The Root Zone Water Quality Model (RZWQM) (http://gpsr.ars.usda.gov/products/rzwqm.htm) was developed during the past 10 years by a team of USDA–ARS scientists. A majority of the team members are part of the present Great Plains Systems Research Unit in Fort Collins, Colorado. RZWQM is a one-dimensional process-based model that simulates the growth of a plant and the movement of water, nutrients, and agrochemicals over, within, and below the crop root zone of a unit area of an agricultural cropping system under a range of common management practices. The primary use of RZWQM will be as a tool for assessing the environmental impact of alternative agricultural management strategies on the subsurface environment. These alternatives may include conservation plans on a field-by-field basis; tillage and residue practices; crop rotations; planting date and density; and irrigation, fertilizer, and pesticide scheduling (method of application, amounts, and timing). The model predicts the effects of these management practices on the movement of nitrate and pesticides to runoff and deep percolation below the root zone.

Pesticide Root Zone Model (PRZM)

The EPA's Pesticide Root Zone Model (PRZM) (http://www.epa.gov/ceampubl/gwater/przm3/index.htm) is a one-dimensional, dynamic, compartmental model that can be used to simulate chemical movement in unsaturated soil systems within and immediately below the plant root zone. It has two major components: hydrology/hydraulics and chemical transport. The hydrologic component for calculating runoff and erosion is based on the Soil Conservation Service curve number technique and USLE. The chemical transport component can simulate pesticides or organic and inorganic nitrogen species.

PRZM can simulate multiple zones. This allows combining different root zone and vadose zone characteristics into a single simulation. Zones can be visualized as multiple land segments joined together horizontally. PRZM (28) simulates the movement of pesticides in unsaturated soils within and immediately below the root zone. Several different field crops can be simulated and up to three pesticides are modeled simultaneously as separate parent compounds or metabolites. The PRZM model has been used under various conditions to assess pesticide leaching under fields (11,13).

Generalized Watershed Loading Function (GWLF)

The Generalized Watershed Loading Function (GWLF) model (http://www.avgwlf.psu.edu/) was developed by Haith and Shoemaker (29). The GWLF model can simulate runoff, sediment, and nutrient loadings from a watershed, given variable-size source areas (i.e., agricultural, forested, and developed land). ANSWERS (30), which has been used in GWLF, is a spatially distributed watershed model. The model is primarily a runoff and sediment model because soil nutrient processes are not simulated. The ANSWERS model has been applied to several small field-sized areas using various management practices (6,31).

During the last 5–10 years, the Pennsylvania Department of Environmental Protection (PADEP) has recognized the indispensability of GIS technology and endeavored to integrate it into all of the agency's internal program areas. Pennsylvania State University has been assisting PADEP in developing and implementing various GIS-based watershed assessment tools, including one called AVGWLF that facilitates using the GWLF model via a GIS software (ArcView) interface. The comprehensive modeling approach was based on this GWLF/ArcView interface that enables accurate prediction of nutrient and sediment loads in watersheds throughout the state of Pennsylvania, particularly for those watersheds for which historical stream monitoring data do not exist. This methodology relies on using statewide data sets to derive reasonably good estimates of various critical model parameters that exhibit significant spatial variability within the state. GWLF is a continuous simulation model that uses daily time steps for weather data and water balance calculations. Monthly calculations are made for sediment and nutrient loads, based on the daily water balance accumulated to monthly values.

Source Loading and Management Model (SLAMM)

The Source Loading and Management Model (SLAMM) (http://wi.water.usgs.gov/slamm/) was originally developed in the late 1970s to understand better the relationships between sources of urban runoff pollutants and runoff quality. Runoff is calculated by a method developed by the University of Alabama at Birmingham for small-storm hydrology. SLAMM is strongly based on actual field observations, and relies minimally on theoretical processes that have not been adequately documented or confirmed in the field. SLAMM is used mostly as a planning tool to understand better sources of urban runoff pollutants and their control. SLAMM incorporates unique process descriptions to predict more accurately the sources of runoff pollutants and flows for the storms of most interest in water quality analyses and quantification of the impacts of management practices.

Regression Methods and Simple Spreadsheet Models

USGS Regression Method. The USGS has developed equations for determining pollutant loading rates based on regression analyses of data from sites throughout the country (76 gauging stations in 20 states). The regression approach is based on a statistical description of historic records of storm runoff responses on a watershed level (32,33). This method may be used for rough preliminary calculations of annual pollutant loads when data and time are limited. Input required for this level of modeling includes drainage data, percent imperviousness, mean annual rainfall, general land use pattern, and mean minimum monthly temperature. Application of this method provides mean planning loads and corresponding confidence intervals for storms.

Simple Method by MWCOG. The “simple method,” as its name implies, is an easy-to-use empirical equation for estimating pollutant loadings of an urban watershed by the Metropolitan Washington Council of Governments (MWCOG). The method is applicable to watersheds less than 1 square mile in area, and can be used for analyzing a smaller watershed or site planning. The method was developed using the database generated during a Nationwide Urban Runoff Program (NURP) study (34) in the Washington, DC, area and the national NURP data analysis. The equations, however, may be applied anywhere in the country. Some precision is lost as a result of the effort to make the equation general and simple. The method is adequate for decision-making at the site-planning level.

FHWA Model. The Federal Highway Administration (FHWA) has developed a simple statistical spreadsheet procedure to estimate pollutant loading and impacts to stream and lakes that receive highway stormwater runoff (35). The FHWA model uses a set of default values for pollutant event mean concentrations that depends on traffic volume and whether the setting of the highway’s pathway is rural or urban. The FHWA uses this method to identify and quantify the constituents of highway runoff and their potential effects on receiving waters and to identify areas that might require controls. The FHWA model is well suited for screening application and can evaluate lake and stream impacts of highway stormwater discharges. However, it assesses seasonal variability in a limited manner and does not consider the soluble fraction of pollutants or precipitation and settling of pollutants in lakes.

PLOAD Model. PLOAD is a simplified GIS-based watershed loading model. It can model combined point and nonpoint source loads in either small urban areas or in rural watersheds of any size. The user may calculate the nonpoint source loads using either the export coefficient or the EPA’s simple method approach. Best management practices (BMPs), which reduce both point and nonpoint source loads, may also be included in computing total watershed loads. PLOAD broadly addresses pollutant loading by land use categories and subwatersheds but does not get at individual nonpoint sources or at actual pollutant fate and transport processes.

PLOAD was designed to be generic, so that it can be applied as a screening tool in a wide range of applications, including NPDES stormwater permitting, watershed management, and reservoir protection projects. The uncertainty of export coefficients is high, but the PLOAD model provides a good fit to the regulatory concept of the phased TMDL. Uncertainty can be reduced by calibrating to local conditions based on multiyear datasets and can be addressed in later phases of the TMDL as more detailed source identification and seasonal data become available (36).

SUMMARY AND CONCLUSION

Water quality models of different complexity level (ranging from simple, midrange, to detailed) for developing soil management practices have been reviewed. In general, complex models potentially have greater accuracy in their predictions than simple models because of the comprehensive simulation of environmental processes. However, more site-specific data are required to use these complex models fully. Application of complex models is usually more expensive than using simple models for developing management practice. Therefore, the trade-off among these models should be one of the key considerations during model selection.

Although guidance is still needed for determining nonpoint source loadings from urban and rural areas (37), the common approaches used currently for estimating wet weather nonpoint pollution loads are (38) (1) unit load concepts (long-term statistical average loads are related to land uses), (2) event-oriented models (water and pollutant loads are calculated for a single storm), and (3) continuous models (water and pollutant loads are calculated using daily or shorter time intervals and complex, mostly deterministic hydrologic models).

The realization that management of nonpoint sources of pollutants is as important an issue as management of the more readily controllable point sources has led to the concept of watershed management and planning. Increased computational power, as well as a desire for watershed planning, has resulted in the advancement of mathematical modeling tools. One of the trends is developing integrated modeling systems that link the models, data, and user interface within a single system. New developments in modeling systems have increasingly relied on a geographic information system (GIS) and a database management system to support modeling and analysis (1). U.S. EPA's BASINS offers a comprehensive modeling system that brings key data and analytical components together "under one roof" (2). USDA's benchmark watershed model SWAT has been incorporated into the BASINS V3 system. The Watershed Modeling System (WMS) is another useful tool for watershed modeling and management practice development. These multipurpose environmental analysis systems are expected to be extensively used by federal, regional, state, and local agencies in watershed and water quality studies in the future.

WATER QUALITY MODELING—CASE STUDIES

Zhen-Gang Ji
Minerals Management Service
Herndon, Virginia

This entry focuses on case studies of water quality modeling. Information on water quality models is provided in Water Quality Models.

MODEL SELECTION

Although a variety of models are available for studying water quality processes, it is still a complex task to select a model (or models) that best meets all (or most) of the study objectives. Model selection should be balanced among competing demands. Time and resources are always limited, to one degree or another, so the goal should be to identify the model(s) that addresses all of the important processes that affect the waterbody. Selecting a model that is too simple can result in lack of accuracy and certainty that are needed in decision making; selecting an overly complex model may result in misdirected resources, study delays, and increased cost.

It is helpful to ask the following questions during model selection:

1. What are the key hydrodynamic processes?
2. What are the water quality concerns?
3. What spatial and temporal scales are adequate for resolving these processes?
4. How will the model be used in supporting management decision making?

It might be desirable to select the simplest model that can meet the study needs. However, in real practice, comprehensive models are often preferred to simple models for a variety of reasons. Typical features of comprehensive models include:

1. three-dimensional (3-D) in space and time dependent
2. turbulent scheme for vertical mixing
3. hydrodynamic, thermal, sediment, and eutrophication processes.

Generally speaking, comprehensive models should (but not always) have better mathematical, physical, chemical, and biological representations of natural waters than simple models. It is often advantageous to adopt a more detailed model to address various scientific and engineering applications than to switch models continuously from one phase of a project to another or from one project to another (1). As discussed later and in the entry WATER QUALITY MODELS: CHEMICAL PRINCIPLES, the Environmental Fluid Dynamics Code (EFDC) model is a comprehensive model (2).

In many applications, comprehensive models have advantages compared to simple models for the following:

1. *The Evolving Understanding of the Waterbody Studied.* A waterbody is understood gradually as the modeling effort progresses. Detailed understanding of the system is often achieved after the modeling study is finished. At the beginning of a study, it is sometimes difficult to know which simple model should be able to describe the system adequately. Therefore, it is helpful to have a model that has the most capability (and flexibility for further model enhancement) to describe important processes (known and to be known) in the system.
2. *The Management Needs.* A primary goal of a modeling study is often to support management decision making, which might change with time and cannot always be foreseeable. It is desirable to choose a model that can meet these "expanding" needs. It is generally more cost-effective to choose a comprehensive model that can address current and future needs than to use a simple model that is later found inadequate and has to be replaced by one more advanced.
3. *The Falling Costs of Computing.* The progress in computer technology has dramatically reduced the costs of computing and makes comprehensive models more affordable.
4. *The Modelers.* A modeler often needs to study hydrodynamic, sediment, toxic, and/or water quality processes in a variety of waterbodies and, therefore, needs models and tools that are versatile enough for these applications. It is common for a modeler to have several modeling studies during any given period and to complete tens of modeling projects over the years. Rather than learning and using a variety of models for different applications, it is advantageous to stick with one (or a few) comprehensive model, know it well, and apply it to modeling rivers, lakes, and estuaries.

Comprehensive models can be applied appropriately only by well-trained and experienced modeling professionals and often need extensive measured data for model calibration and verification. The progress in computer technology, the enrichment of measured data, and the enhancement of water quality models are making comprehensive models powerful tools for water quality management.

Two cases studies are introduced here: the first is on sediment and toxic metals in a shallow river, and the second is on eutrophication in a deep reservoir.

CASE STUDY I: BLACKSTONE RIVER

Many waterbodies are polluted by sediments and toxic metals. This case study illustrates the modeling of hydrodynamics, sediment transport, and toxic metals in the Blackstone River, Massachusetts (3).

Background

The Blackstone River Basin (Fig. 1) consists of approximately 1657 square kilometers encompassing 30 cities and towns. The Blackstone River flows from Worcester, Massachusetts, to Pawtucket, Rhode Island. The river is 77 km long and has 133 meters of total fall. The distances shown in Fig. 1 are river kilometers from Slaters Mill Dam. There are presently 14 dams and impoundments on the mainstem of the Blackstone that are significant to the hydrodynamic and water quality processes in the river. The Blackstone has been the largest source of pollutants discharging into Narragansett Bay, principally from industrial discharge of metals and resuspension of contaminated sediments behind the low head dams in the river. Sediment and metals in certain sections of the riverbed can be traced back 200 years to the American Industrial Revolution.

This study is intended to provide the United Sates Environmental Protection Agency (EPA) with a relatively simplified example of how comprehensive models can be used to evaluate the distributions of heavy metals in a shallow, narrow, urban, industrial river.

Hydrodynamic, Sediment, and Metals Simulations

The Blackstone River model is developed within the framework of the EFDC model (2). The EFDC model is a public-domain modeling package used for simulating three-dimensional flow, transport, and biogeochemical processes in surface water systems, including rivers, lakes, estuaries, reservoirs, wetlands, and coastal regions. The EFDC model has been extensively tested and documented in more than 80 modeling studies and is currently supported by the EPA. The model is used by a number of organizations, including universities, governmental agencies, and environmental consulting firms. Representative applications of the EFDC model include modeling of sediment and metals transport in the Blackstone River (3), wetting and drying simulation of Morro Bay (4,5), and simulating hydrodynamic, thermal, and sediment processes in Lake Okeechobee (6–8). More information on the EFDC model is also provided in the entry WATER QUALITY MODELS: CHEMICAL PRINCIPLES.

The Blackstone River model includes a hydrodynamic submodel, a sediment submodel, and a toxicant submodel. They are coupled together and are executed simultaneously. The hydrodynamic model simulates velocity, water elevation, and turbulent mixing for sediment modeling. The output of the hydrodynamic and sediment models are linked to the toxicant model to simulate the five metals in the river: cadmium (Cd), chromium (Cr), copper (Cu), nickel (Ni), and lead (Pb).

The typical width of the Blackstone River is around 25 meters and varies from less than 10 m upstream to

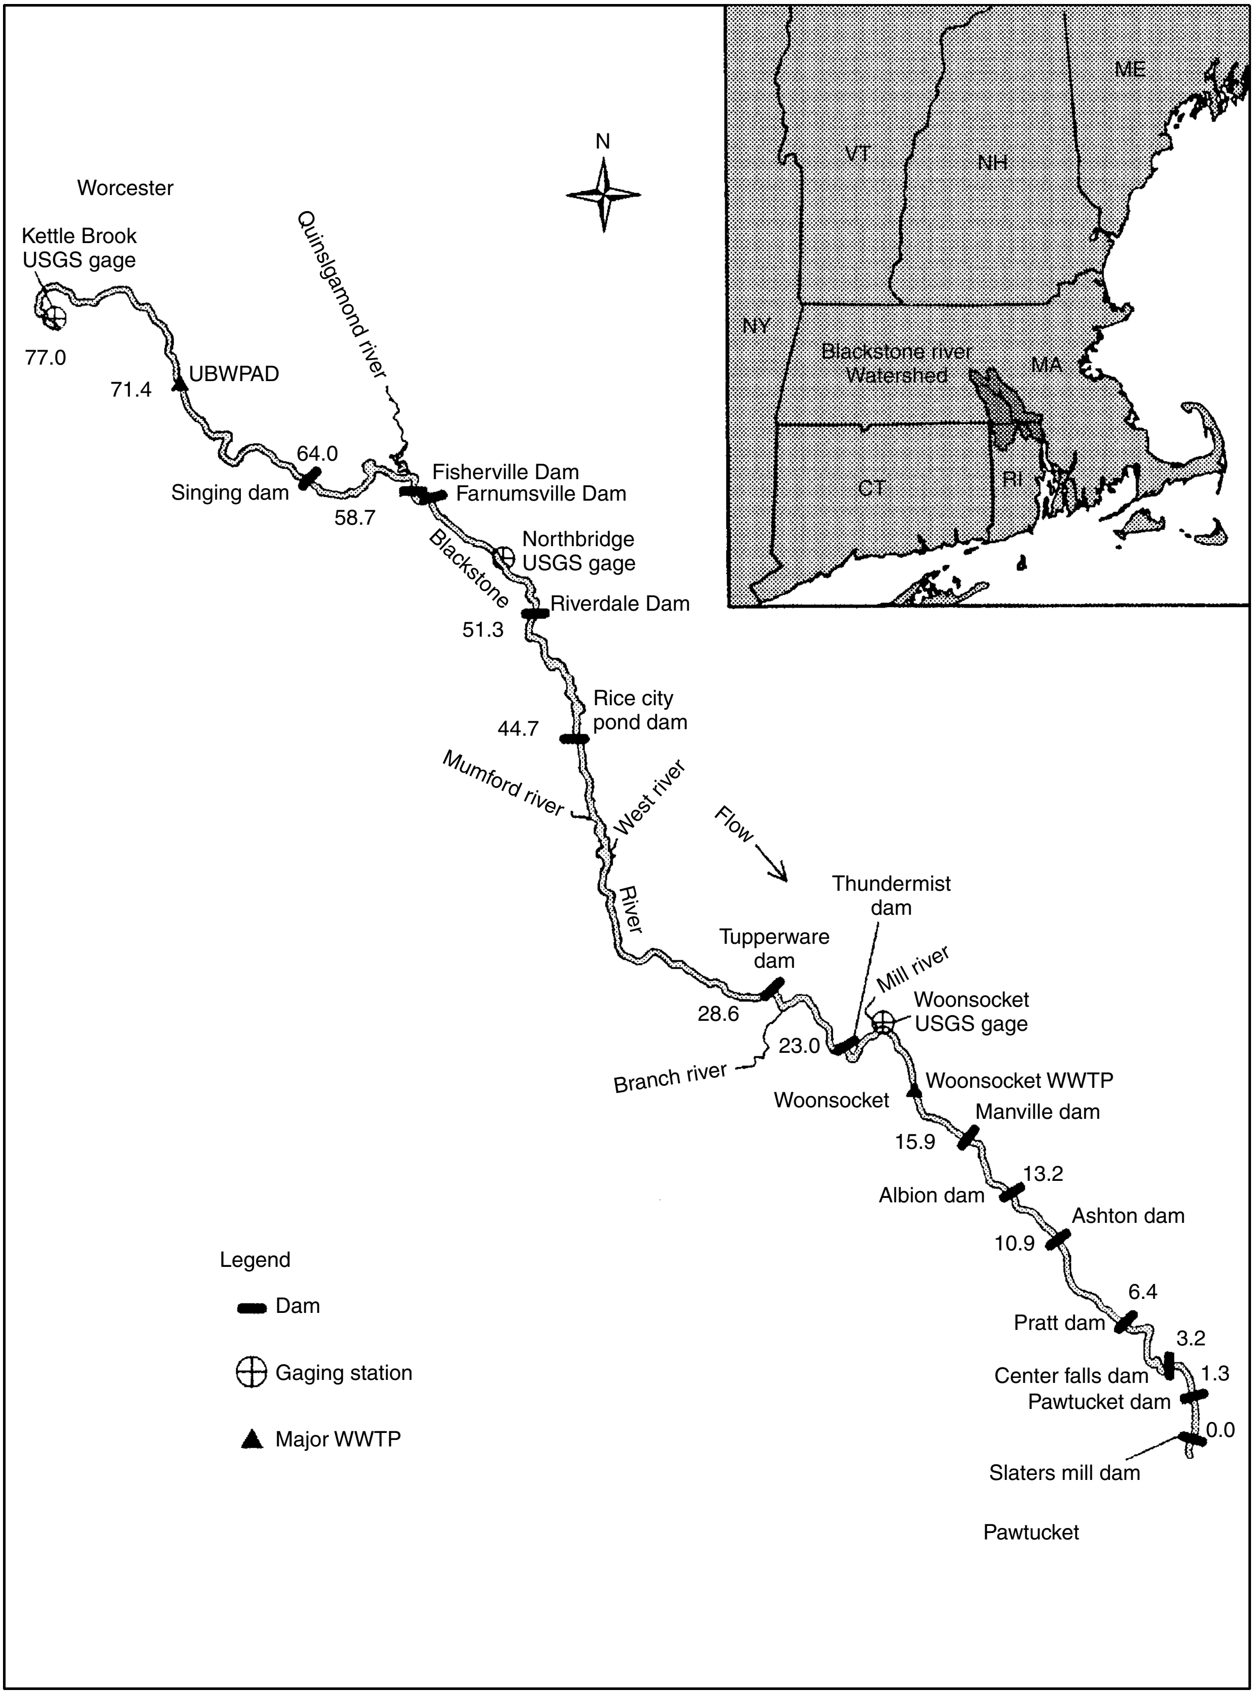

Figure 1. Blackstone River study area. The distances are river kilometers from Slaters Mill Dam.

more than 35 m downstream. It has an average drop of 1.73 m/km, so the Blackstone is a gravity-driven river. The grid of the Blackstone River model has one cell across the river and one layer in the vertical. Along the river, there are 256 grid cells of varying cell widths and a uniform cell length of 300 m. A time step of 30 seconds is used throughout the simulation.

Figure 2 presents the time series of the modeled and measured concentrations of total suspended solids (TSS) along the Blackstone River during a storm (November 2–6, 1992). The horizontal axis is in days from November 2, 1992, and the vertical axis is in milligram/liter. The closed circles represent the measured TSS, and the solid line represents the model results. The river kilometers are also shown in the plots. The model realistically simulates the sediment resuspension processes at dams, including Singing Dam (km = 64.0), Fisherville Dam (km = 58.4), Riverdale Dam (km = 51.3), and Rice City Pond Dam (km = 44.7). The high sediment concentration at km = 37.3 is caused by flows from upstream and from tributaries. Figure 3 is similar to Fig. 2, except for Pb concentrations and shows that the model simulates Pb processes well.

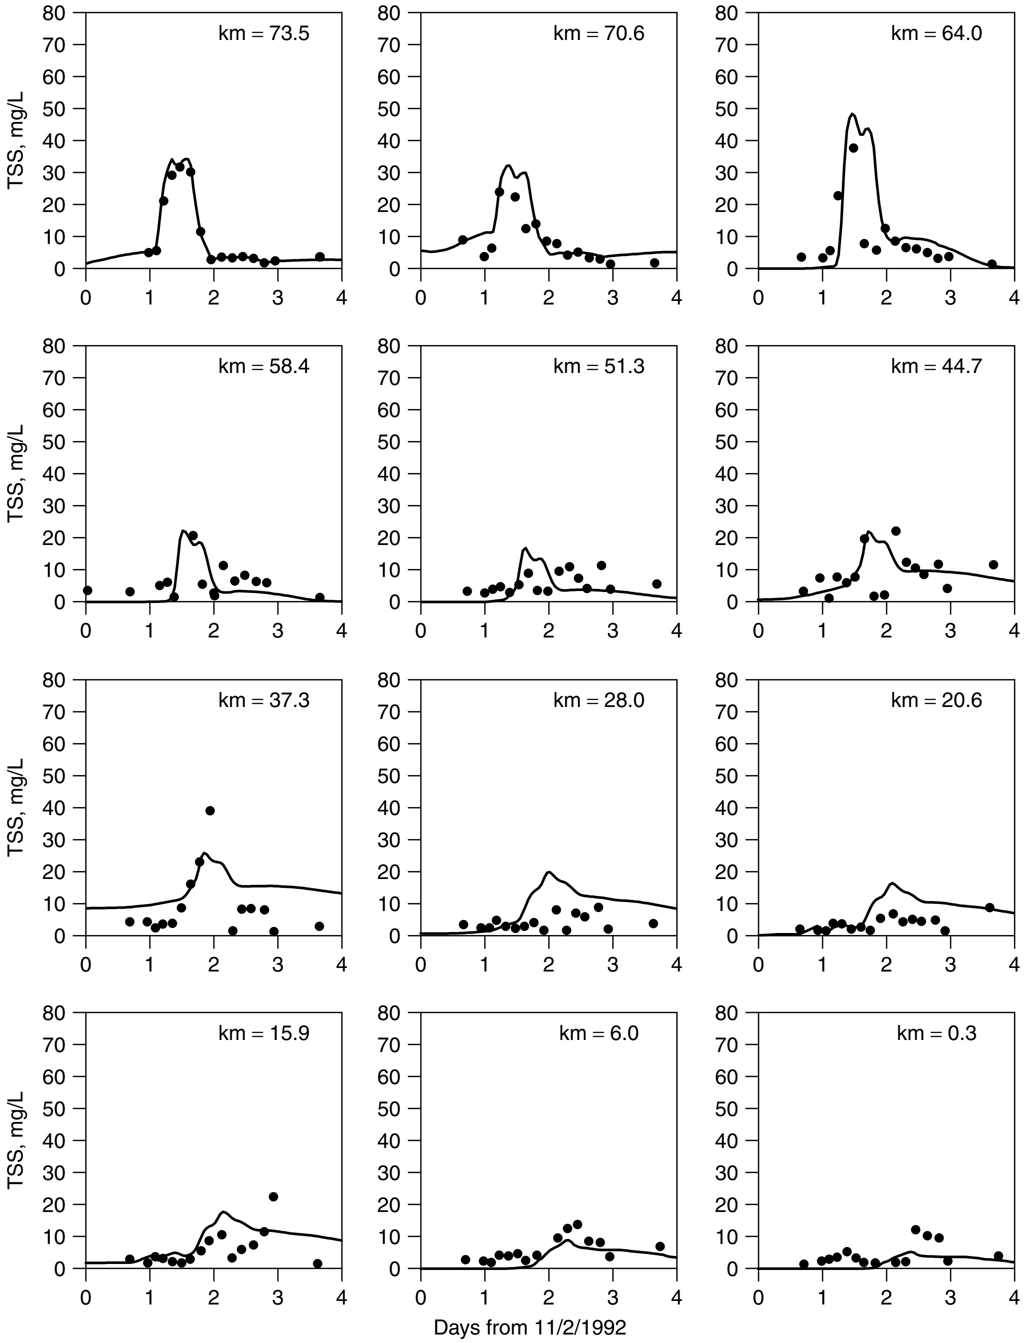

Figure 2. Measured and modeled total suspended solids (TSS) concentration along the Blackstone River from November 2–6, 1992.

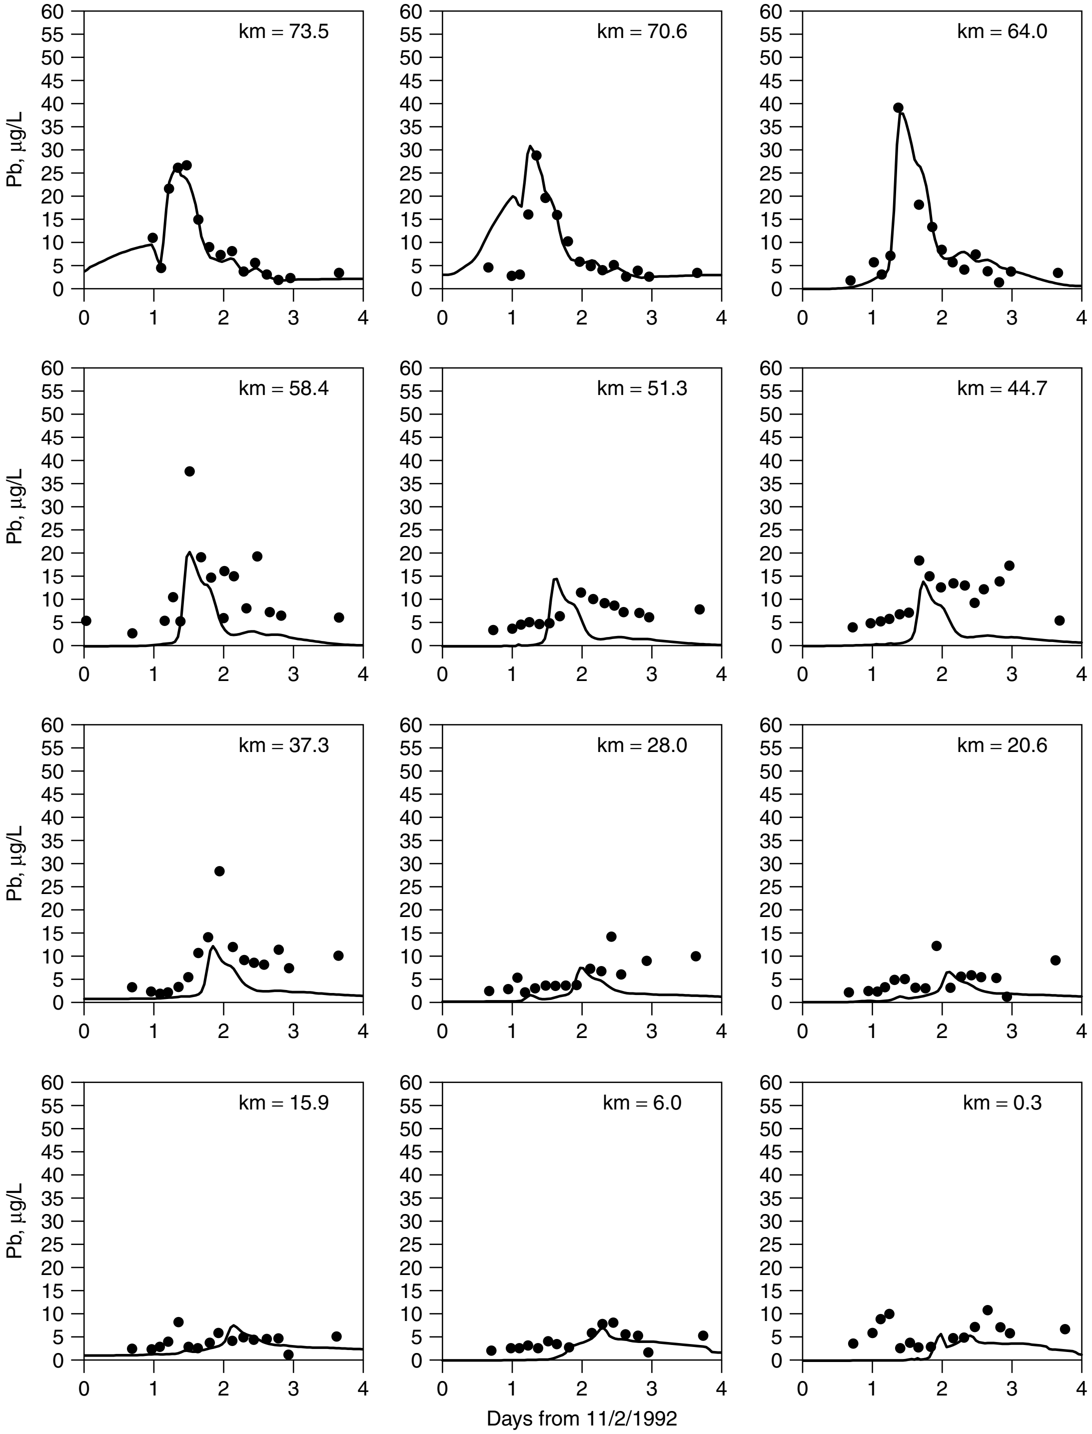

Figure 3. Measured and modeled lead (Pb) concentration along the Blackstone River from November 2–6, 1992.

To conduct a statistical analysis, the model results are also saved at the same locations and times at which the data were collected. Table 1 summarizes the error analyses of seven variables: river flow rate (Q), TSS, Cd, Cr, Cu, Ni, and Pb. The table presents the values of observed mean, modeled mean, absolute mean error, root mean square (rms) error, observed change, and the percentage of relative rms error. The relative rms error is defined as the rms error divided by the observed change. These analyses show that the simulations agree well with the observed data. The relative rms errors range from 6.17% (Q) to 17.27% (TSS), and the relative rms errors for the five metals are no more than 15.03%.

Conclusions

It is a challenge to apply coupled hydrodynamic, sediment, and contaminant fate and transport models to studies of surface water systems. Contaminant transport depends

Table 1. Error Analysis of Observed and Modeled River Flow Rate (*Q*), Total Suspended Sediment (TSS), Cadmium (Cd), Chromium (Cr), Copper (Cu), Nickel (Ni), and Lead (Pb)

Variable	Obs. Mean	Modeled Mean	Mean abs. err.	rms err.	Obs. Change	Relative rms err. (%)
Q (m^3/s)	9.53	10.95	1.86	3.42	55.39	6.17
TSS (mg/L)	6.80	8.20	4.54	6.53	37.80	17.27
Cd (μg/L)	0.88	1.22	0.52	0.71	5.12	13.95
Cr (μg/L)	4.08	1.99	2.27	3.17	27.08	11.71
Cu (μg/L)	12.27	12.09	5.77	8.69	57.80	15.03
Ni (μg/L)	7.92	7.73	2.31	3.52	25.70	13.68
Pb (μg/L)	7.52	4.57	4.00	5.43	37.80	14.38

on hydrodynamic and sediment conditions. Heavy metals and toxic chemicals can preferentially adsorb and desorb with solids in the water column and sediment bed. High flow events, such as storms, increase solid loadings from the watershed, increase river flow velocity, reintroduce previously deposited chemicals back into the water column via resuspension, and transport the resuspended contaminants further downstream until they settle out in deposition zones.

So far, there are few published modeling studies on sediment and metal transport in rivers that simulated storms on an hourly basis and used comprehensive data sets for model input and model calibration. This study can simulate the sediment and metal transport processes in detail. Statistical analysis and graphic presentation indicate that the model results are in very good agreement with the data. For shallow and narrow rivers like the Blackstone, the EFDC model with a 1-D grid can represent the hydrodynamic, sediment, and metals processes reasonably well.

CASE STUDY II: LAKE TENKILLER

Water quality management requires scientifically credible numerical models for evaluating pollution control options. This case study summarizes the eutrophication and water quality modeling of Lake Tenkiller, Oklahoma (9).

Lake Tenkiller (Fig. 4) is a reservoir located in northeastern Oklahoma. The lake is 48 km long, up to 3 km wide, and 70 km^2 in area. Its depth varies from more

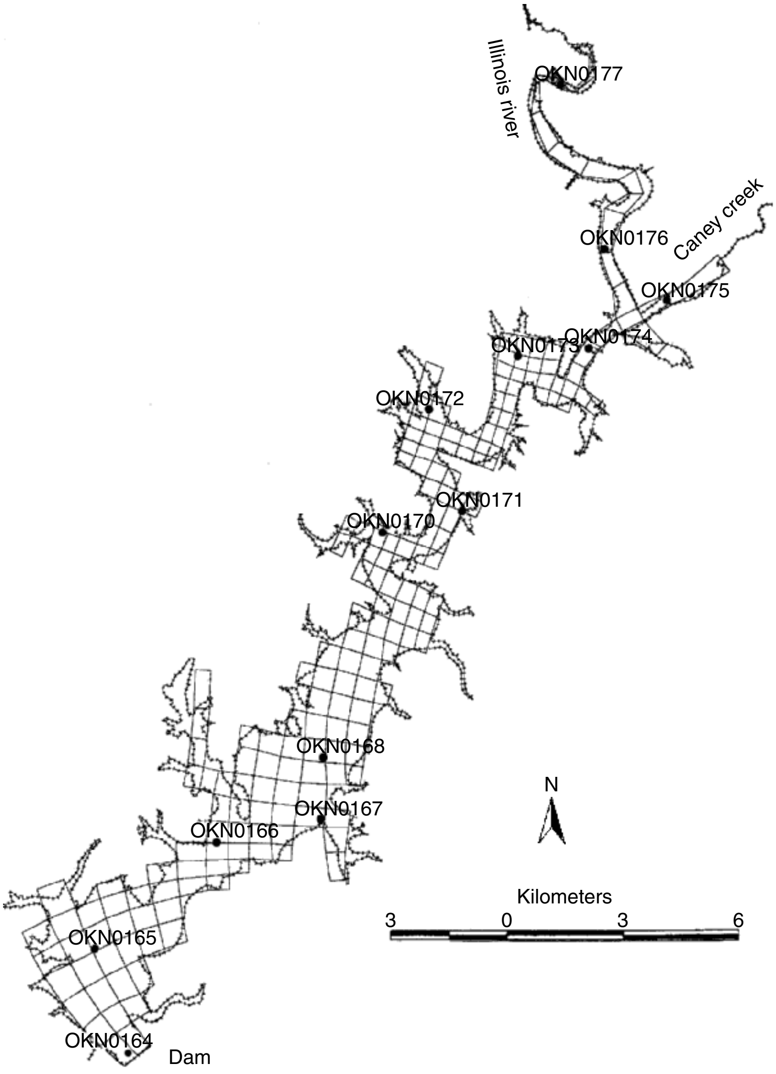

Figure 4. Lake Tenkiller study area, model grid, and data stations.

than 45 m near the dam to less than 6 m in the northern section. The lake has a retention time of 1.76 years. Major water quality issues include nutrient enrichment, eutrophication, and hypolimnetic dissolved oxygen (DO) depletion. Because of the 3-D variability of the lake, it is critical to simulate the hydrodynamic and water quality processes using a 3-D model, so that water quality parameters in the lake can be described in detail and cost-effective water management approaches can be proposed and evaluated.

Water Quality Simulations

The Lake Tenkiller model is also developed within the framework of the EFDC model (2) and includes the hydrodynamic, sediment, and water quality submodels. The water quality parameters considered, as presented in the entry WATER QUALITY MODELS: CHEMICAL PRINCIPLES, include algae, DO, organic nitrogen, ammonia, nitrite and nitrate, organic phosphorus, and phosphates.

The study area is divided into a grid of discrete cells. Figure 4 shows the model grid overlaying an outline of

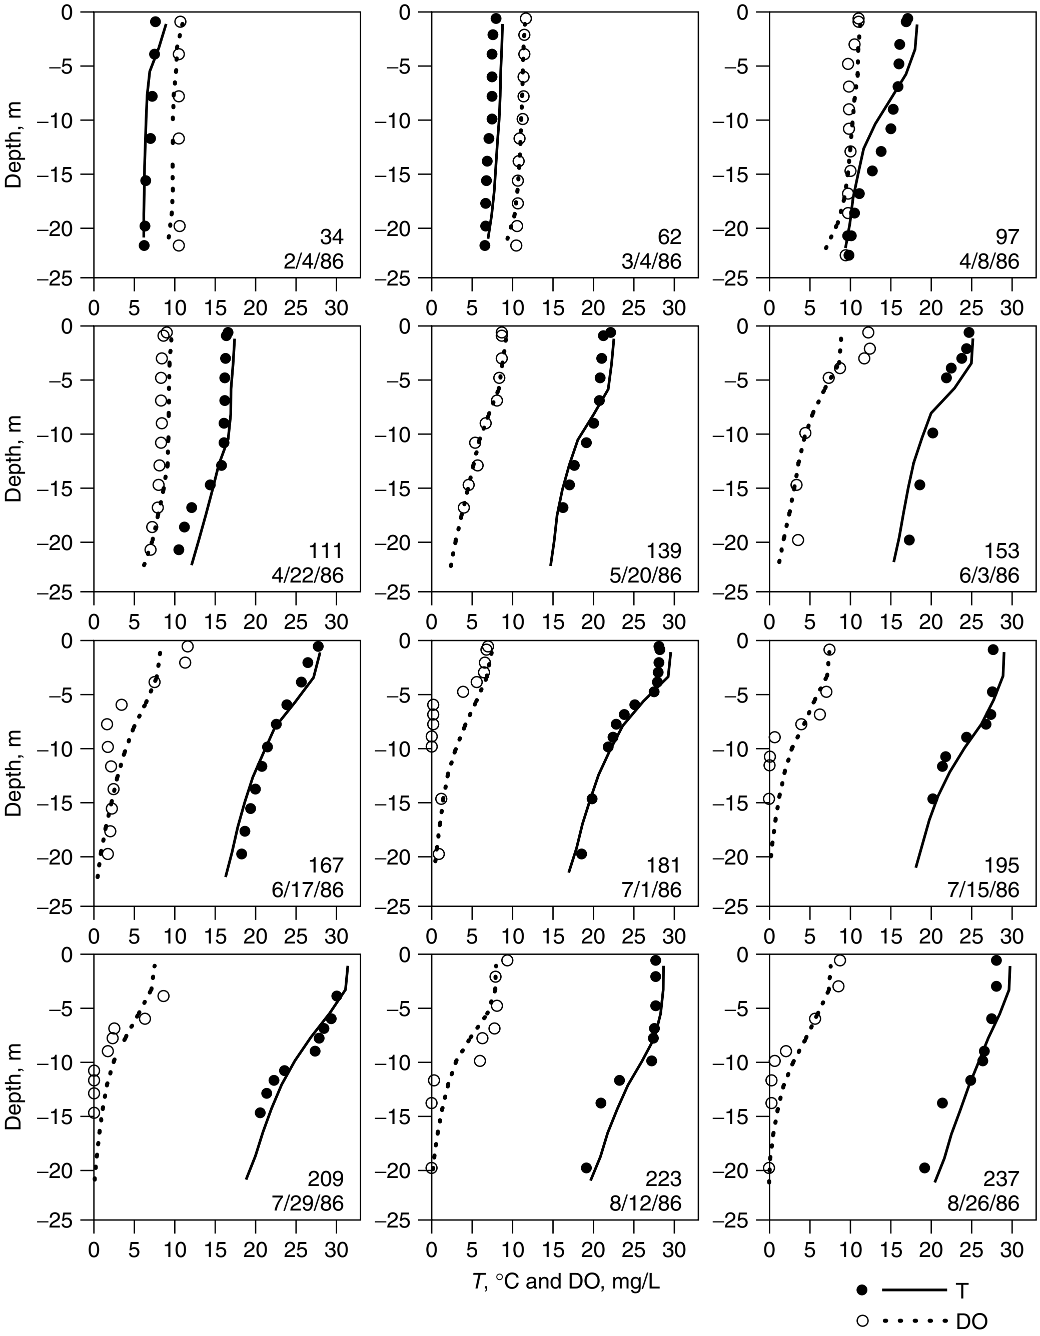

Figure 5. Vertical profiles of temperature and dissolved oxygen (DO) at Station OKN0166. Solid line = modeled temperature, dashed line = modeled DO, closed circles = measured temperature, and open circles = measured DO.

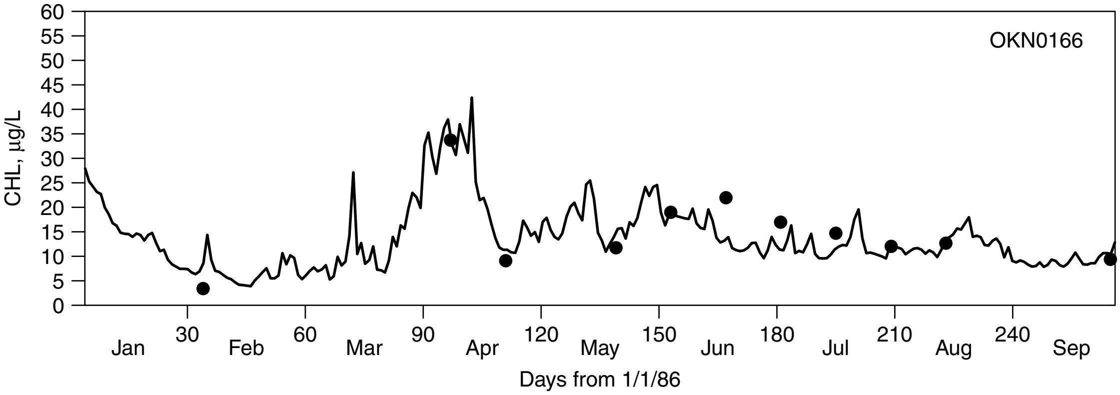

Figure 6. Model-data comparison of chlorophyll-*a* (CHL) at Station OKN0166. Solid line = modeled surface CHL, and closed circles = measured surface CHL.

Lake Tenkiller. The numerical grid consisted of 198 cells in the horizontal plane and 10 vertical sigma layers. The 10 vertical layers are necessary and important for resolving the vertical temperature and DO profiles in the lake. The time period for model calibration is 262 days from January 5, 1986 to September 24, 1986. Solutions of the model are obtained using a 50-second time step. Using a 2.4-Ghz Pentium IV PC, approximately 6 CPU hours are required for a 262-day simulation.

The 12 plots in Fig. 5 show the vertical profiles of modeled and measured water temperature (T) and DO at Station OKN0166. The horizontal axis represents T in °C and DO in mg/L. The vertical axis represents water depth in meters. The solid curve is the modeled T, and the closed circles are the measured T. The dashed curve is the modeled DO, and the open circles are the measured DO. Overall, the modeled T and DO are consistent with the measured data. Both the model and the data indicate that DO is vertically mixed at values around 10 mg/L in the winter and is very stratified at 8 mg/L or more on the surface and almost 0 mg/L at the bottom in the summer. The lake started to become stratified in April and exhibited strong thermal stratification in the summer; the surface-bottom T difference was up to 15 °C, and the DO difference up to 10 mg/L. It also appears that the model might need more vertical layers to resolve DO stratifications better in the summer.

Algae levels are often measured by chlorophyll-*a* concentrations (CHL) in water quality models. Figure 6 gives the modeled CHL (solid line) and the measured CHL (closed circle) at OKN0166, the same station whose T and DO are displayed in Fig. 5. Figure 6 reveals that algae in the lake vary from less than 10 μg/L in the winter to around 25 μg/L in the summer, both the model and the data indicate a strong algae bloom in the spring.

Conclusions

The dynamic simulation of eutrophication in a deep water system is a very complicated and computationally intensive endeavor because a large number of chemical, biological, and biochemical processes interact and the reaction rates and external inputs vary with time. Despite the progress in 3-D hydrodynamic, water quality, and sediment diagenesis models and their successful applications in estuaries and bays (10), few similar 3-D modeling studies on lakes and reservoirs have been published.

The primary purpose for developing the Lake Tenkiller model is to use the model as a tool for proposing and testing load-management strategies aimed at limiting eutrophication processes in the lake. The Lake Tenkiller model is calibrated and represents existing hydrodynamic and water quality processes in the lake satisfactorily and is a useful tool for managing eutrophication in the lake (11).

FIELD SAMPLING AND MONITORING OF CONTAMINANTS

Timothy J. Downs
Clark University
Worcester, Massachusetts

INTRODUCTION

Field sampling and monitoring of water/wastewater contaminants are strategically important for more sustainable integrated water resources management (IWRM). One of the vital first steps in IWRM is the collection of an inventory that characterizes existing watershed conditions. Relevant features include geographic and environmental aspects (e.g., land use, topography, wetlands), infrastructure (e.g., supply, sewerage and drainage), municipal data (e.g., numbers of people, growth rate, regulations, by laws), pollution sources/discharges (point and nonpoint sources, e.g., landfills, underground storage tanks), and the characteristics of receiving surface waters and groundwaters (indicators of flow rates and physical, chemical, biological, and microbiological quality).

Water quality problems that require characterization through sampling and monitoring are a combination of the effects of human use and degradation of water in domestic, industrial, commercial, and agricultural activities (and its discharge as wastewater), and the impact of human activities that change land use/land cover on the water quality of runoff. Wastewater discharge can be handled by treatment technologies, but during rainstorms, combined sewer overflows (CSOs) and sanitary sewer overflows (SSOs) can degrade water quality. In urban areas, domestic wastewaters contain sanitary sewage composed of oxygen-demanding wastes, nutrients, and pathogens. Industrial wastewaters contain metals and organic pollutants. Urban runoff from paved surfaces contains hydrocarbons, runoff from eroded land surfaces produces sediment-laden flows to receiving waters.

Chief among inventory data are contaminant-related data (1):

- pollutants of concern and effects on water resources;
- a base map for locating pollution sources and controls;
- areas of concern where pollutant loadings pose high public health and ecological health risks and where control efforts should focus;
- areas of high water quality where protection should focus; and
- information for developing water quality models, if needed.

The inventory of existing data reveals gaps to be filled by sampling and monitoring. Chambers Dictionary defines sampling as: the “taking of, testing of a sample; the examination and analysis of data obtained from a random group in order to deduce information about the population as a whole”; to monitor is to “watch, check, supervise” (2). The inventory also provides information resources for setting clear concise IWRM goals. The goals and data gaps determine sampling and monitoring regimes.

Six basic practical considerations of environmental sampling/monitoring are as follows

- Which environmental media to sample (surface water, groundwater, air, soil, sediment, biota), and which standardized sampling method to use to obtain the sample?
- Where in the contaminant-environment cycle to take samples (physical location)?
- Which indicators/parameters of environmental quality to measure and which laboratory analysis methods to apply to detect them?
- When to take samples (times of the year, e.g., wet and dry seasons, cold and hot seasons)?
- How often to sample (frequency of sampling, subhourly, hourly, daily, weekly, monthly)?
- How to report contamination results (implied risks, impacts, data and modeling limitations and assumptions)?

Figure 1 shows stages in sampling/monitoring as an adaptive process and its input data.

Knowing the following greatly informs water–contaminant system sampling and characterization:

- physicochemical characteristics of the contaminant of interest especially its degree of water phase affinity (hydrophilicity) or water phase aversiveness (hydrophobicity),
- dominant removal processes—decay by chemical reaction (e.g., hydrolysis, aqueous oxidation or reduction), sunlight degradation (photolysis), and/or microbial (bio-) degradation;
- dominant transport processes: sediment transportation in runoff, soil erosion and washing into rivers and lakes, leaching into aquifers, dry deposition, or wet deposition from air into water;
- contaminant toxicity and risk: human cancer and noncancer health effects from sufficient exposure by ingestion, inhalation, and/or dermal/ocular contact; and nonhuman health effects (ecotoxicology).

SPATIAL CONSIDERATIONS—WHERE TO SAMPLE AND MONITOR

Conservation of mass (see Eq. 1) always applies, so scientific sampling and monitoring of water/wastewater quality

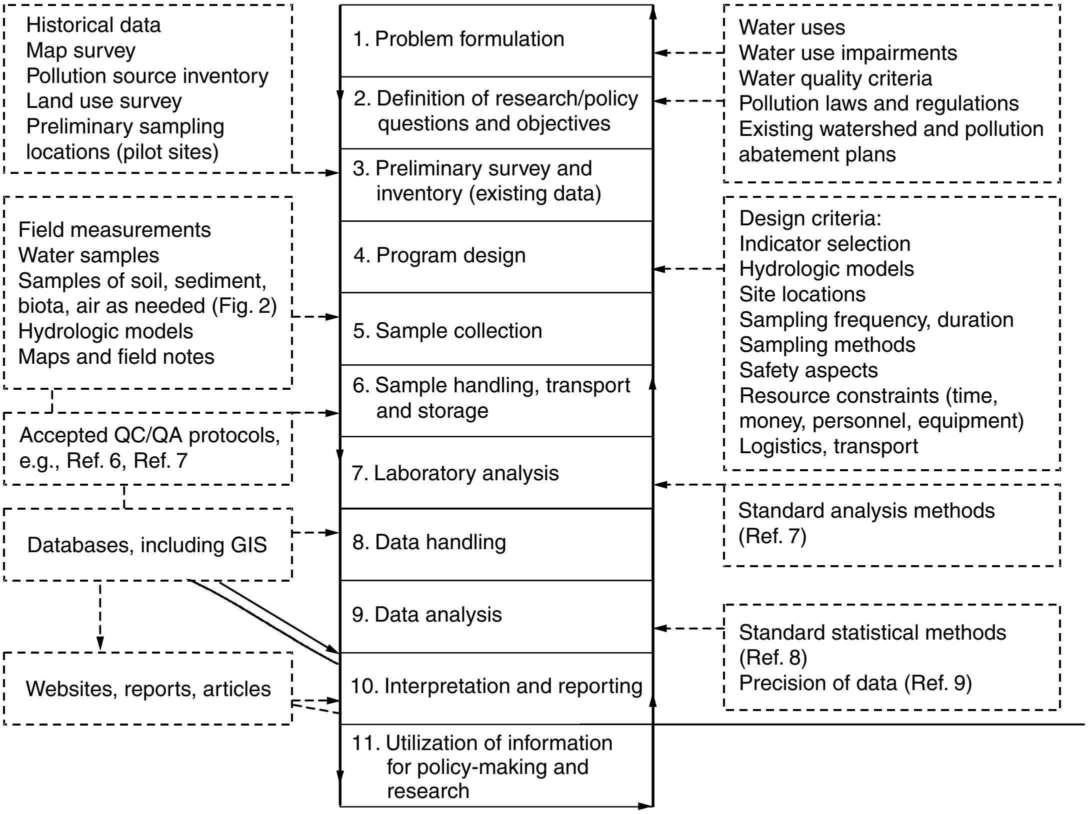

Figure 1. Stages of water quality monitoring. Shows determining factors, sources of data, and standard methods (expanded from Ref. 5). Stages 1–11 can be thought of as an adaptive feedback loop, responding to changing conditions, interests, capabilities, and priorities over time. In this way, the sampling/monitoring becomes sustainable. A key dimension to the relative sustainability is the strengthening of capacities/resources (human, informational, policy-making, financial, and equipment).

seek to take measurements that provide information about the following aspects of the contaminant source stream and the receiving water stream (4):

- transport processes of contaminants from sources to receiving waters (advection, diffusion, volatization, atmospheric deposition)
- contaminant transformation processes from pollution source to receiving waters
- the timescale on which dominant processes operate
- the spatial scale on which dominant processes operate
- the factors governing these time and space rates
- the existing data providing information about the above
- the missing data needed to be collected
- the models that can be used to represent the processes and to explore contaminant control and water management change scenarios.

$$\begin{aligned}&\text{Rate of contaminant mass increase in water}\\&\text{(or any bounded space)} = \text{rate of mass input}\\&- \text{rate of mass output} + \text{rate of mass created}\\&\text{internally} - \text{rate of mass lost internally}\end{aligned}\tag{1}$$

Under different hydrologic conditions, the relative contribution to pollution loading by nonpoint versus point sources can change dramatically. For example, agricultural sources of nutrients and urban runoff sources of hydrocarbons may become dominant during storms compared to factory effluents and sewage treatment effluents that dominate pollution loading in dry conditions. Figure 2 provides a useful schematic framework for sampling/monitoring water and wastewater flows.

TEMPORAL CONSIDERATIONS—WHEN AND HOW OFTEN TO SAMPLE

Watershed assessments can be simple or detailed; the latter require more data collected over an extended period of time. Simple assessments (taking weeks) can be used to design more detailed ones (taking months or years) or are used when there are extreme constraints on resources that can be applied (the case in many poor countries). The following conditions require a detailed assessment (4):

- high variability in water quality and quantity in time and/or space;
- receiving waters for pollution are complex (e.g., large lakes, rivers, nonuniform aquifers), requiring two- or three-dimensional sampling over time;

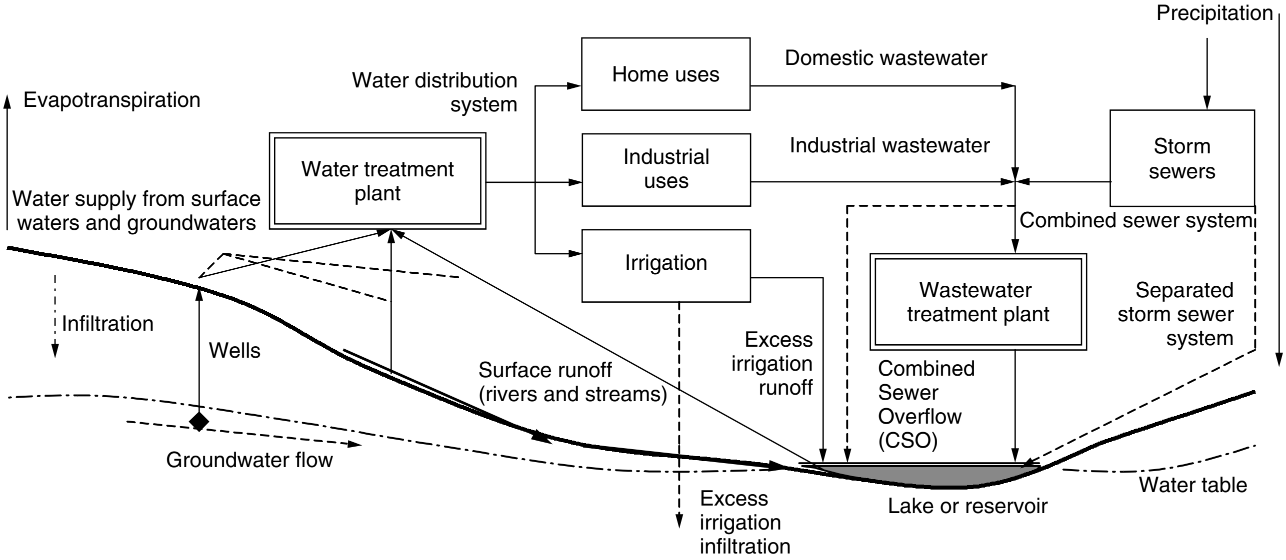

Figure 2. Water and wastewater flows to and from receiving waters. A full hydrologic picture is needed to assess where sampling of water quality and quantity should occur for baseline (preaction) characterization and where sampling should be done to monitor the performance of contaminant controls and water management actions (expanded from Ref. 3).

- existing data are insufficient to model the impacts of management alternatives on the water resources; and/or
- complex supply and sanitation systems need to be modeled to optimize their performance under varying conditions (e.g., treatment plants that have multiple unit process stages between influent and effluent).

Contaminants are sampled and monitored to determine the nature and magnitude of contamination and the sources of it. Simple assessments rely largely on existing data; detailed water quality assessments involve considerable field sampling to estimate the hydrograph (flow vs. time) and its associated pollutograph (pollution levels vs. time).

Sampling design is a statistical question. A hypothesis is posed, for example, "Groundwater contamination by arsenic (a highly toxic, naturally occurring substance that has potential cancer and noncancer health effects) represents a potential health risk (if enough water is consumed) because levels exceed health standards on the average." To test such hypotheses requires taking samples that allow us to estimate the 'real' variability of the values. Samples allow us to determine the sample mean (x_m) and sample variance (s^2), that are used to estimate the population/complete system's mean (μ) and variance (σ^2). The challenge, as in any sampling, is to characterize population variability using a representative sample. Sample statistics and a knowledge of the way values are distributed by probability (normally, log normally, or otherwise), allows us to accept or reject a hypothesis at a given confidence level. Detailed sampling methods for specific situations are given in Reference (10).

The minimal water quality sample requirements are three samples, representative of low, moderate, and high contaminant concentrations. But to gauge "representativeness" requires knowledge of variability. The goal of a good sampling program is to provide information to scientists and policy-makers on the following (4):

- probable maximum and minimum values;
- variability on different timescales (hours, days, months, years, decades as required);
- correlations with associated variables (hydrological, meteorological, pollutant production rates); and
- evidence about sources of contamination, environmental transport, and degradative/transformative processes.

Point-pollution sources, such as factories and sewage treatment plants, can be highly variable in time for the level (concentration as mass of contaminant per unit volume) and type (microbial, organic chemical, inorganic chemical, conservative, or nonconservative) of contaminants. Adding natural variability in environmental conditions and receiving waters (flow rates, temperatures, pH, other contaminant levels), it is evident that data quality and reliability are highly sensitive to the sampling regime selected.

Samples are either discrete or composite. If sampling seeks merely to estimate average levels of contaminants in water or wastewater, composite samples can save time by combining subsamples (aliquots) of discrete samples together. However, information about variability (mean, median, mode, variance, ranges, 90–95% confidence intervals, probability distributions) is lost, and it is these data that are most relevant to risk assessments and management policy. There are important trade-offs between sampling/monitoring costs and information value. Clear sampling/monitoring objectives must guide the optimization of this trade-off.

Rapidly changing conditions of water quantity and quality over time often call for flow- or quality-sensitive sampling: the higher the variability, the higher the sampling frequency. Under such conditions, it is desirable to monitor the qualities and quantities of contaminant sources (wastewater flows) and receiving waters simultaneously.

WATER QUALITY INDICATORS—CRITERIA FOR SAMPLING/MONITORING PARAMETERS

It is helpful to classify water contaminants into eight groups: pathogens, oxygen-demanding wastes, nutrients, salts, thermal pollution, heavy metals, pesticides, and volatile organic compounds (11). Each water use has quality requirements monitored by these indicators.

Pathogens (Disease-Causing Organisms)

These belong to four main groups:

1. bacteria—causing diseases like cholera, bacillary dysentery (shigellosis), typhoid, and paratyphoid fever;
2. viruses—diseases including infectious hepatitis, poliomyelitis;
3. protozoa—causing amoebic dysentery, giardiasis, and cryptosporidiosis;
4. helminths (parasitic worms)—causing schistosomiasis, and dracunculiasis (guinea worm)

There are four main types of water pollution diseases: waterborne (by ingestion); water-washed (lack of clean water for washing); water-based (involve water contact, no ingestion); and water-related (pathogen host relies on water habitat; humans need no water contact).

Oxygen-Demanding Wastes (ODWs)

Dissolved oxygen (DO) is a primary water quality indicator (8 mg/L needed for coldwater fish; 5 mg/L often used for others) and a saturation value 8–15 mg/L (depending on temperature, salinity). ODWs oxidize in receiving waters as bacteria use oxygen to degrade them. As DO drops, aquatic life is threatened, and odors, tastes, and color become undesirable. ODWs are mainly biodegradable wastes from households and livestock and effluents from food processing and paper production. The wastewater indicators are chemical oxygen demand (COD)—the amount of oxygen needed to oxidize wastes chemically—and biochemical oxygen demand (BOD)—the amount needed by microbes. The BOD of a diluted wastewater sample after 5 days (BOD_5) is used to measure the performance of wastewater treatment plants (WWTPs).

Nutrients

The chemicals essential to life—nitrogen (N), phosphorus (P), carbon (C), calcium (Ca), potassium (K), iron (Fe), manganese (Mn), boron (B), and cobalt (Co)—are viewed as contaminants when their levels allow excessive algal growth and compromise drinking uses, recreation, and habitat for other species. Nutrient enrichment occurs by *eutrophication*, important in lakes. C, N, and P are the most important nutrients. The limiting nutrient controls growth, and it is usually N in seawaters and P in freshwaters. Major N sources are WWTPs, animal feedlot runoff, chemical fertilizers, and N deposits from polluted air. NO_3 (nitrate) is the most common form in water. P is limited in nature, but human actions contribute it: runoff of fertilizers and domestic sewage (feces and detergents).

Salts

Dissolved solids, cations, anions—total dissolved solids (TDS)—is the indicator used: TDS <1500 mg/L is freshwater, 1500–5000 mg/L is brackish water, and saline water is >5000 mg/L. Seawater has 30–34,000 mg/L TDS. Drinking water levels must be <500 mg/L for humans but can be higher for livestock. Irrigation waters with TDS >500 mg/L and poor drainage can lead to salt buildup in soils that affect crops. Water is unsuitable for irrigation above 2100 mg/L.

Thermal Pollution

Cooling waters from power plants change water temperature, affecting aquatic species. Warming benefits some species over others, but power outages create sudden drops in temperature. Increases in temperature increase organism metabolic rates so oxygen demand goes up, waste degradation rates also go up, and the amount of DO that water can hold drops. All these factors mean that DO is drawn down.

Heavy Metals

These elements give up one or more electrons in aqueous solution to form cations (X^{n+}). "Heavy" means that the specific gravity is >4–5. Those most important for environmental impact are mercury (Hg), lead (Pb), cadmium (Cd), and arsenic (As). Metals are nondegradable and become toxic above trace levels.

Pesticides

Insecticides, herbicides, rodenticides, and fungicides are of three main chemical groups: organochlorines (OCPs or chlorinated hydrocarbons, e.g., DDT, Kepone®, aldrin, dieldrin), organophosphates (OPPs, e.g., parathion, malathion, diazinon), and carbamates (e.g., aldicarb). OCPs are persistent and tend to bioaccumulate in fatty tissue. OPPs are not persistent, but they are more acutely toxic to humans than OCPs. Carbamates are also short-lived and of high acute toxicity to humans.

Volatile Organic Compounds (VOCs)

Their high volatility means we find low levels in surface waters (a few μg/L), but when released as solvent waste into soil, they migrate to groundwater, and levels can be 100–1000 times surface water levels. Five VOCs are very toxic: vinyl chloride (VC), tetrachloroethylene (PCE), trichoroethylene (TCE), 1,2-dichloroethane (metal degreaser), and carbon tetrachloride (household cleaner, grain fumigant, solvent). VC is a known human carcinogen that is used in the production of PVC resins. TCE, a solvent cleaner used on engines, electronics, even septic tanks, is the most common groundwater contaminant in the United States.

WATER QUALITY STANDARDS—U.S., EUROPEAN UNION, AND WORLD HEALTH ORGANIZATION

Water quality (and treatment) standards depend on the usage of the water—drinking, recreational, industrial, agricultural, hydroelectric, or ecological.

World Health Organization (WHO) Standards

WHO standards are used as the reference for all national standards (12,13). There are five types of sampling/monitoring parameters:

1. Bacteriological: *E. coli* or thermotolerant coliform bacteria and total coliform bacteria must not be detectable in drinking water anywhere in the distribution system (once leaving the treatment plant).
2. Inorganic chemical (levels in mg/L): 19 inorganics.
3. Organic chemical (levels in μg/L): 11 classes of organic substances: (i) chlorinated alkanes (five parameters, e.g., dichloromethane); (ii) chlorinated ethenes (five, e.g., vinyl chloride); (iii) aromatic hydrocarbons (six, e.g., benzene); (iv) chlorinated benzenes (five, e.g., 1,2-dichlorobenzene); (v) miscellaneous organics (nine, e.g., acrylamide); (vi) pesticides (30, e.g., lindane); chlorophenoxy herbicides (six, e.g., 2,4-DB); (vii) disinfectants (five, e.g., chlorine); (viii) disinfectant by-products (12, e.g., bromoform); (ix) chlorinated acetic acids (five, e.g., dichloroacetic acid); (x) haloacetonitriles (six parameters, e.g., chloropicrin).
4. Radionuclide (Bq/L): gross alpha-particle and gross beta-particle activity screening levels.
5. Secondary physicochemical "nuisance" parameters: 18 inorganic/physical parameters (e.g., iron, copper, color, turbidity); and 13 organics.

Standards for carcinogens, such as the pesticide alachlor, are given as levels for a given acceptable risk, based on the precautionary assumption that any exposure to a carcinogen has a finite risk.

European Union Standards

Domestic Supply. In the European Union (EU), raw surface waters intended for domestic supply (the most stringent quality) are placed into three categories—A1, A2, A3—based on the sampling of 46 parameters from pH, odor, through metals, organics, nitrate, nitrogen, ammonia, to total and fecal coliforms, fecal streptococci and *Salmonella*. Each category has a guide limit and a (higher) mandatory limit, and each must undergo different water treatment, ranging from simple physical treatment and disinfection (A1), through normal physicochemical treatment and disinfection (A2), to intensive physicochemical treatment and disinfection (A3) (14). Once the waters have been treated, drinking water must be sampled and monitored to meet the new (1998) EU drinking water standard grouped as follows (15):

- Microbiological monitoring: Tap water—*E. coli* and enterococci (both 0/100 mL); water for sale in bottles and containers—*E. coli* and enterococci (both 0/250 mL), bacterial colony counts at 22 °C (100/mL), 37 °C (20/mL), *Pseudomonas aeruginosa* (0/250 mL).
- Chemical monitoring: 26 parameters—acrylamide, antimony, arsenic, benzene, benzo(a)pyrene, boron, bromate, cadmium, chromium, copper, cyanide, 1,2-dichloroethane, epichlorohydrin, fluoride, lead, mercury, nickel, nitrate, nitrite, specified pesticides, total specified pesticides, specified polyaromatic hydrocarbons (PAHs), selenium, tetrachloroethene plus trichloroethane, total specified trihalomethanes, and vinyl chloride.
- Indicator monitoring parameters: aluminum, ammonium, chloride, *Clostridium perfringens*, color, conductivity, pH, iron, manganese, odor, sulfate, sodium, taste, bacterial colony count, coliform bacteria, total organic carbon, turbidity, tritium (radioactivity), and total indicative radiation dose.

Sampling is done exclusively at consumers' taps under the EU Directive (98/83/EEC).

Surface Waters Not Used Primarily for Supply. The EU Freshwater Fish Directive specifies 14 physicochemical parameters to protect salmonid and cyprinid waters: temperature (where there is a thermal discharge), dissolved oxygen, pH, suspended solids, biochemical oxygen demand, total phosphorus, nitrite, phenolic compounds, petroleum hydrocarbons, nonionized ammonia, total ammonium, total residual chlorine, total zinc, and dissolved copper. Guide and mandatory values are given. The EU also has a Bathing Water Directive (76/110/EEC) for inland and coastal waters. Coastal and estuarine waters are monitored using these physicochemical and microbial water quality parameters, most sampled every two weeks or more frequently when water quality is compromised (15):

- Microbiological: total coliforms, fecal coliforms, fecal streptococci, *Salmonella*, entero viruses;
- Physicochemical: pH, color, mineral oils, surfactants that react with methylene blue, phenols, transparency, dissolved oxygen (% saturation), tarry residues and floating debris, ammonia, nitrogen (Kjeldahl), plus any other substances chosen as appropriate indicators of pollution (site specific).

Wastewaters. The EU monitoring of wastewaters is broken into toxic, persistent, and potentially bioaccumulating substances (black list) and less toxic substances or those whose effects are confined to a limited area depending on the nature of the receiving water (gray list). The Dangerous Substances Directive provides for monitoring the following parameters in wastewater streams:

- List 1 ("black" list): organohalogen compounds (or substances that may form them in aquatic environments), organophosphorus compounds, organotin compounds, carcinogens in the aquatic environment (from gray list), mercury and its compounds, cadmium and its compounds, persistent mineral oils and petroleum hydrocarbons, and persistent synthetic substances.
- List 2 ("gray" list): metalloids/metals and their compounds, biocides and their derivatives, substances that adversely affect taste and odor, toxic/persistent silicon compounds (or substances that may form them in aquatic environments), inorganic compounds of phosphorus and elemental phosphorus, nonpersistent mineral oils and petroleum hydrocarbons, cyanides, fluorides, and oxygen-depleting substances such as ammonia and nitrites.

Groundwaters. EU List 1 substances must be prevented from entering groundwaters, and pollution by List 2 substances must be strictly regulated and monitored. Strict hydrologic and environmental impact must be assessed before any listed substance can be licensed for disposal to groundwater in the EU.

U.S. Standards

U.S. Chemical Standards. In the United States, drinking water standards are of two types: (1) primary standards, specified as maximum contaminant levels (MCLs) derived from health concerns; and (2) unenforceable secondary standards based on taste, odor, color, hardness, and corrosivity. Maximum contaminant level goals (MCLGs) are levels that represent no anticipated health effects, including a margin of safety, regardless of attainment cost and feasibility. Inorganic substances that must be monitored (and for which there are MCLs in the U.S.) include toxic heavy metals (e.g. arsenic, cadmium, lead, mercury); nitrites (NO_2) and nitrates (NO_3); fluoride; and asbestos fibers. Organic chemical contaminants that have MCLs in the United States can be put in three groups (16):

1. Synthetic organic chemicals (SOCs)—used in the manufacture of agricultural and industrial products, such as insecticides and herbicides.
2. Volatile organic chemicals (VOCs)—synthetic substances that vaporize at room temperature. Examples include degreasing agents, paint thinners, glues, dyes. Specific examples include benzene, trichloroethylene (TCE), and vinyl chloride.
3. Trihalomethanes (THMs)—by-products of water chlorination, including chloroform, dibromochloromethane, and bromoform.

The levels are measured in milligrams per liter (mg/L). For the MCLs of primary drinking water contaminants regulated in the United States see (17,18).

U.S. Microbiological Standards. Instead of testing routinely for single pathogenic organisms, simpler tests are used that measure indicator organisms, principally coliform bacteria (e.g., *E. coli*), that indicate the contamination by fecal material. Levels of coliform bacteria in feces and untreated domestic wastewater are very high. In the United States, microbial standards require that for 'large' water supplies (serving more than 1000 people), no more than 5% of test samples can show any coliforms in smaller systems, testing less than 40 samples/month, no more than one sample can test positive (16). This method works when pathogen survival rates in water (outside their host) are less than those of coliforms. But nonbacterial pathogens—especially viruses, *Cryptosporidium* and *Giardia* cysts—often outlive coliforms and can be present when no coliform are detected. Treatment techniques for these contaminants are specified instead of MCLs in the United States. Coliform sampling is also used to monitor water-contact recreational water quality; typical standards are 1000 coliforms per 100 milliliters.

U.S. Radionuclide Standards. Naturally occurring radionuclide contaminants include radon and radium-226, often found in groundwater. Others, such as strontium-90 and tritium contaminate surface water after nuclear fallout. The levels are measured in picocuries per liter (pCi/L). Dissolved radon gas is the most prominent groundwater contaminant of this type. Colorless, odorless, and tasteless, the risk derives not from ingestion but from inhalation as it outgases from heated shower water.

WATER QUALITY MODELS: CHEMICAL PRINCIPLES

Zhen-Gang Ji
Minerals Management Service
Herndon, Virginia

Water quality represents the physical, chemical, and biological characteristics of water resources and is used to measure the ability of a waterbody to support beneficial uses. Eutrophication is a process of nutrient overenrichment of a waterbody, resulting in accelerated biological productivity (growth of algae and weeds). Symptoms of eutrophication include algal blooms, reduced water clarity, and oxygen depletion. In modeling studies, water quality and eutrophication are sometimes used interchangeably to represent the processes of waterbody enrichment by nutrients. Key state variables in water quality models include algae, nutrients, and dissolved oxygen (DO).

This entry focuses on water quality models. Information on applications of water quality models is provided in Water Quality Modeling—Case Studies.

ALGAE AND PHYTOPLANKTON

Algae are a group of aquatic microscopic plants that contain chlorophyll and grow by photosynthesis. Algae takeup nutrients, including phosphate, ammonium, nitrate, silica, and carbon dioxide, from water or benthic sediments and release oxygen to the water. Algae may be free-floating or rooted on the bottom of a waterbody. An overabundance of algae in a waterbody is known as eutrophication.

Phytoplankton are a group of tiny, free-floating plants transported by currents. In water quality modeling studies, phytoplankton are frequently referred to as free-floating algae and are often more important than rooted aquatic vegetation in the basic food production of an ecosystem. They are the most biologically active plants in aquatic ecosystems and generally have greater influences on water quality than other plants. Phytoplankton is also the most important element and the first stage in the food chain: it provides food for zooplankton, fish, and small aquatic animals.

NUTRIENTS

Nutrients are chemical elements or compounds necessary for algal growth. The essential nutrients include nitrogen, phosphorus, carbon dioxide, and silica. A host of other micronutrients, such as iron, manganese, potassium, sodium, copper, zinc, and molybdenum, are also required for algal growth. However, these minor nutrients are generally not considered in water quality modeling because they are needed only in trace amounts, and they are usually present in quantities sufficient for algal growth.

Excessive nutrient levels can be harmful to ecosystems by causing eutrophication and unwanted algal blooms. Major processes affecting nutrient concentrations include

1. algal uptake
2. mineralization and decomposition of dissolved organic nutrients
3. hydrolysis converting particulate organic substances into dissolved organic form
4. chemical transformations of nutrients
5. sediment sorption and desorption
6. settling of particulate matter
7. nutrient fluxes from benthic sediments
8. external nutrient loadings

The two nutrients of greatest concern are nitrogen and phosphorus. Nitrogen, one of the most abundant elements on the earth, makes up 78% of the earth's atmosphere as a gas. Nitrogen exists in these different forms:

1. organic nitrogen (ON)
2. ammonia (NH_3)
3. nitrite and nitrate ($NO_2 + NO_3$)
4. nitrogen gas (N_2)
5. algae
6. zooplankton and aquatic animals

Phosphorus is one of the vital nutrients for algal growth. However, too much phosphorus can cause excessive algal growth and can lead to eutrophication. Compared to nitrate (NO_3), phosphates dissolve less readily and tend to attach to sediment particles. Phosphorus exists in different forms, including

1. organic phosphorus
2. phosphates (largely orthophosphates—PO_4)
3. algae
4. zooplankton and aquatic animals

In modeling water quality processes, these are the major differences between nitrogen and phosphorus:

1. Unlike nitrogen, phosphorus does not have a gas phase, which can be a major nitrogen loss mechanism in certain aquatic systems.
2. Forms of inorganic nitrogen are easily dissolved in water; phosphates are often strongly sorbed to sediment. Therefore, phosphates can settle with sediment solids to the bottom of a waterbody, such as a lake or a reservoir, and become a phosphorous source to the waterbody. In many waterbodies, bottom sediments contain enough phosphorus to accelerate eutrophication, even after external sources have been terminated.

Figure 1 illustrates processes that affect nutrients in an aquatic system:

1. Physical transport: Nutrients are advected and dispersed within the water column and are transported into the system by inflow and out of the system by outflow.
2. Exchange with the atmosphere: Atmospheric deposition adds nutrients to a waterbody, and volatilization removes gaseous nutrients from the waterbody. Reaeration adds DO to the waterbody.
3. Sorption and desorption: Exchanges between particulate nutrients and dissolved nutrients are affected by the total suspended solid concentrations and the partition coefficients.
4. Reaction and algal uptake: Chemical reactions and algal uptake transform nutrients and reduce the concentrations of dissolved nutrients.
5. Exchange on the bed–water interface: Dissolved nutrient is exchanged between the sediment bed and the water column via diffusion, and the particulate nutrient can be settled onto or be resuspended from the bed, depending on flow conditions.
6. Sediment diagenesis: In the sediment bed, sediment diagenesis can be a significant factor in nutrient cycling and oxygen balance in the water column.

Note that not all processes shown in Fig. 1 are essential to every nutrient. For instance, volatilization is insignificant to phosphorus cycling, and sorption and desorption are not essential to nitrogen transformation.

DISSOLVED OXYGEN

Dissolved oxygen, the amount of oxygen that is dissolved in water, is one of the most important parameters of water quality. Most fish and aquatic insects need DO to survive. Fish, especially larvae, die when DO levels get too low. Low DO is a sign of possible pollution in a waterbody. As DO levels in water drop below 5.0 milligrams/liter (mg/L), aquatic life is put under stress. The lower the concentration, the greater the stress. Low DO levels for a prolonged period can result in large fish kills.

Oxygen enters water by reaeration from the atmosphere and by plant photosynthesis. Oxygen concentrations in the water column fluctuate under natural conditions, but severe oxygen depletion usually results from human pollution. Figure 2 shows the measured DO for 20 months from November 1992 to June 1994 in Lake Wister, Oklahoma (1). The lake exhibits strong seasonal DO variations. During the winter months (November, December, and January), DO in the lake is high; values are around 10 mg/L, and it is well mixed vertically. In the summer, DO is very stratified; values are less than 1.0 mg/L in the lower portion of the lake (water depth from 9 to 18 m), whereas the surface DO can still be 8 mg/L or higher. This large DO gradient in the vertical is caused primarily by temperature stratification of the lake, biochemical processes in the water column, and benthic oxygen demand at the lake bottom.

WATER QUALITY MODELS

Variations in water quality variables, such as algae, nutrients, and dissolved oxygen, are often described by

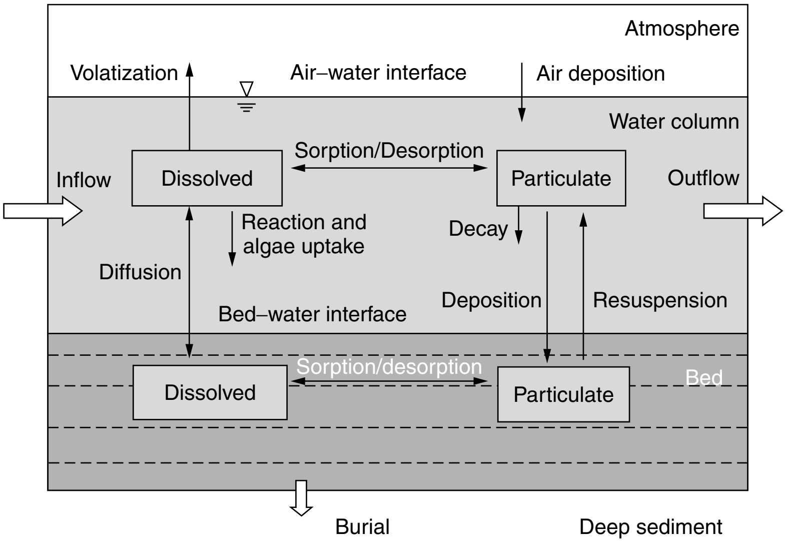

Figure 1. Processes of nutrient transformation.

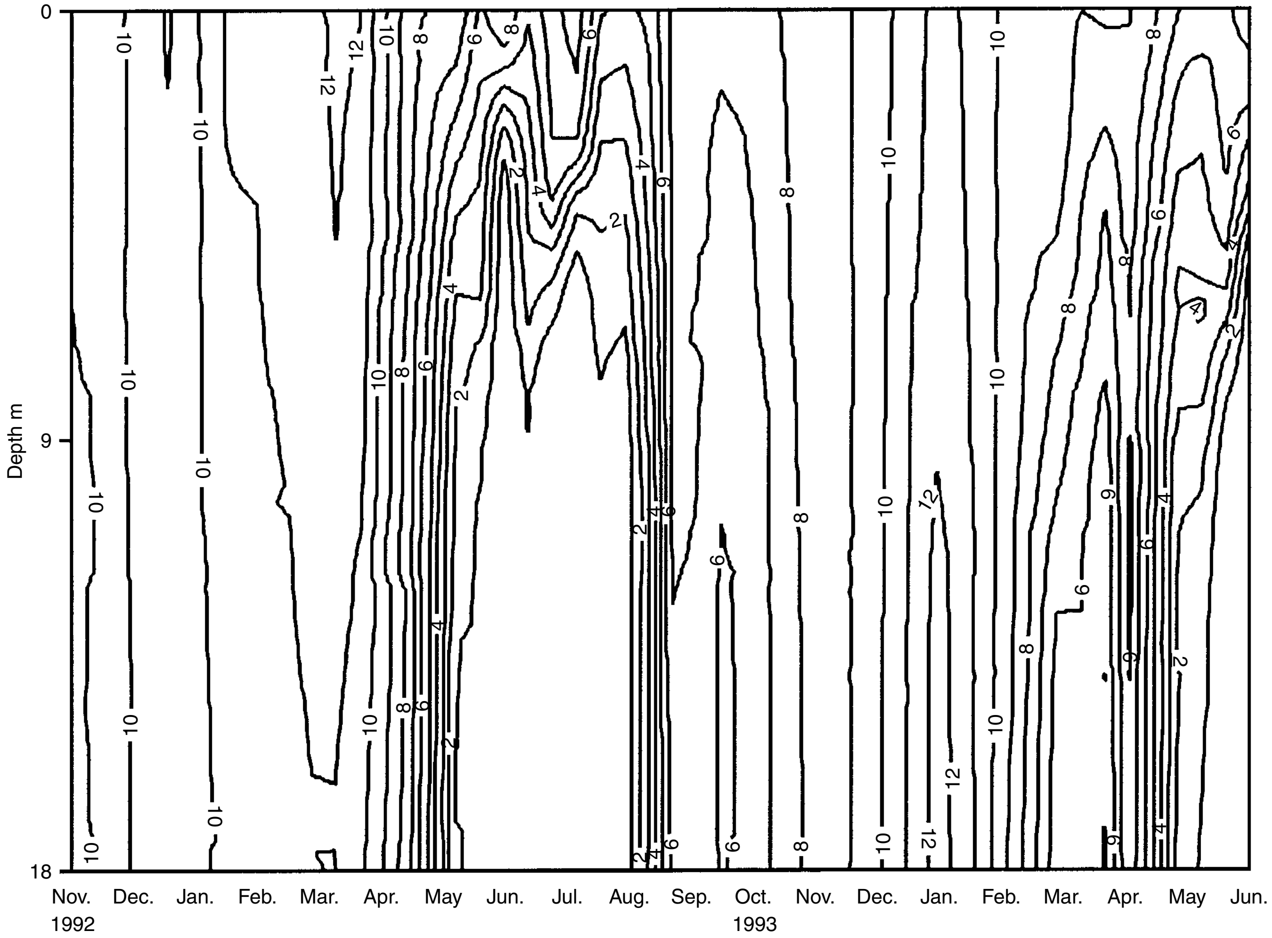

Figure 2. Dissolved oxygen (mg/L) in Lake Wister (1).

using a set of mass conservation equations in a water quality model. The conservation of mass accounts for all material entering or leaving a waterbody; transport of material within the waterbody; and physical, chemical, and biological transformations of the material. Therefore, all governing equations for water quality processes have a form similar to

$$\frac{\partial C}{\partial t}+\frac{\partial (uC)}{\partial x}+\frac{\partial (vC)}{\partial y}+\frac{\partial (wC)}{\partial z}=\frac{\partial}{\partial x}\left(K_x\frac{\partial C}{\partial x}\right)+\frac{\partial}{\partial y}\left(K_y\frac{\partial C}{\partial y}\right)+\frac{\partial}{\partial z}\left(K_z\frac{\partial C}{\partial z}\right)+S_{\mathrm{C}} \tag{1}$$

where C = concentration of a water quality state variable

u, v, w = velocity components in the x, y, and z directions, respectively

K_x, K_y, K_z = turbulent diffusivities in the x, y, and z directions, respectively

S_{C} = internal and external sources and sinks per unit volume

Equation 1 incorporates transport due to flow advection and dispersion, external pollutant inputs, and kinetic interaction among water quality variables. The last three terms on the left-hand side of Equation 1 account for advection transport. The first three terms on the right-hand side of Equation 1 account for diffusion transport. The term S_{C} represents kinetic processes and external loads.

In water quality models, kinetic processes are often decoupled from physical transport processes. By linearizing S_{C} with respect to C, the equation for kinetic processes and external loadings, called the kinetic equation, is

$$\frac{\partial C}{\partial t}=S_{\mathrm{C}}=k\times C+R \tag{2}$$

where k = kinetic rate (time^{-1})

R = source/sink term due to external loadings and/or internal reactions (mass volume^{-1} time^{-1}).

The governing equations, Equations 1 and 2, are widely used in water quality models. Water quality and eutrophication processes are very complicated. Even though all kinetic equations are based on mass-balance equations, empirical formulations are often used as approximations for specifying model parameters, such as k and R. Therefore, for the same water quality process, there might be a variety of ways to describe it mathematically. The major differences among water quality models are

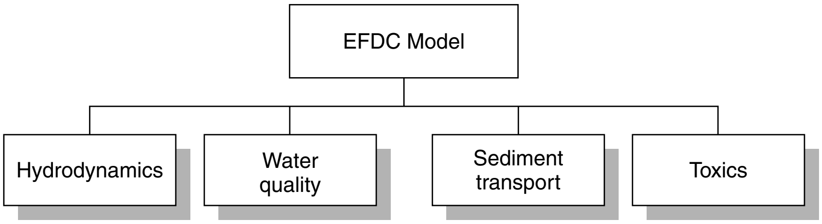

Figure 3. Primary modules of the EFDC model.

primarily in the way the kinetic equations are specified, how many nutrients are considered, and how many state variables are used to describe each nutrient cycle. Mathematical expressions of these terms can vary from model to model (such as References 2 and 3).

