; \theta, \eta) \pi(\theta, \eta)}{\iint \prod f(x_i; \theta, \eta) \pi(\theta, \eta) d\theta d\eta}.$$

π is called the **prior density** and \bar{p} the **posterior density** for the parameters. Then all the information obtained from the sample is considered to be contained in the **posterior distribution** with the density $\bar{p}(\theta, \eta)$, and conclusions on the parameters can be drawn from it.

The prior density $\pi(\theta, \eta)$ does not necessarily represent a frequency function of a population of which the parameters are a random sample, but in most cases treated by the **Bayesian approach** it is considered to be a summary of the statistician’s judgment over relative possibilities of the different values of the parameters based on all the information obtained before the observations are made. **Bayesians** claim that it is always possible to determine such a **prior distribution** in a coherent way, specifying the **subjective probability**, representing a person’s judgment under uncertainty, as opposed to the **objective probability**, representing the relative frequencies in a population. L. J. Savage [7] succeeded in developing a formal mathematical theory of the subjective probability from a set of postulates about the consistent behavior of a person under uncertainty.

The non-Bayesian statisticians, however, do not accept the Bayesians’ viewpoint and insist that statistical inference should be free from any subjective judgment and be based solely on the objective properties of the sample derived from the assumed model. The theory developed by R. A. Fisher, J. Neyman, and E. S. Pearson, and others is based on the non-Bayesian approach.

C. Problems of Non-Bayesian Inference

The most commonly used forms of statistical inference are **point estimation**, used when we want to get a value as the estimate for the parameter; **interval estimation**, when we want to get an interval that contains the true value of the parameter with a probability not smaller than the preassigned level; and **hypothesis testing**, when it is required to determine whether or not some hypothesis about the parameter values is wrong (\rightarrow 399 Statistical Estimation, 400 Statistical Hypothesis Testing).

In any type of statistical inference, the problem can be abstractly formulated by determining a procedure that defines a rule, based on the sample observed, for choosing an element from the set of possible conclusions.

Such a procedure is evaluated by the probabilistic properties derived under different values of the parameter from the distribution of the sample, and it is usually required to satisfy some type of validity criteria (such as unbiasedness of an estimator, size of a test, etc.), and among those satisfying them, one which is considered to be best according to some optimality criterion (such as minimum variance or most-powerfulness) is looked for. But in the sense of objective probability, the probabilistic property of a procedure is relevant only for the frequencies in repeated trials when the same procedure is applied to a sequence of samples obtained from the population and has no direct implications for the conclusion obtained by applying the procedure to a specific sample we have in hand. For this reason Neyman argued that in statistical inference there is really no such thing as inductive inference but only inductive behavior. Fisher disagreed strongly with this argument and emphasized that statistical analysis is induction and that its purpose is to allow us to draw the proper conclusions from a particular sample and that the probabilistic properties of the procedure should and could have relevance for a particular conclusion obtained from a specific sample, provided that all the information contained in the sample is used. The arguments between Fisher and Neyman led to a heated controversy between their followers that is still not completely settled. Fisher's arguments lead to the **principle of sufficiency** and the **principle of conditionality**. The principle of sufficiency dictates that all inferences should be based on a sufficient statistic if there is one, and the principle of conditionality requires that any inference should be based on the conditional distribution given the **ancillary statistic**, i.e., a statistic whose distribution is independent of the parameter, if there is such a statistic. These two principles are accepted by many statisticians who do not follow all of Fisher's arguments, though the principle of conditionality sometimes leads to difficulties due to nonuniqueness of the ancillary.

D. Specification Problem

It is often difficult and sometimes impossible to have an exactly correct model for the data, and we must be satisfied with a model that gives a sufficiently close approximation and is mathematically tractable as well. It may also happen, however, that a model first specified may be far from reality and could lead to erroneous conclusions if relied on blindly. Here, the problem of **model selection** arises (→

403 Statistical Models), i.e., choosing the best of various possible models.

We may also seek procedures that are little affected by the departure of the distribution of the data from the assumed or some other model that satisfies the condition of validity without any assumption about the exact shape of the distributions (→ 371 Robust and Nonparametric Methods). Generally, the problem of determining the model or specification should not be dealt with by mathematical methods alone, and it should be considered by taking into account the properties and nature of the subject under consideration and also the process of measurement or experimentation.

E. History

The first appearance of statistical inference as a method of grasping numerical characteristics of a collective was seen in the study by J. Graunt (1662) of the number of people who died in London. W. Petty applied Graunt's method further to the comparison of communities in his *Political arithmetic* (1690). J. P. Süßmilch, a member of the Graunt school, perceived the regularity in mass observations and stressed the statistical importance of this regularity. The development of the theory of probability inevitably affected the theory of statistical inference. The method of T. Bayes was the first procedure of statistical inference in the current meaning of this expression. We now have a theorem bearing his name (the Bayes theorem), which is stated in current language as follows: If we know the probability $P_C(E)$ that a cause C produces an effect E and if the prior (or *à priori*) probability $P(C)$ of the existence of the cause C is also known, then the posterior (or *à posteriori*) probability of C , given an effect E , is equal to

$$P_E(C) = \frac{P(C)P_C(E)}{\sum_C P(C)P_C(E)}$$

(→ 342 Probability Theory F). This theorem, easily extendable to the continuous case, suggests the following inference procedure: If we are informed that an effect E has taken place, then we calculate the probabilities $P_E(C)$ for every cause C , compare them, and infer that the C^* with $P_E(C^*) = \max_C P_E(C)$ is the **most probable cause** of E .

Both P. S. Laplace and C. F. Gauss discussed the theory of estimation of parameters (→ 399 Statistical Estimation) as an application of the Bayes theorem. In his research, Laplace considered a monotone function $W(|t - \theta|)$, and $W = |t - \theta|$ in particular, of the distance $|t - \theta|$ between a parameter value θ and its

estimate t as a measure of significance of the error of the estimate t . Gauss, following Laplace, used this weight function $W(|t - \theta|)$ of error, and going beyond Laplace, realized that it would be mathematically fruitful to put $W(|t - \theta|) = (t - \theta)^2$. Such considerations led him to the study of the †least squares method, in which the terminology and notation he devised are still in use. He also developed the theory of errors and recognized the importance of the normal distribution and found that the least square estimate is equal to the most probable value if the errors are normally distributed.

F. Galton, a biologist, revealed the usefulness of statistical methods in biological research and explored what we call †regression analysis (\rightarrow 403 Statistical Models) by introducing the concepts of regression line and †correlation coefficient. His research on regression analysis originated from the study of the correlation between characteristics of parents and children, but he failed to realize the difference between †population characteristics and †sample characteristics.

Following Galton, K. Pearson developed the theory of regression and correlation, with which he succeeded in establishing the basis of biometrics (\rightarrow 40 Biometrics). He arrived at the concept of population in statistics: A statistical **population** is a collective consisting of observable individuals, while a **sample** is a set of individuals drawn out of the population and containing something telling us about characteristics of the population. Thus statistical research is regarded as investigation that focuses not on a sample as such but on a population from which the sample has been drawn. This consideration raised the problem of the **goodness-of-fit test** (\rightarrow 400 Statistical Hypothesis Testing), that is, the problem of knowing whether a sample is likely to have been drawn from a population whose distribution was determined by theoretical considerations. K. Pearson characterized some population distributions occurring in practice by a differential equation, and classified them into several types. Using this classification, he discussed goodness-of-fit tests and developed the χ^2 -distribution (†chi-square distribution) in relation to the problem of testing hypotheses.

Statisticians in the time of K. Pearson thought of a population as a collective having infinitely many individuals (i.e., an **infinite population**), which led to the idea that the larger the **size** of a sample (i.e., the number of individuals in the sample), the more precisely could the sample give information about the population. They carried out inferences, including the testing of hypotheses (\rightarrow 400 Statistical Hypothesis Testing), by approximate

methods, which later came to be termed **large sample theory**. Suppose, for instance, that $\{X_1, \dots, X_n\}$ is an †independent sample of size n from a normal population $N(\mu, \sigma^2)$. The random variable $Z = \sqrt{n}(\bar{X} - \mu_0)/\sigma$ with $\bar{X} = \sum_i X_i/n$ is distributed according to $N(0, 1)$ when $\mu = \mu_0$. Therefore, if the size n is sufficiently large ($n \rightarrow \infty$), we estimate σ by $\hat{\sigma} = \{\sum_i (X_i - \bar{X})^2 / (n - 1)\}^{1/2}$ and deal with the random variable $T = \sqrt{n}(\bar{X} - \mu_0)/\hat{\sigma}$ obtained by inserting $\hat{\sigma}$ in place of σ in the expression for Z , as if T itself were distributed according to $N(0, 1)$.

F. Development in the 20th Century

W. S. Gosset, writing under the pen name “Student,” reported in 1908 the discovery of the exact distribution of T and thereby opened the new epoch of **exact sampling theory** (\rightarrow 374 Sampling Distributions). This work of Student made it possible to perform statistical inference by means of **small samples** and consequently changed statistical research from the study of collectives to that of uncertain phenomena; in other words, the concept of population was once again related to a †probability space with a †probability distribution (i.e., a **population distribution**) containing unknown **parameters**. Thus it began to be emphasized that a sample has to be drawn **at random** (i.e., a **random sample**) from the population if we are to make an inference about a parameter based on the sample.