A water quality model typically has the following water quality variable groups:

1. algae
2. organic carbon
3. phosphorus
4. nitrogen
5. silica
6. other water quality variables

Each group may consist of several state variables, representing different components of the group. For example, a nutrient can be dissolved, particulate, refractory, or labile.

A water quality model is a discretized version of a set of differential equations, such as Equations 1 and 2, that describe processes in a waterbody. The discretized set of equations is converted into computer code, so that numerical solutions of the model can be derived by computer.

Numerical models span a wide variety of approaches and levels of sophistication and are typically categorized in terms of their representation of space and time:

1. steady-state or time-dependent (dynamic)
2. zero-, one-, two, or three-dimensional

The temporal characteristics indicate whether the model is steady-state (inputs and outputs constant over time) or time-dependent (dynamic). A steady-state model uses constant values of input variables to produce time-independent results, in which the state variables are independent of time. In contrast, a time-dependent model describes the temporal variability of a waterbody.

Since the 1990s, three-dimensional hydrodynamic and water quality modeling has matured from a research subject to a practical analytical technology. The rapid development of the computer industry provides more and more powerful computing ability for numerical simulation. Computational requirements for realistic three-dimensional modeling have changed from supercomputers and high-end workstations to desktop personal computers. Water quality models are more and more widely used in water resource management (4,5).

A variety of water quality models have been developed for modeling rivers, lakes, estuaries, and coastal areas. They can be categorized as

1. One-dimensional and steady-state models. They are one-dimensional in space and do not vary with time, such as the QUAL2E model (2).
2. Two-dimensional and time-dependent models. They are two-dimensional in space and time-dependent, such as the laterally averaged W2 model (6).
3. Comprehensive models. They are (1) three-dimensional in space and time-dependent, (2) with a hydrodynamic submodel to provide physical transport to the water quality submodel, and (3) coupled with a sediment diagenesis submodel to calculate sediment fluxes from the benthic sediments. The Environmental Fluid Dynamics Code (EFDC) (7,8), supported by the U.S. Environmental Protection Agency, is in this category. The primary modules of the EFDC model are shown in Fig. 3, which indicates submodels for hydrodynamics, water quality process, sediment transport, and toxic processes.

WATER QUALITY MODELS: MATHEMATICAL FRAMEWORK

K.W. Chau
The Hong Kong Polytechnic University
Hung Hom, Kowloon, Hong Kong

INTRODUCTION

In recent decades, accompanying agricultural and industrial development and population growth, it has often been observed that an increasing tendency exists for some water bodies, for example, the North Sea (1), along the coast of Brittany to marine waters (2), some rivers in western North America (3), the Chesapeake Bay in the United States (4), and the coastal waters in Hong Kong (5–7), to exhibit increases in the severity and frequency of algae blooms and growth of aquatic weeds apparently as a result of elevated levels of nutrients, including nitrogen and phosphorus. Many of these problems, including bottom-water anoxia, decline in fisheries, and loss of submerged aquatic vegetation, are associated with the deteriorated water quality caused by eutrophication.

Water quality models are employed to describe the balance of mass and energy within an aquatic ecosystem. The problem can be defined as the input of polluting materials including organic and inorganic nutrients into a water body that stimulate the growth of algae or rooted aquatic plants resulting in the interference with desirable water uses of aesthetics, recreation, fish maintenance, and water supply. This topic has been discussed extensively, and many studies, including water quality control and modeling, have been conducted (4,8). Initially, water quality modeling focused on seasonal steady-state conditions (9,10) and, later, time-varied modeling for an entire year was explored with reasonable success (11). Nowadays, the forefronts of water quality modeling are the integration of hydrodynamic and water quality models and the development and incorporation of sediment layers to investigate the long-term recovery of an aquatic ecosystem (4,12,13).

TYPICAL MODEL FRAMEWORK

Typically, in an ecosystem under an aquatic environment, several physical, chemical, biochemical, and biological processes can affect the transport and interaction among the nutrients, dissolved oxygen (DO), phytoplankton, zooplankton, and carbonaceous material (10). The mass and energy transformations are regulated by processes such as growth, respiration, mortality, and decomposition; these in turn are governed by environmental quality parameters such as temperature, toxicity, and nutrient concentrations. The principal variables of importance then in the analysis of eutrophication are as follows:

1. Solar radiation at the surface and with depth, water temperature, and chloride
2. Geometry of water body
3. Flow, velocity, diffusion, and dispersion
4. Nutrients: phosphorus, nitrogen, silica, and so on
5. Phytoplankton, zooplankton, and so on

As shown in Fig. 1, the system is highly coupled, and energy and mass balance for individual constituents are invariably linked to several others. A system of state variables, including organic parameters (carbon, nitrogen and phosphorus), inorganic parameters (DO, ammonia nitrogen, nitrite + nitrate nitrogen, and orthophosphate), and biological constituents (phytoplankton and zooplankton), is used to develop an unsteady multilayered two-dimensional or even three-dimensional water quality model. It should be recognized that the nutrients above are present in several forms in the water body, and not all forms are readily available for uptake by phytoplankton nor are limited nutrients for growth of phytoplankton. In the system, ammonia, nitrite + nitrate, and orthophosphate are taken as the available nutrients uptaken by phytoplankton (13). Moreover, available historical field data of solar radiation intensity, layer-averaged water temperature, and salinity are often taken as the known variables that will mainly affect some parameters and the saturated DO.

GOVERNING EQUATIONS

Because of the difficulty in obtaining regular, high-frequency spatial and temporal field data with reasonable accuracy, it is almost improbable to select a unique correct formulation for a specific process in an ecosystem. Such difficulties can partly be overcome by examination of the actual processes in the laboratory, but this is only, as indicated, partly a solution, because the processes in the ecosystem can never be isolated from their environments and it is impossible to take into account all natural coupling mechanisms. Consequently, each process has several alternative mathematical formulations that, at this stage of ecological modeling, are equally valid to a certain extent.

A water quality model is established to solve the partial differential equations describing conservation of mass and momentum of incompressible fluid and pollutants over the depth of each layer. The layer-averaged water quality variables and transport equations of pollutants solved in the model are defined and derived in a similar way to those of the hydrodynamic model. The hydrodynamic and water quality models are run simultaneously. The water quality algorithms are integrated directly into the hydrodynamic

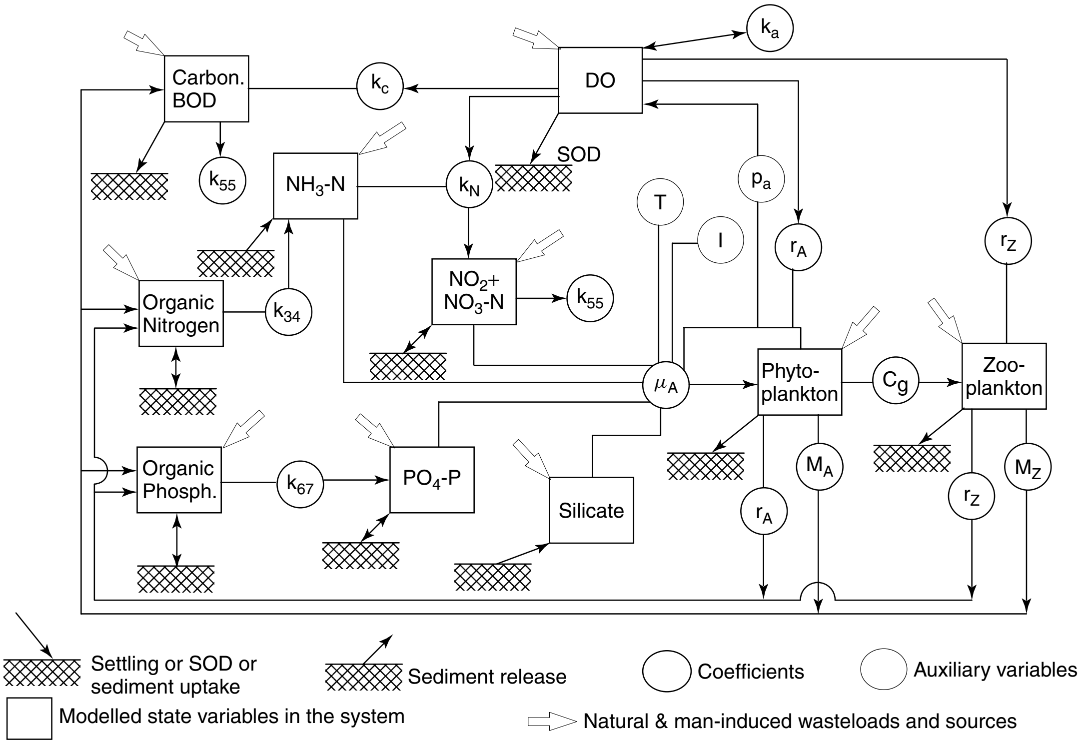

Figure 1. State variable interactions in a water quality model.

model, so that they share the same computational grid and time steps. The water body can be very irregular on the lateral topography and includes some small side cove. To adapt the complicated boundaries of the water body, a boundary-fitted orthogonal curvilinear grid system can be employed. It can be generated numerically by solving two elliptical equations (14). A grid "block" technique (15,16) has been introduced to overcome the computational difficulty caused by the unsteady fluctuation of the water surface level.

In the following sections, subscript "u" and "l" of all variables mean the value in the upper and the lower layer, respectively, and subscript "0", "s", and "b" denote the value at the layer interface, at the free water surface, and at the bed, respectively. Subscript k is the index of layer: $k = u$ or l. Notation $X_{y,20}$ designates the value of X_y at temperature 20 °C, and θ is the corresponding temperature correction coefficient. In this way, the general differential transport equation for the layer-averaged concentration of each state variable in the boundary-fitted orthogonal curvilinear coordinate system is expressed as follows:

$$\frac{\partial(h_k\varphi_k)}{\partial t}+\frac{1}{g_{11}g_{22}}\left\{\frac{\partial}{\partial\xi}\left[g_{22}h_k\left(u_k^*\varphi_k-\frac{\Gamma_{\xi,k}}{g_{11}}\frac{\varphi_k}{\partial\xi}\right)\right]\right.$$
$$\left.+\frac{\partial}{\partial\eta}\left[g_{11}h_k\left(v_k^*\varphi_k-\frac{\Gamma_{\eta,k}}{g_{22}}\frac{\varphi_k}{\partial\eta}\right)\right]\right\}=\Phi_{\varphi,k} \qquad (1)$$

$$\Phi_{\varphi,k}=w_0\varphi_0+\mathrm{Flux}_{s,\varphi}-\mathrm{Flux}_{0,\varphi}+S_{\varphi,k} \qquad (2)$$

where u_k^* and v_k^* = kth-layer-averaged velocity components in $\xi - \eta$ orthogonal curvilinear coordinates; h_k = depth of kth layer; φ_k = kth-layer-averaged concentration of a state variable, and it may represent phytoplankton, DO, and so on; $\Gamma_{\xi,\kappa}$ and $\Gamma_{\eta,\kappa}$ = longitudinal and transverse dispersive coefficients, respectively, in the kth layer (17); g_{11} and g_{22} = coordinate transformation coefficients between Cartesian and orthogonal curvilinear coordinates (ξ,η); $S_{\varphi,k}$ represents reaction kinetics, settling, sediment release, and external sources and/or sinks in the kth layer, and its expression for each water quality variable is listed in Table 1; w_0 = vertical velocity at the layer interface (positive upward); and φ_0 = concentration of φ at the layer interface.

In this context, $\mathrm{Flux}_{s,\varphi}$, $\mathrm{Flux}_{b,\varphi}$, and $\mathrm{Flux}_{0,\varphi}$ are the vertical diffusive fluxes of φ across the water surface, the bed, and the layer interface, respectively. $\mathrm{Flux}_{s,\varphi}$ is assumed to be zero. Density stratification affects the mixing across the layer interface, and $\mathrm{Flux}_{0,\varphi}$ is derived as follows:

$$\mathrm{Flux}_{0,\varphi}=\left(\Gamma_m\frac{\partial\varphi}{\partial Z}\right)_{z=Z_0}\approx\Gamma_m\frac{\varphi_u-\varphi_l}{\delta},$$
$$\Gamma_m=\Gamma_{m0}(1+\beta_C\mathrm{Ri})^{\alpha_C},\ \Gamma_{m0}=\frac{\varepsilon_{m0}}{\sigma_t}, \qquad (3)$$

in which Γ_m = vertical flux diffusive coefficient, Γ_{m0} and $\varepsilon_{m0}(\approx \kappa\ h_l(1-h_l/h)u_*)$ = values of Γ_m and turbulent viscosity coefficient for the case without density stratification, respectively; h = total water depth; u_* = friction velocity; δ = mixing layer thickness at the interface and is approximated by $\delta \approx \kappa\ h_l(1-h_l/h)^{1/2}$. κ ($\approx$0.4) and σ_t ($\approx$0.9) are the von Kármán constant and turbulent Schmidt number, respectively; β_C (= 10/3) and α_C (= −1.5) are the empirical coefficients (18). Ri is a gradient Richardson number

Table 1. List of Notations and Source Terms for Water Quality Variables

Description	Notation	Sources and/or Sinks (S_φ)
(1) Phytoplankton (chlorophyll-*a*)	A (μg Chl-*a*/L)	$h(\mu_A - r_A - M_A)A - w_{\mathrm{SA}}A - hC_gAZ + S_A$
(2) Zooplankton (organic carbon equivalence)	Z (mg ZooplC/L)	$h(\alpha_2 \frac{K_Z}{K_Z + A} C_g \alpha_{12} A - r_Z - M_Z)Z - w_{\mathrm{SZ}}Z + S_Z$
(3) Organic nitrogen	N (μg N/L)	$h[f_{\mathrm{ON}}\alpha_{13}(r_A + M_A)A + f_{\mathrm{ON}}\alpha_{23}(r_Z + M_Z)Z$ $-k_{34}N] - w_{\mathrm{SN}}(1 - f_{\mathrm{DON}})N + \mathrm{SEDI}_N + S_N$
(4) Ammonia nitrogen	$\mathrm{NH_3}$ (μg N/L)	$h\{(1 - f_{\mathrm{ON}})[\alpha_{13}(r_A + M_A)A + \alpha_{23}(r_Z + M_Z)Z] + k_{34}N -$ $f_{\mathrm{pref}}\alpha_{14}\mu_A A - k_N\mathrm{NH_3}\} + \mathrm{SEDI}_{\mathrm{NH_3}} + S_{\mathrm{NH_3}}$
(5) Nitrite + nitrate nitrogen	$\mathrm{NO_{23}}$ (μg N/L)	$h[k_N\mathrm{NH_3} - (1 - f_{\mathrm{pref}})\alpha_{15}\mu_A A - k_{55}NO_{23}] + \mathrm{SEDI}_{\mathrm{NO_{23}}} + S_{\mathrm{NO_{23}}}$
(6) Organic phosphorus	P (μg P/L)	$h\{f_{\mathrm{OP}}[\alpha_{16}(r_A + M_A)A + \alpha_{26}(r_Z + M_Z)Z] - k_{67}P\} - w_{\mathrm{SP}}(1 - f_{\mathrm{DOP}})P +$ $\mathrm{SEDI}_P + S_P$
(7) Orthophosphate phosphorus	$\mathrm{PO_4}$ (μg P/L)	$h\{(1 - f_{\mathrm{OP}})[\alpha_{16}(r_A + M_A)A + \alpha_{26}(r_Z + M_Z)Z] - \alpha_{17}\mu_A A + k_{67}P\} -$ $w_{\mathrm{SPO_4}}(1 - f_{\mathrm{DOP_4}})PO_4 + \mathrm{SEDI}_{\mathrm{PO_4}} + S_{\mathrm{PO_4}}$
(8) Carbonaceous BOD	BOD (mg $\mathrm{O_2}$/L)	$h[2.67(\alpha_{18}M_A A + \alpha_{28}M_Z Z) - (k_C\mathrm{BOD} + \frac{5}{4}\alpha_{\mathrm{ON}}k_{55}\mathrm{NO_{23}})] -$ $w_{\mathrm{SBOD}}\mathrm{BOD} + S_{\mathrm{BOD}}$
(9) Dissolved oxygen	DO (mg $\mathrm{O_2}$/L)	$h\{k_a(\mathrm{DO}^s - \mathrm{DO}) - \alpha_{19}r_A A - \alpha_{29}r_Z Z + \mu_A[\alpha_{19} + \frac{48}{14}\alpha_{13}(1 - f_{\mathrm{pref}})]A -$ $(k_C\mathrm{BOD} + \alpha_{49}k_N\mathrm{NH_3})\} - \mathrm{SOD} + S_{\mathrm{DO}}$

Note: A in the equations for zooplankton, carbonaceous BOD, and DO is in mg Chl-*a*/L; Z in the equations for organic nitrogen, ammonia, organic phosphorus, and orthophosphate is in μg ZooplC/L; and $\mathrm{NH_3}$ in the equation for DO and $\mathrm{NO_{23}}$ in the equation for CBOD are in mg N/L.

at the layer interface and is calculated by

$$\mathrm{Ri} = -\frac{g}{\rho}\frac{\frac{\partial\rho}{\partial z}}{\left(\frac{\partial u}{\partial z}\right)^2} \approx \frac{\rho_l - \rho_u}{\rho}\frac{g\delta}{[(u_u^* - u_l^*)^2 + (v_u^* - v_l^*)^2]} \tag{4}$$

in which ρ_u and ρ_l = density of water in the surface and the bottom layer, respectively; ρ = averaged density of water column; and $g(= 9.81\ \mathrm{m/s^2})$ = acceleration due to gravity. Temporal water temperature and salinity are estimated from the field data.

The quantities of water quality variables decrease because of the corresponding settling—w_{SA}, w_{SZ}, w_{SN}, w_{SP}, $w_{\mathrm{SPO_4}}$, and w_{SBOD} (m/day). The algal growth relates to many factors, including available nutrients, water temperature, solar radiation, zooplankton grazing, and tidal flushing. Organic nitrogen undergoes a bacterial decomposition whose end product is ammonia ($\mathrm{NH_4}$-N). Organic phosphorus converts to $\mathrm{PO_4}$-P by mineralization. Ammonia nitrogen, in the presence of nitrifying bacteria and oxygen, is converted to $\mathrm{NO_3}$-N (k_N). Denitrification (k_{55}) occurs under anaerobic conditions and CBOD decreases because of stabilization (k_C). Both $\mathrm{NH_4}$ and $\mathrm{NO_2 + NO_3}$ are available for algae uptake, although the preferred form is $\mathrm{NH_4}$-N for physiological reasons. The ammonia preference is described by a factor f_{pref} (9):

$$f_{\mathrm{pref},k} = \frac{\mathrm{NH}_{4,k}}{K_{\mathrm{mNN}} + \mathrm{NO}_{23,k}} \times \left(\frac{\mathrm{NO}_{23,k}}{K_{\mathrm{mNN}} + \mathrm{NH}_{4,k}} + \frac{K_{\mathrm{mNN}}}{\mathrm{NH}_{4,k} + \mathrm{NO}_{23,k}}\right) \tag{5}$$

A by-product of photosynthetic carbon fixation is the production of DO. An additional source of oxygen from algal growth occurs when the available ammonia nutrient source is exhausted and the phytoplankton begins to use the available nitrate. For nitrate uptake, the initial step is a reduction to ammonia, which produces oxygen. DO also increases by atmospheric re-aeration (k_a, day^{-1}) because of the deviation from the saturation concentration DO^s (mg $\mathrm{O_2}$/L) (19). The re-aeration rate in natural waters depends on internal mixing and turbulence caused by velocity gradients and fluctuation, temperature, wind mixing, waterfalls, dams, rapids, surface films, and so on. It is expressed in the following forms:

$$k_a = k_{a,20}\theta^{T-20}, \theta = 1.005 \sim 1.030 \approx 1.024 \tag{6}$$

$k_{a,20}$ represents re-aeration as a function of velocity and depth, with the following formula (19):

$$k_{a,20} = \begin{cases} \dfrac{3.9\ V^{0.5}}{h^{1.5}} & \text{when } W < 6.0\ \mathrm{m/s} \\ \dfrac{3.9\ V^{0.5}}{h^{1.5}} + \dfrac{0.728W^{0.5} - 0.317W + 0.0372W^2}{h} & \text{when } W \geq 6.0\ \mathrm{m/s} \end{cases} \tag{7}$$

$$\ln \mathrm{DO}^s = -139.3441 + \frac{1.5757 \times 10^5}{T + 273.15} - \frac{6.6423 \times 10^7}{(T + 273.15)^2} + \frac{1.2438 \times 10^{10}}{(T + 273.15)^3} - \frac{8.6219 \times 10^{11}}{(T + 273.15)^4} - S\left[1.7674 \times 10^{-2} - \frac{1.0754 \times 10}{T + 273.15} + \frac{2.1407 \times 10^3}{(T + 273.15)^2}\right] \tag{8}$$

where V is velocity of flow in meters/second; W is wind speed in meters/second at 10 m above water surface (it will be taken into account when wind speed $W \geq 6$ m/s); and T ($^\circ$C) and S (ppt) are the relevant water temperature and salinity. A minimum value of 1.6/h is imposed on $k_{a,20}$ (9).

Moreover, an adsorption–desorption interaction occurs between dissolved inorganic phosphorus and suspended particulate matter in the water column. The subsequent settling of the suspended solids together with the sorbed inorganic phosphorus can act as a significant loss mechanism in the water column and is a source of phosphorus to the sediment.

Table 2 lists typical kinetic parameters used in water quality models from the literature (9,19,20). The growth and proliferation of phytoplankton is a result of the utilization and conversion of inorganic nutrients into organic plant material through photosynthesis. μ_A depends on three principal components: (1) temperature—T, (2) solar radiation—I, and (3) nutrients—N_{nutri}. Multiplicative effects are assumed, that is, $\mu_A = f(T, I, N_{\text{nutri}}) = g(T)g(I)g(N_{\text{nutri}})$.

The relationship with temperature is as follows:

$$g(T)_k = \mu_{A,k}^{\max} = \mu_{A,20}^{\max}\theta^{T_k - 20} \tag{9}$$

where $\mu_{A,20}^{\max}$ = maximum growth rate of phytoplankton at 20 °C under optimal light and nutrient conditions in the kth layer. The light-limitation function, represented by $g(I)$ over a given water depth of layer (h_k), is approximately integrated as follows (19):

$$g(I)_k = \frac{1}{h_k}\int_{h_u}^{h_u+h_k} \frac{I}{I_s} e^{(1-I/I_s)} dz = \frac{2.718}{\gamma_k h_k}[e^{-\alpha_2} - e^{-\alpha_1}]$$

$$\alpha_2 = \alpha_1 e^{-\gamma_k h_k}, \alpha_0 = \frac{I_0}{I_s}, \alpha_1 = \alpha_0 e^{-\gamma_u h_u} \tag{10}$$

$$\frac{dI}{dz} = -\gamma_k I, \quad I = I_0 \text{ @ } z = 0$$

and z-axis is upward vertically

where I, I_0, and I_s = light intensity at depth z, incoming solar radiation intensity just below the surface, and saturating light intensity (the optimum light intensity at which the relative photosynthesis is a maximum), respectively; and γ_κ = overall extinction coefficient in m^{-1}. Phytoplankton may adjust its chlorophyll composition to adapt to the changes in solar radiation. Therefore, I_s is determined to be the weighted average of the light intensity for the previous 3 days as follows: $I_s = 0.7I_1 + 0.2I_2 + 0.1I_3$, where $I_i = 0.5\times$ [daily average visible light intensity beneath the surface] i days earlier (20). The annual average of daily solar radiation intensity is used in the modeling.

The minimum value of nutrient limitations computed by Michaelis–Menten-type expression is chosen for

Table 2. Typical Kinetic Parameters Used in Water Quality Models

Parameters	Description	Value (and θ)
$\mu_A^{\max}$	Maximum phytoplankton growth rate	2.10 (1.066)
K_{mNN}	Half-saturation constant for nitrogen uptake	15.0
K_{mNP}	Half-saturation constant for phosphorus uptake	1.50
r_A	Endogenous respiration rate of phytoplankton	0.05 (1.08)
M_A	Nonpredatory mortality rate of phytoplankton	0.10
C_g	Grazing (filtering) rate of zooplankton	0.30 (1.066)
r_Z	Endogenous respiration rate of zooplankton	0.02 (1.045)
M_Z	Mortality rate of zooplankton	0.10
α_{12}	Assimilated carbon per unit algae mass ingested (average CCHL)	112.5
α_2	Zooplankton assimilation efficiency	0.6
K_Z	Half-maximum-efficiency food level for zooplankton filtering	12.0
k_{34}	Conversion efficiency of organic nitrogen to ammonia nitrogen	0.05 (1.08)
α_{13}	Stoichiometric ratio of cell nitrogen to algae chlorophyll-a	10.0
α_{23}	Stoichiometric ratio of cell nitrogen to zooplankton carbon	α_{13}/CCHL
k_N	Nitrification rate of ammonia to nitrate via nitrite nitrogen	0.05 (1.08)
k_{55}	Denitrification rate	0.09 (1.045)
k_{67}	Conversion efficiency of organic phosphorus to inorganic one	0.03 (1.08)
α_{16}	Stoichiometric ratio of phosphorus to algae chlorophyll-a	1.00
α_{26}	Stoichiometric ratio of phosphorus to zooplankton carbon	α_{16}/CCHL
k_C	Deoxygenation or decay rate of carbonaceous BOD	0.23 (1.047)
BOD_{u-5}	Ratio of the ultimate to 5-day carbonaceous BOD	1.54
α_{18}	Stoichiometric ratio of phytoplankton to organic carbon	CCHL
α_{28}	Stoichiometric ratio of zooplankton to organic carbon	1.00
α_{ON}	Oxygen to nitrogen ratio	2.28
α_{19}	Stoichiometric ratio of phytoplankton to oxygen	2.67CCHL
K_{mpc}	Half saturation constant for phytoplankton affects mineralization	10.0
K_{NIT}	Half saturation DO constant for oxygen limitation of nitrification	2.0
K_{NO}	Half-max. DO constant for oxygen limitation of denitrification	0.1
K_{BOD}	Half saturation DO constant for CBOD deoxygenation.	0.5
w_{SA}	Settling rate of phytoplankton	1.10
w_{SN}	Settling rate of particulate organic nitrogen	0.30

$g(N_{\text{nutri}})$. Thus, the full expression for layer-averaged phytoplankton growth rate is expressed as follows (19):

$$\mu_{A,k} = \mu_{A,k}^{\max} g(I)_k \min \times \left\{ \frac{\text{NH}_{4,k} + \text{NO}_{23,k}}{K_{\text{mNN}} + \text{NH}_{4,k} + \text{NO}_{23,k}}, \frac{\text{PO}_{4,k} \cdot f_{\text{DPO}_4}}{K_{\text{mNP}} + \text{PO}_{4,k} \cdot f_{\text{DPO}_4}} \right\} \quad (11)$$

in which $\text{NH}_{4,k}$ (μg N/L), $\text{NO}_{23,k}$ (μg N/L), and $\text{PO}_{4,k}$ (μg P/L) = concentrations of NH_4-N, $\text{NO}_2 + \text{NO}_3$-N, and PO_4-P in kth layer, respectively; and K_{mNN} (μg N/L) and K_{mNP}(μg P/L) = Michaelis constants for nitrogen and phosphorus uptake by algae, respectively.

Depending on the history of the algal cells, the CCHL ratio (mg C/mg Chl-a) is affected by light intensity, temperature, and nutrient availability as follows (21):

$$\text{CCHL} = \frac{\alpha I_s}{2.718 \mu_{A,k}^{\max}} \quad (12)$$

where α can be obtained from laboratory results.

A saturating recycle equation is used for hydrolysis and bacterial decomposition of organic nitrogen to ammonia (k_{34}) and the mineralization of organic phosphorus to inorganic phosphorus (k_{67}):

$$k_{34} = k_{34,20} \theta^{T_k - 20} \frac{A_k}{K_{\text{mpc}} + A_k}$$

$$k_{67} = k_{67,20} \theta^{T_k - 20} \frac{A_k}{K_{\text{mpc}} + A_k} \quad (13)$$

This expression is a compromise between the conventional first-order temperature-corrected mechanism and a second-order recycle mechanism, with the recycle rate being directly proportional to the amount of phytoplankton biomass. It approaches second-order dependency at low phytoplankton concentrations ($A \ll K_{\text{mpc}}$), where K_{mpc} is the half-saturation constant for recycle, and it approaches first-order recycle when the phytoplankton greatly exceeds the half-saturation constant. This mechanism slows the recycle rate if the algal population is small, but it does not permit the rate to increase continuously as phytoplankton increases.

The following processes, namely, nitrification (k_N) of NH_4 to NO_3 via NO_2-N, denitrification (k_{55}) of NO_3-N, and deoxygenation (k_C) of CBOD, are considered temperature and oxygen dependent:

$$k_N = k_{N,20} \theta^{T_k - 20} \frac{\text{DO}_k}{K_{\text{NIT}} + \text{DO}_k}$$

$$k_{55} = k_{55,20} \theta^{T_k - 20} \frac{K_{\text{NO}}}{K_{\text{NO}} + \text{DO}_k}$$

$$k_C = k_{C,20} \theta^{T_k - 20} \frac{\text{DO}_k}{K_{\text{BOD}} + \text{DO}_k} \quad (14)$$

where $\text{DO}_k(\text{mg O}_2/\text{L})$ = concentration of DO; K_{NIT} and $K_{\text{BOD}}(\text{mg O}_2/\text{L})$ = half-saturation DO constants for oxygen limitation of nitrification and of organic carbon stabilization; and $K_{\text{NO}}(\text{mg O}_2/\text{L})$ = half-maximum DO constant for denitrification.

Primary production by phytoplankton in surface waters is a major source of labile organic carbon to coastal sediment. Particles from the euphotic zone sink to the sediment–water interface, where benthic organisms rapidly degrade the labile organic compounds present in the settled materials (22). Sediment algal carbon is expressed as follows (23):

$$\frac{dC_{\text{sedi}}}{dt} = \alpha_{\text{sediCA}} w_{\text{SA}} A_l - \frac{v_{\text{sedi}}}{h_{\text{sedi}}} C_{\text{sedi}} - k_{\text{Csedi}} C_{\text{sedi}} \quad (15)$$

where $C_{\text{sedi}}(\text{g C/m}^2)$ = sediment algal carbon; α_{sediCA} (g C/g Chl-a) = sediment algal carbon per unit algal mass settled; $v_{\text{sedi}}(\text{m/day})$ = sediment accumulation rate; $h_{\text{sedi}}(m)$ = thickness of the sediment layer; $k_{\text{Csedi}}(\text{day}^{-1})$ = oxidation rate of sediment algal carbon.

SUMMARY

Temporal simulation of phytoplankton growth in a coastal water system is complicated, resource demanding, and computationally intensive because several chemical, biological, and biochemical processes interact, and the reaction rates and external inputs vary with time. Furthermore, the flow and associated circulation are also functions of time, with time scales ranging from minutes to months, even years. Flow and pollutant transport in a natural water body commonly interact with density stratification that resulted from salt water intrusion and solar radiation, which may be described as a layered system. Nowadays, with the advances in computing resources, water quality models are capable of addressing this problem efficiently and flexibly because of their grid system and good numerical performance. In the near future, more work should be undertaken on seeking more accurate pollution source data, including the point/nonpoint sources and atmospheric loads carried directly to the water surface by rain and wind, and for more information on the sediment release of nutrients to obtain much better simulations by the present model.

ENVIRONMENTAL APPLICATIONS WITH SUBMITOCHONDRIAL PARTICLES

Diana J. Oakes
John K. Pollak
University of Sydney
Lidcombe, Australia

It is now recognized that the supply of sufficient clean and safe water for drinking and growing food as well as for supplying adequate volumes of water for the maintenance of ecosystems will be one of the most significant problems facing the population of the twenty-first century. Shortages of clean water have already a direct effect on human health, causing many deaths as well as severely damaging plant and animal life and thus affecting the ecology as well as the production of agricultural crops. Hence, it is important that the quality of water is routinely evaluated.

The classic toxicological methods that have been developed and used by scientists over many years for risk assessments often evaluate the outcomes of exposures to single chemicals. However, in the present environment, in which exposures to mixtures of chemicals have been significantly increased, it is inappropriate to only evaluate the toxic effects of individual chemicals or toxins. It is now widely recognized that the toxic effects caused by exposures to chemical mixtures may even be caused by extremely low concentrations of individual chemicals because of the additive or even synergistic actions of other chemicals in a water sample. Thus, it was demonstrated in 105 extracts of sediments collected from aquatic environments that many of the extracts with low or barely detectable levels of priority pollutants were highly toxic when evaluated with the Microtox bioassay (1). Jacobs et al. (1) suggested that "... chemical data alone provides no direct indication of the potential effects that contaminant mixtures may have on the aquatic biota. Toxicity bio-assays furnish reasonable estimates concerning the biological impacts of sediment contaminants; both chemical and biological analyses should be performed." Although some of these toxic samples did not contain any significant concentrations of priority pollutants, it is likely that these extracts contained unidentified and possibly unregulated pollutants at low concentrations.

Even nontoxic chemicals have the potential to increase the toxicity of other chemicals in a mixture. An example of such an effect is the increased toxicity of phenytoin by the presence of lactose in the mixture (2). In this context, it is questionable whether the guidelines for permissible concentrations of individual chemicals (such as ADI—acceptable daily intake; MRL—minimal risk level; NOAEL—no observable adverse effect level) provide meaningful safety levels either for the ecology or for human health, because these parameters focus only on individual chemicals and do not consider the potential effects of other chemicals on the overall toxicity of a chemical mixture. It is, therefore, important that we use bioassays for the evaluation of the toxic effects of aquatic samples.

For the past 24 years, the Organization for Economic Co-operation and Development (OECD) has provided standardized test protocols to evaluate aquatic toxicity with laboratory-based representative single-species toxicity tests, such as fish, Daphnia spp., and algae (3). These bioassays provide useful data of the overall toxicities of chemical mixtures that are present in aqueous samples.

An example of a subcellular bioassay is the submitochondrial particle (SMP) test. With this test, we use the cellular organelle, the mitochondrion, which is present in all eukaryotic (nucleated) cells. Mitochondria are effectively the powerhouses of the cell, providing over 90% of all energy produced in all eukaryotic organisms. Mitochondria catalyze reactions in which molecules with a low energy content are oxidized (lose electrons) to give rise to "energy-rich" molecules, such as adenosine-triphosphate (ATP). ATP is required for synthetic metabolic processes or for mechanical or heat energy. The metabolic activities of mitochondria are so fundamental to aerobic life that their functional organization, their proteins and enzymes, are very similar in all aerobic organisms (from amoeba, plants, or even fungi to humans). Hence, the evaluation of cellular toxicities by mitochondria from one species is likely to apply to other species. Stable SMPs are produced by the disruption of the internal membranes of isolated bovine heart mitochondria (4,5). Once prepared, the SMPs are stable for at least 2 years when kept at −80 °C. SMPs are now commercially available in the United States from Harvard Bioscience, Inc., Madison, WI. SMPs consist of inverted, vesicular portions of the inner mitochondrial membranes that can perform the integrated enzymatic functions of electron transport and oxidative phosphorylation (6).

The test measures inhibitory effects that chemicals present in contaminated water may exert on SMP enzyme activity. Two different assay procedures have been devised for SMPs (7,8) as illustrated in Fig. 1. Figure 1a illustrates the complexes of the inner mitochondrial membrane that are involved in the so-called forward electron transfer reaction (ETR), whereas Fig. 1b illustrates the reverse transfer reaction (RET) in which access to complex III and complex IV is blocked with the inhibitor antimycin A.

The ETR assay measures the flow of electrons from NADH via complexes I, II, III, and IV to molecular oxygen. Measurements of the oxidation are carried out in six 1-mL cuvettes. Five cuvettes receive different concentrations of the samples that are tested, whereas one cuvette serves as the control. The extent of the inhibition of the oxidation of NADH provides an indication of the toxic effects of the aqueous sample that is being evaluated. The assay buffer consisted of 0.25 M sucrose, 20 mM Hepes buffer (pH 7.4), 6 mM $MgCl_2$, and 200 nM NADH (25 μL). The decrease in the absorption at 340 nm measures the oxidation of NADH to NAD with a Beckman DU650 spectrophotometer (Fullerton, CA), with the automatic six-cell holder that is maintained at 30 °C.

In the RET assay, succinate is added as a substrate and because access to complexes III and IV is blocked (see Fig. 1b), the NAD that has been added is reduced to NADH by the SMPs. Hence, the RET assay measures the reduction of NAD to NADH leading to the increased absorption at 340 nm. The assay buffer consisted of 0.18 M sucrose, 50 mM Tris buffer (pH 7.5), 0.1 M sodium succinate, 0.7 μg/mL antimycin A, 30 mM $MgCl_2$, and 1 mM NAD. The NAD reduction was measured at 340 nm with a Beckman DU650 spectrophotometer, with an automatic six-cell holder maintained at 30 °C. This test evaluates the inhibitory effect exerted by chemicals in the aqueous samples on the oxidation of succinate that leads to the reduction of NAD to NADH. For further details of the SMP assay protocols see Oakes and Pollak (9).

The SMP test has evaluated the toxicities of 113 different chemicals (10,11). SMP test procedures have also been validated in field trials through the participation in several ongoing U.S. Environmental Protection Agency

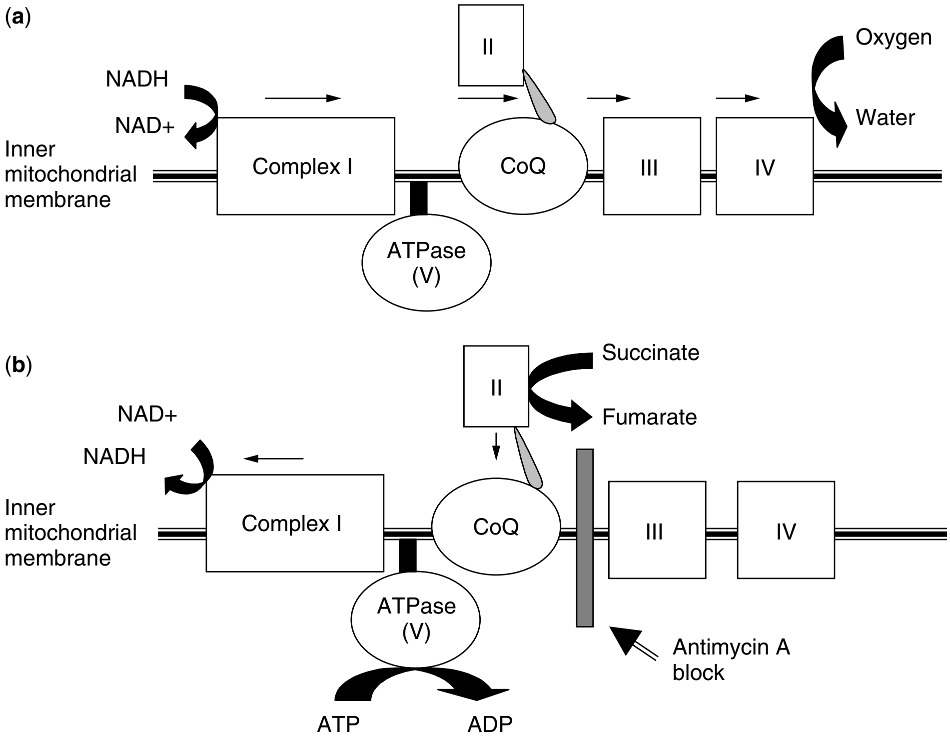

Figure 1. (**a**) Diagram of the ETR adapted from Ref. 7. (**b**) Diagram of the RET adapted from Ref. 7.

Geological Surveys and by the Wisconsin Department of Natural Resources Bio-Monitoring Projects, as well as in studies in the Illinois and Minnesota River Basins (11). Other studies have shown that the results obtained by the SMP test correlate well with the results obtained with *in vitro* and *in vivo* bioassays, such as Microtox, mammalian cell cultures, nematode, Daphnia spp., and fish assays or sea urchin fertilization and larval development tests (6,10,12–15). A further example of the useful information that the SMP test can provide was established when the toxicity of the herbicide formulation Tordon 75D was investigated (9). The herbicide Tordon 75D consists of a mixture of the triisopropanolamine salts of 2,4-dichlorophenoxy acetic acid (2,4-D) and 4-amino-3,5,6-trichloropicolinic acid (Picloram) as well as other components, such as the solvent triisopropanolamine and diethyleneglycol monoethyl ether, a silicone defoamer, and a proprietary surfactant (polyglycol 26-2). Using both the ETR and the RET assays and testing the complete formulation as well as the individual components, researchers have shown that although the proprietary surfactant by itself severely inhibited the oxidative functions of the SMPs, the mixture of only the active components had no significant effects on the oxidative functions of the SMPs. These results suggested that the surfactant damaged the inner mitochondrial membrane and was the primary component of Tordon 75D that inhibited the oxidative functions of the SMPs. A later study assessed the potential toxicity of three related herbicide formulations containing the ester derivatives of 2,4,5-T and 2,4-D. It was shown that in these formulations, the “other components” such as diesel oil and surfactants contributed significantly (approximately 50%) to the overall toxicity in an additive manner (16). More recently, the SMP test evaluated the toxicities of leachates that emanated from the Sydney Olympic Site. The leachates were also evaluated with several other bioassays as well as by chemical analyses. The SMP test, although less sensitive than other bioassays, such as the sea urchin fertilization and development tests, provided useful information as a rapid prescreening tool (15). Of the two SMP assays, only the RET was suited for evaluation of the leachate toxicity because it is known that samples containing significant levels of divalent cations can activate the SMP activity when measured with the ETR assay, effectively masking any inhibitory effect (6,15).

Overall, these studies have demonstrated that the SMP test is a useful prescreening tool for evaluating the toxic effects of aqueous media or chemical formulations. The SMP test is less sensitive than the Microtox assay to changes in pH and to the presence of solvents; hence, it can evaluate a greater range of aqueous samples. The major limitation of the SMP test as well as other cellular and subcellular *in vitro* assays is that they cannot account for pharmacokinetic and pharmacodynamic processes that may affect the actions of chemicals *in vivo*, nor can the SMP test evaluate the action of chemicals on specific receptors or enzymes (e.g., acetyl choline esterase) other than mitochondrial enzymes.

INTEREST IN THE USE OF AN ELECTRONIC NOSE FOR FIELD MONITORING OF ODORS IN THE ENVIRONMENT

Jacques Nicolas
University of Liege
Arlon, Belgium

INTRODUCTION

The increasing number of complaints related to malodors generated by agricultural, landfill, and wastewater treatment facilities give rise to a growing interest in the measurement of olfactive annoyance. Instrument manufacturers have sought to provide suitable environmental monitoring solutions. Because the need for such devices is generally driven by legislation, compliance with the standardized validation of techniques is often mandatory. So, current standard methods remain the references to measure odor annoyance.

Two procedures are generally proposed: either olfactometry, based on odor assessment by human panels, or chemical analysis by chromatographic techniques. However, neither meets the requirements of on-line monitoring for environmental applications.

New emerging technologies such as electronic noses, based on nonspecific sensor arrays, may offer objective and on-line instruments for assessing environment odors. But, despite the recent appearance of commercial devices that can be implemented in the field, a number of limitations can be highlighted, both from the technology itself and its application to environmental studies.

BASIS OF THE CHIEF ODOR MEASUREMENT METHODS

Olfactometry is the scientific measurement of odor concentration using a system of sampling and a methodology regulated to European (EN 13 725) (1) and American (ASTM E679-91) (2) standards. The odor concentration of a gaseous sample is determined by presentation to a panel of observers, who have known acuity to odor, in varying dilutions. The procedure aims at determining the dilution at which only half the panel can detect the odor. The odor concentration is then the number of dilutions required for the sample to reach this threshold. It is expressed in multiples of one odor unit per m^3 (ou/m^3). This technique provides directly comparable data for different odor types. Although this technique gives the right human sense evaluation and is now based on standard methodology, it remains strongly influenced by subjectivity and is time-consuming, labor-intensive, and expensive. Olfactometry laboratories are often remote from the odor source: it is obviously not appropriate for real-time and continuous operation on-site.

Alternatively, chemical analysis of the odorous mixture by gas chromatographic techniques (such as GC-MS) provide an accurate concentration of specific compounds in the sample (3). Some instruments can be used on-site and for continuous assessment, but analytic methods never provide the global olfactive perception, as most environmental odors are complex mixtures of compounds. Moreover, they do not take into account the interactions between different odorants and interfering background substances, which may lead to synergistic or antagonistic effects.

The electronic nose is a more recent technique based upon a fixed array of nonspecific gas sensors, each of which responds differently to an odorant and the global pattern of responses that is characteristic of that odorant (4).

The heart of the electronic nose is an array of chemical sensors (metal oxide semiconductors, conductive polymers, quartz microbalances). When exposed to a gaseous atmosphere, these individual sensors provide individual signals. Subsequently, a signal pattern is deduced by analyzing these signals by suitable statistical and mathematical methods. The diagnosis is thus based on the “fingerprint” of the gas mixture classified by pattern recognition techniques (artificial neural networks, discriminant function analysis). Before applying such an instrument on a real atmosphere for on-line recognition of odors in the environment, it must be trained with typical gas mixtures for this environment. After the training, the system can identify one of the learned odors by establishing similarities between the actually observed pattern of signals and those previously observed. Hence, the electronic nose is an analytical instrument that can characterize an odor without reference to its chemical composition. The signal provided is the odor, considered as a whole. That makes this method particularly attractive and shows its great potential.

STATE OF THE ART

Reported developments in complex odor analysis are focused chiefly on quality assessment in the food, drink, and perfume industries. So far, few attempts have been made to characterize and monitor complex odor in the environment. Although original work carried out with laboratory-based systems and more recent field investigations have shown promising results, the number of trials carried out under realistic environmental conditions is relatively limited.

Some papers review the current status of sensor array technology and discuss its potential application to the assessment of olfactive annoyance in the environment by referring to exhaustive literature surveys (5–8).

Early investigations include the analysis of single substances, but some works deal with more complex odors. In a review of odor measurement techniques for sewage treatment works, Gostelow et al. (9) listed some examples of electronic nose application to environmental odor problems. However, the use of electronic noses to monitor water quality in the field remains a virtually unexplored domain with only few applications reported so far.

TYPICAL USER NEEDS

In the field of environmental monitoring and more particularly of water quality, the typical needs of the final user of electronic nose require both qualitative (classification) and quantitative (regression) approaches.

From a qualitative point of view, different annoyance odors must be discriminated, and the identity of unknown samples must be predicted using a previously calibrated learning model. A range of data processing techniques may be used to analyze sensor array data, but due to the large number of variables (i.e., number of sensors) and samples, pattern recognition techniques (such as multivariate statistics and artificial neural networks) are employed to reduce the dimensionality of the sensor array data. The relationships between the samples can then be compared and correlated using simple scatter plots. The choice of analysis technique depends on the amount and nature of information available and the type of information required from the analysis.

Figure 1 could refer to a typical result of a discriminant function analysis (DFA) of observations made at a landfill site by an electronic nose. Three types of odor tonalities can be perceived: the fresh refuse, the odor of landfill gas, and one of the leachates. The scatter plot of the observations in the plane of the two calculated roots shows clustering into the three expected groups. The model so calibrated by DFA can further be used by the landfill manager to classify a new observation. For example, the emergence of an odor identified as "leachates" can let us suspect a problem in the leachate treatment system.

This ability of an electronic nose to discriminate rapidly between slight variations in complex mixtures makes the technique ideal for on-line process diagnostics and screening across a wide range of applications.

Quantitative approaches imply regression procedures by correlating sensor responses with some quantitative parameter obtained either by another instrument or by human perception. In some cases, reasonable fits are obtained when the sensor responses are compared with odor concentration resulting from olfactometry measurements. However, this approach is impeded by the subjectivity of the olfactive evaluation, the nonlinear relation between the perceived intensity of an odor and its concentration, as well as by adaptation phenomena (perception) as a result of extended exposure to that odor (8). This complicates the elaboration of quantitative models. Moreover, the model so calibrated is often site specific, and its validity over long periods of time must be demonstrated before sensor array systems can be used for quantitative analysis.

In the field of water quality, the overall electronic nose output is often compared with classical water characterization variables, such as volatile suspended solids (10) or global organic parameters (biochemical oxygen demand and total organic carbon) (11). Studies generally conclude that a number of different wastewater quality relationships could be formulated from the electronic nose analysis of a sewage liquid. In all cases, the principal advantages put forward by the authors to justify an electronic nose with respect to traditional analytical methods are the rapidity of the response and the noninvasive nature of the measurement.

The model obtained by regression could be used as an on-line monitoring tool for a process. For example, Fig. 2 highlights a "stress" episode in a composting process, caused by the absence of aeration of the compost pile. A specific indicator is constructed by relating the sensor signals to the four families of compounds emitted during that "stress" phase (nitrogen compounds, carboxylic acids, ammonia, and chlorinated compounds). It is constructed by a canonical correlation analysis. The figure shows the temporal evolution of that combination of the sensor signals applied to the whole data set obtained by continuous signal monitoring for 11 days. The root value exhibits a peak during the "stress" period. Of course, such a global odor indicator could be calculated for other environmental processes, such as wastewater treatment, and it could be monitored as a global process control variable.

More generally, the purposes of continuous, *in situ* monitoring of odorous emissions by an electronic nose could be

— to predict the rise of malodor in the background before it becomes an annoyance for the surroundings;

— to use the odor as a process variable, aiming at a better understanding of the odor release and

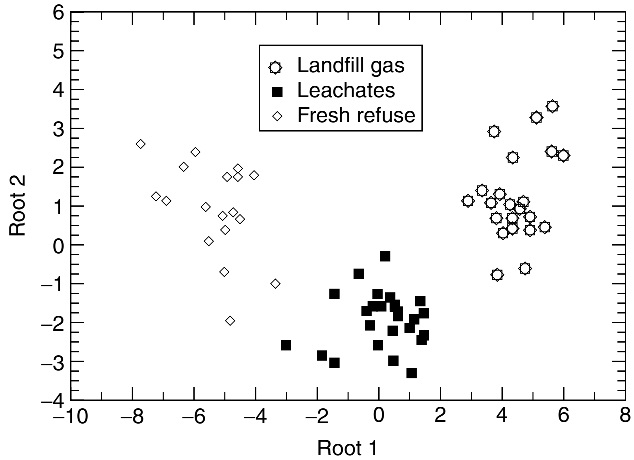

Figure 1. Possible scatter plot of electronic nose observations at a landfill site in the plane of the two first roots of a discriminant function analysis.

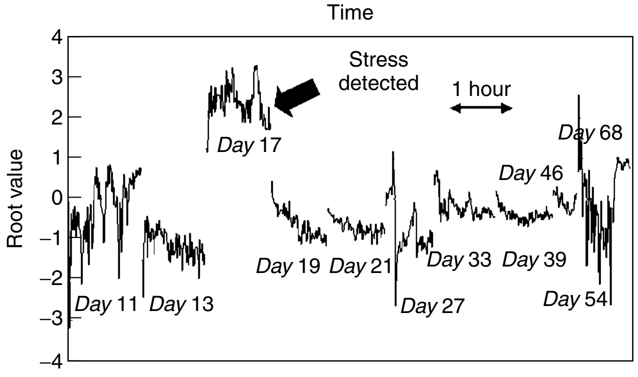

Figure 2. Global odor signal obtained from the response of a sensor array to detect a stress episode in a composting process.

relating this emission to the process phase, or the problem that caused the emission;
- — to control odor abatement techniques in real time, such as atomization of neutralizing agents.

Simple sensory early warning devices that can detect sudden changes in a process stream obviously present great interest.

APPLICATIONS RELATED TO WATER QUALITY

The use of electronic noses to monitor water quality in the field may involve the agricultural and industrial effluents allowed to seep into groundwater or to flow into streams or rivers (6). The electronic nose can be used in these applications by collecting samples of the effluent. Boreholes can also be employed to collect samples to test groundwater contamination.

A very promising area is the detection of hydrophobic and highly volatile organic compounds (VOCs) in water systems (8). The recent developments in on-line detection of oils and petroleum hydrocarbons (12) have arisen from the recent advances in sensor technology as well as from progress in computing and pattern recognition. Studies aim also at real-time control of wastewater treatment plants (13) and at the quality tests of potable water (14).

A specific obstacle when dealing with liquid samples is to generate or collect a headspace gas that can be reliably and safely measured by the sensor array. Because parameters such as flow, temperature, or suspended solids constantly change, the major difficulty lies in drawing a headspace sample that is representative of the liquid phase (8). But several applications involve also monitoring odors emitted in the air from wastewater (9). Odor abatement and control are major issues facing municipal sewage treatment facilities.

SPECIFIC PROBLEMS FOR ENVIRONMENTAL APPLICATIONS

Much of the original work on environmental applications has used sensor arrays in laboratory-based conditions. However, to understand the effects of environmental parameters on localized odor pollution, it is necessary to translate these laboratory-based experiences into formats that can be applied to measurements under variable conditions (15). Although new sensor materials and designs are continuously being reported, the major limitation of currently available sensors remains their sensitivity to changes in temperature, humidity, and flow rate.

The solution to this obstacle is generally to work under fixed experimental conditions, that is, to incorporate the effects of variations in ambient temperature and humidity into the design of instruments by using sample pretreatment systems. That was demonstrated for headspace pretreatment in on-line wastewater monitoring (13). However, when considering the practical application of a sensor array, this can make the overall instrument more complex and expensive and can also affect its portability or limit sample throughput.

A second approach is to measure these parameters and calibrate the sensors under varying humidity levels to compensate for changes in subsequent data analysis (16). Yet, the method has still to be validated for real-life environmental applications where pollutants must be analyzed rapidly under ever changing background conditions and in the presence of interfering compounds.

Alternatively, the development of a classification model under a wide range of operating and meteorologic conditions makes those conditions “neutral” for odor recognition (17). It is an effective but sometimes fastidious solution.

Sensor drift is another serious impairment of chemical sensors. They alter over time and so have poor repeatability because they produce different responses for the same odor. That is particularly troublesome for electronic noses for which the sensor signals can drift during the learning phase, requiring repeated exposure to the same type of odor.

The consequences of sensor drift on classification results exclude the possibility of further odor identification (18). Though drift correction algorithms could be applied for each individual sensor, the usual way to counteract the global drift of a sensor array is to correct the whole pattern, using multivariate methods. First, the main direction of the drift is determined in the first component space of a multivariate method, such as principal component analysis (PCA). The drift component can then be removed from the sample gas data, thus correcting the final score plot of PCA (19).

Moreover, the combination of multiple sensors, cross-selectivity, and pattern recognition analysis makes the usual techniques of instrument calibration difficult to apply to electronic noses. As a result of this issue there are, to date, no international standards that directly refer to electronic nose measurement.

An additional problem occurs when the concentration of volatiles is low, which is often the case in the environment: the limit of detection of the sensors and the limits of recognition of the electronic nose are reached. A possible solution to this problem should be to improve the sample uptake, for example, by preconcentrating the analytes prior to investigation (20).

Other requirements of field monitoring include low cost, low maintenance, small size, low response time, and low power consumption where autonomous, portable instruments are concerned.

TRENDS AND FUTURE WORK

Electronic nose technology exhibits several possibilities for environmental monitoring. There is a true potential for sensor array in this area, provided that some conditions are respected. With the technology used so far, it is unrealistic to envisage a universal electronic nose to cope with any odor type. Specific data processing and sometimes specific instruments must be designed for each application. In the field of water quality, sewage odor profiles are specific for individual treatment works and for different unit processes within a work. These different sewage odor compositions induce a scatter of observations, which must be removed before trying to find a relationship with odor concentration determined by other methods (21).

Results to date have been based mainly on assessing environmental odors measured near emission sources. This is due to the constraints of using commercial chemical sensors that exhibit a limit of detection often higher than the threshold of smell (generally on the order of 1 ppmv). So, environmental monitoring by an electronic nose must be envisaged only in the surroundings of the emission.

Potential applications in odor assessment by electronic noses are numerous, but, before these specific applications can become a reality, a number of challenges still need to be overcome. Programs of experimental work should be undertaken to assess various characteristics of electronic nose performance, including drift, comparability of sensors before and after replacement, environmental influence, sensitivity, and signal-to-noise ratio.

There are not, so far, any possible comparisons between different electronic nose results. Even an instrument whose sensors were replaced is no longer the same as the original: the learning phase must be started again. In the frame of environmental applications, that particularly excludes the possibility of using the electronic nose to test compliance with standards.

So, it is necessary to develop calibration procedures and to realize suitable calibration artifacts. Any new “calibration standards” will need to consist of generic mixtures that reflect the gas components typically found in the environment and have a significant effect on the various detector responses. It is also essential to validate the quantitative assessment of sensor array responses against other methods, such as olfactometry measurements, to confirm comparisons with human perception.

There is a need to develop internationally acceptable methodologies for harmonizing electronic nose characterization and performance testing. This requirement can be best met by developing standardized procedures and protocols that enable making quantitative and objective comparisons between different types of instruments. These procedures could then form the basis of future international standards in this area.

OIL-FIELD BRINE

Dusan P. Miskovic
Northwood University
West Palm Beach, Florida

INTRODUCTION

From the beginnings of oil production, oil producers started to separate the oil field brine (OFB) mixture of oil and salt water from crude oil. The basic saline constituents of an OFB are as follows: chlorides, sulfates, hydrocarbonates, and sulfides of Na, Ca, Mg, ferrous Fe, and Sr. Much smaller concentrations of K, Li, B, Zn, Cu, bromides, and iodides can be attributed to total salinity as well. The actual salt content (qualitative and quantitative) may vary in a broad range of appearance and concentrations (1,2). Very often, the total concentration of salts in OFB can exceed several times the salinity of sea water. The separation of oil and OFB is a logical consequence of the oil production process due to the fact that much more OFB than oil is more often produced, especially in older oil wells. However, until recently neither the oil drillers nor any governmental agency paid much attention to disposal of OFB as a by-product of crude oil production. A simple procedure for OFB was diluting it in streams, rivers, and natural fresh and marine waterbodies. That practice took place until interest in crude oil production and consequently consumption of derivatives dramatically increased. Widespread oil production worldwide is constantly increasing, but the pollution aspects came to a focal point of environmental concern. To keep a high profit margin in the industry and satisfy strict environmental quality regulations, more sophisticated technologies for OFB treatment are becoming viable alternatives to the conventional OFB management practice.

HISTORICAL REVIEW OF OFB CONTROL PRACTICE

A chronology of OFB control was presented recently in the context of a concurrent increase in oil production efficiency and environmental quality self-regulation (3). It was pointed out through ethical consideration that technically improved efficiency of oil production did not successfully resolve pollution problems caused by OFB.

Generally, since the beginning of commercial oil production in the 1920s, a relatively small amount of OFB was lifted from formations. In most cases, oil producers did not realize that they had a disposal problem until someone objected. There are few records about early OFB control practices worldwide. In most inland oil fields, OFB was dumped into shallow evaporation pond (pits).

Since the first lawsuits were filed, simple OFB control practices were used. During the 1930s in California, for example, up to 200,000 barrels/day were simply discharged into the ocean (3). A common way to "control" OFB was in the context of early wastewater control practice; "dilution can be a solution for pollution." Saline water from oil fields would be released into dry channels when rain turned these into fast moving streams. Other practical modes to cope with the lack of systematic regulation in a particular industry were an oil producer's acceptance of the costs associated with storage reservoirs, evaporation ponds, and pipes to the ocean. These were ways to prevent damage suits.

The period of OFB management, as a method of pollution prevention, started in the 1930s. In Texas, for example, limited production from most wells was introduced. A more technical approach to the problem was addressed to prevent the field's hydrostatic pressure from dropping too quickly. Reducing and stopping production when the water-to-oil ratio exceeded a certain value was recommended. Also, it was concluded that evaporation ponds that created more concentrated brine did not resolve the disposal problem. A new alternative for OFB disposal in the form of brine injection wells became more suitable.

The brine injection technology seemed to be very promising as a way of disposing of OFB and also as a way to boost oil production. It was their own technology, which was being improved until now (see next section). In the beginning, an "environmentally friendly" method had been put to additional good use. Not long after the practice was widely accepted, some abandoned injecting wells came to life either as artesian salt springs or as steady salty streams polluting surface freshwater bodies.

Summarizing this brief historical review of OFB pollution control practice, it is possible to point out that a positive shift from increasing industrial efficiency to environmental quality improvement occurred after long-term experience in monitoring. Finally, a new approach to OFB control in the form of wastewater treatment technology emerged.

OFB USE FOR IMPROVING OIL PRODUCTION

Crude oil produced by natural reservoir pressure is referred to as primary production. Any additional production of oil from the introduction of artificial energy into a reservoir is considered enhanced recovery. As mentioned before, OFB injection technology was introduced primarily to recover as much as 50–70% of the original remaining petroleum. A comprehensive historical development emphasizing the environmental issues was presented (3), and a concise review of oil field water injection technology is given in Reference 2. In addition, there is much information scattered in oil production literature (4–6). Specific data focused on improving the quality of OFB before reinsertion is found elsewhere (7–10).

A whole industry supporting well injection was established. It deals with the conditioning of the physico-chemical properties of OFB, to remove remaining oil, as well as to prevent scaling (11). It is of great importance to establish injection water (OFB) quality criteria to prevent interruption or a decrease in oil production. There are three categories of substances affecting reinsertion of OFB: inorganic (dissolved gases, TDS, and TSS), organic (residual oil), and microorganisms. More important qualitative features of OFB and their pollution consequences after well injection will be discussed later.

To understand the many sources of wastewater originating in oil production and some of the polluting characteristics most relevant for OFB management as its major component, the schematic presented in Fig. 1 will be discussed.

Assuming that up to 90% of all fluid lifted from an oil well is practically OFB, the main source of wastewater in oil production is OFB itself. The initial volume of OFB is somehow decreased after two steps of crude oil dehydration, free water knock out (FWKO)

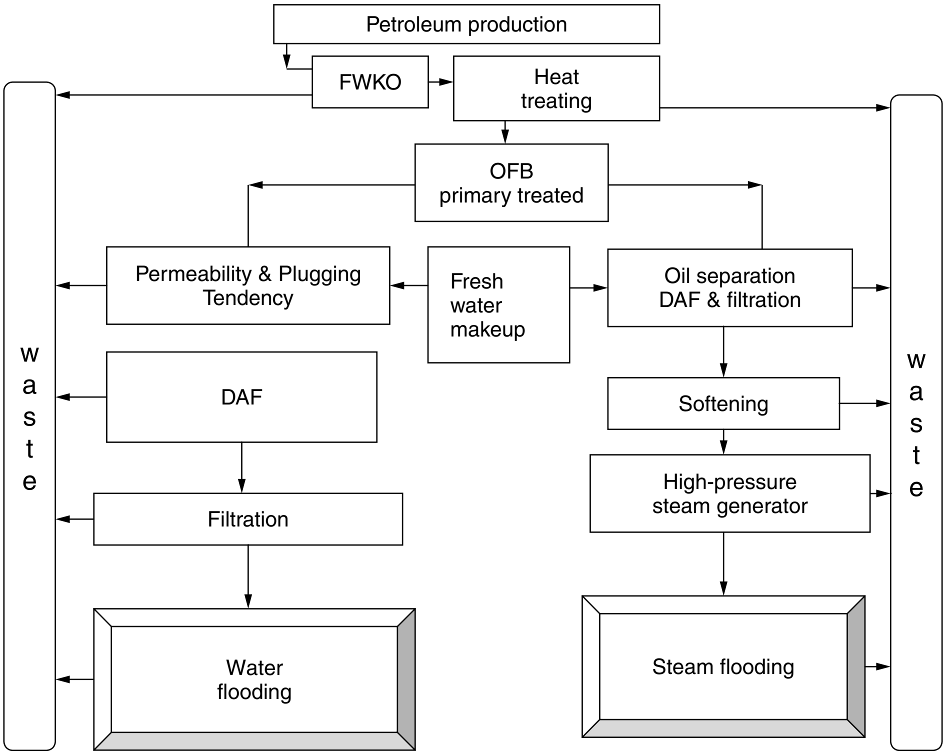

Figure 1. Schematic of OFB use for improving oil production.

and heat treating. Following the removal of oil and gas from the fluid produced, primary treated OFB is now prepared for additional treatment in the course of enhanced recovery. Water and steam flooding are the most common processes for secondary recovery of crude oil. Several steps of additional preparation/purification of the produced water (OFB) have to be conducted, regardless of the type of process applied. In flooding, specific tests have to be done to evaluate permeability and the plugging tendency of a core subjected to a particular floodwater (3). The produced water has to be clarified after mixing with supplemental fresh makeup water. A combination of dissolved air flotation (DAF) and filtration methods can be applied to produce brine physicochemically compatible with the formation rock (12). Also, a more sophisticated method such as radially entrained vapor extraction (REVEX) was considered for removing oil and solids from brine (13). This technology uses well-accepted principles of gravity and centrifugal sedimentation, as well as flotation.

On the other hand, a more complex train of consecutive stepwise processes have to be performed to prepare OFB for steam flooding. Here are three steps of OFB treatment:

- physicochemical removal of oil by gravity separation, primary/secondary DAF, and filtration;
- two-stage softening to provide water suitable for a high-pressure boiler;
- high-pressure steam generation based on previously deoiled and clarified OFB.

The serious disadvantage of steam flooding is condensed water, which contains all solids (salts) concentrated several times compared to the feed water. Practically, very concentrated brine as a disposal stream must be reinserted. An improvement in the existing process was achieved recently in German and Dutch oil fields (14). This new process allows the production of high quality boiler feed water by using mechanical vapor compression, without salt content for steam generation. It was accomplished by ensuring a closed water cycle, thus preventing the excessive volume of injected steam from brine, by continuously adding fresh water instead.

It is possible to conclude that no matter which process is chosen to improve oil production, a far from ideal elimination of excess OFB by reinsertion is a reality. Generally speaking, the OFB used in crude oil production by reinserting it into wells still remains a major source of groundwater pollution (see next section).

POLLUTION ASPECTS OF OFB

The extensive use of injection wells for disposal of a variety of chemical wastes, including OFB, started in the late 1960s. The first concrete action to protect drinking water supplies from possible contamination by injection wells came from the Safe Drinking Water ACT of 1974 (3). The same practice continued, and during the 1990s, there were approximately 170,000 active and more than 2 million abandoned injection wells in the United States. Generally, to estimate the total quantitative or qualitative budget of OFB even on a single oil field requires a very systematic analysis of a long-term record. That was also the problem in pollution control treatment (15).

For example, the concentration range of TDS contained in an OFB varies from 10 to more than 350 g/L, of which sodium chloride contributes about 80% or more. In contrast to the extreme high levels of TDS, TSS values are at incomparably lower levels, in most cases around 100 mg/L, even though, three categories of constituents affect OFB well injection: inorganic, organic, and microorganisms. The crucial impact on freshwater pollution is due to TDS content.

A concise review of the impact of OFB liquidation on water quality in reverse chronological order is presented in Table 1. Based on the available data, it is possible to distinguish two types of research activity: the water management approach and specific characterization of OFB in selected regions with different implications for water quality. In most cases, two categories of water sources were investigated. Because deep well injection is the most common OFB liquidation technique, particular attention was paid to groundwater quality change (16–21). After many years in use, OFB pits and injection wells have started to impact the quality of streams and shallow aquifers too (22–30). Some cases applied an integrated approach to a combined quality control management of groundwater and surface water affected by OFB disposal (31).

In addition to the two main categories of water sources affected by OFB contamination, there is a third group of more specific and very diversified implications of OFB management practice. Some illustrative examples are briefly described below.

An interesting result was obtained from a simulating study of the use of OFB as a deicer on a gravel roadbed (16). Constituents of brine were detected in water samples from groundwater monitoring wells. The map of an OFB plume was generated based on groundwater quality and surface geophysical methods.

A recently published article illustrates research in progress that quantifies human health risks from naturally occurring radioactive materials (NORM) related to OFB streams, pipe scale, and sludge (33). In another risk-based approach, the status of the water quality of a former OFB disposal pit, whose operation was discontinued in the mid-1940s, was evaluated (34). After a thorough water analysis, it was found that a long-term

1981	Chemical characterization of brines in salt mines (LA)	Potential impact of OFB on salt mines	36

natural remediation process gradually turned brine into freshwater that sustained aquatic plants. The pond was categorized for potential recreational use.

Specific microbiological investigation has proven that OFB can be a good substrate for the growth of strictly anaerobic bacteria (35). In another microbiologically focused study, two novel nitrate-reducing and sulfide-oxidizing strains of bacteria were isolated from production fluid (32).

An interesting study was performed on the impact of OFB on salt mines (36). Based on isotopic studies, it was hypothesized that active leaks, stalagmites, and stalactites in salt mines, which contained high levels of Ca, K, and bromides, arose from OFB formation water.

Generally, it is possible to conclude that a very broad spectrum of monitoring research data clearly indicates the significant impact of OFB management practice on the deteriorating quality of different water resources.

OFB CONTROL BY WASTEWATER TREATMENT METHODS

The previously considered aspects of OFB management such as environmental monitoring, socioeconomic aspects and improvement of crude oil production by using OFB were based on a broad pool of literature sources. In contrast, reports on the control of OFB by wastewater treatment methods are rather limited and sporadic.

It is worthwhile mentioning that there are some attempts to treat oil field effluents in a different engineering context. Cationic polyelectrolytes were developed to partially treat effluents containing a high percentage of residual free oil, as well as stable emulsions (37). Also, there are reports of treating OFB by using configurations similar to those employed for oil refinery wastewater (38–41). Two case studies of systematic approaches will be presented below. In both studies the OFB was considered wastewater that needed to be purified and discharged or reused.

Table 2. Alternatives of Microbiological[a] and Advanced Treatment[b]

No.	Description
Alternative I	[a]Activated sludge [b]Advanced treatment with GBAC
Alternative II	[a]Activated sludge + 25% dilution with freshwater [b]Advanced treatment with GBAC
Alternative III	[a]Activated sludge + PAC [b]Advanced treatment with GBAC
Alternative IV	[a]Activated Sludge + 25% dilution with freshwater + PAC [b]Advanced treatment with GBAC
Alternative V	[a]Activated sludge + 50% dilution with freshwater + PAC [b]Advanced treatment with GBAC

Various aspects of an innovative technology for OFB treatment were investigated on a laboratory and pilot scale (15,42–44). Both free and dispersed oily matter were separated by gravitation and sedimentation. Apart from physicochemical oil removal processes, special attention was paid to different variants of improved microbiological treatment (see Table 2). In that regard, two approaches were applied; dilution with freshwater and powdered activated carbon (PAC). The aim was to intensify the microbiological process and neutralize its inhibitors by adsorption on PAC. Advanced treatment was carried out on granular biological activated carbon (GBAC). It was found that the GBAC removed up to three times more organic matter than its adsorption capacity, and thus its adsorption power was not exhausted. This was a clear indication that the microorganisms present in the biofilm on GBAC oxidize the adsorbed pollutants and regenerate it at the same time. A technological scheme for complete treatment was proposed (see Fig. 2). It was concluded that the complete treatment employed here was very efficient. The organic matter content in the effluent did not exceed

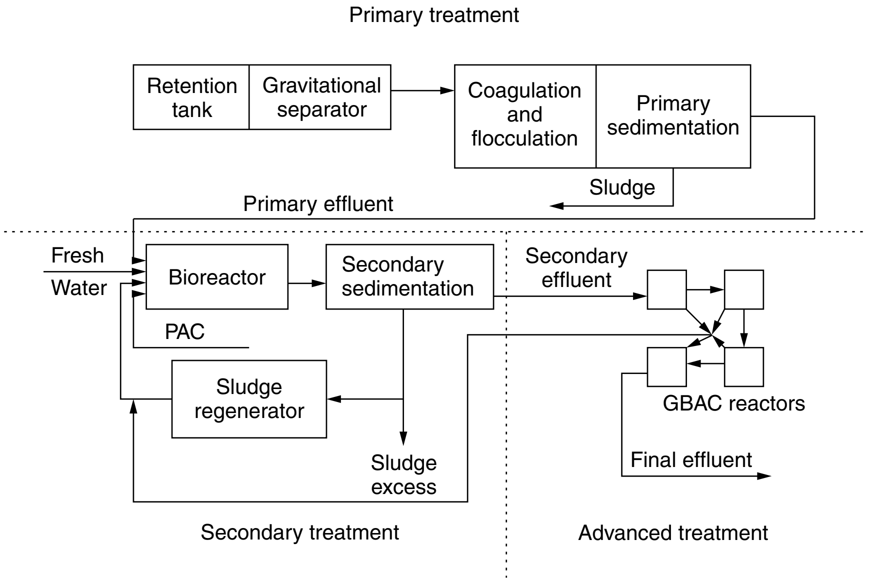

Figure 2. Block schematic of a complete OFB treatment.

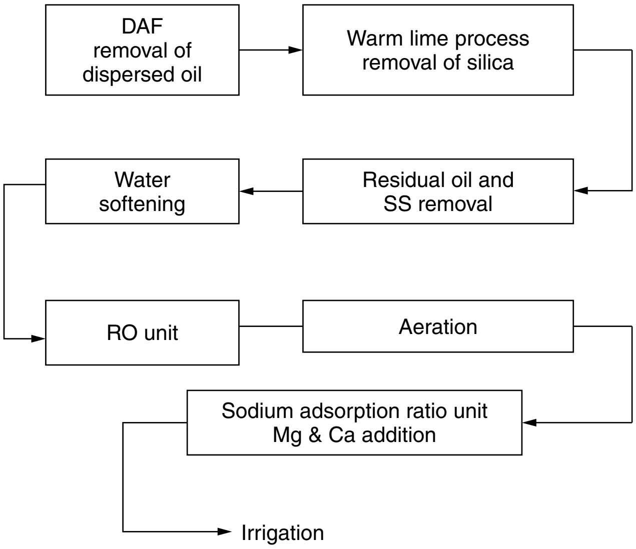

Figure 3. Block schematic of RO pilot unit for treating OFB.

2.5 ppm of BOD. Also, a final decrease of salinity was achieved by mixing effluent in an adequate proportion with the recipient water (44). Thus the treated OFB can be discharged into recipients of low self-purification capacity. Based on a preliminary cost analysis, it was estimated that a complete OFB treatment would cost 10% more than a conventional PAC/GBAC treatment of municipal wastewater.

The second case study of complete OFB treatment represents a state-of-the-art process based on reverse osmosis (RO). The configuration applied converts an oil field effluent into freshwater (45). The simplified block schematic of the process is presented in the Fig. 3. The input to the process contained a relatively low level of salinity (about 7 g/L).

The concentration of a soluble oil was also at a moderate level, below 200 ppm. Still, due to the passage of oil through the filters, RO membrane fouling was observed. Despite that, the overall results showed clearly successful conversion of OFB into freshwater of irrigation quality. The operating cost was less then 10¢/bbl.

Concluding this section, it is possible to draw out some positive outcomes. Crude oil still represents the most important energy source, so it is crucial to continue further improvement of OFB treatment technologies. The case studies presented clearly show the feasibility and the cost-effectiveness of the complete OFB treatment. It is quite obvious that OFB pollution control by wastewater treatment methods is superior to the liquidation–reinsertion practice of the past.

OIL POLLUTION

Kusum W. Ketkar
Rajiv Gandhi Chair
Jawaharlal Nehru University
New Delhi, India

The word oil refers to hydrocarbons—crude oil, gasoline, heating oil, fuel oil, diesel, jet fuel, and other refined oil-based products. Oil pollution refers to input of hydrocarbons into a water body, either on the surface of the earth or underground. Oil may directly enter surface water bodies like ponds, rivers, streams, and oceans, and it may leach into underground water. Recognizing that moving water cleans itself, oil pollution occurs when more oil enters water than natural, physical, and chemical processes can absorb it.

Accidental oil spills by oil tankers are only one of many causes of oil pollution, but they attract a lot of media attention. Media attention is justified because accidents spill a lot of oil in a short period of time. For example, oil tanker *Exxon Valdez* spilled 11 million gallons of crude oil in Prince William Sound, Alaska, in 1989. In addition to accidental oil spills, oil may enter marine environment through natural seepage, off-shore oil drilling, illegal disposal of waste water containing oil from tankers, tank barges and other vessels, land-based petrochemical industrial complexes, runoff containing oil from roads, oil-contaminated stormwater, and sludge from municipalities and numerous other land-based activities. Initially, oil-contaminated water may enter local streams, rivers, lakes, or ponds, but ultimately it is dumped into the oceans. According to Oceana, 80% of oil dumped into the sea is from inland operators, of which 44% is the result of direct dumping or coastal drainage, 33% is transported through the atmosphere, and the remaining 20% comes from accidental or deliberate spills from vessels and marine facilities (see Fig. 1) (1).

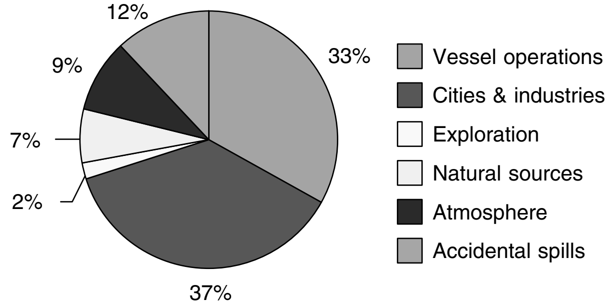

Figure 1. Causes of oil pollution. *Source*: Euoropa Oceana.

Worldwide, accidental oil spills account for about 12% of the total oil input into our oceans, whereas deliberate dumping from vessels and illegal dumping from tankers on the high seas account for 33%. Every year, over 6000 oil tankers use oceans as highways to transport crude oil. In 1983, 1.21 billion tons of crude oil was transported, and by 2002, that quantity had risen to 2 billion tons of crude. Table 1 gives estimated world maritime operational and accidental sources of oil entering marine environment.

On average, 25 major accidents and many smaller ones spill over 700 tons of oil into the seas every year (see Table 2). Overall, 2 to 10 million tons of oil leaks into the oceans annually.

Table 3 lists oil spills over a million gallons (3367 tons) in U.S. waters. After 1990, no spill in U.S. waters has been over a million gallons, and overall, there has been a sharp decline in large oil spills since the passage of the Oil Pollution Act of 1990. Most oil spill incidents in the United States occur along Alaska and the western and southern coasts. Alaska, Texas, and Louisiana are the major oil-producing states in the United States.

Since World War II, unprecedented increases in the world demand for energy and the rapid economic growth of the world economy have gone hand in hand. Oil is an indispensable source of energy in the production of goods and services in general and particularly in transportation. Most countries are poorly endowed with this valuable product also known as “black gold.” The result is that oil-poor countries have to import it from oil-rich countries. Petroleum and petroleum products are transported in tank ships or tank barges. According to Oceana, over 6000 tankers traverse world oceans carrying crude oil and oil products. The United States is the world’s largest consumer of oil, and it imports over 50% of the oil that it needs. Oil comes from both short-hauls like Mexico, Venezuela, and Nigeria and long hauls like Saudi Arabia,

Russia, the North Sea, and Indonesia. Over 4000 tankers make port calls every year, and the ports experiencing the highest tanker traffic are the ports of New York-New Jersey, Houston, Los Angeles/Long Beach, and San Francisco Bay. As the New York seaboard is shallow and has a soft bottom, only smaller tankers make port calls there. Crude from the Middle East and other long-haul countries is transported in very large crude carriers (VLCCs) and ultra-large crude carriers (ULCCs) to New York and other shallow ports. Lightering operation is used offshore to bring crude in smaller tankers to the shallow ports. These long-haul tankers (VLCCs) that bring crude to the United States have a capacity of 200,000 tons or more. They make calls to ports on the West Coast and the Gulf of Mexico because the coastal waters there are deep with rocky bottoms. Also, tank vessels use U.S. coastal waters, rivers, and lakes to distribute over 90% of petroleum and petroleum products, which results in over 20,000 port calls annually. As the vessel traffic increases, the risk of casualties and oil spills increases. Navigational risk in coastal waters is significantly influenced by vessel traffic, width of shipping channels, and the number of course changes. But the risk rises less than proportionately as vessel traffic increases (2). In addition to transportation of oil and refined products, there is offshore drilling and the crude is transported via pipelines to the mainland refineries. Alaskan crude is transported in tankers to the refineries. Thus, oil drilling, transfer, processing, and distribution make intensive use of the country's marine resources. With this intensive use comes the risk of oil input into the marine environment. The consumption of crude-based products generates waste, which releases oil into the natural environment. Hydrocarbons that are disposed of on land ultimately enter oceans.

The question is as follows: What is the impact of input of hydrocarbons on the marine environment? Scientists seem to agree that, in the long run, little adverse impact occurs on the marine environment. Take the Persian Gulf, for instance. Oil-producing Middle Eastern countries use ports on the Persian Gulf coast to ship crude oil and refined products. But biologists have observed that the Persian Gulf has experienced sharp increases in the concentration of oil-eating bacteria as oil input in the Gulf has increased (3). The environmental impact of oil input depends on the spill amount, its type—heavy or light crude or refined oil—the time of the year, location, previous exposure, and current length of exposure (4). The 1989 *Exxon Valdez* spill of 37,000 tons of crude in winter in Prince William Sound did more damage to the marine environment and the beaches than did the spill of 83,000 tons of crude by *Brear* on the high seas off the coast of Scotland. Temperate climates tend to have fewer oil-eating bacteria than do the tropics, and natural degradation takes much longer in the former climates than in the latter.

Generally, industrial, urban, and heavily populated areas are located near waterways and ports. Inputs of stormwater, sewerage, and industrial waste containing oil and oil-based products and input of oil from operational and accidental spills causes severe damage to the marine environment of the coastal waterways. For instance,

Table 3. Oil Spills in U.S. Coastal Waters

Source: U.S. Coast Guard.

coastal waters around New Orleans, Houston, Galveston, New York, and many other ports are dead in the sense that they can support no marine life. These waters continue to violate the mandate of the Clean Water Act of 1977. Coastal waters around New York–New Jersey ports are neither suitable for fishing nor swimming. To go fishing or swimming in New Jersey, one has to drive about 50 miles south from New York City. Similarly, the Hudson and East Rivers around New City have not been able to support any marine life until recently. The ecological impact of oil trapped in environmentally sensitive areas like marshes, wetlands, estuarine and freshwater communities, and intertidal and subtidal zones is the heaviest, although these effects appear to last from a few months to 15–20 years. But there can be exceptions. For instance, long-term and concentrated exposure of oil has killed colonies of coral reefs in Indonesian coastal waters and is suspected to have adversely affected invertebrates and plants in the coral reef community. The number 2 fuel oil that oil barge *Bouchard* 65 spilled in the west entrance of the Cape Cod canal in Buzzards Bay, Massachusetts, in 1974 entered salt marshes of Winsor Cove; and these mashes had not fully recovered by 2000 (5). The National Research Council observed that the most damaging effects of petroleum are oiling and tarring of beaches through the modification of benthic communities along polluted coastlines and the endangering of seabird species (6). Neither human health nor the food chain seems to be endangered by oil spills. The images of blackened beaches and dead birds are eye-catching, and television and the print media have effectively used them to win ratings and earn advertising revenues (7).

Large oil tankers crisscrossing the world's oceans and coastal waters pose a major threat for accidents leading to the spillage of large quantities of oil in a short period of time. Oil spreads quickly and evaporates. Heavy oils take longer to evaporate than do lighter and refined oils. If the spill is not quickly contained, it can trap sea birds and choke fish and other sea animals to death. If the spill is near a coastal area, it can kill life and damage property onshore and adversely affect commercial and subsistence fishing. The oil spill from the *Exxon Valdez* spread over hundreds of miles into numerous and remote coves, inlets, and bays from Prince William Sound through the Southern Kenai Peninsula and further south to Kodiak Island. Public outcry over the spoilage of pristine, rugged Alaskan environment cost Exxon-Mobile Corporation several billion dollars in cleanup costs. Organisms under rocks where hot water washing was used are taking longer to return to normal levels than those under those rocks that were left for nature to clean. In the aftermath of the accidental oil spill by the *Exxon Valdez*, the U.S. Congress passed the Oil Pollution Act in 1990 with the goal of preventing future oil spills and minimizing damage from accidental oil spills from operations and transportation of crude or refined petroleum products. The European Union followed the American example and passed a similar act after oil spills off the Spanish and British coasts. Among the preventive measures, the most controversial measures are the replacement of single hull tankers by double hull tankers and tanker owners' liability in case of a spill. As a result of various regulatory measures and increased vigilance by tanker ship owners, the number of large oil spills world wide has declined.

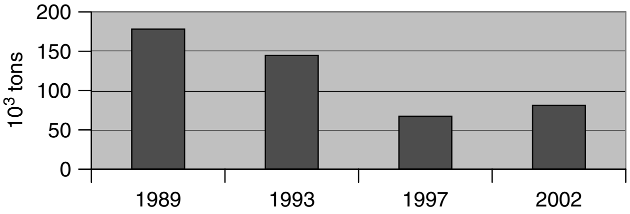

Figure 2. The world maritime operational oil spills. *Source*: International Tanker Owners Pollution Federation.

According to INTERTANKO, the quantity of oil spilled due to maritime operations has declined worldwide since 1989 because of the Oil Pollution Act of 1990 and the adoption of International Convention MARPOL 73/78 by the International Maritime Organization. The European Union followed the U.S. example and passed a law to prevent future oil spills after accidental spills by *Brear* off the coast of Scotland and by the *Aegean Sea* off the coast of Spain in the early 1990s. Figure 2 gives the quantity of oil spills from maritime operations.

INDICATOR ORGANISMS

Gary P. Yakub
Kathleen Stadterman-Knauer
Allegheny County Sanitary Authority
Pittsburgh, Pennsylvania

INTRODUCTION

Assessing biological contamination has always been an important part of any water quality study. Sources of fecal contamination include natural or agricultural sources and infrastructure problems that result in the release of untreated sewage into natural waters. This contamination can result in releasing dangerous human pathogens into recreational waters and source waters used to supply potable drinking water. People who contact contaminated water through bodily contact or ingestion are at risk for a variety of infections.

Since 1920, 1884 waterborne disease outbreaks, 882,144 cases of illness, and 1169 deaths in the United States have been from contaminated drinking and recreational waters (1). The causative agents responsible for these diseases could be bacteria, fungi, viruses, helminthes (worms), protozoa, or other pathogenic organisms. An attempt to characterize the biological quality of a water sample by investigating all of the known causative agents of waterborne disease would be impractical due to the large number of possible agents and the time-consuming methodology required. In addition, some agents can cause disease even at very low concentrations, and other causative agents can be difficult, if not impossible, to culture in the laboratory. These factors point to the need for a system to monitor biological water quality quickly, easily, and cost-effectively.