Fisher presented a complete derivation, using the multiple integration method, of the † t -distribution (the sampling distribution of T). In addition, Fisher introduced the concepts of †null hypothesis and significance test, which were the starting points for later progress in the theory of hypothesis testing. He also added the concepts of †consistency, †efficiency, and †sufficiency to the list of possible properties of †estimators, and he studied the connection between the information contained in a sample and the accuracy of an estimator, which led to the idea of amount of information. Fisher also proposed the †maximum likelihood estimator, which is formally equivalent to the most probable value, but he renamed it and gave it a foundation completely independent of any prior information and showed that it leads to the at least asymptotically efficient estimator.

Fisher made efforts to obtain a distribution of the parameter directly from the sample observation, hence independently of the concept of prior probability. He sought in this way to be released from the weakness of the Bayes method. For this purpose he introduced

the concept of **fiducial distribution**, which was the subject of bitter controversy in the period that followed. As an example of a fiducial distribution, we consider here the †Behrens-Fisher problem: Let X_1, \dots, X_m and Y_1, \dots, Y_n be samples drawn independently from the populations $N(\mu_1, \sigma_1^2)$ and $N(\mu_2, \sigma_2^2)$, respectively, where the parameters μ_1, μ_2, σ_1 , and σ_2 are all unknown. The problem raised is to test the hypothesis $\mu_1 = \mu_2$ or to estimate $\delta = \mu_1 - \mu_2$ by an interval. To solve this problem, we put

$$\bar{X} = \sum_i X_i/m, \quad \bar{Y} = \sum_j Y_j/n,$$

$$S_1^2 = \sum_i (X_i - \bar{X})^2/(m-1),$$

$$S_2^2 = \sum_j (Y_j - \bar{Y})^2/(n-1),$$

and learn that $T_1 = \sqrt{m}(\bar{X} - \mu_1)/S_1$ and $T_2 = \sqrt{n}(\bar{Y} - \mu_2)/S_2$ are mutually independent and distributed according to the t -distribution with degrees of freedom $m-1$ and $n-1$, respectively. From this fact Fisher reasoned as follows: Given observed values $\bar{x}, \bar{y}, s_1, s_2$ of the variables $\bar{X}, \bar{Y}, S_1, S_2$, the distributions of the parameters μ_1 and μ_2 are induced from the distributions of T_1 and T_2 by means of transformations

$$\mu_1 = \bar{x} - \frac{T_1 s_1}{\sqrt{m}}, \quad \mu_2 = \bar{y} - \frac{T_2 s_2}{\sqrt{n}}.$$

Consequently the distribution of $\delta = \bar{x} - \bar{y} - (T_1 s_1/\sqrt{m} - T_2 s_2/\sqrt{n})$ is obtained. These distributions are called the fiducial distributions of the parameters μ_1, μ_2 , and δ . The interval $|\delta - (\bar{x} - \bar{y})| < c$ of δ deduced from the fiducial distribution of δ is called a **fiducial interval** of δ .

Neyman and E. S. Pearson developed a mathematical theory of testing hypotheses, in which they deliberately defined a family of population distributions admissible for formal treatment and considered alternative hypotheses within the family. They proposed to relate a test to its †power function, on the basis of which the test would be judged. Their ideas brought mathematical clarity to the theory of inference. Furthermore, concerning interval estimation, Neyman devised an alternative to the fiducial interval, the †confidence interval, which has full mathematical justification. Unfortunately it was later found that the confidence interval, fiducial interval, and the Bayes posterior interval based on the posterior distribution often gave distinctly different results to the same problem, which became a source of controversy among different schools of thought.

Since the publication of A. Wald's theory of statistical decision functions (\rightarrow 398 Statistical

Decision Functions) in 1939, there has been a steady increase in its importance. In this theory the totality \mathcal{D} of available statistical procedures, which is considered implicitly in the Neyman-Pearson theory, is put forth explicitly as a set and defined as the space of decision functions. Wald also defined the †risk function of a statistical decision procedure and used it as a basis for judging procedures. In addition, he employed the concept of prior probability and the Bayes procedure for the purpose of proving the †complete class theorem. Wald's idea of bringing the concept of prior probability back into statistical theory carried a great deal of weight, and much literature has now been accumulated on this subject. Prior probability as a technique in statistics was abandoned after Fisher's introduction of the maximum likelihood method independent of prior probability and Neyman's assertion that a probability distribution on the †parameter space made no sense. In addition, Wald linked statistical inference to games (\rightarrow 173 Game Theory) and introduced the †minimax principle into statistics. The decision-theoretic setup also enabled him to develop a theory of sequential analysis by comparing the cost of sampling with the risk of erroneous decisions (\rightarrow 400 Statistical Hypothesis Testing).

After the publication of Savage's book in 1954, there was a revival of the Bayesian approach, i.e., one based on the concept of subjective probability, and now the group of those statisticians who accept the Bayesian approach are called Bayesians or neo-Bayesians.

G. Applications

Methods of statistical inference are applied in many fields where statistical data are used for scientific, engineering, medical, or managerial purposes. Methods of producing data that are appropriate for statistical inference have also been developed. R. A. Fisher developed the method of statistical †design of experiments (\rightarrow 102 Design of Experiments) that when it is impossible or impractical to eliminate completely experimental errors or variabilities, provides the procedures to obtain such data. These data, though subject to random errors, are susceptible to rigorous statistical inference. For this purpose Fisher introduced the principles of †randomization, †local control, and †replication in the design of experiments. W. A. Shewhart defined the †state of statistical control in mass-production processes, where the variabilities of the products can be considered to be due to chance causes alone and hence are statistically analyzable.

Statistical Inference

Applying the idea of statistical inference to this situation, Shewhart established the method of statistical quality control (→ 404 Statistical Quality Control). Neyman introduced the method of random sampling into statistical surveys and developed the theory of estimation and allocation based on the theory of statistical inference (→ 373 Sample Survey).

In many applied fields there exist systems of statistical methods which have been developed specifically for the respective fields, and although all of them are based essentially on the same general principles of statistical inference, each has its own special techniques and procedures. Specific names have been invented, such as biometrics (→ 40 Biometrics) econometrics (→ 128 Econometrics), psychometrics (→ 346 Psychometrics), technometrics, sociometrics, etc.

402 (XX.19) Statistical Mechanics

A. General Remarks

One cubic centimeter of water contains about 3×10^{22} water molecules. A macroscopic system of matter thus consists of an enormous number of particles incessantly moving in accordance with the laws of dynamics (→ 271

Mechanics; 351 Quantum Mechanics). Dynamical description of such microscopic motion in full detail is impossible and even meaningless. A physical process in thermodynamics or hydrodynamics is described in terms of a relatively small number of macroscopic variables, such as temperature, pressure, and a velocity field. Such a process shows a remarkable simplicity which is a statistical result of the molecular chaos. This is the reason why statistical mechanics is needed as a theoretical model to unify microscopic dynamics and probability theory. Thus **statistical mechanics** aims at deriving physical laws in the macroscopic world from the atomistic structures of the microscopic world on the basis of microscopic dynamical laws and probabilistic laws. Its function is twofold. First, statistical mechanics should give microscopic proofs of the macroscopic laws of physics, such as those of thermodynamics or the laws of macroscopic electromagnetism. Second, it should also provide us with detailed knowledge of physical properties of a given material system once its microscopic structure is known. In this sense, statistical mechanics is an essential basis of the modern science of materials.

Strictly speaking, the dynamics of the microscopic world obeys quantum mechanics. However, even before the birth of quantum mechanics, statistical mechanics had progressed on the basis of classical mechanics. This stage of statistical mechanics is often called **classical statistical mechanics**, in contrast to **quantum statistical mechanics** based on quantum mechanics. Statistical mechanics has a fully developed formalism to apply to physical systems in thermal equilibrium. This is sometimes called **statistical thermodynamics** or **equilibrium statistical mechanics**. Until the 1950s the term “statistical mechanics” had often been used in this narrow sense. In a wider sense it is concerned with systems in more general states, for instance, in nonequilibrium states. In the modern literature, a general statistical mechanical theory of nonequilibrium systems is often referred to as the statistical mechanics of **irreversible processes**.

B. History

The early stage of statistical mechanics can be traced back to the **kinetic theory of gases**, which started in the 18th century. In dilute gases, gas molecules fly freely through the whole volume of the vessel and collide only from time to time. In thermal equilibrium, the average energy of each molecule is determined by the temperature of the gas; namely

$$m \overline{v_x^2}/2 = m \overline{v_y^2}/2 = m \overline{v_z^2}/2 = kT/2,$$

where (v_x, v_y, v_z) is the velocity, an overbar means the average, m is the mass of a molecule, T is the absolute temperature, and k is the **Boltzmann constant** ($= 1.38 \times 10^{-16}$ erg · deg⁻¹). The velocity of each molecule is only probabilistic, and a †distribution function $f(v_x, v_y, v_z)$ is defined as the †probability density that the velocity of a given molecule is found to be in the neighborhood of (v_x, v_y, v_z) . In a dilute gas, this is given by

$$f(v_x, v_y, v_z) = C \exp \left[-\frac{m}{2} (v_x^2 + v_y^2 + v_z^2) / kT \right], \quad (1)$$

the **Maxwell-Boltzmann distribution law**.