Indicator bacteria are the most common way of assessing biological water quality. Indicator bacteria are bacteria that can predict the presence of pathogenic organisms. To be a successful indicator, the following criteria must be met:

1. Indicator bacteria must be easy to cultivate in the laboratory using simple, cost-effective procedures.
2. Indicator bacteria must be present in high enough concentrations to be readily detectable in a manageable sample volume.
3. Indicator bacteria must effectively predict the risk of illness from exposure to the waterborne pathogens present in contaminated water.

Indicator bacteria are used in epidemiological studies to establish a correlation between bacteria levels and the rate of disease in a given population. From this information, water quality standards can be developed for a particular indicator bacteria based on acceptable risk limits. These water quality standards can then be used for quantitative evaluation of biological water quality.

Indicator bacteria are currently used to assess water quality for a variety of applications. Wastewater treatment facilities use fecal coliforms or *Escherichia coli* as indicators of proper disinfection. Drinking water plants monitor total coliforms as an indicator of water quality in their distribution systems. Recreational water quality standards are based upon fecal coliforms, *E. coli*, or enterococcus bacteria levels depending upon water type and usage.

THE COLIFORM GROUP

The coliform group is the group of bacteria that has received the most attention for application as an indicator of fecal pollution. Coliform bacteria are found in the intestinal tract of humans and other animals; therefore, their presence in ambient water indicates fecal pollution and the potential presence of pathogens (2).

During the late 1940s and early 1950s, the United States Public Health Service began a series of studies based on coliform bacteria levels (3). Its goal was to determine if coliform concentrations in recreational water were correlated with the incidence of gastroenteritis in swimmers. From these studies, total coliform was used as the indicator bacteria for recreational waters. In the mid 1960s, total coliforms were replaced by fecal coliforms, which showed a greater specificity for mammalian fecal pollution and less variation due to environmental conditions. Fecal coliforms made up about 18% of total coliforms (3). In 1976, the U.S. EPA recommended fecal coliforms to the regulatory community as indicator organisms for the presence of pathogens in recreational waters (2). In 1986, based on new research data, U.S. EPA recommended new monitoring guidelines, including the use of *E. coli* as an indicator to replace fecal coliforms. The presence of *E. coli*, it was found, correlated with swimming-associated gastrointestinal illness better than fecal coliform levels (2).

THE ENTEROCOCCUS GROUP

In its 1986 Bacterial Water Quality Criteria report, the U.S. EPA also concluded that members of the enterococcus group of bacteria were acceptable as an indicator of fecal pollution due to the high correlation between enterococcus bacteria levels and swimming-related gastrointestinal illness. The strong correlation was noted in both freshwater and saltwater, and enterococci have been proposed as an indicator of water quality for both environments (3).

Enterococcus bacteria are a subgroup of the fecal streptococci that includes *S. faecalis, S. faecium, S. gallinarum,* and *S.avium*. Enterococci are differentiated from other streptococci by their ability to grow in 6.5% sodium chloride, at pH 9.6, and at 10 °C and 45 °C.

There has been some attempt to use the fecal coliform to fecal strep ratio to differentiate the source of fecal pollution. A ratio higher than four was proposed to suggest human sources, and a ratio of less than 0.7 was proposed to suggest nonhuman sources. However, factors such as a difference in die-off rates among the enterococci and a variability to chlorine disinfection resulted in a recommendation that the fecal coliform to fecal strep ratio should not be used for source differentiation (4).

THE FUTURE OF INDICATOR ORGANISMS

There are many organisms that do not correlate with the indicators used to determine fecal contamination in surface waters. The ecology, prevalence, and resistance to stress of indicator organisms may differ from many of the pathogenic microorganisms for which they serve as proxies. For example, fecal coliform does not indicate many disease-causing viruses, such as hepatitis A or E, Coxsackie viruses, adenoviruses, and Norwalk viruses or indigenous bacteria such as *Helicobacter* or *Legionella*. *Giardia* and *Cryptosporidium*, two parasitic protozoa, also do not correlate with fecal coliform levels (5). A

2001 American Academy of Microbiology report advocates the advancement of molecular techniques for detecting waterborne pathogens in the context of a risk-based analysis (5). Molecular tools could allow rapid detection of an organism, and also determine its virulence, prevalence, and source of contamination. However, many of these techniques are in development and may not be available to utilities for many years. Therefore, indicator organisms will continue to play a role in water quality analysis until these new techniques become available and cost-effective.

pH THEORY

Some chemical compounds, when dissolved in water, dissociate to yield hydrogen ions (H^+, e.g., protons), as in Equation 1, and are called acids. Other compounds called bases yield hydroxide ions (OH^-), when dissolved in water, as in Equation 2.

$$HA = H^+ + A^- \tag{1}$$

$$MOH = M^+ + OH^- \tag{2}$$

The chemical species in Equations 1 and 2 represented by A^- and M^+ are anions (negatively charged ions) and cations (positively charged ions), respectively. Acids and bases can be organic (containing two or more of the following atoms: carbon, hydrogen, oxygen, and nitrogen), such as acetic acid ($HC_3H_2O_2$), or inorganic (consisting of a metal and nonmetal), such as the base sodium hydroxide (NaOH). In addition to classification as organic or inorganic, acids and bases can also be ranked according to their strengths. Some common acids and bases are listed in Table 1.

The relative strength of an acid or base is related to the degree of dissociation that the compound undergoes according to either Equation 1 or 2. A strong acid is one that dissociates completely to yield a relatively large number of hydrogen ions, whereas a strong base is a compound that yields a relatively large number of hydroxide ions.

For strong acids and strong bases, the reactions described by Equations 1 and 2 proceed from left to right to form products and the reverse reactions are negligible. The converse is true for weak acids and weak bases; only a relatively small number of either hydrogen ions or hydroxide ions are produced. In the case of a weak acid or base, the reverse reactions described by Equations 1 and 2 are significant. Weak acids and bases are characterized by an acid dissociation constant (K_a) or a base dissociation constant (K_b) (see Table 1). The larger the value of either K_a or K_b, the greater is the degree of dissociation of the acid or base.

The hydrogen ion concentration in a solution of 1 mol/L hydrochloric acid would be approximately 1 mol/L. However, for a 1 mol/L sodium hydroxide solution (a base), the hydrogen ion concentration is approximately

Table 1. Common Strong and Weak Acids and Bases

Strong Acids		Strong Bases	
HCl, Hydrochloric acid		LiOH, Lithium hydroxide	
H_2SO_4, Sulfuric acid		NaOH, Sodium hydroxide	
HNO_3, Nitric acid		KOH, Potassium hydroxide	
$HClO_4$, Perchloric acid		$Ca(OH)_2$, Calcium hydroxide	
HBr, Hydrobromic acid		$Sr(OH)_2$, Strontium hydroxide	
HI, Hydroiodic acid		$Ba(OH)_2$, Barium hydroxide	
Weak Acids	K_a@25 °C[a]	**Weak Bases**	K_b@25 °C[b]
HF, Hydrofluoric acid	6.8×10^{-4}	$(CH_3)_2$ NH, Dimethylamine	5.1×10^{-4}
$HCHO_2$, Formic acid	1.7×10^{-4}	NH_3, Ammonia	1.8×10^{-5}
$HC_7H_5O_2$, Benzoic acid	6.3×10^{-5}	N_2H_4, Hydrazine	1.7×10^{-6}
$HC_2H_3O_2$, Acetic acid	1.7×10^{-5}	NH_2OH, Hydroxylamine	1.1×10^{-8}
HClO, Hypochlorous acid	3.5×10^{-8}	C_6H_5 NH_2, Aniline	4.2×10^{-10}
H_3BO_3, Boric acid	5.9×10^{-10}	NH_2CONH_2, Urea	1.5×10^{-14}

[a] Reference 1, p. 672.
[b] Reference 1, p. 680.

10^{-14} mol/L. In pure water, the hydrogen ion concentration is 10^{-7} mol/L. In the preceding examples, the hydrogen ion concentration varies by a factor of 10^{14} in going from acid to base. Therefore, it is more convenient to express the relative acidity of a solution by using a logarithmic scale based on hydrogen ion concentration and referred to as pH.

pH is expressed mathematically as

$$\mathrm{pH} = -\log[\mathrm{H}^+] \tag{3}$$

where $[\mathrm{H}^+]$ is the hydrogen ion concentration in the solution expressed in mol/L or molarity (M). Using this definition, the pH values for 1 M hydrochloric acid, water, and 1 M sodium hydroxide are 0, 7, and 14, respectively. Although the pH scale is technically defined from 0 to 14, pH values below 0 and above 14 are possible.

To contrast, consider the pH of a 1 M HCl solution and a 1 M acetic acid solution. From the previous example, we know that the pH of the 1 M HCl solution is 0, whereas the 1 M acetic acid solution will have a pH of 2.4. The difference in pH between the two solutions lies in the fact that acetic acid is a "weak" acid, and hence it does not completely dissociate in aqueous solution. For this reason, a simple relationship between pH and weak acid or weak base concentration does not hold true.

In our previous example, we stated that the pH of a 1 M NaOH is 14. To arrive at this result, one must first calculate the pOH:

$$\mathrm{pOH} = -\log[\mathrm{OH}^-] \tag{4}$$

and then calculate the pH:

$$\mathrm{pH} = 14 - \mathrm{pOH} \tag{5}$$

pH BUFFERS

The reaction shown in Equation 1 will proceed from left to right to a limited extent for a weak acid. In this case, the reverse reaction (formation of HA) can also occur to a significant extent. The same is true for weak bases (Equation 2). As an example, consider the weak acid acetic acid (Equation 6) and the weak base ammonia (Equation 7):

$$\mathrm{HC_2H_3O_2} = \mathrm{H}^+ + \mathrm{C_2H_3O_2}^- \tag{6}$$

$$\mathrm{NH_3} + \mathrm{H_2O} = \mathrm{NH_4}^+ + \mathrm{OH}^- \tag{7}$$

Acetic acid dissociates to form hydrogen ion and acetate ion ($\mathrm{C_2H_3O_2}^-$). Acetate ion is referred to as the conjugate base to acetic acid because it can acquire a hydrogen ion and reform acetic acid. Ammonia, on the other hand, acquires a hydrogen ion from a water molecule to form ammonium ion ($\mathrm{NH_4}^+$) and hydroxide ion. Ammonium ion is referred to as the conjugate acid of ammonia because it can lose a hydrogen ion to reform ammonia.

Solutions that can resist pH changes upon the addition of limited quantities of an acid or base are called buffers. Buffer solutions may contain either an acid and conjugate base or a base and conjugate acid. The presence of both species (acid/conjugate base or base/conjugate acid) permits the unique properties of these solutions. Buffers can be acidic, neutral, or basic.

Buffers can be prepared in the laboratory by combining the acid or base species with a salt consisting of the corresponding conjugate acid or conjugate base. In the case of acetate buffer, acetic acid is combined with an acetate salt such as sodium acetate. The quantity of each component used can be obtained from reference literature or calculated (1). Standard buffer "recipes" are available for numerous buffer compositions and pH ranges (2).

Alternatively, buffers can be purchased commercially. These are typically available in pH values from 1 to 14. The accuracy with which a buffer is prepared can depend upon the manufacturer and composition of the buffer. The National Institute of Standards and Technology (NIST) sells salts for preparing buffer standards with an uncertainty of ±0.005 pH units. Other manufacturers typically sell buffers having uncertainties ranging from 0.01 to 0.02 pH units. Most buffers will state that they are traceable to NIST standards. This means that during the manufacture of the buffer, its value is standardized using NIST buffers.

The pH values of buffer solutions depend on temperature. For example, the pH value for the standard NIST borax buffer at 25°C is 9.180. At 50°C, the pH decreases to 9.011 (3). Commercially available buffers usually state the pH value at 25°C. pH values for other temperatures can be obtained from the buffer manufacturer.

pH MEASUREMENT

There are two well-accepted methods for determining solution pH: colorimetry and sensor-based technology. Each method has advantages and disadvantages, and each has utility based primarily on the application and desired accuracy of the determination.

Colorimetry

The colorimetric determination of pH employs dye compounds, called indicators, which change color depending upon solution pH. The dyes used exhibit colors in the visible spectrum and can undergo one or more color changes as a function of pH. The indicator can be immobilized on a paper substrate (pH paper) or can be prepared as a solution using water or water combined with an organic solvent. The simplest indicators are those that undergo only a single color change such as litmus paper or phenolphthalein solution. For example, acidic solutions cause the color of litmus paper to change from blue to red whereas basic solutions cause phenolphthalein solution to change from colorless to red (or pink). Table 2 lists several acid–base indicators along with their color changes as a function of pH.

The pH paper method offers greater utility because the immobilized indicators can undergo several different color changes across the full pH scale. Some papers are designed to indicate only a single unit pH change; others can indicate changes of 0.1 or 0.2 pH units.

Sensor-Based Measurement

These technologies employ sensors that either generate a potential (glass pH sensors and solid-state sensors) or use

Table 2. Compounds Used to Indicate Solution pH

Indicator	Transition pH	Acid Color	Base Color
Methyl violet	0.0–1.6	Yellow	Blue
Cresol purple	1.2–2.8	Red	Yellow
Methyl orange	3.1–4.4	Red	Orange
Congo red	3.0–5.0	Violet	Red
Methyl red	4.8–6.0	Red	Yellow
Litmus	5.0–8.0	Red	Blue
Phenolphthalein	8.0–9.6	Colorless	Red
Thymolphthalein	8.3–10.5	Colorless	Blue
Alizarin yellow	10.1–12.0	Yellow	Orange red

optical principles to determine the pH. Signal conditioning electronics are required in addition to the sensor for measurement, display, and data transmission. Both types of sensor technology can be used in the laboratory or in the field.

Glass pH Sensor. A glass pH electrode consists of two electrode elements; a silica glass membrane that selectively responds to hydrogen ions and a reference element. The two elements can be separate or combined as one into a single sensor, as shown in Fig. 1. When the elements are combined, the unit is referred to as a combination pH electrode. The combined electrode and the separate pH and reference elements are available commercially.

pH Glass Element. A pH glass element consists of a short section (<1 cm) of special glass that produces a voltage in the presence of hydrogen ions. This section of glass is attached to a shaft of lead glass that can be 10 or more centimeters long. The bulk of the membrane glass matrix usually consists of silicon dioxide. Other compounds, such as oxides of lithium, calcium, lanthanum, cesium, and uranium, are added to provide unique characteristics such as low resistance, high selectivity to hydrogen ions, and high strength. When immersed in aqueous solution, the glass matrix forms a hydrated layer, often called a gel layer, which is approximately 5 to 20 nm thick (4). The processes responsible for the sensing function of the glass can be viewed as an equilibrium binding of hydrogen ions within the gel layer (Fig. 2). The inside of the pH glass element is filled with a buffer saturated with silver chloride. Electrical contact is completed through a silver chloride coated silver wire immersed in the buffer. Usually the buffer is designed to have a pH of 7. Therefore, when the electrode is immersed in a pH 7 buffer, the potential difference across the glass membrane will be 0 volts versus the reference element. The shaft glass plays no role in the function of the electrode, aside from providing a substrate that is a good electrical insulator to which the membrane glass can be attached.

Reference Element. The reference element provides a reference potential against which the potential of the pH element is measured. The pH element and reference element form a complete electrical circuit when they are immersed together in the same solution. The reference is characterized by its ability to maintain a constant potential regardless of solution conditions. Additionally, the potential of the reference must not drift with time and should exhibit little or no hysteresis when the element undergoes a change in temperature. The reference element is simply a tube filled with an electrolyte into which a porous material called a frit is imbedded (Fig. 1). The frit allows the solution being tested to come in contact with the reference electrolyte. Usually, references are designed so that a small amount of the reference electrolyte will flow through the frit into the test solution. Ideally, there is no bulk flow of test solution into the reference

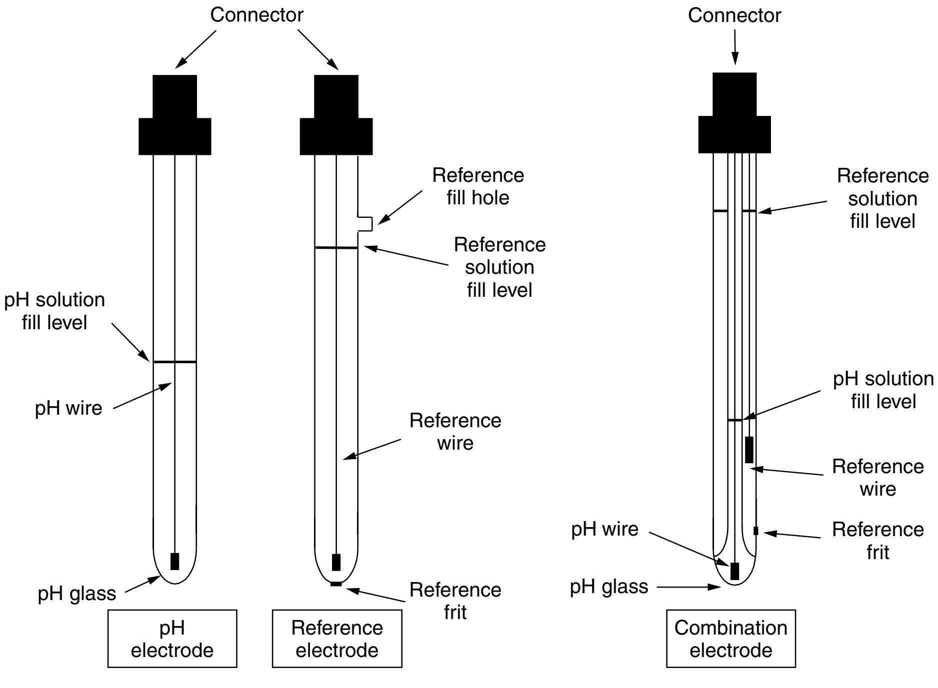

Figure 1. Separate pH and reference electrodes and the combination pH electrode.

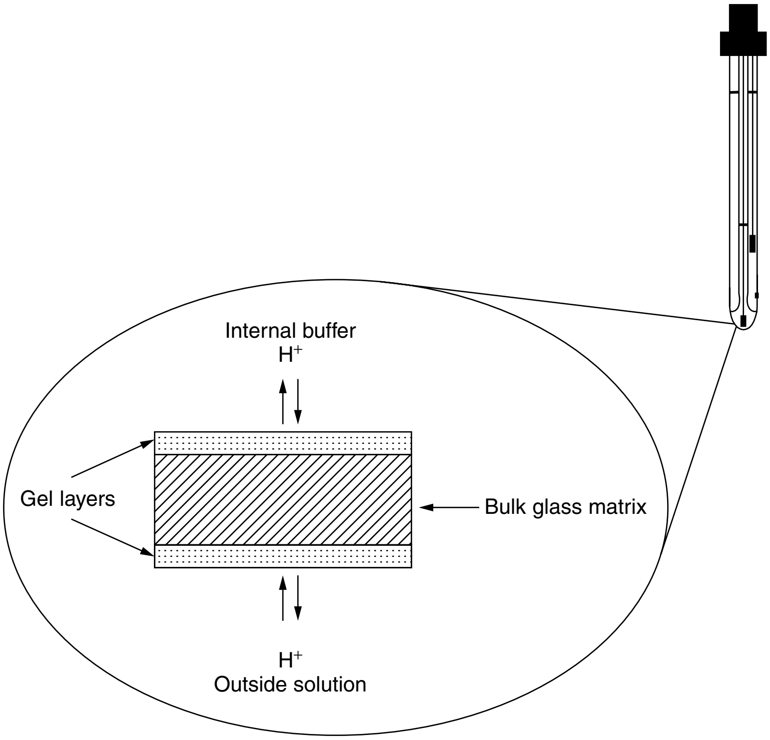

Figure 2. Representation of a cross section of a pH glass membrane showing gel layers and bulk glass membrane.

element. However, some test solution components may diffuse across the frit and contaminate the reference electrolyte after exposure for an extended period of time. The most common reference is based on a silver–silver chloride electrochemical cell. The system consists of a silver chloride coated silver wire immersed in a solution containing a high concentration of potassium chloride, usually either 3.5 M or saturated potassium chloride.

In use, the pH and reference elements are electrically connected to a high input impedance measuring device called a meter. Both the pH and reference elements are immersed to a depth great enough to ensure that the test solution completely covers the pH glass and the reference frit. The potential measured and displayed by the meter (E_{meter}) is the difference in potential between the two elements:

$$E_{\text{meter}} = E_{\text{pH}} - E_{\text{ref}} + E_J \tag{8}$$

where E_{pH} and E_{ref} are the potentials of the pH and reference elements, respectively. The other potential in the equation, E_J, is the reference junction potential. This potential results from the charge separation occurring due to differences in the migration rates of ions across the reference electrolyte/test solution interface. Reference electrodes are designed to keep this term small and constant, regardless of solution conditions.

The potential E_{meter} as a function of solution pH is given by the following expression;

$$E_{\text{meter}} = \left(\frac{2.303\,RT}{F}\right)(7 - \text{pH}) \tag{9}$$

where R is the ideal gas law constant (8.314 J/mol·K), T is the temperature in K, and F is Faraday's constant (96485 C/mol). At 25 °C, the slope term in ( ) has a value of 59.2 mV. This is the operational form of the Nernst equation applied to a glass pH electrode (see Reference 4 for a discussion of the Nernst equation). Equation 9 yields a plot that has a negative slope, as shown in Fig. 3.

When the pH is measured at temperatures different from the calibration temperature, a measurement error can result. This is due to the change in electrode response as a function of temperature. For this reason, practically all commercially available pH meters provide automatic temperature compensation (ATC). This feature corrects only for the effect of temperature on electrode response, not for the true temperature coefficient of a solution resulting from chemical equilibria shifts with temperature. For ATC, the temperature at calibration and measurement are either entered into the meter manually, or a temperature sensor sends this information to the meter automatically. The temperature sensor can be built into the pH probe, or it may be separate.

Calibration. The probe and meter are calibrated as a pair. During calibration, the meter relates the potential produced by the electrode immersed in a buffer to the pH value of the buffer. Calibration is performed either using standard buffer solutions or a sample solution of known pH value. In laboratory use, the calibration is generally done either daily or just before the system is used for a series of measurements. The time interval between calibrations in an industrial process depends upon how quickly solution conditions degrade electrode performance. The interval can be as often as every few days or as little as a month or more. Detailed procedures for the proper use and calibration of glass pH electrodes can be found in reference sources (5,6).

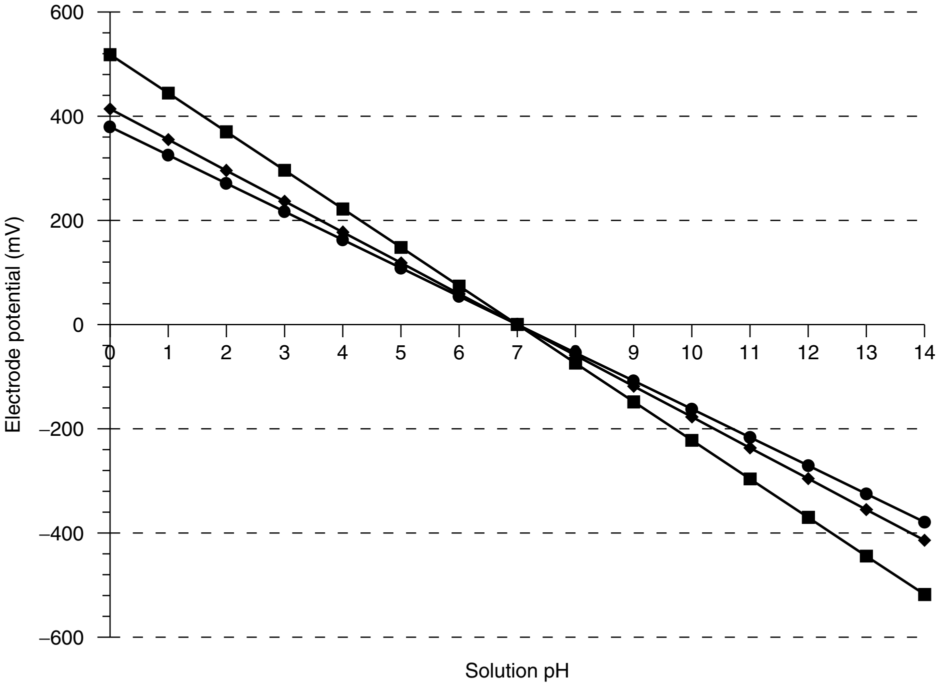

Figure 3. pH electrode potential as a function of solution pH at 0 °C (●), 25 °C (♦), and 100 °C (■).

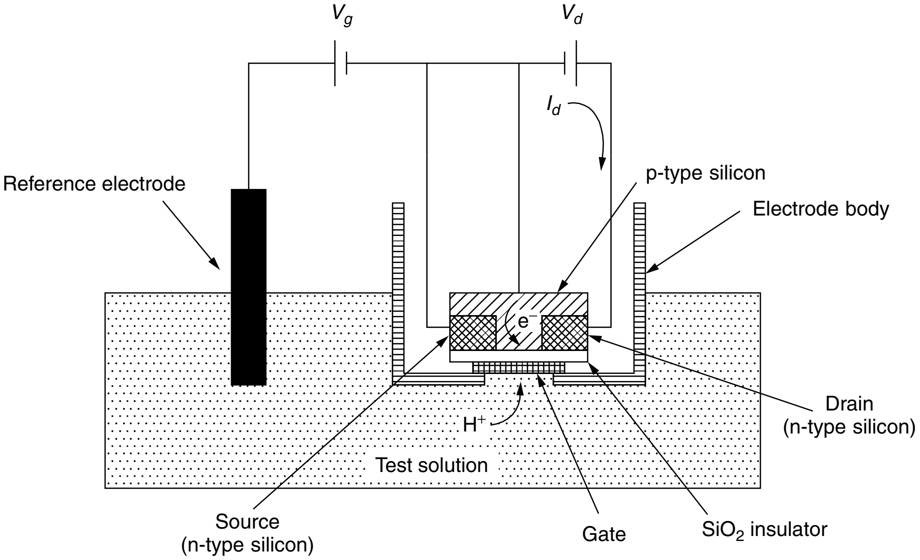

Figure 4. Typical arrangement of an ISFET sensor used for pH measurement. V_g and V_d are the gate and drain voltages, respectively. I_d is the drain current.

Solid State Sensors. More recently, pH sensitive electrodes have been developed based on metal-oxide semiconductor field effect transistor (MOSFET) technology. The sensors are similar in construction and operation to a traditional MOSFET, except that the gate is modified by an ion selective coating. The sensor is then referred to as an ion-selective field effect transistor (ISFET) (Fig. 4) (7–9).

The ISFET is enclosed in the electrode body so that only the gate is exposed to the solution. The sensors can be made to respond selectively to many different ions. For pH measurement, the gate is coated with either an oxide of silicon, aluminum, or tantalum or a nitride of silicon. In operation, a bias voltage is applied to the gate and the drain. Protons adsorbed to the gate alter the conductance of the p-type silicon above the gate. This results in current flow in the n-p-n region between the source and drain. Under these conditions, the drain current (I_d) is approximated by the following equation (10):

$$I_d = AV_d[V_c + V_g - E_{\mathrm{N}}(\mathrm{pH})] \tag{10}$$

where A is a constant, V_d is the drain potential, V_c is a combination of the threshold potential of the p-n junction and phase boundary potentials, V_g is the potential applied to the gate, and E_{N} is the Nernst potential (or slope, equal to 59.2 mV at 25 °C). Either the voltage or current generated at the ISFET can be monitored by the meter. If the gate voltage is monitored, then the drain current is kept constant, or conversely, if the drain current is monitored, the gate voltage is kept constant.

The ISFET sensor uses the same type of reference element as the glass electrode. Attempts have been made to modify the ISFET to act as a reference electrode (11). Thus far, work has not produced significant improvement over a conventional reference system.

Optical pH Sensors. The concept of pH determination using colorimetry and absorbance spectrophotometry has been integrated into a sensor that is the size of a conventional laboratory glass pH electrode (12). The measurement is based on using indicator dyes immobilized in a polymer film. Several different indicator films are available, depending upon the pH range desired for the measurement.

PERCHLOROETHYLENE (PCE) REMOVAL

Enos C. Inniss
University of Texas
San Antonio, Texas

INTRODUCTION

Perchloroethylene (C_2Cl_4) or PCE is also known by other names, tetrachloroethylene and perc. Often in chemistry, one might see the -ethylene replaced with -ethene. PCE is a chemically synthesized compound that has been used as a solvent since the 1940s because of its nonflammable nature. This characteristic eliminated many accidental fires in the workplace, which resulted in increased employee safety and reduced cost of operation. Since it is a volatile organic compound (VOC), PCE was considered "clean" because it quickly volatilizes when exposed to air. Appropriate applications of this chlorinated solvent include dry cleaning, metal degreasing, brake cleaning (replacing 1,1,1-trichloroethane), and production of HFC134a (a hydrofluorocarbon alternative to the chlorofluorocarbons or CFCs phased out as refrigerants in the early 1990s) (1).

By the early 1980s widespread use of PCE coupled with historically poor handling and disposal practices led to its regulation under the Safe Drinking Water Act Amendments of 1986 (SDWAA–1986) (2). Now a common groundwater contaminant and a priority pollutant, PCE has been observed to degrade both biologically and chemically.

The biological transformation process is reductive dechlorination, an anaerobic process where microorganisms use the chlorinated ethylenes as electron acceptors (3). Once reduced, the reduction products may also be further transformed by cometabolic oxidation, a gratuitous metabolic reaction under aerobic conditions where the microorganisms are growing on another substance and gain no energy from the cometabolized substance (4).

The chemical transformations may also be either reductions or oxidations. The reductions are achieved through interactions with zero valent metals (ZVMs). Oxidative processes include potassium permanganate or photochemical oxidation.

REDUCTIVE DECHLORINATION

Microbial metabolism requires that energy and carbon sources be readily available. Most sugars, a common hydrocarbon, have the ability to give electrons by simply breaking the carbon–hydrogen bond and are therefore referred to as electron donors. The highly oxidized nature of PCE (with all of the chlorine substitutions) makes it nearly impossible to further oxidize. This quality promotes its recalcitrance or persistence in the environment. Therefore, any transformations of this compound require that a reduction (with the chlorinated ethylene serving as the electron acceptor) first take place. In the presence of microorganisms, this process is referred to as reductive dechlorination (Fig. 1). Under anaerobic conditions a number of identified microorganisms with the proper dehalogenase enzyme are expected to be able to sequentially reduce PCE to trichloroethylene (TCE), then to several isomers of dichloroethylene (DCE), then to vinyl chloride (VC), and finally to ethylene (ETH), where it could be taken up by microorganisms and plants as part of regular metabolic pathways (7).

Because of the significant energy required to push this reaction pathway to the innocuous ethylene product, the process is more likely to halt at either DCE or VC production. Note that the higher the potential ($E^{\circ\prime}$) the more likely the compound will be reduced. All of the chlorinated ethylenes (PCE, TCE, DCE, and VC) are considered priority pollutants under SDWAA–1986. So an additional transformation step is usually required to achieve removal of all contaminants of concern.

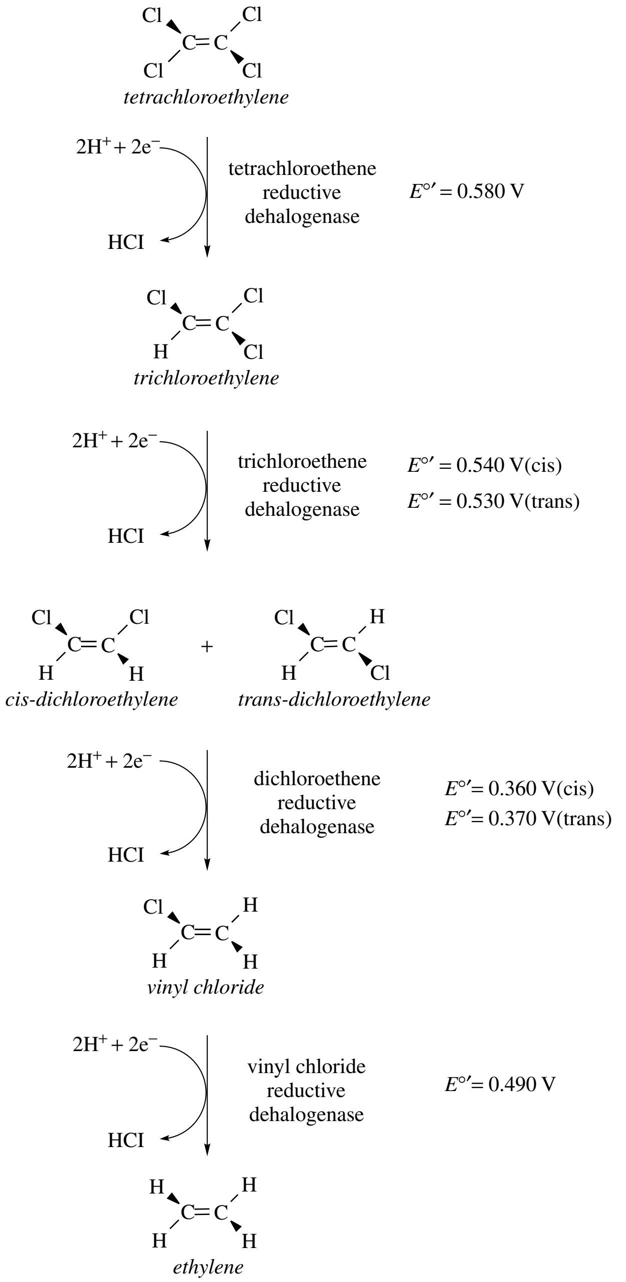

Figure 1. The biologically mediated reductive dechlorination process from perchloroethylene all the way to (the nonchlorinated) ethylene (5) with the corresponding standard reduction potentials, $E^{\circ\prime}$, for each half-reaction (6).

COMETABOLIC OXIDATION

Concerns for the incomplete reduction of the chlorinated ethylenes led to consideration of additional transformation pathways/mechanisms. Biologically, the reductive dechlorination may be forced to try to get beyond the VC production or a different pathway may be followed. Once PCE is initially reduced to TCE, then this and the remaining reduction products may more readily be cometabolically oxidized. The pathway shown for TCE (Fig. 2) oxidation is assumed to be similar for DCE and VC oxidation (8). The energetics of this process also suggest that the lesser chlorinated products are more easily oxidized by microorganisms possessing the appropriate oxygenase enzymes.

The commonality of the enzymes is that they do chemistry on the carbon nucleus of the compound, weakening the carbon–carbon double bond. These transformations are further considered cometabolic because the enzymes are produced to do chemistry on compounds with similar chemical structures to that of the chlorinated ethylenes (Fig. 3). Sustainability of this process therefore requires the addition of both the similar target compound (e.g., phenol) and reducing equivalents [e.g., NAD(P)H] as cometabolites (9).

The resulting products from this cometabolic oxidation are innocuous compounds that can readily be incorporated into typical metabolic function of microorganisms.

METAL REDUCTION

Similar to the biologically mediated reductive dechlorination, zero valent metals (ZVMs, typically granular iron) when they corrode either produce hydrogen or serve as an electron donor directly (10). ZVMs are used in permeable reactive barriers (PRBs) as well as in canister filters to allow for on-site treatment.

CHEMICAL OXIDATION

Photocatalytic oxidation uses a titanium dioxide catalyst, which is excited by the UVA spectrum (315–400 nm) of ultraviolet light to produce hydroxyl radicals. The process is used with volatilized contaminants at ambient temperature and pressure. Therefore, photocatalytic oxidation is an appropriate treatment option to use in conjunction with either air stripping or soil vapor extraction (11).

Potassium permanganate is another stronger oxidizer that rapidly degrades chlorinated ethylenes either in solution or in soils. This compound, similar to the biological oxygenase enzymes, attacks and weakens the carbon–carbon double bond (12).

CONCLUSION

There are both chemical and biological treatment options available for removal of PCE. Depending on cost, availability, and preference of options, one can choose from biologically mediated reductive dechlorination of PCE and its reduction products. Recognizing the likely limitation in achieving complete transformation to innocuous compounds, one could switch to biologically mediated cometabolic oxidation. Or depending on the form the chlorinated ethylenes are in, solubilized versus volatilized, a chemical reduction (ZVMs) or oxidation process (photocatalytic or potassium permanganate) may be chosen.

A PRIMER ON WATER QUALITY

Gail E. Cordy
U.S. Geological Survey

WHAT IS IN THE WATER?

Is it safe for drinking? Can fish and other aquatic life thrive in streams and lakes that are affected by human

---

activities? What is the water quality? To answer these questions, it is helpful to understand what "water quality" means, how it is determined, and the natural processes and human activities that affect water quality.

WHAT DO WE MEAN BY "WATER QUALITY"?

Water quality can be thought of as a measure of the suitability of water for a particular use based on selected physical, chemical, and biological characteristics. To determine water quality, scientists first measure and analyze characteristics of the water such as temperature, dissolved mineral content, and number of bacteria. Selected characteristics are then compared to numeric standards and guidelines to decide if the water is suitable for a particular use.

HOW IS WATER QUALITY MEASURED?

Some aspects of water quality can be determined right in the stream or at the well. These include temperature, acidity (pH), dissolved oxygen, and electrical conductance (an indirect indicator of dissolved minerals in the water). Analyses of individual chemicals generally are done at a laboratory.

WHY DO WE HAVE WATER-QUALITY STANDARDS AND GUIDELINES?

Standards and guidelines are established to protect water for designated uses such as drinking, recreation, agricultural irrigation, or protection and maintenance of aquatic life. Standards for drinking-water quality ensure that public drinking-water supplies are as safe as possible. The U.S. Environmental Protection Agency (USEPA) and the States are responsible for establishing the standards for constituents in water that have been shown to pose a risk to human health. Other standards protect aquatic life, including fish, and fish-eating wildlife such as birds.

HOW DO NATURAL PROCESSES AFFECT WATER QUALITY?

Natural water quality varies from place to place, with the seasons, with climate, and with the types of soils and rocks

through which water moves. When water from rain or snow moves over the land and through the ground, the water may dissolve minerals in rocks and soil, percolate through organic material such as roots and leaves, and react with algae, bacteria, and other microscopic organisms. Water may also carry plant debris and sand, silt, and clay to rivers and streams making the water appear "muddy" or turbid. When water evaporates from lakes and streams, dissolved minerals are more concentrated in the water that remains. Each of these natural processes changes the water quality and potentially the water use.

WHAT IS NATURALLY IN THE WATER?

The most common dissolved substances in water are minerals or salts that, as a group, are referred to as dissolved solids. Dissolved solids include common constituents such as calcium, sodium, bicarbonate, and chloride; plant nutrients such as nitrogen and phosphorus; and trace elements such as selenium, chromium, and arsenic.

In general, the common constituents are not considered harmful to human health, although some constituents can affect the taste, smell, or clarity of water. Plant nutrients and trace elements in water can be harmful to human health and aquatic life if they exceed standards or guidelines.

Dissolved gases such as oxygen and radon are common in natural waters. Adequate oxygen levels in water are a necessity for fish and other aquatic life. Radon gas can be a threat to human health when it exceeds drinking-water standards.

HOW DO HUMAN ACTIVITIES AFFECT WATER QUALITY?

Urban and industrial development, farming, mining, combustion of fossil fuels, stream-channel alteration, animal-feeding operations, and other human activities can change the quality of natural waters. As an example of the effects of human activities on water quality, consider nitrogen and phosphorus fertilizers that are applied to crops and lawns. These plant nutrients can be dissolved easily in rainwater or snowmelt runoff. Excess nutrients carried to streams and lakes encourage abundant growth of algae, which leads to low oxygen in the water and the possibility of fish kills.

Chemicals such as pharmaceutical drugs, dry-cleaning solvents, and gasoline that are used in urban and industrial activities have been found in streams and ground water. After decades of use, pesticides are now widespread in streams and ground water, though they rarely exceed the existing standards and guidelines established to protect human health. Some pesticides have not been used for 20 to 30 years, but they are still detected in fish and streambed sediment at levels that pose a potential risk to human health, aquatic life, and fish-eating wildlife. There are so many chemicals in use today that determining the risk to human health and aquatic life is a complex task. In addition, mixtures of chemicals typically are found in water, but health-based standards and guidelines have not been established for chemical mixtures.

WHAT ABOUT BACTERIA, VIRUSES, AND OTHER PATHOGENS IN WATER?

The quality of water for drinking cannot be assured by chemical analyses alone. The presence of bacteria in water, which are normally found in the intestinal tracts of humans and animals, signal that disease-causing pathogens may be present. Giardia and cryptosporidium are pathogens that have been found occasionally in public-water supplies and have caused illness in a large number of people in a few locations. Pathogens can enter our water from leaking septic tanks, wastewater-treatment discharge, and animal wastes.

HOW CAN I FIND OUT MORE ABOUT MY WATER QUALITY?

Contact your local water supplier and ask for information on the water quality in your area. The USEPA requires public-water suppliers to provide water-quality data to the public on an annual basis in an understandable format. State agencies that deal with health, environmental quality, or water resources also can provide information on the quality of your water. Additional resources can be found on the Internet at:

OVERVIEW OF ANALYTICAL METHODS OF WATER ANALYSES WITH SPECIFIC REFERENCE TO EPA METHODS FOR PRIORITY POLLUTANT ANALYSIS

Ralph J. Tella
Lord Associates, Inc.
Norwood, Massachusetts

INTRODUCTION

This article is an overview of the analytical chemistry behind the analyses of common environmental contaminants. Specific reference is made to the U.S. Environmental Protection Agency (EPA) "priority pollutants." The list of priority pollutants was first published in the *Federal Register* in 1980 as the list of toxic pollutants for which categorically defined industries were required to analyze their effluent streams to obtain wastewater discharge permits under the National Pollution Discharge Elimination System (NPDES).

To require industry to analyze for pollutants, the EPA was compelled to develop standardized test procedures. As scientists and engineers became familiar with these procedures, the priority pollutant list developed into a commonly requested set of analyses used to characterize and evaluate the toxicity of various environmental media including soils, groundwater, and air.

The priority pollutant list is comprised of several classes of compounds or "fractions," grouped according to similar chemical and physical characteristics. A complete list of the priority pollutants is provided in Table 1. These fractions include 111 organic compounds, and 15 inorganic elements and compounds, a total of 126 parameters.

Note that these 126 parameters are not the only toxic pollutants in the world. Rather, they are only a convenient list of common pollutants for which there are standardized test methods. Many more pollutants can be analyzed for, some use the same analytical techniques. However, to gain this information from the laboratory, you must specifically ask for it. Many commercial laboratories have developed economical techniques, which "screen" for these nonpriority pollutants, such as "library searches," or "extended runs." Many of these techniques are, however, only semiquantitative and qualitative.

Because petroleum products in the aqueous environment comprise a large focus of attention in the field of environmental restoration, this article also describes various methods of analyses for petroleum products. Note that only some components of petroleum are regulated as EPA "priority pollutants."

GAS CHROMATOGRAPHY

Gas chromatography (GC) is a powerful and highly versatile instrumental method of analysis that was developed in the early 1950s. The number of technological advances in the technique since then has been so tremendous that a complete and detailed discussion of the technique is beyond the scope of this article. Rather, this discussion is limited to those techniques that are commonly used in environmental analyses.

Theory

This is the basic process by which a GC works. A sample is introduced into the instrument in a vapor state, and the various gaseous components are separated so that they can be individually identified and quantitatively measured. A schematic diagram of this process is provided in Fig. 1. The basic components are a gas cylinder with a reducing valve, a constant pressure regulator, a port for injecting the sample, a chromatographic column, a detector, an exit line, and a data collection device such as a strip chart recorder or computer.

The gas cylinder contains a carrier gas such as hydrogen, helium, or nitrogen, which is continuously swept through the chromatographic column at a constant temperature and flow rate. A small sample for analysis is injected, usually with a syringe, into the sample port, where it is flash-evaporated to convert its components into a gas. The constantly flowing stream of carrier gas carries the gaseous constituents through the chromatographic column. The gases travel through at different rates so that they emerge from the column at different times. Their presence in the emerging carrier gas is detected by chemical or physical means, and the response of the detector is fed to the data collection device. A typical chromatogram produced by this process is shown in Fig. 2. Each peak represents a specific chemical compound or mixture of compounds that has the same rate of movement through the column. The time for each compound to emerge from the column is a characteristic of the compound known as its retention time. The area under the peak is proportional to the concentration of the compound in the sample.

Standard packed chromatographic columns are generally glass or metal tubes varying from about 1–10 m in length and about 3–6 mm in diameter. The tube is packed with a inert solid impregnated with a nonvolatile liquid, such as silicone oil or polyethylene glycol. As a gaseous sample passes through the column, its components are partitioned between the stationary liquid phase of the column and the moving gas phase. Components that are relatively soluble in the liquid phase move through the column at slower rates than components that are not so soluble. Most gaseous materials can be separated by selecting suitable stationary phases and column lengths. More recently, capillary columns with diameters of 0.2–0.4 mm and lengths of 20–30 m have replaced standard packed columns. These columns contain the solid phase on the inside wall of the capillary tube. The gas containing the organic components passes through the center of the capillary tube, and the organics partition themselves between the gas and the stationary phase, emerging from the column at different times.

Table 1. 126 EPA Priority Pollutants

A. Chlorinated benzenes
Chlorobenzene
1,2-Dichlorobenzene
1,3-Dichlorobenzene
1,4-Dichlorobenzene
1,2,4-Trichlorobenzene
Hexachlorobenzene

B. Chlorinated ethanes
Chloroethane
1,1-Dichloroethane
1,2-Dichloroethane
1,1,1-Trichloroethane
1,1,2-Trichloroethane
1,1,2,2-Tetrachloroethane
Hexachloroethane

C. Chlorinated phenols
2-Chlorophenol
2,4-Dichlorophenol
2,4,6-Trichlorophenol
Parametachlorocresol
(4-chloro-3-methyl phenol)

D. Other chlorinated organics
Chloroform (trichloromethane)
Carbon tetrachloride
(tetrachloromethane)
Bis(2-chloroethoxy)methane
Bis(2-chloroethyl)ether
2-Chloroethyl vinyl ether (mixed)
2-Chloronaphthalene
3,3-Dichlorobenzidine
1,1-Dichloroethylene
1,2-*trans*-Dichloroethylene
1,2-Dichloropropane
1,2-Dichloropropylene
(1,3-dichloropropene)
Tetrachloroethylene
Trichloroethylene
Vinyl chloride (chloroethylene)
Hexachlorobutadiene
Hexachlorocyclopentadiene
2,3,7,8-Tetrachloro-dibenzo-*p*-dioxin
(TCDD)

E. Haloethers
4-Chlorophenyl phenyl ether
2-Bromophenyl phenyl ether
Bis(2-chloroisopropyl) ether

F. Halomethanes
Methylene chloride (dichloromethane)
Methyl chloride (chloromethane)
Methyl bromide (bromomethane)
Bromoform (tribromomethane)
Dichlorobromomethane
Chlorodibromomethane

G. Nitrosamines
N-Nitrosodimethylamine
N-Nitrosodiphenylamine
N-Nitrosodi-*n*-propylamine

H. Phenols (other than chlorinated)
2-Nitrophenol
4-Nitrophenol
2,4-Dinitrophenol
4,6-Dinitro-*o*-cresol
(4,6-dinitro-2-methylphenol)
Pentachlorophenol
Phenol
2,4-Dimethylphenol

I. Phthalate esters
Bis(2-ethylhexyl)phthalate
Butyl benzyl phthalate
Di-*n*-butyl phthalate
Di-*n*-octyl phthalate
Diethyl phthalate
Dimethyl phthalate

J. Polnuclear aromatic hydrocarbons
(PAHS)
Acenaphthene
1,2-Benzanthracene (benzo(*a*)
anthracene)
Benzo(*a*)pyrene (3,4-benzo-pyrene)
3,4-Benzofluoranthene (benzo(*b*)
fluoranthene)
11,12-Benzofluoranthene (benzo(*k*)
fluoranthene)
Chrysene
Acenaphthalene
Anthracene
1,12-Benzoperylene (benzo(*ghi*)
perylene)
Fluorene
Fluoranthene
Phenanthrene
1,2,5,6-Bibenzanthracene (dibenzo(*ah*)
anthracene)
Indeno (1,2,3-*cd*) pyrene
(2,3-*o*-phenylene pyrene)
Pyrene

K. Pesticides and metabolites
Aldrin
Dieldrin
Chlordane (technical mixture and
metabolites)
Alpha-endosulfan
Beta-endosulfan
Endosulfan sulfate
Endrin
Endrin aldehyde
Heptachlor
Heptachlor epoxide
(BHC-hexachlorocyclohexane)
Alpha-BHC
Beta-BHC
Gamma-BHC (Lindane)
Delta-BHC Toxaphene

L. DDT and metabolites 4,4-DDT
4,4-DDE (p,p-DDX)
4,4-DDD (p,p-TDE)

M. Polychlorinated biphenyls (PCBS)
PCB-1242 (Arochlor 1242)
PCB-1254 (Arochlor 1254)
PCB-1221 (Arochlor 1221)
PCB-1232 (Arochlor 1232)
PCB-1248 (Arochlor 1248)
PCB-1260 (Arochlor 1260)
PCB-1016 (Arochlor 1016)

N. Other organics
Acrolein
Acrylonitrile
Benzene
Benzidine
2,4-Dinitrotoluene
2,6-Dinitrotoluene
1,2-Diphenylhydrazine
Ethylbenzene
Isophorone
Naphthalene
Nitrobenzene toluene

O. Inorganics
Antimony
Arsenic
Asbestos
Beryllium
Cadmium
Chromium
Copper
Cyanide
Total lead
Mercury
Nickel
Selenium
Silver
Thallium
Zinc

The absence of packing minimizes the dispersion of the contaminants so that excellent resolution of the different compounds is obtained, even when there are 20 or more in the sample. This makes it possible to identify a greater number of compounds in highly complex mixtures.

The temperature of the sample and column must be held sufficiently high during movement through the column and subsequent detection to maintain them in the gaseous state. Only materials that can be volatilized or converted to volatile compounds can be detected by gas chromatography.

Sample Introduction Techniques

Samples may be introduced into the GC system in only two phases: liquid and gaseous. For successful liquid phase introduction, the injection port and column temperature

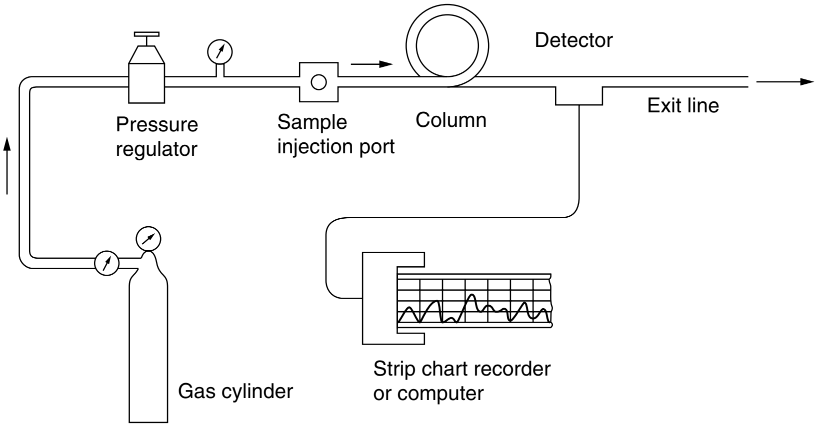

Figure 1. Schematic of a gas chromatograph system.

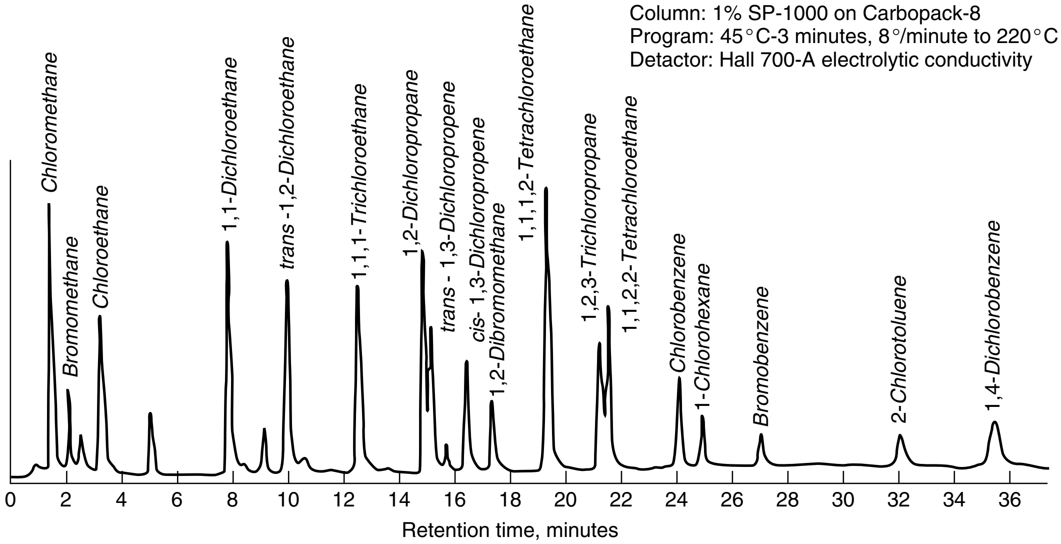

Figure 2. Gas chromatogram of purgeable halocarbons.

must be sufficiently high to permit complete volatilization of the material to be analyzed. A solid sample may be introduced by dissolving the sample in a low boiling solvent, thereby treating the sample as a liquid. Gas samples may be either directly injected via a gastight syringe or by using a gas sampling valve that uses the principle of having the carrier gas purge, under pressure, a calibrated volume loop within which the gas sample was trapped.

A major consideration in sample analysis is the required level of sensitivity or limit of detection. A common way of increasing a procedure's detection limit is to concentrate the substance being analyzed (the analyte). Three common procedures are used in gas chromatography: purge and trap, headspace, and solvent extraction.

Purge and Trap. The purge and trap procedure is commonly used in environmental analysis to determine volatile organic compounds or "purgeables," such as in EPA Methods 624, 601, and 602. In each of these methods, the purge and trap apparatus must be similar (although trap materials differ). The purge and trap device consists of three separate pieces of equipment: the sample purger, the trap, and the desorber.

An inert gas is bubbled through the sample in a specially designed purging device at ambient temperature. The purgeables are efficiently transferred from the aqueous phase to the vapor phase. The vapor is swept through a sorbent column where the purgeables are trapped. After purging is completed, the sorbent column is heated and backflushed with the inert gas to desorb the purgeables into a GC column.

Headspace. The headspace technique is commonly used for analyses of solid samples, although it can as easily be used for liquids. In this technique, EPA Method 5020, a known volume or weight of sample is collected in a sealed glass container and allowed to equilibrate at 90 °C for 1 hour. A sample of the headspace gas is then withdrawn for analysis. The advantages of this technique are its speed of sample preparation and its ability to leave potentially interfering semivolatile compounds behind.

Solvent Extraction. Solvent extraction is any procedure by which a solvent is used to extract an analyte into a liquid phase for direct injection (with or without preconcentration) into a GC. Solvent extraction techniques include both liquid/liquid and solid/liquid procedures. Although these procedures work best for semivolatile and nonvolatile compounds, the EPA has established similar procedures for analyzing volatiles in solid materials.

A popular liquid/liquid technique is used in EPA Method 625 (or 8270) for acid/base/neutral extractable organics. In this method, a liquid sample is separately extracted under both acidic and base/neutral conditions. A variety of glassware and apparatus has been developed for use in this method, although the separatory funnel is probably the simplest and most commonly used.

Solid/liquid techniques typically employ either Soxhlet extraction glassware or ultrasound. A Soxhlet extractor is a device that ensures intimate contact of the sample matrix with the extraction solvent by continuously deluging the sample with solvent. Alternatively, the EPA has approved ultrasound (Method 3550) for analyzing certain solid matrices.

Air Sampling Techniques. A variety of techniques are used to extract and concentrate air pollutants. The two most common procedures use either solid or liquid trap materials. Liquid traps, called "impingers," are used when the analyte can be easily absorbed into a stable liquid phase, such as cyanide into sodium hydroxide.

Solid trap materials may range from simple paper filters to exotic polymers. The difficulty in using solid trap materials is getting the analyte off of the trap back into a gaseous phase. This can be accomplished by either eluting the trap material with a solvent or by thermal adsorption.

If the analysis does not require concentration, air samples may be collected in any inert gastight device of known volume such as gastight syringes, evacuated glass bulbs, inert bags, or canisters. The methods most commonly used in the environmental industry are the EPA "TO" series of methods or others adapted from NIOSH approved procedures.

Detectors

The photoionization detector (PID) has become well known as a useful tool in the environmental industry. It is a nondestructive detector that lends itself to series operation with other detectors; thereby it enhances the selectivity and sensitivity of the GC.

The PID is the required detector for EPA Method 602 (or 8020/8021) for purgeable aromatics. Because it does not require the use of a fuel gas, it has become a popular detector for handheld portable organic vapor analyzers.

The PID operates on the principle of photoionization. The fact that certain molecules can be ionized by light is related to their characteristic molecular structure. The PID consists of a high-energy ultraviolet lamp located adjacent to an ionization chamber that contains a pair of electrodes. When a positive potential is applied to one electrode, the field created collects any ions formed by the absorption of UV light at the other electrode. The measured current is proportional to the concentration.

A PID responds to all compounds whose ionization potentials are less than or equal to the energy of the UV light source. Typical UV lamp energies in use are 10.2 eV and 11.7 eV. The magnitude of the ionization potential does not by itself dictate the sensitivity of the PID response. The degree of ionization depends on molecular structure. The number, type, and structure of the carbon bond, therefore, dictate the sensitivity of the detector to the compound. In general, the PID shows the greatest response to condensed-ring aromatic compounds (i.e., polyaromatic hydrocarbons), followed by aromatic compounds. These are other general selectivity rules:

- aromatics > alkanes > alkenes
- ketones > aldehydes > esters > alcohols > alkanes
- cyclic compounds > noncyclic
- branched compounds > nonbranched
- iodine-substituted > bromine-substituted > chlorine-substituted> fluorine-substituted

Because of the PID's response to aromatic compounds, it is the detector of choice for EPA Method 602 (or 8020/8021). The aromatic compounds in petroleum-based products such as benzene, toluene, and xylene are easily detected by this procedure. The aliphatic compounds in petroleum-based products such as methane, pentane and octane are suppressed. The flame ionization detector responds well to these compounds.

The Flame Ionization Detector. The flame ionization detector (FID) is probably the oldest and most generally used GC detector. The FID responds to most organic compounds, which can be both a benefit and liability in its application. As a benefit, the FID can be nearly universally used in a number of applications. This property lends itself to "fingerprinting" analysis of complex mixtures such as petroleum products. As a liability, the FID may respond to so many compounds that individual compound separation in a complex mixture, may become difficult, if not impossible.

The FID operates on the principle of flame ionization. As gases are eluted from a column, they are burned in a tiny hydrogen flame. A device continuously monitors the electrical conductivity of this flame. As organic compounds ionize in the flame, this conductivity is altered, proportional to the concentration, and measured. Most FIDs have sufficient energy to ionize any organic species with an ionization potential (IP) of 15.4 eV or less.

The use of FIDs in portable instrumentation has been hampered by the problem of maintaining a stable flame and fuel gas requirements. However, now there are many popular field instruments that have overcome these obstacles and are frequently used where gases such as methane are of interest.

The Electron Capture Detector. The electron capture detector (ECD) is used to detect compounds that have halogen atoms or polar functional groups such as pesticides, herbicides, and PCBs. EPA Method 608 (or 8080) uses an ECD for organochlorine pesticides and PCBs. The ECD uses a small radioactive source such as nickel 63 or tritium to emit beta particles. The ECD measures the ability of compounds to capture these particles from the ion current. The reduced current is measured and converted into an electrical signal for detection.

Mass Spectroscopy. Mass spectroscopy is the most rapidly developing analytical technology today. When coupled with a gas chromatograph (GC/MS), it is a powerful tool for positive identification and quantification of a large number of organic compounds. Recent advances in computer technology have dramatically expanded these systems' capabilities, speed of analyses, and cost efficiency. EPA Methods 624 or 8260 (purgeables) and 625 or 8270 (acid/base/neutral extractables) use this technique.

The mass spectrometer sorts charged gas molecules or ions according to their masses. The substance to be analyzed is vaporized in the GC and converted to positive ions or ion fragments by bombardment with rapidly moving electrons. These ions or ion fragments are pulled from the gas stream by an electrical field, accelerated, and separated by their mass-to-charge ratio. A computer then records the fragmentation pattern of the molecule, which is characteristic of a particular compound. The relative retention time and abundances of key ions and secondary ions are used to identify the compound qualitatively.

Most commercial labs have access to spectral libraries with information on more than 50,000 compounds. Compounds identified in this manner are referred to as "tentatively identified compounds" or "TICs." As the name implies, the data collected in this manner should be used with caution because an actual analytical reference standard has not been used. The quanitation of TICs may be orders of magnitude in error.

Other Detectors

Microcoulometric Detectors. Microcoulometric detectors such as the "Hall" detector are used for halide specific analyses such as EPA Method 601 (or 8010) for purgeable halocarbons. In this detector, halide-containing compounds are catalytically reduced using hydrogen, and the resulting "HX" is measured by a highly sensitive conductivity meter.

Thermal Conductivity. Thermal conductivity detectors use a heated wire that is placed in the stream of eluting gases. Each gas has a different thermal conductivity or ability to carry away heat from the wire and thus changes the temperature of the wire. These changes alter the resistivity of the wire from which a signal is generated.

Thermal conductivity detectors respond to a wide range of compounds but are relatively insensitive to low concentrations. For these reasons, they are usually used in the environmental industry for permanent gas analysis such as automobile and stack gas emissions. Many portable combustible gas meters also operate on the principle of thermal conductivity, such as units known as "explosimeters."

Flame Photometric Detectors. The flame photometric detector uses the optical emission of a gas burned in a flame to detect pollutants, typically sulfur and phosphorus containing compounds such as H_2S and phosphorus-based pesticides. The EPA has several interim pesticide and herbicide procedures that use this detection system.

Dry Electrolytic Conductivity Detectors. The dry electrolytic conductivity detectors (DELCD) are halogen specific. Often paired with other detectors such as FIDs, the DELCD can be used for highly selective identification of halogen containing compounds in gas streams.

HIGH PERFORMANCE LIQUID CHROMATOGRAPHY

High performance liquid chromatography (HPLC) is another analytical tool used for compounds not readily accessible by GC. As the name implies, HPLC uses a liquid carrier instead of a gas to sweep the sample through the column for separation. Compounds that are high in molecular weight (such as polynuclear aromatic hydrocarbons) or are thermally liable (i.e., decompose when heated) are good candidates for this technique. Many detectors are available to analyze both inorganic and organic species.

METALS ANALYSES

There are thirteen priority pollutant metals (see Table 1), and two EPA accepted methodologies used to analyze for them, atomic absorption spectroscopy (AA) and inductively coupled plasma (ICP). The former method uses the technique of absorption spectroscopy and the latter emission spectroscopy. Each technique has its advantages and disadvantages relative to selectivity, sensitivity, interferences, cost, and speed of analysis.

Atomic Absorption Spectroscopy

Atomic absorption spectroscopy (AA) is the most commonly used technique to analyze for metals. This technique has been around since the 1950s and was the first instrumental method of metal analysis accepted to replace what were previously colorimetric or gravimetric methods of analyses.

Because instrumental operating conditions vary from metal to metal, the EPA has published specific methods for each metal. Collectively, these methods are known as the "200 series" in water or the "7000" series in solid materials.

Theory. Atomic absorption is based on the principle that all atoms absorb light at particular wavelengths corresponding to the energy requirements of a particular atom. For example, copper atoms absorb light strongly at 324.7 nm because this particular wavelength has the right energy to alter the atom's electronic state from a ground state to an excited state. Other elements have their own specific wavelengths. Because each atom may have several different electronic states, a spectrum of these characteristic wavelengths can be created. The wavelength lines that are used in AAS are those that originate in the ground state, called resonance lines.

The basic AA system consists of a stable light source of particular wavelength, a flame or other excitation device, a

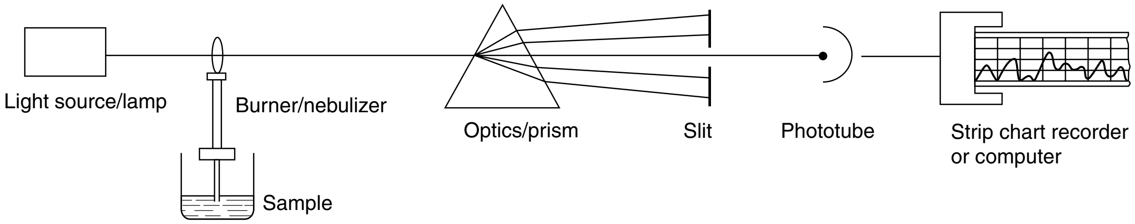

Figure 3. Schematic diagram of atomic absorption spectrometer.

prism to disperse and isolate emission lines, and a detector with appropriate amplifiers (see Fig. 3). The light source is directed into the flame or other excitation device, and its intensity is measured with and without the introduction of a sample. The decrease in intensity or absorption is proportional to the concentration. Two different excitation devices are commonly used. Flame AA is used to detect concentrations in the approximate parts per million range and flameless AA or a heated graphite furnace is used to detect in the parts per billion range. Flameless AA or a heated graphite furnace uses an electrically heated graphite tube to concentrate the atoms, instead of a flame.

Because mercury is unique in that it can be liberated in its ground state at room temperature a special cold vapor technique, EPA Method 245.1 should be used to measure low (ppb) concentrations. This technique uses a chemical reaction to liberate mercury atoms instead of a heated excitation source as in flame or graphite furnace techniques.

Inductively Coupled Plasma

Inductively coupled plasma (ICP) is another commonly used technique for metals analyses. The main attraction of ICP is that it can analyze many elements at once, and for certain refractory elements such as beryllium, it is much more sensitive.

However, AA must still be used to detect low levels of mercury and other metals. For these reasons, many laboratories that have ICP systems use both techniques to analyze for the 13 priority pollutant metals. Because of its multielement capabilities, ICP is also very useful in screening unknown samples. The EPA method for multielement ICP analysis is Method 6010.

Theory. The technique by which ICP operates is emission spectroscopy. Using a radio-frequency generated, argon sustained plasma, atoms are excited to a much higher energy state that can be achieved in normal AA systems. As the electrons fall back to their original state, they emit radiation at element specific or characteristic wavelengths. This radiation is in turn sensed by a detector; the signal is amplified and recorded. Prior to recent computer advances, this signal processing was often extremely time-consuming and subject to interferences.

Metal Sample Preparation

Nearly all samples require some preparation prior to metals analysis. This is required to isolate selectively the element you are analyzing for (the "analyte") from the rest of the sample (its "matrix") and to put it into a more readily analyzable state. This preparation usually begins in the field with the addition of nitric acid as a preservative. Nearly all aqueous samples for metals analysis should be preserved with nitric acid if they cannot be delivered to the laboratory on the same day.

The exception to this rule is discriminating between valence states of certain metals such as chromium. Samples of hexavalent chromium should not be preserved with acid. Although the chemistry of hexavalent chromium is not completely understood, it is believed that acid may promote the reduction of the hexavalent to the trivalent state.

Acidification of the sample helps to (1) promote digestion of the sample matrix and dissolution of the metal and (2) inhibits its precipitation or "plating" out on the walls of the sample container. Preserving metals samples with acid is not intended to inhibit microbial activity. It does not matter if microbes ingest or otherwise alter the metallic compounds because the sample will be digested and analyzed for total metals, regardless of valence state. For this same reason, samples for total metals analyses need not be refrigerated.

Samples submitted for dissolved metals should not be acidified until they have been filtered. Acidification would promote dissolution of the larger particles and bias the results. Note that "dissolved" metals is an empirically defined term. Specifically, "dissolved" metals mean all metals that are filterable (pass through) a 0.45-micron membrane filter.

"Total" metals mean the entire element irrespective of valence or physical state. To enhance the analysis and reduce the chance of matrix interferences, most metals samples undergo rigorous acid digestion. Through this procedure, solids and semisolid samples may be broken down into a dissolved aqueous state that allows the nebulizer of the instrument to aspirate or pass the sample into the flame.

Metals samples may also be treated or prepared through various solvent extraction or preconcentration techniques to enhance sensitivity and/or eliminate matrix effects. However, most of these techniques are not required by the modern instrumentation manufactured today.

CYANIDE AND TOTAL PHENOLICS

Cyanide and total phenolics are typically analyzed by colorimetry. These techniques involve lengthy wet chemical digestions and distillations to eliminate interference.

Once these steps are taken, the analyte is reacted chemically to produce a color, whose intensity is proportional to concentration. Various procedures exist that cover the variety of instrumentation manufactured to help automate these analyses. However, the most commonly used methods for these analyses are EPA Method 335.1 for cyanide and EPA Method 420.1 for total phenolics.

Sample Preparation

Cyanide. It is extremely important to preserve all aqueous samples for cyanide analysis with sodium hydroxide at a pH greater than 12 to ensure that the sample is not volatilized to hydrogen cyanide, an extremely toxic gas. In addition, the sample should be kept refrigerated.

Total Phenolics. Approved preservatives for total phenolics have varied in recent years. However, the generally agreed upon preservative is either phosphoric or sulfuric acid. Although not specifically required, copper sulfate may be added to inhibit microbial growth and initiate the analysis.

ASBESTOS

Although asbestos is a priority pollutant, it is rarely analyzed in water during routine or initial site investigations because its occurrence in groundwater is unusual. When it does occur, it is typically the result of localized dumping of asbestos insulation. Exceptions to this occur where asbestos fibers are locally mined, are part of an industrial process effluent, or when an asbestos cement pipe has deteriorated.

Because the focus of concern with asbestos is its previously common use as an insulator, it has been largely considered an industrial hygiene or indoor air pollution problem. As such, it has been the responsibility of the National Institute for Occupational Safety and Health (NIOSH) to promulgate standardized testing procedures for the material.

Generally, asbestos-containing material (ACM) contains chrysotile or amosite asbestos in a matrix of other fibers or particles such as glasswool or gypsum. This fibrous matrix makes positive identification of asbestos difficult, and it is best left to the experts. State laboratory certification for asbestos analysis is generally not available. Therefore, one should ascertain if the laboratory satisfactorily passed the latest EPA "round-robin" asbestos proficiency exam.

Bulk asbestos can be efficiently identified by phase-contrast microscopy. Because its effective range is for fibers approximately 5 microns or more in length, more sensitive microscopic methods are often employed for water analyses or other surface (filter) counting techniques. Transmission electron microscopy (TEM) is often specified for full-spectrum fiber size evaluations or comparisons of fiber abundances. Scanning electron microscopy (SEM) is also a powerful tool and can provide semiqualitative and quantitative analysis when coupled with energy dispersive X-ray instrumentation.

NONPRIORITY POLLUTANT PETROLEUM HYDROCARBON ANALYSES

Petroleum hydrocarbon products such as gasoline, diesel, fuel oil, and asphalt are complex mixtures of hundreds of individual compounds. They are manufactured according to performance-based standards, not chemical composition per se; therefore, their composition is not fully known and also varies based on the crude source. These petroleum compounds are primarily alkanes, although depending upon the distillation fraction (as well as the original parent crude), various amounts of unsaturated hydrocarbons (aromatics), nitrogen and sulfur compounds may also be present. In addition to these "base" compounds, various manufacturers add different proprietary additives such as tetraethyl lead, methyl *tert*-butyl ether, ethyl *tert*-butyl ether, ethanol, detergents, lubricants, and antifreezes.

Complicating matters for the environmental scientist, as soon as many of these compounds enter the environment, they begin transforming partitioning into the atmosphere, water, and biosphere. This all happens at highly variable rates depending on temperatures, pressures, redox potentials, available bacteria, and nutrients. No single analytical method can be used to quantify or qualify all petroleum hydrocarbons. The scientist must instead carefully decide which compounds are of most significance and whether or not an empirically derived method or surrogate parameter will suffice to describe conditions.

The lighter molecular weight volatile aromatic compounds, benzene, toluene, ethylbenzene, and xylenes (BTEX) can be resolved in any of the EPA purgeable VOC methods, such as 624 (or 8260), 602 (or 8021). The PID detector for a 602 analysis is highly sensitive to aromatics and where only petroleum hydrocarbons are a concern, is the cost-effective method of choice. There are also specialized petroleum analysis labs that routinely analyze for additives, other petroleum hydrocarbon background components, and can match ("fingerprint") and date petroleum types.

Heavier molecular weight polynuclear aromatic compounds associated with petroleum compounds may be detected via EPA Method 625 (or 8270). These compounds include benzo(*a*)pyrene, anthracene, and pyrene. As previously described, the PNA fraction may also be resolved by HPLC techniques.

Due to the difficulty in analyzing petroleum products as a "whole," it has become common to use various surrogate parameters for the different petroleum hydrocarbon fractions within different product types. Some of these surrogate parameters include total ionizable compounds (TIC); total oil and grease; total petroleum hydrocarbon oil and grease (TPH); total petroleum hydrocarbons by FID (TPH); volatile petroleum hydrocarbons (VPH); extractable petroleum hydrocarbons (EPH); total organic compounds (TOC); total volatile solids (TVS); and except for aromatics, chemical oxygen demand (COD). A discussion of each of these procedures is beyond the scope of this article, but because national regulatory guidelines have been established for total petroleum hydrocarbon oil and grease, a discussion of these procedures is in order.

Total Oil and Grease

Total oil and grease by EPA Method 418.1 or Standard Method 503 includes any compound that is extractable by Freon® and may be quantified either gravimetrically (503 A) or by infrared spectroscopy (503 B). More recently, Freon has been replaced by hexane due to Freon's ozone depletion properties. Because the solvent is not specific (no solvent is), a variety of "interfering" compounds which may not be of particular importance to the scientist, such as sulfuric compounds, humic substances, and chlorophyll, may also be extracted. To help discriminate between oil and grease of petroleum origin and that of animal or vegetable origin, one should request total petroleum hydrocarbon oil and grease (TPH), Method 503 E. This method takes the additional step of passing the Freon extract through silica gel. Silica gel preferentially adsorbs polar compounds such as fatty acids. The material that passes through the silica gel is defined as TPH. This separation is by no means absolute. Many complex aromatic hydrocarbons, sulfur and nitrogen compounds may also be adsorbed by the silica gel.

The scientist must carefully choose between the procedure and the relative benefits and drawbacks of each before requesting laboratory services. In general, gravimetric procedures should be used only when a higher detection limit is adequate (approximately 5 ppm for water) and the "oil and grease" does not volatilize below 700 °C. This would include most components of gasoline and No. 2 fuel oil. When lower detection limits (approximately 0.1 ppm for water) are required and the "oil and grease" is a lighter fraction, the IR procedure is the method of choice.

Gas chromatography largely replaced infrared spectroscopy in the analysis of TPH in the 1990s. A modification of EPA Method 8100 lends itself well to producing a FID chromatogram of the various petroleum hydrocarbons from C_6 through higher than C_{38}. By simply altering the temperature program of the GC, gasoline and diesel range organics can be selectively identified. Moreover, by combining various detector arrangements with selective resins to presort and separate alkane fractions from aromatic fractions, more selective groupings of various hydrocarbon fractions can be made. These selective groupings have been useful as surrogate parameters for assessing the toxicity of petroleum in environmental risk assessments.

SOURCE-WATER PROTECTION

National Water-Quality
Assessment (NAWQA)
Program—U.S. Geological
Survey

Not all water resources are equally vulnerable to contamination. Even areas having similar land uses and sources of contamination can have different degrees of vulnerability and, therefore, different response rates to protection and management strategies. NAWQA findings clearly demonstrate that natural features—such as geology, soils, and hydrology—and land-management practices—such as tile drainage and irrigation—can affect the movement of chemicals over land or to aquifers. Effective management of nonpoint source pollution may, therefore, require targeted strategies based on different degrees of vulnerability rather than uniform treatment of contaminant sources. Linking knowledge on natural features with the use, occurrence, and transport of chemicals through the watershed makes it easier to set priorities in streams and aquifers most vulnerable to contamination and increase the cost-effectiveness of strategies designed to protect water resources in diverse settings.

State of Washington. The Washington State Department of Health, in concert with USGS, assessed the vulnerability of public water-supply wells to pesticide contamination based on geology, well characteristics, land-use activities, and low levels of detection. NAWQA information on pesticide contamination enabled the health department to identify wells with low vulnerability to contamination and obtain waivers for quarterly monitoring required under the Federal Amendments to the Safe Drinking Water Act, 1996. By using the information to meet USEPA requirements for safe drinking water, Washington State was able to protect their drinking-water source while saving at least $6 million in costly additional monitoring. This is an annual savings of as much as $70 per household on small public supply systems that were granted full monitoring waivers.

State of New Jersey. NAWQA data on organic compounds are used heavily in New Jersey's source-water assessment. USGS and the New Jersey Department of Environmental Protection are developing models to assess the vulnerability of public water supplies (including surface-water intakes and ground-water community and non-community wells) in the State to contamination by regulated compounds.

I coordinate the Upper Mississippi River Source Water Protection Initiative, an effort that will lead to the development of source-water protection plans for public water suppliers within the upper Mississippi River basin. The water quality data that have been generated and documented through NAWQA will figure prominently in the preparation of these plans. The information on certain contaminant levels in various settings within the basin, and the information describing the sources of contaminants provide documentation and solid rationale for identifying source water protection strategies, priorities, and protection measures for public water suppliers. In my opinion, more than any single information source, the Upper Mississippi River NAWQA provides an extremely valuable substantive basis for source water protection in the Upper Mississippi River basin (Mr. David Brostrom, Coordinator, Upper Mississippi River Source Water Protection Initiative, March 2001).

In addition to the examples cited above, more than 30 other states use USGS information to develop source-water protection plans for drinking-water sources. The collaborative projects in these states address nearly 40 percent of the nation's public water supply, serving more than 90 million people.

USGS information is also used widely by states to develop management plans for constituents, such as pesticides, nutrients, and MTBE. Specifically, state environmental and natural resource agencies prioritize streams and ground-water areas for assessment of these constituents on the basis of vulnerability concepts, contaminant occurrence data, and quality-assurance protocols of the NAWQA Program.

State of Kansas. NAWQA findings on elevated concentrations of atrazine (frequently approaching or exceeding the USEPA drinking-water standard) in water-supply reservoirs in the Lower Kansas River Basin were used by the Kansas State Board of Agriculture as the basis for establishing a pesticide management area in northern Kansas (Delaware River Basin). Within this management area, the State of Kansas called for both voluntary and mandatory restrictions on pesticide usage on cropland to improve water quality. The management area was the first in the nation to focus on reducing atrazine in runoff to streams and reservoirs.

State of Washington. The Washington State Department of Ecology created a Ground Water Management Area to protect ground water from nitrate contamination. The management area covers Grant, Franklin, and Adams counties, located in an intensive agricultural region of the Central Columbia Plateau. NAWQA information and communication of those findings in the USGS publication "Nitrate Concentrations in Ground Water of the Central Columbia Plateau" provided the scientific basis for implementing the management area. As follow-up to the NAWQA findings, USGS works with the Department of Ecology to (1) identify areas with lower nitrate concentrations, which could potentially serve as sources of future drinking-water supplies, (2) statistically correlate nitrate concentrations with natural features and human activities to better assess vulnerability; and, (3) design a long-term monitoring strategy for assessment of changes in nitrate concentrations over time.

State of California. USGS works with the California State Water Resources Control Board and Department of Health Services to assess the vulnerability of public supply wells to contamination. The State uses USGS ground-water-age-dating analyses as one indicator of vulnerability. In addition, on the basis of NAWQA findings on the occurrence of industry-related and petroleum-based chemicals in ground water, the State has included the collection and analysis of VOCs in their vulnerability assessment. More than 200 wells have been sampled in southern California, and these efforts will be extended to northern California and the Central Valley.

State of Idaho. NAWQA information formed the framework for predictive models and maps showing the vulnerability of ground water to contamination by the widely used herbicide atrazine in Idaho. The maps are used by the Idaho State Department of Agriculture to develop its State Pesticide Management Plan. Atrazine data from the NAWQA study in the Upper Snake River Basin were used to calibrate and verify the predictive models, which showed that significant factors associated with elevated atrazine concentrations in ground water were atrazine use, land use, precipitation, soil type, and depth to ground water. These modeling tools aid in the design of cost-effective programs for monitoring and protecting ground-water resources throughout the State.

State of Pennsylvania. The Pennsylvania Department of Environmental Protection works with USGS as a follow-up to NAWQA findings on the prevalence of MTBE in ground water and its potential to contaminate public drinking-water supplies. Through the partnership, consistent and quality-assured data will be compiled, and a qualitative vulnerability rating for MTBE will be developed for different hydrogeologic settings throughout the State of Pennsylvania. The State will use the results to prioritize areas where MTBE should be assessed and where public-supply wells should be tested, and to target inspections of gasoline storage tanks.

National scale. At the request of the USEPA's Office of Ground Water and Drinking Water, the NAWQA Program published a national map that shows the patterns of risk for nitrate contamination of shallow ground water (available in *Nitrate in Ground Waters* *of the United States—Assessing the Risk*, USGS FS-092- 96). By targeting regions with the highest risk of nitrate contamination, resources can be directed to areas most likely to benefit from pollution-prevention programs and long-term monitoring. Use of risk guidelines to locate areas for prevention of contamination also can result in cost-effective management. Once ground water is contaminated, it is expensive and, in many cases, virtually impossible to clean up.

VULNERABILITY CAN CHANGE OVER TIME

NAWQA findings show that the vulnerability to contamination of streams and ground water can differ seasonally in nearly every basin. For example, in streams that drain agricultural areas in many parts of the nation, the highest levels of nutrients and pesticides occur during spring and summer when recently applied chemicals are washed away by spring rains, snowmelt, and irrigation. Excessive amounts of contaminants can also enter streams during storm events. For example, sampling of nutrients and pesticides through a large storm event on the Potomac River in 1996 showed that concentrations and total amounts of nutrients and atrazine can increase during localized large storms, sometimes with overwhelming effects on receiving waters, such as the Chesapeake Bay. In this case, concentrations of individual compounds exceeded USEPA drinking-water standards during and following the extreme storm events. Such information helps water suppliers better understand the role of the short-term and seasonal events, and raises considerations related to timing of withdrawals, mixing, and storage to most effectively deliver high quality water at a minimum cost.

PROTOZOA IN WATER

Christine L. Bean
University of New Hampshire
Durham, New Hampshire

Protozoa are eukaryotic unicellular animals that possess membrane-bound genetic material and other cellular organelles that carry out various life functions (1). They are colorless and lack cell walls. These motile Eukarya obtain food by ingesting other organisms or organic particles. The uptake of these macromolecules occurs by a process called pinocytosis (2), whereby fluid is sucked into a channel formed by cell membrane invagination and enclosing the fluid within a membrane-bound vacuole. Particulate matter such as bacteria may also be ingested by phagocytosis.

Protozoa may be found in a variety of freshwater and marine habitats and in soil. Pathogenic protozoa include *Giardia lamblia, Entamoeba histolytica*, and *Cryptosporidium parvum. Giardia* and *Cryptosporidium* have been frequent causes of waterborne outbreaks in the United States. Many protozoa are parasitic in animals as well as humans. Reservoirs of protozoa include wild and domestic animals and humans. *Giardia* may be found in cats, dogs, sheep, pigs, goats, and cattle. *Cryptosporidium* has long been known as a pathogen of calves.

Morphologic differences in groups of protozoa can identify and differentiate them microscopically. They move and reproduce in various ways that can categorize them into groups or phyla such as amoeba (move by means of pseudopodia), flagellates, and ciliates. Most protozoa that can be found in water multiply by binary fission and are transmitted to humans through the ingestion of the infective stage of the parasite.

Free living protozoa such as flagellates, ciliates, and thecamoebae may feed on bacterial communities and actually multiply in water distribution systems (3).

FLAGELLATES

The taxonomic group of protozoa that use flagella are called Mastigophora. Motility is performed with the flagellum by either pushing or pulling the organism. Flagella can occur singly, in pairs, or in large numbers. Nearly one-half of the known species of protozoa are flagellates (4). Many of these are free-living, but several are parasitic for both humans and animals. Free-living protozoa include the green flagellate *Euglena*, which may be found in freshwater ponds (4). *Giardia lamblia* is an example of a parasitic freshwater flagellate that has a cyst and a trophozoite form. The cyst is the resting, environmentally resistant, infective form, and the trophozoite is the motile, feeding stage.

AMOEBAS

The taxonomic group of protozoa that use pseudopods for motility are called Sarcodina. Pseudpods may capture algae, bacteria, and other protozoa in the process of phagocytosis (4). Amoebic dysentery is caused by *Entamoeba histolytica*, which results in ulcerations of the intestinal tract and bloody diarrhea. Exposure may be from fecally contaminated freshwater or food supplies as well as person-to-person transmission of the cyst form. *Acanthamoeba* spp. is free-living amoebas that normally live in soil or in fresh water. They are capable of causing human infection in the brain, skin, and eye after exposure takes place through the respiratory tract, skin, or mucosal ulceration or open wounds (1).

CILIATES

The taxonomic group of protozoa that move by beating of cilia are called Ciliophora. Cilia are hair-like structures arranged in longitudinal or spiral rows that beat and result in an organized motion that moves the organism in one direction. Ciliates have two kinds of nuclei: the micronucleus and the macronucleus. The micronucleus is concerned only with inheritance, and the macronucleus is involved in the production of mRNA for cell growth and function (2). The genus *Paramecium* is a common protozoan in water. These are huge ciliated cells measuring about 50 μm in diameter. *Balantidium coli* is an example of a pathogenic ciliate. It is primarily a parasite of domestic animals such as pigs, but it has been shown to parasitize humans also.

SPOROZOANS

The taxonomic group of protozoa once believed to be spores is called Apicomplexa or Sporozoa. These protozoa have complex life cycles in which sexual and asexual reproductive phases occur sometimes in different hosts (4). Sporozoa do not have cilia, flagella, or pseudopods. Microsporidia have recently been recognized as a waterborne pathogen. The term "Microsporidia" describes protozoans belonging to the phylum *Microspora* (5). These protozoa are very small (<2 μm in diameter), and detection has been problematic. *Toxoplasma gondii* is another sporozoan highly associated with immunocompromised patients. The oocyst is shed in cat feces and is highly resistant to environmental degradation.

WATER QUALITY

Kenneth M. Mackenthun
Arlington, Virginia

To most people, water quality means water whose characteristics represent a high degree of purity for the use to which the water is put. For drinking, this means cool, clear water, free from harmful contaminants and conditions that produce off-flavors. Other uses require a quality whose characteristics best support the particular use.