L. Boltzmann viewed the velocity distribution function as changing in time as a result of molecular collisions and gave an equation of the form

$$\frac{\partial f}{\partial t} = A[f] + \Gamma[f], \quad (2)$$

where $A[f]$ is the change of the distribution function f by acceleration due to the presence of external forces and $\Gamma[f]$ is the change caused by molecular collisions. $\Gamma[f]$ is an integral which is nonlinear in f . This type of equation is called a **Boltzmann equation** [1, 2].

Boltzmann introduced the **H-function** by the definition

$$H = \iiint f \log f \, dv_x \, dv_y \, dv_z \quad (3)$$

and proved on the basis of equation (2) that $dH/dt \leq 0$. This theorem is known as the **H-theorem** [1–4]. The equilibrium distribution (1) is therefore obtained from equation (2) as the solution that makes H a minimum. In fact the H -function is related to the **entropy** S by

$$S = -kH. \quad (4)$$

Boltzmann further showed (1877) that the distribution function of a system in thermal equilibrium can be obtained on more general grounds without relying on a kinetic equation of the type (2) and that the statistical mechanics of systems in equilibrium can thus be constructed on a basis much more general than that given by a kinetic theory. It was W. Gibbs, however, who clearly established (1902) the complete framework of statistical thermodynamics, although he had to confine himself to classical statistical mechanics [5].

C. The Ergodic Hypothesis

For a given dynamical system with n †degrees of freedom, the **phase space** is defined as a $2n$ -dimensional space with †generalized coordinates q_1, \dots, q_n and †generalized momenta

p_1, \dots, p_n . Dynamical states of the system constitute a set of points in this space. At a given time, the state of the system is represented by a point P in the phase space, and hence the motion of the system is represented by the motion of P . If the system is conservative, its energy function is constant. Let \mathcal{H} be the †Hamiltonian function. Then the motion of P is confined to an **energy surface** defined by the condition $\mathcal{H} = E = \text{constant}$. Measure on an energy surface is defined as the limit of the volume element lying between two neighboring energy surfaces corresponding to the energies E and $E + dE$. The motions of P form a †topological group that makes this measure invariant (†Liouville's theorem).

A dynamical quantity $A(p, q)$ of the system changes its value as the phase point P moves on the energy surface. The time average \bar{A} of A is identified with the value of A observed in the equilibrium state of the system, namely, the average of A with respect to the invariant measure. Boltzmann justified this assumption by the following reasoning. If the energy surface has a finite measure and the trajectory of P does not make a closed curve on the energy surface, it can be assumed that the trajectory will move around practically everywhere on the surface. Mathematically formulated, the only measurable subset of the surface that has a nonzero measure and is invariant under the motion is the whole surface. This assumption is the **ergodic hypothesis** [6–9]. The long-time average of A will then equal the average of A over the entire energy surface with weight function equal to the measure previously introduced. The latter average is called the **phase average** and is denoted by $\langle A \rangle$. Boltzmann thus asserted that

$$\bar{A} = \langle A \rangle. \quad (5)$$

Efforts of mathematicians to study the ergodic hypothesis created an important branch of mathematics called ergodic theory (→ 136 Ergodic Theory).

D. Ensembles in Classical Statistical Mechanics

Once we admit the ergodic hypothesis, or more specifically the assumption (5), the calculation of the observed value of a physical quantity A for a system in equilibrium is reduced to finding the phase average of A on an energy surface. The task of statistical mechanics of systems in equilibrium is thus reduced essentially to calculating phase averages and establishing relationships between them [10–13].

For a set (called an **ensemble** in this case) of

identical systems with the same energy, we consider the phase average for the †probability space with the measure mentioned in Section C on the energy surface corresponding to the given energy value. Gibbs called a probability space of this kind a **microcanonical ensemble**. An average in this probability space is defined by

$$\langle A \rangle = \int_{\mathcal{H}=E} \frac{A dS}{|\text{grad } \mathcal{H}|} \Big/ \int_{\mathcal{H}=E} \frac{dS}{|\text{grad } \mathcal{H}|}, \quad (6)$$

where \mathcal{H} is the Hamiltonian function, $\text{grad } \mathcal{H}$ is its gradient in the $2n$ -dimensional phase space, and the integration is carried over the energy surface with dS as surface element.

When the observed system is in mechanical contact with a heat reservoir, the composite system consisting of the system and the heat reservoir is regarded as an isolated system with constant energy. Then an ensemble of the composite systems is treated as a microcanonical ensemble. It is more convenient and more physical, however, to consider the heat reservoir simply as providing an environment characterized by its temperature T , and to concentrate only on the system in which we are interested. Then the system is no longer isolated and exchanges energy with its environment. Since the energy of the system is no longer constant, the system will be found in any part of the phase space with a certain probability. To find the probability distribution for an ensemble of this system is a problem of asymptotic evaluation which is solved on the basis of the ergodic hypothesis and the fact that a heat reservoir has an extremely large number of degrees of freedom. This asymptotic evaluation is traditionally done with the help of †Stirling's formula or by using the Fowler-Darwin method [10], but it is essentially based on the †central limit theorem [11].

The probability space of this kind of ensemble of systems in contact with heat reservoirs was called a **canonical ensemble** by Gibbs [5]. If $d\Gamma$ is a volume element of the phase space of the system, the probability of finding a system arbitrarily chosen from the ensemble in a volume element $d\Gamma$ is given by

$$\text{Pr}(d\Gamma) = C \exp(-\mathcal{H}/kT) d\Gamma. \quad (7)$$

Accordingly, the average of a dynamical quantity A is given by

$$\langle A \rangle = \int A e^{-\mathcal{H}/kT} d\Gamma \Big/ \int e^{-\mathcal{H}/kT} d\Gamma. \quad (8)$$

For example, the average energy is

$$\langle \mathcal{H} \rangle \equiv E = \int \mathcal{H} e^{-\mathcal{H}/kT} d\Gamma \Big/ \int e^{-\mathcal{H}/kT} d\Gamma. \quad (9)$$

By a traditional convention we introduce the parameter

$$\beta = 1/kT$$

and write (9) as

$$E = -\partial \log Z(\beta) / \partial \beta,$$

where $Z(\beta)$ is called the **partition function** or the **sum over states** and is given for a system composed of N identical particles by

$$Z(\beta) = \int e^{-\beta \mathcal{H}} d\Gamma / N!. \quad (10)$$

If an exchange of particles with the environment takes place in addition to an exchange of energy, the probability of finding a system with particle number N in the volume element $d\Gamma$ is given by

$$C \exp(-\beta \mathcal{H} + \beta \mu N) d\Gamma / N!,$$

where μ is a real parameter called the **chemical potential**; this characterizes the environment with regard to the exchange of particles. This ensemble is called the **grand canonical ensemble**. The average of a dynamical quantity A is then given by

$$\langle A \rangle = \sum_N N!^{-1} \int A_N e^{-\beta \mathcal{H}(N) + \beta \mu N} d\Gamma / \Xi(\beta, \mu), \quad (11)$$

where the dependence of A and \mathcal{H} on N is now explicitly written, and where

$$\Xi(\beta, \mu) = \sum_N N!^{-1} \int e^{-\beta \mathcal{H}(N) + \beta \mu N} d\Gamma \quad (12)$$

is called the **grand partition function**.

E. Ensembles in Quantum Statistical Mechanics

The quantum counterpart of the classical ergodic hypothesis is that to each of these quantum states an equal probability weight should be assigned [10]. A **microcanonical ensemble** is then defined by this **principle of equal weight**, which yields in turn

$$\langle A \rangle = \sum_l A_l / \sum_l 1 \quad (13)$$

instead of (6). Here the index l refers to the quantum states lying in the interval ΔE , and A_l is the quantum-mechanical expectation of a dynamical variable A in the quantum state l . A canonical ensemble is now defined by assigning

$$P_j = e^{-\beta E_j} / \sum_j e^{-\beta E_j} \quad (14)$$

to the j th quantum state as the probability that the system will be found in that state. The

expectation value of A must be given by

$$\langle A \rangle = \frac{\sum_j A_j e^{-\beta E_j}}{\sum_j e^{-\beta E_j}} = \text{tr} A e^{-\beta H} / \text{tr} e^{-\beta H}, \quad (15)$$

where H is the Hamiltonian. The partition function is defined by

$$Z = \sum_j e^{-\beta E_j} = \text{tr} e^{-\beta H}, \quad (16)$$

corresponding to (10).

For a system consisting of identical particles, quantum mechanics requires a particular symmetry of its \dagger wave function; namely, the wave function must be even or odd with respect to permutation of any two particles according as the particles are bosons or fermions. This symmetry requirement is peculiar to quantum mechanics. Thus, even for an ideal gas consisting of noninteracting particles, quantum statistics leads to results characteristically different from those of classical statistical mechanics. This difference becomes more significant when the particle mass is smaller, the density is larger, and the temperature is lower. Quantum effects of this kind are seen in metallic electrons, in liquid helium, in an assembly of photons or phonons, and in high-density stars. The statistical laws obeyed by bosons are called **Bose statistics**, and those obeyed by fermions, **Fermi statistics**.