The Water Quality Act of 1965 first designated broad water uses when requiring the establishment of water quality standards for "public water supplies, propagation of fish and wildlife, recreational purposes, and agricultural, industrial, and other legitimate uses." The current Clean Water Act maintains those uses in Section 303(c)(2)(A) and adds language to take into consideration the use and value for navigation.

CHRONOLOGY OF EVENTS

In the decades of the 1950s and 1960s, many waterways in the United States showed signs of gross pollution. The Potomac River near the nation's capital was too dirty for swimming; the Cuyahoga River near Cleveland burned because of ignited oil on its surface; the Androscoggin River in Maine carried logs to pulp and paper mills and was treated with sodium nitrate to enhance dissolved oxygen through nitrification; the city of St. Louis collected its garbage, ground it, and barged it to the center of the Mississippi River for dumping; and the Flambeau River in Wisconsin carried so much black liquor from sulfite paper pulping that its bottom was covered with wood fibers, the river would rumble from escaping gases of decomposition, and boils of wood fibers and slime would rise to the river surface 6 inches thick and 10 feet in diameter. Many lakes of that era were overcome with algal and other vegetation growths from excessive nitrogen and phosphorus nutrients. These lakes included Lake Sebasticook in Maine, Lake Okeechobee in Florida, the Madison Lakes in Wisconsin, Detroit Lakes in Minnesota, and Lake Washington in Washington. Boston Harbor emitted sufficient hydrogen sulfide to blacken white-painted shoreside houses because of decomposing marine algae stimulated by nitrogen and phosphorus from the discharge of inadequately treated sewage.

The decade of the 1960s awakened the nation to the fact that water pollution must be better controlled. Prior to the 1970s, water quality went through a period of field investigation, investigative equipment development, and understanding of the relationship among aquatic organisms, chemistry, and physical conditions. Lake and stream sampling equipment was developed by Ekman (1), Petersen (2), and Surber (3). The writings of Kolkwitz and Marsson (4), Forbes and Richardson (5), Birge and Juday (6), Bartsch (7), and Hutchinson (8) influenced relationship understanding. The North American Benthological Society, formed in 1953, had its first meeting in Havana, Illinois, to share investigative information among the state biologists and coordinate taxonomic difficulties associated with stream benthic organisms.

In the decade of the 1970s, federal regulatory controls were instituted. Initial laws and regulations were refined in later years, increased emphasis was placed on identifying and controlling toxic pollutants, and efforts were made to manage nonpoint source pollutants and stormwater runoff. Water quality standards and point source discharge permits were refined and enhanced. The North American Lake Management Society held its first meeting in 1979.

LAWS AND REGULATIONS

The basic law controlling freshwater quality, with implementing regulations, dates to the River and Harbor Act of 1899 (33 USC 401). There have been many amendments along the way, and the present law was rewritten in the Federal Water Pollution Control Act Amendments of 1972 (33 USC 1251), which was significantly amended by the Clean Water Act of 1977 to emphasize toxic pollutant control. The latter laws now are commonly referred to as the Clean Water Act. The basic laws controlling marine water quality include the Marine Protection, Research and Sanctuaries Act (33 USC 1401), the Coastal Zone Management Act (16 USC 1451), the Act to Prevent Pollution from Ships (33 USC 1901), and the Magnuson–Stevens Fishery Conservation and Management Act (16 USC 1801). Other federal laws that impact actions that may affect water quality include the Endangered Species Act (16 USC 1531), the Fish and Wildlife Conservation Act (16 USC 2901), the Marine Mammal Protection Act (16 USC 1361), the National Environmental Policy Act (42 USC 4321), the National Invasive Species Act (16 USC 4701), and the Oil Pollution Act (33 USC 2701).

PROGRAMS

Defining water quality has a long record of accomplishments. Ellis (9) reviewed the literature for 114 substances and, in a 72-page document for the U.S. Bureau of Fisheries, listed lethal concentrations found by the authors. California published a 512-page book on water quality criteria that contained 1369 references. This publication was revised and enhanced the following year to include 3827 references. In 1968, the Secretary of the Interior appointed nationally recognized scientists to a national technical advisory committee to develop water quality criteria for the five recognized uses of water. This resulted in the Green Book, which constituted the most comprehensive documentation of its time on water quality requirements for defined water uses. The Blue Book followed in 1974 as the result of a contract with the National Academy of Sciences and the National Academy of Engineering. Section 304 of the Clean Water Act mandates that the Environmental Protection Agency (EPA) develop and issue Federal water quality criteria, which resulted in the Red Book, "Quality Criteria for Water," in 1976. The EPA published 65 separate water criteria documents for the 65 toxic pollutants in 1980. The Gold Book summaries followed in 1986. Presently, water quality criteria are defined in 63 *Federal Register* 68354, 10 December 1998.

Section 303 of the Clean Water Act requires that water quality standards be developed by the states and approved by EPA for all waters of the United States. Water quality standards along with national pollutant discharge elimination system permits are the hallmarks of water quality controls in the Clean Water Act. All permits required by the Act must be written in a manner that does not violate water quality standards, and Section 401 of the Act provides for state certification to that fact.

The discharge of any pollutant to the waters of the United States is controlled in Section 402 of the Clean Water Act by a national pollutant discharge elimination system (NPDES) permit. Section 301 (b)(1)(C) of the Act requires that such permits meet water quality standards. The elements of a NPDES permit include identification, description, and a unique number for each discharge; effluent limits based upon effluent guidelines, new source performance standards, toxic effluent standards, applicable water quality standards, and the best professional judgment of the permit writer; requirements for monitoring and reporting; delineation of best management practices; and a compliance schedule.

A Clean Lakes Program was established by the EPA in 1972, pursuant to Section 314 of the Clean Water Act, to provide financial and technical assistance to states in restoring publicly owned lakes. The program has funded approximately $145 million in grant activities, but there have been no appropriations since 1994.

The storage and retrieval of water quality data are vested in the EPA's STORET system. Begun in 1962, STORET contains more than 206 million analyses of chemical and physical water quality constituents at more than 761,000 locations across the United States, including coastal and international waters. Biological data are also included.

States are required by Section 305(b) of the Clean Water Act to submit a biennial report to the EPA that describes the water quality of the state. The EPA, in turn, prepares a National Water Quality Inventory, which is submitted to the Congress biennially. According to these reports, the United States has 3.5 million miles of rivers and streams; 41 million acres of lakes, ponds, and reservoirs; 34,000 square miles of estuaries; 58,000 miles of ocean shoreline; and 277 million acres of wetlands such as marshes, swamps, bogs, and fens. Rivers are polluted by bacteria, siltation, nutrients, oxygen-depleting substances, metals, habitat alterations, and suspended solids. Lakes are polluted by nutrients, siltation, oxygen-depleting substances, metals, suspended solids, pesticides, and organic toxic pollutants.

WATER QUALITY ETHIC

Nationally, water quality is significantly improved over the conditions of the 1950s and 1960s. Fish now inhabit waterways where once they were restricted from doing so because of unsuitable water quality. There is evidence, also, that an environmental ethic is gaining ground among the general population. An environmental ethic means exercising respect and consideration for the integrity, stability, and beauty of the water and its inhabitants. Such an ethic needs to be nurtured and expanded in its application. Regulations are required to keep societal goals focused on future attainment and to protect and preserve the environment for humans. A dedicated environmental ethic, coupled with viable regulations allowing flexibility for adjustment to a particular circumstance, will foster the Clean Water Act's Section 101 national goal that, wherever attainable, water quality shall provide for the protection and propagation of fish, shellfish, and wildlife and provide for recreation in and on the water.

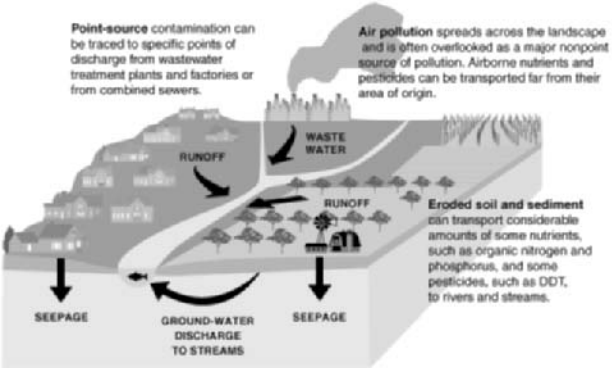
WATER QUALITY

U.S. Geological Survey

Water quality is a term used to describe the chemical, physical, and biological characteristics of water, usually in respect to its suitability for a particular purpose. Although scientific measurements are used to define a water's quality, it's not a simple thing to say that "this water is good," or "this water is bad." After all, water that is perfectly good to wash a car with may not be good enough to serve as drinking water at a dinner party for the President! When the average person asks about water quality, they probably want to know if the water is good enough to use at home, to play in, to serve in a restaurant, etc., or if the quality of our natural waters are suitable for aquatic plants and animals.



As the diagram above shows, assessment of the occurrence of chemicals that can harm water quality, such as nutrients and pesticides in water resources, requires recognition of complicated interconnections among surface water and ground water, atmospheric contributions, natural landscape features, human activities, and aquatic health. The vulnerability of surface water and ground water to degradation depends on a combination of natural landscape features, such as geology, topography, and soils; climate and atmospheric contributions; and human activities related to different land uses and land-management practices.

More and more nowadays we are hearing about situations where the quality of our water is not good enough for normal uses. Bacteria and microorganisms have gotten into drinking-water supplies, sometimes causing severe illness in a town; chemical pollutants have been detected in streams, endangering plant and animal life; sewage spills have occurred, forcing people to boil their drinking water; pesticides and other chemicals have seeped into the ground and have harmed the water in aquifers; and runoff containing pollutants from roads and parking lots have affected the water quality of urban streams.

Yes, water quality has become a very big issue today, partly because of the tremendous growth of the Nation's population and urban expansion and development. Rural areas can also contribute to water-quality problems. Medium- to large-scale agricultural operations can generate in animal feed, purchased fertilizer, and manure, more nitrogen and phosphorus than can be used by crops or animals. These excess nutrients have the potential to degrade water quality if incorporated into runoff from farms into streams and lakes All this growth puts great stress on the natural water resources, and, if we are not diligent, the quality of our waters will suffer.

EMERGING AND RECALCITRANT COMPOUNDS IN GROUNDWATER

Tom Mohr
Santa Clara Valley Water District
San Jose, California

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

During the last two decades, the dominant groundwater contamination issues have focused on petroleum hydrocarbons (including gasoline, diesel, motor oil, lubricants, and jet fuel), chlorinated solvents, metals, and pesticides. Recently, attention has shifted to a variety of newly discovered compounds in groundwater. Some of these compounds were additives to fortify or stabilize the previously mentioned products. As additives, these compounds were present at low ratios, ranging from 10% to less than 1% of the total volume of the product. Though widely used in industry for decades, these emerging compounds were, until recently, not analyzed or regulated. Emerging and recalcitrant compounds include, but are not

---

limited to, methyl tertiary-butyl ether (MtBE), a gasoline oxygenate additive; perchlorate, the major component of solid rocket motors and a minor ingredient of highway safety flares, and various stabilizers of chlorinated solvents such as 1,4-dioxane. Many of these recalcitrant compounds are also suspected to be carcinogenic or to cause other adverse health effects. Consequently, advisory drinking water action levels have been adopted for many emerging contaminants; regulatory agencies have added these compounds to their list of Compounds of Interest at remediation sites.

In the past, when confronted by new and emerging contaminants, consultants in the environmental industry generally did not have all the required remedial information because it was not immediately available. Consequently, many of these contaminants, when first encountered, are described in the literature as recalcitrant. Some compounds that were thought to be recalcitrant years ago, such as PCBs and TNT, have since been cleaned up using a variety of biological or chemical methods, following years of laboratory testing.

In approximately 1979, MtBE was added to gasoline as a fuel oxygenate to reduce air emissions and improve performance. MtBE was originally thought recalcitrant by many investigators. As an ether compound, MtBE was recognized as a compound significantly different from other petroleum hydrocarbon compounds and was not thought to be easily treated using existing hydrocarbon remedial technologies. As remedial solutions emerged, the cost of MtBE remediation was considered prohibitive. The state of the art of MtBE remediation has continued to improve in effectiveness and affordability, following years of research in the laboratory, as well as failures and successes in the field.

MtBE is highly soluble in groundwater and has low affinity for organic carbon in the soil. As a result of these physical and chemical characteristics, MtBE retardation by organic matter in soil is minimal. The solubility of MtBE in water is 43,000 mg/L, compared with the 1780 mg/L solubility of benzene. Consequently, MtBE is often found at the leading edge of gasoline plumes, followed by benzene (1).

Over the years, it has been determined that MtBE does break down using chemical oxidation (ozone, Fenton's reagent) as well as aerobic and anaerobic *ex situ* bioremediation methods. The chemical characteristics of MtBE require prompt source control of the fuel leak to minimize groundwater impacts and remediation costs (2). Successful management of MtBE contamination at fuel release sites requires adequate site characterization, selection of the appropriate remedial technology, sound engineering remedial design plans and implementation, proper operation and maintenance of the remedial system, and a cooperative approach with the regulatory agencies. Although MtBE moves quickly in groundwater, when detected soon after a spill, MtBE can be cleaned up at a cost equal to or slightly higher than that for other hydrocarbons, such as benzene. However, at sites where fuel has been leaking for some time, the MtBE plume can be significantly larger than the corresponding benzene plume, and the MtBE cleanup can cost much more.

The widespread release of chlorinated solvents in industrial and commercial cleaning and degreasing operations allowed solvents to impact groundwater throughout the nation from the 1960s through the 1980s. One place where solvent groundwater plumes are abundant is in Silicon Valley, south of San Francisco, California, where printed circuit board and semiconductor manufacturers using various solvents in degreasing operations created numerous large (1 mile or longer) chlorinated solvent plumes in shallow groundwater.

There has been innovation in restoring aquifers impacted with chlorinated solvents, and progress has been made at many of Silicon Valley's solvent release sites. The additives to solvents sometimes have the potential to be as problematic as the solvents themselves. Numerous additives are routinely included with most industrial solvents to ensure that the solvents perform as needed in their intended degreasing application. These additives are collectively known as *solvent stabilizers*, or inhibitors. They mitigate or prevent reactions in the degreaser with water, acids, and metals and inhibit degradation from heat, light, and oxygen. Stabilizers are generally added to TCE and PCE at volumetrically small proportions, generally totaling 1% or less. A few stabilizers, however, were added in the percent range. For example, 1,1,1-trichloroethane (TCA) was stabilized with 1,4-dioxane at 2–5% by volume, and some citations list as much as 8%. 1,4-Dioxane is a cyclic ether that inhibits reactions with metals, particularly aluminum salts.

The stabilizers most commonly associated with the four main solvents, TCA, trichloroethylene (TCE), tetrachloroethylene (PCE), and dichloromethane (DCM), are listed in Table 1.

Once released to the subsurface, the relative rates of migration of TCA and 1,4-dioxane are markedly different, governed by their physicochemical properties, as contrasted in Table 2. 1,4-Dioxane is resistant to both abiotic degradation and biotransformation, and owing to its infinite solubility and low affinity for sorption to soil organic matter, moves through the subsurface relatively unimpeded. Among 123 organic compounds ranked for their subsurface mobility, 1,4-dioxane is ranked first; it is deemed the most mobile among the compounds ranked (3).

Column experiments in the literature and modeling exercises have shown that 1,4-dioxane is extremely mobile in the subsurface. Accordingly, site investigation and remedial designs may require modification to account

Table 1. Solvents and Their Stabilizers

TCA	1,4-Dioxane	1,3-Dioxalane
	Nitromethane	1,2-Butylene oxide
TCE	1,2-Butylene oxide	Cresol
	Tetrahydrofuran	Epichlorohydrin
	Diisopropylamine	Alkyl pyrroles
DCM	Cyclohexane	Cyclohexene
PCE	Cyclohexene	Amines
	Butoxymethyloxirane	Phenols

Table 2. Physicochemical Properties of TCA and 1,4-dioxane

Property	1,4-Dioxane CASRN 123-91-1 $C_4H_8O_2$	TCA CASRN 71-55-6 $C_2H_3Cl_3$
Molecular weight	88.10	133.4
H_2O solubility mg/L at 20 °C	Miscible	1,360
Boiling point at 760 mmHg	101.1 °C	74.1 °C
Vapor pressure mmHg at 20 °C	37 mmHg at 25 °C	96 mmHg at 20 °C

for the presence of 1,4-dioxane. Where 1,4-dioxane has been discovered at solvent release sites, regulators found it necessary to require that monitoring well networks be expanded, due to the larger footprint of 1,4-dioxane occurrence, and capture zones increased. Similarly, it has been necessary to add remediation equipment capable of removing 1,4-dioxane.

Existing groundwater treatment systems designed to remove chlorinated solvents are generally ineffective for remediating 1,4-dioxane, due to its K_{OC} and low Henry's law constant. In El Monte, California, a liquid granular activated carbon treatment system consisting of two 20,000-pound carbon vessels and treating 500 gallons per minute of solvent-contaminated groundwater was ineffective in reducing influent 1,4-dioxane concentrations at 14 μg/L to the treatment target of 3 μg/L (Fig. 1). In the City of Industry, California, an air stripper designed to remove 1.2 mg/L chlorinated solvents at 70 gallons per minute reduced 610 μg/L influent 1,4-dioxane to 430 μg/L in effluent. Conventional activated sludge and other common municipal wastewater treatment technologies have also proved ineffective in removing 1,4-dioxane.

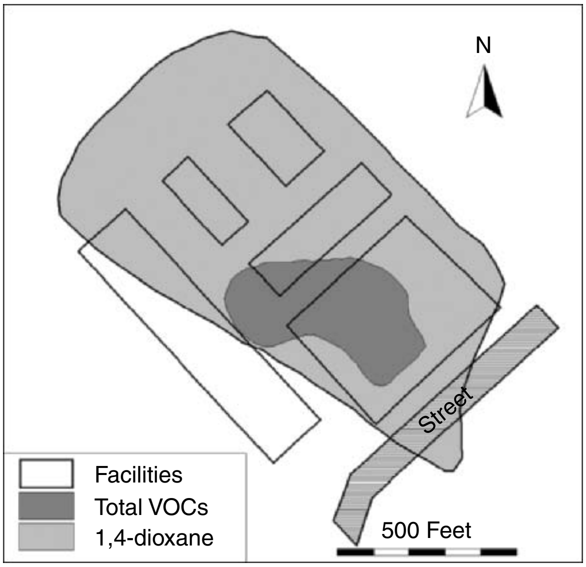

Figure 1. Silicon Valley solvent recycling facility plumes (10 μg/L contour).

The remedial technologies most commonly employed in removing 1,4-dioxane from groundwater *ex situ* are advanced oxidation processes (AOP), often in combination with ultraviolet light. AOP processes include ultraviolet light with ozone, hydrogen peroxide with ultraviolet light, ozone and hydrogen peroxide in combination, and Fenton's reagent (hydrogen peroxide and ferrous iron). Ultraviolet light causes release of hydroxyl radicals from hydrogen peroxide added to influent contaminated water. The hydroxyl radicals can react with 1,4-dioxane to oxidize the molecule to harmless reaction products (water, carbon dioxide, and residual chloride).

Biodegradation of 1,4-dioxane *in situ* is not presently considered a viable remediation option. The ether bond is a highly stable linkage and not readily biodegraded under ambient conditions. Recent research has established that there is promise for engineered bioreactors treating 1,4-dioxane *ex situ* and for *in situ* bioremediation using propane as a substrate. These methods of enhanced biodegradation show promise, whereas the more passive approach of monitored natural attenuation remains a poor candidate for effective management of 1,4-dioxane in groundwater.

SUMMARY

As many sites near closure or switch over to monitored natural attenuation, the specter of finding new and emerging compounds that are very mobile and recalcitrant is real. Discoveries of previously unknown contaminants may delay completion of site cleanup and require expensive revisions to remedial infrastructure to address their presence. Laboratory methods should be employed to obtain a full appreciation of the compounds likely to be present. Many of these emerging recalcitrant compounds are not presently subject to legal standards such as a maximum contaminant level, so there is often confusion regarding how the detection of these compounds affects progress at cleanup sites. Better regulatory guidance for the full gamut of compounds likely to be present at degreasing, fuel release, defense, and other sites is needed to ensure that time, money, and effort are well spent to complete the remedial investigation/feasibility study (RIFS) process once instead of repeating it upon the discovery of each new contaminant.

A more detailed treatment of this topic, with complete reference listings, may be found in the revised *Solvent Stabilizers White Paper* (4). The presentation binder from the Groundwater Resources Association symposium titled *Characterization and Remediation of Emerging and Recalcitrant Contaminants* in San Jose on June 14–15, 2001, and the December 10, 2003 symposium on *1,4-Dioxane and Other Solvent Stabilizers in the Environment* also contains additional information and articles on recalcitrant compounds (5).

ROAD SALT

M. Eric Benbow
Richard W. Merritt
Michigan State University
East Lansing, Michigan

INTRODUCTION

Maintenance of safe winter roadways and walkways is frequently accomplished by the application of chemical deicers and anti-icing compounds before or during snowfall and ice cover (Fig. 1). Road salt has been used since the 1940s and continues to be extensively applied throughout much of North America and Europe. It is estimated that 10 million metric tons of road salt are spread on American roadways each year, while another 3 million metric tons are used in Canada (1,2) (Fig. 2). The total annual cost of applying road salt can be greater than $62 billion in the United States because of damaged roads, bridges, and motor vehicles (1). By far, the most regularly used deicing agent is sodium chloride (NaCl), although several other inorganic salts are available (3). For instance, in the winter of 1997–1998, approximately 5 million tons of NaCl were applied to Canadian roadways compared with 120,000 tons of calcium chloride ($CaCl_2$) (4).

The widespread and increasing use of road salt has raised concerns about its effects on natural resources and drinking water. During roadway application, the components of road salt are left in the environment, typically on the soils adjacent to treated roads or into aquatic ecosystems, such as streams, rivers, wetlands, and lakes. Some salt enters groundwater during its movement. This large-scale input of salt into aquatic ecosystems is thought to have an impact on biological communities. However, the magnitude of these effects on specific ecosystem components is relatively unknown compared with other pollutants, and recent research is beginning to provide important information. In an extensive review by Environment Canada (4), it was found that: "Based upon the available data, it is considered that road salts that contain inorganic salts with or without ferrocyanide salts are entering the environment in a quantity or concentration or under conditions that have or may have an immediate or long-term harmful effect on the environment on which life depends. Therefore, it was concluded that road salts... are 'toxic' as defined in Section 64 of the Canadian Environmental Protection Act, 1999." Concerns exist about the effects of road salt on the natural environment that are balanced by transportation safety and economic issues.

Figure 1. A road salt storage facility open to the elements that can increase runoff during heavy rain effects. This facility is on a parking lot near Lansing, MI (photo by M.E. Benbow).

Figure 2. Residual road salt on the pavement of a parking lot near Lansing, MI (photo by M.E. Benbow).

For this topic on road salt, we will focus on the most commonly used form, NaCl. We briefly discuss its basic physical and chemical properties, ice control alternatives to NaCl, and the potential impacts on surface water biological communities.

DEFINITION AND PROPERTIES

Sodium chloride is the most common road salt used for melting snow and ice on pavements (3,4). Road salt can also be defined as calcium chloride, magnesium chloride ($MgCl_2$), and potassium chloride (KCl_2). In addition, an anticaking agent is often added to road salt, which is usually sodium ferrocyanide ($Na_4Fe[CN]_6 \cdot H_2O$), but is sometimes ferric ferrocyanide ($Fe_4[Fe[CN]_6]_3$), a component that has been listed as a toxic substance in the Clean Water Act (5). These anticaking agents are typically added in amounts ranging from 20 to 100 ppm (6).

The common physical and chemical properties of NaCl are given in Table 1. Pure sodium chloride is composed of 60.7% elemental chlorine and 39.3% sodium that form cubic crystals. Rock salt NaCl usually has other trace elements, including metals such as phosphorus, sulfur, nitrogen, zinc, and copper (4). By lowering the eutectic freezing point of water, the crystalline structure of pure NaCl provides anti-icing properties that results in melting when salt crystals combine with water (H_2O) molecules. The eutectic freezing point is the lowest freezing temperature for water after combining with a salt. Thus, pure NaCl melts snow and ice down to a temperature of −21.12 °C (Table 1). However, NaCl eliminates freezing when temperatures are above −11 °C, and as the difference between ambient temperature and the eutectic temperature decreases, the melting rate of ice and snow slows down (4). It has been reported that the lowest effective deicing temperature for NaCl is from 0 °C to −15 °C (4). When temperatures go below this range, other inorganic road salts are sometimes mixed with NaCl for more effective treatment on roadways, or used in place of NaCl. In addition, abrasives such as sand are mixed with rock salt during application when temperatures drop below the optimal effective temperatures. They also are added to help the salt stick to the pavement surface. Sand and other abrasives can have negative effects on roadside communities (4,7,8).

Table 1. Physical and Chemical Properties of Sodium Chloride

Property	Value or Description
Chemical formula	NaCl
Molecular weight	58.45
Atomic weight of Na	22.9898
Atomic weight of Cl	35.4527
Appearance	Clear or white solid
Solubility	35.7 g/100g water at 0 °C
Density	2.2×10^3 kg/m^3
Melting point	801 °C
Boiling point	1465 °C
Eutectic freezing point	−21.12 °C

ALTERNATIVES TO NACL

Historically, NaCl has been the preferred deicing agent because of its economic cost, easy storage, quick melting properties, and ease of handling and application. However, with recent concerns about its impact on the natural environment (see below), several alternatives have been proposed and tested (1). Table 2 gives a summary of the most common deicing and anti-icing alternatives to NaCl by comparing their eutectic temperatures and relative cost differences. The other inorganic salts ($CaCl_2$, $MgCl_2$, KCl) are more expensive than NaCl and are usually more corrosive to vehicle and roadway structures such as bridges and overpasses (1,6). They are often used in mixtures for snow and ice melting at higher rates and lower temperatures than using NaCl alone, but they also are more expensive (1). Calcium magnesium acetate (a mixture of calcium and magnesium acetates) is even more expensive, but can work well at temperatures (e.g., −9.44 °C) lower than those most effective for NaCl, and has been reported to be the least toxic of the alternatives (1). Other alternatives have been tested, such as methanol and urea. However, methanol is considerably more volatile, toxic, and flammable than NaCl, and urea is a nutrient fertilizer that can quickly contribute to eutrophication of surface waterbodies. The overwhelming argument by government agencies for the continued use of NaCl is based on economic cost–benefit comparisons to the alternatives, despite the potential effects on the environment.

IMPACTS ON AQUATIC ENVIRONMENTS

Road salt enters the air, soil, surface, and groundwater through vehicle splashing and direct runoff into adjacent areas of roadways. During windy conditions, splash and spray from melted road salt slurries can be transported

Table 2. Economic Cost and Melting Temperature Comparisons Among Chemical Alternatives to NaCl for Controlling Ice and Snow

Chemical	Relative Economic Comparison	Eutectic Temperature, °F	Eutectic Temperature, °C	Eutectic Concentration, % w/w
Sodium chloride (NaCl)	1	−6	−21	23.3
Calcium chloride ($CaCl_2$)	7	−67	−55	29.8
Magnesium chloride ($MgCl_2$)	7	−28	−33	21.6
Potassium chloride (KCl)	4	13	−11	19.5
Calcium acetate	35	5	−15	44.0
Magnesium acetate	35	−22	−30	31.0
Methanol	10	−144	−98	100.0
Urea	7	11	−12	32.5

several meters from the side of the road and can cover roadside vegetation (4). As NaCl quickly dissociates into its component ions Na^+ and Cl^- when in solution, it is the concentrations of these ions that can affect communities adjacent to treated roadways. Although Na^+ ions readily bond to negatively charged soil particles and are typically consumed in biological processes in the sediments, Cl^- ions are more mobile and tend to be transported in surface and groundwater, where concentrations can accumulate and persist if the geological conditions are favorable (e.g., clay-lined wetlands). However, if substantial ground–surface water exchange exists, Cl^- will move with the direction of water flow in the system.

ROAD SALT LOADING AND CHLORIDE LEVELS

Studies have shown that deicing salts accumulate in rivers, streams, wetlands, and lakes during application, during snow removal and disposal, and from losses during handling and storage (4,9–11). For instance, it was estimated that road salt input into the Great Lakes was nearly two million tons by 1960: about 700,000 tons in Lake Erie; 500,000 in Lake Ontario; 400,000 in Lake Michigan; 190,000 in Lake Huron; and 90,000 in Lake Superior (12). Environment Canada (4) estimated, from a report by Morin and Perchanok (13), that the total chloride road salt loading for Canada between 1997 and 1998 was nearly 5 million tons. In 1992, 17 states in the United States reported that road salt application was a significant source of groundwater contamination, and four reported degraded wetland integrity because of salinity (14).

Increases have been documented in sodium and chloride concentrations in surface and groundwater over the past 50 years (10,15–17). In New York, it was reported that chloride transport rates increased by 145% from the 1950s to the 1970s, and that road salt application accounted for 69% of that increase (16). Other studies have shown similar trends in other parts of the United States and Canada (18–20). However, Blasius and Merritt (7) reported rather low chloride concentrations from two Michigan streams during winter months, but explained that increased discharge during spring thaw acted to dilute the chloride additions from winter road salt application. This inverse relationship of discharge and chloride levels also has been reported in other studies (21,22).

Environment Canada (4) summarized various chloride studies of urban lakes and retention ponds and reported chloride levels from 200 to 5910 mg/L. In the interstitial peat mat waters of an Indiana wetland, Wilcox (23) reported chloride levels up to 1215 mg/L. Benbow and Merritt (24) measured chloride concentrations from 43 water bodies in 37 counties of Michigan and reported a range from 18 to 2700 mg/L. From a wetland adjacent to a sand-salt storage facility, chloride was reported in another study to be 12,463 mg/L (25).

INDIRECT EFFECTS OF NACL

Residual road salt runoff is known to directly impact aquatic flora and fauna from both elevated chloride levels, and potentially from the anticaking chemicals routinely mixed for application (26,27). Sodium ferrocyanide is one such agent reported to release cyanide ions via photolysis (28); however, little information exists on the amount of ferrocyanide that might be entering impacted waterbodies during road salt application. Another indirect effect is the potential release of heavy metals already present in benthic (stream, wetland, or lake bottom) sediments through ion exchange mechanisms (29–31). For example, Doner (29) found that sodium chloride increased the mobility of Ni(II), Cu(II), and Cd(II) in soil leach columns. Furthermore, the release of mercury-adsorbed sediment particles (exchanged with Na^+) has been documented to increase with chloride ion concentrations in freshwater sediments (32). In laboratory column experiments, nearly 90% of mercury sorbed to sediments was mobilized when salt was introduced (33). Road salt also has been suggested as an agent of lake and stream acidification via ion exchange of Na^+ for H^+ (34), and is suspected to reduce soil fertility through accelerated leaching of calcium and magnesium (31).

Road salt accumulation affects small lake mixing through the establishment of short- and long-term chemoclines that prevent mixing and leading to anoxic conditions (19,35,36). Dense saline layers accumulate at lake bottoms, reducing the likelihood of mixing and prolonging anaerobic conditions of the lower layers, thus resulting in fish kills and destruction of the benthic fauna on which fish feed. Road salts entering surface waters may also trigger excessive blue-green algae growth, stimulating nuisance algal blooms (37). The mechanism of this growth involves facilitated phosphate absorption by algae in the presence of inorganic ions (38). Seasonal influxes of road salt runoff have been reported to maintain high chloride concentrations of lakes so that salt outflow is abnormally high throughout the year (39), thereby creating long-term water chemistry changes downstream.

These studies provide evidence that road salt can have indirect effects on aquatic biological communities beyond that of direct toxicity; however, direct mortality of aquatic animals can have cascading effects on the rest of the ecosystem. As macroinvertebrates commonly serve as biological indicators of aquatic ecosystems and are a dominant food source for higher consumers (40,41), we have provided a more thorough review of road salt toxicity on these organisms. Only a brief summary for zooplankton and fish is given. We refer readers to Environment Canada (4) for more information on these organisms and protozoans, bacteria, and fungi.

DIRECT EFFECTS ON AQUATIC MACROINVERTEBRATES

Before direct toxicity effects can be evaluated, the natural salinity tolerance for invertebrates should be reviewed; and this has been done in several studies. Williams et al. (42) found relationships between macroinvertebrate community structure and chloride levels of Canadian springs. In that study, they attributed high chloride levels to groundwater contamination by road salt (42). Several authors have reported benthic macroinvertebrate salinity tolerances along natural salt gradients in estuaries (43,44), salt marshes (45), and more recently in hyporheic habitats along a salinity gradient from a freshwater stream into an estuary (46). Overall, these studies have shown that distinct invertebrate communities are often associated with salinity ranges. But what about macroinvertebrates typically found in freshwater that are exposed to elevated salt concentrations from residual road salt?

Road salt toxicity studies on aquatic macroinvertebrates have shown variable results (4,7,24). Early studies found compromised osmoregulatory processes for certain aquatic insects (47–49), and species-specific tolerance variation is common in the literature (Table 3). Most acute (24–96 h) and chronic toxicity (>7 d) studies report LC_{50} values that vary among species and test conditions. The LC_{50} is the lethal concentration at which 50% of the test

Table 3. Review of Field and Laboratory Studies of NaCl Effects on Aquatic Macroinvertebrates

Endpoint Effect	NaCl, Cl^-, or Road Salt[a] Concentrations, mg/L	Reference
LC_{50} for *Culex* sp. (Culicidae)	10,254	Dowden and Bennett (50)
100% Mortality for 12-h exposure for *Chironomus attenatus* (Diptera: Chironomidae)	9995	Thornton and Sauer (47)
100% Mortality for 48-h exposure for *Cricotopus trifascia* (Diptera: Chironomidae)	8865	Hamilton et al. (51)
100% Mortality for 48-h exposure for *Hydroptila angusta* (Trichoptera: Hydroptilidae)	10,136	Hamilton et al. (51)
100% Mortality for 48-h exposure for *Nais variabilis* (Oligochaeta: Naididae)	3735	Hamilton et al. (51)
No effect on drift or mortality for *Gammarus pseudolimnaeus* (Amphipoda: Gammaridae)	800	Crowther and Hynes (27)
No effect on drift or mortality for *Hydropsyche betteni* and *Cheumatopsyche analis* (Trichoptera: Hydropsychidae)	1650	Crowther and Hynes (27)
Some drift activity of macroinvertebrates observed in field experiments	>1000	Crowther and Hynes (27)
No effect on composition or diversity of Ephemeroptera, Plecoptera, Trichoptera and Coleoptera in the field	50–67	Molles (8)
Mortality of *Hydropsyche betteni, H. bronta*, and *H. slossonae* (Trichoptera: Hydropsychidae) unaffected after 10 d	800	Kersey (52)
80% Mortality for 6-day exposure for *H. betteni*	6000	Kersey (52)
Similar growth rates among treatments for *Hexagenia limbata* (Ephemeroptera: Ephemeridae)	0, 2000, 4000, 8000	Chadwick (53)
96-h LC_{50} at 28 °C and 18 °C, respectively, for *H. limbata*	2400 and 6300	Chadwick (53)
96-h LC_{50} for *Tricorythus* sp. (Ephemeroptera: Tricorythidae)	2200–4500	Goetsch and Palmer (54)
Approximate LC_{50} for *Hydropsyche betteni* (Trichoptera: Hydropsychidae); however, no dose-response was tested	13,308	Kundman (55)
No significant drift observed for *H. betteni* in lab	2000–8000	Kundman (55)
96-h LC_{50} for *Lepidostoma* sp. (Trichoptera: Lepidostomatidae)	6000	Williams et al. (10)
70% mortality 96-h exposure for *Nemoura trispinosa* (Plecoptera: Nemouridae)	6000	Williams et al. (10)
100% mortality 96-h exposure *Gammarus pseudolimnaeus*	6000	Williams et al. (10)
No effect on macroinvertebrate functional feeding group assemblages in two rivers	8–16 (Cl^-)	Blasius and Merritt (7)
Drift effects on *Gammarus pseudolimnaeus* (Amphipoda): from 55%—68% in laboratory experiments over 24 h	2500–10,000	Blasius and Merritt (7)
Variable and no significant drift of Perlidae, Limnephilidae, Heptageniidae, Tipulidae in laboratory experiments over 24 h	1000–10,000	Blasius and Merritt (7)
Significantly lower leaf pack decomposition, but due to sand not salt	—	Blasius and Merritt (7)
96 h LC_{50} for *Gammarus* sp. (Amphipoda)	7700	Blasius and Merritt (7)
96 h LC_{50} two limnephilid caddisflies (Trichoptera)	3526	Blasius and Merritt (7)
No significant mortality for two Perlidae (Plecoptera) and one Tipulidae (Diptera) species in lab	>10,000	Blasius and Merritt (7)
100% mortality after 7 days for *Hexagenia limbata* (Ephemeroptera)	12,000	Chadwick et al. (56)
Loss of osmoregulation and increased mortality	>8000	Chadwick et al. (56)
96 h LC_{50} estimated for *Callibaetis fluctuans* (Ephemeroptera) and *Physella integra* (Gastropoda) under different test conditions (lab and field)	5000–10,000 (road salt)	Benbow and Merritt (24)
96 h LC_{50} estimated for *Hyallela azteca* (Amphipoda) and *Chaoborus americanus* (Diptera: Chaoboridae) under different test conditions (lab and field)	>10,000 (road salt)	Benbow and Merritt (24)

[a] When Cl^- or road salt was used instead of NaCl in a study, it is indicated in parentheses.

organisms die. In sublethal tests, the EC_{50} is reported, which is defined as the effective concentration where the tested variable (e.g., number of eggs or growth rate) is reduced by 50%. We provide Table 3 as a summary of tolerance levels of macroinvertebrates reported in the literature. This table was modified and expanded from Blasius and Merritt (7).

From the literature in Table 3, it is apparent that salt tolerance for aquatic macroinvertebrates is relatively high, with highest acute toxicity reported from mayflies (Ephemeroptera: *Hexagenia limbata*). Acute toxicity studies reported LC_{50} values (or greater mortality) from 2400 to >13,000 mg/L NaCl (or road salt). Variable mortality was evident among taxa with *Culex* mosquitoes (Culicidae) having an LC_{50} of 10,254 mg/L NaCl and caddisfly (Trichoptera) taxa with values from 3526 to 13,308. Nonlethal effects also were variable. Drift effects for various taxa (amphipods, caddisflies, mayflies, stoneflies, and craneflies) ranged from 2500 to 10,000 mg/L NaCl, with some drift effects found at concentrations >1000 mg/L NaCl. Growth rates for a mayfly (*H. limbata*) did not differ among treatments from 0–8000 mg/L NaCl; however, osmoregulation was lost at higher concentrations. This variation in lethal and nonlethal road salt tolerance may be a product of artificial testing conditions that do not represent natural environmental changes in temperature and other variables.

In addition, many taxonomic groups have not been tested, indicating that unstudied, yet sensitive species may exist. Most studies did not evaluate the background chloride levels of waterbodies typically occupied by the invertebrates tested, and when background chloride levels were measured, they were often below the invertebrate toxicity levels. In several studies, it was noted that chloride levels were sometimes diluted with snow melt runoff at the time of the highest expected impact (early spring). Nonlethal effects (e.g., drift, fecundity, production) have been understudied and may be important to invertebrates impacted by residual road salt runoff. Additional data and studies can be found in the review by Environment Canada (4).

EFFECTS ON ZOOPLANKTON AND FISH

Road salt tolerance variability has been reported for several species of zooplankton, with *Daphnia pulex, D. magna*, and *Ceriodaphnia dubia* being the most commonly tested taxa (4). Results from short-term acute toxicity studies ($\leq$24 to 96 h) reported LC_{50} values ranging from 2308 to 7754 mg/L NaCl (4). In studies lasting 7–10 d, LC_{50} values ranged from about 2000 to 6000 mg/L NaCl, whereas EC_{50} for zooplankton mean brood size, number of broods, or total progeny ranged from about 1400 to 6000 mg/L NaCl (4).

Fish road salt toxicity was low during studies <24 h, with LC_{40} and LC_{50} values ranging from 20,000 to 50,000 mg/L NaCl (4). In 24 h studies, road salt toxicity was higher, but LC_{50} values were >7000 mg/L NaCl for bluegill (*Lepomis macrochirus*), indian carp fry (*Cirrhinius mrigalo, Labeo rohoto*, and *Catla catla*), brook trout (*Salvelinus fontinalis*), and rainbow trout (*Oncorhynchus mykiss*) (4). Longer acute toxicity studies reported LC_{50} values for bluegill, rainbow trout, and indian carp fry to be >9500, 11,112, and 4980 mg/L NaCl, respectively (4). The American eel (*Anguilla rostrata*) was reported to have LC_{50} values from about 18,000 to 22,000 mg/L NaCl in one study, and fathead minnow (*Pimephales promelas*) values were from >7500 to 10,831 mg/L NaCl (4). In seven to ten day acute toxicity studies on fathead minnow and frog (*Xenopus laevis*) embryos, eggs, and larvae, LC_{50} values ranged from 1440 to 5490 mg/L NaCl depending on life stage (4).

CONCLUSIONS

The sustained and increasing use of road salt for winter roadway maintenance is becoming a popular issue as a result of raised awareness of potential ecological effects on natural waterways. Balancing human transportation safety with potential ecological repercussions drives this issue, and it is clear from the literature that the answer will be complicated, if ever resolved. The economics associated with using deicer alternatives suggest that, at present, road salt is the best practical agent for winter snow and ice removal. Chlorides are known to have effects on organisms in nature, and in many reports, it is evident that chloride concentrations are rising in waterbodies associated with roadways that are heavily treated with road salt. However, short-term toxicity studies have shown that mortality among aquatic zooplankton, macroinvertebrates, and fish is highly variable, species-dependent, and related to test conditions. Many toxicity studies are done under laboratory conditions that are far removed from the natural variation of climatic and biological components of natural waterbodies, which may influence true mortality of certain taxa. Apart from toxicity studies, larger scale studies that evaluate complex community and ecosystem level responses are needed for a better understanding of road salt effects in nature.

REVIEW OF RIVER WATER QUALITY MODELING SOFTWARE TOOLS

Anne Ng
B.J.C. Perera

Hawthorne, Victoria, Australia

INTRODUCTION

Rivers supply valuable water resources for humans, and many aquatic ecosystems. However, due to population increase and its adverse effects on the rivers, and other adverse activities, the water quality in rivers has generally declined. Therefore, appropriate river water quality management strategies aimed at controlling and improving water quality should be seriously considered. To manage river water quality in the most effective and efficient way, the cause and effect relationships of the river system must first be investigated. River water quality modeling tools are extensively used in water quality management to identify these cause and effect relationships.

River water quality modeling software is designed to model the water quality in a river system. Many generic water quality modeling software tools are widely available, and most of them are in the public domain and available at no cost. The applicability of these software tools depends on the study objectives. Therefore, it is necessary to review available water quality software modeling tools, so that the most appropriate software tool can be selected for the specific application.

Here, we mainly concentrate on reviewing available public domain river water quality modeling software tools, although a brief review of catchment water quality modeling software tools is also presented. A case study is also included to identify and select the most suitable software for modeling of water quality in the Yarra River, Australia.

WATER QUALITY MODELING SOFTWARE TOOLS

In general, the water quality modeling software tools can be categorized into three broad groups, namely, catchment, river, and integrated software tools. Under these groups, the available public domain software is shown in Fig. 1. Since the focus here is on river water quality software tools, they are further divided into two groups, namely, steady and unsteady state modeling software tools.

Catchment Water Quality Modeling Softwares

Catchment water quality modeling software tools are used to estimate the amount of pollutant loadings generated from different land surfaces in catchments, which affects the water quality in streams and rivers. A listing of commonly used catchment water quality modeling software is shown in Fig. 1.

The most commonly used catchment water quality modeling software is the Agricultural Nonpoint Source Pollution Software (AGNPS) (1), which was developed by the United States Agricultural Research Services. AGNPS can be used in both event and continuous simulation modes, to estimate sediment and nutrient loads from agricultural areas. The catchment is divided into a number of cells to determine pollutant loadings. Tim et al. (2) used AGNPS (linked with a GIS system) to examine the effect of varying widths of vegetated buffer strips on sediment yield of the bluegrass catchment in Iowa, USA. AGNPS was also used to predict pollutants generated from site-specific catchment characteristics in Missouri, USA (3)

Storm Water Management Model (SWMM) is an urban stormwater quantity and quality software tool that was developed by the United States Environmental Protection Agency (U.S. EPA) (4), which can be used in both event and continuous simulation modes. Data required by SWMM are relatively intensive. It has the most versatile hydrological and hydraulic simulation modules, while the water quality simulation is relatively weak

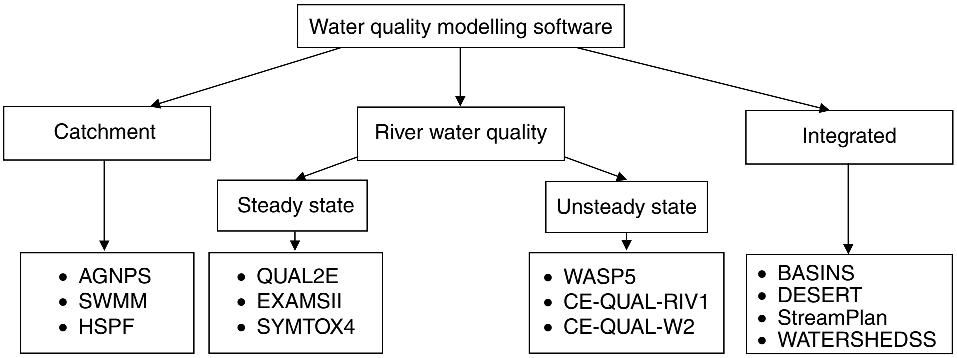

Figure 1. Summary of available public domain water quality software.

in representation of the true physical, biological, and chemical processes (5).

The Hydrological Simulation Program–FORTRAN (HSPF) is one of the comprehensive software tools, which simulates the catchment runoff processes together with a minor component on river water quality (6). This software tool can be used to simulate nonpoint source runoff. Major conventional water quality constituents such as dissolved oxygen (DO), biochemical oxygen demand (BOD), and all forms of nitrogen and phosphorus can be simulated. As discussed in References 5 and 7, HSPF is a highly complex software tool, which requires extensive resources and data. Moore et al. (8) used HSPF on the North Reelfoot Creek catchment, located in the northwest corner of Tennessee, USA to examine several best management practices in reducing erosion and sedimentation. Runoff and sediment load in the Upper Changjiang River Basin in China was simulated using HSPF (9). They found that HSPF underestimated the suspended solid concentration by up to 72% of the actual. The error in the model may have resulted from lack of data to produce a well-calibrated model.

River Water Quality Modeling Software Tools

River water modeling software tools are used to simulate the effects of pollutants generated from catchment and point sources (stormwater/treated sewage discharge outfall), on river and stream water quality. They do not estimate the nonpoint source pollutant load from the catchments. This category is reviewed in detail, since the focus is on review of river water quality modeling software tools. Two types of software tools exist, namely, steady and unsteady state.

Steady-State Software Tools. The steady-state river water quality modeling software assumes that the magnitude of flow and pollutant entering the stream do not vary with time (10). Therefore, in these software, the "average" inputs of flows and pollutants are considered for the flow event, giving "average" values for output water quality concentrations. Although these software tools cannot assess the water quality for time varying conditions, they can be useful in determining the critical water quality concentrations under design conditions. The results obtained from steady-state software are always more conservative than the results obtained with the unsteady-state software (11). The steady-state software tools are commonly used because they are less complex, easy to use, and require less input data. Below is a review of some commonly used public domain steady-state river water quality modeling software tools and their applications.

The Enhanced Stream Water Quality Model (QUAL2E) is a one-dimensional steady-state river water quality simulation software tool, which was developed and is supported by U.S. EPA (12). In 1995, QUAL2E was upgraded with a Windows interface to enhance its user-friendliness. Although QUAL2E is a steady-state flow software tool, it can also account for diurnal variation (difference in temperature between the warmest and coolest parts of the day) in temperature or algal photosynthesis and respiration. QUAL2E can model all conventional water quality constituents, as well as three other user-defined water quality constituents. QUAL2E can be applied to different waterbody types and allows modeling of multiple waste discharges and diversions. It also includes components that allow implementation of uncertainty analysis of model parameters using first-order error analysis, one-at-a-time, and Monte Carlo simulation (see Uncertainty Analysis in Watershed Modeling in this encyclopedia).

QUAL2E has been extensively used in many applications. The majority of these applications used this software tool to simulate major conventional water quality constituents in rivers. Some recent applications on modeling conventional water quality constituents in rivers include the work of Ghosh and McBean (13), Cvitanic and Kompare (14), and Ning et al. (15). In comparison, limited applications were cited in the literature using QUAL2E to simulate microbial water quality (16).

Ghosh and McBean (13) used QUAL2E to develop a water quality model of the Kali River in India. Although they experienced data limitations in their application, they commented that provided adequate data were available, QUAL2E can be effectively used to model water quality in rivers that have water pollution problems. This is consistent with the findings of Barnwell et al. (17), who stated that it is important to have site-specific data representing the properties of the actual system to model river water quality successfully.

Cvitanic and Kompare (14) applied QUAL2E to simulate and predict the possible changes in water quality in the River Sava in Croatia with the construction of impoundments. However, they found that QUAL2E was not suitable for their application, because the model prediction could not be validated during the validation stage. They concluded that a two-dimensional model is more suitable to predict water quality in impoundments, since large variations of river water quality exist in the river (laterally and vertically) during summer periods. They could have simply avoided this problem by selecting the most suitable software tool for their study, since they had a good prior knowledge of lateral and vertical water quality variations of the river.

Ning et al. (15) developed and calibrated a model for the Kao-Ping River Basin in Taiwan using QUAL2E. They successfully used the model as a simulation tool to assess the water quality standard requirements downstream by hypothetically eliminating pig farming activities and constructing a sewer system in the upstream areas. Although QUAL2E has been successfully used as a simulation tool in this study, they commented that an economic instrument for controlling and reducing the wasteload allocations would also be needed in the long term.

Steynberg et al. (16) used QUAL2E in an effort to simulate the effect of various management strategies, which can result in the desired level of fecal coliform in the Rietspruit catchment in South Africa. It was found that the model was unsuccessful in predicting the measured fecal coliform level. Due to the time varying discharge of effluent and different levels of wastewater treatment, the use of the steady-state model QUAL2E was inadequate for their study.

Reviewing the river water quality modeling software, Shanahan et al. (18) reported that QUAL2E has become the standard modeling software tool and has shown to be most applicable in situations where point source pollutants are dominant. Therefore, QUAL2E has been integrated and linked into a number of other modeling software tools. For example, QUAL2E has been integrated into decision support systems (DSSs), as in BASIN (5). Mulligan and Brown (19) and Ng (20) linked QUAL2E with genetic algorithm optimization software, GENESIS (21). As stated in Yang et al. (22), the use of remotely sensed water quality data with QUAL2E in the Te-Chi Reservoir in Taiwan can accurately interpret the spatial variation in water quality and monitor the water quality. De Azevedo et al. (23) linked QUAL2E with a water quantity network flow allocation model MODSIM of Labadie (24) to assess and evaluate six management alternatives for strategic river basin planning.

Exposure Analysis Modelling System (EXAMSII) (25) can be used in modeling of streams, rivers, and reservoirs in one-, two-, and three-dimensional modes. It accounts for many water quality transformation processes, such as photolysis, hydrolysis, oxidation, and sorption with sediments and biota (5).

SYMTOX4, the Simplified Method Program–Variable Complexity Stream Toxics Model (26), is a one-dimensional software tool that can be used to simulate the water column and benthic toxicity caused by point sources discharged into rivers. Major conventional water quality constituents can be simulated using SMYTOX4. This software is Windows based and has the capability to perform uncertainty and sensitivity analyses. One example was citied in Reference 5 using SMPTOX 4 on the Flint River, Michigan, in the United States.

Unsteady-State Software Tools. Unsteady-state (or dynamic) water quality software tools can be used to simulate water quality response in rivers whose flow and water quality characteristics change with time. All natural rivers and streams have unsteady-state flow characteristics, especially during high flow period, and therefore unsteady-state modeling software tools are more realistic. However, they require more data inputs compared to steady-state software tools. Below is a review of the available public domain unsteady-state water quality software tools (which are also listed in Fig. 1), together with their applications.

Water Quality Analysis Simulation Program (WASP5) is a well-known unsteady-state water quality simulation software tool supported by U.S. EPA (27). This software has flexible compartments such as hydrodynamics, eutrophication (DO/nutrients/algal/carbon), and toxins. The user can use these compartments selectively or all compartments simultaneously. This software tool can be used to model rivers and streams in one-, two-, and three-dimensional modes.

Lung and Larson (28) successfully used WASP5 to predict the impact of eutrophication under steady state in the Upper Mississippi River and Lake Pepin in the United States. They recognized that the unsteady-state mode should be used to study algal growth; however, relevant data inputs for algal growth dynamics were not available to them for unsteady-state flow modeling. They justified the use of steady-state mode after ascertaining that the phytoplankton population did not vary greatly from hour to hour.

Suárez et al. (29) developed an unsteady-state water quality model of the Nalón River in Spain using WASP5. This model was used to assess the impact of combined sewer flow (with daily fluctuations) on river quality and its effect on the aquatic system. The majority of the water quality related inputs required in WASP5 (e.g., reaeration rate methods, decay rates) were obtained from preliminary water quality modeling using QUAL2E. The WASP5 model was successfully calibrated, which adequately simulated the water quality and activities occurring in the river accounting for time variation. However, the decay rates were required to be the same for all reaches of the river in WASP5, which they found to be one of the main deficiencies.

A eutrophication model was developed for the Tolo Harbour in Hong Kong using WASP5 by Lee and Arega (30). This model accounts for sediment water interaction together with time and spatial variation in water quality. They successfully simulated DO and chlorophyll-*a* concentrations and matched them with observations. The model was developed to study the long-term trends of eutrophication in the harbor.

As reported by the World Bank (31), WASP5 is not appropriate for basins with large catchment areas, since it is complex and time consuming to calibrate and simulate water quality conditions of rivers and streams associated with these large basins.

The Hydrodynamic and Water Quality Model for Streams (CE-QUAL-RIV1) is a one-dimensional software tool developed by The U.S. Army Experiment Waterways Experiment Station (32). It has two separate compartments: hydrodynamics and water quality. The results obtained from the hydrodynamics compartment are used as input to the water quality compartment. Many conventional water quality constituents can be modeled, including the effects of algae and macrophytes. One advantage of using this model is that it allows modeling of river structures such as dams. This model is less widely used compared to QUAL2E and WASP5 (33). CE-QUAL-RIV1 has been applied to the Cumberland River, the Chattahoochee River, and the lower Ohio River in the United States (5).

CE-QUAL-W2, also developed by The U.S. Army Waterways Experiment Station (32), is a two-dimensional experiment, laterally averaged, hydrodynamic and water quality model. It contains one module, which models both hydrodynamics and water quality. It can model DO, nutrients, and algae interactions. Since this software accounts for variations in longitudinal and vertical directions (not in lateral direction), this software is best used in situations where large variations in lateral velocities and water quality concentrations do not occur (5). Martin (34) used CE-QUAL-W2 for DeGray Lake in Arkansas (USA) and demonstrated its usefulness.

Integrated Water Quality Modeling Software Tools. The integrated software tools consist of several stand-alone tools in one package. For example, catchment and river modeling software tools can be integrated into one package to analyze both flow and water quality in rivers and associated catchments. When some form of decision support is available in integrated software, they are called decision support systems (DSSs). There is an increased use of DSSs in river water quality management in recent times. The purpose of a DSS is to effectively allow decision-makers to simulate the whole process of decision-making, related to the particular application (e.g., improving river water quality), to investigate and simulate alternative decision management scenarios, and to improve the effectiveness of decision-making. Below are descriptions of four public domain integrated water quality software tools (or DSSs) found in the literature.

Better Assessment Science Integrating Point and Nonpoint Sources (BASINS), developed by the U.S. EPA Office of Water (35), consists of a catchment water quality modeling software tool (NPSM) and a river water quality modeling software tool (QUAL2E). The Nonpoint Source Model (NPSM) is a Windows interface that works with the catchment model HSPF (6). The graphical system in BASINS uses Arc-View GIS software. One disadvantage of this system is that the data management module is less useful to countries other than the United States, since all relevant information and data are only applicable for basins in the United States, which are updated annually.

Decision Support System for Evaluating River Basin Strategies (DESERT) is a flexible, Microsoft Windows-based tool for decision support for water quality management at the catchment scale. DESERT was developed by two organizations jointly: International Institute for Applied Systems Analysis in Austria (IIASA) and the Institute for Water and Environmental Problems in Russia (36). This software tool provides a powerful instrument for developing least-cost river catchment policies, and for assessing these policies under conditions that are deviating from the design scenario (37). Fan (38) used DESERT to identify the most efficient water quality management strategy in terms of wastewater treatment alternatives for the Veszprémi-Séd River in Budapest, Hungary.

StreamPlan (Spreadsheet Tool for River Environmental Assessment Management and Planning) was developed at IIASA in 1996 (39). It is a DSS that allows decision-makers to evaluate river and catchment water quality policies considering local and regional water quality goals, effluent standards, costs, financing, economic instruments, municipal water management issues, and generation of wastewater treatment plant alternatives. StreamPlan was developed for use on a Microsoft Excel platform, which is familiar to most model users. Jolma et al. (40) discussed the use of StreamPlan in three degraded river catchments in Central and Eastern Europe: Narew (Poland), Morava (The Czech Republic), and Nitra (Slovak Republic).

Water, Soil and Hydro-Environmental Decision Support System (WATERSHEDSS) is similar to BASINS, except WATERSHEDSS is more focused on nonpoint source pollution (41). The U.S. EPA Office of Research developed this system in 1994, with the cooperation of North Carolina State University water quality group and the Department of Biological Engineering of Pennsylvania State University (42).

EVALUATION AND SELECTION OF WATER QUALITY SOFTWARE FOR THE YARRA RIVER, AUSTRALIA

To manage river quality in the most effective and efficient way, the cause and effect relationships of the river system must first be identified. A river water quality modeling tool is required for the Yarra River, Australia, for this purpose mainly to identify the cause and effect relationships in the river from different settings of effluent license limits from sewage treatment plants (STPs). Furthermore, this modeling should be able to simulate and study the effects of various “what-if” management strategies prior to implementation.

The catchment water quality software tools mainly deal with the generation and transport of overland pollution and do not directly consider river water quality. Therefore, they are not suitable for modeling Yarra River water quality, although quantifying overland pollutant runoff into streams is an important component in the modeling of river water quality. However, modeling of overland pollutant runoff is outside the scope of modeling in-stream water quality in the Yarra River. The river water quality software tools deal with river water quality and therefore are relevant to modeling water quality in the Yarra River. Although the integrated water quality modeling software (or DSS) tools are very efficient simulation and management systems as complete decision-making tools, they require extensive data, which were not available for the Yarra River at the time of selection of the appropriate modeling tools and, therefore, were not considered. Thus, the river water quality software tools were further investigated for modeling the Yarra River, its tributaries, and associated STPs.

Four criteria, as listed below, were used in selecting the river water quality software for use in the Yarra River, from the computer software tools listed in Fig. 1.

- Data availability for use in the modeling software and the purpose of using the model
- Ability to simulate major conventional water quality constituents such as DO, BOD, and nutrients
- Ability to produce longitudinal profiles (upstream/downstream) of water quality concentrations
- Wider successful usage of the software

These broader criteria will certainly reduce the number of river water quality software tools that can be used for the Yarra River. QUAL2E and WASP5 were the only two software tools that fitted the above criteria and therefore can be used for development of the Yarra River water quality model. Both software tools can simulate conventional water quality constituents, can produce longitudinal water quality profiles, and have been used successfully on many applications.

As stated in References 5 and 18, both QUAL2E and WASP5 software tools are well known and credible, with extensive capabilities and wide usage. These software tools were further evaluated for modeling the Yarra River. A summary of the evaluation results is given in Table 1. Three main categories, namely, fundamentals, water quality, and others, were considered in classifying the attributes of these software tools. Some of these attributes were considered in a comparative study by Ambrose et al. (27).

The first category consists of attributes, which forms the basic structural framework of the software tools. Most attributes are self-explanatory. Hydrodynamics is an extremely important attribute in water quality modeling, because the movement of water affects the fate of the water quality constituents. WASP5 has an independent compartment for simulating hydrology of the water body system, whereas QUAL2E requires hydrology (or flows)

Table 1. Evaluation Summary of QUAL2E and WASP5 Attributes

Fundamentals		QUAL2E	WASP5
Operational requirements	Documentation	Y	Y
	Support	Y	Y

as input. Both software can be operated in a steady-state environment, which is the most common water quality modeling application, although WASP5 can also be used in an unsteady-state environment. A one-dimensional longitudinal process can be modeled with both software tools and is considered as the dominant transport process in most river systems, since the water quality process in the river is considered well mixed in both lateral and vertical directions (10). WASP5 can simulate river water quality in two and three dimensions. The possible increase in DO concentration by water quality structures such as dams and weirs can only be considered in QUAL2E.

The second category is related to water quality constituents. Both software tools account for most sinks on DO processes. Built-in reaeration formulas are available in both QUAL2E and WASP5. QUAL2E accounts for the four forms of nitrogen in the nitrogen cycle: Org-N, NH_3, NO_2, and NO_3 (10). WASP5 combines NO_2 and NO_3, in the overall nitrification process from NH_3 to NO_3. However, as stated in Reference 7, lumping of NO_2 and NO_3 does not cause any significant effect in the overall result, since the transformation of NO_2 to NO_3 is rapid. All phosphorus processes including the algae cycle can be accounted for in both software tools. Both software tools have the ability to simulate both settling and benthic activity, which are important for streams with low velocity. QUAL2E is the only software tool that can simulate temperature using the atmospheric heat balance equation.

The third category deals with the additional attributes. QUAL2E provides a built-in uncertainty and sensitivity analysis module, which is useful in determining the sensitivity of input parameters to output water quality. The uncertainty and sensitivity analysis of model parameters is a major component in the overall model development.

Based on the above evaluation, WASP5 is considered to be “over qualified” for the development of the Yarra River water quality model. Steady-state simulation is considered sufficient for this study, because it can be used to determine the critical water quality concentrations under design conditions. This is necessary when the model is used to simulate and study the effect of different effluent license limits on river water quality. Furthermore, only grab sample water quality data of the river and at sewage treatment plants are available for the Yarra River. This data limitation can at best be considered as steady state and only suitable to model water quality in one dimension. QUAL2E is also less complex and provides all the essential elements that are required for modeling Yarra River water quality. These elements include modeling of interaction of conventional water quality constituents and the built-in uncertainty and sensitivity analysis. The use of QUAL2E is also supported by a large number of applications in river water quality modeling (15,19).

CONCLUSION

Management of river water quality has become increasingly important due to a decline in water quality caused by human activities. Successful implementation of efficient management strategies requires the development of river water quality models. These water quality models can be used to simulate and assess the cause and effect relationships of river water quality and then to study various management strategies to improve water quality, before their implementation.

Many water quality software tools are available in the public domain, which can be used to develop river water quality models. They were reviewed here. After a detailed evaluation of the river water quality modeling tools, QUAL2E was considered as the most suitable tool for use in the Yarra River model development. The major purpose of the development of the Yarra River water quality model is to assess the effect of various sewage treatment plants (STPs) effluent license limits on river water quality and this can be adequately done with QUAL2E software. The major evaluation criteria were the appropriateness of available data for use in the modeling software and the purpose of using the model.

CALIBRATION OF RIVER WATER QUALITY MODELS

Introduction

River water quality models play an important role in water quality management. Through these models, the cause and effect relationships and the river assimilative capacity can be determined so that the appropriate strategies can be implemented in managing river water quality.

The process of the model development involves data collection and model selection, model assembly, calibration, validation, and uncertainty and sensitivity analysis. Once the river water quality model is developed using the appropriate river water quality modeling software (refer to REVIEW OF RIVER WATER QUALITY MODELING SOFTWARE TOOLS in this encyclopedia) and data, it is necessary to calibrate the model before it can be confidently used as a decision-making tool. Model calibration is necessary when the model parameters cannot be measured physically. One such parameter (which cannot be physically measured) is the decay rate of biochemical oxygen demand (BOD), and there are other such parameters in river water quality models. Model calibration is frequently referred to as parameter estimation (1), because the calibration yields the model parameters.

Here, methods and techniques used in model calibration (specifically in water related applications) are reviewed first. Then the overall methodology used in calibrating the river water quality model developed for the Yarra River, Australia, using genetic algorithms is presented.

Model Calibration Methods

Model calibration techniques can broadly be divided into two categories: manual and automatic, as shown in Fig. 1. The manual method is a trial and error method, where the model output due to different parameter sets is compared with observations visually and the parameter set that best matches the model output with observations is selected as the optimum parameter set (2,3). This method is subjective and time consuming. It can also miss the optimum parameter set. It may even lead to unrealistic parameter sets (4,5).

The automatic calibration method provides some measure of objectivity to parameter estimation and generally is conducted through optimization. Parameter optimization is achieved in the automatic calibration method through an objective function, which minimizes or maximizes a user-defined function. Several objective functions have been used in the past to assess modeled and observed responses in mathematical models in determining the optimum parameter set. The minimization of the sum of the squared difference of modeled output (due to different model parameters) and observations residual sum of squares between the actual and modeled values has been commonly used as the objective function in many hydrological studies (5–9). The use of this objective function is known as the least squares method. There are two variations from the least squares method, and they are the simple least squares method (5) and the weighted least squares method (8,9). The difference between these two methods is that the weighted least squares method requires different weights to be attached to each data point in the objective function, whereas in the simple least squares method, the weights are assumed to be equal. As stated by Sorooshian and Gupta (4), the selection of the objective function can be subjective and can produce different results for different objective functions. For example, the optimum model parameters obtained from a catchment model using two different objective functions—one considering peak flows and the other considering runoff volumes—can produce different results.

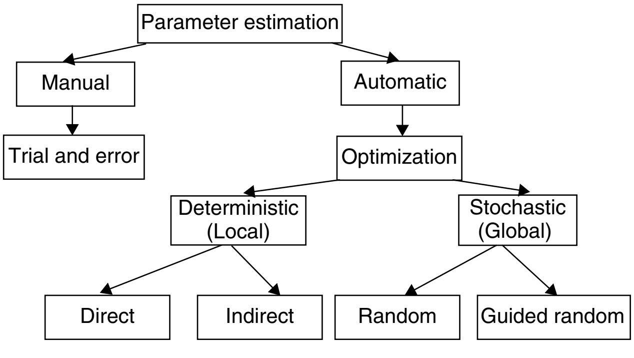

Figure 1. Broad methods in model parameter estimation.

In parameter optimization, an optimization technique is used to determine the optimum parameter set within a prescribed parameter space. As Fig. 1 shows, the optimization techniques can be divided into two broad categories: deterministic and stochastic. The deterministic techniques (also defined as local search methods) determine the optimum parameter set through a systematic search. They are designed to locate the optimum parameter set when the response surface defined by the user-defined function is unimodal (i.e., a single peak/trough). However, if the response surface is multimodal, the parameter set obtained from deterministic methods may not produce the global optimum, since the solution can be trapped at a local optimum point. Starting the optimization with different "seeds" (i.e., starting with different parameter sets for the optimization) may alleviate this problem to a certain extent. Sorooshian and Gupta (4) stated that in calibration of hydrologic models, the optimum parameter set is very rarely found through deterministic methods, since the hydrological problems contain multimodal response surfaces. Duan et al. (10) showed that there were more than hundreds of local optimum solutions in their rainfall and runoff model.

Direct and indirect search methods are two deterministic optimization methods. The direct method seeks the optimum by "hopping" around the search space of a predefined grid, where each grid point defines a parameter set, and assessing the objective function at each of these grid points. Basically, these methods use the objective functions of previous two points to determine the next point to be considered in the optimization. Sorooshian and Gupta (4) listed the most common direct search methods used in hydrologic models: Rosenbrock (11), pattern search (12), and Nelder–Mead downhill simplex methods (13). The indirect method (also known as the gradient search method) seeks the optimum solution by defining the next search point, considering both the objective function value and its gradient. Steepest decent, Hessian matrix, and Newton method are examples of indirect methods (4). These three methods have the common feature that they start from a user-defined starting point, but they differ from each other in the direction of moves and the lengths of moves.

As compared to deterministic methods, the stochastic methods are more efficient in locating the optimum parameter set, when the response surface is multimodal. However, they can also be used when the response surface is unimodal. Stochastic methods are also known as global search methods, since they are designed to produce the global optimum parameter set. They can be subdivided into two main categories, namely, random and guided random. The random search method generates the parameter sets randomly from the parameter range and optimizes the parameter sets. Generally, the random search method generates a parameter set from a uniform distribution of parameters. It does not consider the history of previous solutions in terms of optimality to determine the next parameter set, and hence the method can be inefficient. On the other hand, the guided random search method provides guided information for the next search based on the history of previously considered points (14).

Several guided random search methods exist, such as simulated annealing, adaptive random search, shuffled complex algorithms, and evolutionary algorithms (EAs) (10,14). Of these four methods, EAs have recently been used by many researchers successfully and have attracted wide attention from diverse fields, such as different areas of engineering, computer science, operations research, mathematics, and political science. The growing number of these applications is due to their ease of interfacing, simplicity, and extensibility (15).

Evolutionary Algorithms (EAs)

Evolutionary algorithms (EAs) are stochastic optimization methods that utilize the natural process of evolution (16). It has been demonstrated that EAs are robust search techniques that outperform the traditional optimization methods in many applications, in particular, when the response surface is discontinuous, noisy, nondifferentiable, and multimodal (9,17,18). Bäck and Schwefel (19) stated that EAs have become common and successful techniques in model parameter optimization and have been successfully used in model parameter optimization by Mulligan and Brown (9) and Seibert et al. (20).

There are three main forms of EAs: evolutionary programming (21), evolutionary strategies (22), and genetic algorithms (GAs) (17). Apart from these three forms of EAs, there are two other forms that were originally derived from GAs: classifier system (17) and genetic programming (23). These five forms share the common conceptual principle of EAs. That is, they repeatedly apply sequential evolutionary operators that simulate the evolution of parameter sets from the search space. These evolutionary operators are parameter representation, parameter initialization, selection, crossover, and mutation to yield offsprings (or new parameter sets) for the next generation. Depending on the type of EAs, these evolutionary operators are applied simultaneously or selectively. Of these five forms, GAs have proved to provide robust search in complex parameter search spaces. It is also the only form of EAs that utilizes all above five evolutionary operators (i.e., parameter representation, population initialization, selection, crossover, and mutation) (24).

Genetic Algorithms (GAs)

Genetic algorithms (GAs) are the most prominent and powerful optimization techniques that have been applied successfully recently in many disciplines (25). They are robust search techniques that are based on concepts of natural selection and genetics. For this reason, the terminology used in GAs is borrowed from natural genetics. The reader is referred to Goldberg (17) for details of GAs. The overall GA process as applicable to parameter optimization of river water quality models (or any mathematical model) is described below.

Mathematical models have their own model parameters. According to the genetics terminology, each model parameter is a gene, while a complete set of model parameters is a chromosome. The process of a GA begins with an initial population of a number of model parameter sets, which are chosen at random or are heuristic (requires some prior knowledge of the likely “optimum” parameter set) within a specified parameter range. This is the first generation of a number of generations (generally with a constant population size for all generations) in a GA run. Each model parameter set is then evaluated via an objective function to yield its fitness value.

The second and subsequent populations (or generations) are generated by combining model parameter sets with high fitness values from the previous population (i.e., parent) through selection, crossover, and mutation operations to produce successively fitter model parameter sets (i.e., offspring). The selection GA operator favors those parent parameter sets with high fitness value over those of lower fitness value in producing offspring. The crossover operator exchanges model parameter values from two selected model parameter sets. The mutation operator adds variability to randomly selected model parameter sets by altering some of the values randomly. Several generations are considered in one GA run, until no further improvement (within a certain tolerance) is achieved in the objective function.

The proper selection of GA operators is important for efficient optimization of model parameters. Franchini and Geleati (26) and Ng and Perera (27) investigated the effect of these GA operators on model parameters and found that they were insignificant in achieving the optimum parameter set provided that the widely used GA operators methods and values are used. Wardlaw and Sharif (28), on the other hand, found that different GA operators could produce different optimal solutions.

CALIBRATION OF RIVER WATER QUALITY MODEL USING GENETIC ALGORITHMS

River Model Development

The procedure of calibrating a river water quality model is discussed in this section. The case study discussed is of Yarra River in Australia. No attempt is made to discuss technical results; rather, the overall methodology of calibration using GAs is presented to give readers an overview of the calibration procedure. GAs were selected because they have proved to provide a robust search in complex parameter search space. Interested readers can refer to Ng (29) for complete details of the calibration and the results of the case study.

The QUAL2E (30) river water quality modeling software tool was selected and used to develop the Yarra River Water Quality Model (YRWQM) (refer to REVIEW OF RIVER WATER QUALITY MODELING SOFTWARE TOOLS in this encyclopedia). A precalibration uncertainty/sensitivity analysis was first undertaken to identify the sensitive and insensitive model parameters. This step was necessary because more effort could then be given to calibration of sensitive parameters during the model calibration. Monte Carlo simulation (MCS) was used for precalibration uncertainty/sensitivity analysis, since it has the ability to consider many different input parameter sets sampled from their distributions and to analyze the output response probability distributions. Interested readers can refer to PARAMETER UNCERTAINTY AND SENSITIVITY ANALYSIS IN RIVER WATER QUALITY MODELS (in this encyclopedia) for a review of different methods used for uncertainty/sensitivity analysis of model parameters. The precalibration uncertainty/sensitivity analysis of YRWQM model parameters and results were discussed in detail in Ng and Perera (31).

Linking of YRWQM and GA Software

A public domain GA software, namely, GENESIS (32), was used in calibration of YRWQM. GENESIS was selected for this study, since it has been used successfully for different applications (9,33,34) in the past. However, it was necessary to link YRWQM and GENESIS in order to perform the model calibration, since the calibration requires several simulation runs of YRWQM with model parameters generated from GENESIS. Linking was done through input and output files of YRWQM and GENESIS for each calibration event.

Procedure in River Water Quality Calibration

Several flow events were available for modeling of Yarra River water quality. Each event had information on flow in the river and tributaries, emissions from sewage treatment plants (STPs), and water quality measurements. Three flow events were used in calibration (35), and a further three events were used in validation.

Eleven decay rates, which were responsible for nitrogen, phosphorus, and dissolved oxygen, were considered in this calibration (Table 1). This table also shows the influence and relationships of these decay rates on water quality output responses. To use GAs, an appropriate decay rate range is required. These ranges for BOD_d, NH_3, NO_2, Org-N_d, Org-P_d, BOD_s, Org-N_s, and Org-P_s reaction rates were derived by applying the standard first-order reaction equation (36) using field data (35). The decay rate range for SOD, NH_3 benthos, and Diss-P benthos could not be estimated, because of lack of data. Therefore, the range of decay rates for the three parameters were obtained from Bowie et al. (37), who had compiled results from previous studies.

Four water quality output responses, total kjeldahl nitrogen (TKN), total nitrogen (TN), total phosphorus (TP), and dissolved oxygen (DO), were used in calibration and compared with respective observations at six water quality monitoring stations located along the Yarra River. These four output responses require the estimation of eleven water quality decay rates (Table 1). There is some interaction between these output responses (i.e., TKN affects TN, and both TN and TP affect DO) as shown in Fig. 2.

Table 1. Water Quality Decay Rates Considered in Calibration

Decay Rates	Symbols Used in Text	Influence on Output Responses
Org-N decay	Org-N_d	TKN
Org-N settling	Org-N_s	TKN
NH_3 decay	NH_{3-d}	TKN
NH_3 benthos	NH_3ben	TKN
NO_2 decay	NO_{2-d}	TN
Org-P decay	Org-P_d	TP
Org-P settling	Org-P_s	TP
Diss-P benthos	Diss-Pben	TP
CBOD decay	$CBOD_d$	DO
CBOD settling	$CBOD_s$	DO
SOD (sediment oxygen demand)	SOD	DO

The procedure for estimating decay rates was done in a systematic way as shown in Fig. 2 and also stated by McCutheon (38), Wesolowski (39), and U.S. EPA (40). First, the parameters of the water quality constituents that were not affected by other water quality constituents were estimated. Then, these parameters were kept constant, and the parameters of other water quality constituents were estimated as previously. In this study, the objective function based on simple least squares was used, since no information was available on the weights. The simple least squares objective function is given in Equation 1. This equation considers the minimization of squared difference between observed and modeled water quality concentrations at the water quality stations. This squared difference in Equation 1 is known as the fitness in GA. The lower the value, the fitter is the parameter set.

$$\mathrm{Min} \sum_{i=6} (\mathrm{OBS}_i - \mathrm{MOD}_i)^2 \qquad (1)$$

where OBS_i is the observed water quality concentration at water quality station i, and MOD_i is the modeled water quality concentration at water quality station i.

The first set of parameters considered was Org-N_d, Org-N_s, NH_{3-d}, and NH_3 benthos, which are responsible for TKN. Then, these parameters were kept constant as discussed previously and the second parameter set, NO_{2-d}, was optimized considering the output response of TN. The third set of parameters includes Org-P_d, Org-P_s, and Diss-P benthos and was optimized using the output response of TP. Optimization of decay rates for phosphorus can be done in parallel with TKN and/or TN, since TKN and TN are not influenced by TP and vice versa. The last set of parameters of $CBOD_d$, $CBOD_s$, and SOD was “optimized” using DO, keeping all other parameters at their optimized values.

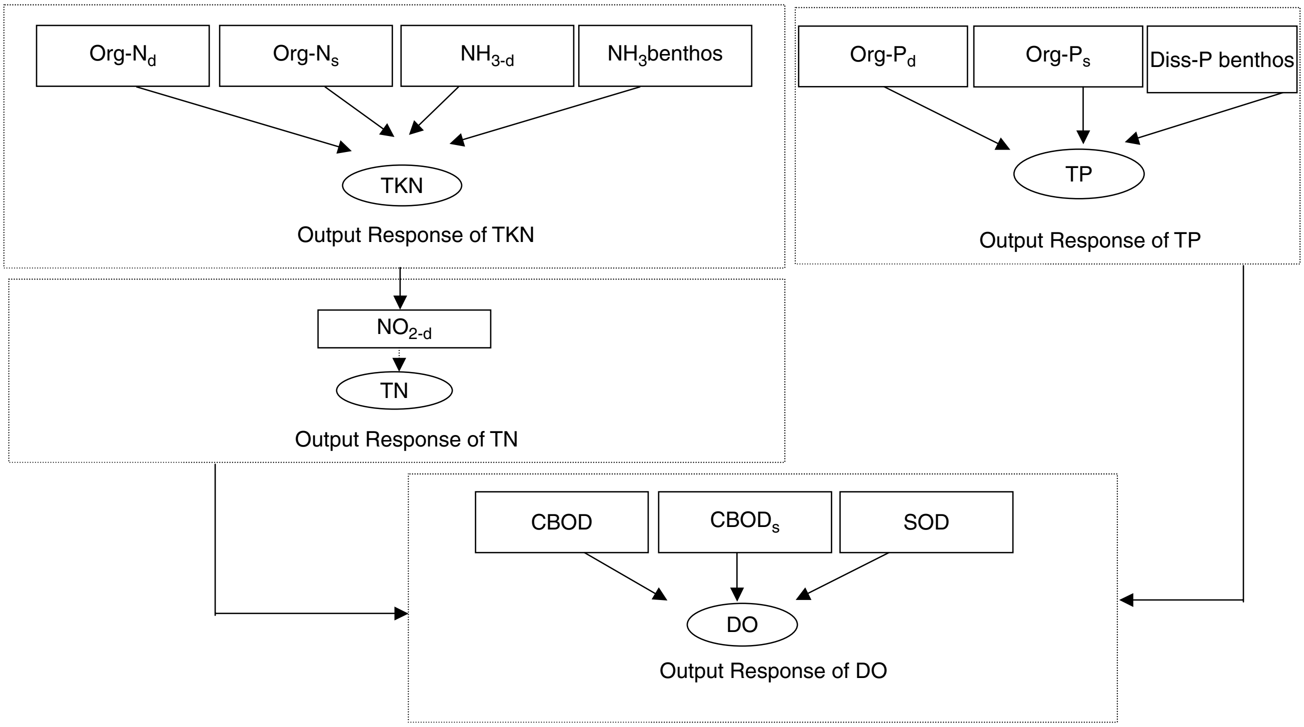

Figure 2. Systematic process used in calibration of YRWQM.

Selection of a Single Optimized Parameter Set

Three flow events used in calibration produced three sets of optimum model parameter sets. Selection of a single optimum parameter set from these sets for use in YRWQM requires subjective judgment. An attempt was made to select the single "optimum" parameter set, which models the observed water quality with reasonable accuracy for all three events. The standard student t-test (41) showed the three optimal decay rate sets (obtained from three events) produced equally good water quality predictions that match the observations at 95% significant level. In other words, the use of the three respective optimal decay sets in YRWQM has produced output water quality prediction that does not show any significant difference between modeled and observed water quality. Therefore, another statistical test, known as cumulative absolute relative error (CARE) cited in Reference 40, was used to quantitatively assess which parameter set had produced the overall lowest error with respect to all three events. The CARE value was determined using the following function:

$$\mathrm{Min} \sum_{i=1}^{3} \sum_{j=1}^{4} \sum_{k=1}^{6} \left(\frac{\mathrm{OBS}_{i,j,k} - \mathrm{MOD}_{i,j,k}}{\mathrm{MOD}_{i,j,k}} \right) \qquad (2)$$

where OBS is observed water quality, MOD is modeled water quality, i is event used in the calibration (three events), j is output water quality constituents of TKN, TN, TP, and DO (four constituents), and k is water quality sampling stations (six stations).

Once the single optimum parameter set was obtained, this set was then used in the validation process. Validation is a process that assesses the predictability of the model once it has been calibrated. This was done using three independent events, which were not used in the calibration. The model validation will enhance the confidence in using YRWQM for analysis for various management schemes in improving water quality. The student t-test results also showed that the observed and modeled water quality concentrations were not significantly different from each other at 95% significance level for all three validation events.

CONCLUSION

Simulation models are used to assess various management scenarios in improving river water quality. In order to use these simulation models confidently, the models must be well calibrated. Model calibration (or often referred to as parameter estimation) yields a set of model parameters that best estimate conditions that match with the observations. The calibrated model can then be used to simulate various management scenarios so that the implementation of water quality policy can be done in the most efficient way.

Model calibration can be done using manual and automatic methods. The manual methods use trial and error approaches, which are time consuming and require subjective judgment in defining the optimum parameter set. They can often miss the optimum parameter set. The automatic calibration methods provide some measure of objectivity in calibrating the mathematical models and obtaining the optimum model parameters. Genetic algorithms (GAs) are widely used stochastic search methods, based on the concepts of natural selection and genetics, which have proved to be successful and efficient in identifying the optimum parameter set in many water-related applications.

Due to the proven success of GAs as a calibration method, this method was used here to demonstrate the overall methodology in calibrating a river water quality model using the case study of the Yarra River in Australia. The methodology, including model development and linkage with GAs, the process of water quality calibration, and validation, was discussed.

SALMONELLA: MONITORING AND DETECTION IN DRINKING WATER

Hemant J. Purohit
Atya Kapley
National Environmental
Engineering Research Institute,
CSIR
Nehru Marg, Nagpur, India

INTRODUCTION

Providing safe drinking water is one of the challenges faced by most countries due to increasing population and industrialization. The Water Quality Guidelines stated that the most simple waterborne disease risk management involves, among other factors, identifying potential sources of contamination (1). The World Health Organization (WHO) report of March 2001 states that more than three million people die annually from waterborne related diseases. Unsafe drinking water and inadequate sanitation are two of the reasons for this problem. The WHO, conducting a workshop on hazard characterization of pathogens in food and water, launched a program of work with the objective of providing expert advice on risk assessment of microbiological hazards. *Salmonella* has been identified as one of the key pathogens for risk analysis.

Salmonellosis and typhoid fever are the main diseases caused by infection of *Salmonella*. Salmonellosis is a major public health problem because of its large and varied animal reservoir, the existence of human and animal carrier states, and the lack of a concerted nationwide program to control *Salmonella*. However, the epidemiology of typhoid fever and other enteric fevers primarily involves person-to-person spread because these organisms lack a significant animal reservoir. Contamination with human feces is the major mode of spread, and the usual vehicle is contaminated water. Typhoid fever is a public health problem of which there are an estimated 33 million cases, resulting in 500,000 deaths each year worldwide (2).

Different culture media and enrichment methods have been proposed for the isolation of *Salmonella* species from environmental samples (3,4). Conventional methods for testing *Salmonella* include the most probable number (MPN) technique (5). Additionally, selective growth media like tetrathionate broth (TB), tetrathionate broth with brilliant-green (TTBG), bismuth sulfide (BS) agar, *Salmonella*-Shigela (SS) agar, and xylose lysine deoxycholate (XLD) agar are used for enumeration of *Salmonella* (3). However, these organisms are sometimes difficult to detect or enumerate from the natural ecosystems (6). This is due to *Salmonella* often entering into the viable and nonculturable state, when exposed to environmental stresses. The routine surveillance of drinking water relies on the growth and biochemical properties of the microorganisms, which is time consuming (3,4). These drawbacks are overcome with the use of molecular tools that can detect even the viable but nonculturable forms with sensitivity and specificity.

Molecular tools involve the use of gene probes, enzyme linked assays, and the polymerase chain reaction (PCR). Use of molecular tools for detection of *Salmonella* has mainly been demonstrated in food samples. There are not many reports that describe detection methods in water samples. Purohit and Kapley (7) have proposed the use of PCR as an option in microbial quality control of drinking water. It is estimated that there are over 40, 000 references to PCR that describe its use in various applications (8). The bottleneck is in getting the PCR as a diagnostic tool from the laboratory to the field, but this needs to be done as a case-specific solution.

METHODOLOGY FOR DETECTION USING MOLECULAR TOOLS

Sampling and Generation of DNA

Methods recommended by the United States Food and Drug Administration require the culture of a sample prior to testing. An aliquot of the overnight grown sample is to be inoculated onto selective media for *Salmonella*. The suspected colonies are identified by a set of biochemical tests and, if required, further confirmed by conventional serology for *Salmonella* detection (9). Use of DNA probes and immunodetection systems also require culturing or pre-enrichment of the test sample for a few hours on selective media prior to testing with antibody or DNA probe. Immunofluorescence methods (10) and enzyme immunosorbent assays (11,12) have been successfully used to enrich *Salmonella* in primary enrichment broths. An electrochemical enzyme-linked immunosorbent assay (ELISA) coupled with flow injection analysis (ELISA-FIA) was used for detecting *Salmonella* in meat after only 5 h of incubation of pre-enrichment broth (13). Meckes and MacDonald (14) demonstrated the use of a commercially available molecular probe system to isolate and enumerate *Salmonella* spp. in sludge in less time than cultural techniques with biochemical confirmation. Nucleic acid sequence-based amplification (NASBA) results demonstrated the detection of *Salmonella* in food samples after 18 h of pre-enrichment at initial inoculum levels of 10^2 and 10^1 CFU per 25 g food sample. The primer and probe set were based on mRNA sequences of the *dnaK* gene of *Salmonella* (15).

Direct detection of *Salmonella* spp. in water samples has also been demonstrated without the use of any pre-enrichment steps using molecular methods (6,16,17). These methods have the advantage of being able to detect *Salmonella* that are in viable but nonculturable form. Bacteria enter into the nonculturable state on prolonged exposure to river or seawater, due to environmental stresses and limiting nutrient conditions (16,18,19). Such bacteria can still work as etiological agents when they come across the suitable host. Knight et al. (6) demonstrated the use of gene probe for detection from 500–1500 mL seawater samples. Kapley et al. (16) have shown the use of multiplex PCR to detect *Salmonella* from river water. In this case 5-liter samples were collected and filtered on-site through a 0.2 μm filter. The filter paper with residue was suspended in phosphate buffered saline and brought to the lab on ice within 2 h for analysis. The filter paper with buffer was thoroughly mixed and the cells were harvested from buffer. The total DNA was extracted using proteinase K treatment. The lysed cell preparation was used directly as template for PCR for detection of *Salmonella*.

PCR Based Monitoring

The polymerase chain reaction (PCR) is an established molecular technique, which reliably identifies a segment of DNA; and it uses a set of specific subsequences to amplify target segment DNA from a mixed template population. There are some loci reported for amplification target *Salmonella* along with other members of the Enterobacteriaceae family to detect the main waterborne pathogens but some are highly specific to *Salmonella*. Way et al. (20) have used multiplex PCR to detect *Salmonella* and other coliform bacteria. *PhoP* primers, specific to the phoP/phoQ loci of coliform pathogenic bacteria such as *Salmonella*, *Shigella*, *Escherichia coli*, and *Citrobacter* species served as presumptive indicators of enteric bacteria. In addition to the *phoP* primers, the *Hin* primers, 5′CTAGTGCAAATTGTGACCGCA 3′ and 5′ CCCCATCGCGCTACTGGTATC 3′, targeting a 236-bp region of hin/H2 and the *H-1i* primers, 5′ AGCCTCGGCTACTGGTCTTC 3′ and 5′ CCGCAGCAAGAGTCACCTCA 3′, amplifying a 173-bp region of the H-1i flagellin gene, were used. Both *Hin* and *H-1i* primers are specific to motile *Salmonella* species and are not present in *Shigella*, *E. coli*, or *Citrobacter* species. Cohen et al. (21) evaluated the suitability of the *fimA* gene amplification by PCR as a specific method for detection of *Salmonella* strains. *Salmonella typhimurium* and other pathogenic members of the Enterobacteriaceae family produce morphologically and antigenically related, thin, aggregative, type 1 fimbriae. Waage et al. (22) demonstrated the detection of low numbers of *Salmonella* in environmental water by a nested polymerase chain reaction assay. The target loci selected were the conserved sequences within a 2.3 kb randomly cloned DNA fragment from the *Salmonella typhimurium* chromosome. The nested PCR assay correctly identified 128 of a total of 129 *Salmonella* strains belonging to subspecies I, II, IIIb, and IV with a sensitivity of the assay was 2 CFU. No PCR products were obtained from any of the 31 non-*Salmonella* strains examined. Riyaz-Ul-Hassan et al. (23) also describe a PCR reaction using *Salmonella* enterotoxin gene (*stn*) as target loci. The protocol describes the detection of less than 10 cells of *Salmonella* in 250 mL of blood and approxmately 1 cell in 1 mL of water without any enrichment.

Duplex or multiplex reactions further improve over the limitation of the locus-specific detection in PCR or gene probes. A duplex PCR described by Kapley and co-workers demonstrates the use of *phoE* primers to detect *Salmonella* in drinking water where *Vibrio* specific primers were also used in the same reaction (24). Multiplex PCR to detect *Salmonella* along with different pathogens in a single reaction has also been demonstrated (17,25). While Kapley and co-workers have demonstrated the use of the gene locus that has been shown to be essential for the invasion of *Salmonella* into epithelial cells of the host's intestine (inv), Kong and co-workers have used the invasion plasmid antigen B (*ipaB*) gene of *Salmonella typhimurium*. The primers for *ipaB*, forward primer 5′ GGACTTTTTAAAAGCGGCGG 3′ and reverse primer 5′ GCCTCTCCCAGAGCCGTCTGG 3′, amplified a 314 bp region. A multiplex PCR that amplifies five different loci in a single reaction has been reported for detection of *Salmonella* from river water samples (16). The gene markers used were *invA*, *SpvA*, *Spv*, and *phoE* for pathogenic *Salmonella, and* 16S rRNA specific primers to assess the total eubacterial load in the water samples. The *inv* locus was chosen as its expression has been shown to be essential for the invasion of *Salmonella* into epithelial cells of the host's intestine; causing the gastrointestinal infections (26). The *invA* gene codes for a protein, which is necessary for virulence of the bacterium. The primers used, upper 5′-CCTGATCGCACTGAATATCGTACTG 3′ and lower 5′GACCATCACCAATGGTCAGCAGG 3′, amplified a 598 bp fragment. The other pathogenic determinants in *Salmonella* are the plasmid coded virulence *Spv* genes; *SpvA*, *SpvB*, and *SpvC* (27). More than 80% of all *Salmonella* isolated from food and clinical specimens contain the virulence factors coded through plasmid (28). The primers reported for *spvA* upper 5′ TGTATGTTGATACTAAATCC 3′ and lower 5′ CTGTCATGCAGTAACCAG 3′, amplify a 470 bp product, while the primers reported for *spvB*, upper 5′ ATGAATATGAAT CAGACCACC 3′, and lower 5′ GGCGTATAGTCG GCGGTTTTC 3′ amplify a 669 bp product (16). The *phoE* gene encodes for a phosphate limitation-inducible outer membrane pore protein and has been shown to be *Salmonella* specific. The primers, upper 5′ AGCGCCGCGGTACGGGCGATAAA 3′ and lower 5′ ATCATCGTCATTAATGCCTAA CGT 3′, from the *phoE* locus have already been tested for 133 different *Salmonella* strains (29). The key to this detection tool has been provided through the thermocycling steps used in the M-PCR. The protocol has used gradient temperature steps, which has provided the selective annealing of primers. The developed multistep program could coamplify the target gene markers, used in the study. The specificity of the program has been proved with the DNA template derived from even the river water samples, which represents the heterogeneous microbial population.

The most widely used selective primer set for detection of *Salmonella* has been reported, which are designed from *invA* locus (30). An extended determination of selectivity by using 364 strains showed that the inclusivity was 99.6% and the exclusivity was 100% for the *invA* primer set (31).

FUTURE OPTIONS IN DETECTION OF *SALMONELLA* IN WATER SAMPLES

With the increasing incidences of spread of waterborne diseases, there is a great need to be able to detect waterborne pathogens like *Salmonella* (31). The key to this problem is to monitor subtle impacts that may have long-term effects that are hazardous. Genomic tools provide an option for analyzing basic resources at the nucleic acid level of an organism or population of microorganisms. Purohit et al. (32) have reviewed the use of genomic tools in monitoring and assessment processes that can help evaluate the environment impact. These tools can be extrapolated for assessing the mixing of raw sewage waters with water resources. A shortened PCR time with quantification and assured selectivity could be achieved by real time PCR. Based on this concept, an advanced nucleic acid analyzer (ANNA) has been reported that can detect bacteria within 7 min (33). This battery-operated device can be used in the field and has software that can be used by first timers. Inclusion of fluorescent dyes to the DNA during amplification has led to fresh advances in detection methods. Use of molecular beacons, oligonucleotide probes that become fluorescent upon hybridization, have been used in real time PCR assay to detect as few as 2 colony forming units (CFU) per reaction of *Salmonella* species. This method uses a 122 bp section of the *himA* as the amplification target. This method could also discriminate between amplicons obtained from similar species such as *E. coli* and *C. freundii*. The assay could be carried out entirely in sealed PCR tubes, enabling fast and direct detection of *Salmonella* in a semiautomated format (34). Detection of 1 colony forming unit/mL in food products was also demonstrated by real time PCR using *SipB* and *SipC* as target loci (35). Beyond the real time PCR, protocols need to be developed that can directly detect the pathogen using a biosensor. Kramer and Lim (36) have demonstrated a rapid and automated fiberoptic biosensor assay for the detection of *Salmonella* in sprout rinse water. Alfalfa seeds contaminated with various concentrations of *Salmonella typhimurium* were sprouted. The spent irrigation water was assayed 67 h after alfalfa seed germination with the RAPTOR (Research International, Monroe, WA), an automated fiberoptic-based detector. *Salmonella typhimurium* was identified in spent irrigation water when seeds were contaminated with 50 CFU/g. Viable *Salmonella typhimurium* cells were also recovered from the waveguides after the assay. This biosensor assay system has the potential to be directly connected to water lines and can assist in process control to identify contaminated water.

LYSIMETER SOIL WATER SAMPLING

Ken'ichirou Kosugi
Kyoto University
Kyoto, Japan

INTRODUCTION

The solute concentration of soil water provides important information regarding spatial and temporal distribution of plant nutrients, salinity, and trace elements (1); biological and chemical reactions in soil; and soil and groundwater contamination by industrial wastes and pesticides. For quantifying convective chemical transport in soil, both the water flux and the solute concentration of flowing water should be measured (2). In such a case, a sampling methodology for soil water needs to provide quantitative information on soil water flow as well as to maintain the physical soil environment of the water-sampling profile in a state similar to that of the natural soil profile, as the soil environment affects biological and chemical reactions.

TENSION-FREE LYSIMETER

One of the traditional techniques for sampling soil water is the tension-free lysimeter, which is also referred to as the zero-tension lysimeter. In this method, a horizontally buried pan intercepts infiltrating water, forming a temporary saturated zone above the pan, and the water drains into a sampling bottle. The tension-free lysimeter collects water only when the soil immediately above the pan has a positive pressure (3). Therefore, the soil in the sampling profile above the lysimeter is wetter than the soil surrounding the lysimeter. With this matric pressure gradient, water will tend to flow from the lysimeter into the surrounding dry-soil region, resulting in an underestimation of the natural water flux (e.g., 4,5).

CAPILLARY LYSIMETER

In the capillary lysimeter, a wick made of glass or nylon fibers is attached to the base of the water-collecting pan (Fig. 1) in order to establish drier conditions above the lysimeter and to lessen the problem of bypass flow around the lysimeter (6,7). Thus, this device is also referred to as the wick lysimeter. In order to make the water-sampling rate the same as the natural water flux, the length, number, and material of the wicks of the capillary lysimeter must be designed to match the local soil hydraulic properties as well as to respond to the range of fluxes to be encountered (8). However, Gee et al. (3) pointed out that capillary lysimeters tend to undersample when the soil water flux is less than 1000 mm/yr, even if the wick length is optimized for a given soil type. In a laboratory test, Kosugi (9) showed that the capillary lysimeter resulted in wetter conditions in the sampling soil profile than in a natural soil profile, given heavy irrigation of 18.6 mm/h. Recently, Gee et al. (3) proposed extending an impermeable pipe, of about the same diameter as the water-collecting pan, from the base of the pan to a height of

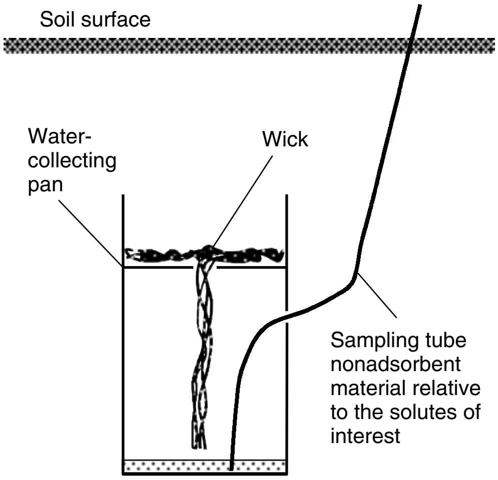

Figure 1. Schematic diagram of the capillary lysimeter.

15 cm or more, in order to control water divergence around the lysimeter. Although they succeeded in reducing the flux divergence to less than 10% for coarse sand by using a 15-cm-long pipe, they concluded that finer-textured soils might require a pipe that was at least 60 cm long. Such a long pipe might disturb the water-sampling profile and might reduce root water uptake by cutting root systems. Detailed descriptions of the capillary lysimeter are found in Selker (10).

TENSION LYSIMETER

A generalized version of the capillary lysimeter is the tension lysimeter, which is one of the most frequently used water-sampling techniques. In this method, water is collected through a porous cup or plate by applying suction with a vacuum source instead of a wick. In most cases, porous cup samplers (also referred to as suction cups) are used because of their ease of installation, simplicity of design, and low cost (Fig. 2). However, owing to their small sphere of measurement, the suction cups provide only "point information," which does not adequately integrate spatial variability (11,12).

With the tension lysimeter method, the suction for water extraction is fixed at an empirically decided value between about 20 and 85 kPa (1,13). As a result, the soil moisture condition in the water-sampling profile can be altered depending on the suction applied. In addition, as the volume of soil that is sampled by the tension lysimeter depends on the soil moisture condition at the time of sampling, the soil hydraulic properties, and the flow properties of the lysimeter (12), the water-sampling rate is not necessarily the same as the natural water flux. Moreover, it is reported that the solute concentrations in the sampled water depend on the duration and degree of the sampler vacuum because water extracted from large pores at low suctions may have a different composition from that extracted from micropores at high suctions (14).

Corwin (1) provides more information on the tension lysimeter with regard to equipment preparation, installation procedure, and problems.

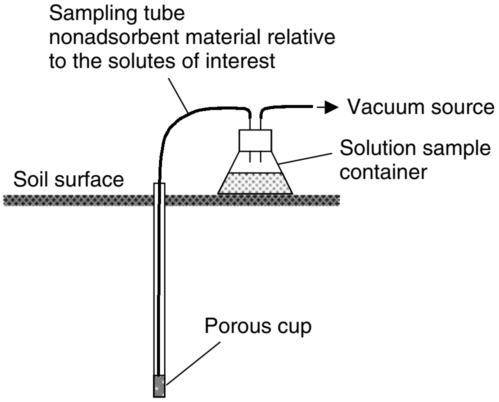

Figure 2. Schematic diagram of the tension lysimeter.

CONTROLLED-TENSION LYSIMETER

In contrast to the above-mentioned techniques, some recent studies have proposed controlling the suction for extracting soil water by referring to matric pressure observations made in the surrounding natural soil profile. The suction control is intended to make the rate of water extraction by the lysimeter the same as the unsaturated water flux in the natural soil profile. Such a "controlled-tension lysimeter" seems to be the most accurate alternative to the methods traditionally used to measure water and convective chemical fluxes in soil.

In the controlled-tension lysimeter, the suction is manually or automatically adjusted to a target value determined from tensiometer observations in the natural soil profile (2,15–17), or the suction control is set so that the soil matric pressure immediately above the porous plate should be similar to the matric pressure at the same depth in the natural soil profile (9,18–20). When the two matric pressures are the same, the rate of water extraction by the lysimeter is expected to be similar to the unsaturated water flux in the natural soil profile, because the water-sampling profile has the same upper (i.e., the flux boundary condition defined by rain and irrigation rate) and lower (i.e., the hydraulic head boundary condition) boundary conditions as the natural profile. Thus, the controlled-tension lysimeter method is soundly in accordance with unsaturated flow theory.

Figure 3 shows a schematic of a type of controlled-tension lysimeter proposed by Kosugi (9) and Kosugi and Katsuyama (20). The equipment consists of two tensiometers (TE) and a ceramic porous plate (PP) connected to a suction system by a sampling tube. The porous plate is buried horizontally in the water-sampling profile. One tensiometer monitors the soil matric pressure immediately above the plate, ψ_a. The other tensiometer monitors the matric pressure, ψ_b, at the same depth in a natural soil profile, adjacent to the sampling profile. In the sampling profile, infiltrating water is extracted through the porous plate by applying suction so that $\psi_a = \psi_b$. The suction system consists of a water collection container (WC) connected to a vacuum pump (PU), a valve for releasing the suction (RV), and a pressure transducer (PT) for monitoring the air pressure, p_c, in the water collection

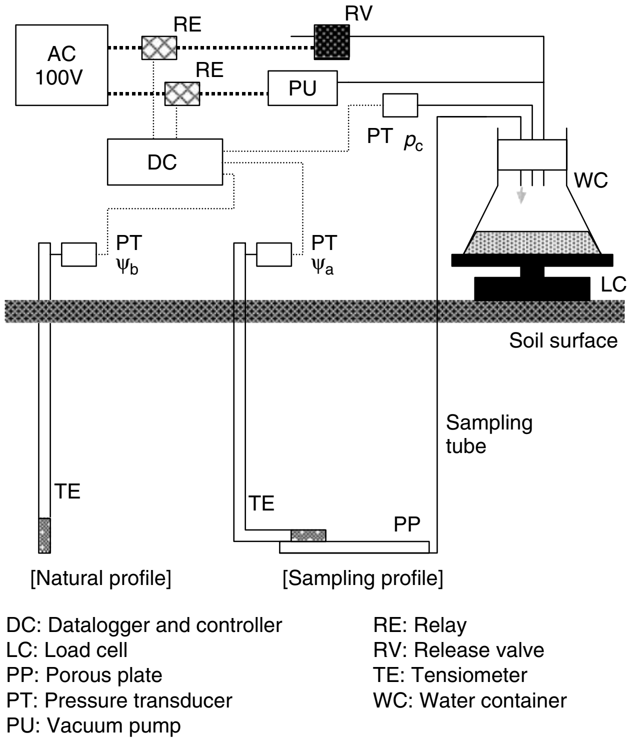

Figure 3. Schematic diagram of the controlled-tension lysimeter (modified from Ref. 9).

container. The values of ψ_a, ψ_b, and p_c are continuously monitored at 3-second intervals. When $\psi_a > \psi_b$ (i.e., the sampling profile is wetter than the natural profile), the vacuum pump is turned on in order to extract the water above the porous plate. When $\psi_a < \psi_b$ (i.e., the sampling profile is dryer than the natural profile), the pump is turned off and the valve is opened in order to immediately stop water extraction by releasing the suction in the water collection container. During a field test for more than 400 d, the lysimeter maintained the soil moisture condition in the sampling profile similar to that in the natural soil profile and extracted a reasonable amount of water (20).

COMMENTS

Problems common to the capillary, tension, and controlled-tension lysimeters include sample biases caused by contaminations and adsorption as the solution passes through wicks and porous cups or plates. Sample contamination can be significantly reduced by pretreatment of the sampler with an acid wash (1 M HCl solution) and repeated rinsing with a salt solution similar to the soil solution that will be sampled (21). Ceramic, Teflon, and stainless steel are commercially available as materials for porous cups and plates. From among these, ceramic is the greatest in trace metal adsorption (22). Various studies have detailed the adsorption of NH_3, P, and K by ceramic cups. Nonetheless, ceramic is most commonly used for porous cups and plates because it has the lowest cost. Although Teflon is the least reactive, it is hydrophobic and has poor flow characteristics. Hence, Teflon is not necessarily a suitable material for porous cups and plates (1).

Another complicating issue is the change in pH that results from CO_2 degassing (23). To reduce CO_2 degassing, it is effective to minimize the gas/liquid ratio in the sample container. Collected samples should be tightly capped with the smallest airspace possible remaining in the sample bottle.

REGULATORY AND SECURITY REQUIREMENTS FOR POTABLE WATER

Suzanne Du Vall Knorr
Ventura County Environmental
Health Division
Ventura, California

INTRODUCTION

Water is essential for the nutrients, metabolic processes, and cellular activity that all living bodies need to survive and thrive. One adult human requires approximately 2.5 liters of potable water from food or liquid sources every day (1). Potable water is water that is fit to drink, free of pathogenic microorganisms or chemicals that are harmful to human health, and free of offensive taste and odors. Drinking water sources include surface waters such as lakes and rivers, and groundwater accessed by wells. Desalination can produce potable water from ocean water, though cost often prohibits widespread use of this method. Public water systems include community, noncommunity, and transient water systems. A water system includes the source water, treatment steps, storage, and the distribution network. Contamination can occur at any point in the water system.

Standard treatment methods typically involve several filtration steps to remove larger particles and objects from the source water and sedimentation to allow smaller particles to settle out. Coagulation and flocculation follow sedimentation to remove unsettleable particles. Disinfection to inactivate pathogens commonly involves chlorine, bromine, or ozone, and fine filtration to remove protozoa. The treated water may also be pH-stabilized. These treatment methods control most pathogens and inorganic contaminants, such as arsenic and lead, and the secondary drinking water standards of taste, odor, color, and balance. The most common types of industrial chemicals, volatile organic compounds (VOCs), such as benzene (a known carcinogen), toluene, and methyl-tertiary-butyl ether, have been routinely found in groundwater. Removing VOCs requires more extensive treatment methods.

Known waterborne disease pathogens can infect healthy adults as well as sensitive populations (young children, pregnant women, elderly adults, and immunocompromised individuals). The Centers for Disease Control (CDC) estimated that over 900,000 incidents of waterborne intestinal disease occur annually, resulting in 900 deaths per year (2). More recently, 39 waterborne disease outbreaks occurred between 1999 and 2000, affecting over 2000 people and resulting in two deaths. Twenty-eight of the 39 were from drinking water that used groundwater sources.

Treatment and protection of drinking water sources will not prevent contamination after delivery (point-of-use). Illness resulting from point-of-use contamination is not considered a waterborne disease incident by the CDC. Household point-of-use treatment methods typically do not remove many organic chemicals (3). Drinking water requirements change as the federal Environmental Protection Agency (EPA) and the CDC further discover the causes of waterborne disease. This article briefly reviews selected contaminants and current regulatory and security requirements that seek to ensure safe and reliable sources of drinking water.

SELECTED BIOLOGICAL CONTAMINANTS

Cryptosporidium

Cryptosporidium parvum oocysts (cysts) are the infective form of a protozoan smaller than *Giardia* that is highly resistant to chlorine disinfection and can cause symptoms of acute watery diarrhea (cryptospiridiosis) from as few as 10 cysts. The surface water treatment rule in effect in 1993 did not require the fine filtration needed to remove *Cryptosporidium* cysts. It is estimated that over 80% of surface water sources are contaminated with *Cryptosporidium* or *Giardia* (4). *Cryptosporidium* can spread in fully chlorinated water, even in the absence of detectable coliforms (5), and medical therapy to treat cryptospiridiosis is limited.

The most notable outbreak of waterborne disease caused by *Cryptosporidium parvum* happened in Milwaukee, Wisconsin, in 1993. This outbreak affected an estimated 403,000 people, resulting in 4400 hospitalizations and 104 deaths (5). It cost city residents an estimated $54 million in medical costs and lost wages (2). Two weeks passed before the waterborne nature of the outbreak was recognized and boil water notices were issued to the public (6). Widespread absenteeism, increased emergency room visits for diarrhea, and a citywide shortage of over-the-counter antidiarrheal medicines led to the detection of the cryptospiridiosis outbreak (5).

Investigation of the outbreak revealed that the public water supply came from Lake Michigan and was treated and chlorinated before distribution. Decreased raw source water quality and decreased coagulation and flocculation effectiveness led to increased turbidity in the treated water. The turbidity standards in effect in 1993 allowed daily turbidity measurements in a month not to exceed 1.0 NTU, though periodic spikes above 1.0 NTU were allowed. The highest turbidity measurement was 1.7 NTU, and the treated water had met all state and federal standards at that time (6). The investigation did not find the original source of contamination, but it was determined that the water quality standards "were not adequate to detect the outbreak" (6). This outbreak led to the Interim Enhanced Surface Water Rule in 1998 and later adoption of a primary regulatory standard requiring 99% cyst removal by filtration. *Cryptosporidium* contaminated water can be disinfected with ozone (4). Point-of-use treatment includes boiling water for 1 minute or filtration with a pore size of 1 micron or smaller (4), which is capable of 99% removal.

Escherichia coli O157:H7

Escherichia coli is a fecal coliform, found in the intestines of both humans and animals, that may contaminate water through contact with sewage discharges, leaking septic systems, or water runoff from animal feedlots. *Escherichia coli* O157:H7 is an enterohemorrhagic strain of one of the four classes of virulent pathogenic *E. coli* that cause gastroenteritis in humans. It produces a potent verotoxin that damages the intestinal lining, often accompanied by severe bloody diarrhea, particularly in sensitive populations. Severe cases of *E. coli* O157:H7 can cause renal failure and loss of kidney function (hemolytic uremic syndrome). Unlike other fecal coliforms, *E. coli* O157:H7 can cause illness from ingesting as few as 10 organisms. One study of a waterborne *E. coli* O157:H7 outbreak involved 243 patients who used an unchlorinated groundwater supply (32 hospitalizations, 4 deaths) in Burdine township, Missouri, between 12/15/89 and 1/20/90 (7). The case study determined that the largest number of cases of bloody diarrhea was in the municipal water supply service area (7). More recently, four waterborne outbreaks of *E. coli* O157:H7 occurred between 1999 and 2000, including one in Albany, New York, in 1999. The suspected source in Albany, New York, was contaminated well water consumed at a fair that caused 127 cases of illness, 71 hospitalizations, including at least 10 children with bloody diarrhea; 14 cases of hemolytic uremic syndrome; and two deaths (8,9).

The detection of coliforms during routine sampling leads to detecting the presence of fecal coliforms, including *E. coli*. Standard treatment methods inactivate or remove *E. coli* O157:H7 or other fecal coliforms. These and other waterborne disease pathogens are included in Table 1.

SELECTED CHEMICAL CONTAMINANTS

Methyl-*tertiary*-butyl Ether

Methyl-*t*-butyl ether (MTBE) was introduced in the 1970s as a substitute for lead in gasoline, to reduce emissions and maintain the oxygen level required by the Clean Air Act. MTBE is water-soluble and moves rapidly through soil into groundwater. It is the second most frequently detected chemical in monitoring wells, according to the U.S. Geological Survey (4). Contamination can come from leaking underground fuel

Table 1. Selected Waterborne Pathogens and Parasites[a]

Pathogens	Disease	Incubation Period	Estimated Infective Dose, # Organisms	Survival in Water, Days
Hepatitis A virus	Type A infectious hepatitis	Up to 50 days	10–50[b]	Up to 140 days in groundwater
Salmonella typhi	Typhoid fever	7–21 days	10,000–100,000	Unknown[c]
E. coli O157:H7	Hemorrhagic colitis; hemolytic uremic syndrome	2–8 days	As few as 10[d]	Up to 20 days in wastewater[e]
E. coli (all others)	Enteropathogenic diarrhea	12–72 hours	10^8	Up to 45 days in groundwater
Vibrio cholerae	Cholera	1–5 days	10^6–10^9	5–16 days in surface water
Shigella spp.	Bacillary dysentery	1–7 days	10–100	35 days in groundwater; 24 months in surface water
Cryptosporidium spp.	Cryptosporidiosis	2–21 days	10–100 cysts	Up to 6 months in a moist environment (ova)
Giardia lamblia	Giardiasis	6–22 days	5–100 cysts	Up to 4 months in surface water (ova)
Leptospira spp.	Leptospirosis, hemorrhagic jaundice	4–19 days	Unknown	3–9 days in surface water
Entamoeba histolytica	Amebic dysentery	2–4 weeks	10–20 cysts	Up to 1 month in surface water (ova)
Ascaris lumbricoides	Ascariasis	2 months	1 cyst, egg or larvae	Up to 7 years in soil

[a] Information compiled from Reference 10, unless otherwise indicated.

[b] Based on contaminated food consumption (11).

[c] 240 days survival in ice (12).

[d] The infective dose is unknown, but the FDA estimates that the dose may be similar to that of *Shigella* spp., based on outbreak data and the organism's ability to transmit person-to-person (13).

[e] Based on information in agricultural research (14).

tanks, leaking gasoline pipelines, and surface spills. It was detected in groundwater in 55% (3180 out of 5738 sites) of underground leaking gasoline tank sites under investigation in 1998 (15).

The oral LD_{50} for MTBE is approximately 4000 mg/kg, and MTBE was tentatively classified as a possible carcinogen (16). MTBE use has been banned in 11 states. In 2000, the California Senate approved an executive order requesting the ban of MTBE and a proposed phase-out by December 31, 2003 (17). This proposed phase-out has not yet occurred. California has set both primary and secondary standards for MTBE. At the federal level, MTBE is an unregulated contaminant, subject to the Unregulated Contaminant Monitoring Rule (UCMR), and is on the EPA drinking water contaminant candidate list (18). The UCMR requires that all large and selected small public water systems monitor for MTBE. MTBE can be removed in varying amounts through granular activated carbon, air stripping, or advanced oxidation.

Perchlorate

Perchlorate is an ion with four chlorine attachments, most commonly used in industrial applications. Ammonium perchlorate is used as an energetics booster in explosives, pyrotechnics, rocket fuel, and highway safety flares (19). It has been detected in groundwater in several states, including the Colorado River which supplies water to millions of people (20), and was found most recently in milk and lettuce (21,22). The concern is that perchlorate interferes with iodide uptake by the thyroid gland, leading to a disruption of thyroid hormones that regulate metabolism and growth; continuous thyroid disruptions could cause a hormone imbalance, particularly in pregnant women, developing fetuses, and infants. Several studies show conflicting results, though two studies indicated adverse health effects in susceptible populations at levels as low as 0.01 μg/kg (20,23). Perchlorate can be removed by treatment with ion exchange, ultraviolet light and peroxide, or peroxide and ozone (24).

A maximum contaminant level (MCL) has not been established by EPA. The Perchlorate Community Right to Know Act of 2003 mandated an enforceable national perchlorate contaminant standard by July 1, 2004; however, the projected research completion date set by the EPA, necessary for setting a standard, extends beyond this deadline (20,25). The EPA set a reference dose (RfD) of 1 ppb (or 2.1 μg/kg for a 70 kg adult) (26) as part of the draft Health Assessment on Perchlorate in 2002, currently under review by the National Academy of Sciences (NAS) (18). NAS estimates that it will complete the review by December 2004 (13). The RfD is an estimate of the daily dose below which health risks would be considered negligible based on lifetime exposure.

The California Department of Health Services (CDHS) was required by law to establish a maximum contaminant level (MCL) for perchlorate by January 1, 2004, although one has not yet been established (27). CDHS set an action level of 6 ppb (28), equivalent to the public health goal (PHG) set by the California Environmental Protection Agency (Cal-EPA) Office of Environmental Health Hazard Assessment (OEHHA). The studies used to establish the PHG were criticized by environmental organizations (20). The action level and the PHG are advisory levels, not regulatory requirements. If an action level is exceeded in groundwater, the water system must notify the local governing body (city council or board of supervisors), and CDHS recommends public notification. If an action level is exceeded by ten times, CDHS recommends discontinuing consumption until treated. Eight other states have set advisory levels for perchlorate, ranging from 1 to 18 ppb (29).

REGULATORY DRINKING WATER STANDARDS

Drinking water must meet the requirements of the Safe Drinking Water Act (SDWA), with monitoring and reporting as specified in the regulation. Individual states may either adopt the federal standard (SDWA) or stricter standards. California adopted stricter standards through the Calderon-Sher Safe Drinking Water Act. Other local drinking water requirements can be found at http://www.epa.gov/safewater/dwinfo.htm. Drinking water sources that include surface waters must be disinfected prior to distribution to the consumer. Current laws and regulations do not require routine treatment of groundwater, unless blended with surface water, although EPA has proposed the Ground Water Rule (GWR) which would require disinfection (8,18). Primary drinking water standards are legally enforceable standards applicable to public drinking water systems, defined as water systems with 15 or more service connections, serving 25 or more people, or operating at least 60 days per year (30). CDHS regulates water systems with five or more service connections. These standards address both biological and chemical contamination and are summarized in Table 2. The maximum contaminant levels (MCL), or specific treatment techniques, such as filtration, used in place of the MCL, as required by the SDWA, are established through evaluation and research to protect public health. Ensuring a safe potable water supply requires vigilance by wholesale and retail water purveyors and water treatment facilities.

SDWA requires testing for coliforms, a group of aerobic or facultative anaerobic bacteria commonly found in soil, vegetation, and the intestinal tracts of warm-blooded animals. The presence of coliforms indicates potential fecal coliform contamination and the probability that other pathogens or parasites are also present. Some fecal coliforms survive in water as long as 10 weeks (32). The maximum contaminant level for coliforms is less than or equal to 5% of the water samples that are positive for coliforms when 40 or more samples are collected per month, or one positive sample when less than 40 samples are collected per month (33). The largest public water systems, serving millions of people, must take at least 480 samples per month (34). Smaller systems must take at least five samples per month, unless the state conducted a sanitary survey during the previous 5 years (34). Under certain circumstances, the smallest systems, those serving less than 1000 people, could take one sample per month, not counting repeat sampling (34). Any samples positive for coliforms must also be tested for fecal coliforms. In California, analytical results must be

Table 2. Current Primary Regulatory Standards for Selected Contaminants[a]

Contaminant	Potential Health Effect	EPA, MCL in mg/L[b]	CDHS, MCL in mg/L[b]
Cryptospiridium spp.	Gastrointestinal illness	99% removal	99% removal
Giardia lamblia	Gastrointestinal illness	99.9% removal	99.9% removal
Total coliforms	Pathogen indicator organism	5.0%[j]	5.0%[j]
Viruses, enteric	Gastrointestinal illness	99.99% removal or inactivation	99.99% removal or inactivation
Arsenic	Circulatory problems, skin damage, increased risk of cancer	0.010	0.05[k]
Asbestos	Intestinal polyps from ingestion	7 MFL	7 MFL
Benzene	Anemia, reduced blood platelets, increased risk of cancer	0.05	0.001
Chromium[e]	Variable	0.1	0.05
Copper[a]	Gastrointestinal illness, liver and kidney damage	1.3	1.3
Free cyanide	Nervous system and thyroid problems	0.2	0.2
Ethylene dibromide (EDB)	Liver, stomach, kidney, and reproductive problems; increased risk of cancer	0.00005	0.00005
Fluoride	Bone disease; dental discoloration and pitting	4.0[f,g]	2.0
Lead[c]	Developmental effects in children	0.015	0.015
Inorganic mercury	Kidney damage	0.002	0.002
MTBE	Tentatively classed as possible carcinogen	None	0.013[g]
Nitrate (as nitrogen)	Blue baby syndrome	10	10
Nitrite(as nitrogen)	Blue baby syndrome	1	1
Polychlorinated biphenyls (PCBs)	Immune, thymus, reproductive and nervous system damage, increased risk of cancer	0.0005	0.0005
Styrene (vinyl benzene)	Liver and kidney damage; circulatory problems	0.1	0.1
Toluene(methyl benzene)	Nervous system; liver and kidney damage	1.0	0.15
Trichloroethylene (TCE)[h]	Liver damage; increased risk of cancer	0. 005	0.005
1,1,1-Trichloroethane (1,1,1-TCH)	Liver, nervous system, and circulatory system problems	0.2	0.2
Trihalomethanes (TTHMs)	Disinfection by-product; liver, kidney, central nervous system effects; increased risk of cancer	0.08[f]	0.10
Uranium	Kidney toxicity, increased risk of cancer from radionuclides	30 μg/L	20 pCi/L
Vinyl chloride	Increased risk of cancer	0.002	0.0005
Xylenes (total)	Nervous system damage	10	1.750[d]

[a] Information from U.S. EPA and California Department of Health Services websites, unless otherwise indicated.

[b] MFL = million fibers greater than 10 μm in length per fluid liter; pCi/L = picocuries per liter; 1 pCi = 37 becquerels (Bq) per cubic meter. Food intake is generally measured in Bq/kg or Bq/L. EPA uses 0.9 pCi/μg as a conversion factor (11).

[c] U.S. EPA has a maximum contaminant level goal (MCLG) of 1.3 mg/L for copper and 0.015 mg/L for lead based on the number of samples taken at point-of-use. Additional monitoring, corrosion control, and treatment are required if the regulatory action level is exceeded in more than 10% of samples. Public education is required if the regulatory action level is exceeded for lead.

[d] As a single isomer or the sum of all isomers.

[e] All chromium levels. Hexavalent chromium causes severe diverse health affects, including cancer. It was the groundwater contaminant affecting public health in Hinkley, California, portrayed in the movie "Erin Brockovich."

[f] EPA standard effective January 1, 2004 for all water systems.

[g] Also has a secondary standard.

[h] TCE was the groundwater contaminant involved in a large leukemia cluster (28 cases in 20 years, four times the national average) in Woburn, Massachusetts, portrayed in the movie, "A Civil Action" (31).

[j] Based on 40 or more samples per month, or one positive sample when less than 40 samples are collected per month.

[k] California must adopt the federal standard, or stricter, by 2006. EPA handles enforcement until the new standard is adopted.

reported electronically by the tenth day of the following month. The water supplier must retain bacteriological analysis records for at least 5 years, and chemical analysis records for at least 10 years. Wholesale and retail water suppliers are required to provide an annual water quality report (AWQR) to their customers. In California, the Consumer Confidence Report (CCR) acts as the AWQR, but must adhere to CDHS regulations, which requires contaminant reporting in easy to read table format (35).

A violation of a primary drinking water standard requires that the water system take corrective action and notify its customers. The notification must include a description of the violation, what it means using appropriate health effects language, when it occurred, what action they should take, and who to contact for more information. Violations are classified by tiers under the Public Notification Rule (36,37). A Tier 1 violation requires public notification within 24 hours by radio, television, hand delivery, or other approved means, and concurrent consultation with the appropriate implementing agency (CDHS or EPA where it directly implements the program). Examples of Tier 1 violations are exceeding the MCL for nitrates or nitrites, failure to test for fecal coliforms or *E. coli*, a repeat fecal coliform positive sample, a waterborne disease outbreak, or other emergency. A Tier 2 violation requires public notification within 30 days. An example of a Tier 2 violation is exceeding the MCL for total coliforms or turbidity. Water system customers must receive notification of a Tier 3 violation within 12 months of the violation. Examples of Tier 3 violations are testing procedure violations or nonfecal coliform monitoring violations. The implementing agency must receive a copy of the public notification within 10 days of initiation for Tier 2 and 3 violations. The water system must send out repeat notifications every 3 months for Tier 2 violations, or every 12 months for Tier 3 violations, for as long as the violation exists. Copies of public notices for Tier 1, 2, and 3 violations must be retained for at least 3 years. The water system must also conduct public notification within 12 months of available monitoring results for unregulated contaminants (36).

The implementing agency has formal and informal enforcement actions available to address a failure on the part of the water system to take corrective action or to notify the public or the implementing agency properly. Formal enforcement includes administrative orders, penalties, and civil and criminal actions. States may also refer a recalcitrant water system to the EPA for further enforcement action.

Secondary drinking water standards are nonenforceable guidelines for secondary contaminants that may cause cosmetic effects, such as tooth discoloration from high fluoride levels, or aesthetic effects such as a disagreeable taste, odor, or color. Secondary contaminants are defined as any contaminant that adversely affects taste, odor, or appearance, or that may cause a substantial number of people to discontinue use, or that may otherwise adversely affect public welfare. Selected secondary drinking water standards are summarized in Table 3. The water purveyor must notify the public when a secondary drinking water standard is exceeded. Treatment is at the option of the purveyor or the customer at point-of-use.

Table 3. Current Secondary Drinking Water Standards for Selected Contaminants[a]

Constituent	U.S. EPA[b]	CDHS[b]
Color	15 color units	15 color units
Chloride	250 mg/L	250 mg/L
Fluoride	2.0 mg/L	None[c]
Iron	0.3 mg/L	0.3 mg/L
Odor	3 threshold odor units	3 threshold odor units
pH	6.5–8.5	6.5–8.5
Turbidity	0.5 NTU	0.5 NTU
Sulfates	250 mg/L[d]	250 mg/L[d]
Total dissolved solids	500 mg/L	500 mg/L
MTBE	None	0.005 mg/L

[a] Information from U.S. EPA and California Department of Health Services websites, unless otherwise indicated.
[b] NTU = nephelometry turbidity units. 0.5 NTU is required for 95% of the daily measurements taken in a monthly period, with no spikes above 1.0 NTU.
[c] Primary standard in California.
[d] 250 mg/L is the lower limit; 500 mg/L is the upper limit.

ENHANCED SECURITY REQUIREMENTS

The danger of a contaminated water supply to large populations became one focus of the Department of Homeland Security as part of a national directive to protect critical infrastructures. An intentionally introduced biological or chemical contaminant may have a limited effect unless introduced in sufficient quantity. However, the 1993 Milwaukee *Cryptosporidium* outbreak demonstrated that sometimes a small quantity is all that is necessary to affect a significant portion of the population adversely.

Two federal laws involving two agencies were passed in 2002: the Homeland Security Act and the Public Health Security and Bioterrorism Preparedness and Response Act (Bioterrorism Act). Both laws pertain to public water systems. The Homeland Security Act requires reporting knowledge of a potential threat to a critical infrastructure, including public water systems, to the Department of Homeland Security. The Bioterrorism Act amended the SDWA to address terrorist and intentional or malevolent acts (threats) against public drinking water supplies. It requires that each public water system serving more than 3300 people conduct a vulnerability assessment (VA), to submit the VA to EPA by deadlines mandated by system size, to prepare an emergency response plan (ERP), and to implement any necessary security enhancements. Interaction between both laws and both agencies must be coordinated within a legal framework.

The purpose of the VA is to evaluate the susceptibility of the water system to potential threats and the risk to the community served by the water system and to plan for reducing risks. The VA must include six basic elements (38):

1. characterization of the water system, its mission, and objectives
2. identification and prioritization of adverse consequences to avoid
3. determination of critical assets that may be subject to a threat and potential undesirable consequences
4. assessment of the probability of different types of threats
5. evaluation of existing countermeasures
6. analysis of current identified risks and development of a prioritized plan to reduce these risks

The first element involves prioritizing the utility services and the facilities necessary to provide those services to the community it serves. Characterizing the water system may include a review of operating procedures and management practices for each element within the water system. The systems' objectives also depend on other utilities, such as power, and the need to evaluate the risk to the system if a threat affects another critical infrastructure.

The next two elements involve a review of each component within the water system in relation to any possible threat, including but not limited to physical barriers, water collection, treatment and pretreatment, storage facilities, distribution (including all piping, conveyances, and valves), automated systems, computer systems, and chemical use and storage areas. Preparing these two elements must consider how a threat could affect each element and the potential consequences, such as service disruption, illness, death, or economic impacts. For example, the introduction of a threat contaminant (TC) could involve concentration changes at every stage in the water system as it mixes with clean water or involve reactions with water or piping. Even a weak solution could adversely affect public health, either as an acute exposure to TC dangerous at low doses, or as a chronic health threat to low TC doses over long exposure periods. Each potential disruption in a system's ability to provide a safe and reliable water supply requires prioritization based on potential magnitude.

The fourth element involves identifying different types of threats the system has experienced in the past or that could occur in the future and the probability of each identified possibility. Specific types of threats such as a fire, vandalism, or cyberattacks, might already have specific countermeasures in place. The fifth element involves evaluating the capabilities and limitations of existing risk reduction methods. Examples of these include intrusion detection systems, delay mechanisms (locks, fencing, vehicle access points), and water quality monitoring alarms. The sixth element requires reviewing the vulnerabilities and countermeasures identified in the first five elements and providing recommendations for improvement.

VAs were to be completed and sent directly to EPA no later than 3/31/03 for water systems serving 100,000 or more people, no later than 12/31/03 for systems serving 50,000 to 99,000 people, and no later than 6/30/04 for water systems serving less than 50,000 people (39). Compliance with this requirement was voluntary for water systems serving less than 3300 people and updates to the VA are also voluntary (39). The EPA will determine system size based on data in the Safe Drinking Water Information System, submitted by each state in 2002 (30).

Some state agencies may require duplicate submission; neither CDHS nor Cal-EPA required a copy of the VA. The EPA plans to review each VA (38).

The next requirement of the Bioterrorism Act was for each water system to prepare an Emergency Response Plan (ERP), incorporating the results of the VA. Emergency response planning is essential for the water system to continue to provide a safe and reliable water supply in the event of an emergency. The ERP must include all procedures and equipment that will significantly reduce the impact of a threat, including basic information such as owner, address, emergency contacts, system components, population served, and number of service connections. The ERP must also identify alternative equipment and water sources, access control, emergency response, and incident specific procedures. Examples of incident specific procedures include policies for handling bomb threats, contamination incidents, or workplace violence.

The ERP is to be maintained securely on site. The water system is required to certify to EPA that the ERP was completed within 6 months of VA submission. The water system has the responsibility for ensuring and upgrading security procedures and equipment.

CONCLUSION

Drinking water laws and regulations were enacted to protect public health. Both the EPA and CDHS also provide information for individuals on private wells so they can protect their water quality. Some waterborne disease outbreaks demonstrate a need to evaluate water quality monitoring methods, and, as in the case of the 1993 Milwaukee cryptospiridiosis outbreak, could lead to a change in regulatory standards. Concerns over the security of critical infrastructures and evaluation of existing systems may also lead to changes that will ultimately enhance protecting public health. As science and technology advances and as more is known about the health affects of waterborne chemical and biological contaminants, drinking water laws and regulations will continue to change. The goal of both the regulatory agencies and the water purveyors should always be to ensure a safe and reliable drinking water supply.

THE WEIGHT OF EVIDENCE APPROACH—DEFINITIONS AND LINES OF EVIDENCE

During recent years, different initiatives have been carried out to use multiple lines of evidence with the aim to assess sediment quality in aquatic ecosystems. One of the most useful and widely used methods was the design and application of integrative assessments to establish sediment quality (1). These methods comprise the synoptic use of different methodologies such as chemical analysis in sediments to establish contamination, in sediment toxicity to address the biological effects under laboratory conditions, chemical residue analyses in organism tissues to determine the bioavailability of the contaminants, and the structure of the benthic community or the histopathological lesions in resident organisms to determine the biological effects under field conditions (1,2). One of these integrative assessments widely used in the studies of sediment quality is the Sediment Quality Triad that was used synoptically for the first time in Spain and in Europe in the early 1990s (3,4). This method also permits using convenient statistical tools to derive sediment quality guidelines (SQGs), which can be used to derive concentrations associated and not associated with the biological effect in the overlapping area of the different lines of evidences (Fig. 1).

Recently, these integrative assessments, and especially the SQT, have suffered some modifications in their interpretation and the representation of their results. In this sense, new methodologies have been incorporated to establish the chronic effects under laboratory conditions, some new parameters were incorporated to avoid the influence of natural casuistry, and especially some new format or representation of the data have been proposed to avoid loss of information, which lacks association with the classic representations (1,6).

The main change suffered by the integrative assessment is the change in the names of these methods and they are more precisely known during recent years as weight of evidence approaches (WOE) and defined as concepts instead of as methods. The WOE approach is defined by Burton et al. (7) as "...a process used in environmental assessment to evaluate multiple lines-of-evidence concerning ecological conditions... and include

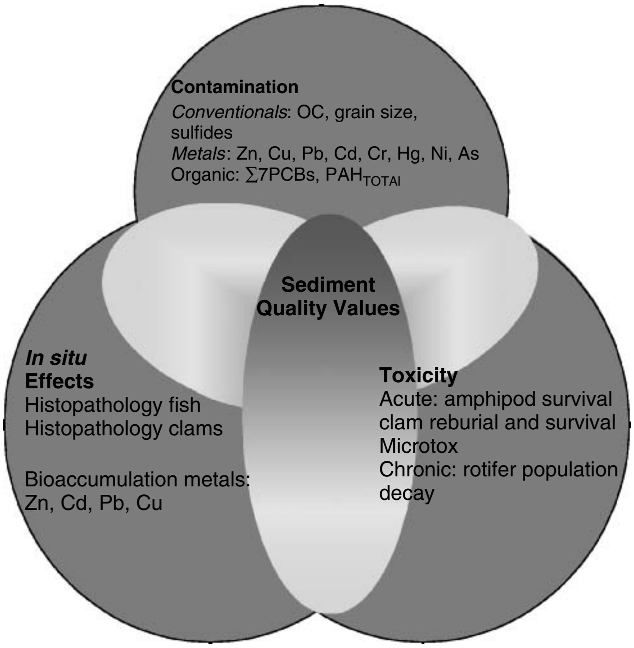

Figure 1. Schematic representation of a widely used weight of evidence approach such as the Sediment Quality Triad (SQT). Adapted from Riba et al. (5).

assessment of impairment, prioritization of site contamination, and decision-making on management actions." This definition goes farther than the classic definition related to the integrative assessment and the Sediment Quality Triad that were considered methods or concepts instead of processes, including the decision-making process.

In this sense, we have reviewed here the evolution of the different lines of evidence that have been growing during recent years associated with the use of this kind of WOE approach in Spain from the classic application of the Triad in 1990s and with emphasis on the potential new application for the decision-making processes in the management of sediment quality, including dredged material characterization. Basically, it describes the application of the different lines of evidence in new environmental problems in Spain that have been and are the marine accidental wastes, the management of dredged material, and the assessment of sediment quality in aquatic ecosystems. It describes the use of a conveniently designed battery of sediment toxicity tests to be incorporated in the tier testing approach for the management of the dredged material in Spain, the use of caged animals to help in the relationship between biological effects measured in laboratory and field conditions, the use of bioaccumulation studies either at field or at laboratory conditions to determine the bioavailability of contaminants, and finally, the use of histopathological methods as part of the weight of evidence approach and its use in combination with bioaccumulation of contaminants in different tissues to derive tissue quality values (TQVs) (5,8,9). Finally, some recommendations of the correct process to integrate these results under a weight of evidence approach using the sediment quality triad is proposed for further sediment quality assessment in Spain.

DESIGN OF ACUTE SEDIMENT TOXICITY TESTS FOR THE CHARACTERIZATION OF DREDGED MATERIAL IN SPAIN

The incorporation of the toxicity test in the management of dredged material disposal is part of a tier testing that is under final development by CEDEX and uses a battery of sediment toxicity tests as a complementary tool to the classic physicochemical analysis using a modification of the sediment quality guidelines (10). This battery of toxicity tests includes the commercial screening test Microtox® in the same samples in which chemical analyses are necessary. If doubts about hazardousness of these samples are found in the other two tests, the bioassay using amphipods and the bioassay using sea urchin larvae are conducted classifying the samples as hazardous if any of the tests show positive responses compared with the biological guidelines proposed.

THE USE OF CHRONIC, BIOACCUMULATION, AND SUBLETHAL BIOASSAYS TO CHARACTERIZE SEDIMENT QUALITY IN DREDGED MATERIAL

One of the recent improvements proposed by different agencies is the possibility to use chronic bioassays having endpoints different from mortality. The main objective is to compare the chronic and acute responses using bioassays to characterize the quality of sediments or dredged material.

The toxicity tests involve the comparison of the three proposed acute sediment toxicity tests versus different chronic bioassays using fish (*Solea senegalensis*) and clams (*Scrobicularia plana*) and using different sublethal endpoints such as the modification of biomarkers of exposure (methallotioneins, EROD, enzymatic activities of the oxidant stress, etc.) and biomarkers of effect (vitellogenin/vitellin; histopathology). Besides, the complete cycle of an amphipod species (*Corophium volutator*) is used to address the sediment quality of this material. Results suggest that the biomarkers are a powerful tool to identify the effect in the gray areas in which acute toxicity tests do not show positive responses. In this sense, the use of histopathological studies has permitted the identification of moderate toxicity associated with PCBs that showed absence of effect using the battery of acute toxicity tests (11).

The complexities at issue are even greater in the case of evaluating concerns for fish and wildlife at a management site. Assessing the potential for impacts of concern on such receptors requires information about the bioaccumulation potential of contaminants from the sediments or dredged material (e.g., results from a bioaccumulation test), how receptors use the management site, and how specific contaminants will move through the local food web. The proposed chronic tests can be used in the same design as bioaccumulation tests and different chemicals could be analyzed in the same tissues in which biomarker, including histopathological, analysis was performed. These studies will permit one to address the mobility of the different contaminants through the food chain and, specifically in some contaminants, to identify the hazardousness associated with the dredged material, such as in the case of PCBs that can suffer biomagnification processes.

The link between the chemical residues and the analysis of biomarker, especially including histopathological diseases in the same tissues by means of bioaccumulation-chronic tests, could permit one to derive tissue quality values (TQVs) in a similar approach to those used to derive sediment quality values or guidelines (SQGs) as reported by Riba et al. (5,9). These TQVs could be used to prevent the risk associated with the contaminants in human food of commercial species and contaminants that cannot be identified by the standardized acute toxicity tests.

USING *in situ* APPROACHES TO CHARACTERIZE DREDGED MATERIAL IN SPAIN—CAGING ANIMALS

Sediment toxicity tests provide information about toxicity or hazard to sediment-dwelling organisms. However, exposure conditions for benthos at a management site may differ significantly from those occurring in the laboratory. Understanding this difference will require information about the management site, including hydrodynamics (is the site dispersive or depositional?), the area extent of coverage once the material is deposited, how organisms at the disposal site interact with the sediment and overlying water, and so on. In this sense, different initiatives have been carried out in Spain to address the biological effects under field conditions funded by the Ministry of Science and Technology (DREDGED REN2002_01699/TECNO; TRIADA; VEM2003_−20563/INTER).

One of the studies designed to address part of the deficiencies associated with laboratory assays is the use of caged animals at the dredged or disposal site to the measurement of different endpoints, either lethal (12,13) or sublethal (8,13). Some designs of benthic chambers are used with this aim; an example is shown in (Fig. 2). The organisms, basically benthic, are confined in the chamber for ideally the same period of exposure as that used in the bioaccumulation-chronic laboratory assays. The tests need the anchorage of either field-collected or laboratory-cultured animals under field conditions exposed to the sediment of concern. The advantages compared with laboratory-exposed devices are that the exposure conditions are representatives of actual conditions at the site. The disadvantages of these field assays are related to the complexities of field-based experimentation, including the difficulties to discriminate the endpoints from noncontaminant variables.

In caged experiments, the same parameters as those registered in the laboratory assays are included in the bioassays under field conditions: biomarkers of exposure and effects, chemical concentration in the biological tissues, mortality, and other sublethal endpoints. Another advantage associated with these studies is the potential complementary use with the laboratory tests that permits one to determine the biological effect under field conditions and, by comparing with the laboratory responses, to discriminate some natural causality that is associated with other kinds of approaches to establish biological effect under field conditions, such as the macrobenthic community studies (10).

Figure 2. Schematic representation of the benthic chambers used to expose caged organisms under field conditions. The animals are transported from the laboratory in cold poliespan boxes to the boat. The chambers (50 cm by 25 cm by 15 cm) were immersed and anchored in each sampling station from every port by scuba divers.

FUTURE DEVELOPMENTS

The complexity of the matrix defined by sediments or dredged material usually located in highly dynamic ecosystems, such as the littoral areas and especially the estuaries, ensures that successfully using any analytical tool requires having an appreciation for the uncertainties associated with its use. No single test or evaluative tool is able to provide a complete and accurate picture of the complexities inherent in evaluating contaminated sediments. In Table 1, some of the sources of uncertainty associated with applying biological tests to manage dredged material are shown.

Notwithstanding the uncertainties included in Table 1, biological tests provide the most direct and certain means for assessing the potential for toxicity and contaminant bioavailability in sediments.

Other contaminants exist that are not usually considered in the studies of sediment quality, such as the presence of pathogens in sediments. Microbial pathogens in aquatic systems can contaminate drinking water supplies and/or shellfish and are responsible for hundreds of beach closure events annually. The proximity of sediments to be dredged to sources of pathogens (e.g., sewage outfalls and agricultural runoff) and the presence of conditions favorable for the long-term viability of microbes makes pathogens in sediments or dredged material a matter of growing concern. Unfortunately, standard microbial methods in use worldwide fail to provide adequate information on which to base management decisions. Some pathogens of concern are not associated with the widely used fecal coliform indicator. In addition, some pathogens cannot be cultured from environmental samples using standard media and conditions. Molecular methods are currently being developed to address the deficiencies in current approaches. The molecular approaches under development are not based on the need to culture the pathogens of concern but on extracting and analyzing their DNA. The use of gene-probe technology has the potential to provide a reliable and highly specific method for detecting a pathogen as well as its virulence potential, that is, its ability to cause disease. When such methods are refined and available for widespread use, more credible assessments of pathogens in sediments will be possible.

Another point of future research is related to the effects of two key environmental variables, such as pH and salinity in aquatic ecosystems. These two variables control most processes occurring in these environments, and they are especially of interest in the border of aquatic systems, such as those defined by estuaries between marine and freshwater environments. In this kind of ecosystem, these variables, and especially salinity, can play a significant role not only in the partitioning of the contaminants but in the bioavailability and thus in the toxic effects associated with the chemicals. Recently, Riba et al. (14,15) reported the high influence of these variables in the bioavailability of metals from a mining spill that occurred in Spain in April 1998 that affected the Guadalquivir estuary. Their results showed that the same sample tested at different salinity or pH values using a truly estuarine species (*Ruditapes phillipinarum*) showed significantly higher

Table 1. Summarized List of Most Common Uncertainties Associated with Biological Testing of Dredged Material. The Uncertainty Description and the Palliative Action to Minimize the Effects on the Final Results Are Included

Topic	Uncertainty	Palliative-Minimizing
Handling and sampling	How the sample is taken and handled prior to testing, and the conditions the sample is subjected to during testing, can affect the accuracy and precision of test results	Careful and standardized procedures conducted during sediment assessments are necessary to minimize the source of uncertainty in sediment assessment
Extrapolation and number of species in the battery	The battery of tests will be composed of a relatively small number of taxa in comparison with the number residing at the site of concern	Testing with multiple species that are closely associated with the sediment and have a demonstrated sensitivity to the contaminants of concern
Dynamism of the ecosystem	Provide only a snapshot of the processes affecting contaminant exposure and effects in sediments	Development of more significant tests including chronic tests (at least one cycle of life of the organism)
Space scale is limited	The laboratory tests are conducted under controlled conditions of space and may overestimate the extent of exposure and effects given that the movement of the organism are restricted to the material being tested, and water movement (i.e., flow) is minimal	Conduct bioassays under field conditions increasing the space scale in which they are performed to avoid the lack in the extent of exposure and effects associated with the mobility of the organisms
Extrapolation to ecological scales	Biological tests most commonly measure effects on individual organisms, whereas the ecological impacts of concern occur at the level of populations and communities	Selection of the appropriate battery of ecologically relevant organisms
Experimental variables	Test organisms will respond positively and negatively to different experimental variables that are unrelated to the degree of contamination present in a sediment (grain size, food frequency, etc.)	Developing a thorough experimental understanding of the biology and ecology of the test organisms used in biological tests
Results analysis (statistical)	Over or underestimate of the hypothesis used in the different tests	Ensuring that adequate replication is prescribed to detect a desired magnitude of effect

toxicity at salinity values of 10 or lower or at pH values of 6 or lower compared with the toxicity tested at higher salinity or pH values. They relate the effect based on the higher mobility of some metals from sediments to water and also in the speciation of them that changed when the pH and salinity values changed. It informs one of the necessity to incorporate this kind of environmental effect in the final design of the weight of evidence approach, taking into account the potential influence of the pH and salinity values, especially under estuarine conditions.

Finally, we recommend to integrative assessment or the more recently cited weight of evidence approaches to avoid or at least minimize most of the deficiencies and uncertainties associated with laboratory and field bioassays. Furthermore, specifically applied WOEs for sediments or dredged material quality assessment is the use of the sediment quality triad incorporating some modifications and improvements to assess the sediment quality in both the disposal and the dredged site. One premise of the method is the design of a tier testing approach based on the definition of the Triad (Fig. 3). In this sense, the incorporation of new chemicals of concern specifically detected in the area to be dredged should be taken into account in the first tiers together with some biological tests for screening of the biological effects. The next steps will lead one to conduct laboratory sediment toxicity and bioaccumulation (if contaminants of concern are present) tests. In this sense, design specific and low-cost chronic tests, including sublethal endpoints such as histopathology, to avoid false negatives of toxicity such as those associated with specific contaminants. In the last tiers, the use of *in situ* surveys or those assays under field conditions using caged animals to establish the overall pollution status of the sediment to be dredged are included. The integration of these measurements will permit one to address the environmental quality of the systems and, furthermore, to establish the correct decision-making when selecting the beneficial use and/or the disposal options of the dredged material.

These recommended methods are not unique and a more extensive list of potential lines of evidence (7) that can be incorporated into the final tier testing using the weight of evidence approaches, such as the Triad, are included in Table 2. Each of these lines of evidence (LOEs) has their own advantages and limitations, but what is clear is that only one LOE will not be sufficient to address the sediment quality to determine the different management options for dredged material, and the use of several of these LOEs under the final design of a tier testing is recommended using a weight of evidence approach, such as that shown in Fig. 3.

Acknowledgments

This work has been partially funded by grants funded by the Spanish Ministry of Development (BOE 13-12-02) and of Education and Science (REN2002_01699/TECNO and VEM2003_−20563/INTER). The design of the acute toxicity tests for dredged material characterization was conducted under joint contract between CEDEX and the University of Cádiz (2001 and 2003).

Table 2. Description of Different Lines of Evidence, Including Their Advantages and Limitations When Used to Assess Sediment Quality and Dredged Material Characterization (7)

Line of Evidence	Advantage	Limitation
Sediment chemistry	Relatively simple and standardized. Widely used and utility proved. Cause information	Lack in the effect of information. Assumed feasibility to measure all existing chemicals
Toxicity tests (laboratory)	Relatively simple and standardized. Utility proved and widely used. Effect information	Lack in the determination of cause. Difficulty in field extrapolation. Natural stressors not assessed
Tissue chemistry	Determination of bioavailability and measure of exposure. If biomagnifications proved: useful in food chain models (human risk)	Lack in the effect measurements. Difficult to eliminate influence from essential and nonessential chemicals, food chain measurements, acclimation/adaptation
In situ alteration (field studies)	Measurements under real environment conditions	No cause is identified. No standard method. Difficult to discriminate natural effects
Biomarkers of exposure (EROD, methallotioneins, etc.)	Indicators of exposure under either field or laboratory conditions, including natural variables	No clear identification of cause, although relative information. Relative relationship to effects. Influenced by natural variables
Biomarkers of effects (histology, etc.)	Indicators of effects under either field or laboratory conditions, including natural variables	Lack in the cause identification. Nonspecific to contaminants and affected by natural variables
Benthic community structure	Standard methods, *in situ* conditions. Long-term measure of effects, including natural variables	Highly affected by natural variables. Not predictive. Confounding factors different from stressors. Absence of organisms in highly disturbed (natural or not) areas
Laboratory TIE	Partitioning of chemicals under laboratory conditions	Not widely proved. Insensitive. Not available for all chemicals
Field TIE	Partitioning of chemicals under field conditions	Highly complex design on the device used. Problems with interpretation of the results. Not possible for all the chemicals. Not standardized
Bethic fluxes of nutrients and/or contaminants	Functional capability of the ecosystems	High complexity in the devised use. No standard methods. Not widely used for sediment quality but for biogeochemical cycles
Caging animals	Toxicity and chemical residues under field conditions. Direct exposure to sediments	Difficult to clearly extrapolate to real conditions. Complex to devise and casualty inherent
Tissue quality values (TQVs)	Relationship between sublethal and chemical residues in organisms tissues	Not standardized. Relatively new. Large and temporal data base. Not easily available for all chemicals

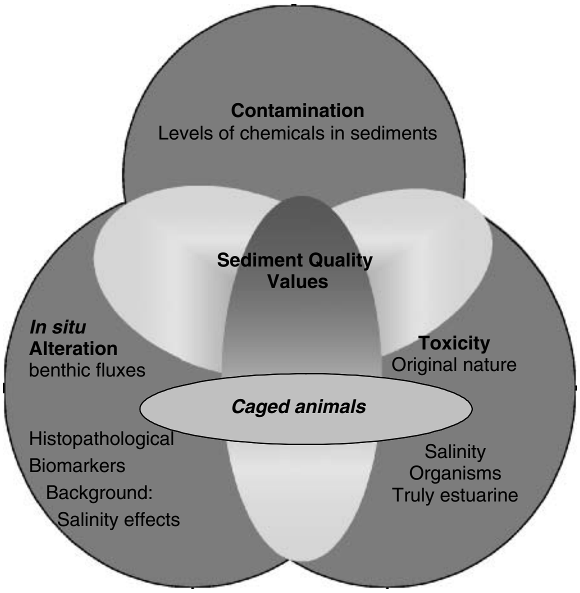

Figure 3. Synoptic representation of the weight of evidence approach recommended in the design of a convenient tier testing method either to assess sediment quality in littoral ecosystems or to manage dredged material. Each circle represents different areas including different lines of evidence (Table 2) to be integrated in the overall integrated approach. The overlapping area permits derivation of sediment quality values and tissue quality values for those overlapping areas, including histopathological and bioaccumulation studies under either field or laboratory conditions.

GENERAL AND HISTORICAL BACKGROUND

The trace element selenium (atomic symbol Se) occurs naturally in soils, water, and biota, including food. It is nutritionally required due to various Se-bearing proteins that incorporate selenocysteine, now recognized as the 21st essential amino acid. In addition to being a required nutrient, Se in excess is toxic to biota (1). The first recorded cases of Se toxicity were penned by Marco Polo during his travels in western China, based on symptoms he observed in livestock (2). In the 1930s, the element Se was attributed to these symptoms, by then known variously as "alkali disease" and "blind staggers," which afflicted livestock in the western United States (3). However, in certain cases, such symptoms could have been due to other factors (4).

For Se, the margin between nutritional requirement and toxicity is unusually narrow and depends on the individual species and circumstance (3). This fact creates a quandary when setting environmentally protective Se criteria. Health benefits of consuming vegetables high in Se are widely touted (5), as cases of human toxicity and crop damage from Se are rare (6). Livestock face both deficiency and toxicity (7), while toxicity is the primary concern with fish, birds, and in particular various aquatic-associated wildlife (8). The latter issue roared to the news headlines as the aquatic bird disaster at California's Kesterson Reservoir surfaced in the early 1980s (9)—a harbinger of widespread Se problems such as fish mortality and deformities in Belews Lake (10) and numerous other cases internationally (8).

A closer look at the affected biota and circumstances surrounding Se toxicity reveals *water* as the transmitting medium of highest concern (8). Natural water processes (precipitation) and human activities relocate the naturally occurring Se in soils, rocks, and groundwater into collected water bodies that harbor and attract wildlife (8), which might also be used for growing forage and watering livestock (6). Human mobilization of Se mainly consists of irrigation, mine drainage, and surface discharge of groundwater; the latter includes petroleum processing, agriculture, and urban uses. We focus here on the factors important in Se-contaminated water; for the reader interested in the physiology and biochemistry of Se wildlife toxicity, there is an excellent recent review on this complex topic by Spallholz and Hoffman (11).

UNDERSTANDING THE PROBLEM: FUNDAMENTALS OF SELENIUM BIOGEOCHEMISTRY

In order to solve a problem, it is essential to first understand the nature of the problem. In the case of Se toxicosis of wildlife, exposure to Se primarily occurs through the diet, not by direct exposure to water (12). Therefore, it is vital to understand the "biogeochemistry" of Se: how it moves from contaminated water and sediment to work its way up the foodweb. Figure 1 illustrates the various paths comprising the biogeochemistry of Se. This figure illustrates the first four fundamental facts about wildlife exposure to Se:

1. The paths of Se are numerous and interrelated.
2. Most of the paths eventually lead up the foodweb.
3. Se changes chemical form from an inorganic salt to various organic forms.
4. Some of the organic forms lead to volatilization, a natural path for Se to leave an aquatic system altogether.

A fifth important fact, not evident in Fig. 1, is that Se "bioaccumulates" as it heads up the foodweb, generally becoming more concentrated in tissues. This concept may be familiar to many readers, as this phenomenon is discussed widely in the general press and health advisories regarding foodweb bioaccumulation of mercury, pesticides, polychlorinated biphenyls (PCBs), and many other contaminants. Table 1 (13) is an example from the scientific literature that documents this process for Se. Note the very large variation in bioaccumulation factors (BCFs), illustrating the effects of site-specific biogeochemistry in different aquatic systems. A comprehensive study illustrating the complex pathways of bioaccumulation has recently been published (14).

SETTING THE REMEDIATION TARGET: THE AQUATIC LIFE CRITERION

For remediation to occur, there must first be measurable targets to achieve. The complexity of Se biogeochemistry makes setting such a target extremely difficult to accomplish or even define. An earlier United States Environmental Protection Agency (U.S. EPA) Water Quality Criterion for Se, which set a maximum of 5 μg/L total Se, provided a clear target (15).

We focus here on the factors important in Se-contaminated water; for the reader interested in the physiology and biochemistry of Se wildlife toxicity, there is an excellent recent review on this complex topic by Spallholz and Hoffman (11).

UNDERSTANDING THE PROBLEM: FUNDAMENTALS OF SELENIUM BIOGEOCHEMISTRY

In order to solve a problem, it is essential to first understand the nature of the problem. In the case of Se toxicosis of wildlife, exposure to Se primarily occurs through the diet, not by direct exposure to water (12). Therefore, it is vital to understand the “biogeochemistry” of Se: how it moves from contaminated water and sediment to work its way up the foodweb. Figure 1 illustrates the various paths comprising the biogeochemistry of Se. This figure illustrates the first four fundamental facts about wildlife exposure to Se:

1. The paths of Se are numerous and interrelated.
2. Most of the paths eventually lead up the foodweb.
3. Se changes chemical form from an inorganic salt to various organic forms.
4. Some of the organic forms lead to volatilization, a natural path for Se to leave an aquatic system altogether.

A fifth important fact, not evident in Fig. 1, is that Se “bioaccumulates” as it heads up the foodweb, generally becoming more concentrated in tissues. This concept may be familiar to many readers, as this phenomenon is discussed widely in the general press and health advisories regarding foodweb bioaccumulation of mercury, pesticides, polychlorinated biphenyls (PCBs), and many other contaminants. Table 1 (13) is an example from the scientific literature that documents this process for Se. Note the very large variation in bioaccumulation factors (BCFs), illustrating the effects of site-specific biogeochemistry in different aquatic systems. A comprehensive study illustrating the complex pathways of bioaccumulation has recently been published (14).

SETTING THE REMEDIATION TARGET: THE AQUATIC LIFE CRITERION

For remediation to occur, there must first be measurable targets to achieve. The complexity of Se biogeochemistry makes setting such a target extremely difficult to accomplish or even define. An earlier United States Environmental Protection Agency (U.S. EPA) Water Quality Criterion for Se, which set a maximum of 5 μg/L total Se, provided a clear target (15).

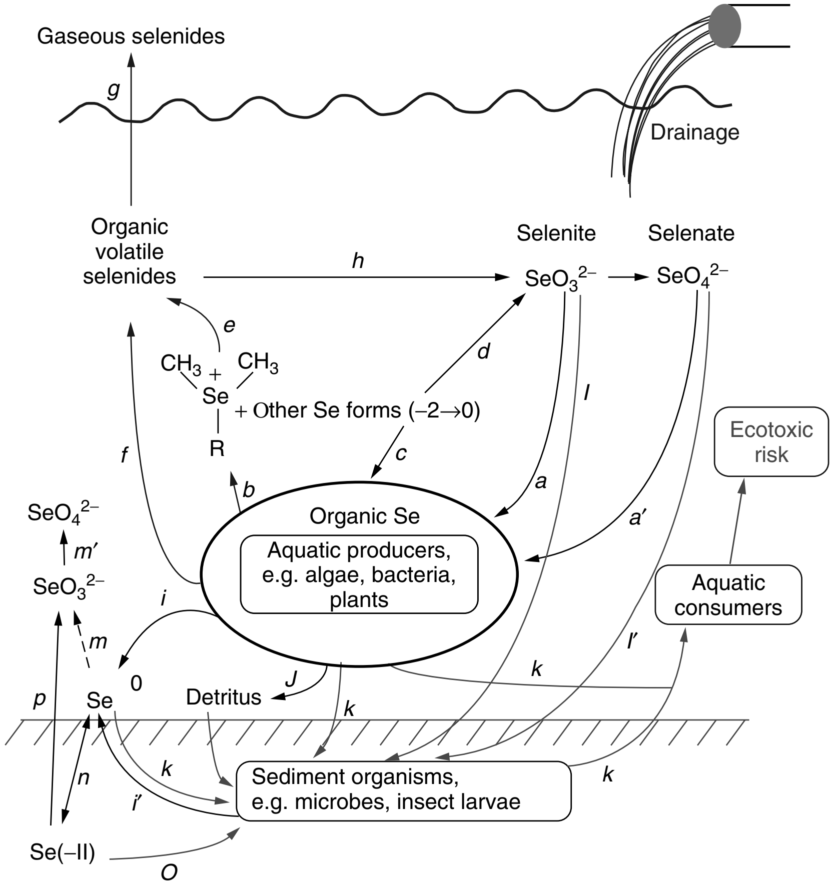

Figure 1. Biogeochemical cycling of Se in aquatic ecosystem. This scheme is modified from Reference 13. Arrows indicate processes that can lead to risk from foodweb accumulation of Se ("ecotoxic" risk). Other arrows trace the Se volatilization process by which Se can be lost from the aquatic system.
a, Uptake and transformation of Se oxyanions by aquatic primary and secondary producers; much of the biotransformation pathway is yet to be defined.
b, Release of selenonium and other organic Se metabolites by aquatic producers.
c, Uptake of organic Se compounds by aquatic producers.
d, Abiotic oxidation of organic Se compounds to Se oxyanions.
e, Release of alkylselenides from selenonium or other alkylated Se precursors through abiotic reaction.
f, Release of alkylselenides from selenonium or other alkylated Se precursors through aquatic producers.
g, Volatilization of alkyselenides into the atmosphere.
h, Oxidation of alkylselenides to Se oxyanions.
i, Formation of red amorphous Se element by aquatic and sediment producers.
j, Detrital formation from aquatic producers.
k, Se bioaccumulation into the foodchain with potential ecotoxic consequences; the toxic form(s) are yet to be defined.
l, Assimilation of waterborne selenium oxyanions into sediment biota.
m, Oxidation of sediment Se(0) to oxyanions.
n, Reduction of sediment Se(0) to Se(−II) or vice versa.
o, Assimilation of sediment Se(−II) into sediment biota.
p, Oxidation of sediment Se(−II) to selenite.

The setting of this temporary value spawned numerous attempts to apply the three traditional strategies of remediation, which are containment, removal, and treatment (16).

However, such a criterion for remediation remains very much a "moving target" due to the complexity of the biogeochemistry. In particular, there are currently attempts to develop a more scientifically sound U.S. EPA Aquatic Life Criterion for Se (17), for which there is now a draft (18). What follows is a very abbreviated description of the issues surrounding the setting of an Aquatic Life Criterion. For a more complete understanding, the reader should refer to the cited literature.

Several independent studies submitted to the U.S. EPA estimated that the 5-μg/L Se toxicity threshold was either too high or too low; interestingly, arguments for higher or lower thresholds appear to be closely associated with whether researchers were affiliated with the corporate-service (arguing that 5 μg/L is too low) or public-service (arguing that 5 μg/L is too high) scientific communities. A slightly different formulation of this observation has also been presented elsewhere (19). Additionally, the proposed California Toxics Rule of 5 μg/L Se in water (20) was judged by the U.S. Fish and Wildlife Service to be too high (21), jeopardizing 15 species protected by the Endangered Species Act (22), the majority of which were aquatic-dependent wildlife that do not actually live *in* the water. The lesson here is that, because of the biogeochemistry of Se, it is important to include consideration of the entire aquatic-based foodweb, not just aquatic organisms.

Recently, the U.S. EPA contracted the Great Lakes Environmental Center to derive chronic Se criteria on a fish-tissue basis, rather than the traditional water concentration basis. The results of this analysis were considered to have limited applicability because it produced a threshold (7.9 μg Se/g tissue) based on an LC_{20} (lethal concentration at which 20% mortality is expected), which is not adequately protective of the species of concern (22). Several other flaws were found in the study, which essentially compiled experimental data from 17 published studies (18). One of these (23) is qualitatively distinct because it incorporated a "winter-stress" design accounting for the increase in toxicity of dietary Se to birds, fish, and mammals under low temperatures. Adjustment of these data for the

Table 1. Excerpted Data from Reference 13 Illustrating Bioaccumulation of Se and the Great Variance in the Bioconcentration Factors of Se

	Salinity, ppth	Waterborne Se, μg/L	Body Burden, μg/g	BCF
Algae	76	13.5	11.8	873
Algae	14	7.9	14.8	1877
Algae	41	7.0	16.0	2281
Algae	136	13.1	9.7	745

Average	67.5	46.0	14.1	2665
S.D.	35.8	138.3	9.4	4389

chronic-level protection needed (<5% mortality) would result in a limit of less than 5.8 μg/g on a whole-body fish-tissue basis.

Situations under which fish tissues would be contaminated to that level, however, may still be unacceptable to birds eating lower on the trophic level (e.g., invertebrate eaters) (24). Bioconcentration factors relating the transfer of Se from aquatic invertebrates to whole-body tissue of invertebrate-eating fish have been documented in the field to vary from 0.67 to 1.36, when whole-body fish tissue contains 5–10 μg/g Se. Applying those bioconcentration factors to the recently proposed fish-tissue criterion for Se of 7.9 μg/g (18) suggests that the corresponding Se content of aquatic invertebrates would range from 5.8 to 11.8 μg/g, which would result in an EC_{20}–EC_{85} range (effects concentrations, a range for which 20–85% of a population would show toxic effects) in mallard ducks (and other birds) (23) that also utilize the invertebrates as food (24).

STRATEGIES FOR REMEDIATION

From the preceding section, it is evident that there is no universally accepted water or tissue threshold concentrations for the protection of wildlife, and the issues are likely to remain unsettled for some time. Therefore, there is no fixed “target concentration” for remediation to achieve. This section on remediation strategies is written with this situation in mind.

Most of the past remediation attempts are mentioned only briefly here, as they were based on the obsolete 5-μg/L water criterion and do not incorporate the vital concepts of Se biogeochemistry. The following description attempts to discuss Se remediation efforts on the basis of the three strategies of remediation, which are containment, removal, and treatment (16). However, as the reader will see for Se, sometimes none of these three textbook categories are appropriate.

Containment

The first strategy of remediation, containment, remains difficult to achieve in many cases, as much Se contamination occurs in open lentic systems such as reservoirs, in lotic systems such as streams and rivers, and in receiving waters such as deltas and estuaries. To this end, the U.S. EPA has embarked on regulation based on the total maximum daily load (TMDL) for lotic and receiving waters, under Section 303(d) of the Clean Water Act (25). More recently, the best waterfowl protective estimates (based on empirical data from multiple environments) argue for reduction of the old 5-μg/L limits (8), forcing TMDL limits downward. This is an illustration of the “moving target” frustrating remediation efforts. Clearly, any remediation strategy must be compatible with changing regulations, but despite this clarion call, no traditional remediation strategies have met the challenge. For further description of TMDLs in general, the reader is referred to Reference 25.

The TMDL for Se basically collapses the complexity of Se biogeochemistry into a single box and a single total Se value, which may be protective of a given receiving water. However, this approach does not engender remediation solutions, since it does not account for Se biogeochemistry, provides little guidance for lotic system remediation, and provides no guidance at all for remediation of lentic systems.

In the United States, the lotic Se containment strategy is already implemented under TMDL regulations in California and elsewhere (25). For example, selected agricultural drainage from California's San Joaquin Valley is metered into the San Joaquin River, the allowed volume of which is based on quick turnaround time of Se analysis of the discharged water. For descriptions and issues surrounding the implementation of Se TMDL, the reader is referred further to Reference 25.

Simple containment of lotic Se into terminal water evaporation basins can avoid restrictive TMDL regulations since there is no discharge of water into lotic systems, and this strategy therefore has been suggested as worthy of further investigation (26). However, those authors also recognized that this simply obligates the discharger to use another remediation strategy, since the real problem is foodweb accumulation from either lotic or lentic systems. Therefore, while such total containment might "remediate" the downstream lotic systems, there is still a need to remediate the contaminated lentic system that has been created in the process.

Removal

The strategy of removal of Se is highly vulnerable to changing threshold regulations, as discussed earlier. Moreover, simple removal of Se is not necessarily "remediation" because the focus is put on waterborne concentrations of Se. In spite of this, several removal strategies have been tested in the past and tests of several more are currently underway. For the few that are in the peer-reviewed published literature, the reader is referred to a recent compilation (27). Removal of Se has been categorically difficult because of its typically low starting concentrations in the parts-per-billion range, its chemical similarity to sulfur (which can be present at more than a millionfold higher concentrations), the very high volumes of water for agricultural drainage, and especially because of the ever-lowering threshold target, as discussed previously.

Treatment

The third textbook strategy, treatment of Se, has much overlap with removal approaches, and again the focus here has been on reducing waterborne concentrations of Se, which does not equate to remediation (28).

An instructive example of a combined removal–treatment strategy is the algal–bacterial process (29) using the dissimilatory reduction capability of bacteria to reduce selenate into elemental Se, which has been developed to the point of large-scale trials. Although it can remove approximately 80% of the total Se from agricultural drainage water, the microbial and algal action on Se increased the levels of the more bioavailable selenite and organic Se, resulting in 2–4 times greater Se concentrations in the test invertebrates (30).

The lesson here is that waterborne Se is an inappropriate focus for remediation, one of the key reasons for drafting a new U.S. EPA Aquatic Life Criterion for Se based on tissue concentrations (18). The algal–bacterial process is also an example of how TMDL regulations, while written to be protective of wildlife in receiving waters, can inadvertently misguide major remediation efforts because it is based on waterborne Se.

Management for Mitigation

For Se remediation, there is a fourth strategy, that of management. This strategy is embodied by, for example, a California Waste Discharge Requirement under the Porter-Cologne Water Quality Act, which specified "a program of management actions to reduce, avoid, and mitigate for adverse environmental impacts to wildlife" (26). Management with this goal is a bona fide remediation strategy.

Along this vein, there has been much effort, especially in the western United States, to manage impacts on wildlife using a watershed-based approach, some of which are briefly outlined in Reference 6. In that paper, Engberg and co-workers have stated that "of the five management options presented, mitigation (option 5) may be the only long-term solution to managing selenium." A key tool in such mitigation is the construction of "alternative" and "compensation" habitats to build wetland habitats with clean water for impacted species (6,26). Note that this remediation strategy does not draw upon any of the textbook "remediation" strategies of containment, removal, or treatment.

The mitigation approach also has its downsides. In the western United States, water supply issues can complicate the Se remediation in water drainage. For example, the cost of land and water is a major obstacle to building and maintaining compensation and alternative habitats. In general, the management approach may require extraordinary effort: it has been stated that "managers must translate the complexities of selenium chemistry and biochemistry into cogent management and regulatory approaches, all the while understanding and blending financial, economic, and social constraints into the solutions" (6). Furthermore, since Se is a semi metal (or metalloid) with a wide variety of forms in many types of samples, it is exceptionally challenging to analyze.

Natural Bioremediation of Se

As mentioned above, the containment of waterborne Se into terminal water basins eliminates downstream impacts but creates a contaminated lentic system. Use of the mitigation approach is probably needed (26), but combinations of water treatment and management of the terminal basins have also been investigated. Only a few of these take advantage of the natural biogeochemistry to focus on removal of Se from the natural foodweb accumulation. Such an approach differs from the above strategies, which have an underlying assumption that the contaminated system presents only a problem that must be "fixed" somehow (containment, removal, treatment) or bypassed (management–mitigation). Rarely is consideration given that the aquatic system may be mostly functioning "right," and only a few particular processes that are awry need to be addressed.

"Biovolatilization" of Se is one such approach, since it takes advantage of the natural biogeochemistry to remove Se. The problem with biovolatilization of any type, as Fig. 1 outlines, is that the process also draws Se into the biota, and consequently up the foodweb. This tendency has been particularly troublesome in attempts to utilize aquatic vascular plants to volatilize Se. For example, vascular plants volatilize a relatively small amount of Se while sequestering it in bioavailable foodweb materials such as the shoots and roots. Although the shoots could be harvested and disposed, the Se is mostly contained in the below-ground portions of the plants (31), which are not practical for harvesting.

Fan and Higashi (28,32) have described natural algal Se volatilization as part of an alternative remediation process in terminal basins. The overall remediation process, outlined in Fig. 2, combines volatilization of Se with interrupting the foodweb accumulation of Se (33). In this strategy, photosynthetic algae function to volatilize Se while serving as food to macroinvertebrates (brine shrimp). The brine shrimp graze the algae, ideally preventing algal accumulation and participation in the detrital cycle. In turn, the brine shrimp are harvested as a marketable product, thereby intercepting the foodweb-accumulated Se before it can impact fish and birds. Both volatilization and harvesting of brine shrimp result in a net removal of Se from the aquatic system. The resulting blockages to the foodweb accumulation of Se are shown by the X's in Fig. 2.

A full-scale evaporation basin system has been monitored for over three years in this regard (33). The terminal evaporation basins are brine, which allows the flourishing of brine shrimp that has commercial value—in fact, at California's Tulare Lake Drainage District, there has been successful commercial harvesting of brine shrimp for over five years (34). The efficacy of the approach is clear: (1) the algae that volatilize Se and feed the brine shrimp grow naturally in these basins; (2) the brine shrimp also grow naturally in these basins to a high density; (3) much of the scheme utilizes water management that is familiar to drainage operators; and (4) costs of encouraging and managing brine shrimp growth is offset by marketing harvested materials.

Comparisons with analogous systems where brine shrimp harvesting is not implemented has demonstrated that, under active brine shrimp harvesting (33):

- Waterborne Se concentrations are not increased.
- Se volatilization—a removal process of Se—appears to be enhanced.
- Concentrations of Se in algae and macroinvertebrates—a risk indicator for fish and bird toxicity—are not increased.
- Benthic macroinvertebrate biomass—a key foodweb accumulation indicator—is greatly decreased.
- Total Se as well as organic Se deposited to the sediment (available for biogeochemical refluxing as in Fig. 2) is decreased >90%.