The expectation value of A in the **grand canonical ensemble** is given in quantum statistics by

$$\langle A \rangle = \Xi(\beta, \mu)^{-1} \text{tr}(A e^{-\beta H + \beta \mu N}), \quad (17)$$

where H is the \dagger second-quantized Hamiltonian, N is the number operator, the trace tr is taken on the (nonrelativistic) \dagger Fock space (symmetric or antisymmetric according to Bose or Fermi statistics), and $\Xi(\beta, \mu)$ is the **grand partition function** given by

$$\Xi(\beta, \mu) = \text{tr} e^{-\beta H + \beta \mu N}. \quad (18)$$

F. Many-Body Problems in Statistical Mechanics

Since statistical mechanics is primarily concerned with systems with large numbers of particles, problems in statistical mechanics are essentially many-body problems. In practice, however, there are some cases where extreme idealization is possible, as in ideal gases, where the interaction between gas molecules is ignored. In some cases we can proceed by successive approximation, taking the particle interactions as perturbations. Such perturbational treatments are, however, entirely useless for some problems, such as phase transitions, of which an example is the condensation of gases into liquid states, where the

interaction of particles plays a critical role. Such problems are clearly many-body problems. There are a number of important and interesting problems in this category, for example, transitions between ferromagnetic and paramagnetic states and those between the superconducting and normal states of metals. Transition from a high-temperature phase to a low-temperature phase is generally regarded as a consequence of the appearance of a certain type of order in thermal motion. This kind of phase change is called an **order-disorder transition** [14–16].

G. Thermodynamic Limit and Characterization of Equilibrium States

Although an actual system is finitely extended, the enormous sizes of the usual macroscopic systems in comparison to the sizes of their constituent particles justifies the idealization to infinitely extended systems. At the same time, there are several mathematical advantages in considering infinitely extended systems, such as the absence of walls (replaced by the boundary condition at infinity, should it be relevant), appearance of phase transitions as mathematical discontinuities rather than mathematically smooth though quantitatively sudden changes, and mathematically clear-cut occurrence of broken symmetries.

Equilibrium states of infinitely extended systems are usually obtained by taking the limit of the equilibrium states of systems in a finite volume V as both V and the number of particles N tend to ∞ with the density $\rho = N/V$ fixed; this is called the **thermodynamic limit**.

It is sometimes possible to formulate the dynamics of infinitely extended systems directly and to characterize their equilibrium states, which more or less coincide with the thermodynamic limit of equilibrium states of finitely extended systems [17–21]. The simplest and most fully investigated case of **lattice spin systems** is explained below in detail [17]. Since classical systems can be viewed as special cases of quantum systems, we start with the latter. To be definite, we take a ν -dimensional cubic lattice Z^ν with a lattice site $n = (n_1, \dots, n_\nu)$ specified by its integer coordinates n_j . (In the lattice case, the thermodynamic limit is simply the limit as $V \rightarrow \infty$.)

The C^* -algebra \mathfrak{A} of observables is generated by the subalgebra \mathfrak{A}_n at each lattice site n , which is assumed to be the algebra of all $d \times d$ matrices (for example, linear combinations of \dagger Pauli spin matrices $\sigma^{(n)} = (\sigma_x^{(n)}, \sigma_y^{(n)}, \sigma_z^{(n)})$ and the identity for $d=2$) and to commute with operators at other lattice sites. The group of lattice translations $n \rightarrow n + a$ is represented by

automorphisms γ_a of \mathfrak{A} , satisfying $\gamma_a \mathfrak{A}_n = \mathfrak{A}_{n+a}$ ($\gamma_a \sigma^{(n)} = \sigma^{(n+a)}$). For any subset Λ of \mathbb{Z}^v , $\mathfrak{A}(\Lambda)$ denotes the C^* -subalgebra of \mathfrak{A} generated by $\mathfrak{A}_n, n \in \Lambda$.

A model is specified by giving a **potential** Φ which assigns to each finite nonempty subset I of \mathbb{Z}^v an operator $\Phi(I) = \Phi(I)^* \in \mathfrak{A}(I)$. The Hamiltonian for a finite subset Λ of \mathbb{Z}^v is given by $U(\Lambda) = \sum_{I \subset \Lambda} \Phi(I)$. In order to control long-range interactions, various assumptions are introduced. Examples are finiteness of either of the following:

$$\|\Phi\| = \sup_n \sum_{I \ni n} N(I)^{-1} \|\Phi(I)\|, \tag{19}$$

$$\|\|\Phi\|\| = \sup_n \sum_{I \ni n} \|\Phi(I)\|. \tag{20}$$

Here $N(I)$ is the number of points in I .

Let $\mathfrak{A}_n^{\text{cl}}$ be a maximal Abelian $*$ -subalgebra of \mathfrak{A}_n (such as $\{c_1 + c_2 \sigma_z^{(n)}\}$) satisfying $\gamma_a \mathfrak{A}_n^{\text{cl}} = \mathfrak{A}_{n+a}^{\text{cl}}$ and \mathfrak{A}^{cl} be the Abelian C^* -subalgebra of \mathfrak{A} generated by $\mathfrak{A}_n^{\text{cl}}, n \in \mathbb{Z}^v$. If $\Phi(I)$ is in \mathfrak{A}^{cl} for all I , we call the potential Φ **Abelian** or **classical**. There exists a conditional expectation π^{cl} which is a positive mapping of norm 1 from \mathfrak{A} onto \mathfrak{A}^{cl} satisfying $\pi^{\text{cl}}(ABC) = A\pi^{\text{cl}}(B)C$ for A and C in \mathfrak{A}^{cl} and $\pi^{\text{cl}}(1) = 1$. If a state φ on \mathfrak{A} satisfies $\varphi(A) = \varphi(\pi^{\text{cl}}(A))$, we call the state φ **classical**. Classical states are in one-to-one correspondence with the restriction on \mathfrak{A}^{cl} , which can be viewed as a probability measure on the spectrum (also called **configuration space**) of the C^* -algebra \mathfrak{A}^{cl} of observables for classical spin lattice systems. This correspondence makes it possible to view classical spin lattice systems as quantum spin lattice systems with Abelian interactions.

For a given potential Φ , the time evolution of the infinitely extended system is described by the one-parameter group $\alpha_t, t \in \mathbf{R}$, of $*$ -automorphisms of \mathfrak{A} defined as the following limit:

$$\alpha_t(A) = \lim_{\Lambda \nearrow \mathbb{Z}^v} e^{itU(\Lambda)} A e^{-itU(\Lambda)} \quad (A \in \mathfrak{A}). \tag{21}$$

The limit exists if $\Phi(I) = 0$ for $N(I) > N$ and $\|\|\Phi\|\| < \infty$, or if for some $\lambda > 0$ $\sum_n e^{\lambda n} (\sup_x \sum_I \{\|\Phi(I)\| \mid I \ni x, N(I) = n\}) < \infty$, or if $v = 1$ (1-dimensional lattice) and $\sup_x \sum_I \{\|\Phi(I)\| \mid I \cap (-\infty, x) \neq \emptyset, I \cap [x, \infty) \neq \emptyset\} < \infty$. An alternative way is first to define $\delta_\Phi(A) = \sum_I i[\Phi(I), A]$ for $A \in \bigcup_\Lambda \mathfrak{A}(\Lambda)$ (Λ is a finite subset of \mathbb{Z}^v), which exists if $\|\|\Phi\|\| < \infty$, and to prove that the closure $\bar{\delta}_\Phi$ of δ_Φ is a generator of a one-parameter subgroup $\alpha_t (= \exp t\bar{\delta}_\Phi)$. In the above cases, $\bar{\delta}_\Phi$ is a generator.

A general canonical ensemble for a system in a finite subset Λ of the lattice \mathbb{Z}^v , with some boundary condition in the outside $\Lambda^c = \mathbb{Z}^v \setminus \Lambda$, is given by $\varphi_\Lambda(A) = (\tau_\Lambda \otimes \psi)(e^{-\beta H(\Lambda)} \times$

$A e^{-\beta H(\Lambda^c)/2}$), where $\tau_\Lambda \otimes \psi$ is the product of the unique tracial state τ_Λ on $\mathfrak{A}(\Lambda)$ and a state ψ on $\mathfrak{A}(\Lambda^c)$ (the boundary condition), $H(\Lambda) = U(\Lambda) + W(\Lambda)$ and $W(\Lambda) = \sum_I \{\Phi(I) \mid I \cap \Lambda \neq \emptyset, I \cap \Lambda^c \neq \emptyset\}$ (the **surface energy**). The following conditions on a state φ of \mathfrak{A} are mutually equivalent under the condition that $\bar{\delta}_\Phi$ is a generator (which holds under any one of the conditions described above) and is satisfied by any limit state of the above φ_Λ as $\Lambda \nearrow \mathbb{Z}^v$ (i.e., a state in $\bigcap_{\Lambda'} \{\overline{\varphi_\Lambda} \mid \Lambda' \subset \Lambda, \psi\}$, with the bar denoting weak closure).