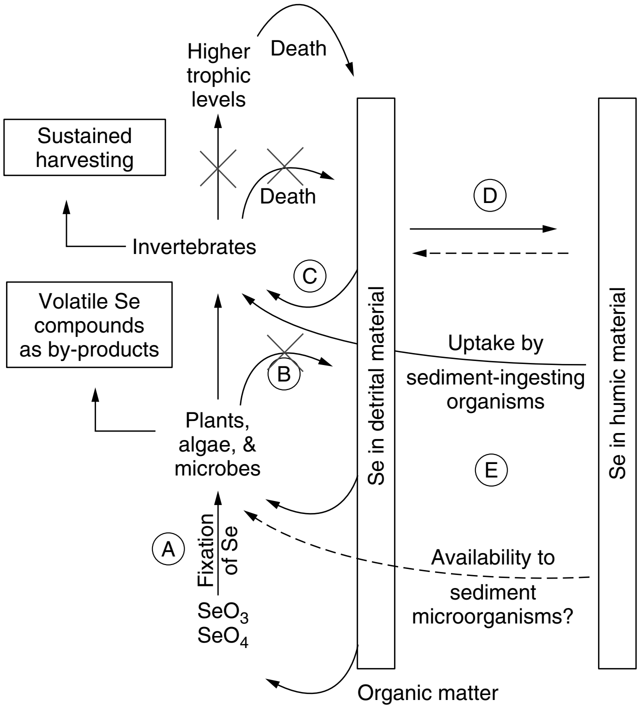

Figure 2. Bioremediation in drainage basins by reducing Se ecotoxic risk through invertebrate harvest and Se volatilization. In this "biogeochemical reflux" scheme, the drainage inorganic Se forms are initially biologically fixed by aquatic algae and microbes Ⓐ. The fixed Se does not directly head up the foodchain in the water column, as is often portrayed. Instead, a major fraction enters into organic matter, taking a detour through detritus (recently dead organic matter) and sediment Ⓑ, then reentering the foodchain at several trophic levels Ⓒ. Over longer periods, part of the detrital material is converted to recalcitrant humic material Ⓓ, locking up the Se until sediment-ingesting organisms reintroduce them to the foodchain Ⓔ. Through sustained harvesting (upper left box) of water-column invertebrates that consume algae and microbes, the bioavailable Se is removed from water, plus detrital formation resulting from the death of water-column organisms is also blocked. Both types of blockages are shown by the three X's. In turn, this would help minimize the sediment–detritus foodchain pathway for Se. In the meanwhile, additional Se can be removed by manipulating the algae/microbe community for optimal Se volatilization (lower left box).

Research is continuing to determine how this strategy can be applied to other systems and to achieve long-term sustainability. At present, the combined strategy of impounding Se-contaminated water in basins, applying the algal volatilization–foodweb interruption process, and constructing compensation/alternative habitats illustrates the advantages of an integrated management approach. In fact, such watershed-scale management appears to be required in order to remediate a contaminant with complex biogeochemistry such as Se.

SHELLFISH GROWING WATER CLASSIFICATION

Linda S. Andrews
Mississippi State University
Biloxi, Mississippi

Seafood-related illnesses in the United States are primarily associated with the consumption of bivalve molluscan shellfish (1,2). As these animals are water filter feeders and are often consumed raw, the water that they are grown in affects their safety and quality.

Bivalve molluscs feed by filtering microscopically sized particles out of the water. Via their inhalant siphon, they pump water through their gills. The gills sort out particles of the correct size and "feel" and direct them to their gut (3). The large volume of water that the bivalves pump through their siphons causes concern among public health officials. Consequently, it is imperative that water authorities, usually shellfish producer states, monitor the quality of water in and around the shellfish beds or reefs. For commercial markets, harvesting is only permitted from approved growing areas. The microbial acceptability of growing areas is classified on the basis of a sanitary survey of the shoreline to detect potential pollution sources and bacteriological analysis of water samples taken from the area (4).

Shellfish sanitation programs originated at the national level in the United States in 1925 after a series of typhoid epidemics spread by the consumption of raw shellfish threatened the collapse of the oyster industry (3). Today, through the National Shellfish Sanitation Program, NSSP (5), State and federal public health regulators have established guidelines for water quality in shellfish growing areas to decrease the risk of illness associated with these seafood products.

Sanitation surveys are normally performed by the state regulatory authority and include a written report of a shoreline survey, bacterial quality of the water, and an evaluation of the effect of any meteorological, hydrodynamic, and geographic characteristics of the growing area. Each surveying state maintains records of the surveys. For example, for Mississippi, survey results are filed with the Mississippi Department of Marine Resources (http://www.mississippiwebsite.com/deptmarinerec.htm). An analysis of the data from this survey determines the appropriate growing area classification. During shoreline surveys, the state authority identifies and evaluates all actual and potential sources of pollution to the growing area. If a pollution source exists, the distance from pollution to growing area is determined with an assessment of the potential impact. The effectiveness of sewage treatment and other wastewater treatment systems is evaluated for removal of the microbial and/or chemical contaminants.

Comprehensive sanitation surveys for each growing area must be performed at least once every 12 years with triennial reevaluation based on water quality analysis and potential for any new sources of pollution. If this triennial evaluation determines that conditions have changed from the 12-year survey, the area in question may then be reclassified. On an annual basis, the sanitary survey shall be updated to reflect changes in the conditions of the growing area based on "drive through" surveys, observations made during routine sample collection, or information from other sources.

In general, each growing area is classified as approved, conditionally approved, restricted, conditionally restricted, or prohibited based on the survey results (see Table 1). Status of a growing area is separate from its classification and may be either considered open or closed for harvesting of shellstock. All correctly classified growing areas are normally open for harvesting unless they are classified as prohibited. Closures may occur temporarily because of adverse weather conditions, the presence of biotoxins in concentrations of public health significance, or when the state authority fails to complete the written sanitary survey or triennial review evaluation report. A growing area may be placed into a remote status if the sanitation survey determines that the area has no human habitation and is not impacted by human pollution sources.

Table 1. Shellfish Harvest Area Classification Categories (5)

Classification	
Approved	Growing areas are classified as approved when the sanitation survey finds the area safe for the direct marketing of shellfish or is not subject to human or animal fecal pollution.
Conditional	Growing areas are classified as conditional when the area in question is in the open status for a reasonable period of time and when pollution factors are predictable. There may be direct potential for distribution of pollutants based on unusual conditions or specific times of the year when bacterial numbers are increased by heavy water runoff that affects wastewater treatment plant function.
Restricted	Growing areas are classified as restricted when the sanitary survey indicates a limited degree of pollution and when levels of fecal pollution, human pathogens, or poisonous or deleterious pollutants are at such levels that shellstock can be made safe through either relaying or depuration.
Prohibited	Growing areas are classified as prohibited when no current sanitary survey exists or when the survey determines that the growing area is adjacent to a sewage treatment plant outfall or other point source with public health significance or when the water is polluted because of previous or current sources of contamination.

The NSSP allows for a growing area to be classified using either a total or fecal coliform standard. Two sample collection strategies are used: adverse pollution condition and systematic random sampling. Each state authority may choose one of these sampling plans or use both depending on the location of the shellfish bed. Each state authority determines the number and location of sampling stations based on potential sources of pollution contamination as determined by the shoreline survey. Except for prohibited areas, the original or new classification of a shellfish growing area that has the potential to be impacted by a pollution source requires a minimum of 30 samples collected under various environmental conditions. For an area not impacted by a pollution source, 15 samples are required for initial classification. When using fecal coliforms (FC) as the indicator bacteria, the water quality must meet the following standards: FC median or geometric mean most-probable-number (MPN) may not exceed 14 per 100 mL, with not more than 10% of samples exceeding 43 MPN per 100 mL for 5 tube decimal dilution or 49 MPN per 100 mL for 3 tube decimal dilution. When classifying point source growing sites, the bacterial quality of every station in the growing area must meet the fecal coliform standards as described above. Sample stations must be located adjacent to actual or potential sources of pollution. Refer to the NSSP Model Ordinance Chapter IV for details on sampling to achieve statistically reliable results (5).

Separate standards are used for shellstock that will be processed by depuration posterior to harvesting. For the restricted classification of growing areas that are affected by point sources or nonpoint sources, FC median or geometric mean MPN of the water samples shall not exceed 88 per 100 mL and not more than 10% of the samples shall exceed an MPN of 260 per 100 mL for a 5 tube decimal dilution test or 300 MPN per 100 mL for a 3 tube decimal dilution test.

Numerous factors are involved in interpreting FC data. Fecal coliforms are common as indicators of human fecal pollution and potential human fecal pathogens. However, pathogenic microorganisms typically do not occur in direct proportion to the number of FC present (3). This is especially true with viruses that move through tidal water at a much faster rate than heavier coliforms. Also, FC may die off at a rate different from other pathogenic organisms, thus giving a false sense of security that the shellfish are safe for human consumption. Another problem with using FC as an indicator of potential human pathogens is that FC may originate from sources other than humans. In rural areas, wild animals are likely to be the primary source of FC found in runoff. Major human pathogens of concern in shellfish waters usually originate on land, but exceptions include sewage discharges from boats and sewage treatment facilities. Runoff from land varies with rainfall, soil type, and degree of saturation. Consequently, one or even a few samples collected periodically may indicate very little about the pollution potential. Numerous samples collected under all weather conditions (heavy rain and high tides) are the only way to properly evaluate and classify a particular growing site.

The restrictive rules for classification of shellfish growing waters have been established to provide the safest shellfish possible. All shellfish for human consumption are marked with a harvesters tag that indicates that they were harvested only from approved harvest areas. Today, illness outbreaks caused by the consumption of human pathogens that are present in raw molluscan shellfish are rare because of these rules for classification.

SORPTIVE FILTRATION

K.A. Matis
N.K. Lazaridis
Aristotle University
Thessaloniki, Greece

INTRODUCTION

Although filtration is one of the principal unit operations in the treatment of potable water, the filtration of effluents is less practiced; usual examples are supplemental removals of suspended solids from wastewaters of biological and chemical treatment processes and also the removal of chemically precipitated phosphorus (1). The available references dealing with filtration are quite voluminous—see, among others, the articles on filter presses, deep bed, cartridge, batch, variable volume, and continuous filters (2). Hence, the information provided in this section serves only as an introduction to the subject; for additional details, the literature should be consulted. In this article, no mention will be made of chromatographic applications (3).

The seepage of rainfall and runoff into porous solids and rocks and the storage and movement of groundwaters in open-textured geologic formations are important elements in the resource and quality management of water and wastewater. Although fine-textured granular materials remove pollutants, the water drawn from them is acceptable only when natural filtration together with a time lapse between pollution and use bar the transport of pollutants to springs, wells, and infiltration structures (4).

SORPTION

A typical recent example of sorption is the removal of copper by suspended particulate matter from river water (5). Iron, silicon, and aluminum oxides were used as adsorbents, serving as models of naturally occurring suspended particles. On the other hand, sorption upstream of filtration constitutes a solution; the combined process has been also termed adsorptive filtration (6). In this module (offered by Separation Technologies), fundamental aspects of the process are illustratively given, such as inertial impaction and diffusional interception; however, the latter is effective only in gas filtration. Sorption, in general, is defined as a surface process irrespective of mechanism, adsorption or precipitation (7).

Batch and column sorption studies of zinc, cadmium, and chromium were conducted on calcite to determine its retention capacity for these elements common in industrial effluents and to explore its behavior as a purification filter in a continuous flow system (8). Fibrous carbon materials were examined for heavy oil sorption (9); oil spill accidents have caused serious problems in the environment, including disasters in living systems. Elsewhere (10), biologically active carbon (followed by ultrafiltration) was used for simultaneous sorption and biodegradation of organic constituents. Naturally occurring diatomaceous earth was tested as a potential sorbent for lead ions; the intrinsic exchange properties were further improved by modification with manganese oxides (11). Today, effective low-cost adsorbents for toxic metals are available; for instance, the case study to remove (by Metsorb™ adsorptive filtration media) depleted uranium from contaminated water at a U.S. Army testing site (12).

In recent years, contamination of ground and surface waters with heavy metals has become a major concern. The knowledge of the oxidation state of pollutant ions is often a prerequisite for the application of efficient treatment methods, as in the case of arsenic. The inhibition of conventional metal precipitation due to the presence of chelating or complexing compounds, such as acetate, citrate, and tartrate ions, ammonia, and EDTA, which may be present in most real wastewater streams, is another problem for examination. Thermodynamic equilibrium diagrams and software packages (such as Mineql+) have been employed to construct aqueous speciation diagrams for the metals under investigation and, then, to interpret the removal mechanism involved. Sorption isotherm equations for equilibrium uptake, such as that of Freundlich and Langmuir, have been often used to fit the experimental data, and the activation energy of the process was calculated (13).

Figure 1a presents some typical kinetic results for hexavalent chromium ions in batch sorptive removal under different conditions by (uncalcined) hydrotalcite as the appropriate sorbent, noting that desorption, particularly in successive stages, has received much less attention in the literature. The data were effectively fitted by a second-order kinetics equation.

Another suitable (for metal cations) inorganic sorbent material is the group of natural or synthetic zeolites (Fig. 1b); the nonselectivity of the process is also apparent, sorbing zinc or calcium. Stress was given to electrokinetic measurements (expressed as zeta-potential) of the system for its surface charge under the applied conditions to predict its behavior (14). The solution pH is important and influences metal speciation. So, for example, at pH lower than 6.8, corresponding to the pristine point of zero charge of α-FeOOH, the surface of these particles is positively charged. Therefore, in the pH range examined, the adsorption of anionic metal species was more pronounced (15).

Fixed-Bed Sorption

Ferric hydroxides, such as goethite, are another good example extensively studied; fixed-bed operation is the appropriate configuration for large-scale applications such as wastewater treatment (see Fig. 2a). The adsorbent material was granulated by crystallization through controlled freezing. Column adsorbers, due to pressure drop, require a suitable shape and size of the bonding material used. The experimental results are presented, expressed typically by the breakthrough curve concept, service time versus breakthrough (column outlet concentration related to the initial metal concentration—$C_{\text{outlet}}/C_{\text{initial}}$), as a percentage. In the inplots, the isoremoval lines of treatment time versus the respective quantity of sorbent are also presented at various breakthrough points.

The major aim when sizing adsorptive columns is the ability to predict the service time until the column effluent exceeds a predefined solute (pollutant) concentration. The bed depth–service time model (abbreviated as BDST) relates the service time of a fixed-bed to the height of adsorbent in the bed, hence to its amount, because quantity is directly proportional to bed height. The measurement of sorbent quantity is more precise than the determination of the respective volume, especially for granules. Therefore, the sorbent quantity is preferably used instead of the bed height (15,16).

Surface complexation models were used to describe metal cation adsorption on adsorbent materials; models, such as constant capacitance, diffuse layer, and triple layer were applied, showing that they could simulate experimental results. The fundamental concepts on which all these models are based remain, more or less, the same (17).

The computer program PHREEQC (of the U.S. Geological Survey) permits a wide variety of aqueous geochemical calculations; surface-complexation modeling, applying mainly the diffuse double layer (DDL) model,

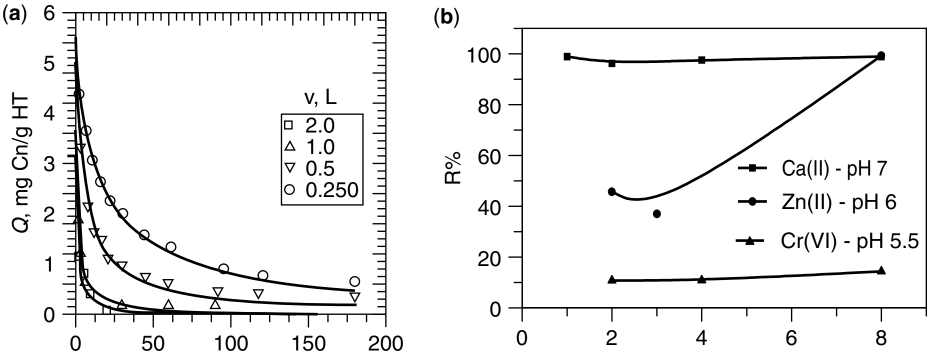

Figure 1. (**a**) Time variation of chromium(VI) loading on hydrotalcite (1 g/L) at various eluant volumes. Reprinted with permission from Reference 13; copyright (2004) American Chemical Society. (**b**) Removal of calcium, zinc, or chromate ions (50 mg/L) by zeolites as a function of their concentration, at different pH values. is included in the program. The program uses a modification of the usually applied Newton–Raphson method iteratively to revise the values of the variables until a solution of the equation system is accepted within specified tolerances. A limitation of the program may be that uncertainties occur in determining the number of sorption sites, the surface area, the composition of sorbed species, and the appropriate surface-complexation constants. It was demonstrated that some of the surface complexation model (SCM) parameters might be incorrect due to an experimental artifact, though they give good simulations of data. This may be due to the success of least-squares fitting programs, such as FITEQL, in finding model parameters to describe experimental data sets.

The results of the model, according to surface-complexation reactions and constants (see Table 1), are presented in Fig. 2b, in comparison with the experimental data for arsenic(III) oxyanions; they show good agreement, although the diffusion effects (external, or liquid film, and intraparticle transport resistance) were not taken into consideration (18). Similar conclusions were obtained with As(V). The arsenic problem is of particular concern for small communities in rural areas around the world (a characteristic case is that of Bangladesh), where groundwater comprises the main drinking water source. Arsenite is favored under reducing (i.e., anaerobic) conditions. In this *Encyclopedia*, refer to another article on Sorption Kinetics in the chapter on Physics and Chemistry of Water.

Table 1. As(III) Species Distribution and Surface-Complexation Reactions and Their Reaction Constants[a]

Species Distribution	Reaction Constants, log *K*
$AsO_3^{3-} + 4H^+ = H_4AsO_3^+$	34.44
$AsO_3^{3-} + 3H^+ = H_3AsO_3$	34.74
$AsO_3^{3-} + 2H^+ = H_2AsO_3^-$	25.52
$AsO_3^{3-} + H^+ = HAsO_3^{2-}$	13.41
Surface-Complexation Reaction	
$Goeth\_OH + H_3AsO_3 = Goeth\_H_2AsO_3 + H_2O$	4.51

For a number of ion exchangers of ultrafine particle size (for efficient use in packed column beds), a convenient binding polymer, such as modified polyacrylonitrile, has been used. The resulting sorbents were tested for separation and preconcentration of different contaminants, including radioactive wastes. The sorption characteristics of these composite materials were not affected by the binding polymer, whereas their physicochemical properties (hydrophilicity, mechanical strength, etc.) can be modified by the degree of cross-linking of the polymer, the use of suitable copolymers, or by changing the composition and temperature of polymerization (19). Certainly, an alternative to facilitate their solid/liquid separation downstream, particularly if fine adsorbents are to be dispersed, is to apply flocculation (20); note that many low-cost synthetic sorbents are produced as powders.

THE COMBINED PROCESS

Liquid-phase carbon adsorption is a full-scale technology in which groundwater is pumped through one or more vessels containing activated carbon to which dissolved organic contaminants adsorb (21). When the concentration of contaminants in the effluent from the bed exceeds a certain level, the carbon can be regenerated in place; removed and regenerated at an off-site facility; or removed and disposed of. Carbon used for explosive- or metal-contaminated groundwater probably cannot be regenerated and should be removed and properly disposed of. Adsorption by activated carbon has a long history of use in treating municipal, industrial, and hazardous wastes. Figure 3a illustrates a sorptive filtration system.

Another innovation has been proposed by introducing a two-stage process in a compact microfiltration (MF) hybrid cell (Fig. 3b). A large number of techniques have been used to limit membrane fouling; among them is air bubbling that also constitutes the transport medium in flotation, as applied in wastewater treatment; flotation is

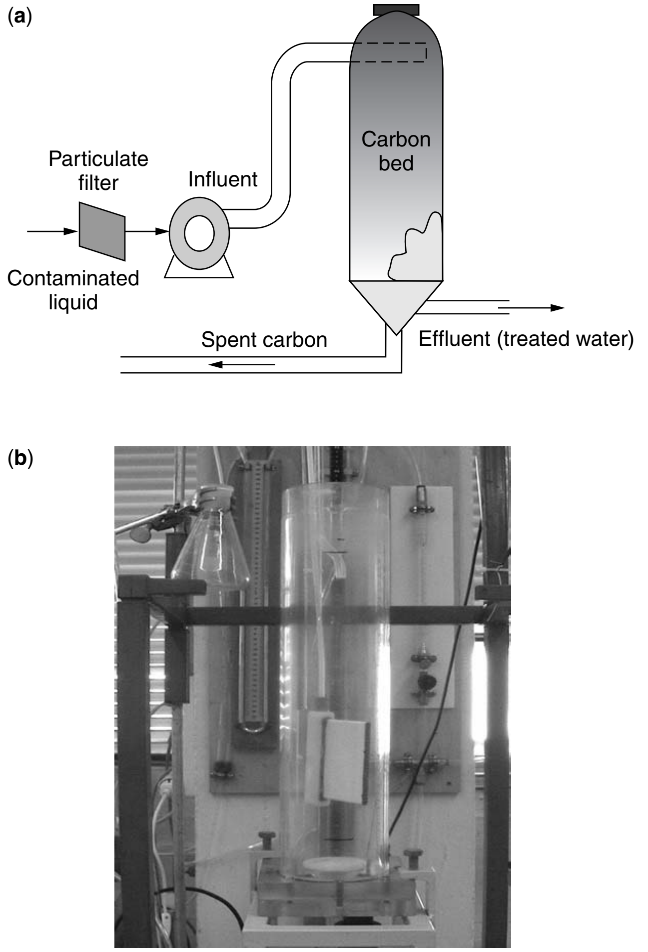

Figure 3. (**a**) Typical fixed-bed carbon adsorption system. From Reference 21. (**b**) A close-up photograph of the hybrid MF laboratory cell based on flotation (22).

suitable as a pretreatment stage for microfiltration. The former accounted for around 90% solids removal.

Ceramic flat-sheet membrane modules of multichannel geometry were used in this cell. The objective was to apply microfiltration by submerged membranes for efficient separation of metal-loaded zeolites. By this hybrid process, low residual metal concentration in treated water at maximum water yield and a higher concentration of metal bonding agent in the concentrates can be achieved (22). During the experimental series of continuous-flow separations by the membranes, all samples collected showed 100% zeolite recovery due to membrane filtration, hence, efficient solid/liquid separation. The metal (zinc) removal depended only on the amount of zeolite sorbent used; the remaining process parameters, examined in detail, had absolutely no influence on the former.

One of the early notable investigations of adsorptive filtration is that by the EPA (23) at Superfund sites, those sites classified as uncontrolled and abandoned places where hazardous waste is located, possibly affecting the local ecosystem or people. In this application, toxic metals were removed by attachment to a thin layer of iron oxides that were immobilized on the surface of an appropriate filter medium, such as sand grains.

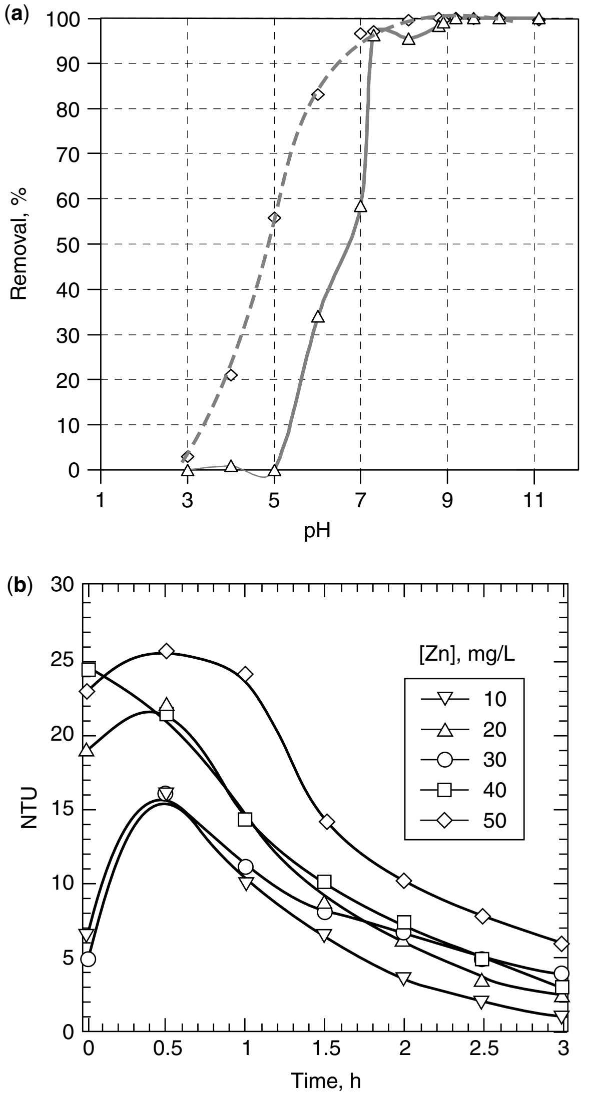

Figure 4. (**a**) Removal of copper by biosorption (rhombic symbols) or simply, precipitation (triangles): A comparison of the two processes. Modified from experimental results published by Zouboulis et al. (24). (**b**) Influence of linear velocity on residual concentration expressed as turbidity (pH 9.5). Reprinted with permission from Reference 26; copyright (2002) Dekker.

An alternative sorbent that has been tried quite extensively is microbial biomass (24). The reason is that thousands of tons of residual biomass are produced each year from the fermentation, pharmaceutical, and chemical (i.e., citric acid biosynthesis) industries and also from biological wastewater treatment plants. The bacterial cell surfaces are known to be anionic, due to ionized groups in the various cell wall polymers. From a comparison of biosorption and other metal separation methods, such as filtration and centrifugation, it was found that the former favors the removal efficiency and applicability at lower (acidic) pH. In these conventional processes, metal cation removal is mainly due to their precipitation as hydroxides from pH alteration; this is presented in Fig. 4a showing a pH front/edge moving to the right toward alkaline values; precipitation was followed by flotation with dodecylamine as a surfactant. Of course, in sorption, metals are bonded on dead biomass (*Streptomyces rimosus*). Oxidation processes leading to insoluble products can also be mediated by specific bacteria, for example, for Mn(II) and Fe(II) (25); in these papers, from our lab, upflow filtration units were tested. One of the objectives was to obtain low sludge volumes, which often depends upon the method of precipitation.

Upflow filtration has a theoretical advantage because coarse-to-medium filtration can be achieved by a single medium (such as sand) with almost perfect gradation of pore space and grain size from coarse to fine in the direction of flow. The bed is backwashed in the same direction but at higher flowrates, so the desired relative positions of fine media are maintained or reestablished by each run (1,4,26). The shortcomings of upflow filtration were overcome by using floating filter media. This type of filter can be backwashed with minimum water consumption and at lower rates. It also appeared from the laboratory experiments that metal removal was not limited by the solubility of the respective zinc hydroxide but by the effectiveness of the subsequent solid/liquid separation method (Fig. 4b). This semibatch unit, consisting of two columns in series and external recirculation of the filtered wastewater from the unit to the feed tank, was suitable for small- to medium-scale applications.

In conclusion, sorptive filtration presents a promising technique. Today, there is a tendency for combined and compact processes, offering both the capacity for effluent treatment for environmental reasons, plus the recovery of metals that otherwise would be lost and, more importantly, water reuse.

QUALITY OF WATER IN STORAGE

Paulo Chaves
Toshiharu Kojiri
Water Resources Research Center
Kyoto University, Japan

Water is our most precious natural resource. It is not only indispensable for the survival of all living beings but also has social and economic importance. It is no coincidence that most early human settlements were located near sources of freshwater. However, available water resources are increasingly under pressure from human population growth, increased standard of living, urbanization, and development of extensive areas for agriculture. As a result, available water may, at times, become insufficient to fulfill all the needs of human living, particularly during dry periods, which are caused by the natural randomness of the hydrological cycle.

Therefore, it becomes necessary to find and to develop new sources of freshwater in order to secure a constant and appropriate supply of water. Certainly, many methods to maintain the stable supply of water exist, such as groundwater exploitation and water deviation from wet to dry areas. Undoubtedly, however, the most popular way worldwide to stabilize water supply is through the operation of stored water, particularly in lakes and manmade reservoirs. This concept was appreciated long ago, and reservoir construction has a long history, with the first dam believed to be built in ancient Egypt around 2800 B.C. (1).

In the last few decades, most of these water storage systems have suffered from poor water quality, mainly caused by human activities within their watersheds and inefficient operation of these reservoirs. Although a variety of techniques to improve water quality in storage exist, most are either very costly or not sustainable. Therefore, efforts to find new methods to achieve better water quality are extremely important. One way is by taking advantage of the close relationship between quality (limnological) and quantity (hydrological and climatological characteristics) of water to better manage stored volumes to yield optimal benefits for water use while at the same time improving its quality.

In the following sections, the main issues that impact on the quality of water in storage are presented. First, the important relationship between quantity and quality of water, and the potential improvement of water quality through the proper operation of storage volumes are highlighted. Then, the main issues related to evaluation of water quality are explained, showing the importance of proper water quality for different uses. Finally, all these topics are combined within the storage management and operation framework when water quality is considered.

WATER QUALITY AND STORAGE

Manmade reservoirs and lakes used for water storage, like other water bodies, are vulnerable to increasingly frequent problems of water quality. Some of the most common problems concerning the quality of water in storage are organic pollution, anoxia (deficiency in oxygen), eutrophication (increase of phytoplankton because of high nutrient concentrations), toxicity, turbidity, siltation, and waterborne diseases. In the same way, a variety of different possible causes of these problems exist, such as industrialization, increase of population, overexploitation of agricultural land, bad farming practices, poverty, lack of proper sanitation systems, runoff from cities, deforestation, lack of proper enforcement of the regulations for pollution control, and overuse of water resources with decrease of water volumes and levels.

Probably, the most effective method to control pollution and improve quality of water in storage is through comprehensive watershed management, which includes reduction and control of nonpoint and point sources of pollution, such as nutrient and organic matter loads. On the other hand, other techniques exist that may be applied directly to the water bodies themselves, such as artificial mixing, aeration, sediment removal, chemical manipulation, algaecides, and biomanipulation of species like fishes and aquatic plants. However, most of these techniques are costly and difficult to implement.

Basically, three main components of a reservoir system exist: inflow, storage, and release. Inflows may be defined as natural events, whereas storage and release may be considered under human control. Nevertheless, both natural variability and human decision can greatly influence the water quality of a reservoir. Reservoirs tend to present water of different quality during wet and dry hydrologic periods. With the increased runoff during periods of rain, higher nutrient loads would be expected in the reservoir, and these nutrients stimulate algae blooms and, therefore, may lower the water quality. Moreover, higher levels of inflow may also increase the inputs of organic matters resulting in dissolved oxygen (DO) depletion, which is defined as the decrease of dissolved oxygen concentrations, vital for sustaining aquatic life. On the other hand, higher inflows increase flushing rates and enhance mixing characteristics, decreasing stratification and potentially improving water quality. Hydrological factors, however, are not the only influences on water quality. Climatologic characteristics also play an important role, because during warm periods a higher probability of reservoir thermal stratification exists, because of a difference in temperature between water layers, leading to a difference in water density. The phenomenon of stratification, defined as the difference in density through the water column, which is commonly caused by variations of temperature, restricts the mixing of water between different layers. The isolated lower layer, called hypolimnion, can suffer from DO depletion by anaerobic processes and an increase in nutrients and other materials from bottom sediments.

Water quality is closely tied to storage volumes. Clearly an increase of water volume results in increased dilution of pollutants, but, in addition, other physical, chemical, and biological processes that influence the quality of water may be closely related to controllable hydrological factors, such as the variation of release discharge, storage volumes, and water levels. For example, an increased retention time (defined as the ratio between reservoir volume and discharge rate) can influence water quality in many ways, such as decreasing mixing proprieties, increasing phosphorus retention, increasing the difference between surface-bottom temperatures (stratification), and decreasing turbidity that can enhance chances of algae bloom. Moreover, fluctuation of water levels may also enormously affect water quality, such as increased erosion from the shores that may result in higher turbidity, increasing washout of margins, and decreasing reproduction of some fish species (that lay eggs on coastal vegetation), consequently changing the phytoplankton (algae) population of the aquatic system. The quality of stored water may also be affected by the release of water with poor quality from different levels, such as bottom-spillway discharge.

Zalewski et al. (2) emphasizes the importance of ecohydrology to use ecosystem properties as management tools for sustainability of water resources, such as through adequate management of quantities to improve water quality. Moreover, his paper presents an example of the relationship between storage levels and the eutrophication process for the Sulejow Reservoir. Straskraba and Tundisi (3) discuss, in a general way, many aspects related to the management of reservoir water quality, such as ecotechnologies, relation between storage and water quality, and the possible impacts of different volumes and quality of discharged water from reservoirs.

Therefore, the proper operation of release discharges and storage volumes considering single or multiple outlets and offtakes can also be considered an efficient method to improve the quality of stored water, by discharging water of undesirable quality or by increasing the storage volume with additional water, hence diluting water of poor quality (4,5). Although some general idea of the relationships between hydrologic and climatologic variables and water quality condition could be described, it is not possible to make a definitive statement about such relations. Specific studies for each reservoir system are needed to truly understand its limnology characteristics. Such studies need to include data collection and analysis, application of mathematical models, biological and hydrologic investigations, and, lastly, an understanding of the socioeconomic characteristics of the reservoir basin.

Mathematical models can play an important role in the decision-making process, as these tools may support the decision makers in making the “best” decisions. The outcome of different decisions may be simulated and explored virtually with relatively low costs and in a short period of time. For more detailed explanation behind the mathematics of physical, chemical, and biological concepts of the quality models, the readers are referred to Jorgensen (6), Orlob (7), and Thomann and Mueller (8).

WATER QUALITY EVALUATION

Water quality directly affects virtually all water uses. Fish survival, diversity, and growth; recreational activities; corrosion of turbines of hydropower plants; municipal, industrial, and domestic water supplies; agricultural uses like irrigation and livestock; waste disposal; and general aesthetics are all affected by the physical, chemical, biological, and microbiological conditions that exist in water bodies. Some water uses can affect water quality, which can influence other water uses. For instance, navigation may cause increased bank erosion leading to accelerated loss of storage volumes (reservoir sedimentation) and higher water turbidity. Water bodies used for wastewater assimilation may suffer from depletion of DO, which is required to sustain aquatic life, and an increase in total dissolved solids (TDSs), which is highly relevant to water supply, as higher TDSs increase treatment costs.

The minimum acceptable quality of water depends very much on the water use itself. Water for irrigation, for example, should be low in dissolved salts, but water intended for livestock should be low in bacteria. Water used in industrial processes should usually be of a much higher quality than water used for industrial cooling. As for municipal supply, water must not only be safe to drink, but ideally should contain low concentrations of materials such as calcium and iron, as they may cause costly infrastructure damage or add unpleasant characteristics to the water even after treatment (9).

A water quality index may be an efficient way to objectively measure water quality using a vast number of existing water quality parameters, helping decisions to be taken in a more efficient and less subjective way. Many of the water quality indices tend to be developed based on local characteristics and local expertise (10). Water quality indices may also be developed to express the conformity or net benefits of a water body with regard to a particular type of water use. In this scenario, different indices may be developed for the evaluation for a specific use or of the natural state of the system, such as for domestic drinking water supply, recreational use, wildlife preservation, trophic state situation (measure of eutrophication), and toxicity levels of water. Indices can be based on a single quality parameter or can even be presented as a combination of many quality parameters, such as the well-known Water Quality Index developed by the U.S. Environmental Protection Agency (EPA). Therefore, their use in the management and operation framework has to be closely studied and discussed among all stakeholders involved in the decision-making process. As a result of the vagueness involved in defining these indices, some new attempts have been made to evaluate water quality using fuzzy theory, such as in works by Norwick and Turksen (11), Dombi (12), and Chang et al. (13).

MANAGEMENT OF STORAGE WATER QUALITY

Water volume has always been a prime consideration in the design and construction of storage reservoirs, but quality has not. In the same way that quantity is regulated, water can be stored and released for the improvement of water quality and net benefits. As described in the previous sections, assessment, evaluation, and modeling of water quality are very complex tasks for water resource managers. Some of the reasons why water quality is still being left out from the decision-making framework process include:

- Multiple stakeholders and multiple objectives are present in most cases.
- A large number of physical, chemical, and biological water quality parameters exist to be considered.
- Quality conditions present great spatial and temporal variability.
- It is difficult to economically evaluate water and environmental quality.
- Quality may be highly influenced by human activities and natural conditions.
- Complete and representative spatial and temporal water quality data are seldom available.
- Water quality simulation is a complex task because of the high levels of uncertainty involved in this process.

The uncertainties when analyzing water quality are much greater than when dealing with water quantity. Uncertainty may strongly affect water quality management and the decision-making process of storage operation. However, from where does uncertainty come? Basically, uncertainty is inherent to many processes, such as measurement, natural randomness, and human perception. In a more concrete way, some sources of uncertainties assessing water quality include:

- Construction problems of treatment facilities
- Structures and parameters of a simulation model
- Uncertainty of mismeasurement and incomplete data sets
- Future and changing conditions (e.g., new socioeconomic activities in the watershed, global warming)
- Vagueness of objectives (e.g., “improvement” of water quality)
- Situations of accidents and disaster (e.g., traffic accidents or chemical leakage from factories)
- Natural randomness of climate and hydrological variability (e.g., extreme events such as floods or long drought periods)

Proper identification of the system uncertainties can support a more flexible and effective management framework, where components identified with greater uncertainty are considered for further investigation and the ones with less uncertainty may become more important decision tools, as the consequences can be more accurately predicted. Moreover, it may increase the public acceptance of a certain decision regarding reservoir management. Results after uncertainty analysis can be given in different ways, such as probability density function and confidence intervals, giving a range of possible outcomes avoiding the common “unexpected” results.

Moreover, information on cost is frequently needed to improve the water quality management prior to the water quality impact assessment. Such costs may be related to water treatment; penalties for excessive pollution; socioeconomic losses, such as associated with tourism activities; and decrease of benefits of certain objectives when a multipurpose operation is considered.

The operation of single and multiple outlet reservoir systems can present different objectives, such as improvement of water quality in stored volumes, released discharges, and intake water. Moreover, the management horizon can be specified to deal with different problems, such as related to the long-term planning, real-time operation, and emergency situations.

Management of water quality can be considered together with the various types of reservoirs that may present different water use, such as reservoirs for water supply, irrigation, hydropower generation, flood control, recreation, and, of course, multipurpose systems. As explained previously, for each type of reservoir, a different evaluation method may be necessary.

Besides the improvement of water quality condition itself, many advantages to considering water quality in the operation process exist, such as wider acceptance of reservoirs among the general public, decrease in maintenance costs, increase in net benefits, preservation of aquatic life, and achievement of sustainable policies.

Straskraba and Tundisi (3) present many management models that combine quality simulation with management tools. Research in this field is in constant development, and some of the new models are imbedded with complex components, such as remote sensing information, geographic information system (GIS), management and optimization techniques, artificial intelligence (AI), and decision support systems (DSSs).

It seems that much still exists to be accomplished and developed in the field of water quality in storage. The focus should be on integrated quality management, which must consider quantity and quality along with the three main components of a storage reservoir system: inflow, storage, and release. Moreover, other topics should be considered such as simultaneous combination of stochastic optimization and water quality simulation models, including uncertainty analysis, multiple water quality parameters in a multiobjective optimization framework, and multipurpose reservoirs considering the different stakeholders and water uses. The potential success in solving water quality related problems will depend on the ability of different professionals, including researchers, hydrologists, limnologists, and decision-makers, to work together in an interdisciplinary and holistic manner.

QUALITY OF WATER SUPPLIES

Xinhao Wang
Diana Mitsova-Boneva
University of Cincinnati
Cincinnati, Ohio

Adequate quantity and quality of water are necessary for human living and activities. A broad definition of water supply includes any quantity of available water. A more restricted concept of water supply refers to water collected and distributed to the general public or to other public or private utilities for residential, commercial, and industrial use. An even narrower definition of water supply only includes the water collected and conveyed for use in a community or a region (1). In the discussion here, water supply refers to water from the process of collection and distribution to meet human demand.

WATER RESOURCES

Water resources are renewable but finite and scarce. As shown in Fig. 1, 97.22% of earth's water is captured in oceans. Its total volume is enormous—1.3 billion cubic kilometers—but inadequate for human consumption because of the salt content. Approximately 2% of water is locked up in polar icecaps and glaciers. Water found in land, including surface water and groundwater, makes up less than 1% of the earth's water resources (2). Groundwater is found in aquifers, moisture-laden strata where water fills the spaces between rock particles. Although only about half of groundwater can be economically withdrawn for human use, it represents more than 97% of the usable freshwater resources. In addition, groundwater is a major source of replenishment for surface water.

WATER CONSUMPTION

Human water consumption consists of three major categories—agricultural, industrial, and domestic water use (3). According to the Food and Agriculture Organization of the United Nations (FAO), agricultural use accounts for 70% of global water withdrawals, while industrial and municipal use account for another 20% and 10%, respectively (4). Farming withdraws large amounts of water from rivers, lakes, reservoirs, and wells in order to irrigate crop fields and sustain plant growth in agricultural and horticultural practices. Almost 60% of the world's freshwater withdrawals are used for irrigation purposes. In Asia, irrigated agriculture averages approximately 82% of all water consumption. The proportion in the United States is 41% and about 30% in Europe (5). Irrigation water is applied through irrigation systems for the purposes of field preparation, preirrigation, application of chemicals, weed elimination, dust reduction, plants cooling, frost protection, leaching salts from roots, and harvesting. Irrigation water is also used by golf courses, parks, nurseries, turf farms, and cemeteries.

Industry consumes the second largest amount of water. In heavily industrialized regions, the percentage could

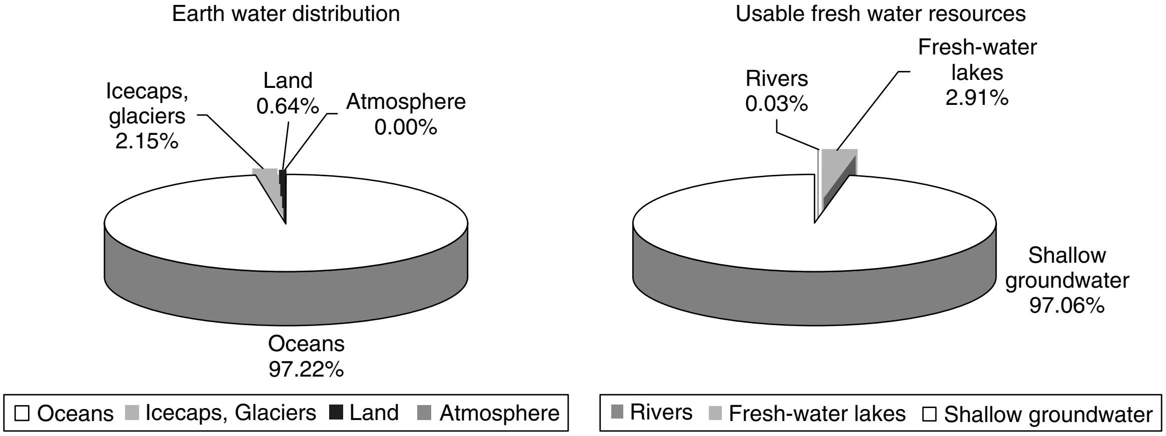

Figure 1. Earth's water resources.

be much higher. In Europe, industry accounts for 52% of the total water consumption and in North America, 44% (6). Almost one-half of the industrial withdrawals are utilized for generating thermoelectric power with steam-driven turbine generators. Much of the industrial water is used for purposes such as cooling and is returned to its source. Large amounts of water are required also by food processing and paper producing industries, oil refineries, and chemical and metallurgical plants.

Domestic water usage accounts for the last 10% of the total water consumption. This category refers to domestic consumption of water for drinking, hygiene, and other household uses, as well as commercial and institutional uses. The consumed domestic water is collected and treated in wastewater treatment plants before being discharged back to a natural water body.

TYPES OF WATER SUPPLY

Water supply systems refer to private (self-supplied, such as private wells) or public (may be operated by public agencies or private companies) withdrawals from ground and surface water designated to serve specific users. The most common is the public or municipal water supply system, which provides water to domestic, public, and commercial users and, occasionally, to industries, hydroelectric and thermoelectric plants, or for irrigation (7). The majority of the population throughout the world, especially urban population, is served by public water supply systems. Figure 2 illustrates the average percentage of the large city population served by each type of water supply service, by region. Household connection or yard tap and public tap are public water supplies. In the more developed regions, such as Europe and North America, more than 96% of the urban population has household connection to public water supply services. In Africa and Asia, considerable numbers of people are not served by public water supply systems.

QUALITY OF WATER SUPPLY

Water is an excellent solvent that can dissolve many elements. The amount of each element affects water quality, reflected in the chemical, physical, or biological condition of water. Therefore, water quality is often measured with what is contained in water, such as dissolved oxygen, suspended solids, pesticides, metals, oils, minerals, and nutrients. Pathogenic bacteria might affect human and animal health and so they are often measured. Physical conditions are another set of water quality measurement, such as water temperature, water color, and turbidity. Water quality also can be assessed with biological indicators, which measure the type and diversity of fish, macroinvertebrate species, and plants (9).

Some uses of water for industrial activities, such as mining, cooling water supply, washing, fire protection, or oil well repressurization, may not depend on water quality. Different industries may have different requirements for water quality, such as the turbidity or temperature. Normally, industrial water use does not require filtration and chlorine treatments.

Quality criteria for irrigation water include measurements of its salinity, alkalization, toxicity, and electrical conductivity. Salinity indicates the presence of high concentrations of chloride, sulfate, and bicarbonate compounds of sodium, calcium, and magnesium. In regions with significant rainfalls, those soluble salts are flushed out from the crop root zone on a regular basis. In arid and semiarid areas, water percolating through the soil is not sufficient to leach those salts. The increasing concentrations may adversely affect crops with low level salt tolerance thresholds. Therefore, irrigation waters must be controlled for their content of dissolved salts in order to prevent further deterioration of the soil quality and reduction of crop yields. There is a direct positive relationship between salt concentrations and the electrical conductivity of irrigation water. Alkalization occurs when the soil is more saturated with sodium than calcium and magnesium. Excess sodium results in high pH, reduced oxygen content, soil erosion, and less nutrient absorption by plants. Some constituents of the irrigation waters such as boron, chloride, and sodium are toxic to crops. Irrigation waters containing such chemicals are not recommended for use in watering soybeans, citrus, or grape plants (10).

Water quality of domestic water supplies has a direct effect on human health. Microbial pathogens that are found to cause enteric diseases in humans include bacteria (such as *Vibrio cholerae, Shigella, Salmonella, Campylobacter*, and *Escherichia coli*), viruses (such as hepatitis A virus and rotavirus), and parasites (such a *Giardia lamblia* and *Cryptosporidium*). Bacterial waterborne infections include cholera, dysentery, salmonellosis, typhoid fever, “traveler’s disease,” and *E. coli* outbreaks. The most common viral disease contracted through contaminated water is hepatitis A. Sewage-tainted drinking water can also cause certain parasitic protozoan diseases such as amebic dysentery and giardiasis. Those diseases are usually contracted by drinking water or eating food contaminated with pathogens of fecal origin. They are characterized by severe diarrhea, vomiting, and cramps, and in some cases, by high fever, headache, and muscle pains. The most common cause of death associated with those ailments is rapid dehydration and subsequent collapse of the vascular system (11).

Domestic water supply for drinking purposes is the most critical of all. The World Health Organization (WHO) estimates that each year approximately 2.5 million children all over the globe, ages 0–12, die of waterborne diarrhea illnesses. Waterborne diseases are the leading cause of death in most developing nations in Africa, Asia, and Latin America. Despite efforts to render safe drinking water to an increasing number of people, as a result of the unprecedented population growth, approximately 1.1 billion people still use unsafe drinking water (12). Water disinfection in the last century has largely reduced the incidence of infectious waterborne diseases. Health officials today and the general public, however, are more and more concerned about chronic health effects potentially caused by the presence of toxic chemicals in drinking water. Ingestion of even small amounts of some inorganic pollutants such as arsenic, lead, cadmium, chromium, mercury, asbestos, cyanide, or nitrates can

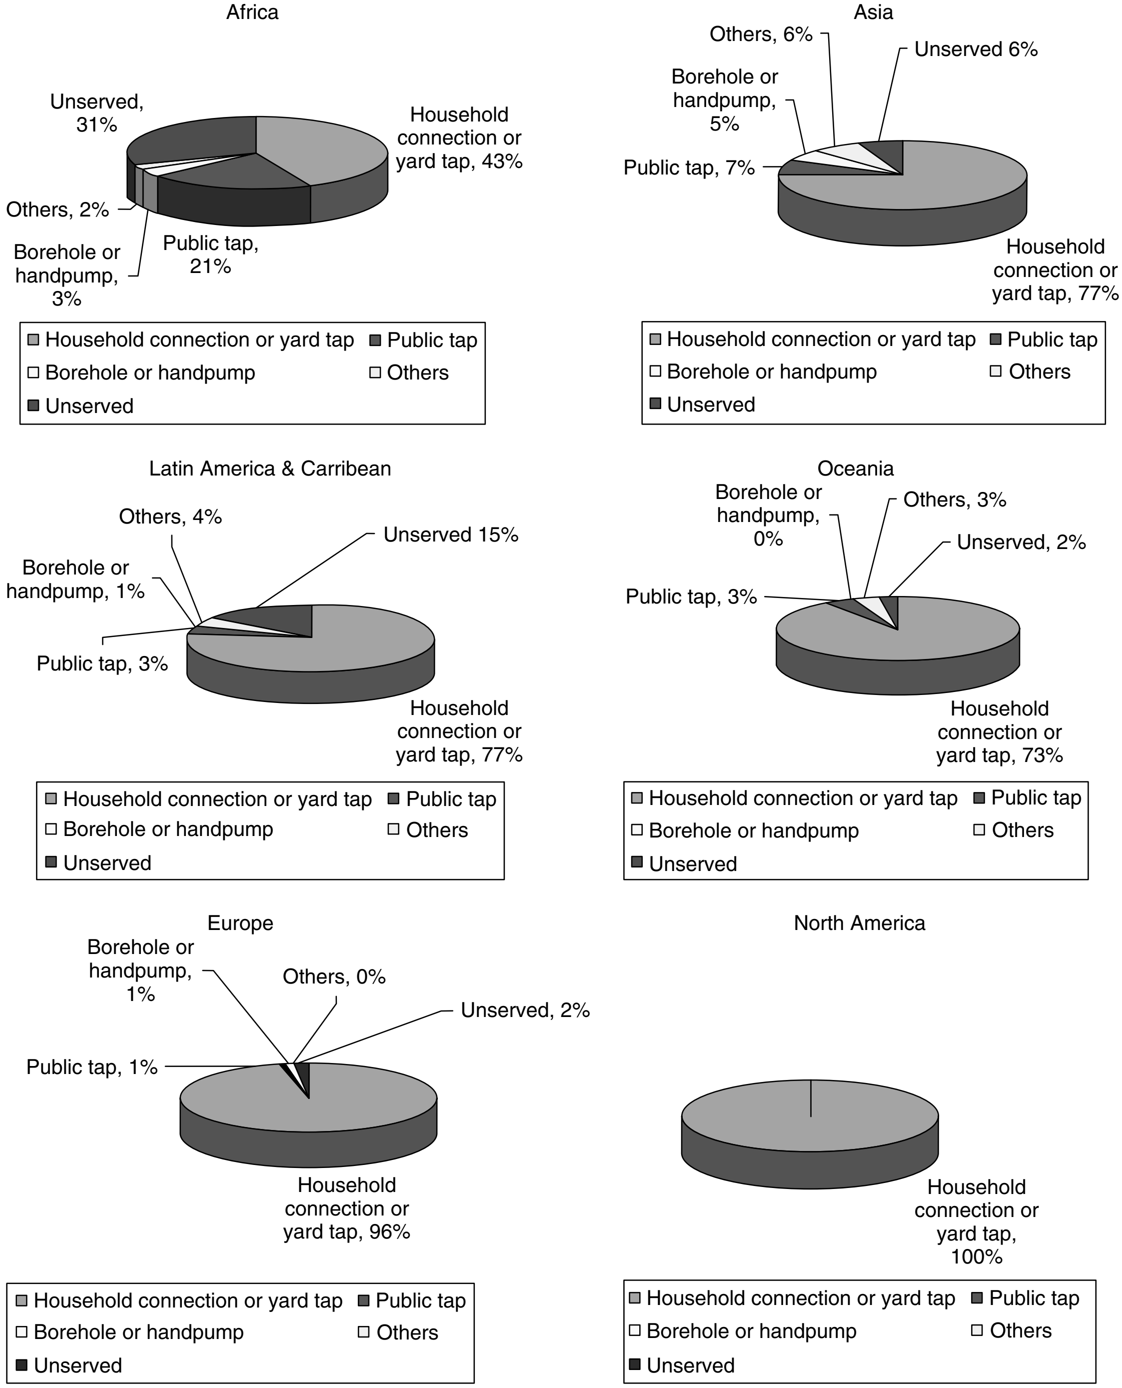

Figure 2. Water supply in the largest cities: average percentage of the population served by each type of service, by region (8).

cause a wide range of health problems. Especially vulnerable to lead poisoning are young children. Ingested lead can result in anemia, neurological disorders, kidney problems, sterility, and birth defects. Evidence suggests that exposure to even very low levels of asbestos in drinking water can result in cancers of the gastrointestinal tract. Although conclusive evidence about cause-and-effect link between chemical contaminants and cancers, birth defects, miscarriages, nervous and reproductive system disorders, and organ damage has not yet been established, there is little doubt that prolonged exposure to some organic and inorganic substances can result in chronic health conditions. Nitrates are another inorganic chemical with serious health effects. The intake of nitrate-containing water by infants under the age of six months may cause methemoglobinemia, known also as the "blue baby syndrome" (13).

The organic compounds detected in drinking water include a wide variety of herbicides and pesticides, disinfection by-products, PCBs, solvents, oils, and so on.

They are volatile and nonvolatile in nature. Many of them are suspected carcinogens (14). *Radionuclides* are also known to be present in some drinking water supplies.

The quality of the drinking water supplies in the United States is one of the highest on earth. With the adoption of the Safe Drinking Water Act in 1974, subsequently amended in 1986 and 1996, the U.S. Congress empowered the U.S. Environmental Protection Agency (U.S. EPA) to enforce regulations aimed at protecting the quality of drinking water supplies. The U.S. EPA has established two sets of standards for water quality: *primary* and *secondary*. The objective of the primary standards is to protect human health. They are based on toxicological, epidemiological, and clinical data. The *maximum contaminant level* (MCL) is the primary standard enforced by the U.S. EPA. Secondary drinking water standards refer to contaminants that create unpleasant odor, taste, and color or may be corrosive or staining. They can cause minor skin irritations or damage clothing and appliances (15). Table 1 displays the major contaminant categories, their potential health effects, and sources of contaminants in drinking water.

FACTORS AFFECTING THE QUALITY OF WATER SUPPLY

The quality of the water source is critical for the quality of water supply. Water pollution refers to the deteriorating quality of water due to the presence of pollutants in the water. Effluent discharges from industries and municipal sewage plants are considered point source pollution. They are relatively easy to identify, regulate, control, and monitor since they are usually located near factories, wastewater treatment plants, septic tanks, or stormwater outfalls. In the United States, industries discharging directly into rivers and lakes are required to apply for permits in accordance with the National Pollutant Discharge Elimination System (NPDES) program. The permit specifies the volume, type, and permissible concentrations of pollutants allowed to be released in the waterways. The other option for controlling industrial discharges is to reuse the treated wastewater instead of discharging it into receiving waters.

Nonpoint source pollutants consist of suspended solids, nutrients, petroleum, inorganic, and radioactive compounds. A major contributor of sediment to the waterways is the runoff from agricultural fields and construction sites. Silt and soil increase the turbidity of water, which impairs the productivity of photosynthetic plants, reduces water depth, endangers bottom-dwelling animals, and suffocates fish. Nutrients enter waterways in the form of fertilizer and sewage runoff, leaves and grass, or as runoff from livestock farms and pastures. Many hazardous chemicals such as asbestos, hydrocarbons, PCBs, pesticides, mercury, and lead enter the waterways

Table 1. The U.S. EPA's National Primary Drinking Water Standards

Contaminant	Potential Health Effects from Ingestion of Water	Sources of Contaminant in Drinking Water
Microorganisms	Gastrointestinal illness, legionnaire's disease	Human and fecal animal waste
Disinfection by-products	Increased risk of cancer, anemia; in infants and young children—central nervous system effects, liver and kidney problems; increased risk of cancer	Human and fecal animal waste
Inorganic chemicals	Increase in blood cholesterol; problems with circulatory system; increased risk of developing benign intestinal polyps; intestinal lesions; kidney damage; allergic dermatitis; nerve damage or thyroid problems; bone disease (pain and tenderness of the bones); delays in physical or mental development of infants and children	Discharge from petroleum refineries; ceramics; erosion of natural deposits; runoff from glass manufacturing sites; decay of asbestos cement in water mains; erosion of natural deposits; discharge from metal refineries; corrosion of galvanized pipes; discharge from steel and pulp mills, plastic and fertilizer factories; water additive that promotes strong teeth; corrosion of household plumbing systems; erosion of natural deposits
Organic chemicals	Nervous system or blood problems; increased risk of cancer; eye, liver, kidney, adrenal gland, or spleen problems; anemia; cardiovascular system or reproductive problems; circulatory system problems; thymus gland problems; immune deficiencies	Added to water during sewage/wastewater treatment; runoff from herbicide used on row crops; leaching from gas storage tanks and landfills; leaching from linings of water storage tanks and distribution lines; leaching of soil fumigant used on rice and alfalfa; discharge from chemical plants, agricultural chemical factories, and other industrial activities; residue of banned termiticide; runoff from herbicide used on rights of way; runoff/leaching from soil fumigant used on soybeans, cotton, pineapples, and orchards; emissions from waste incineration and other combustion; discharge from wood preserving factories; discharge from rubber and plastic factories; leaching from landfills; discharge from factories and dry cleaners; runoff/leaching from insecticide used on cotton and cattle; discharge from textile finishing factories; breakdown of heptachlor; residue of banned insecticide

through airborne deposition. Acid rainfall is a typical example of airborne pollution that affects the waterways.

In addition to water quality at sources, the contamination of distribution pipelines may be a major concern for the quality of water supply. One cause of contamination is cross-connection, where there is a physical connection between a drinking water supply line and a source of contamination, such as viruses, bacteria, and nitrate. The materials of pipes could also be the source of contamination, such as lead dissolved from pipes and plumbing fixtures.

TREATMENT OF WATER SUPPLIES

A water supply system normally consists of facilities for water withdrawal, storage, treatment, and distribution. After treatment, water is usually resent into the distribution system or to water storage reservoirs (16). Water suppliers apply different types of treatment according to the type of water use and the quality of their source water. Some groundwater supplies can meet the standard requirements without any additional treatment. In most cases, however, and especially when it comes to surface water supplies, a combination of treatment methods is applied to remove contaminants from raw water.

The first stage of the water treatment process is usually to settle the water in order to separate the large solid debris. During the process of c*hemical coagulation* the synthetic organic polymers (cationic and anionic) are aplied to coagulate colloidal material. During *flocculation*, often preceded by *rapid mixing*, tiny particles combine into larger and heavier “flocs.” S*edimentation* is used to reduce sediment loads in raw water both before and after flocculation. It allows for the removal of sand, silt, gravel, and alum floc. Some hard waters require an additional chemical treatment before filtration. Lime-soda softening is applied to raw waters rich in calcium and magnesium. As in flocculation, softening converts hardness-creating ions into insoluble precipitates, which are then removed through settling and filtration. Some raw water supplies containing iron, manganese, and volatile organic compounds need to be treated by *aeration*. This method allows for the oxidation of chemicals, formation of precipitates, and their subsequent removal by filtration. *Filtration* is mostly a physical process in which the water flows through beds of gravel, sand, anthracite, or diatomaceous earth. However, in order to increase its effectiveness, coagulants are also applied throughout the filtration process. *Adsorption* involves the application of activated carbon, which adsorbs nonvolatile organics and some taste- and odor-causing compounds. Ion exchange is used to remove inorganic chemicals (such as arsenic, chromium, or excess fluoride) as well as nitrates and radionuclides (17).

Chlorination, ozonation, and ultraviolet radiation are methods used during the proccess of *disinfection*. Chlorination is very effective in killing bacteria but less effective in eliminating viruses and protozoans. However, it has the advantage to continue the process of disinfection in the distribution pipes. Ozonation and UV radiation have powerful germicidal effect but both have disadvantages. Ozone has a very short half-life and must be generated electrically at the point and at the moment of use. UV disinfection is applied through UV lamps, which allows for contamination (18). Figure 3 illustrates the process in a domestic water treatment plant in Cincinnati, Ohio (19).

Desalination is not a typical water treatment method. However, in arid coastal areas or in regions with mounting pressure on existing freshwater resources, desalination is routinely used to transform seawater into potable water. Saudi Arabia is the leading producer of desalted water in the world. Two methods of desalination are usually applied. Smaller plants rely mainly on reverse osmosis, while larger producers use multistage flash distillation processes (20).

PROTECTION OF WATER RESOURCES

Rapid industrialization since the nineteenth century has been accompanied by reckless waste management practices, which had turned many surface water bodies into sewers or algae-coated cesspits containing microorganisms, toxic chemicals, heavy metals, organic pollutants, pesticides, fertilizers, and their by-products. In addition, these contaminants penetrate the soil, where they can

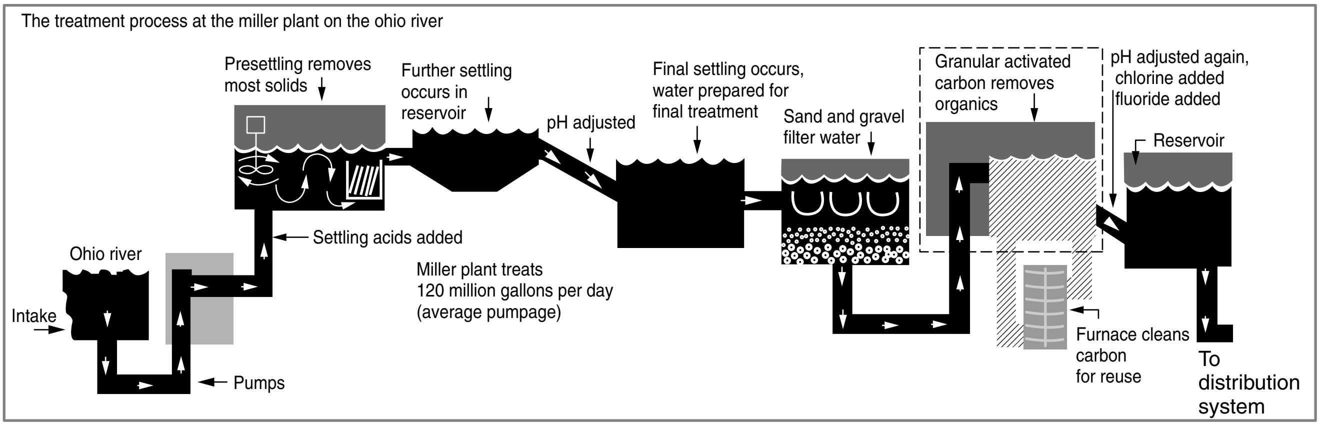

Figure 3. A domestic water treatment plant.

reach the water table and deteriorate the quality of groundwater. Since most of the freshwater supplies rely on groundwater and the slow flow of groundwater, it is critical to keep groundwater from being contaminated. Both the United States and the European Commission have come to the conclusion that setting chemical quality standards for groundwater is not appropriate, as it creates the impression of an allowed level of pollution.

The World Bank estimates that during the past century water consumption has risen sixfold, which is twice as fast as the rate of population growth. By the year 2025, four billion people, particularly in Africa, the Middle East, and South Asia, are expected to live under conditions of severe water stress, if appropriate actions are not taken (21). The total volume of water consumption also affects the quality of water supply. In order to keep the demand within the safe yield of the system, many cities are implementing water-saving policies and restrictions (22).

Three major irrigation methods—sprinkler, microirrigation, and surface (flood)—are applied (23). In general, only a small portion of the irrigation water is actually reaching its intended target. The majority is transformed into vapor through the processes of evaporation and transpiration or is lost in transit (24). Many conventional methods should be supported to increase field water use efficiency and the crop productivity of unit water consumption. Through more efficient irrigating practices such as the automated drip irrigation, alternate irrigation in controlled root zones, and water-deficit-regulated irrigation can substantially reduce water demand in agriculture without reducing crop yield (25). Research has shown that comprehensive water-saving farming technology can increase irrigation productivity 10–15% (26).

Water conservation approaches should also be applied in manufacturing and mining industries and in urban areas to establish a water-saving society. To do so, industrial wastewater should be treated and reused to increase the utilization ratio. Sustainable water resources will not only efficiently support the existing socioeconomic systems but will also provide the required quantity and quality of water at reasonable cost in the future (27).

THE SUBMITOCHONDRIAL PARTICLE ASSAY AS A BIOLOGICAL MONITORING TOOL

Francis G. Doherty
AquaTox Research, Inc.
Syracuse, New York

BACKGROUND

While studies assessing the toxicity of environmental contaminants to aquatic organisms date back to the early 1900s, the use of toxicity testing as a tool for monitoring the environmental acceptability of discharges from wastewater treatment and manufacturing facilities to surface waters (i.e., rivers, lakes, and oceans) did not begin to evolve until the 1970s. One of the primary motivating factors behind the development of biological monitoring, or biomonitoring, was the manufacture of exponentially increasing numbers of new chemicals for which analytical procedures were generally lacking. Biomonitoring was viewed as an approach to detect the presence of potentially toxic chemicals in facility discharges without necessarily having to identify the contaminants at that stage of the assessment. Additional advantages included the reduced expense associated with biologically testing significantly greater numbers of samples in comparison with analytical procedures. This approach also focused on only biologically available forms of the chemicals in solution reflecting any interactive effects (synergistic or antagonistic) that might be occurring among contaminants within a complex sample.

Initial research efforts in the biomonitoring field tended to focus on identifying a "most sensitive species" that satisfied a variety of other criteria. These criteria included, but were not necessarily limited to, widespread geographic distribution and ease of culture in the laboratory so as to provide a steady supply of consistently healthy test organisms. A significant amount of effort was also invested in the development of standardized protocols that focused on the control of test variables to provide guidance to laboratories conducting aquatic toxicity tests, thereby permitting direct comparisons of toxicity data from multiple sources.

This preliminary round of research tended to use common endemic fish species (e.g., salmonids and cyprinids) and planktonic invertebrates (e.g., Cladocerans) that served as a food source for larval fish stages as the primary test species in whole organism assays. Lethality and growth or reproduction served as test endpoints. These efforts ultimately led to the development of acute ("short-duration") and chronic ("long-duration") standardized protocols most often employing the fathead minnow, *Pimephales promelas*, and the Cladoceran *Ceriodaphnia dubia* for discharges to freshwater systems (1,2). Companion protocols were also developed for discharges to brackish and marine environments employing saltwater organisms.

This initial focus, however, quickly and almost simultaneously expanded to include other less common fish and invertebrate species along with surrogate microorganisms and *in vitro* biochemical assays in a continuing attempt to identify that elusive "most sensitive species or assay." Alternately, these activities addressed refining or enhancing existing protocols with the primary, preferred species. Other objectives included in this broad research effort included accelerating the pace at which analyses were conducted by primarily reducing the exposure time for standardized tests, which also resulted in a reduction in the cost of testing.

SUBMITOCHONDRIAL PARTICLE ASSAY

One such surrogate assay developed during the early to mid-1980s was the *in vitro* submitochondrial particle (SMP) assay (3–6). This assay exposes processed mammalian mitochondria to samples of interest and spectrophotometrically monitors the concentration of NADH to assess the level of "toxicity" exerted by contaminants present in the test solution. SMPs are prepared from bovine heart mitochondria according to the procedure detailed in Hansen and Smith (7). Briefly, the patented SMP production process involves sonically disrupting isolated mitochondria and separating the inner and outer membranes by differential centrifugation. The inner-membrane isolates retain more than 60 fully functional interacting enzymes associated with cellular electron transport and oxidative phosphorylation. Since the test system is in direct contact with test material, there are no physical barriers interfering with the interaction between the test material and receptors as there are in whole organism tests, thereby creating a potentially ultrasensitive assay.

There are two distinct and functional complementary assays utilizing SMPs. The electron transfer (ETr) assay assesses forward electron transfer through the entire electron transport chain. The test endpoint is the loss of NADH monitored as a decrease in absorbance at 340 nm in a standard spectrophotometer using 1-cm path length disposable methyl acrylate cuvettes. The reverse electron transfer (RET) assay assesses effects on electron transfer and energy coupling processes. In this test, energy derived from the hydrolysis of ATP drives electrons in the reverse direction, up the electron transport chain. The test endpoint is the production of NADH also monitored at 340 nm on a standard spectrophotometer. Sample preparation and absorbance measurement patterns for the RET assay parallel that described for the ETr assay.

Processed SMP and associated reagents for conducting tests are commercially available. Reagents for conducting the assays include SMP diluent for diluting particles to 1.5 mg/mL; RET and ETr concentrated reaction mixtures (CRM) containing buffer, electron donors (RET CRM only), and cofactors required by the SMP, adenosine-5-triphosphate (ATP) for activating the RET reaction, and ß-nicotinamide adenine dinucleotide sodium salt, reduced

Table 1. Final Concentrations of Particles, Activating Agents, and Concentrated Reaction Mixture (CRM) Components for the Reverse Electron Transport (RET) and Electron Transport (ETr) Submitochondrial Particle (SMP) Assays

SMP	RET	ETr
Particles	0.05 mg/mL	0.0167 mg/mL
Activating agents	3.33 mM ATP	0.137 mM NADH
CRM components	50 mM HEPES (pH 7.5) 6 mM Mg^{2+} 5 mM K^+ succinate 1 mM NAD^+	50 mM HEPES (pH 7.5) 6 mM Mg^{2+}

form (NADH $2Na^+$) for activating the ETr reaction. Unpublished data generated in the author's laboratory has revealed that particles held at −80 °C for up to six months remain fully functional. In contrast, some vials of particles held at −20 °C for that same period of time exhibit a reduction to complete loss of activity that is not directly related to storage duration. The final concentrations of particles and reagents in the two assays are provided in Table 1.

The objective of an individual test is to determine the median effective concentration (EC_{50}): the concentration at which the rate of NADH loss (ETr) or production (RET) is twofold the rate observed in the control treatment. Individual rates of NADH loss or production (as expressed by the slopes of the lines-of-best-fit for each treatment) are determined by simple linear regression analysis for the relationship between time and the mean NADH concentration between replicates within a treatment. Individual slopes are then used to calculate percent inhibition values relative to the control treatment for each toxicant treatment. The EC_{50} for an individual test is determined from the linear portion of the regression of individual treatment percent inhibition values versus concentration. Determination of linearity (i.e., which points to include in the generation of the line-of-best-fit) is achieved through both qualitative and quantitative criteria. Plots are visually assessed to identify a linear portion to the curve and supplemented with the generation of coefficient of determination (R^2) values to confirm the most consistent relationship among points to include in the lines-of-best-fit. The statistical analyses can be conveniently performed by routine spreadsheet software.

EXISTING LITERATURE REVIEW

Published studies assessing the sensitivity of SMPs to test materials can be segregated into two broad classes—those dealing with pure chemicals and those dealing with environmental samples. Studies focused on assessing the toxicity of pure chemicals did not directly relate to the use of SMPs for environmental monitoring. Rather, these studies for the most part simply attempted to demonstrate the potential for use of SMPs for biomonitoring by invoking the limitations associated with existing methods and comparing the sensitivity of the SMP assay with other more established tests. For example, Bragadin and Dell'Antone (8) cited the cost and duration of acute fish tests as motivation for the development of alternatives such as the SMP assay. They reported the EC_{50} values for a few dozen toxic compounds using a modified approach to the assay described above and concluded that the results from their assay compared favorably with published values of toxicity for other species that included rainbow trout and the commercial bacterial luminescent assay, Microtox®.

Similar approaches were adopted using the RET variant by Argese et al. (9) with linear alkylbenzene sulfonates, nonylphenol polyethoxylates, and their derivatives; by Argese et al. (10) with chlorophenols; by Argese et al. (11) with heavy metals; and by Argese et al. (12) with chloroanilines. Each study compared their in-house generated toxicity values from the RET variant of the SMP assay with published literature values for other species, and in general concluded there were significant levels of correlation with many of the existing assays. Researchers associated with the development of the SMP assays also published their own results with a substantial set of diverse chemicals ($n = 162$) tested with one of the SMP assay variants while comparing toxicity values with published endpoints for other species (13). Their conclusions mirrored those of other researchers in this field while they also summarized other current issues related to the state of the SMP assays.

A second group of studies also reported relationships between toxicities of test materials (both pure chemicals and environmental samples) generated through the SMP assays and other species but relied on data generated within their own laboratories rather than from published literature values. This approach tends to be more reliable since each investigator has control over test variables associated with each assay conducted within their lab. Data drawn from multiple published studies containing data generated by a variety of individuals is inherently more variable due to inconsistencies in test protocols and investigator techniques from one laboratory to another.

Miana et al. (14) compared the toxicity of tributyltin to the green alga *Selenastrum capricornutum* and the Cladoceran *Daphnia magna* to submitochondrial particles and concluded that SMP assay was fast, reproducible, and easily handled. Bettermann et al. (15) assessed the toxicity of elutriate samples from sediments previously demonstrated to be toxic to the amphipod *Hyalella azteca*. They reported a significant correlation between ETr EC_{50} values and amphipod survival for two of three watershed sites. No such relationship was observed between results from the RET assay and sediment elutriates from any of the watersheds. Dutka et al. (16) used a multispecies test battery to assess water and sediment toxicity from two river basins in Chile. The SMP RET assay was among those suggestive of toxicity in several of the samples collected during this study.

Weideborg et al. (17) compared the RET variant with six other routine toxicity tests to assess the toxicity of 82 soluble and non-water-soluble chemicals. They reported similar EC_{50} values for both the RET variant and Microtox tests for low toxicity chemicals, with Microtox being the more sensitive of the two. However, the relationships among all of the tests for a diverse set of test substances was variable and may have been a function of test design rather than test sensitivity. Sherry et al. (18) assessed the toxicity of refinery effluents with Microtox, a variety of algae, invertebrate, and fish tests, and the RET variant of the SMP assay. They reported that acute toxicity was detected only by the Microtox and SMP tests. Argese et al. (19) compared the RET assay with Microtox for their sensitivity to 14 organotin compounds. They reported good agreement between the two assays with comparable sensitivity for organotins with an R^2 of 0.92. Sheesley et al. (20) used the RET variant, the invertebrate *Ceriodaphnia dubia*, and the green alga *S. capricornutum* to assess the toxicity of aqueous and organic solvent extracts of atmospheric particulate matter from the Lake Michigan airshed. Based on a direct comparison of LC_{50} and EC_{50} values, the RET SMP assay was the most sensitive of the three for aqueous extracts of particulate matter from three different sites.

ENVIRONMENTAL MONITORING WITH SMPs

As outlined above, studies assessing the potential for SMPs as a routine biomonitor generally attempted to compare the sensitivity of one or more of the SMP assay variants with that of an established assay. Investigators either ranked assays by comparing each assay's sensitivity to an individual chemical or environmental sample or generated regression analyses for pairs of assays over a range of toxicities from groups of test substances. However, while sensitivity should be a factor in the selection of surrogate assays, it is not the only parameter that needs to be considered.

Biological monitoring, as taken in the current context, was instituted for protection of natural aquatic systems, not wildlife or human health protection. To that end, the initial species selected for that task were considered representative of the aquatic environment. Consequently, the most appropriate surrogate species or assay for that purpose would be one that is equally, but not overly, sensitive to a broad range of chemicals as the primary biomonitoring species while incorporating advantages not provided by the primary species. Such advantages might include reduced test duration time or reduced expense associated with the conductance of those tests. Adopting a surrogate assay that exhibits increased sensitivity relative to the primary test species may prompt expensive remedial actions that are not necessary for the protection of the system under study. SMP assays have exhibited the potential to be among the most sensitive assays conducted with a group of chemicals or environmental samples.

One of the confounding issues related to sensitivity rankings is the change in rank among assays for different types of contaminants. The SMP assay variants are not immune to this type of variability as demonstrated by some of the studies cited above. The solution to this dilemma involves the development of multispecies test batteries with the components of those batteries exhibiting alternating sensitivities to varying chemical classes. Positive (toxic) responses by one or more components within the test battery should then be taken as an indication of contamination. SMP assays have exhibited the potential for being a constructive component of a multispecies or multiassay test battery.

As noted above, any assay adopted for biomonitoring purposes needs to be standardized so that results from different groups of investigators are compatible and comparable. In this regard, the SMP assays are only in a rudimentary stage of development. Manual test protocols only include an approach for generating EC_{50} values involving serial dilution of test solutions. There are no formalized screening procedures for whole environmental samples or order-of-magnitude dilutions for chemical samples. Additionally, the data analysis approach currently in use involves a subjective selection of data points used in the generation of an EC_{50}. This aspect of the assay will need to be evaluated so as to minimize differences in the test endpoints not necessarily related to the toxicity of the test material itself.

Included within the standardization process is the reproducibility of an assay. There have been no studies addressing between-laboratory reproducibility for either of the SMP assay variants. The only published study related to this point focused on the within-laboratory repeatability of the ETr and RET assay variants (21). They reported coefficients-of-variation that were comparable to more traditional assays using three different reference toxicants. Since the level of variability exhibited by an assay increases in between-laboratory round robin studies in comparison with in-laboratory results, such a study is necessary to further consider SMP assays as surrogates for traditional aquatic toxicity tests.

Lastly, SMPs are a manufactured test system in contrast with existing traditional assays that use whole organisms. A great deal of research has been invested in developing culture methods for standard test species so that tests are conducted with consistently healthy test organisms. There are no published studies available assessing variabilities associated with the manufacturing process aside from a preliminary study conducted within the author's laboratory.

CONCLUSION

The SMP assay variants have exhibited the potential to serve as surrogate biomonitoring assays in freshwater systems. Test results have demonstrated that the one or both variants are as sensitive or more sensitive than traditional assays. However, SMP assays are only in a rudimentary stage of development with respect to biomonitoring applications. Both the manufacturing and testing protocols need to be standardized and evaluated prior to serious consideration of SMP assays as a legitimate surrogate biomonitoring option.

MICROSCALE TEST RELATIONSHIPS TO RESPONSES TO TOXICANTS IN NATURAL SYSTEMS

JOHN CAIRNS, JR.
Virginia Polytechnic Institute
and State University
Blacksburg, Virginia

A primary purpose of ecotoxicology is to estimate toxicity thresholds below which no observable deleterious effects can be detected upon ecosystems. Since uncertainty is unacceptably high when extrapolations are made from single species (1), tests at higher levels of biological organization are much more effective (2). Moreover, such levels of testing permit increased opportunities of testing for alteration of functional attributes (3). Large-scale tests are both risky and expensive; consequently, microscale testing has been developed.

Microscale testing can be carried out with standardized communities, which are superb in furnishing a validated set of results. However, standardized communities do not closely resemble communities from natural systems. Communities from any two natural systems rarely contain the same species. However, any naturally derived community will contain species that span a range of tolerance to stress. This range of tolerance can be generalized from one natural community to another. This extrapolation provides predictive capabilities, which are the ultimate goal of ecotoxicological testing. Furthermore, culturing test organisms for use in microscale testing customarily consumes as much or more time than the testing itself.

Microscale toxicity testing with communities obtained from natural systems has many benefits, in addition to reducing culture problems typical of laboratory-assembled communities. Methods are even available for carrying out microscale toxicity testing in natural systems (4). Communities of organisms that have colonized artificial substrates can be collected. These collections are not artificial communities, although convenience sometimes dictates naming these communities "artificial" in order to distinguish them from collections made directly from natural substrates. Artificial substrates (5) have major advantages in microscale testing.

1. The age of the community is known.
2. A determination can be made of when the community has reached a dynamic equilibrium comparable to that of the system that furnished the colonizing organisms.
3. Natural systems are not disturbed by sampling efforts.
4. Communities can be moved to the microscale test system with minimal disturbance to the community that is the subject of the test.
5. Communities in the natural system can be monitored to determine if changes in either structure or function have occurred that were evident in the microscale system as a result of toxic stress.
6. Since microbial species have a cosmopolitan distribution, results from different geographic regions can be compared.
7. Since microorganisms and macroinvertebrates are much more abundant than larger organisms higher in the food chain, their use in toxicity testing is more likely to be accepted by animal rights groups.
8. Microscale tests allow a setup of many more concentrations in the same space that would be necessary for far fewer larger scale tests.
9. Automation is possible for the counting of numbers of individuals per species and total number of some species used in microscale toxicity tests (6).

Microscale testing units are not miniature ecosystems. Properly designed, they can mimic selected cause–effect pathways (e.g., nutrient cycling and prey relationships) (7) not observable at lower levels of biological complexity. However, they do not have all the cause–effect pathways found in natural ecosystems and landscapes. Some relevant discussions of complex system testing (8) and examples of microscale testing (9,10) are available in the literature. Suitability of the microscale test design can be confirmed by comparing measurements made in it to similar measurements in natural systems (11). Methods are available for the statistical analysis of this unique evidence (12–14). One of the most difficult attributes to include in microscale testing is the invasive pressure of organisms that are attempting to colonize (12). This invasion pressure is one of the major factors in succession of species in natural systems.

The major disadvantage to microscale toxicity testing is that sometimes a modest degree of taxonomic ability is essential. Taxonomy is often not taught in many American institutions of higher learning. However, staff members with no taxonomic ability can be instructed in just a few months in levels of identification necessary in some microscale tests, although years of experience are necessary for the more complex microscale toxicity tests.

TOXICITY IDENTIFICATION EVALUATION

Philip J. Markle
Whittier, California

Bioassays for aquatic chronic and acute toxicity testing using standardized methods have been used to measure toxic effects and in some cases can even estimate the magnitude of toxicity for many years. Their use has been incorporated into regulatory requirements for point and nonpoint discharges to both marine and freshwater environments. However, these standard methods provide virtually no information on which constituent(s) are responsible for the observed effect. Reliance on only chemical-specific analyses to determine the causative agent(s) in a water sample exhibiting toxicity or suspected of being toxic to aquatic organisms can be misleading. Initially, the list of potential toxicants that would need to be quantified is nearly limitless, not to mention costly.

Additionally, even GC/MS analyses may not be sensitive enough to detect low concentrations of some toxic substances. Furthermore, even if elevated levels of a particular compound are identified, the compound may or may not be bioavailable, and receiving water characteristics (i.e., total organic carbon, hardness, salinity, pH) may confound the observed toxicological sensitivity. Chemical quantification will also not identify any additive, synergistic, or antagonistic properties of many toxicant combinations. It was specifically because of these concerns that aquatic toxicity testing was developed and incorporated into many water pollution control plans.

The U.S. EPA has developed and published several manuals detailing specific methods for identifying toxic constituents (1–4). These methods are collectively referred to as "toxicity identification evaluations" (TIEs) and are often incorporated as part of a larger site-specific study identified as a "toxicity reduction evaluation" (TRE). The ultimate goal of a TRE is to identify toxic constituents, identify their sources, evaluate toxicity control options, and eventually eliminate the toxicity. The TIE is typically used to identify the toxic constituents and to evaluate the effectiveness of the toxicity control mechanisms. During the initial stages of a TIE (phase 1), toxicity is characterized through a series of sample manipulations followed by toxicity testing. These manipulations typically include pH adjustments, chemical additions (EDTA and sodium thiosulfate), chemical extractions (solid phase extraction), and physical manipulations, (filtration and aeration) followed by toxicity testing to assess any increases or decreases resulting from the manipulation.

The relative increases or decreases in observed toxicity in the subsequent toxicity tests conducted on the manipulated sample often characterize the properties of the chemical constituent(s). For example, a decrease in toxicity observed in the EDTA addition tests would indicate possible metal toxicity. A list of commonly applied phase 1 TIE manipulations and their interpretation is contained in Table 1. Other manipulations and result interpretations are specifically detailed in the U.S. EPA manuals. Once characterized in phase 1, the investigator would proceed to phase 2 to identify the individual constituent(s). The phase 2 TIE procedures incorporate additional toxicity testing and/or analytical methods. The testing and/or analytical measurements vary, depending on the phase 1 characterization interpretations. The last phase of the TIE procedure (phase 3) consists of a series of final confirmation steps designed to provide a "weight of evidence" approach in confirming the causative agent(s). Through the establishment of causal links and correlations, the approach is designed to ensure that suspected toxicants are conclusively identified and consistent from sample to sample.

Table 1. Summary of Commonly Applied Phase 1 TIE Manipulations and Associated Interpretation

TIE Manipulation	Purpose/Interpretation
Baseline—no manipulation	Conducted to determine if toxicity is present
EDTA addition	Controls most metal (cationic) toxicity
Sodium thiosulfate addition	Reduces easily oxidizable compounds such as chlorine or some metals
Piperonyl butoxide addition	Controls toxicity due to organophosphate pesticides An increase in toxicity would indicate possible pyrethroid pesticide toxicity
pH control at 6.5	Controls ammonia/metal toxicity A decrease in toxicity may indicate ammonia/metal toxicity
pH control at 8.5	Controls some metal toxicity An increase in toxicity would indicate ammonia and/or some metal toxicity
Aeration	Removes volatile compounds and some surfactants
Filtration	Removes solids and some surfactants
Solid phase extraction (SPE)	Removes nonpolar organic compounds and some surfactants Recovery of toxicity from the SPE column indicates nonpolar organic toxicity Failure to recover toxicity from the SPE column indicates surfactant toxicity

Identification of what is "toxic" in aquatic toxicity tests is most often determined quantitatively through the regulatory process as permit limits or objectives and no definitive standards have been defined or are universally used. Although no universal definitions exist, several measures of toxicity are more commonly employed and seem to have achieved greater acceptance. These include the use of the "no observed effect concentration" (NOEC) or "no observed effect level" (NOEL). The NOEC and NOEL use hypothesis testing to identify statistically significant differences relative to a nontoxic control. The NOEC or NOEL is defined as the highest concentration not significantly different from the control. Another commonly used analysis involves various point estimation techniques. These quantitative analyses use dose–response data to estimate "safe" or "nontoxic" concentrations or effects using metrics such as the LC_{50} (lethal concentration causing a 50% effect) or EC/IC_{25} (effective or inhibition concentration causing a 25% effect). Due to the large amount of toxicity testing required in the TIE process, reductions in testing replication and exposure volume and duration are often made to save on sample and staffing resources. Results are typically represented qualitatively as opposed to quantitatively that is, relative increases or decreases in toxicity compared to the no manipulation treatment or appropriately manipulated control were observed. Although fairly straightforward, several things can significantly complicate the TIE process. To identify the causative agent, a sample must first exhibit toxicity. For this reason, the persistence of toxicity is often a confounding factor. Multiple samples eventually need to be collected and tested during the course of the analysis. If toxicity is episodic or sporadic, collection and subsequent testing of a suitably toxic sample will also be more unlikely. Most TIEs are conducted during the course of 1 to 2 weeks requiring extended holding of samples. Constituents that rapidly degrade during this extended holding time can often confound identification due to a loss of toxicity. Furthermore, the numerous manipulations and increased holding time necessary in conducting a TIE may also alter basic water quality characteristics that may artificially affect the observed toxicity. For these reasons, successful completion of a TIE is much more likely in samples exhibiting a large amount of toxicity. Another common complication involves multiple constituents. If a sample contains two or more toxic constituents, the investigator will need to identify at least one of the constituents and selectively remove or control its toxicity without impacting the others prior to attempting to identify the other constituent(s).