1. **KMS condition:** $\varphi(A\alpha_{t\beta}(B)) = \varphi(BA)$ for any $A, B \in \mathfrak{A}$ such that $\alpha_t(B)$ is an entire function of t . (φ is called a **β -KMS state**.)

2. **Local thermodynamic stability:** For any finite subset Λ of \mathbb{Z}^v and for any state ψ having the same restriction to $\mathfrak{A}(\Lambda)$ as the state φ under consideration, $\tilde{F}_{\Lambda, \beta}(\varphi) \leq \tilde{F}_{\Lambda, \beta}(\psi)$ (the minimality of the **free energy** multiplied by β), where $\tilde{F}_{\Lambda, \beta}(\varphi) = \beta\varphi(H(\Lambda)) - S_\Lambda(\varphi)$, $S_\Lambda(\varphi) = \lim \{S_{\Lambda'}(\varphi) - S_{\Lambda' \setminus \Lambda}(\varphi)\}$ as $\Lambda' \nearrow \mathbb{Z}^v$ (the **open system entropy**), $S_\Lambda(\varphi) = -\varphi(\log \rho_\Lambda(\varphi))$ (the **closed system entropy**) and the density matrix $\rho_\Lambda(\varphi) \in \mathfrak{A}(\Lambda)^+$ is defined by $\varphi(A) = \tau_\Lambda(\rho_\Lambda(\varphi)A)$ for all $A \in \mathfrak{A}(\Lambda)$.

3. **Gibbs condition:** For every finite subset Λ of \mathbb{Z}^v , the perturbed state $\varphi^{\beta W(\Lambda)}$ (not necessarily normalized) is the product $\varphi_\Lambda^G \times \psi$ of the Gibbs state $\varphi_\Lambda^G(A) = \text{tr}(e^{-\beta U(\Lambda)} A) / \text{tr} e^{-\beta U(\Lambda)}$ on $A \in \mathfrak{A}(\Lambda)$ and some (unknown) state ψ on $\mathfrak{A}(\Lambda^c)$, where the representative vector Φ for φ for the GNS representation π_φ is assumed to be separating for $\pi_\varphi(\mathfrak{A})''$, and then $\varphi^{\beta W(\Lambda)}(A) = (\Omega, \pi_\varphi(A)\Omega)$ for

$$\Omega = \sum_{n=0}^{\infty} \beta^n \int_0^{1/2} ds_1 \int_0^{s_1} ds_2 \dots \int_0^{s_{n-1}} ds_n \Delta_\Phi^{s_n} \pi_\varphi \times (W(\Lambda)) \Delta_\Phi^{s_{n-1} - s_n} \dots \Delta_\Phi^{s_1 - s_2} \pi_\varphi(W(\Lambda)) \Phi, \tag{22}$$

where Δ_Φ is the \dagger modular operator for Φ and the series converges.

For a classical potential, this condition reduces to the conditions that φ is classical and that the restriction of φ to \mathfrak{A}^{cl} as a measure on the configuration space $\{1 \dots d\}^{\mathbb{Z}^v}$ satisfies the following **DLR equation** due to R. L. Dobrushin, O. E. Lanford, and D. Ruelle: The conditional probability for $\xi(\Lambda) \in \{1 \dots d\}^\Lambda$ knowing $\xi(\Lambda^c) \in \{1 \dots d\}^{\mathbb{Z}^v \setminus \Lambda}$ is proportional to $\exp(-\beta H(\Lambda))$, where $H(\Lambda) = U(\Lambda) + W(\Lambda)$ is a function of $\xi(U(\Lambda))$ depending only on $\xi(\Lambda)$.

4. **Roepstorff-Araki-Sewell inequality:** For any $A \in \bigcup_\Lambda \mathfrak{A}(\Lambda)$, $i\varphi(A^* \bar{\delta}_\Phi(A))$ is real and $-i\beta\varphi(A^* \bar{\delta}_\Phi(A)) \geq S(\varphi(A^* A), \varphi(AA^*)), \tag{23}$

where $S(u, v) = u \log(u/v)$ if $u > 0, v > 0, S(0, v) = 0$ for $v \geq 0$ and $S(u, 0) = +\infty$ for $u > 0$.

5. **Roepstorff-Fannes-Verbeure inequality:**

For α -entire $A \in \mathfrak{A}$,

$$\beta^{-1} \int_0^\beta \varphi(A^* \alpha_{i,\lambda}(A)) d\lambda \leq F(\varphi(A^* A), \varphi(AA^*)), \quad (24)$$

where $F(u, v) = (u - v) / \log(u/v)$ for $u > 0, v > 0, u \neq v$, $F(u, u) = u$ for $u > 0$, $F(u, 0) = F(0, v) = 0$.

If the interaction is translationally invariant (i.e., $\gamma_a \Phi(I) = \Phi(I + a)$ for all $a \in \mathbb{Z}^v$ and I) and if we restrict our attention to translationally invariant states (i.e., $\varphi(\gamma_a(A)) = \varphi(A)$ for all $A \in \mathfrak{A}$ and $a \in \mathbb{Z}^v$), then the following conditions are also equivalent to the above.

6. Variational principle: $\beta e(\varphi) - s(\varphi) \leq \beta e(\psi) - s(\psi)$ for all translationally invariant ψ (the minimality of the **mean free energy**), where $e(\varphi) = \lim N(\Lambda)^{-1} \varphi(U(\Lambda)) = \lim N(\Lambda)^{-1} \varphi(H(\Lambda))$ (the **mean energy**), $s(\varphi) = \lim N(\Lambda)^{-1} S_\Lambda(\varphi)$ (the **mean entropy**), the infimum value $\beta e(\varphi) - s(\varphi)$ is $-P(\beta\Phi)$ with $P(\beta\Phi) = \lim N(\Lambda)^{-1} \log \tau_\Lambda(e^{-\beta U(\Lambda)})$ (the **pressure**), and the limits exist if $\Lambda \nearrow \mathbb{Z}^v$ is taken in the following **van Hove sense**: For any given cube C of lattice points, the minimal number $n_\Lambda^+(C)$ of translations of C that cover Λ and the maximal number $n_\Lambda^-(C)$ of mutually disjoint translations of C in Λ satisfy $n_\Lambda^+(C)/n_\Lambda^-(C) \rightarrow 1$ as $\Lambda \nearrow \mathbb{Z}^v$.

7. Tangent to the pressure function: $P(\Phi)$ is a continuous convex function on the Banach space of translationally invariant Φ with $\|\Phi\| < \infty$. A continuous linear functional α on this Banach space is a **tangent** to P at Φ if $P(\Phi + \Psi) \geq P(\Phi) + \alpha(\Psi)$ for all Ψ . For a translationally invariant state ψ , we define $\alpha_\psi(\Psi) = \psi(\sum_{I \ni 0} N(I)^{-1} \Psi(I))$. The condition is that $-\alpha_\psi$ is a tangent to P at $\beta\Phi$. (Conversely, any tangent α to P at $\beta\Phi$ arises in this manner.)

The set K_β of all (normalized) β -KMS states is nonempty, compact, and convex. A β -KMS state φ is an extremal point of K_β if and only if it is factorial (i.e., the associated von Neumann algebra $\pi_\varphi(\mathfrak{A})''$ has a trivial center). It then has the **clustering property** $\lim_{a \rightarrow \infty} \{\varphi(A \gamma_a(B)) - \varphi(A)\varphi(\gamma_a(B))\} = 0$ and is interpreted as a **pure phase**. Any β -KMS state has a unique integral decomposition into extremal β -KMS states.

For any Φ , K_β is a one-point set for sufficiently small $|\beta|$. For a 1-dimensional system ($v = 1$), K_β consists of only one point (uniqueness of equilibrium states usually interpreted as indication of no phase transition) if the surface energy $W([-N, N])$ is uniformly bounded (H. Araki, *Comm. Math. Phys.*, 44 (1975); A. Kishimoto, *Comm. Math. Phys.*, 47 (1976)). For the two-body interaction $\Phi(\{m, n\}) = -J|m - n|^{-\alpha} \sigma_2^{(m)} \sigma_2^{(n)}$, this condition is satisfied if $\alpha > 2$ while $\|\Phi\| < \infty$ and α_i defined if $\alpha > 1$. There is more than one KMS state (with spontaneous magnetization) for $2 \geq \alpha > 1$ and large $\beta J > 0$, and hence a phase transition exists (F. J.

Dyson, *Comm. Math. Phys.*, 12 (1969); J. Fröhlich and T. Spencer, *Comm. Math. Phys.*, 83 (1982)). If a 1-dimensional interaction has a finite range (i.e., $\Phi(I) = 0$ if the diameter of I exceeds some number r_0) or if it is classical and $\sum_{I \ni 0} N(I)^{-1} (\text{diam } I + 1) \|\Phi(I)\| < \infty$ for $d = 2$, then $\varphi(A)$ for $\varphi \in K_\beta$ and $A \in \mathfrak{A}(\Lambda)$ for a finite Λ is real analytic in β and any other analytic parameter in the potential (Araki, *Comm. Math. Phys.*, 14 (1969); [22]; M. Casandro and E. Olivieri, *Comm. Math. Phys.*, 80 (1981)).

For a 2-dimensional **Ising model** with the nearest-neighbor ferromagnetic interaction [23], K_β consists of only one point for $0 \leq \beta \leq \beta_c$, while K_β for $\beta > \beta_c$ has exactly two extremal points corresponding to positive and negative magnetizations (M. Aizenman, *Comm. Math. Phys.*, 73 (1980); Y. Higuchi, *Colloquia Math. Soc. János Bolyai*, 27 (1979)). In this case, all KMS states are translationally invariant, while there exist (infinitely many) translationally noninvariant KMS states for sufficiently large β if $v = 3$ (Dobrushin, *Theory Prob. Appl.*, 17 (1972); H. van Beijeren, *Comm. Math. Phys.*, 40 (1975)).

The accumulation points of β -KMS states as $\beta \rightarrow +\infty$ (or $-\infty$) provide examples of **ground** (or **ceiling**) states defined by any one of the following mutually equivalent conditions $1_+, 2_+$ (or $1_-, 2_-$) (O. Bratteli, A. Kishimoto, and D. W. Robinson, *Comm. Math. Phys.*, 64 (1978)):

1_+ (1_-). Positivity (negativity) of energy: For any $A \in \bigcup_\Lambda \mathfrak{A}(\Lambda)$, $-i\varphi(A^* \delta_\Phi(A))$ is real and positive (negative).

2_+ (2_-). Local minimality (maximality) of energy: For any finite subset Λ of \mathbb{Z}^v and for any state ψ with the same restriction to $\mathfrak{A}(\Lambda^c)$ as the state φ under consideration, $\varphi(H(\Lambda)) \leq \psi(H(\Lambda))$ ($\varphi(H(\Lambda)) \geq \psi(H(\Lambda))$).

For translationally invariant potentials and states, the following condition is also equivalent to the above:

3_+ (3_-). Global minimality (maximality) of energy: $e(\varphi) \leq e(\psi)$ ($e(\varphi) \geq e(\psi)$) for all translationally invariant states ψ .

The totality of KMS, ground, and ceiling states can be characterized by the following formulation of the impossibility of **perpetual motion**: Let $P_t = P_t^* \in \mathfrak{A}$ be a norm-differentiable function of the time $t \in \mathbb{R}$ with a compact support, representing (external) time-dependent perturbations. Then there exists a unique perturbed time evolution α_t^P as a one-parameter family of *-automorphisms of \mathfrak{A} satisfying $(d/dt)\alpha_t^P(A) = \alpha_t^P(\delta_\Phi(A) + i[P_t, A])$ for all $A \in \mathfrak{A}$ in the domain of δ_Φ . A state φ changes with time t as $\varphi_t(A) = \varphi(\tau_t^P(A))$ under the perturbed dynamics α_t^P , and the total

energy given to the system (mechanical work performed by the external forces) is given by $L^P(\varphi) = \int_{-\infty}^{\infty} \varphi_t(dP_t/dt) dt$. For KMS states at any β , as well as ground and ceiling states, $L^P(\varphi) \geq 0$ for any P_t . If φ is a factor state, the converse holds, i.e., $L^P(\varphi) \geq 0$ for all P_t implies that φ is either a KMS, ground, or ceiling state. The condition $L^P(\varphi) \geq 0$ for all P_t is equivalent to $-i\varphi(U^* \delta_{\mathfrak{p}}(U)) \geq 0$ for all unitary U in the domain of $\delta_{\mathfrak{p}}$ and in the identity component of the group of all unitaries of \mathfrak{A} . A state φ satisfying this condition is called **passive**, and a state φ whose n -fold product with itself as a state on $\mathfrak{A}^{\otimes n}$ is passive relative to $\alpha_t^{\otimes n}$ for all n is called **completely passive**. The last property holds if and only if φ is a KMS, ground, or ceiling state (W. Pusz and S. L. Woronowicz, *Comm. Math. Phys.*, 16 (1970)).

The totality of KMS, ground, and ceiling states can be characterized by a certain stability under perturbations (P_t considered above) under some additional condition on α_t (R. Haag, D. Kastler, and E. B. Trych-Pohlmeyer, *Comm. Math. Phys.*, 38 (1974); O. Bratteli, A. Kishimoto, and D. W. Robinson, *Comm. Math. Phys.*, 61 (1978)).

When a lattice spin system is interpreted as a lattice gas, an operator $N_n \in \mathfrak{A}_n^{\pm 1}$ (such as $(\sigma_z^{(n)} + 1)/2$) is interpreted as the particle number at the lattice site n and $N(\Lambda) = \sum_{n \in \Lambda} N_n$ is the particle number in Λ . It defines a representation of a unit circle T by automorphisms τ_{θ} of \mathfrak{A} defined as $\tau_{\theta}(A) = \lim e^{iN(\Lambda)\theta} A e^{-iN(\Lambda)\theta}$ ($\Lambda \nearrow \mathbb{Z}^v$), called **gauge transformations** (of the first kind). The **grand canonical ensemble** can be formulated as a β -KMS state with respect to $\alpha_t \tau_{\mu t}$ (instead of α_t), where the real constant μ is called the **chemical potential**. It can be interpreted as an equilibrium state when the gauge-invariant elements $\{A \in \mathfrak{A} \mid \tau_{\theta}(A) = A\}$ instead of \mathfrak{A} are taken to be the algebra of observables or as a state stable under those perturbations that do not change the particle number.

H. The Boltzmann Equation

Statistical mechanics of irreversible processes originated from the kinetic theory of gases. Long ago, Maxwell and Boltzmann tried to calculate viscosity and other physical quantities characterizing gaseous flow in nonequilibrium. The \dagger Boltzmann equation is generally a nonlinear \dagger integrodifferential equation. On the basis of this equation mathematical theories were developed by D. Enskog, S. Chapman, and D. Hilbert [2].

Free electrons in a metal can be regarded

as forming an electron gas, in which electron scattering by lattice vibrations or by impurities is more important than electron-electron scattering. Following the example of gas theories H. A. Lorentz set forth a simple theory of irreversible processes of metallic electrons. His theory was, however, not quite correct, since metallic electrons are highly quantum-mechanical and classical theories cannot be applied to them. Quantum-mechanical theories of metal electrons were developed by A. Sommerfeld and F. Bloch.

I. Master Equations

The Boltzmann equation gives the velocity distribution function of a single particle in the system. This line of approach can be extended in two directions. The first is the so-called master equation. For example, consider a gaseous system consisting of N particles, and ask for the probability distribution of all the momenta, namely, the distribution function $f_N(p_1, \dots, p_N; t)$, where p_1, \dots, p_N are the momenta of the N particles. The equations of motion are deterministic with respect to the complete set of dynamical variables $(x_1, p_1, \dots, x_N, p_N)$. The equation for $f(p_1, \dots, p_N, t)$ may not be deterministic, but it may be stochastic because we are concerned only with the variables p_1, \dots, p_N , with all information about the space coordinates x_1, \dots, x_N disregarded. This situation is essentially the same in both classical and quantum statistical mechanics. If the duration of the observation process is limited to a finite length of time and the precision of the observation to a certain degree of crudeness, the time evolution of the momentum distribution function f_N can be regarded as a \dagger Markov process. In general, an equation describing a Markov process of a certain distribution function is called a **master equation**. Typically it takes the following form for a suitable choice of variables x :

$$\begin{aligned} &(\partial/\partial t)f(x, t) \\ &= \int dx'(W(x', x)f(x', t) - W(x, x')f(x, t)), \end{aligned} \quad (25)$$

where $W(x, x')$ is the transition probability from x to x' . By expanding the first integrand into a power series in $x - x'$, with x' fixed and by retaining the first few terms, we obtain the **Fokker-Planck equation**:

$$\begin{aligned} &(\partial/\partial t)f(x, t) = -(\partial/\partial x)(\alpha_1(x)f(x, t)) \\ &\quad + (\partial^2/\partial x^2)(\alpha_2(x)f(x, t))/2, \end{aligned} \quad (26)$$

$$a_n(x) = \int W(x, x+r)r^n dr. \quad (27)$$

J. The Hierarchy of Particle Distribution Functions

Another way of extending the Boltzmann equation is to consider a set of distribution functions of one particle, of two particles, and generally of n ($< N$) particles selected from the whole system of N particles. For example, a two-particle distribution function is the function $f_2(x_1, v_1, x_2, v_2, t)$ for positions and velocities of two particles at time t . The complete dynamics of the entire system of particles can be projected to the time evolution of this hierarchy of distribution functions. The equation of motion for f_1 then contains the function f_2 if the interaction of particles is pairwise, the equation for f_2 contains f_3 , and so on. Thus the equations of motion for the set of distribution functions make a chain of equations. The whole chain is equivalent to the deterministic equations of motion for the dynamics of N particles. However, if the particle number N is made indefinitely large, with the time scale of observation always finite, the chain of equations for the distribution functions asymptotically approaches a stochastic process if certain conditions are satisfied. Approximate methods of solving the hierarchy equations in classical cases have been developed by J. Yvon, J. G. Kirkwood, M. Born, H. S. Green, and others.