Although much more work conducted using freshwater organisms has resulted in greater acceptance and standardization in the freshwater methods, the described TIE procedures have been successfully used to identify and ultimately control toxic compounds in effluents and freshwater and marine receiving waters. It would be impractical to detail all of the possible TIE manipulations and their interpretation in this overview. The referenced manuals provide specific details on all aspects of the conduct and interpretation of TIE results. Copies of the referenced manuals may be obtained directly from the U.S. EPA (http://www.epa.gov/waterscience/WET/).

WHOLE EFFLUENT TOXICITY CONTROLS

Philip J. Markle
Whittier, California

The selection of an appropriate control sample/water for whole effluent toxicity testing is a critical experimental design component. Whole effluent toxicity (WET) testing has been an important tool for toxicity compliance and research testing alike to identify acute and chronic toxicity in effluents and receiving waters. The U.S. EPA and others have developed several manuals detailing specific WET methods; many have been incorporated into the National Pollutant Discharge Elimination System (NPDES) permit program for compliance determination. The primary objective of these aquatic toxicity tests is to estimate a maximum "safe" concentration of toxic substances in a discharge or receiving water that will allow for normal growth and propagation of aquatic organisms. A typical WET test experimental design consists of exposing organisms under controlled laboratory conditions to a series of effluent, receiving water, and/or toxicant dosed samples and recording biological observations such as reproduction, growth, and survival.

A set of exposures is concurrently conducted using control water. The biological results obtained from the effluent/receiving water exposures are then qualitatively or quantitatively compared to the results obtained in the control water exposure to identify relative reductions in biological response as an indication of toxicity. Effects relative to the control are used to estimate toxicity in a WET test, so control water selection can be critical. Control water that stimulates an unusually large response or enhancement when compared to a more normal response in the effluent/receiving water is more likely to identify falsely that a sample is "toxic," when it was not. Likewise, control water that exhibits a suppressed response when compared to an effluent/receiving water that exhibits toxicity is more likely to be identified as nontoxic when in fact it was toxic. Nontoxicity related factors associated with control waters can elicit a stimulatory or inhibitory response in test organisms. These factors need to be identified by the investigator and carefully controlled to minimize any misidentification of toxicity or nontoxicity in a WET test.

In multiconcentration tests, the same control water is also used to dilute the effluent or receiving water to the appropriate concentration. For this reason, control water is often referred to as *dilution water*. Although the amount of sample increases as concentration increases, the amount of dilution water likewise decreases as concentration increases. The U.S.EPA whole effluent toxicity testing protocols define acceptable dilution water as water that is appropriate for the test objectives, supports adequate test organism response measured in the test, is consistent in quality, and is free of contaminants that could cause toxicity (1–3). Although test organisms may have a wide range of tolerance to many commonly measured water characteristics (pH, hardness, conductivity, salinity, etc.), it is likely that the organisms have a much narrower "optimal" range. Differences in these basic water characteristics between control water and effluent samples may account for an apparent observed difference in toxicological response in a WET test when in reality, the sample was actually nontoxic. Furthermore, control water/effluent sample interactions in multiple concentration tests could increase or decrease apparent toxicity and result in improper identification of toxicity.

Selection of an appropriate control water will depend in some part on the objectives of the experiment. If the primary objective of the test is to quantify the relative toxicity of a sample over time or location (i.e., is sample "A" more or less toxic than sample

"B," or is discharge "A" more toxic this month than it was last month), synthetic control water would be most appropriate. Dilution water characteristics such as hardness, pH, magnesium/calcium ratios, and many others can drastically effect the toxicological response in a test. It is impossible to understand or predict all of the dilution water/sample interactions that may effect the toxicological response, so the incorporation of standard synthetic control water allows the investigator to eliminate these concerns when the objective of toxicity testing is to measure relative toxicity. Synthetic dilution water is prepared by dissolving fixed amounts of reagent grade salts into high purity de-ionized water. For synthetic freshwater, $NaHCO_3$, $CaSO_4$, $MgSO_4$, and KCl are the most commonly incorporated reagent salts. Commercially available seawater reagents are available for testing with estuarine and marine species. The referenced U.S. EPA method protocols provide detailed preparatory procedures for many of these waters. The advantages of synthetic waters are that they are very consistent from batch to batch, would not be expected to contain toxic constituents, and are easily prepared. The disadvantages of synthetic waters are that they are typically nutrient poor and although adequate, may not be "optimal" water for the test organisms.

If the objective of the test is to estimate or predict ecological impacts on the receiving water, control water with similar receiving water characteristics should be used. The more similar the control water characteristics are to the receiving water, the more predictive the toxicity test will be. Characteristics most commonly simulated include pH, hardness, alkalinity, and conductivity. However, differences between receiving water and control water in other less understood characteristics such as total organic carbon and micronutrient concentration, to name only a few, may significantly compromise the predictive ability of the toxicity test and may require further investigation. An immediate upstream receiving water not influenced by the discharge may be a suitable source. The advantages to using receiving water is that sample/control water interactions are accounted for in the toxicity test design with little effort and surface waters tend to be higher in micronutrient content than synthetic waters. Disadvantages of using receiving water include the possibility that they may contain toxic constituents, they may contain pathogens or predatory organisms, water quality characteristics are not typically consistent over time, and upstream receiving water may not be available.

Additionally, any manipulations of a sample prior to or during a toxicity test should also be incorporated into the control/dilution water. For instance, if a sample requires aeration to maintain appropriate dissolved oxygen levels, the control should be similarly aerated to compensate for any "artifactual" increase or decrease in toxicological response that may occur from the manipulation. This becomes increasingly more important when conducting toxicity identification evaluations (TIEs). In a TIE, toxic effluent or receiving waters are manipulated to isolate or remove specific compounds or classes of compounds. Many of these manipulations involve chemical extractions and/or the addition of substances that could affect the response. Appropriately manipulated control water aliquots must also be tested and compared to identify any potentially stimulatory or inhibitory effects.

DEVELOPMENT AND APPLICATION OF SEDIMENT TOXICITY TESTS FOR REGULATORY PURPOSES

M.G.J Hartl
F.N.A.M. van Pelt
J. O'Halloran
Environmental Research Institute
University College Cork,
Ireland

INTRODUCTION

Traditional approaches to sediment toxicity assessment have employed chemical analysis to identify and quantify pollutants present. This approach, however, will only provide information on chemical classes that are analyzed and, when used alone, is of little value in ecotoxicological assessment, because toxicity cannot be determined on the basis of chemistry alone (1). Toxicity is ultimately defined as a measurable biological response to a particular substance or mixture of substances (2,3). Toxicity testing provides a more direct means of assessing the potential adverse effects of contaminants. In a complementary way, ecotoxicological assessment should provide a measure of the combined effects of the compounds in a complex sample, thereby taking into account any additive, antagonistic, or synergistic effects and include a degree of biological relevance.

An ecotoxicological sediment assessment necessitates a tiered approach using different endpoints and several test species representing different trophic levels, because the effect of pollutants may differ between species. Thus, a battery of bioassays rather than single species assays should be employed. Battery style approaches in the evaluation of sediment toxicity (both freshwater and marine) have been described (2,4–8). For example, the SED-TOX Index recommends the integration of multitrophic and multiexposure route tests (different sediment phases) in toxicity assessment of sediments (8). The ecotoxicological triad explores a similar concept (9). In this article, we define sediments, consider their ecotoxicological significance, and summarize some of the key sediment toxicity test systems in use and/or development.

WHAT ARE AQUATIC SEDIMENTS?

Sediments represent an open, dynamic, and heterogeneous biogeochemical system (10) that is formed by an accumulation of particulate matter derived from continental runoff, coastal erosion, or atmospheric deposition, which precipitates to the bottom of a water body. Typically, sediments are an accumulation of particulate mineral matter, inorganic matter of biogenic origin, organic matter in various stages of synthesis or decomposition, and water (11,12). Sediments normally consist of an inorganic matrix coated with organic matter (13), giving rise to a wide variety of physical, chemical, and biological characteristics. Control sediments can be formulated from particulate matter of known origin and characteristics for use in toxicity testing (12,14,15).

The ecotoxicological significance lies in the tendency of many pollutants, especially the less polar organic contaminants and trace elements, to show a strong affinity to suspended particulate matter (16,17). They are sequestered from the water column and incorporated into the sediment. Redox conditions influence the chemical speciation, sorption behavior, and partition coefficients of incorporated compounds and trace elements. Undisturbed sediments tend to accumulate many chemical compounds, and so act as sinks. The retention capacity of sediments for many pollutants is dependent on salinity, pH, E_{h}, and/or mechanical disturbance. Changes in these conditions can result in release of the contaminants, and therefore sediments may act not only as sinks but also as secondary sources, directing often highly concentrated pulses of pollutants at benthic organisms (i.e., organisms intimately associated with sediments). Fine-grained, organically rich sediments play a major role in the biogeochemical fate of chemicals, both of natural and anthropogenic origin, and, along with water quality, have increasingly become the focus of attention in assessing the state of the aquatic environment.

In situ sediment toxicity assessments are rarely performed because of logistics, the difficulties of identifying reference and control sites, and controlling or correcting for confounding environmental variables. Thus field-collected sediment samples are used in laboratory-based toxicity test models. Sediments vary on both a spatial and temporal scale and are structured systems of oxic and anoxic zones (18). These two zones display very different chemical conditions (19,20). Accordingly, during the collection of sediment samples, one must ensure that these zones are not mixed, as this may result in differences in redox status, which will affect the bioavailability of contaminants. The oxic layer of the sediment is preferably sampled and used for toxicity testing especially because this layer interfaces with the water column *in situ* (21,22).

Sediments are not homogeneous but are composed of the following phases: whole sediment, sediment–water interface, pore water, and elutriates. Examination of any single sediment phase may be insufficient to give an accurate ecotoxicological assessment (23,24).

Recent investigations using field-collected sediment samples have demonstrated that the whole sediment phase can be used in toxicity assessment under controlled laboratory conditions (see Tables 1–4).

TEST SYSTEMS

A comprehensive assessment of potential sediment toxicity requires the consideration of multiple exposure phases and multiple test models representing different trophic levels and sediment related habitats.

Primary criteria for test species selection for assessing sediment contamination and toxicity include the species' ecological and/or economical importance and its relative sensitivity to sediment contamination, predictable and consistent response of control organisms, ease of culture and maintenance, short duration, replicable, relatively inexpensive, comparable, and ecologically relevant (6,25,26). In addition to species selection, the endpoints in sediment toxicity tests depend on the question being addressed in the environmental risk assessment (2) and may include acute and long-term toxicity, endocrine, reproductive, and genotoxic effects.

The majority of test systems in use for regulatory purposes are commercial test kits assessing acute general effects on microorganisms using sediment extracts (Table 1). Sediment pore water extracts (also known as interstitial water) are defined as the water occupying the space between sediment particles (27). Contaminants in pore water represent the water-soluble, bioavailable fraction and, as a result, may be a major route of exposure to infaunal species (28–30). The use of elutriate extracts, as opposed to pore water extracts, provides information on the leaching potential of sediment-associated contaminants and may therefore yield important data on the potential adverse effects to benthic organisms, following disturbance of the underlying sediment (6,31). Methods applicable to whole sediment, sediment suspension, sediment elutriate, pore-water extracts, and/or sediment extracts from the marine and freshwater environment have been previously reviewed (32).

These test systems are well established, validated and reproducible, fast, cheap, and require little specialized training. In addition, *in vitro* models, using cells derived from a range of taxa, are currently being developed and validated (22). All these tests are suitable for screening purposes and initial hazard identification. However, they have limited ecological relevance because they are often restricted to nonspecific endpoints or a single trophic level. Therefore, the use and development of a multiple test system or test battery, using various endpoints for both general toxicity (see Tables 1 and 2) and specific toxicities (e.g., genotoxic and reproductive effects; see Tables 3 and 4) in sediment-associated organisms from several taxa representing different trophic levels, is desirable. These models may have a higher ecological relevance than the microbial test systems. In some cases, multiple endpoints for different toxic effects (acute, long term, and specific)

or single endpoints in multiple organ systems have been used in the same test species in order to observe potential toxicity on various levels of biological organization (33). Unfortunately, this type of approach is currently not accepted for regulatory purposes, because many of the bioassays involved are generally less well validated.

Therefore, we recommend that sediment toxicity assessments should be further developed and evaluated using a tiered approached, consisting of screening using short-term general toxicity tests (Tier 1); hazard identification applying more specific (multiple) endpoints in multiorganism experiments, representing different trophic levels and habitats associated with sediments, as well as different modes of bioavailability by using both sediment extracts and whole sediments (Tier 2); and *in situ* ecosystem function, for example, lifetime reproductive success, and components of biodiversity (Tier 3).

ALGAL TOXINS IN WATER

B. Ji
M.H. Wong
R.N.S. Wong
Y. Jiang
Hong Kong Baptist University
Kowloon, Hong Kong

INTRODUCTION

Algal toxins have various adverse implications on the ecosystem directly and indirectly. Cyanotoxins, a group of algal toxins produced by toxic cyanobacteria, are of great concern. The understanding of their occurrence, properties, detection, and removal from water bodies is of importance for monitoring and management of cyanotoxins in freshwater bodies.

ECOLOGY OF TOXIC CYANOBACTERIA IN WATER

Over 40 genera of cyanobacteria are toxic, and the toxic species with particular public health concern generally inhabit freshwater bodies. They are classified into three groups according to the toxin produced: hepatotoxin-producing species (e.g., *Anabaena, Anabaenopsis, Microcystis, Nodularia, Oscillatoria*, and *Cylindrospermopsis*); neurotoxin-producing species (e.g., *Anabaena, Aphanizomenon*, and *Lyngbya*); and dermatotoxin-producing species (e.g., *Lyngbya*; and *Schizothrix*) (1,2).

The toxic cyanobacterial bloom usually occurs in the surface, near-shore area of slow-flowing freshwater bodies. The formation of cyanobacterial bloom and the associated occurrence of cyanotoxins are affected by a number of environmental parameters such as light intensity, temperature, nutrients, trace metals, and organic matters (3). The progressive eutrophication has been reported to be the major cause for the formation of cyanobacterial blooms (4).

CYANOTOXINS AND RELATED HEALTH PROBLEMS

Cyanotoxins are basically classified into three types according to their toxicological targets: hepatotoxins (e.g., microcystins, nodularins, cylindrospermopsins), neurotoxins (e.g., anatoxins, saxitoxins), and dermatotoxins (e.g., aplysiatoxin, lyngbyatoxin A) (5).

Hepatotoxins

The hepatotoxins mainly target the liver. The three major hepatotoxins are microcystins, nodularins, and cylindrospermopsins. Microcystins are the most implicated cyanotoxins in animal and human poisonings and can be produced by several genera, including *Microcystis, Anabaena, Oscillatoria, Nostoc*, and *Anabaenopsis*. Microcystins are cyclic peptides that are made up of five nonprotein amino acids and two protein amino acids (Fig. 1). The toxicity of microcystins is associated with the presence of Adda (3-amino-9-methoxy-2,6,8- trimethyl-10-phenyldeca-4,6-dienoic acid), which has a characteristic violet absorbance at 238 nm (6). Structural variants of microcystins differ in the presence of two protein amino acids (X and Z), two groups (R1 and R2), and two demethylated positions (3 and 7). The molecular weight of microcystins ranges from 800 to 1100 daltons (7).

Microcystins can inhibit hepatocyte protein phosphatases 1 and 2A (8,9). The contamination of microcystins in drinking water is associated with a high incidence of primary liver cancer. The LD_{50} of the extreme toxic microcystin, microcystin-LR, is 50 $\mu g\,kg^{-1}$ body weight in mice by intraperitoneal (i.p.) injection (10).

Nodularins are cyclic pentapeptides and structurally similar to microcystins (Fig. 2). Until now, only four variants of nodularin have been identified in *Nodularia spumigena*. Nodularin can also inhibit the activities of protein phosphatases 1 and 2A and potently promote tumor formation (11,12). The LD_{50} of nodularin in mice is 30 $\mu g\,kg^{-1}$ body weight by i.p. injection (10). In addition, long-term exposure to a low dose of nodularins or microcystins may cause progressive changes in liver tissue, leading to chronic inflammation and focal degeneration of hepatocytes (13).

Cylindrospermopsins are tricyclic alkaloids (Fig. 3) and are produced by *Cylindrospermopsis raciborskii, Aphanizomenon ovalisporum, Umezakia natans*, and *Raphidiopsis curvata*. Cylindrospermopsins are potent inhibitors of protein synthesis and their main target organ is the liver. Unlike the other hepatotoxins, cylindrospermopsins can also affect other organs (e.g., kidney, thymus, and heart). The LD_{50} of cylindrospermopsin in mice is 2100 $\mu g\,kg^{-1}$ body weight at 24 hours by i.p. injection (14).

Neurotoxins

The cyanobacterial neurotoxins are relatively unstable and less common when compared with hepatotoxins. They are, however, diverse in terms of the chemical structures and mammalian toxicities. The major neurotoxins are anatoxins and saxitoxins.

Anatoxins are produced mainly by *Anabaena* species. The two common anatoxins are anatoxin-a and anatoxin-a(s) (Fig. 4). Anatoxin-a is a cholinergic agonist that binds to nicotinic acetylcholine receptors in nerves and neuromuscular junctions. Anatoxin-a(s) mainly inhibits acetylcholinesterase acitivity. The values of LD_{50} of anatoxin-a

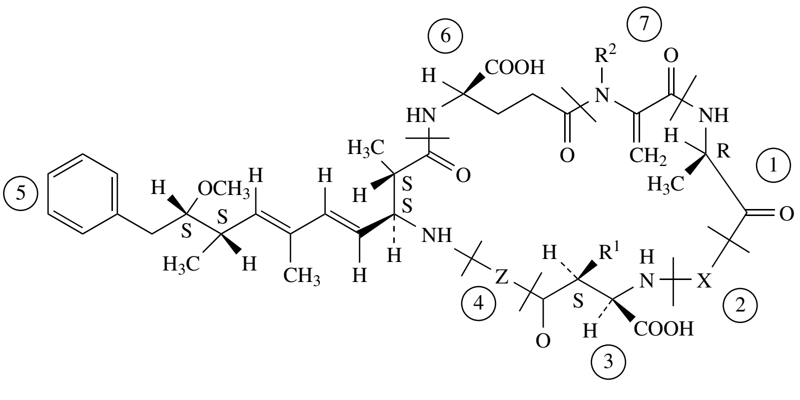

Figure 1. General structure of microcystins [cyclo-D-Ala^1-X^2-D-methyl-isoaspartic acid (MeAsp)^3-Z^4-Adda^5-D-isoglutamic acid (Glu)^6-N-methyldehydroalanine (Mdha)^7, R=H or CH_3].

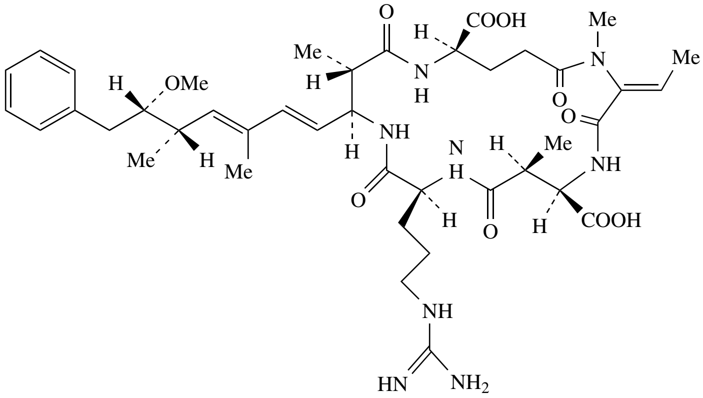

Figure 2. Structure of nodularin.

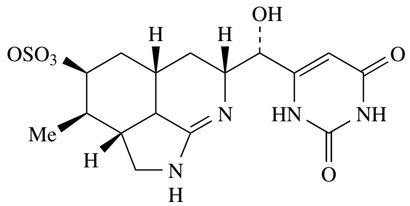

Figure 3. Structure of cylindrospermopsin.

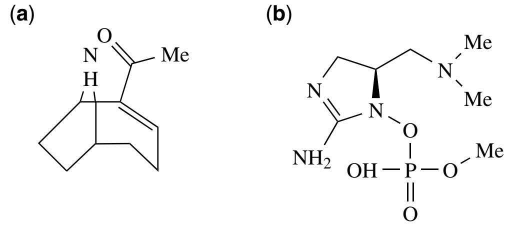

Figure 4. Structures of Anatoxin-a (**a**) and Anatoxin-a(s) (**b**).

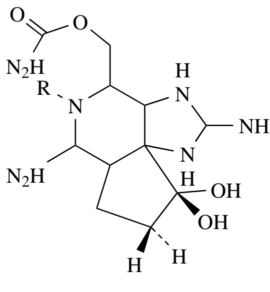

Figure 5. Structure of saxitoxin.

and anatoxin-a(s) are 200 $\mu g\,kg^{-1}$ and 20 $\mu g\,kg^{-1}$ body weight in mice by i.p. injection, respectively (15).

Saxitoxins (Fig. 5), known as marine paralytic shellfish poisons (PSPs), are recently found in freshwater cyanobacteria including *Anabaena circinalis, Lyngbya wollei, Cylindrospermopsis raciborskii*, and *Planktothrix* sp. The toxicity of saxitoxins in mice is different depending on their variants. Saxitoxin is the most potent PSP with LD_{50} of 10 $\mu g\,kg^{-1}$ body weight in mice by i.p. injection (5).

Dermatotoxins

Dermatotoxins are usually produced by benthic marine cyanobacteria (e.g., *Lyngbya majuscule*). Lyngbyatoxin A and aplysiatoxin are two specific dermatotoxins and are related to acute dermatitis and animal death. Long-term exposure to these toxins may lead to skin tumors (16).

DETECTION OF CYANOTOXINS IN WATER

The general methods developed for detection of cyanotoxins include chemical analyses, for example, high-performance liquid chromatography (HPLC), mass spectroscopy (MS), and nuclear magnetic resonance (NMR); biological assays, for example, mouse, invertebrate, and bacterial bioassays; and biochemical assays, for example, protein phosphatase inhibition assay and immunoassay (ELISA).

In chemical analyses, HPLC is widely used for the detection of most cyanotoxins (17). LC/MS is the best method for the detection of saxitoxins and its variants (18). To identify and differentiate the variants of microcystins, fast atom bombardment mass spectroscopy (FABMS) and FABMS/MS methods have been developed (19).

Mouse bioassay is the only method for the detection of all types of cyanotoxins compared with other methods (17). In invertebrate bioassay, brine shrimp, mosquito, fruitfly, house fly, and locust are commonly used target organisms (20,21). The invertebrate bioassay, however, is limited in the detection of some specific cyanotoxins. For example, house fly and locust are only sensitive to saxitoxins, whereas brine shrimp can be used only for detection of microcystins. Bacterial bioassay is seldom used because of its weakness on the reflection of the correlation between the actual concentrations of known cyanotoxin and the responses of the testing bacterium (17).

Protein phosphatase inhibition assay is the most sensitive biochemical method for the analysis of microcystins and nodularins. It uses ^{32}P-labeled glycogen phosphorylase and the colorimetric protein phosphatase inhibition assay. This assay has proved to be an efficient screening method for water samples because of its simple operation. The protein phosphatase inhibition assay is currently adopted for the analysis of microcystins in drinking water.

The detection limits for microcystin-LR in raw and finished drinking water are 0.87 $\mu g\,L^{-1}$ and 0.09 $\mu g\,L^{-1}$, respectively (22). The protein phosphatase inhibition assay, however, may be affected by various other noncyanobacterial toxins and metabolites (e.g., okadaic acid and tautomycin). Consequently, additional confirmation should be made to validate the presence of specific cyanobacterial hepatotoxins (23).

ELISA is a sensitive and specific method for the detection of cyanotoxins using polyclonal or monoclonal antibodies (24). It has been successfully employed for the quantitative detection of cyanobacterial hepatotoxins including microcystin-LR, -RR, -YR, and nodularins in domestic water supplies with the detection limits of 0.05 $\mu g\,L^{-1}$ for microcystin-LR in water samples, for instance (25–27).

STABILITY OF CYANOTOXINS IN WATERS

Cyanotoxins are normally present inside cyanobacterial cells, which enter into the water bodies during cell senescence and lysis. The release of cyanotoxins is influenced by several factors, including light intensity, application of algicide, chlorination, and the unfavorable conditions that accelerate cell death (28). Hence, the ratio of dissolved cyanotoxins to intracellular ones is different at different growth phases of cyanobacteria. In field study, the breakdown of a cyanobacterial bloom may lead to an increase of dissolved microcystins in water (29), although the concentrations detected are relatively low compared with cyanotoxins inside the cells.

The existence of cyanotoxins in the aquatic environment is also affected by their stability. Factors such as temperature, pH, light intensity, and the existence of other microorganisms and oxidants with respect to their effect on cyanotoxin stability have been investigated. Anatoxin-a, for example, is stable at pH 4 for at least 21 days in reservoir water, whereas less than 5% of the original concentration was detected after 14 days at pH 8–10 (30). Microcystins and cylindrospermopsins can be oxidized by strong oxidants, for example, ozone and sodium hypochlorite (NaOCl), and their degradation under intense UV light can be accelerated by the addition of titanium dioxide (TiO_2) (31–33). Similarly, anatoxin-a and saxitoxins are also unstable when exposed to ozone. Photolysis of microcystin may occur in the presence of humic substances and pigments of cyanobacterial cells (31,34). In addition, microcystin-LR and -RR can be degraded *in vitro* in bacterium *Sphingomonas* sp. by microcystinase (35). The degradation of nodularin can be performed with the presence of the extract of *Nodularia spumigena* (36). Anatoxin-a can be degraded micobiologically by *Pseudomonas* sp. in pure culture (37). On the other hand, microcystins and anatoxins can also adsorb onto sediments, suspended solids, and dissolved organic matters, which may correlate to the accumulation and persistence of these toxins in the environment.

REMOVAL OF CYANOTOXINS FROM WATER

Cyanotoxins may impose fatal, acute, or chronic effects on animals and humans and present a health problem to the public through contamination of drinking water, recreationally used water, and fish or shellfish. The extent of cyanotoxin poisoning can be decreased by reducing human exposure to cyanotoxins, which can be achieved through preventing toxic cyanobacterial bloom formation; monitoring of the number of cyanobacteria or the concentration of cyanotoxins in water; notifying the public of the possible hazards in the water; and providing technical and scientific advice for removal of cyanotoxins in water.

The World Health Organization (WHO) has suggested the value of 1 $\mu g\,L^{-1}$ for microcystin-LR in drinking water resources and provides guidelines on monitoring the number of cyanobacterial cells and the concentration of chlorophyll *a* in drinking and recreationally used waters, which indicates that the concentrations of microcystins can be forecasted from the densities of cyanobacterial cells if microcysin-producing cyanobacteria are dominant (38,39). Cyanobacterial blooms usually can be controlled in several ways, for example, prevention of eutrophication by reduction of external nutrient loading, control of cyanobacteria by raw water abstraction, and application of algicide. The conventional methods adopted in water treatment, including coagulation, flocculation, sand filtration, ultrafiltration, and microfiltration, are effective for removal of cyanobacterial cells from drinking water. However, the cyanotoxins may enter into water because of the lysis of cyanobacterial cells during the water treatment process. The efficiency of these methods to remove dissolved cyanotoxins in water is low (40).

The more effective and practical chemical and physical methods to eliminate the contamination of dissolved cyanotoxins in water are developed based on the adsorption and destruction of the toxins. Ozonation and potassium permanganate, for example, are effective for the destruction of dissolved microcystins. The treatments by chemical oxidants, however, require optimal doses, temperature, pH, and the optimal concentrations of dissolved organic carbon (41). Although the effect of chlorination on destruction of hepatotoxins has been investigated subsequently, the efficiency of conventional chlorination in water treatment on removal of microcystins is low, which might be because of the insufficient chlorine available for microcystin oxidation. The other pertinent techniques for removal of cyanotoxins from drinking water, for example, reverse osmosis, nanofiltration, powdered activated carbon adsorption, granular activated carbon adsorption, and biodegradation, have also been investigated (42–44). However, the efficiencies of these methods for removal of different cyanotoxins are variable. No sole method regarding the removal of all types of cyanotoxins from water bodies efficiently can be adopted. The selection of the appropriate treatment method depends on the target toxin. Further investigation is required to assess the optimization of these treatment methods.

GROUND WATER QUALITY IN AREAS ADJOINING RIVER YAMUNA AT DELHI, INDIA

Chakresh K. Jain
Mukesh K. Sharma
National Institute of Hydrology
Roorkee, India

The groundwater quality in areas adjoining the River Yamuna at Delhi (India) has been assessed to determine the suitability of groundwater for domestic use. Thirty-eight groundwater samples from shallow and deep aquifers were collected each during pre- and postmonsoon seasons in the year 2000 and analyzed for various physicochemical and bacteriological parameters and trace elements. The study indicated concentrations of total dissolved solids, nitrate, sulfate, and sodium higher than water quality standards. The presence of total coliforms indicates bacterial contamination in the groundwater. The grouping of samples according to their hydrochemical facies indicated that the majority of the samples fall into Na-K-Cl-SO_4 followed by Na-K-HCO_3 and Ca-Mg-Cl-SO_4 hydrochemical facies. The qualitative analysis of data depicted higher concentrations of various physicochemical and bacteriological parameters on the western side of River Yamuna, even in deep aquifers.

INTRODUCTION

Water is an essential and vital component of our life support system. In tropical regions, groundwater plays an important role within the context of fluctuating and increasing contamination of surface water resources. Groundwater has unique features (excellent natural quality, usually free from pathogens, color, and turbidity), which render it particularly suitable for a public water supply. Groundwater also plays an important role in agriculture for watering of crops and for irrigation of dry season crops. It is estimated that about 45% of the irrigation water requirement is met from groundwater sources. Unfortunately, the availability of groundwater is not unlimited nor is it protected from deterioration. In most instances, the extraction of excessive quantities of groundwater has resulted in drying up of wells, damaged ecosystems, land subsidence, saltwater intrusion, and depletion of the resource. Groundwater quality is being increasingly threatened by agricultural, urban, and industrial wastes. It has been estimated that once pollution enters the subsurface environment, it may remain concealed for many years, disperses over wide areas of the groundwater aquifer, and renders groundwater supplies unsuitable for consumption and other uses. The rate of depletion of groundwater levels and the deterioration of groundwater quality are of immediate concern in major cities and towns of the country.

The National Capital Territory (NCT) of Delhi is facing severe problems in managing groundwater quality and quantity. Surface water bodies play a significant role in groundwater flow. The hydraulic gradient has a significant role in lateral and vertical migration of contaminants in groundwater aquifers. Therefore, the present study has been carried out to assess the suitability of groundwater for domestic uses in areas adjoining the River Yamuna at Delhi and to examine the likely impact of Yamuna River water quality on groundwater. The suitability of each well for drinking has been reported in an earlier report (1).

STUDY AREA

Delhi generates about 1900 MLD of sewage against installed capacity of 1270 MLD of sewage treatment. The balance of untreated sewage along with a significant quantity of partially treated sewage is discharged into the River Yamuna every day. The river receives sewage and industrial wastes through various drains, which join the River Yamuna between Wazirabad and Okhla. Thus Delhi is the largest contributor of pollution to the River Yamuna, which receives almost 80% of its pollution load through these drains.

The climate of Delhi is influenced mainly by its inland position and the prevalence of continental type air during the major part of the year. Extreme dryness with an intensely hot summer and cold winter are the characteristics of the climate. Only during the monsoon months does air of oceanic origin penetrate to this area and cause increased humidity, cloudiness, and precipitation. The normal annual rainfall in the National Capital Territory of Delhi is 611.8 mm. The rainfall increases from southwest to northeast; about 81% of the annual rainfall is received during the three monsoon months of July, August, and September. The balance of annual rainfall is received as winter rains and as thunderstorm rain during pre- and postmonsoon months.

Thirty-eight groundwater samples from shallow and deep aquifers were collected from both sides of the River Yamuna at Delhi (Fig. 1). The details of sampling locations are given in Table 1.

METHODOLOGY

The groundwater samples were collected in polyethylene bottles during pre- and postmonsoon seasons in the year 2000 from open wells, hand pumps, and tube wells and were preserved by adding an appropriate reagent (2,3). The water samples for trace element analysis were collected in acid-leached polyethylene bottles and preserved by adding ultrapure nitric acid (5 mL/L). Samples for bacteriological analysis were collected in sterilized high-density polypropylene bottles. All samples were stored in sampling kits maintained at 4 °C and brought to the laboratory for detailed chemical and bacteriological analysis. The details of sampling locations are given in Table 1. The physicochemical and bacteriological analyses were performed following standard methods (2,3).

RESULTS AND DISCUSSION

The National Capital Territory of Delhi has the peculiar feature of infiltration of surface water to groundwater from the River Yamuna and from various drains in addition to customary recharge from rainfall. Groundwater recharge also occurs through stagnant water pools in low-lying areas, where surface runoff water collects. The quartzite ridge, which is the prolongation of the Aravalli mountain range, forms the principal watershed in the south, southeast, and southwest parts of Delhi. Because of it, the eastern surface runoff and drainage join the River Yamuna, whereas the runoff from the western part of Delhi goes into the Najafgarh drain. The ever increasing discharge of domestic and industrial wastes into improperly lined sewage drains in Delhi leads to a high risk of contaminating the groundwater. The excessive groundwater uplift also has an adverse impact on water quality in groundwater aquifers of limited thickness.

General Characteristics

The hydrochemical data for the two sets of samples collected from the areas adjoining the River Yamuna at Delhi are given in Table 2. The pH in the groundwater

of areas adjoining the River Yamuna is mostly within the range 6.7 to 8.3 during the premonsoon season and 6.6 to 8.2 during the postmonsoon season; most of the samples point toward the alkaline range in both seasons. The pH of all the samples is within the limits prescribed by BIS (4) and WHO (5) for various uses of water, including drinking and other domestic supplies. The conductivity varies from 628 to 3540 μS/cm during the premonsoon season and from 620 to 3250 μS/cm during postmonsoon; the conductivity of more than 70% of the samples was above 1000 μS/cm during both pre- and postmonsoon seasons. The maximum conductivities of 3540 and 3250 μS/cm were observed at Golf Course during the pre- and postmonsoon seasons, respectively. Higher values of conductivity in the areas nearby the River Yamuna indicate high mineralization of the groundwater.

The total dissolved solids (TDSs) in the groundwater vary from 402 to 2266 mg/L during the premonsoon season and from 397 to 2080 mg/L during the postmonsoon season. The TDSs of only about 10% of the samples analyzed were within the desirable limit of 500 mg/L. The TDSs of more than 80% of the samples were above the desirable limit of 500 mg/L. An almost similar trend was observed during the postmonsoon season. Water containing more than 500 mg/L of TDSs is not considered desirable for drinking water, though more highly mineralized water is also used where better water is not available. For this reason, 500 mg/L as the desirable limit and 2000 mg/L as the maximum permissible limit has been suggested for drinking water (4). Water containing TDSs of more than 500 mg/L causes gastrointestinal irritation (4). One sample at Golf Course (BW, 80) even crosses the maximum permissible limit of 2000 mg/L.

Carbonates, bicarbonates, and hydroxides are the main cause of alkalinity in natural waters. Bicarbonates represent the major form because they are formed in considerable amount from the action of carbonates on basic materials in the soil. The alkalinity value in the groundwater varies from 116 to 380 mg/L during the premonsoon season and from 106 to 310 mg/L during postmonsoon. About 60% of the samples from the study area fall within the desirable limit of 200 mg/L, and about 40% of the samples cross the desirable limit but are within the maximum permissible limit of 600 mg/L. No sample of the study area crosses the maximum permissible limit of 600 mg/L. The high alkalinity in the study area may be attributed to the action of carbonates upon basic materials in the soil. Such water has an unpleasant taste.

Calcium and magnesium along with their carbonates, sulfates, and chlorides make the water hard, both temporarily and permanently. A limit of 300 mg/L has been recommended as the desirable limit for drinking water (4). The total hardness in the study area ranges from 116 to 871 mg/L during the premonsoon season and from 114 to 792 mg/L during postmonsoon. More than 80% of the samples were found well within the desirable limits for domestic use during both pre- and postmonsoon seasons. However, one sample from Golf Course even crosses the maximum permissible limit of 600 mg/L during both seasons.

The desirable limits for calcium and magnesium in drinking water are 75 and 30 mg/L, respectively (4). In groundwater in the study area, the levels of calcium and magnesium vary from 25 to 240 and from 9 to 64 mg/L, respectively, during the premonsoon season. Slightly lower levels of calcium and magnesium were observed during the postmonsoon season. In groundwater, the calcium content generally exceeds the magnesium content in accordance with their relative abundance in rocks. The increase in magnesium is proportionate to calcium in both seasons.

The concentration of sodium in the study area varies from 55 to 340 mg/L during the premonsoon season and from 51 to 322 mg/L during postmonsoon. The sodium concentration of more than 50 mg/L makes the water unsuitable for domestic use. The sodium concentration was higher at all sites in the study area. The high sodium values may be attributed to base-exchange phenomena. Groundwater with high sodium is unsuitable for irrigation due to the sodium sensitivity of crops/plants.

Table 2. Hydrochemical Data of Groundwater Samples of Delhi (Pre- and Postmonsoon, 2000)[a]

Parameter	Minimum	Maximum	Mean
pH	6.7 (6.6)	8.3 (8.2)	7.1 (7.1)
Conductivity, μS/cm	628 (620)	3540 (3250)	1463 (1370)
TDSs, mg/L	402 (397)	2266 (2080)	936 (879)
Alkalinity, mg/L	116 (106)	380 (310)	201 (194)
Hardness, mg/L	116 (114)	841 (792)	235 (225)
Chloride	17 (17)	400 (390)	86 (86)
Sulfate, mg/L	43 (48)	690 (680)	180 (177)

[a] Values in parentheses represent postmonsoon data.

The concentration of potassium in groundwater varies from 4.2 to 121 mg/L during the premonsoon season and from 2.2 to 103 mg/L during postmonsoon. Potassium is an essential element for humans, plants, and animals and is derived in the food chain mainly from vegetation and soil. The main sources of potassium in groundwater include rainwater, weathering of potash silicate minerals, potash fertilizers, and surface water used for irrigation. It is more abundant in sedimentary rocks and commonly present in feldspar, mica, and other clay minerals. The Bureau of Indian Standards has not included potassium in drinking water standards. However, the European Economic Community has prescribed a guideline level for potassium at 10 mg/L in drinking water. Though potassium is found extensively in some igneous and sedimentary rocks, its concentration in natural waters is usually quite low because potassium minerals are resistant to weathering and dissolution. A higher potassium content in groundwater is indicative of groundwater pollution.

The concentration of chloride varies from 17 to 400 mg/L during the premonsoon season. Almost the same trend was observed during the postmonsoon season. The maximum chloride content in groundwater was recorded at Golf Course. No sample in the study area crosses the maximum permissible limit of 1000 mg/L. The limits of chloride have been laid down primarily from taste considerations. A limit of 250 mg/L chloride has been recommended for drinking water supplies (4,5). However, no adverse health effects on humans have been reported from intake of waters containing a higher chloride content.

The concentration of sulfate in the study area varies from 43 to 690 mg/L during the premonsoon season and from 48 to 680 mg/L during postmonsoon. Most of the samples fall within the permissible limit (400 mg/L) for drinking water supplies. Only two samples from Himmat Puri and Golf Course exceeded the maximum permissible limit. In groundwater, sulfate generally occurs as soluble salts of calcium, magnesium, and sodium. The sulfate content of water may change significantly with time during infiltration of rainfall and groundwater recharge, which takes place mostly from stagnant water pools, puddles, and surface runoff water collected in low-lying areas.

The nitrate content of drinking water is considered important for its adverse health effects. The occurrence of high levels of nitrate in groundwater is a prominent problem in NCT-Delhi. The nitrate content in the groundwater of areas adjoining the River Yamuna varies from 1 to 286 mg/L during the premonsoon season. Almost the same trend was observed during postmonsoon. Of the 38 samples analyzed, 20 samples (52.5%) had nitrate content less than 45 mg/L, whereas in about 20% of the groundwater samples, the nitrate content exceeded even the maximum permissible limit of 100 mg/L. The higher level of nitrate at certain locations may be attributed to the surface disposal of domestic sewage and runoff from agricultural fields. It has also been observed that the groundwater samples collected from hand pumps at various depths have a high nitrate content, which may be attributed to wellhead pollution.

Nitrate is an effective plant nutrient and is moderately toxic. A limit of 45 mg/L has been prescribed by WHO (5) and BIS (4) for drinking water supplies. A concentration above 45 mg/L may be detrimental to human health. In higher concentrations, nitrate may produce a disease known as methemoglobinemia (blue baby syndrome), which generally affects bottle-fed infants. Repeated heavy doses of nitrates by ingestion may also cause carcinogenic diseases.

Fluoride is present in soil strata due to the presence of geological formations such as fluorspar and fluorapatite and amphiboles such as hornblende, tremolite, and mica. Weathering of alkali, silicate, igneous, and sedimentary rocks, especially shales, contributes a major portion of fluorides to groundwaters. In addition to natural sources, considerable amounts of fluoride may be contributed by human activities. Fluoride salts are commonly used in the steel, aluminum, brick, and tile industries. Fluoride containing insecticides and herbicides may be contributed by agricultural runoff. Phosphatic fertilizers, which are extensively used, often contain fluorides as an impurity, and they may increase the levels of fluoride in soil. The accumulation of fluoride in soil eventually results in leaching by percolating water, thus increasing the fluoride concentration in groundwater. However, in the groundwater of the area adjoining the River Yamuna, the fluoride content was within the maximum permissible limit of 1.5 mg/L in all samples.

Bacteriological Parameters

The presence of coliforms in water is an indicator of contamination by human or animal excrement. The presence of fecal coliforms in groundwater is a potential public health problem, because fecal matter is a source of pathogenic bacteria and viruses. Groundwater contamination from fecal coliform bacteria is generally caused by percolation from contamination sources (domestic sewage and septic tank) into the aquifers and also by poor sanitation. Shallow wells are particularly susceptible to such contamination. The bacteriological contamination of groundwater in Delhi is mostly attributable to indiscriminate dumping of waste and garbage without any precautions or scientific disposal practices. In Delhi, most of the hand pumps withdraw groundwater from upper strata, which is most susceptible to contamination from polluted surface water.

The groundwater samples collected from the area adjoining the River Yamuna in Delhi have significantly high total coliform. Bacteriological analysis indicates the presence of coliforms in more than 75% of samples during both pre- and postmonsoon seasons. The presence of coliforms was reported mostly from hand pumps. More than 30% of the samples have MPN coliforms >100 per 100 mL during the premonsoon season. Inadequate maintenance of hand pumps and unhygienic conditions around the structures may be responsible for bacterial contamination. Indiscriminate land disposal of domestic waste on the surface, improper disposal of solid waste, and leaching of wastewater from landfills further heighten the chances of bacterial contamination.

Trace Elements

Most of the trace metals are of immediate concern because of their toxicity and nonbiodegradable nature. Cadmium, chromium, and lead are highly toxic to humans even in low concentrations. The concentrations of heavy metals in groundwater except iron, which is present in appreciable concentration, were below the prescribed maximum permissible limits in most of the samples. The concentration of iron varies from 0.39 to 5.74 mg/L during the premonsoon season and from 0.128 to 5.842 mg/L during postmonsoon. The concentration ranges of copper and zinc were well below maximum permissible limits.

The study clearly indicated higher concentration of total dissolved solids, electrical conductivity, nitrate, sulfate, and sodium. The presence of total coliforms indicates bacterial contamination in groundwater. The presence of heavy metals in groundwater was recorded in many samples, but the levels were not significant. Water quality standards have been violated for TDSs, nitrate, sulfate, and sodium at a few places.

Chadha's Diagram for Hydrochemical Classification

Chadha's diagram (6) is a somewhat modified version of the Piper trilinear diagram (7). In this diagram, the difference in milliequivalent percentage between alkaline earths (calcium plus magnesium) and alkali metals (sodium plus potassium), expressed as percentage reacting values, is plotted on the x axis and the difference in milliequivalent percentage between weak acidic anions (carbonate plus bicarbonate) and strong acidic anions (chloride plus sulfate) is plotted on the y axis. The resulting field of study is a square or rectangle depending on the size of the scales chosen for x and y coordinates. The milliequivalent percentage differences between alkaline earth and alkali metals and between weak acidic anions and strong acidic anions would plot in one of the four possible subfields of the diagram. The main advantage of this diagram is that it can be made simply on most spreadsheet software packages.

The square or rectangular field describes the overall character of the water. The diagram has all the advantages of the diamond-shaped field of the Piper trilinear diagram and can be used to study various hydrochemical processes, such as base cation exchange, cement pollution, mixing of natural waters, sulfate reduction, saline water (end product water), and other related hydrochemical problems.

The chemical analysis data of all the samples collected from the area adjoining the River Yamuna in Delhi have been plotted on Chadha's diagram (Fig. 2) and results have been summarized in Table 3. It is evident that during the premonsoon season, most of the samples fall in Group 7 (Na-K-Cl-SO_4) followed by Group 8 (Na-K-HCO_3 type) and Group 6 (Ca-Mg-Cl-SO_4). An almost similar trend was observed during the postmonsoon season.

Impact of River Water Quality on Groundwater

Surface waterbodies play an important role in groundwater flow. The infiltration of surface water to groundwater usually occurs in a recharge geographical area; base flow from groundwater to surface waterbodies may occur in a discharge geographical area. In a discharge area, the hydraulic head increases with depth, and net saturated flow is upward toward the water table, but in a recharge area, the water table lies at a considerable depth beneath a thick unsaturated zone. The relationship of surface water

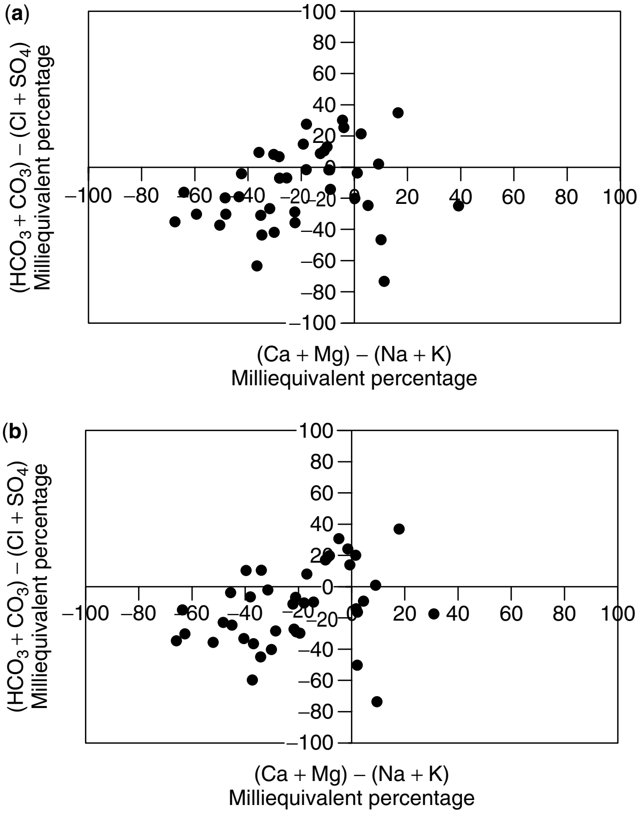

Figure 2. (**a**) Chadha's diagram for hydrochemical classification (premonsoon 2000); (**b**) Chadha's diagram for hydrochemical classification (postmonsoon 2000).

to groundwater and its recharge/discharge characteristics may change seasonally or once during a longer time span. In deep groundwater aquifers, the movement of water from a recharge to a discharge area may take place during several years, but in shallow aquifers, recharge and discharge may be much closer and even adjacent to each other. The hydraulic gradient plays a significant role in lateral and vertical migration of contaminants in groundwater aquifers.

During the present study, 38 groundwater samples were collected within 10 km of the eastern and western banks of the River Yamuna to ascertain the impact of river water on groundwater. The qualitative analysis of data showed higher concentrations of various physicochemical and bacteriological parameters on the western side of River Yamuna, even in deep aquifers. However, due to a paucity of hydrochemical, geologic, and water level data, no specific inferences could be drawn. Further studies are being planned to investigate the impact of Yamuna River water quality on the groundwater system.

CONCLUSIONS

The suitability of groundwater in the area adjoining the River Yamuna in Delhi has been examined per BIS and WHO standards. The quality of the groundwater varies from place to place with the depth of the water table. It also shows significant variation from one season to another. Only about 10% of the total samples analyzed were within the desirable limit of 500 mg/L for TDSs, and more than 80% of the samples were above the desirable limit but within the maximum permissible limit of 2000 mg/L. From the viewpoint of hardness, more than 80% of the samples were well within the desirable limits for domestic use during both pre- and postmonsoon seasons. More than 50% of the samples had a nitrate content of less than 45 mg/L, whereas in about 20% of the groundwater samples, the nitrate content even exceeded the maximum permissible limit of 100 mg/L. The higher level of nitrate at certain locations may be attributed to the surface disposal of domestic sewage and runoff from agricultural fields. The grouping of samples according to their hydrochemical facies clearly indicates that the majority of the samples fall in Na-K-Cl-SO_4 followed by Na-K-HCO_3 and Ca-Mg-Cl-SO_4 hydrochemical facies. The qualitative analysis of data showed higher concentrations of various physicochemical and bacteriological parameters on the western side of River Yamuna, even in deep aquifers. However, due to the paucity of hydrochemical, geologic, and water level data, no specific inferences could be drawn. More detailed studies including contaminant transport modeling studies are needed to understand better the impact of Yamuna River water quality on the groundwater aquifer.

CHLORINE RESIDUAL

Linda S. Andrews
Mississippi State University
Biloxi, Mississippi

Chlorine is a disinfectant added to drinking water to control microbial contamination. Both commercial water bottlers and public water systems use chlorine for this purpose. Levels added are calculated to maintain a disinfectant (chlorine) residual throughout the distribution system from the treatment facility to the end user.

Historically, the disinfection and sanitation of water, food products, and food processing equipment have used halogen-containing disinfectants such as chlorine (1). The worldwide use of chlorine has improved our quality of life and prevented many disease outbreaks caused by waterborne pathogens. Chlorine was first used as a disinfectant in 1897 to treat polluted water mains after an outbreak of typhoid fever in England, and later, in 1912, it was used after a typhoid fever outbreak in Niagara Falls, New York (2). Chlorine was introduced to the food processing industries in 1935. Today, disinfection is considered to be the primary mechanism for the inactivation/destruction of many pathogenic organisms to prevent the spread of waterborne diseases to downstream users and the environment (3).

Three common methods of disinfection exist in the United States and Canada: chlorination, ozonation, and ultraviolet (UV) disinfection. Chlorine, the most widely used disinfectant for municipal wastewater, destroys target organisms by oxidation of the cellular material (3). Chlorine may be applied as chlorine gas, hypochlorite solutions, or other chlorine compounds in solid or liquid form. Hypochlorous acid present in aqueous chlorine solutions is the biocidal “active chlorine” (4).

Advantages for use of chlorination include the following (3):

- Chlorination is an established method for disinfection.
- Chlorination is inexpensive compared with other methods (UV and ozone).
- Chlorine residuals remaining in the wastewater effluent will enhance the long-term effects of disinfection after the initial treatment and can be measured to determine the effectiveness.
- Chlorine is very effective against a wide variety of microorganisms, especially enteric pathogens.
- Chlorine has the ability to oxidize certain undesirable organic and inorganic compounds.
- Levels of chlorine can be adjusted according to biological load.
- Oxidative capacities of chlorine can eliminate off odors during disinfection.

In recent years, some health concerns have developed over the discovery of potentially carcinogenic by-products generated during chlorination in the presence of organic material. These by-products, termed “disinfection by-products,” include such compounds as trihalomethanes, chloroform, and chlorophenols. Tests of chlorine-treated water have identified more than 250 compounds, approximately 10% of which have been classified as potentially mutagenic and/or carcinogenic (5). Both disinfectants and by-products can have adverse health effects (6).

Other disadvantages for use of chlorination include the following (3):

- Chlorine residuals, even in low concentrations, can be toxic to aquatic life and thus may require a dechlorination process.
- Shipping, storage, and handling of chlorine chemicals can pose a safety risk to workers and to the environment.
- Levels of dissolved solids are increased in chlorine-treated effluent.
- Chlorine residuals are unstable in the presence of heavy biological load to the chlorination system, requiring increased dose applications.
- Certain parasitic species known to cause problems in water supplies are relatively resistant to chlorine oxidation treatments. These species include the oocysts of *Cryptosporidium parvum* and the cysts of *Entamoeba histolytica* and *Giardia lamblia* as well as the eggs of some parasitic worms.
- Other long-term effects of chlorination and the presence of chlorine residuals are yet unknown.

Continuous chlorination is a necessity for surface water supplies from lakes, springs, ponds, or cisterns. The effectiveness of chlorine as a disinfectant is a function of contact time, the chlorine solution used, the temperature of the water and environment, and the level of residual chlorine from first introduction to the water system and continuing to the end user. Continuous chlorination typically uses a chlorine residual of 3–5 ppm. Municipalities, however, use lower levels of 0.2–0.5 ppm because they represent larger distribution systems that provide a longer contact time. Also, the higher levels of chlorine residual may cause an objectionable flavor and odor (7).

Several types of chlorine residuals can be measured in treated water. Free chlorine residual is the measure of the disinfectant safety margin and is in the form of hypochlorous acid. The combined chlorine residual includes chlorine as chloramines and chlororganics that are produced when chlorine reacts with ammonia products that may be present because of biological load. The total chlorine residual is the sum of free and combined residuals (7). A growing number of water systems have naturally occurring ammonia and organic contaminants in their water supplies. These contaminants react with their chlorine treatment to form the combined chlorine residuals (8). These combined residuals require up to 100 times the contact time or 25 times the chlorine concentration to be effective disinfectants in water (9).

It is estimated that 3–4% of the total chlorine produced in the United States is used in potable water treatment, wastewater treatment, swimming pools, and cooling water biocide applications. Many health risks are associated with water that has not been disinfected, and health risks are associated with total residual chlorine. Residual chlorines are produced from water treatment facilities and in processing plants. Large power producing plants that use chlorinated water to prevent biofouling of heat exchangers in once-through cooling towers are also a major source of residual chlorine. Approximately 90% of such plants chlorinate cooling water on a periodic basis as compared with a continuous basis for water and wastewater treatment. Typically, chlorine is dosed at 1–2 mg/L for 20–30 minutes two to three times daily. To minimize chlorine residuals in once-through cooling systems, chlorinated effluent from one group of condensers can be blended with nonchlorinated cooling water, or targeted chlorination can be practiced (10).

DECHLORINATION

Chlorination has been used widely for disinfection of wastewater before discharge. Before the passage of the 1972 Federal Water Pollution Control Act and for several years after, significant levels of residual chlorine were routinely discharged into the environment. As the impact of the toxic by-products became known, dechlorination was instituted to remove residual chlorine from wastewater before discharge into sensitive aquatic waters (11). Dechlorination effectively removes free or total combined chlorine residuals remaining after chlorination. A common method of dechlorination is to expose the effluent to sulfur dioxide or sulfite salts. Although expensive, carbon absorption has also been used when total dechlorination is desired. State regulatory agencies set the policy for allowable levels of chlorine residuals, which effectively makes dechlorination essential for certain industries. Dechlorination protects aquatic life from the toxic effects of residual chlorine and prevents formation of harmful chlorinated compounds in drinking water. However, chemical dechlorination can be difficult to control with the potential for significant overdosing with sulfite, which suppresses the dissolved oxygen content and lowers the pH (11).

SOURCE WATER QUALITY MANAGEMENT

LAUREL PHOENIX
Green Bay, Wisconsin

Water utilities serving water authorities or municipalities can have many levels of control over the quality of their source waters. The more control they have over protecting the water quality of their sources, the less money they have to spend on water treatment, and the lower their risk when dealing with unforeseen emergencies. When they have no control of changing water quantities from drought, flood, or industrial pollution, they must spend more money to access backup supplies. Here, the phrase “water utilities” will be used interchangeably with water authorities or municipalities to refer to any local government entity providing public drinking water.

HIGH CONTROL OF SURFACE WATER SOURCES

Water authorities with the highest control own the entire watershed of a surface water source and protect the water quality by keeping people and development out. Others may rely on a river surrounded on all sides by a pristine forest with little or no human activity (e.g., hiking, camping) and would try to extract their water at a point just below this pristine area rather than farther downstream where other land uses could degrade the water. For utilities that cannot practicably deny access to the entire watershed or the waterbody itself, strict guidelines for land use in that area can be locally imposed instead. These guidelines can include such things as restricting the amount of impervious surfaces that can be added through development (e.g., buildings, driveways, roads), forbidding dumping of hazardous materials or use of pesticides, or restricting recreational activities on land and water to prevent animal waste, sediment, or fossil fuels from watercraft from contaminating the water supply. Some states grant water authorities extraterritorial land use control over land in a different municipality in order to create and enforce restrictions that will protect the water supply.

HIGH CONTROL OF GROUNDWATER SOURCES

Groundwater sources can be highly protected if the utility has total control over land use in the aquifer's recharge zone. This type of control occurs when the utility owns all the land in the recharge zone, or where state or local laws require recharge zones to be fenced with signs directing people to stay out. Some states or local governments require this absolute protection of recharge zones, no matter who owns the land or what municipality has political jurisdiction. When total denial of human access or development is impossible, guidelines like the ones aforementioned can be mandated for any land lying over the recharge zone. The distance from the land surface to the water table and the substrate geology can then guide how strict the guidelines are; more restrictions being placed on land parcels overlying more vulnerable aquifers.

LITTLE CONTROL OF WATER SOURCES

Few water utilities have the high degree of control previously mentioned. This is because protecting surface or groundwater supplies can only be done through land use controls, and land use decisions have traditionally been the right of each local government. Therefore, most utilities may have to use a variety of strategies to deal with issues over which they have no control. This section discusses four common problems: (1) when source water is degraded, (2) when supply is uncertain, (3) when drinking water regulations are tightened, or (4) when emergency situations arise.

Degraded Source Water Quality

Surface waters can easily be polluted from increased drainage area development, farm runoff, or heavy rains. Development in the watershed increases erosion and causes sediment loading to surface waters. Farm runoff includes pesticides, sediment, fertilizer or manure, and silage leachate (nitrogen-rich liquid that drips from stored grains in silos). Heavy rains mobilize nonpoint source pollutants from urban landscapes, mines, farms, or silvicultural areas into water bodies. In fact, this "first flush" of runoff into water bodies carries high concentrations of pollutants. This multitude of diverse pollutants—sediment, chemicals, metals, pet waste, and so on—causes different kinds of problems for water treatment plants.

Groundwater can be polluted for the same reasons just stated, because, except for sediment, these nonpoint source pollutants can pollute groundwater by percolating down to the water table. Groundwater can also be degraded as the water table drops, because the quality of the water from that level may be higher in total dissolved solids (TDSs), be briny, or have arsenic or radon. Groundwater can also become unfit for use if compounds such as MTBE, perchlorate, solvents, or methane and diesel fuel from hydraulic fracturing migrate into the aquifer.

Even desalting ocean water does not protect utilities from pollution problems. As coastal waters become more polluted, the costs of the reverse osmosis plants increase. Therefore, source water pollution from poor land use practices, type of geological substrate, or industrial pollutants often leaves municipalities vulnerable to forces they cannot control.

Variability in Surface and Groundwater Supplies—Quantity

Surface water supply quantities can vary for several reasons. First, precipitation patterns can vary from drought conditions that reduce the amount of water available to very stormy conditions that cause flooding and subsequently degrade those floodwaters with everything they come in contact with. In states with riparian water law, the drought conditions will typically cause all utilities using the same water source to equally share the burden of insufficient water. Second, well pumping next to a river or lake can reduce surface water levels for anyone next to or downstream of the pumping. If state water law has no conjunctive use rules to prevent well owners from unfairly "stealing" water from surface supplies, then a utility may receive less water than it expects. Third, a utility may lose access to a water source if it was leased and will not be renewed when the lease is up. And finally, in states with prior appropriation water law, a utility must consider the problems that come along with junior water rights on a stream or lake. In times of drought, a very junior right on a stream may mean it gets little or no water from that stream. If they have water rights on several streams, the different adjudication dates for each stream and the amount of water in each stream will help it calculate which streams will be able to give them how much "wet" water that year. In prior appropriation law, "first in time is first in right." The year the right is obtained determines the order of use, so owners of earlier (and older) water rights will get their turn to use their full amount of allotted water before someone with a more junior right may divert their water.

Groundwater can become inaccessible the moment other well-pumpers over that aquifer draw down the water table to a level below the water utility's well.

Consequently, the uncertainty of water supplies due to the weather, leasing versus owning a water right, or state water law rules means that utilities best serve their public by having numerous water sources available to them. In this way, diverting water from an alternate or several alternate sources protects them from inadequate water available in drought times or highly degraded water resulting from flood. If they do as Phoenix does and purchase a "water ranch" (a local ranch with attached groundwater rights), then they are buying not only a water source, but a clean and nonevaporative storage site as well.

New Regulation

If new federal drinking water regulations are promulgated with lower allowable concentrations of some pollutant, then a utility's water supply becomes automatically degraded with respect to the new regulations. Arsenic is a good example of a pollutant that recently had its maximum allowable concentrations in drinking water reduced. Utilities either must stop using that water, spend enormous amounts to clean that pollutant out of the water, or mix that water with water from another source to "dilute" it down to the new, acceptable drinking water standard.

Planning for Emergency Situations

Preparing for emergencies by planning strategies is always good to do whenever possible. Water source emergencies can be a pollutant spill (e.g., fuel truck falls off highway into a river, accidental release of industrial materials into a river) or a pipeline break. These types of emergencies can only be efficiently dealt with when a utility has several sources from which to draw or sources designated as emergency backup supplies.

THE FUTURE OF SOURCE WATER QUALITY MANAGEMENT

Blending different source waters to upgrade quality, having multiple sources to give a utility options for accessing better quality or larger amounts, or instituting conservation to "create" new water are only a few strategies that utilities must employ to prepare for the future and attenuate rising costs.

Future strategies to manage source waters will need a foundation of federal protection first. Not only is a significant strengthening of the Water Quality Act and Clean Water Act necessary to reduce discharges into water sources, but also much higher, and therefore effective, fines for industrial spills or NPDES permit violations need to be mandated and enforced. After this foundation is laid, there are a few additional strategies that utilities can use. Cooperative interlocal agreements can result in larger, regional water treatment systems that are more efficient. A community downstream of its surface water source or having its groundwater recharge area under a neighboring community can craft agreements to protect the supplies. For example, one community can pay another to reduce development over a recharge area by buying some of their land outright or convincing them to only use conservation subdivision designs with reduced impervious surfaces and installation of water gardens. An upstream community can be paid to improve its stormwater pollution controls or reduce land use practices that create nonpoint source pollution. For source water quality management to improve in the future, it needs not only more cooperative interlocal strategies recognizing land use regulations as the key problem to address, but also effective water pollution controls at the federal level.

DOSE-RESPONSE OF MUSSELS TO CHLORINE

S. Rajagopal
G. van der Velde
Radboud University Nijmegen
Toernooiveld, Nijmegen, The Netherlands

V.P. Venugopalan
BARC Facilities
Kalpakkam, India

H.A. Jenner
KEMA Power Generation and Sustainables
Arnhem, The Netherlands

Chlorine, like any other biocide, produces a dose-dependent response in organisms. However, the response is dependent on a number of parameters. Chlorination of cooling water leaves residuals and by-products that are potential pollutants in the receiving water body and can impact nontarget organisms. Therefore, it is imperative to generate data on the chlorine dose–response relationships of important fouling organisms, such as various mussel species, for efficient but environmentally acceptable biofouling control. Data are presented to show the effects of mussel size (shell length), season of sample collection (spawning vs. nonspawning season), nutritional status (fed vs. nonfed), and acclimation temperature (5–30 °C) on the mortality pattern of different mussel species under continuous chlorination ($0.5–5\ \mathrm{mg\,L^{-1}}$). From the data, it can be concluded that although various factors can influence the dose–response relationships of mussels, generalization is not possible because of species specificity. Among the various parameters, mussel species, mussel size, status of byssal attachment, spawning season, and acclimation temperature have significant effect on chlorine tolerance of mussels, whereas nutritional status shows very little effect.

INTRODUCTION

Chlorination is the most commonly used disinfectant and biocide for treatment of drinking and industrial cooling water (1,2). Depending on the organisms involved and the end result desired, chlorine may be dosed either intermittently or continuously (3,4). A third important criterion that often has a bearing on the applied dose is the concentration of the chlorine (and its reaction products) that reaches the consumer (in the case of drinking water chlorination) or the environment (in the case of cooling water chlorination) (2,5). A fourth factor is chlorine demand, which exhibits variations that are both seasonal and geographical (1). Accordingly, in an actual chlorination program, the chlorine dose is modulated in such a way that the measured level of chlorine residuals is sufficient to bring about the desired result, whether it be microbiological control in drinking water or biofouling control in cooling water (6,7).

For any given organism, one can generate a dose−response curve on the basis of how the organism responds to a given dose. However, in the case of chlorine, it is appropriate to represent this in the form of a concentration−response curve, because dosing of a certain amount of chlorine results in a variable quantity of chlorine that is available for biocidal action. In other words, the available quantity of chlorine may vary depending on the chlorine demand of the water (8).

FACTORS INFLUENCING THE CHLORINE TOXICITY

The response of an organism to chlorine would vary depending on a number of factors. Among the various factors, the type of organism is an important criterion. Shelled organisms (such as mussels) can withstand relatively long-term exposure to chlorinated water (9,10), when compared with soft-bodied organisms, such as hydroids or ascidians (11). A review of literature clearly indicates all other fouling organisms succumb faster than mussels. Therefore, chlorine regime targeted against mussels would also eliminate other fouling organisms. In the present review, chlorine dose−response relationships of mussels are discussed in relation with various factors, including mussel species, mussel size, spawning season, byssus attachment, nutritional status, and acclimation temperature, which can influence the chlorine tolerance of mussels.

MUSSEL SPECIES

Efficacy of chlorine as an antifoulant depends on various parameters, most importantly residual levels of chlorine and contact time (6,9). A survey of existing literature shows that at residual levels commonly employed ($1\ \mathrm{mg\,L^{-1}}$) in power station cooling circuits, mortality takes several days. For example, at $1\ \mathrm{mg\,L^{-1}}$ continuous chlorination, *Mytilus edulis* (blue mussels) takes about 480 h for 100% mortality (12). On the other hand, in tropical marine mussels, *Perna viridis* (green mussels) takes about 816 h for 100% mortality when $1\ \mathrm{mg\,L^{-1}}$ residual chlorine is applied continuously (13). In *Dreissena polymorpha* (zebra mussel), 95% mortality is observed after about 552 h exposure to $1\ \mathrm{mg\,L^{-1}}$ residual chlorine (14). In comparison, *Mytilopsis leucophaeata* (dark false mussel) takes about 1104 h to achieve 100% mortality at $1\ \mathrm{mg\,L^{-1}}$ residual chlorine (Fig. 1). The exposure time required for 100% mortality of *M. leucophaeata* at different chlorine concentrations are much higher than that required for *D. polymorpha* (588 h) and *Mytilus edulis* (966 h).

MUSSEL SIZE

In the case of common fouling organisms such as mussels and barnacles, it is often seen that the size (or age) of the organism is an important factor that influences its sensitivity to chlorine. It has been shown that, for several organisms, a size-dependent variation in the response exists, with larger organisms showing increased tolerance (Fig. 1). However, such size-dependent nature of toxicity is not universal and there are organisms which exhibit uniform sensitivity to chlorine, irrespective of size. An example for mussel size influencing tolerance to chlorine is the mussel *M. leucophaeata* (9). Here, the tolerance is maximum in medium-size mussels (about 10 mm), whereas smaller (2 mm) and larger (20 mm) mussels show greater sensitivity (Fig. 1). This pattern is in contrast with the results reported for *Mytilus edulis*, where the tolerance linearly increases with shell size (15). In the case of *D. polymorpha*, shell size has no effect on the sensitivity of the organism to chlorine (10,16). Therefore, the relationship between mussel size and chlorine toxicity is not similar among different mussel species, and generalizations regarding the size effect should be made after careful observation.

BYSSUS ATTACHMENT

Mussels use byssus threads to attach themselves to hard substrata. The status of attachment is also an important criterion that determines the response of mussels to chlorine (15,17). It has been experimentally shown that mussels, which normally are attached with the help of their byssus threads, become more sensitive to chlorine when they are exposed to it under unattached condition (Fig. 2). Once detached from a substratum, the mussel tries to reattach itself by producing new byssus threads, for which it has to open its bivalve shell and extend its “foot” outside. This kind of enhanced byssogenic activity increases the exposure of the soft tissues of the mussel to chlorine, thereby increasing the toxic effect. On the other hand, attached mussels are byssogenically less active, and in a chlorinated environment their shells remain mostly closed, thereby protecting their soft body from chlorine (12,18).

SPAWNING SEASON

Physiological status of the organism is also an important factor that influences chlorine toxicity. Research using a number of organisms has shown that chlorine toxicity is significantly higher during breeding seasons than during nonbreeding seasons. Mussels collected during the spawning season and those collected during nonspawning season behave quite differently with respect to their sensitivity to chlorine (Fig. 3). Mussel species collected during their spawning season were less tolerant to chlorine, whereas those collected during the nonspawning season were more tolerant. The difference in tolerance between the two groups was nearly 29% (9). Kilgour and Baker (16) and Jenner et al. (1), who reported similar results for *D. polymorpha,* attribute the greater tolerance of mussels during the nonspawning season to low metabolic rates and reduced filtration rates, which would result in reduced exposure to the toxicant. Lower energetic demands during nonbreeding seasons may be the reason for reduced toxicant uptake. On the other hand, mussels tend to be weaker after spawning when they have little energy reserves in the body (19), with the result that

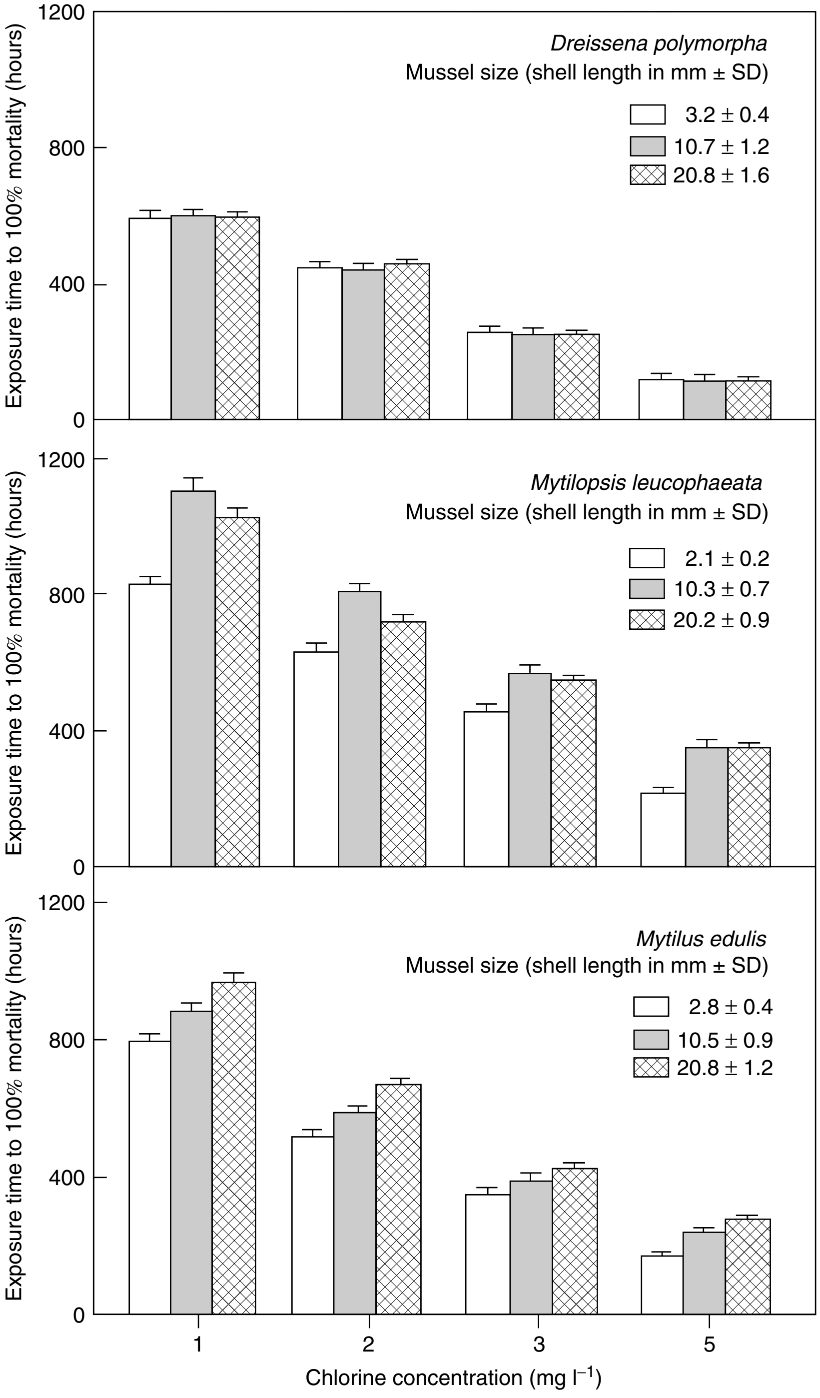

Figure 1. Comparison of exposure times to reach 100% mortality of different size groups of *Mytilopsis leucophaeata, Dreissena polymorpha*, and *Mytilus edulis* at different chlorine concentrations. Mortality data are expressed as mean ±SD ($n = 80$) of four replicate experiments ($n = 20$ individuals in each experiment). Test methods and mortality determinations were similar in all toxicity studies of species.

they are less tolerant to biocide. The data point to the importance of judicious sampling while carrying out toxicity experiments using seasonal breeders.

FED VS. NONFED MUSSELS

Status of feeding may have an effect on the toxicity of chlorine to organisms. Kilgour and Baker (16) showed that mussels *D. polymorpha*, when maintained on a diet of *Chlorella*, were consistently more sensitive to hypochlorite than starved mussels. The effect was attributed to an increased tendency of the fed mussels to filter water, which incidentally increases the exposure of their body parts to chlorine. Mussels that are fed with microalgae are likely to filter more water than those that are unfed. On the other hand, Rajagopal et al. (13) showed that, in the case of the mussel *Perna viridis*, fed and starved individuals showed similar mortality rates when exposed to chlorine. It must be kept in mind that chlorine may act as a strong suppressant of filtration activity in bivalve mussels, which has been shown by Rajagopal et al. (18) using Mussel-Monitor®, an automated instrument with which one can

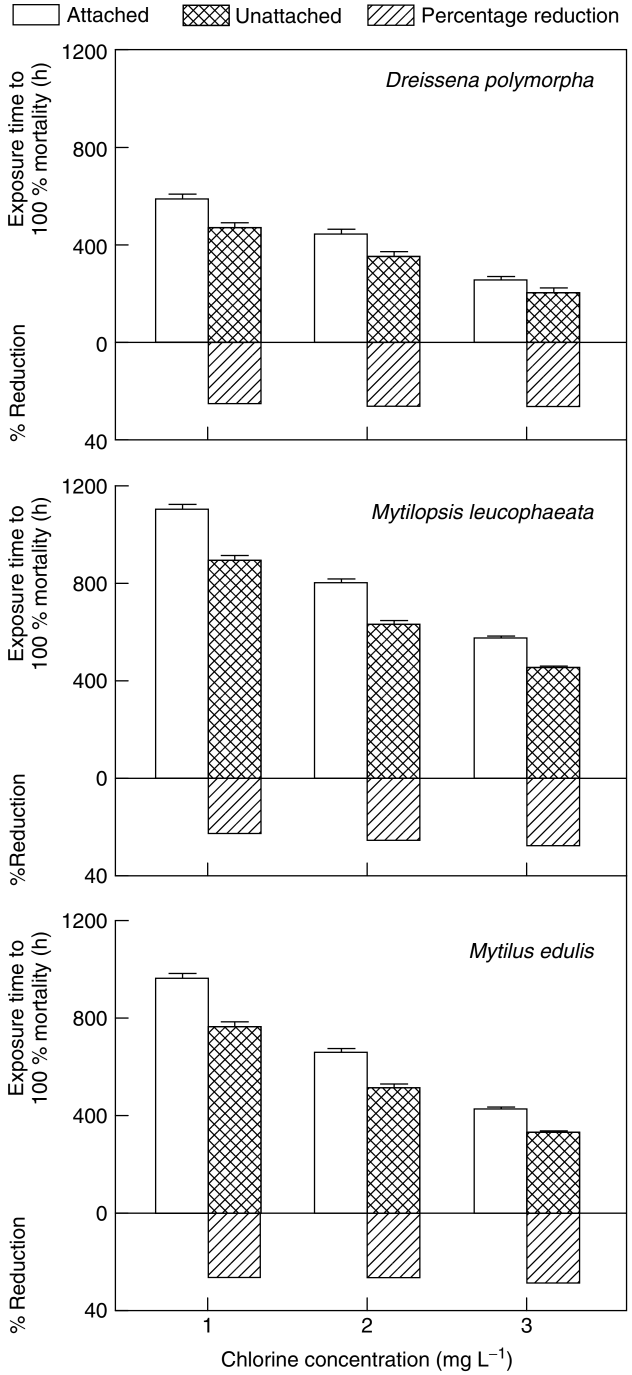

Figure 2. Time difference (%) between byssally attached and unattached *Dreissena polymorpha* (17), *Mytilopsis leucophaeata*, and *Mytilus edulis* (15) for 100% mortality at different chlorine concentrations.

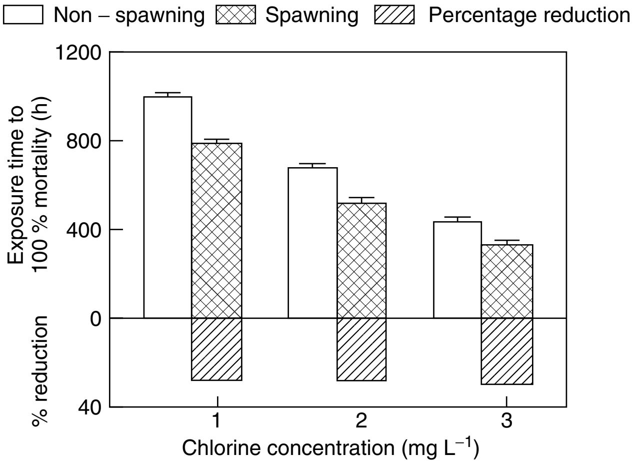

Figure 3. Cumulative mortality (%) of spawning and nonspawning *Mytilopsis leucophaeata* at different chlorine concentrations (TRC = total residual chlorine). Eighty mussels were used at each chlorine dose.

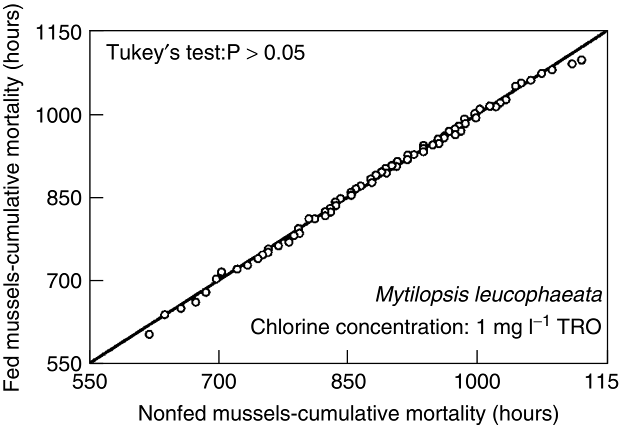

Figure 4. Cumulative mortality (%) of fed and nonfed *Mytilopsis leucophaeata* at different chlorine concentrations (TRO = total residual oxidant).

monitor the opening and closing of mussel shells (1,4). Shell valve movement of *M. leucophaeata* tested with unfiltered brackish water from the Noordzeekanaal in The Netherlands showed little or no filtration in presence of 1 mg L^{-1} residual chlorine. Obviously, presence of microalgae would have no significant effect on *M. leucophaeata* at a residual chlorine concentration of 1 mg L^{-1} (Fig. 4). Rajagopal et al. (20) have also shown that filtration activity in *D. polymorpha* stops almost completely at residual chlorine level of 0.5 mg L^{-1} and higher.

ACCLIMATION TEMPERATURE

Temperature is yet another important factor that influences the sensitivity of organisms to chlorine. Mussels acclimated to different temperatures show significantly different tolerances to chlorine (Fig. 5). Decrease in acclimation temperature from 30 °C to 5 °C increases chlorine tolerance (0.5 mg L^{-1} residual chlorine) of *M. leucophaeata* by 52 days. Such increase in chlorine tolerance at lower acclimation temperatures has also been reported for other mussel species, such as *D. polymorpha* (11,14) and *Mytilus edulis* (1,12). However, at acclimation temperatures above 35 °C, temperature has overriding effects when compared with chlorine. Harrington et al. (21) showed that at 36 °C, combined use of temperature and chlorine resulted in mortality

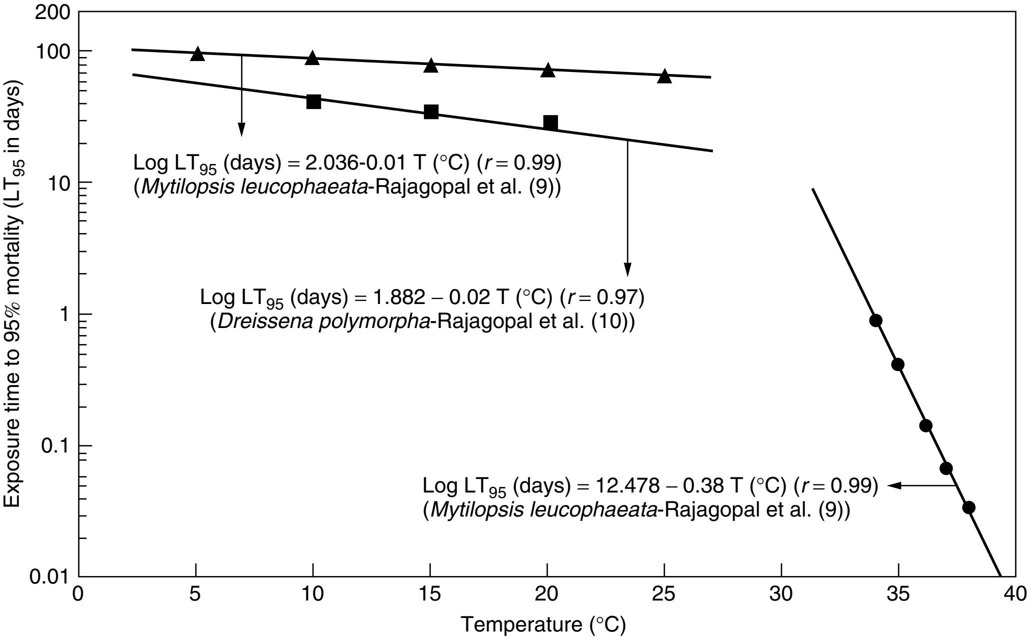

Figure 5. Comparison of exposure times to reach 95% mortality of *Mytilopsis leucophaeata* and *Dreissena polymorpha* at 0.5 mg L^{-1} residual chlorine depending on the acclimation temperature. of *D. polymorpha* at rates similar to that obtained with heat alone.

CONCLUSION

Data available in the literature show that various factors can influence the sensitivity of organisms estimated using chlorine bioassays. Among the parameters, mussel species, mussel size, spawning season, acclimation temperature, and status of attachment seem to have significant influence on chlorine tolerance. Therefore, chlorine bioassays using mussels or such organisms need to be carried out after taking the above factors into consideration.

METALLOTHIONEINS AS INDICATORS OF TRACE METAL POLLUTION

Trifone Schettino
Maria Giulia Lionetto
Università di Lecce
Lecce, Italy

INTRODUCTION

Metallothioneins (MTs) are low molecular weight, cysteinrich metal-binding proteins that are involved in detoxification and homeostasis of heavy metals. Since their discovery in the horse kidney by Margoshes and Vallee (1), metallothioneins have been further identified in most living organisms, vertebrates, invertebrates, algae, fungi, and plants. Today, the term “metallothionein” is used to designate a series of well-known molecules showing a large degree of structural and functional similarities to those first described for horse kidney metallothionein. A nomenclature system for metallothionein was adopted in 1978 (2) and then extended by introducing a subdivision of all MTs into three classes (3). By this convention Class I includes metallothioneins with locations of cysteines closely related to those in the horse kidney metallothionein; Class II comprises metallothionein with locations of cysteines only distantly related to those in horse kidney metallothionein; and Class III subsumes low molecular weight metalloisopolypeptides containing gammaglutamyl-cysteinyl units resembling in their features mammalian MTs. They are called phytochelatin and occur predominantly in plants and fungi. As the number of known MT sequences has grown, this subdivision has become inadequate. In order to better differentiate the several known MTs, in 1999 (4,5) a new classification system was proposed based on sequence similarities and phylogenetic relationships. This system subdivides the MT superfamily into families, subfamilies, subgroups, and isolated isoforms and alleles. As before, the metallothionein superfamily is defined phenomenologically as comprising all polypeptides that resemble equine renal metallothionein in several of their features (2,3). Such general features are low molecular weight, high metal content, characteristic amino acid composition (low content of aromatic amino acid residues, high cystein content, which accounts for MT heavy metal affinity and binding capacity), unique amino acid sequence with characteristic distribution of Cys (i.e., Cys–X–Cys, where X stands for an amino acid residue other than cysteine), and spectroscopic manifestations characteristic of metal thiolate clusters, which provide the protein with a highly stable tertiary structure. The metal affinity for the binding sites follows the general order found for inorganic thiolates: Hg(II) > Ag(I) > Cu(I) > Cd(II) > Zn(II). The MT superfamily is subdivided into several families, each of them including MTs that share a particular set of sequence specific characters. Members of a family can belong to only one family and are thought to be evolutionarily related. The inclusion of a MT in a family presupposes that its amino acid sequence is alignable with that of all members. A common and exclusive sequence pattern, a profile, and a phylogenetic tree can therefore be connected with each family. Each family is identified by its number and its taxonomic range. To date, 15 MT families are known: Family 1, vertebrate MTs; Family 2, mollusc MTs; Family 3, crustacean MTs; Family 4, echinodermata MTs; Family 5, diptera MTs; Family 6, nematoda MTs; Family 7, ciliata MTs; Family 8, fungi-I MTs; Family 9, fungi-II MTs; Family 10, fungi-III MTs; Family 11, fungi-IV MTs; Family 12, fungi-V MTs; Family 13, fungi-VI MTs; Family 14, prokaryota MTs; and Family 15, planta MTs.