In quantum statistics, similar hierarchy equations can be considered. A typical example is the so-called **Green's function method** [27].

K. Irreversible Processes and Stochastic Processes

The statistical mechanics of physical processes evolving in time is a hybrid of dynamics and the mathematical theory of stochastic processes. A typical example is the theory of Brownian motion. A colloidal particle floating in a liquid moves incessantly and irregularly because of thermal agitation from surrounding liquid molecules. For simplicity, an example of 1-dimensional Brownian motion is considered here. Phenomenologically we assume that a colloid particle follows an equation of motion of the form

$$m\dot{u} = -m\gamma u + f(t), \quad (28)$$

called the **Langevin equation**, where m is the mass of the colloid particle and u is the velocity. The first term on the right-hand side is the friction force due to viscous resistance, and the second term represents a random force acting on the particle from surrounding molecules.

If (28) describes the Brownian motion in thermal equilibrium, the friction constant $m\gamma$

402 Ref. Statistical Mechanics

and the random force cannot be independent, but are related by a theorem asserting that

$$m\gamma = \int_0^\infty \langle f(t_1)f(t_1+t) \rangle dt. \quad (29)$$

In an electric conductor, the thermal motion of charge carriers necessarily induces irregularities of charge distribution, and so an electromotive force that varies in time in a random manner is created. This random electromotive force is similar to the random motion of a Brownian particle and is called the **thermal noise**. For such a thermal noise there exists a relation similar to (29) between the resistance and the random electromotive force. This relation is known as the **Nyquist theorem**. These theorems are contained in a more general theorem called the **fluctuation-dissipation theorem**.

When an external force is applied to a system in thermal equilibrium, some kind of irreversible flow, an electric current, for example, is induced in the system. The relationship between the flow and the external force is generally represented by an admittance. If the external force is periodic, the admittance is a function of frequency ω and is given by

$$\chi(\omega) = \int_0^\infty e^{-i\omega t} \psi(t) dt, \quad (30)$$

where $\psi(t)$ is equal to the correlation function of the flow that appears spontaneously as the fluctuation in thermal equilibrium when no external force is applied. This general expression for an admittance, often called the **Kubo formula**, gives a unified viewpoint from which responses of physical systems to weak external disturbances can be treated without recourse to the traditional kinetic approach.

The static limit ($\omega \rightarrow 0$) of the admittance is the **transport coefficient**. The reversibility of dynamics leads to relations among transport coefficients, called **Onsager's reciprocity relations** in the thermodynamics of irreversible processes.

When external disturbances are so large that the system deviates considerably from thermal equilibrium, the responses may show characteristic nonlinearities. Such nonlinear phenomena are important from both experimental and theoretical points of view, and constitute a central subject of modern research (\rightarrow 433 Turbulence and Chaos).

403 (XVIII.5) Statistical Models

A. General Remarks

A statistical model is defined by specifying the structure of the probability distributions of the relevant quantities. When a statistical model is used for the analysis of a set of data, its role is to measure the characteristics of a certain configuration of the data points. R. A. Fisher [1] advanced a systematic procedure for the application of statistical models. The process of statistical inference contemplated by Fisher may be characterized by the following three phases: (1) specification of the model, (2) estimation of the unknown parameters, and (3) testing the goodness of fit. The last phase is followed by the first when the result of the testing is negative. Thus the statistical inference contemplated by Fisher is realized through the process of introduction and selection of statistical models.

We always assume that the true distribution of an observation exists in each particular application of statistical inference, even though it may not be precisely known to us. Our partial knowledge of the generating mechanism of the observation suggests various possible constraints on the form of the true distribution. The basic problem of statistical inference is then to generate an approximation to the true distribution by using the available observational data and a model defined by a set of probability distributions satisfying the constraints.

B. The Criterion of Fit

The use of statistical models can best be explained by adopting the predictive point of view, which defines the objective of statistical inference as the determination of the predictive distribution, the probability distribution of a future observation defined as a function of the information available at present. The performance of a statistical inference procedure is then evaluated in terms of the expected discrepancy of the predictive distribution from the true distribution of the future observation.

The probabilistic interpretation of thermodynamic entropy developed by L. Boltzmann [2] provides a natural measure of the discrepancy between two probability distributions. The **entropy of a distribution** specified by the density $f(y)$ with respect to the distribution specified by $g(y)$ is defined by

$$B(f; g) = - \int \frac{f(y)}{g(y)} \log \left[\frac{f(y)}{g(y)} \right] g(y) dy,$$

where, as in what follows, the integral is taken with respect to some appropriate measure dy . This definition of entropy is a faithful reproduction of the original probabilistic interpretation of the thermodynamic entropy by Boltzmann and allows the interpretation that the entropy $B(f; g)$ is proportional to the logarithm of the probability of getting a statistical distribution of observations closely approximating $f(y)$ by taking a large number of independent observations from the distribution $g(y)$. (For a detailed discussion → [3].)

Obviously we have

$$B(f; g) = \int f(y) \log g(y) dy - \int f(y) \log f(y) dy.$$

The second term on the right-hand side is a constant depending only on $f(y)$. The first term is the expected log likelihood of the distribution $g(y)$ with respect to the true distribution $f(y)$. Thus a distribution with a larger value of the expected log likelihood provides a better approximation to the true distribution. Even when $f(y)$ is unknown, $\log g(y)$ provides an unbiased estimate of the expected log likelihood. This fact constitutes the basis of the objectivity of the likelihood as a criterion for judging the goodness of a distribution as an approximation to the true distribution.

C. Parametrization of Probability Distributions

When we construct a statistical model it is a common practice to represent the uncertain aspect of the true distribution by a family of probability distributions with unknown parameters. This type of family is called a parametric family; the model is called a parametric model. The parameters in a parametric model are the keys to the realization of the information extraction from data by statistical methods. Accordingly, the introduction of mathematically manageable parametric models forms the basis for the advance of statistical methods.

(1) Pearson's System of Distributions. A wide family of distributions can be generated by assuming a rational-function representation of

403 C Statistical Models

the sensitivity of the density function $f(y)$ given by

$$\frac{d}{dy} \log f(y) = \frac{a_0 + a_1 y + \dots + a_p y^p}{b_0 + b_1 y + \dots + b_q y^q}.$$

Pearson's system of distributions is defined by putting $p = 1$ and $q = 2$ and by assuming various constraints on the parameters a_i and b_j and the support of $f(y)$ [4].

E. Wong [5] discussed the construction of continuous-time stationary Markov processes with the distributions of Pearson's system as their stationary distributions. This allows a structural interpretation of the parameters of a distribution of the system.

(2) Maximum Entropy Principle and the Exponential Family. To develop a formal theory of statistical mechanics E. T. Janes [6] introduced the concept of the maximum entropy estimate of a probability distribution. This concept leads to a natural introduction of the exponential family. Following Kullback [7], we start with a distribution $g(y)$ and try to find $f(y)$ with prescribed expectations of statistics $T_1(y), \dots, T_k(y)$ and with maximum entropy $B(f; g)$. Such a distribution $f(y)$ is given by the relation

$$f(y) \propto \exp[\tau_1 T_1(y) + \dots + \tau_k T_k(y)] g(y),$$

where it is assumed that the right-hand side is integrable. By varying the parameters τ_1, \dots, τ_k over the allowable range we get the exponential family of distributions. I. J. Good [8] considered the Janes procedure as a principle for the generation of statistical hypotheses and called it the maximum entropy principle.

(3) Parametric Models of Normal Distributions. Of particular interest within the exponential family is the family of normal distributions. This is obtained by assuming the knowledge of the first- and second-order moments of a distribution and applying the maximum entropy principle [9]. Obviously, the parametrization of a normal distribution is concerned only with the mean vector and the variance-covariance matrix.

Let $\mathbf{X} = (X_1, \dots, X_n)$ be an n -dimensional normal random variable with mean $E\mathbf{X} = (m_1, \dots, m_n)'$ and variance-covariance matrix $\Sigma = (\sigma_{ij})$, where $\sigma_{ij} = E(X_i - m_i)(X_j - m_j)$. (E denotes expectation and $'$ denotes the transpose.) A nonrestrictive family of n -dimensional normal distributions is characterized by $n + n(n+1)/2$ parameters, m_i ($i = 1, \dots, n$), and σ_{ij} ($i = 1, \dots, n; j = 1, \dots, n$). The prior information on the generating mechanism of \mathbf{X} introduces constraints on these parameters and reduces the number of free parameters.

Reduction of the dimensionality of the

parameter vector $\mathbf{m} = (m_1, \dots, m_n)'$ is realized by assuming that \mathbf{m} is an element of a k -dimensional subspace of \mathbf{R}^n spanned by the vectors $\mathbf{a}_1 = (a_{11}, \dots, a_{1n})', \dots, \mathbf{a}_k = (a_{k1}, \dots, a_{kn})'$, i.e., by assuming the relation

$$\mathbf{m} = A\mathbf{c},$$

where $A = (\mathbf{a}_1, \dots, \mathbf{a}_k)$ is an $n \times k$ matrix and $\mathbf{c} = (c_1, \dots, c_k)'$ is a k -dimensional vector with $k < n$. This parametrization is obtained when for each X_i the observation (a_{i1}, \dots, a_{ik}) is made on a set of k factors and the analysis of the linear effect of these factors on the mean of X_i is required. We have the representation $\mathbf{X} = A\mathbf{c} + \mathbf{W}$, where \mathbf{W} is an n -dimensional normal random vector with $E\mathbf{W} = \mathbf{0}$ and variance-covariance matrix Σ (\rightarrow Section D).

To complete the model we have to specify the variance-covariance matrix Σ . One of the simplest possible specifications is obtained by assuming that the X_i are mutually independent and of the same variance σ^2 . This reduces Σ to $\sigma^2 I$, where I denotes an $n \times n$ identity matrix. With this assumption the number of necessary parameters to represent the variance-covariance matrix reduces from $n(n+1)/2$ to 1. The model obtained with the assumptions $\Sigma = \sigma^2 I$ and $\mathbf{m} = A\mathbf{c}$ is called the general linear model (or regression model) with normal error, or simply the **normal linear model**. The model is called a regression model also when the a_i are random variables (\rightarrow e.g., [10, 11]).

A typical example of nontrivial parametrization of the covariance structure of \mathbf{X} is obtained by assuming the representation

$$\mathbf{X} = \mathbf{m} + A\mathbf{F} + \mathbf{W},$$

where $\mathbf{F} = (f_1, \dots, f_g)'$ denotes the vector of random effects and \mathbf{W} the vector of measurement errors. It is assumed that \mathbf{F} and \mathbf{W} are mutually independent and normally distributed with $E\mathbf{F} = \mathbf{0}$ and $E\mathbf{W} = \mathbf{0}$. Also the components of \mathbf{W} are assumed to be mutually independent. The variance-covariance matrix Σ of \mathbf{X} is then given by

$$\Sigma = A\Phi A' + \Delta,$$

where $\Phi = E\mathbf{F}\mathbf{F}'$ and $\Delta = E\mathbf{W}\mathbf{W}'$, which is diagonal.

When A is a design matrix, the parametrization provides a **components-of-variance model** (or **random-effects model**) of which the main use is the measurement of the variance-covariance matrix Φ of the random effects f_1, \dots, f_g rather than the measurement of \mathbf{F} itself. If we consider \mathbf{F} to be representing the effects of some latent factors for which A is not uniquely specified, the above representation of Σ gives merely a formal, or noncausal, parametrization of Σ . In this case the model is

called the **factor analysis model** and the dimension g of \mathbf{F} is called the number of factors. By keeping the number of factors sufficiently smaller than the dimension of \mathbf{X} , we get a parametrization of Σ with a smaller number of free parameters than the unconstrained model. Starting with $g = 1$ and successively increasing the number of factors, we can get a hierarchy of models with successively increasing numbers of parameters. (\rightarrow [12] for a very general modeling of the variance-covariance matrix.)

(4) Parametrization of Discrete Distribution.

Consider the situation where the observation produces one of the events represented by $r = 0, 1, 2, \dots, k$ with probability $p(r)$, where k may be infinite. Represent by $\mathbf{X} = (X_1, \dots, X_n)$ the result of n independent observations. The probability $p(\mathbf{X})$ of getting such a result is given by the relation

$$\log p(\mathbf{X}) = \sum_{r=0}^k \theta_r n_r(\mathbf{X}),$$

where $\theta_r = \log p(r)$ and $n_r(\mathbf{X})$ denotes the number of X_i 's which are equal to r . (The term not depending on the θ_r 's is omitted in the above and subsequent formulas, since it is immaterial for problems of inference.) Thus a nonrestrictive model is obtained by assuming only the relations $\theta_r \leq 0$ and $\sum_{r=0}^k e^{\theta_r} = 1$. Obviously the model defines an exponential family and various useful parametrizations are realized by introducing some constraints on the parameters θ_r .

When the events r are arranged in a 2-dimensional array (i, j) ($i = 1, \dots, m; j = 1, \dots, n$) we have

$$\log p(\mathbf{X}) = \sum_{i=1}^m \sum_{j=1}^n \theta_{ij} n_{ij}(\mathbf{X}).$$

One simple parametrization is given by

$$\theta_{ij} = \mu + \alpha_i + \beta_j + \gamma_{ij},$$

where it is assumed that $\sum_{i=1}^m \alpha_i = \sum_{j=1}^n \beta_j = \sum_{i=1}^m \gamma_{ij} = \sum_{j=1}^n \gamma_{ij} = 0$. Obviously this is a parametrization of θ_{ij} as a linear function of the parameters α_i, β_j , and γ_{ij} , and the model thus obtained is called the **log linear model**. The model shows a formal similarity to the analysis-of-variance model (\rightarrow Section D). By introducing successively more restrictive assumptions on the parameters, we can get a hierarchy of models for the analysis of a two-way contingency table. Extension to cases when more than two factors are involved is obvious (\rightarrow e.g., [13]).

Here we consider that X_i is a dichotomous variable, i.e., $k = 1$, and that the probability of $X_i = 1$ may depend on i , i.e., we have

$$\log p(X_i) = n\theta_{0i} + (\theta_{1i} - \theta_{0i})n_1(X_i),$$

where $\theta_{0i} = \log \text{Prob}(X_i = 0)$ and $\theta_{1i} = \log \text{Prob}(X_i = 1)$. We assume that a vector of observations $\mathbf{a}_i = (a_{i1}, \dots, a_{im})'$ is available simultaneously with X_i and that we are interested in analyzing the relation between \mathbf{a}_i and the probability distribution of X_i . The analysis is realized by exploring the functional relation between $\tau_i = \theta_{1i} - \theta_{0i}$ and \mathbf{a}_i . We can assume a linear relation

$$\tau = A\mathbf{c},$$

where $\tau = (\tau_1, \dots, \tau_n)'$, $A = (\mathbf{a}_1, \dots, \mathbf{a}_n)'$, and $\mathbf{c} = (c_1, \dots, c_m)'$. The parameter $\tau_i = \log\{p(X_i = 1)/(1 - p(X_i = 1))\}$ is the log odds ratio or logit of the event $X_i = 1$, and the model is called the **linear logistic model** [14]. A hierarchy of models can be generated by assuming a successively more restrictive linear relations among the components of \mathbf{c} .

D. General Linear Models

Another class of models often used in practical applications is composed of general linear models or linear regression models, where the observed value is considered to be the sum of the effects of some fixed causes and the error.

Let $\mathbf{X} = (X_1, \dots, X_n)'$ be an n -dimensional random variable, and denote the expectation of \mathbf{X} by $E(\mathbf{X}) = (\mu_1, \dots, \mu_n)'$. If $E(\mathbf{X})$ is of the form $A\xi$ with an unknown parameter $\xi = (\xi_1, \dots, \xi_k)'$, and a given $n \times k$ matrix A , then we can express \mathbf{X} as

$$\mathbf{X} = A\xi + \mathbf{W}, \quad E(\mathbf{W}) = (0, \dots, 0)', \quad (1)$$

with the **error term** $\mathbf{W} = (W_1, \dots, W_n)'$. We frequently assume a set of conditions on the distribution of \mathbf{X} ; for example, (i) X_1, \dots, X_n are mutually independent, (ii) X_1, \dots, X_n have a common unknown variance σ^2 , (iii) (X_1, \dots, X_n) is distributed according to an n -dimensional normal distribution. The equations (1) together with conditions on the distribution are called a **linear model**.

Among the methods of statistical analysis of linear models are regression analysis, analysis of variance, and analysis of covariance as explained below, but these are not clearly distinguished from each other. (I) In **design-of-experiment analysis**, i.e., **analysis of variance**, the matrix A and the vector ξ in (1) are called a **design matrix** and an **effect**, respectively. In this case entries of A are assumed to be either 1 or 0. (II) In **regression analysis**, we are first given a linear form $x = \sum_{j=1}^k a_j \xi_j$ of a vector $\mathbf{a} = (a_1, \dots, a_k)'$ with coefficient vector $\xi = (\xi_1, \dots, \xi_k)'$. Let X_1, \dots, X_n be the observed values of x at n points $\mathbf{a}_1 = (a_{11}, \dots, a_{1k})', \dots, \mathbf{a}_n = (a_{n1}, \dots, a_{nk})'$, respectively, where $n > k$. If the observations are unbiased, that is, if $E(X_i) =$

$\sum_{j=1}^k a_{ij} \xi_j$, $i = 1, \dots, n$, then the model (1) is obtained with $A = (a_{ij})$. Usually one of the components of the vector \mathbf{a} is taken as unity. In this framework the form $x = \sum_j a_j \xi_j$ is called the **linear regression function** or **regression hyperplane**, and for $k = 2$, the graph of the linear function $x = a_1 \xi_1 + \xi_2$ and its coefficient ξ_1 are called the **regression line** and **regression coefficient**, respectively. The components of the vector \mathbf{a} are called **fixed variates** or **explanatory variables**. Frequently we encounter the case where the vector \mathbf{a} , and consequently the matrix A , are random variables. When this is the case, a discussion like that above can be carried out for given A by regarding $A\xi$ in (1) as the conditional expectation of the vector \mathbf{X} .

E. The Method of Least Squares