BIOLOGICAL FUNCTION OF METALLOTHIONEINS

The ubiquitous distribution of MTs in virtually all types of organisms studied to date attests to the conserved nature of MTs and their function. The biological function of MTs is likely related to the physiologically relevant metals that these proteins bind. In mammals, MT is found to bind zinc and copper under normal physiological conditions. Both zinc and copper are trace metals that are essential for life. Recent studies have produced strong evidence to support the idea that MT functions as a metal chaperone for the regulation of gene expression and for synthesis and functional activity of proteins, such as metalloproteins and metal-dependent transcription factors (6–10). MT could thus serve as a reservoir of essential metals.

MTs are inducible proteins. Exposure of the organisms to high levels of heavy metals (e.g., Zn, Cu, Cd, and Hg) and the following increase of heavy metal cations in the cells stimulates metalloprotein neosynthesis by enhancing MT gene transcription. *Cis*-actin sequences, termed metal response elements (MREs), located in multiple copies along the promoter, allow heavy metal ion induction of MT transcripts (11,12). The MT mRNA is translated by cytosolic free ribosomes, leading to an increase of apometallothioneins that will rapidly react with free metal cations, sequestering them and protecting cell structures from nonspecific interaction with heavy metal cations. This process circumvents cellular damage preventing metal toxicity under overload conditions. MT induction can be measured as the concentration or rates of formation of the responsible mRNA, MT, and levels of MT-bound metals. Each of them provides different information on the inductive process and may display differential dynamics.

METALLOTHIONEINS AS BIOMARKERS

The importance of metallothionein (MT) in toxicologic responses to heavy metals was early recognized for potential application as a "biomarker" of organism exposure to heavy metals in aquatic environments. A biomarker is a pollutant-induced variation in cellular or biochemical components or processes, structures, or functions that is measurable in a biological system or sample (13). The biomarker approach in environmental monitoring has been increasingly used in the last 20 years for the ecotoxicological assessment of aquatic ecosystems. Since the harmful effects of pollutants are typically manifested at lower levels of biological organization before disturbances are realized at the population, community, or ecosystem levels (14), the use of biomarkers measured at the cellular level has been proposed as sensitive "early warning" tools for biological effect measurement in environmental quality assessment (15).

One aspect of environmental degradation in aquatic environments is pollution from heavy metals, which are persistent and accumulable by aquatic organisms. A great number of metal pollution events have been reported in fresh waters, coastal waters, and groundwaters, where abnormal metal levels occurred as the consequence of natural and, especially, of manufactured sources of pollution. A crucial aspect of heavy metal pollution, determining the actual ecological risk, is the bioavailability of heavy metals in aquatic environments. Bioavailable heavy metals represent that portion of the total environmental metal load that is of direct ecotoxicological relevance (16). Apart from chemical analytical techniques, some other new approaches have recently been used to determine the availability of toxic metals for living organisms in aquatic environments. One of the most relevant contributions in this field is that provided by MT induction determination.

Due to the interest in MT application in environmental monitoring, different techniques and methodologies have been developed in the last few years for the quantification of total MTs, including chromatographic separation of soluble cytosolic MT-containing fraction associated with the evaluation of the metal concentration, HPLC-AAS (17,18), HPLC-ICP (19–21), metal substitution assays (22,23), radioimmunological techniques (24–26), electrochemical analysis (27,28) and a spectrophotometric method recently developed for routine application in biomonitoring (29). Molecular biology techniques are employed for the analysis of MT mRNA. However, it is important to point out that the expression of MT levels is not implicit from the presence of endogenous MT mRNA levels in tissues.

Thanks to the growing knowledge about MT quantification, induction of MT following heavy metal exposure has been reported in different aquatic species and tissues (30,31), especially in common bioindicator species such as *Mytilus galloprovincialis, Mytilus edulis, Littorina littorea, Ostrea edulis, Crassostreä* virginic*a*, *Dreissena polymorpha*, and *Macoma balthica*.

Recent field studies using *Mytilus galloprovincialis* as a bioindicator have also demonstrated that measurements of MTs can provide an accurate indication of subtle environment increases in metal contamination (32,33), confirming their usefulness as a biomarker of trace metal exposure in aquatic environmental monitoring.

Therefore, these proteins have been proposed by the European Commission and other international scientific organizations to be included in environmental monitoring programs as a biomarker to assess metal pollution in aquatic environments.

It is known that biotic and abiotic factors such as seasonal variation, sex, age, size of the animal, and dietary factors affect MT levels in the aquatic organisms (30,34). Such factors are likely to interfere with MT synthesis in response to metal occurrence (toxic or excess of essential metals) in the aquatic ecosystems. Therefore, it is very important to know how these factors affect MT expression in the utilized bioindicator species before MT can be used in a monitoring program.

Ideally, information obtained by quantification of MT in indicator species could be used to assess adverse effects on the species themselves, on other components of the ecosystem and on humans. This information could be used in routine biomonitoring programs as early warning of potential human health effects, to make decisions about possible cleanup, and to evaluate the efficacy of past cleanup of hazardous waste.

AMPHIPOD SEDIMENT TOXICITY TESTS

Augusto Cesar
Maria del Carmen Casado Martínez
Inmaculada Riba López
Tomás Ángel Del Valls Casillas
Universidad de Cadiz
Cadiz, Spain

INTRODUCTION

General

Amphipod sediment toxicity tests are technically developed and are widely accepted as useful tools for a wide variety of research and regulatory purposes (1–3). For example, they can be used to determine the sediment toxicity of single chemicals and chemical mixtures, the chemical bioavailability, the potential adverse effects of dredged material, and the magnitude and spatial and temporal distribution of pollution impacts in the field (4).

Various methods have been developed to evaluate sediment toxicity and these procedures range in complexity from lethal to sublethal tests that measure effects of chemical mixtures on the amphipod species. The evaluated sediment phase may include whole sediment, suspended sediment, elutriates, or sediment extracts (5–7).

The test organisms include amphipods, algae, macrophytes, fishes, and other benthic, epibenthic, and pelagic invertebrates (8). However, amphipod toxicity tests can provide rapid and effective information on the potential effects of contaminants in sediments.

Historical Background

Historically, the assessment of sediment quality has often been limited to chemical characterizations (9). However, quantifying contaminant concentrations alone cannot always provide enough information to adequately evaluate potential adverse effects that arise from interactions among chemicals, or that result from time-dependent availability of sediment-associated contaminants to aquatic organisms (7).

The evaluation of contaminant has primarily emphasized surface waters and effluents, not sediments, and the first incentive for sediment testing was dredged material (7). In 1977, the U.S. EPA and the U.S. Army Corps of Engineers recommended a series of 10-d toxicity and bioaccumulation tests with amphipods, clams, polychaetes, shrimps, and fishes to evaluate proposed discharge of dredged material into estuarine and marine waters.

Significance of Use

Sediment provides habitat for many benthic organisms and is a major repository for many of the more persistent chemicals that are introduced into surface waters. In the aquatic environment, most anthropogenic chemicals and waste materials including toxic organic and inorganic chemicals eventually accumulate in sediment (3).

The objective of an amphipod sediment toxicity test is to determine whether contaminants in sediment are harmful to amphipod species. The tests can be used to measure interactive toxic effects of complex contaminant mixtures in sediment.

The purpose of the amphipod solid-phase toxicity test is to determine if test sediment samples reduce survival (growth, reproduction, etc.) of exposed organisms relative to that of organisms exposed to control and reference sediment. Test results are reported as treatment (station) or combination of treatments (sites or chemicals) that produce statistically significant reduced survival (growth, reproduction, etc.) from control or reference sediments.

Sediment amphipod tests (3) can be used to (1) determine the relationship between toxic effects and bioavailability, (2) investigate interactions among contaminants, (3) compare the sensitivities of different organisms,

(4) determine spatial and temporal distribution of contamination, (5) evaluate hazards of dredged material, (6) measure toxicity as part of product licensing or safety testing or chemical approval, (7) rank areas for clean up, and (8) set cleanup goals and estimate the effectiveness of remediation or management practices.

Scope and Application

Procedures are described for testing amphipod crustaceans in the laboratory to evaluate the toxicity of contaminants associated with sediments. Sediments may be collected from the field or spiked with compounds in the laboratory. A toxicity method is outlined for diverse species of estuarine, marine, and freshwater sediment amphipods found within coastal and fresh waters. Generally, the methods described may be applied to all species, although acclimation procedures and some test conditions (temperature, salinity, etc.) will be species specific. Procedures described here are principally based on References 1–3. Although it is recognized that a variety of other nonstandardized toxicity test methods are used in ecotoxicologic research, emphasis is placed on standardized protocols provided by the U.S. EPA and ASTM, because these are the tests most commonly used in regulatory applications (10). Other countries such as The Netherlands have adapted and developed standardized protocols using local species for regulatory purposes (11).

Selection of Test Organisms

The choice of a test organism has a major influence on the relevance, success, and interpretation of a test. Test organism selection should be based on both environmental relevance and practical concerns (3). The species should be selected based on sensitivity to contaminant behavior in sediment and feeding habitat, ecological relevance, geographic distribution, taxonomic relation to indigenous organisms, acceptability for use in toxicity assessment (e.g., a standardized method), availability, and tolerance to natural geochemical sediment characteristics (7).

Amphipods have been used extensively to test the toxicity of marine, estuarine, and freshwater sediments (1–3). Ideally, a test organism should have a toxicological database demonstrating relative sensitivity to a range of contaminants of interest in sediment, have a database for interlaboratory comparisons of procedures, be in direct contact with sediment, be readily available year-round from culture or through field collection, be easily maintained in the laboratory, be easily identified, be ecologically or economically important, have a broad geographical distribution, be indigenous (either present or historical) to the site being evaluated or have a niche similar to organisms of concern (e.g., similar feeding guild or behavior to the indigenous organisms), be tolerant of a broad range of sediment physicochemical characteristics (e.g., grain size), and be compatible with selected exposure methods and endpoints.

The sensitivity of an organism is related to route of exposure and biochemical response to contaminants (3). Generally, benthic organisms can receive exposure via from three primary sources: interstitial water, whole sediment, and overlying water. Because benthic communities contain a diversity of organisms, many combinations of exposure routes may be important (3). Therefore, behavior and feeding habits of a test organism can influence its ability to accumulate contaminants from sediment and should be considered when selecting test organisms for sediment testing (3). Table 1 lists some commonly used amphipod species for sediment toxicity testing and some useful information when selecting the proper amphipod species for sediment toxicity assessment.

Amphipods

Amphipods are ecologically important members of benthic infaunal communities and are a primary food resource for a number of marine invertebrate, fish, and bird species worldwide. In general, crustacea are among the most sensitive members of benthic communities to anthropogenic disturbance, including pollution (10).

Table 1. Some Commonly Used Amphipod Species for Sediment Toxicity Testing

Amphipods	Test and Point(s)[a]	Test Period, d	Habitat[b]	References
Fresh water				
Diporeia sp.	S	10–28	B, I	1,12
Hyalella azteca	S, G, R	10–28	B, E	1,13
Salt water				
Ampelisca abdita	S, G, R	10	T, I	2,14
Ampelisca brevicornis	S, G, R	10–28	T, I	15,16
Corophium voluntator	S, I	10	T, I	17,18
Eohaustorius estaurius	S	10	B, I	2,14
Gammarus aequicauda	S	10	E	19,20
Gammarus locusta	S, R	10–28	E	21,22
Grandidierella japónica	S, G	10	T, I	2,14
Hyalella azteca	S, G, R	10–28	B, E	2,23
Leptocheirus plumulosus	S, G, R	10–28	B, I	2,24
Microdeutopus gryllotalpa	S	10	T, I	25,26
Repoxynius abronius	S	10	B, I	2,14
Tiburonella viscana	S	10	B, I	27,28

[a] S = survival, G = growth, I = immobilization, R = reproduction.

[b] B = burrow, E = epibenthic, I = infaunal, T = tube dweller.

Amphipods are a group of small crustaceans that can live in very different habitats. They are found in the sea, in estuaries, in continental waters, and even in certain terrestrial wetlands (29). Their biogeographical distribution embraces the polar waters all the way to the tropics. As for their bathymetric distribution, they extend from humid atmospheres of some forests all the way to abyssal depths. At the present time, more than 6000 species have been registered worldwide (29). Amphipods are widely distributed and common in unpolluted lotic and lentic systems; however, they are less common in hydrodynamics zones and are a primary food source for fish and voracious feeders of animal, plant, and detrital material (30).

Infaunal amphipods are excellent organisms for toxicity tests with sediment (Fig. 1) and are strongly recommended as appropriate test species for toxicity bioassays (14,30,31). Amphipods are often chosen for ecological and ecotoxicological studies due to their ecological relevance, sensitivity to environmental disturbance, and amenability for culture and experimentation (2,21,32). Overall, infaunal amphipods are excellent bioassay organisms for toxicity tests with whole sediment (31).

METHOD DESCRIPTION AND EXPERIMENTAL DESIGN

The test system described by Swartz et al. (14) for the amphipod *Rhepoxynius abronius* is recommended for bioassays with this and other amphipod species. This section describes a general laboratory method to determine the toxicity of contaminated sediments using marine, estuarine, and freshwater amphipod crustaceans, following compiled standards procedures (1–3).

Test sediments may be collected from marine, estuarine, and freshwater environments or spiked with compounds in the laboratory. The toxicity test usually is conducted in 1-L glass chambers containing 2 cm (175 mL) of sediment and 800 mL of overlying seawater (1:4 ratio of sediment to water). For 10-d acute tests the exposure is static, and the organisms are not fed during this period. Survival is most frequently used as the endpoint in studies, and reburial of surviving amphipods is an additional measurement that can be used. However, in chronic exposure, renewal systems can be static and organisms are fed over the 28-d exposure period. The endpoints commonly used are growth and reproduction.

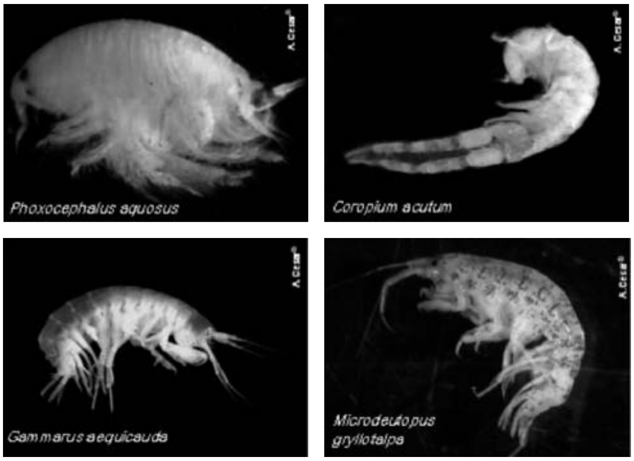

Figure 1. Some species used in amphipod sediment toxicity tests.

A summary of general parameters and conditions to follow when developing an amphipod sediment toxicity test in the laboratory is included in Table 2.

Quality Control

If more than 10% mean mortality occurs in the control, the test must be repeated (3). However, in chronic tests 20% mean mortality in the control is acceptable. Unacceptably

Table 2. Summary of Some Conditions to Develop the Test Using Amphipods in the Laboratory

Parameter	Conditions
Test type	Whole sediment, suspended sediment, elutriates, or sediment extracts, static or renewal (depends on test type)
Temperature	Species dependent (10–25 °C)
Salinity	Species dependent (2–38 psu)
Light quality	Broad-spectrum fluorescent lights
Illuminance	500–1000 lux
Photoperiod	24 light: 0 dark
Test chambers	1-L glass beakers, recommended 10 cm Ø
Sediment volume	175–200 mL (1:4 sediment/water ratio)
Overlying water volume	600–800 mL (1:4 sediment/water ratio)
Water renewal	Not necessary or renewal (depends on test type)
Size and life stage of amphipods	Species dependent, 2–6 mm (no mature males or females)
Number of organisms per chamber	10–20
Number of replicates	At a minimum, 4 to 5 replicates must be used
Feeding regime	Species and test type dependent
Aeration	Trickle flow (<100 bubbles/min)
Overlying water	Clean natural or reconstituted water
Test exposure	10–28 d
Endpoints	Survival, growth, immobilization, reproduction, etc.
Test acceptability	Greater than or equal to 80–90% survival in controls

high control mortality indicates that the organisms are being affected by important stress factors other than contamination in the material being tested, and the test has to be reevaluated. These stresses may be due to injury or disease, unfavorable physical or chemical conditions, improper handling or acclimation, or possibly unsuitable sediment grain size. Species selection and the potential effects of these and other variables should be carefully reexamined in an attempt to reduce unacceptably high mortality.

Reference toxicant tests should be performed routinely in parallel on all populations of organisms in sample testing. When data for a particular reference toxicant have been generated on at least five populations of organisms of a species, two standard deviations above and below the mean are established as the bounds of acceptability. Reference toxicant tests should be conducted at least monthly on each species cultured in house and should be performed on each lot purchased or field collected organisms (3,33). Reference toxicant tests are most often acute lethality tests performed in the absence of sediment (3,7).

Statistical Analysis

The statistical comparisons and interpretations of the results should be appropriate to the experimental design. Study design depends on its objective and each study design has specific statistical design and analytical considerations.

Most amphipod sediment toxicity tests are based on the calculation of a medium effect or lethal and effective concentration or dose (LD_{50}, EC_{50}, IC_{50}, etc.) when sediments are spiked with individual contaminants, or upon the magnitude of response for field-collected sediments. However, the most useful information for predictive purposes is an estimation of the dose–response curve and the subsequent ranking of toxicity.

A variety of techniques are used to calculate these responses or endpoints: probit, moving angle average, and Spearman–Karber are examples. Most of these methods allow calculation of a confidence interval. These NOEC calculations depend on the number of replicates used in the toxicity test and the power of the ANOVA and other multiple comparison techniques used. When sediment samples are independently replicated, results can be statistically compared with control or reference sediments by *t*-test, analysis of variance (ANOVA), or regression analysis. An ANOVA is used to determine differences among treatments. When the assumptions of normality or homogeneity of variance are not met, transformations of the data may remedy the problem, so that the data can be analyzed by parametric procedures, rather than by nonparametric methods. Detailed statistical hypothesis testing, for making decisions about the appropriate method used, is discussed in Reference 3.

Confounding Factors

Interferences are characteristics of a sediment or sediment test system that can potentially affect test organism survival aside from those related to sediment-associated contaminants (3). These interferences can potentially confound interpretation of test results in two ways: (1) toxicity is observed in the test when contamination is not present, or there is more toxicity than expected; and (2) no toxicity is observed when contaminants are present at elevated concentrations, or there is less toxicity than expected.

There are three categories of interfering factors: those characteristics of sediments affecting survival independent of chemical concentration (i.e., noncontaminant factors); changes in chemical bioavailability as a function of sediment manipulation or storage; and the presence of indigenous organisms. For example, survival of some marine amphipods can be significantly affected by the grain size of the sediment (34) or ammonia concentration (35). Other confounding factors within sediment habitats include both abiotic (i.e., salinity, temperature, pH, dissolved oxygen, hydrogen sulfide, alkalinity, hardness, light) and biotic parameters (i.e., food limitation, predators, competitors, disease, biogenic disturbance).

Because of the heterogeneity of natural sediments, extrapolation from laboratory studies to the field can sometimes be difficult. Sediment collection, handling, and storage may alter the bioavailability and concentration by changing the physical, chemical, or biological characteristics of the sediment. Maintaining the integrity of a field-collected sediment during removal, transport, mixing, storage, and testing is extremely difficult and may complicate the interpretation of effects.

FUTURE RESEARCH

Research is continuing in the areas of chronic sediment toxicity methods, field validation of laboratory toxicity and bioaccumulation tests, toxicity identification and evaluations (TIE), and the multispecies experiments. Additional research is also needed to evaluate factors controlling the partitioning or sorption of a compound between water, colloids, and sediment, including aqueous solubility, pH, redox, affinity for sediment organic carbon and dissolved organic carbon, grain size of the sediment, sediment mineral constituents (oxides of iron, manganese, and aluminum), and the quantity of acid volatile sulfides in sediment. Additional research is also needed on aspects of fluid mechanics to quantify the physical processes of colloidal growth and transport and physical mass-transfer processes over a wide spectrum of solute–solid interfaces. The goal of this research would be to assimilate the biological, hydrological, geological, and ecological information necessary for the assessment and management of contaminated sediments. The end result of this research would be an improved understanding of the importance of contaminants in sediment relative to other factors influencing ecosystems.

CILIATED PROTISTS AS TEST ORGANISMS IN TOXICITY ASSESSMENT

Braga, Portugal

TOXICITY ASSESSMENT, CYTOTOXICITY, AND TEST ORGANISMS

Increasing environmental pollution and the continuous development of new drugs have led to an ever growing concern about the potential effects of these compounds on human and/or environmental health, directly or indirectly. Toxicity data collected in the laboratory are the primary source of information that can be used for regulatory or risk assessment proposes.

In vitro cytotoxicity techniques are being increasingly developed and evaluated as alternatives to the use of vertebrates in testing environmental pollutants. Besides the reduction of laboratory animals, these lower cost tests allow for the use of specific endpoints to determine the targets of toxic effects with great precision and reproducibility (1). Because of the long-standing interest in aquatic toxicity testing, a myriad of test species, types of tests, and endpoints have been developed and used.

In recent years, much research has been done to assess the toxicity of various compounds in a series of biotests using several organisms. The appeal of these tests lies in their simplicity and high degree of reproducibility (2). On the other hand, test organisms for assessing environmental risk and impact must possess a lot of desirable features: they must be eukaryotic, their biology and general responses must be well known, the laboratory handling must be relatively easy, and a short generation time is desirable whenever studies of long-term effects are necessary (3).

Ciliated protists fulfill all those requirements. Furthermore, as they have a wide distribution and ecological significance, performing key functions in energy flow and elementary cycling in aquatic foodwebs, they can be ideal early warning indicators of aquatic ecosystem deterioration. Recently, the use of ciliates in toxicological tests has been investigated and their potential in standard bioassays has been demonstrated in aquatic environments and even elsewhere (4–6). Nevertheless, there are only a few works suggesting new test organisms in this group (7–9).

Toxicokinetics and toxicodynamics govern the response of exposed organisms (10). Single-celled organisms are useful test subjects because toxicokinetics is, in this case, very simplified and one can consider that it is proportional to water–lipid partitioning (11). Among protists, the ciliate *Tetrahymena*, and among the several species, *Tetrahymena pyriformis*, is the most commonly ciliated model used for laboratory research: it has been, for more than five decades, the organism of choice in analyses, evaluation of protein quality, and determination of effects of several toxic substances. It was the first protist to be cultivated axenically, that is, in a standard medium, free from bacteria or other organisms (12). This fact could explain the extensive use of this ciliate as a model cell system since the addition of a test compound can be, in principle, the only change in culture conditions (3). Therefore, under axenic culture conditions, standardization and guarantee of reproducibility of assays are obtained (9).

Beyond the rare reviews on this subject (3,13–16), some works demonstrate the potential of ciliates as test organisms, especially *Tetrahymena pyriformis* and *T. termophila*, but also *Colpidium campylum* and, more recently, *Spirostomum teres* and *S. ambiguum*.

Silverman (17) used the movement of *T. termophila*, in axenic cultures, to assess the toxicity of several compounds using the Draise test, concluding its validity. Later, Noever et al. (18) suggested another test to substitute for the Draise test, this time with *T. pyriformis*, using the mobility of the ciliate in only 30 s.

Yoshioka et al. (19) criticized the lack of rigorous establishment of experimental conditions in assays with *T. pyriformis* and validated a growth impairment assay of this ciliate in axenic culture, to assess the toxicity of a series of compounds, comparing the results with the calculation of LD_{50} of *Orizias latipe* and concluding for the validity of *T. pyriformis* in the assessment of toxicity in aquatic environments.

Dive et al. (7) presented, for the first time in a standardized form, a bioassay method using the ciliate *Colpidium campylum* as a test organism. Le Dû et al. (20) compared this bioassay to tests with *Daphnia* or the MICROTOX® test (Microbics) in the detection and modeling of the aquatic toxicity of soluble residuals, concluding for its validity as a complementary test or even a substitute for the other tests.

Nalecz-Jawecki et al. (8) developed a biotest using *S. ambiguum*, one of the biggest protists, 2–3 mm long, to assess water quality. Later, Nalecz-Jawecki and Sawicki (21) implemented a miniaturized and standardized bioassay based on the former and called it the SPIROTOX test. The development of the SPIROTOX test for the toxicity of volatile compounds enabled the creation of a database of toxicity of organic pollutants to *S. ambiguum* (22). Futhermore, comparison of the sensitivity of this test to other bioassay systems used worldwide indicated that the SPIROTOX test can be an important element of an assessment battery as the representative ciliated protists component (23,24).

Sauvant et al. (25) evaluated the toxicity of bottled water using two models in a series of *in vitro* assays: the mammalian fibroblasts L-929 and *T. pyriformis*. They concluded that both models are adequate and that *T. pyriformis* was more sensitive than the fibroblasts in samples bottled for longer periods.

Larsen et al. (26) proposed an international pilot ring test in order to standardize a growth inhibition test protocol with *T. pyriformis*. They concluded that the *Tetrahymena* test could be recommended for ecotoxicological screening purposes, being an ecologically relevant supplement to aquatic toxicity testing. In recent years, the *T. pyriformis* multigeneration growth impairment assay or TETRATOX (26,27) has been used quite often. It uses data from 40-h growth of a population of *T. pyriformis*.

Twagilimana et al. (9) suggested a new indicator, *Spirostomum teres*, a ciliated protist tolerant to low levels of dissolved oxygen; the assay was based on the calculation of the LD_{50} in nonaxenic cultures exposed to the toxic compounds for 24 h. The authors assured the high sensitivity of the assay, especially to heavy metals, in relation to the MICROTOX (Microbics) and to other conventional bioassays.

Schlimme et al. (28) suggested an assay to determine the toxicity of several bacteria strains: in the BACTOX test, these bacteria were given to *T. pyriformis* as prey. The authors highlighted the lack of toxicological assays with whole bacteria and, based on the results of their work, which seem to indicate that toxicity is specific to strains and not to species, they recommend that every bacteria strain should pass the BACTOX test before being produced in large scale.

TOXICOLOGICAL ASSESSMENT WITH PROTISTS

Growth rate and morphological changes have been used in the evaluation of toxicity for some decades. Population growth impairment is an often-used sublethal toxic endpoint for organic and inorganic compounds and does not require special technical expertise. It is considered the most sensitive sublethal parameter, reflecting the global state of a series of parcel effects. Other parameters such as cell motility, swimming patterns, cytoskeleton analysis, phagocytosis rate, and biochemical parameters can be assessed and have been proposed to determine the physiological and energetic state of protists when in contact with toxic compounds.

Tetrahymena pyriformis has been used extensively in studies on effects of heavy metals. Although the mechanisms by which heavy metals affect the microorganisms is not clear, authors have described copper as an essential metal that accumulated in the mitochondria (29) with its distribution observable as small electron-dense dots (3,30). Alteration of *Tetrahymena* morphology after aluminum exposure was reported by Sauvant et al. (31), who observed the presence of large and irregular-shaped monster cells in treated cultures. These morphological abnormalities were detected in zinc-treated cells but not in copper cultures. Most of the works focus on one metal only.

There are also several studies that use protists as test organisms to assess the toxicity of several compounds, both inorganic and organic. Some of these works are collected in Table 1.

Beyond these, Rogerson et al. (70) determined the effects of 17 hydrocarbons on the mortality of *Colpidium colpoda* and *T. ellioti* and Otsuka et al. (71) assessed the toxicity of diphenyl, *o*-phenylphenol, and 2-(4-thiazol)benzimidazol on the growth of *T. pyriformis*. Dias et al. (72) and Nicolau et al. (73) studied the toxicity of metals, Triton X-100, and cycloheximide on biochemical parameters of *T. pyriformis*. Nicolau et al. (74) had already assessed the toxicity of these compounds on the growth, mortality, and grazing of *T. pyriformis*.

NEW APPROACHES IN THE ASSESSMENT OF TOXICITY WITH PROTISTS

Population growth impairment is, as mentioned above, the most frequently used sublethal toxic endpoint. A growth/mortality bioassay using microscopic observation of morphological changes at low magnification is a simple reproducible technique that does not require technical expertise or operational expenses. Nevertheless, some limitations detected in such an assay can make it unsuitable with several toxicants. Recognizing dead cells was sometimes ambiguous, since nonmotile cells as well as altered shape cells were counted as dead cells. It was found that light microscopy observations underestimated the true number of viable cells (i.e., false-negative counting), since several abnormal cells were not in fact dead. Indeed, they recovered their normal shape immediately after toxicant removal and began growing in the recovery assay (75). A novel cellular cytotoxicity assay using two fluorescent dyes was developed by Dias and Lima (75) as an alternative method to standard direct counting of viable protozoa under light microscopy. The compound calcein AM is a nonfluorescent substance that diffuses passively into cells and is converted by intracellular esterases to green fluorescent calcein in viable cells. EthD-1, which binds to DNA-stained red dead cells, was also added. The live/dead assay was found to be a very sensitive method for toxicants that damaged the cell membrane, given that all green cells were established as viable cells even with an altered shape. Recently, an improvement of this approach was developed by Dayeh et al. (69) using *T. termophila* and similar sensitivity was found between the ciliate and piscine and mammalian cells.

Another problem that the toxicologist must deal with is that conventional toxicological assays are often slow and labor-intensive and become impractical when many compounds and/or concentrations are being tested rapidly. This has led to a greater interest in colorimetric and fluorimetric assays that can be miniaturized in 96-well microtiter plates and assessed using an ELISA spectrophotometric microtiter plate reader.

Assays of ATP content have been widely used to characterize biomass viability and to detect potential spoilage microorganisms in the beer and food industry (76,77) assuming that it is possible to use the concentration of ATP to measure the viable cells of a certain species. In cultures of *T. pyriformis*, ATP content was determined to give information about the general energetic state of the culture when submitted to the toxicants (73).

Previous works have been devoted to studying the acid phosphatase (ACP) activity of other hydrolases to detect digestive activity in protozoa (78–81), since there is an intimate relationship between lysosomal function and intracellular digestion in *Tetrahymena* and other ciliates. The ACP activity was used also as an indicator of the metabolic state of the cultures, namely, of the intracellular digestive function, when the ciliates were exposed to toxicants (73,82).

Other colorimetric assays are the assays based on tetrazolium dye reduction, like MTT, which have been extensively used in the *in vitro* evaluation of cellular proliferation and cytotoxicity as well as screening for additives, mycotoxins, or anticancer drugs. The MTT assay is a quantitative method that consists of metabolic reduction of the tetrazolium dye, a group of water-soluble quaternary ammonium compounds, by dehydrogenases of viable immobilized or suspended cells. Production of intensely colored formazan water-insoluble crystals is the result of the tetrazolium reduction assay. Formazan crystals can be either observed microscopically in the cell cytoplasm or extracted and dissolved with organic solvents, such as DMSO, enabling spectrophotometric quantification in cultures of *T. pyriformis* (72).

As mentioned previously, bioactivity of various chemicals can be assessed by means of *Tetrahymena*'s grazing rate determination. For this purpose, fluorescent-labeled latex beads (FLLB) can be used instead of labeled bacteria, assuming that ciliates do not discriminate between different particles on the basis of properties other than size and shape. Therefore, direct counting of fluorescent beads ingested through a period less than 30 min allows an estimate of the xenobiotic's influence on the grazing activity (68,73).

Counting beads one by one inside all digestive vacuoles of a protist is not only tedious but also time consuming. Recently, an automated method of FLLB counting was proposed by Dias et al. (68) to improve the FLLB ingestion toxicity test. It was found that the image analysis is superior to direct FLLB counting, when speed of analysis is the concern.

A different toxicological test approach using *T. pyriformis* was based on calorimetric measurements assuming that protists produce heat by metabolism and movement (83). The addition of toxic substances should result in a reduction of heat production. It was found that the calorimetric measurement showed some advantages compared to the turbimetry.

QSARS: PREDICTING TOXICITY

With the increase of chemical usage, more and more newly manufactured chemicals are created by industry. Today, it is impossible to test all these new products and the already existing ones. Consequently, gaps in toxicity data exist and predictive models have become a means of filling these gaps. Relating chemical structure and toxic potency is a way to predict toxicity. The result of such an approach is known as quantitative structure–activity relationships, that is, QSARs.

There are several ways to do it: the traditional one relies on the use of a set of homologous compounds, each having a functional group common to them all and an alkyl substituent of varied length. In such a set, chemical reactivity, due to the functional group, is ignored because it is the same for all compounds; the hydrocarbon moiety alters hydrophobicity and therefore toxic potency. The models obtained in this way are usually simple regressions of toxicity versus hydrophobicity.

A more complex but innovative approach uses analogous groups of compounds with multiple function groups. The models obtained in this case are often multiple regressions of toxicity versus hydrophobic and stereoelectronic properties (84). It must be assumed, however, that one model predicts only one mechanism of toxic action (85).

Acute toxicity can fall into one of two categories: reversible nonspecific toxicity or narcosis and irreversible specific toxicity (11). Over 70% of organic industrial chemicals cause narcosis (86), which is reversible, physical alterations in the membrane, because they are nonbiding to the macromolecules (10). The remainder of industrial organic chemicals elicited toxicity that is nonreversible (87). These cause reactions that are typically covalent, resulting in changes in the biological systems, and are known as electro(nucleo)philic. The electro(nucleo)philic mechanism of toxic action seems to be dependent on the chemical class of the compound (84).

CONCLUSIONS

Conventional toxicological assays are often labor intensive and become impractical when many compounds and/or concentrations are being tested rapidly. This has led to a greater interest in colorimetric and fluorimetric assays that can be miniaturized and, on the other hand, do not require technical expertise or operational expenses that are needed in bioassays carried out by regulatory agencies at higher trophic levels such as in fish. The use of protists in miniaturized assays seems an excellent option.

All that was referred emphasizes the importance of protists as test organisms and encourages further work in this area, namely, in the establishment of new response patterns to toxicants and in the research of new species to be validated as test organisms, especially species with high indicator value or significant species in certain specific environments (activated sludge, eutrophic waters, amended soils, etc.).

INTRODUCTION

Regulatory quality standards are primarily developed to indicate, scale, or rank the environmental risks of contaminants. For soils and sediments, most countries legally prescribe the chemical extraction of total amounts of contaminants as a first step for risk assessment. Contaminants have mostly been sequestered over a long period of time and may only become available to organisms to a limited extent. The introduction of the bioassay, as a second step, generally increased the understanding of the concept of chemical versus biological availability. This is illustrated in Fig. 1. Aquatic oligochaetes that have been exposed to a number of sediments with a varying degree of cadmium content appear to be particularly susceptible to dissolved fractions. Although location L1 is ranked as seriously contaminated, based on total extracted amounts of cadmium from sediment, *Limnodrilus* spp. accumulated the most cadmium at the “clean” location L2.

The thought that chemical speciation generally determines the adverse toxic effects in biota is well accepted [reviewed by, among others, Campbell (1) in 1995]. In recent years, some techniques have become available to actually measure the availability (i.e., labile metal species) in “natural” solutions. These techniques make use of the (combined) electrochemical, diffusive, or competitive properties of metal ions. Table 1 summarizes some of the most promising techniques. However, only a few of these may find their use in exposure tests because of their disturbance (or destruction) of the sample, or the inability to measure speciation under anoxic conditions.

The purpose of bioassays is typically to determine the toxicity of ambient waters and sediments. Some assays focus on the determination of the exact concentration at which a chemical becomes toxic to an organism, so a biological response is used as a sensor. In order to be useful, this response should be repeatable. Ideally, bioassays are used to make predictions of environmental toxicity required for contaminant management (9,10) and should therefore at all times aim at extrapolating results to the field. Sediment bioassays are a relatively new approach to determine the environmental effects of sequestered metals in sediments. This type of assay has been discussed widely (11,12) in terms of limitations and advantages. Sediments typically consist of oxidized layers, overlying reduced ones. It is well known and documented how redox processes affect metal chemistry (3) and consequently the outcome of the test. Nevertheless, sediments are generally collected as bulk samples that contain this initial redox

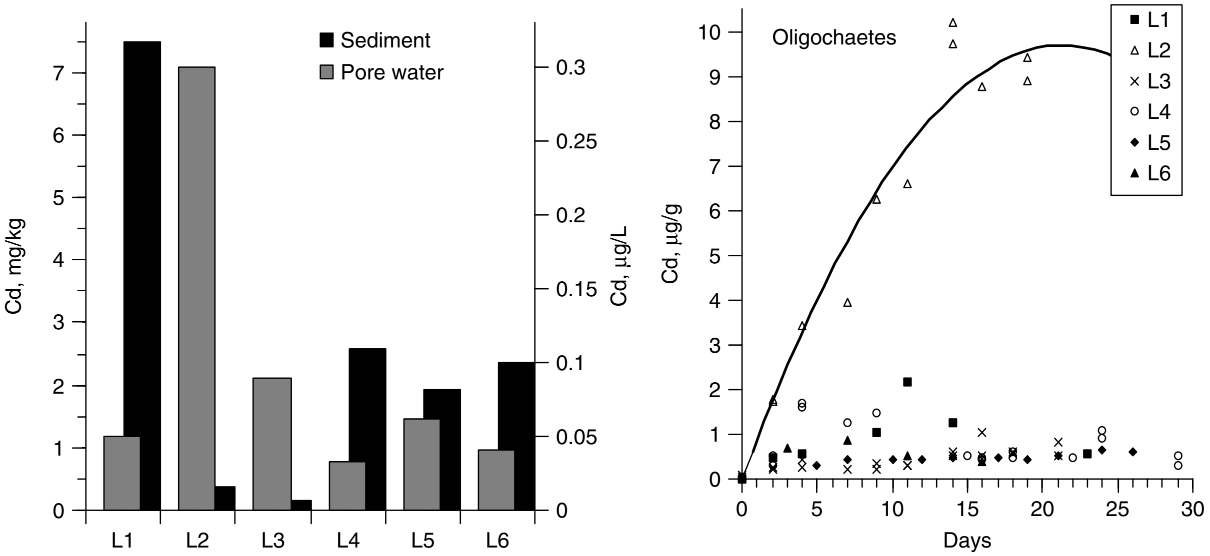

Figure 1. The availability concept in practice: cadmium in sediment, pore water, and oligochaetes at various locations (L1–L6).

zonation. Mostly, these samples are further manipulated by sieving, mixing, and oxygenation in order to increase homogeneity and repeatability. Indeed, variability is likely to be increased if sediments are not homogenized after collection, but these types of handling may destroy important reaction zones that are typical for the sediment in question and its environmental effect.

Data from standardized bioassays (i.e., protocols) generally provide the clear-cut answers that managers find useful as the basis for decisions, regardless of the accuracy to natural conditions. Therefore, these data continue to be the principal tool in the development of regulatory quality standards (12). If a bioassay is conducted in order to meet the objective of field-extrapolation, that is, to assess the environmental risks under natural conditions, a method of minimal sample manipulation should be considered.

Recently, a new approach was introduced that allows for a nondestructive handling and true-to-nature assessment of water/sediment systems. This approach is the "sediment or fauna incubation experiment," or SOFIE, and was developed to measure chemical speciation of metals over redox zones in undisturbed systems, while simultaneously

Table 1. Operational Metal Speciation Sensors

Method		Chemical Separation	Measured Species	Response Time	Remark	Reference

conducting a single or multiple species bioassay. Here, we discuss the performance of this approach and compare it with the outcome of a standardized protocol for sediment or surface water bioassays. Tests were conducted with the sediment dweller *Chironomus riparius* (mosquito larva) and *Daphnia magna* (water flea) for a range of contaminants. Since this study aims at the straightforward comparison between the outcome of both methods, the speciation measurements conducted with SOFIE are not reported here.

METHODS OF EXPOSURE

The Standard Bioassay

The widely applied protocol for water and sediment testing for single species is what we call here the "standard bioassay." This protocol is based on the TRIAD guidelines of 1993 and describes the general procedure of the test, including handling of samples and test species. From this protocol, two test procedures were followed.

Standard Test with Sediment Dwellers. For tests using *Chironomus riparius* as a test organism, use is made of a water/sediment system. A bulk sample of the top 10 cm of a sediment is collected from the field and mechanically homogenized. The sample is then mixed 1:4 v/v with DSW ("standard water"; demineralized water with mineral additives). The water/sediment mixture is shaken for 24 h at ambient atmosphere. Next, 100 mL of the suspension is decanted into dishes to settle, after which test species are introduced. After 28 d of exposure, the organisms are collected by sieving, allowed to void their gut content for 24 h, and freeze dried.

Standard Test with Water Dwellers. For tests using *Daphnia magna*, the protocol prescribes the use of pore water, which is separated from the homogenized sediment by centrifugation (2500 g, 30 min) and stored in bottles. Exposure is carried out in 100-mL glass beakers and pore water is refreshed twice a week. Individuals are periodically collected, rinsed with Elendt medium, and analyzed for metals (not PAHs because of mass and detection limitations).

The Sediment or Fauna Incubation Experiment (SOFIE)

This study was performed with a novel experimental technique (EU patent 1018200/02077121.8, October 2001, J. Vink, Rijkswaterstaat), which was introduced as sediment or fauna incubation experiment, in short SOFIE. This device or "cell" is shown in Fig. 2.

SOFIE is based on the competing ligand exchange technique, which is integrated in a (pore) water probe and combined with a bioassay setting. Full and detailed experimental possibilities have been described earlier (3). The cell consists of a circular core, which is used as a sampling device to obtain undisturbed water/sediment systems. Field samples are taken including the overlying surface water in such a way that the physical and geochemical integrity of the sample (e.g., bulk density, redox status) is guaranteed. After sampling, the core is closed at the bottom with a shutter plate and is mounted on a base socket. The sample does not leave the body core but is now part of the cell. A top socket is attached, ensuring a gas-tight fitting with the body core with an internal silicone seal. The top plate of this socket has four gas-tight connectors for any commercial electrode to probe sediment or overlying water. For experimental scenario purposes, aerobic or anaerobic conditions in the water–sediment system may be manipulated by flushing the atmospheric head space with any desirable gas. The cell wall contains fifteen gas-tight connectors for probes. These probes (diameter 1 mm, length 50 mm) consist of a semipermeable polyethersulfon, which acts as a membrane to discriminate colloidal fractions greater than 0.1 μm. This mesh size is impermeable to bacteria, so pore water that passes the polymer is sterile. The probes can be directly coupled onto micro ion-exchange columns (MICs), as was described in detail by Vink (3), to separate free metal ions from other forms of organic and inorganic metal ligands in solution at the reigning geochemical status of the probed sediment layer.

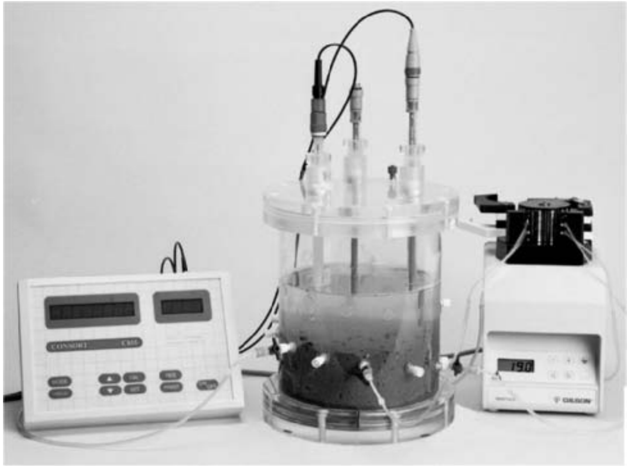

Figure 2. Sediment or fauna incubation experiment (SOFIE).

For a simple, straightforward comparison between the standard bioassay and SOFIE, sediment samples were collected from the river Meuse, The Netherlands, and analyzed for a large amount of properties. An undisturbed water–sediment interface was taken with the cell's body core at 0.4 m water depth. After steady-state metal concentrations were determined, 125 individuals of *Chironomus riparius* were introduced into the SOFIE cell and sampled at the same time intervals as in the standard bioassay. Tests with *Daphnia magna* were performed in the same way.

The Presence of Food During Exposure

In an additional test with *Daphnia magna,* the effect of feeding during exposure was investigated. This test was performed in a two-compartment SOFIE cell, which has two separate chambers that divide the sample while it is cored. In both compartments, daphnids were introduced in comparable amounts as in the standard bioassay. Daphnids in compartment A were fed with the alga *Chlorella,* their natural food source, while those in compartment B were not fed. Organisms and water samples were collected from the cell compartments on several occasions.

Metal concentrations in chironomids and daphnids were determined by digestion in 500 μL of 14.9 M HNO_3 (Ultrex) at 180 °C in a microwave. The digest was analyzed using inductively coupled plasma mass spectrometry (ICP-MS, PerkinElmer Elan 6000). Polycyclic aromatic hydrocarbons (PAHs) in chironomids were determined by refluxing for 6 h with hexane. Analyses were done with an Agilent HP liquid chromatograph using a fluorescence detector and a Vydac 201TP54 reverse phase C18 column. Dolt-2 (certified by the Community Bureau of Reference, BCR, Brussels, Belgium) was used as biological reference material.

RESULTS AND DISCUSSION

The sediment was composed of 14% < 2 μm, 2.3% organic C, and 0.55 inorganic C, at pH = 7.2, and was moderately contaminated with metals (As, 8.5 mg/kg dw; Cd, 1.57; Cr, 27.7; Cu, 25.7; Hg, 0.21; Ni, 20.8; Pb, 79; Zn, 321) and various PAHs (ranging from 100 to 800 ng/g dw).

Collection of pore water from the sediment by homogenization and centrifugation, according to the protocol, generally increased metal concentrations, most significantly for Pb and Cd. Table 2 shows the concentrations that were measured at the start of the exposure test in the standard bioassay and in SOFIE's surface water.

The collected time data for chironomids are, for reasons of survey ability, summarized in Fig. 3, which shows body concentrations of polycyclic aromatic hydrocarbons (PAH) and heavy metals after four weeks of exposure. The data quite clearly show that, in the standard bioassay, chironomids take up PAHs in significantly larger amounts than in the SOFIE environment. Although we did not perform or aim at a mechanistic study here, it is likely that sample handling (and in particular stirring and homogenization) has liberated PAHs from the organic sediment matrix by unlocking and exposing organic surface areas. Many authors have described this phenomenon.

Bioaccumulated metals are shown in Figs. 3 and 4. Accumulated amounts for both test species are lower in the standard bioassay than those collected from SOFIE (note the log scale, differences are significant). This is valid for all metals. Although this observation may appear somewhat counterintuitive [oxidation leads to liberation of metals from sulfides and should therefore increase the (bio)available fraction of metals], the explanation is quite straightforward. Indeed, oxidation leads to enhanced metal concentrations, as is shown in Table 3. Following chemical thermodynamics, this primarily yields large free ion activities. Simultaneously, iron and manganese are oxidized from the reduced state into highly reactive oxyhydroxides (either precipitated or as colloids). Free metal ions have a high affinity for these newly formed sorption sites and are quickly adsorbed and immobilized. In the case of the standard *Daphnia* bioassay, where

sediment is absent, there is obviously no delivery from the sediment (e.g., by diffusion and desorption) to the aqueous phase. Daphnids take up metals from solution and eventually face declining exposure concentrations to a point where concentration levels may become inhibiting to uptake. Figure 5 shows copper for an example. This trend was observed for all metals in the standard bioassays, but not in the SOFIE cells where concentrations remained relatively constant during the exposure period or showed some release from the sediment.

Figure 6 shows the effect of feeding daphnids during exposure. The effect of adding the alga *Chlorella* is profound (note the log scale). In most cases, bioaccumulated amounts of metals are reduced some orders of magnitude compared to the nonfeeding test. Since alga are always present in surface waters in varying amounts, it is obvious that this test is closer to exposure conditions as they occur in the field.

Results show that dissolved metal concentrations change during exposure. These time-varying changes may follow first-order reaction kinetics; that is, $dC/dt = kC$, so the external concentration, or exposure concentration, at a given time $C(t)$, is written as

$$C(t) = C_i e^{k_0 t}$$

where C_i is the initial exposure concentration, and k_0 is a rate term describing the increase or decrease of the initial concentration during the test. A time/concentration-dynamic, two-compartment model approximated metal bioaccumulation patterns of both test species. Body concentrations vary in time and relate to uptake from the water phase at a certain rate. At the same time, uptake is accompanied by elimination, which is kinetically directed by the organism itself. Hence, one may write

$$dQ/dt = k_1 C(t) - k_2 Q(t)$$

where Q is the internal body concentration ($\mu g \cdot g^{-1}$), k_1 and k_2 are uptake and elimination rate constants, respectively (d^{-1}), and t is time. This yields, for $Q(0) = 0$,

$$Q(t) = \frac{k_1 C_0}{k_2 - k_0}(e^{-k_0 t} - e^{-k_2 t})$$

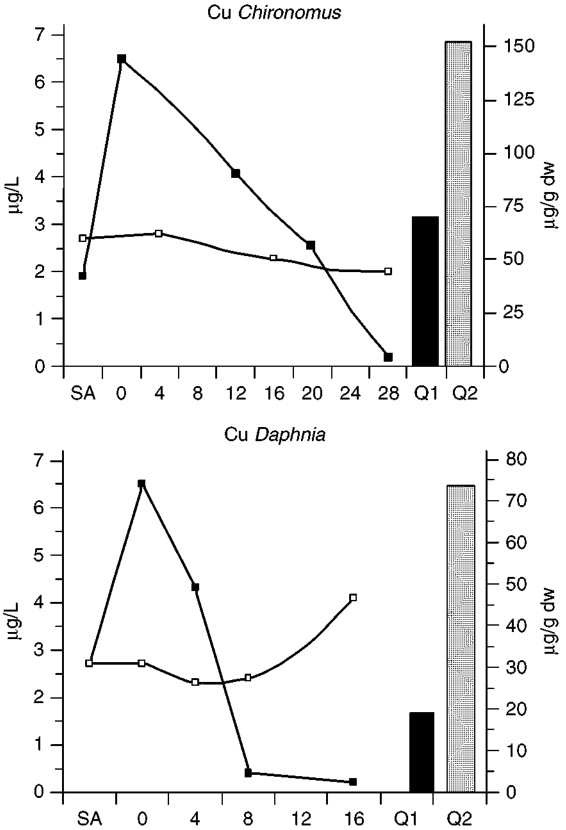

Figure 5. Copper concentrations in overlying water at time of sampling (SA) and during exposure (days) in the standard bioassay (■) and SOFIE (□) for chironomids (top) and daphnids (bottom). Q1 and Q2 are body concentrations from the standard bioassay and SOFIE, respectively. While concentrations in the undisturbed water–sediment system remain relatively constant or increase slightly, those in the standard bioassay show large variation due to the handling and manipulation of the sample, followed by exhaustion from solution.

With the introduction of k_0, time-dependent concentrations determine the overall exposure of organisms, and thus $Q(t)$.

Table 3 summarizes the results of the uptake model. In the standard bioassay, initial concentrations differ

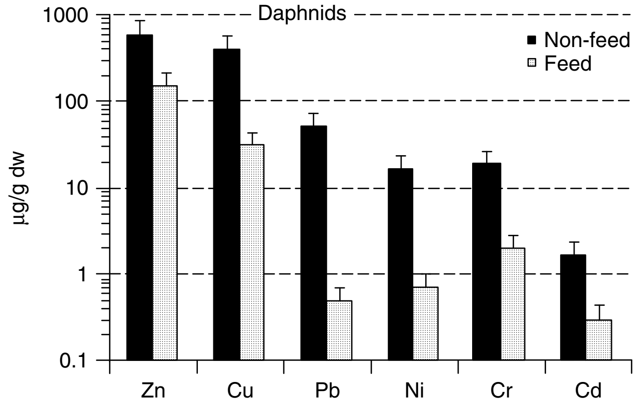

Figure 6. Heavy metals in *Daphnia magna* in two feeding scenarios.

between chironomids and daphnids. This is the result of sample handling and the absence of sediment in the daphnid test. From the viewpoint that bioassays should deliver generic, true-to-nature outcomes, this appears an undesirable starting point. Although *Chironomus* is a sediment dweller and *Daphnia* is not, both species encounter contaminant exposure in an environment that consists of both sediment and surface water, where bioavailability is a combined action of the two compartments.

The rate by which exposure concentrations change during the tests is represented by k_0. Positive values denote an increase, negative values a decrease in concentrations. The outcome clearly shows that in the standard bioassay, k_0 values are in all cases negative and larger than those observed in the assays that were performed with SOFIE. The effect is most profound in the daphnid tests, where k_0 values diverge both in direction and in magnitude. For all metals, and both test species, the two-compartment model performed better with the data that were acquired from the SOFIE setup.

CONCLUSIONS

Based on the outcome of water–sediment testing of two aquatic species with the standard protocol and with the sediment or fauna incubation experiment, SOFIE, the following conclusions are drawn:

- Sample handling such as homogenization and oxygenation affects the chemical speciation of the exposure medium for both organic and inorganic contaminants. Disadvantages of this manipulation (disrupting chemical speciation and bioavailability) outweigh the advantages (homogenization to increase reproducibility) by far and should therefore seriously be reconsidered or applied with great caution.
- Tests conducted with the standard protocol tend to *overestimate* uptake of PAHs by chironomids and *underestimate* uptake of heavy metals by chironomids and daphnids. This may generate both false-positive and false-negative results, respectively.
- Aquatic bioassays should be conducted in sediment/water systems, regardless of whether the tested species are sediment dwellers or not. The physical, chemical, and biological interaction between sediment and the water phase is a site-specific characteristic that determines the ultimate risk of contaminants.
- SOFIE provides the necessary tool to conduct risk assessments in a close-to-nature setting. It may therefore contribute to establish better-founded quality criteria for natural waters.

PASSIVE TREATMENT OF ACID MINE DRAINAGE (WETLANDS)

Arthur W. Rose
Pennsylvania State University
University Park, Pennsylvania

Starting in about 1985, passive treatment has been increasingly used as a method of remediating acid mine drainage (AMD). A passive treatment facility uses natural reactions such as microbial oxidation or reaction with a bed of crushed limestone to improve water quality, with only minimal human attention after construction. The initial passive method was a simple wetland, which was found to improve water quality for some types of AMD. However, for other waters, wetlands were not effective, but a variety of other methods have been developed, as indicated in Fig. 1. Passive treatment contrasts with active treatment in which a chemical such as sodium hydroxide, lime, or similar alkaline agents is added to the water. Active methods require frequent human attention and continued replenishment of the reagents.

Passive methods applicable for a specific site are selected using a flowsheet, as in Fig. 2. The first step is to determine the flow and water chemistry. Key chemical

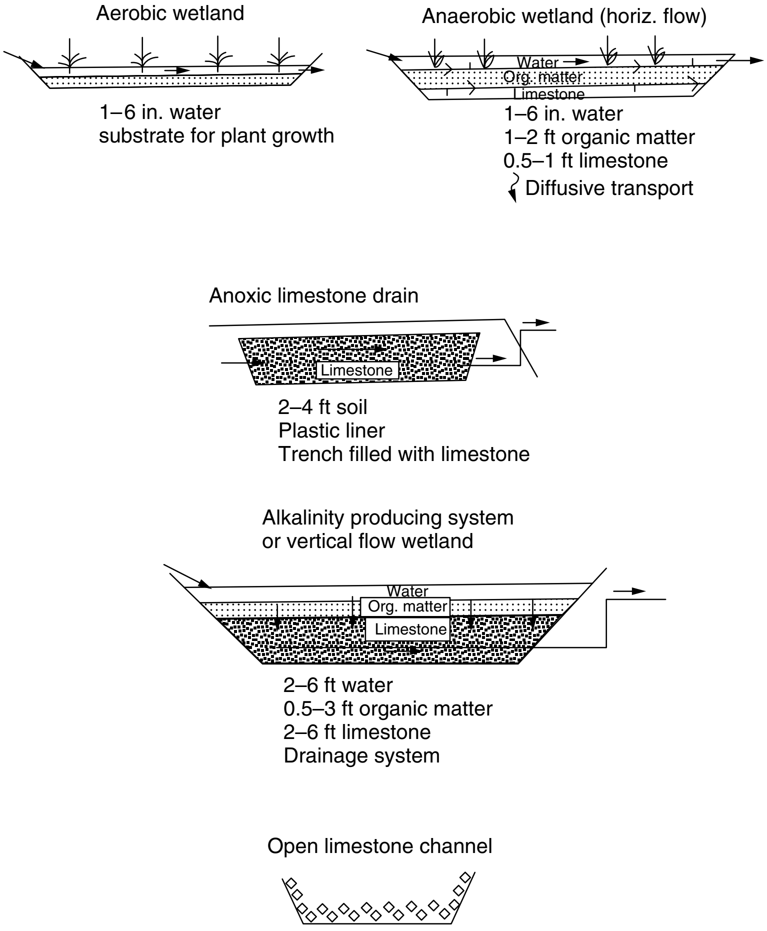

Figure 1. Schematic diagrams for passive treatment systems (after Ref. 1).

variables are the acidity, alkalinity, Fe, Al, Mn, and SO_4. The acidity should be a hot peroxide acidity such as presented in References 2 and 3. In these methods, the Fe and Mn are oxidized so that the total acidity to pH 8.3 is measured and the alkalinity is subtracted during the procedure so the result is a net acidity (4).

If the water is net alkaline (negative acidity), the water can easily be treated by a wetland. Sizing of wetlands is discussed by Hedin et al. (5). In the wetland, Fe and Mn are oxidized in the shallow water, precipitate as hydroxides, and settle in the slowly flowing water. The alkalinity is adequate to maintain a pH above 4.5, usually higher.

If the water is net acid (positive acidity), then the dissolved O_2, ferric iron, and aluminum must be measured. If these are negligible (less than about 1 mg/L each), then an anoxic limestone drain (ALD) can be successful. An ALD is a trench filled with crushed limestone ($CaCO_3$) and covered to eliminate access of air. Acidic water from a subsurface source flows into one end and passes along the limestone bed. The water acquires alkalinity and increases in pH by reaction with the limestone. On emerging from the limestone bed, Fe oxidizes and precipitates in an oxidation-settling pond.

If the water is net acid and contains appreciable dissolved O_2, ferric iron, or aluminum, then a common passive method is a vertical flow pond (also known as a SAPS, successive alkalinity producing system) (6,7). In this method, the water first flows into a settling pond to remove sediment and possibly some Fe. It then passes into the vertical flow pond that drains through the bottom. The top layer in the bottom of the pond is compost that consumes dissolved O_2 and reduces ferric iron to ferrous iron. Some Fe and acidity may be removed by microbial reduction of SO_4 in the compost. The water then enters the lower layer of crushed limestone, where acidity is consumed, alkalinity is added, and pH is increased. The water leaves the limestone layer through perforated pipes and flows to an oxidation-settling pond for Fe precipitation and removal. A wetland may be used to further clean up the water.

A problem in some vertical flow systems is dissolved Al, which can precipitate in the limestone bed and plug the system, or coat limestone leading to inhibited reaction. Some units are constructed to be flushed, so that precipitates are flushed out of the limestone bed. Recent measurements indicate that this method is only partially effective. Trials are underway with back-flushing systems, upflow limestone ponds, mixing of fine limestone into the compost, and other variations.

On relatively steep slopes, an open limestone channel can be successful in neutralizing acidity. To be successful, the flow must be vigorous enough to erode the Fe and Al coatings off the limestone.

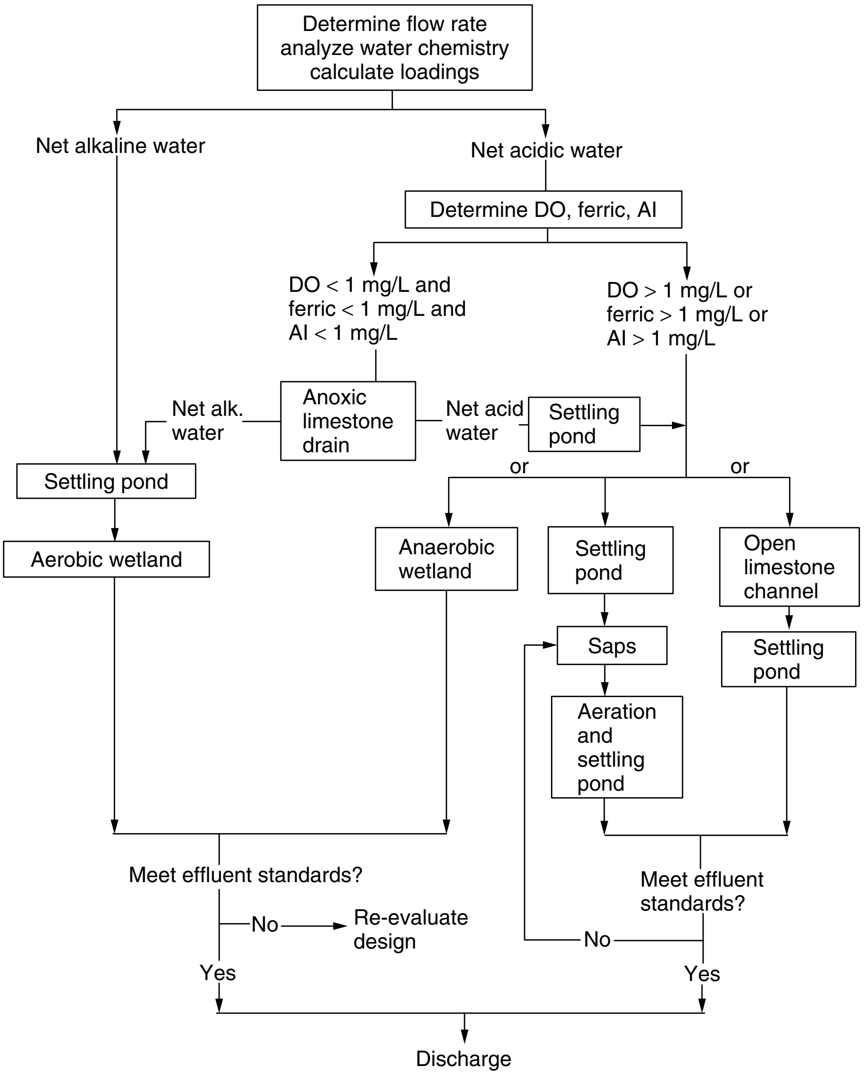

Figure 2. Flowsheet for selection of passive treatment method (after Ref. 1).

Anaerobic wetlands, in which the substrate for the wetland is compost and/or limestone, can be used to treat net acid water. However, the area of such wetlands must be much larger than aerobic wetlands or vertical flow ponds, so these are not common.

Discharge standards for mine waters specify removal of most manganese, which can be removed passively in aerobic limestone beds (8). The influent waters must be oxidizing and have negligible concentrations of Al and Fe. In these beds, Mn-oxidizing bacteria oxidize Mn and precipitate Mn oxides and hydroxides at pH 6.5 and higher. In some such facilities, the limestone bed is inoculated with specific Mn-oxidizing bacteria (9).

Recent publications indicate that periodic inspection, maintenance, and occasional rebuilding are necessary for most passive systems, especially those treating net acid water. Problems include washout during high flow, muskrat penetration of the dams, plugging of pipes by precipitates or vegetation, plugging of limestone by Al or Fe precipitates, accumulation of Fe oxides on top of compost, and channeling of flow through limited portions of the system.

INTRODUCTION

Contaminated sediments pose a risk to aquatic life, human health, and wildlife throughout the world. There is an overwhelming amount of evidence that chemicals in sediments are responsible for toxicological (1) and adverse ecological effects (2). Frequently, the chemicals causing these effects are present in the sediment as mixtures of organic, metal, and other types of contaminants.

Identification of toxicants in sediments is useful in a variety of contexts. Adverse environmental effects from contaminated sediment resulted in international treaties and protocols for the environmental management of these dredged sediments. In this sense the OSPAR and Helsinki Conventions (North Sea, northeast Atlantic, Baltic Sea) proposed guidelines to control the disposal of sediment.

Once a toxicant is identified in the sediment, steps can also be taken to link a toxicant to a discharger and prevent further discharge. In addition, identification of major causes of toxicity in sediments may guide programs such as the development of environmental sediment guidelines and, retrospectively, aid regulators in determining the type of pesticide or manufactured chemical that may cause toxicity in the field. Here, we review the use of biomarkers and bioaccumulation in sediment quality assessment. These different tools provide a more sensitive measure of bioavailability and the effects of the different contaminants in the sediment.

SEDIMENT QUALITY ASSESSMENT

Sediments can act as deposits of contaminants entering the environment and, as a consequence, constitute a source of contamination. Today, remediation and management of contaminated sediments is becoming more and more economically and technologically demanding. Because of this, the scientific community has been developing science-based tools to identify sediments that are impaired and, ultimately, to support effective management decisions and priorities for dealing with contaminated sediments (3). When discussing the adverse effects of pollutants, some consider the accumulation of pollutant residues in the tissues of organisms to be adverse. Others consider an effect injurious only if changes occur in physiological processes in organisms, such as alterations in cellular morphology, metabolic activity, or physiological rates. Ecologists might restrict this definition still further to only those pollutant-induced effects that give rise to ecologically significant changes, that is, those at the population level (4). It is important to take into account the bioindicator species, the toxicity assay, and the different biological measurements that could show the exposure to a contaminant and the effect.

Different sensitive toxicity tests have been developed to assess sediment toxicity. The different toxicity tests can group pore water and whole sediment exposure tests. These tests are conducted using benthic organisms such as amphipods, polychaetes, algae, and juvenile fish (5). Use of these organisms allows one to estimate the effect of sediment ingestion and measure bioaccumulation and different biomarkers of exposure and effect. For example, the role of sediment ingestion, which should not be underestimated, has been identified as an important route of uptake of polycyclic aromatic hydrocarbons (PAHs) by deposit-feeding benthic organisms, as shown in experiments with polychaete worms (6,7).

More appropriately, three ecological life styles (filter feeding, deposit feeding, and burrowing) can be represented by the species used to assess sediment effects (8). Table 1 shows that the most appropriate phyla for potential impact testing in sediment is crustaceans, followed by annelids, mollusks, insects, fish, and echinoderms. Some of the species belonging to the taxonomic groups of crustaceans, mollusks, and fish are estuarine individuals that tolerate salinity fluctuation, which could affect the toxicity evaluation response in an environment affected by variation of physicochemical variables (9).

Bioaccumulation

Bioaccumulation values from different contaminant studies can help identify the bioavailability of chemicals in marine sediments and waters since, unlike chemical analysis, bioaccumulation provides a measurement of bioavailable contaminants (15).

Bioaccumulation is the uptake and retention of a bioavailable chemical from any possible external source (water, food, substrate, air). It is the net result of the uptake, distribution, and elimination of a substance in an organism due to exposure in water, food, sediment, and air. For bioaccumulation to occur, the rate of uptake from

Table 1. Summary of Species Appropriate for Testing Potential Impacts of Contaminated Sediment (10–14)

Taxonomic Group	Name	Test Species	Salinity Tolerance
Crustaceans	Mysid shrimp	*Americamysis* sp.	M
		Neomysis	M
		Americana	M
		Holmesimysis costata	
	Grass shrimp	*Palaemonetes* sp.	M, E
	Sand shrimp	*Crangon* sp.	M, E

	Sea bream	*Sparus aurata*	M
	Turbot	*Scophthalmus maximus*	M

all sources must be greater than the rate of loss of the chemical from the tissues of the organism (16) (Fig. 1).

Toxic effects of anthropogenic compounds in biota and ecosystems are regarded in relation to their chemistry and fate in the environment. The bioavailability of chemicals, which is dependent on biogeochemical and physiological processes, is an important factor, often neglected in ecotoxicological evaluation and hazard assessment. The bioavailable fraction is critical for uptake and, ultimately, for the concentration at the target site in the organisms. The bioavailability of contaminants in sediments depends on several factors: physical (grain size of the sediment and suspended particulate materials), chemical (solubility, reactivity of compounds, complexing agents), and biological (benthic or pelagic organisms, mode of exposure) (17). Nevertheless, not all bioavailable

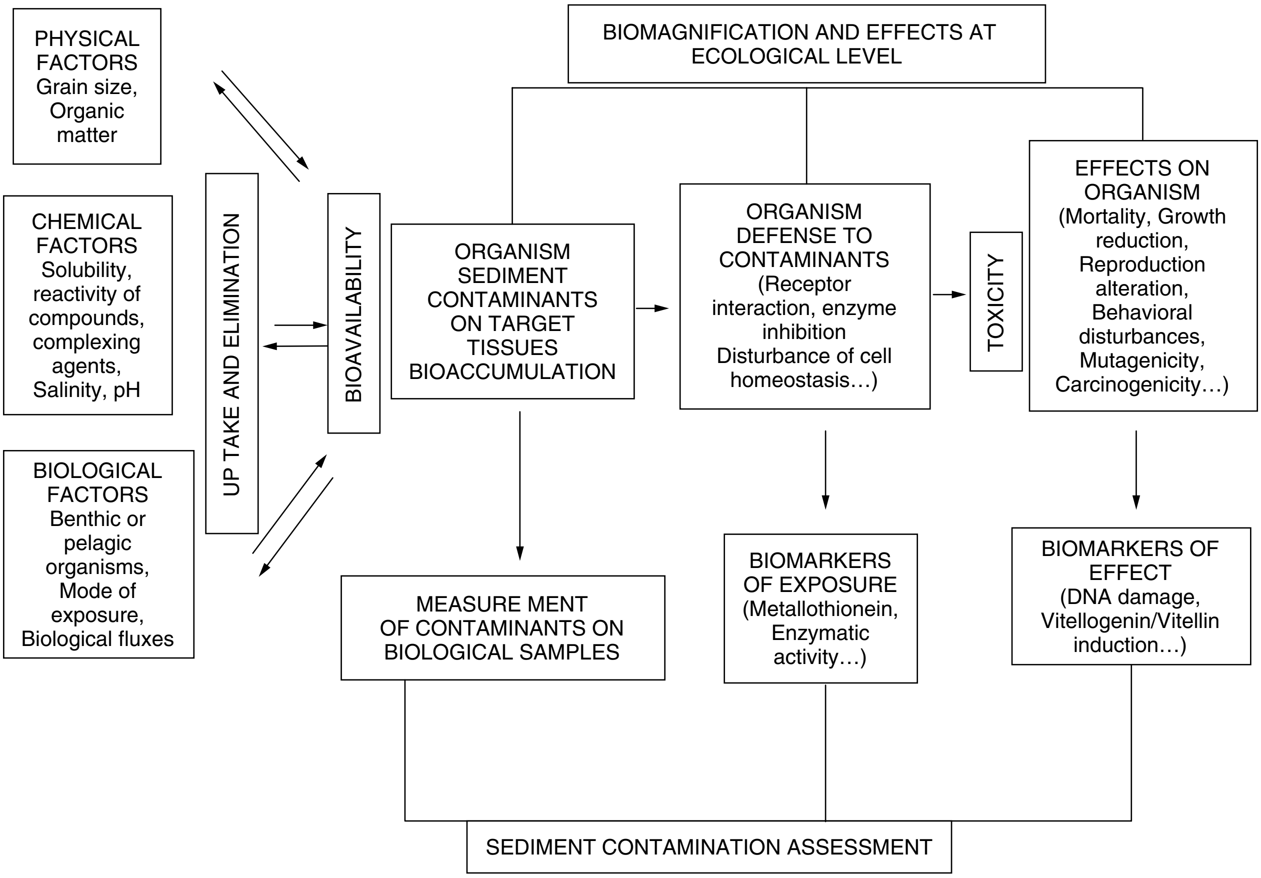

Figure 1. Ecotoxicological effects and assessment of the bioavailable fraction of pollutants in sediment.

chemicals can be bioaccumulated by the organisms in their tissues. For example, highly soluble chemicals, such as ammonia and some inorganic ions, are bioavailable and rapidly penetrate permeable tissues of marine organisms. However, they are not retained and are lost just as rapidly from the tissues by diffusion, metabolic transformation, or active transport. Other bioavailable chemicals are also taken up rapidly but are transformed and/or excreted rapidly by metabolic processes of the organism and are not bioaccumulated (16). In this sense, it is important to take into account the bioaccumulation factor (BAF), which is the ratio of the sum of the uptake rate constants of the chemical from all environmental compartments accessible to the organism to the sum of the release rate constants by active and passive mechanisms from the organism (18). The bioaccumulation factor allows one to predict if a bioavailable chemical is being bioaccumulated.

Once a chemical is bioaccumulated, the concentration of the contaminant at the target tissue in the organism induces molecular manifestations of defense and the effects can be determined (Fig. 1).

Persistent chemicals may accumulate in aquatic organisms through different mechanisms: via the direct uptake from water by gills or skin (bioconcentration), via uptake of suspended particles (ingestion), and via the consumption of contaminated food (biomagnification). Even without detectable acute or chronic effects in standard ecotoxicity tests, bioaccumulation should be regarded as a hazard criterion in itself, since some effects may only be recognized in a later phase of life, are multigeneration effects, or manifest only in higher members of a food web (e.g., impact of PCBs on the hatching success of eggs) (19).

Bioaccumulation of certain persistent environmental contaminants in animal tissues may be considered a biomarker of exposure (20,21). However, based on the definitions provided by Van Gestel and Van Brummelen (22), body burdens are not considered to be biomarkers or bioindicators since they do not provide information on deviations related to “health.” To avoid confusion, Van der Oost et al. (23) proposed that analytical–chemical indicators (body burdens) be referred to as bioaccumulation markers, while all biological (biochemical, physiological, histological and morphological) indicators measured inside an organism or its products be referred to as biomarkers.

The relationship between concentration of contaminants in tissues and toxic effects measured in organisms has received increased attention during the last few decades (1). These relationships should allow one to derive tissue quality guidelines (TQGs), defined as the concentrations of the chemicals measured in the different tissues that are associated or not associated with the biological effects measured using the sediment quality guidelines (SQGs) widely used around the world (24). To identify possible toxic agent(s), one must have body burden data collected from the same organisms exhibiting toxicity.

Biomarkers

Biomarkers are specific biological responses related to metabolism, detoxification, or toxicity induced by pollutants and associated with disposed materials. In this respect, an important advantage of biomarkers in assessing the impact of contaminated sediment is the inherent capability to detect early occurrence of various stress conditions within the organism and monitor the temporal progression (or regression) of the disturbance at various levels of biological organization (25).

Laboratory studies have documented the use of biomarkers to provide rapid quantitative predictions of toxicity on individual organisms. At this time, the use of biomarkers is not a replacement for traditional monitoring techniques, but it can be a useful supplementary approach to demonstrate links between sublethal biochemical exposure and decreases noted in field population studies (26).

A biomarker is defined as a change in a biological response (ranging from molecular though cellular and physiological responses to behavioral changes) which can be related to exposure to or toxic effects of environmental chemicals (27). Van Gastel and Van Brummelen (22) redefined the terms “biomarker,” “bioindicator,” and “ecological indicator,” linking them to different levels of biological organization. They considered a biomarker as any biological response to an environmental chemical at the subindividual level, measured inside an organism or its products (urine, feces, hair, feathers, etc.), indicting a deviation from the normal status that cannot be detected in the intact organism. A bioindicator is defined as an organism giving information on the environmental conditions of its habitat by its presence or absence or by its behavior. An ecological indicator is an ecosystem parameter, describing the structure and functioning of ecosystems.

One of the most important features of biomarkers is that they have the potential to anticipate changes at higher levels of the biological organization (i.e., population, community, or ecosystem). Thus, these “early warning” biomarkers can be used in a predictive way, allowing the initiation of bioremediation strategies before irreversible environmental damage of ecological consequences occurs. Biomarkers are then defined as short-term indicators of long-term biological effects.

According to the National Research Council (20) and the World Health Organization (21), biomarkers can be subdivided into three classes: biomarkers of exposure, biomarkers of effects, and biomarkers of susceptibility. The biomarkers of exposure cover the detection and measurement of an exogenous substance or its metabolite or the product of an interaction between a xenobiotic agent and some target molecule or cell that is measured in an organism. On the other hand, the biomarkers of effect show an established or possible health impairment or disease through a measurable biochemical, physiological, or other alteration in the organism. Finally, biomarkers of susceptibility indicate the inherent or acquired ability of an organism to respond to the challenge of exposure to a specific xenobiotic substance, including genetic factors and changes in receptors which alter the susceptibility of an organism to that exposure.

New techniques allow one to detect the effects of complex mixtures of contaminants. Many are diagnostic of causes, provide information on the bioavailability of contaminants, and allow more accurate assessments of potential ecological damage. Cellular and molecular indicators provide the greatest potential for identifying individuals and populations for which conditions have exceeded compensatory mechanisms and which are experiencing chronic stress, which, if unmitigated, may progress to severe effects at the ecosystem level.

The classification of biomarkers in the literature is very diffuse since biomarkers of exposure and those of effect are distinguished by the way they are used, not by an inherent dichotomy (28).

Good biomarkers are sensitive indices of both pollutant bioavailability and early biological responses (23,29–31). Recently, the biomarker approach has been incorporated into several pollution monitoring programs in Europe and the United States. Likewise, different methods for biological effect measurement have been evaluated in a series of practical workshops organized by the International Council for the Exploration of the Sea (ICES) and the Intergovernmental Oceanographic Commission (IOC), such as those in the North Sea (32). The United Nations Environment Programme has founded a biomonitoring program in the Mediterranean Sea including a variety of biomarkers (10). Biomarkers have also been included in the Joint Monitoring Programme of the OSPAR convention, where Portugal and Spain are members. Nevertheless, the biomarkers approach has not been included in the guidelines for the management and monitoring of dredging and disposal activities. The current guidelines for the control of these activities are based on several approaches, which take into account chemical measurements, analysis of benthic communities, and toxicity tests. Very few studies have been done on the utility of biomarkers.

In this sense, different studies on the use of biomarkers to assess the impact of contaminants on sediment (Table 2) are being carried out. Most of the studies focus on the determination of the activity of biotransformation enzymes, antioxidant enzymes, and biochemical indices of oxidative damage, DNA damage, and metallothioneins. Today, promising biomarker tools are the “genomics” and “proteomics.” In some cases genomic is used as a broad term—including proteomic—and it includes genomic sequencing, functions of specific genes, genome architecture, gene expression at transcriptome level, and protein expression at proteome level and metabolite flux (metabolomics).

USING BIOMARKERS AND BIOACCUMULATION FOR REGULATION PURPOSES

Frequently, the chemicals causing these effects are present in the sediment as mixtures of organic, metal, and other types of contaminants. The foundation for sediment quality assessment in the context of environmental risk assessment (ERA) is the weight-of-evidence (WOE), whose objective is to integrate multiple lines-of-evidence (LOE), both chemical and biological.

Table 2. Biomarkers Used for Sediment Toxicity Assessment in the Laboratory, *In Situ* (Caged Individuals), and in the Field (11–14,26,33–36)

Parameter	Description	Toxicity Assay	Pollutant Response
Metallothionein	Induction of this protein indicates exposure to metals	Field, caged individuals, laboratory	Cd, Cu, Zn, Hg, Co, Ni, Bi, Ag
GSH	Assay that determines the total glutathione content, a natural antioxidant	Field	PAHs, PCBs
DNA damage	Assay that detects single-strand breaks in DNA, a measure of DNA damage	Laboratory, caged individuals	PAHs, PCBs
EROD	Assay for ethoxyresorufin-*O*-deethylase, a phase I detoxification enzyme	Laboratory, caged individuals, field	PAHs, PCBs
CAT	Assay for catalase, an antioxidant enzyme	Caged individuals, field	PAHs, PCBs
SOD	Assay for superoxide dismutase, an antioxidant enzyme	Field	PAHs, PCBs
GR	Assay for glutathione reductase, an antioxidant enzyme	Laboratory, field	PAHs, PCBs
GPX	Assay for glutathione peroxidase, an antioxidant enzyme	Field	PAHs, PCBs
GST	Assay for glutathione-*S*-transferase, a phase II detoxification enzyme	Laboratory, field, caged individuals	PAH, PCB, BNF
LPO	Assay to determine the level of thiobarbituric reactive substances from lipid peroxide breakdown	Laboratory, caged individuals	Cd, PCB
Vitellogenin/vitellin	Induction of this protein indicates the exposure to substances that could perturb endocrine function	Laboratory, caged individuals	Cd, Zn, PAHs, PCBs
TOSC	Total oxyradical scavenging capacity	Field	PAHs, PCBs
Imposex, intersex	Sex change	Field, laboratory	TBT

Different tools are proposed in order to obtain multiple LOE in sediment quality assessment: (1) sediment chemistry including numeric sediment quality guidelines (SQGs), (2) toxicity tests, (3) bioaccumulation tests, (4) biomarkers, and (5) resident aquatic community structure. These tools should provide adequate estimation of the influence of the physical, chemical, and biological factors in the level of exposure and bioavailability of the different xenobiotics in the sediment (37).

These tools, expressing different lines of evidence, are integrated in environmental risk assessment methodologies and utilized in monitoring and assessment sediment programs. In this regard, a tiered approach to testing is recommended. At each tier, it will be necessary to determine whether sufficient information exists to allow a management decision to be taken or whether further testing is required (8).

The toxicological significance and complexity increase with each tier (Fig. 2). On Tier 0, a recompilation of information that already exists is developed. Tier I testing involves physical–chemical studies and ecotoxicological screening of the dredged material. If toxic effects are observed at Tier I (major hazard concern), the material may be evaluated on this basis. If no toxic effects are observed at this stage, but chemical analyses indicate that there may be reasons for concern, Tier II is entered and further biotests are requested. Tier II testing covers a wide range of effects parameters, including long-term and sublethal toxicity. In most cases, the Tier II results will allow a comprehensive evaluation of the (dredged) sediment. Only if the results are still inconclusive will it be necessary to add further tests on specific effects depending on evidence for particular contaminants, assessment of biomarkers of exposure and effect, and/or verification of laboratory measurements in the field (Tier III). Tier III testing may be used to monitor possible impacts of dredging operations in the field. The available techniques comprise nonspecific monitoring methods that respond to a wide range of environmental contaminants, biomarkers (fish, shellfish) of specific exposures depending on evidence for particular (bioaccumulation) contaminants, and assessment of long-term effects on benthos community structure and function (33).

FUTURE RESEARCH NEEDS

The evaluation of sediment quality in the environmental risk assessment context requires the use of more sensitive tools for sediment evaluation and the extrapolation to the field. The use of bioaccumulation and biomarkers in different bioindicator species is being researched for the assessment and management of sediment. There is an increasing consensus and interest in the valuable information that they could provide. Nevertheless, although they are more sensitive tools, they show higher variability with respect to the physical–chemical characteristics of the sediment, their extrapolation from laboratory to the field, and their intercalibration.

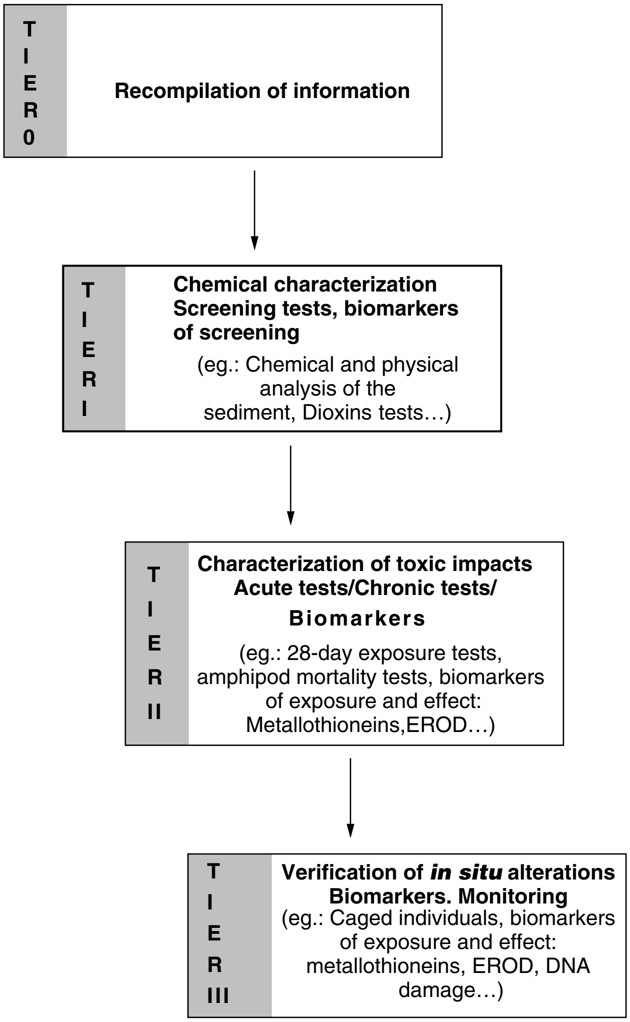

Figure 2. Schematic representation of the tier testing steps including biomarkers and bioaccumulation measurements.

In summary, some recommendations are proposed for the incorporation of biomarkers and bioaccumulation in research programs for the evaluation of dredged material quality using a weight of evidence approach:

1. Determination of biomarker screening responses to contaminated and control sediments for different sites and organisms in order to determine the advantages and disadvantages of the use of different biomarkers for the identification of different sources of contamination.
2. Study of the bioavailability of contaminants in sediment and biomarker responses through the exposure–dose–response triad methodology (exposure–chemical/biomarkers of exposure and bioaccumulation; dose/response—biomarkers of effect). It could allow the analysis of the sensitivity of different biomarkers to different availabilities of contaminants in sediment and to different contamination.
3. Measurement of biomarkers and bioaccumulation response to natural environmental conditions (pH, temperature, salinity). It could allow the application of biomarkers to environments that support high variability of environmental conditions, avoiding the “noise” that could produce this variability in a biomarker’s response.
4. Determination of biomarkers and bioaccumulation response over time through a toxicokinetic study of these responses. It could provide knowledge of biomarker and bioaccumulation behavior in the different organisms.
5. Intercalibration of bioaccumulation and biomarker responses; determination of biomarkers and bioaccumulation of the same contaminated sites in different laboratories. It could provide knowledge of the biomarkers and bioaccumulation response variation due to handling of organisms and methodology of measurement.
6. Biomarkers and bioaccumulation extrapolation from laboratory to field conditions through the determination of biomarkers and bioaccumulation response to laboratory and field contaminated toxicity exposure. These measurements could allow the analysis of responses due to realistic environmental conditions. It should be developed for three species: filter feeding, deposit feeding, and burrowing. The link between both sets of data will allow derivation of tissue quality values that need to be validated for human health and regulatory purposes.

LEAD AND ITS HEALTH EFFECTS

INTRODUCTION

Lead (Pb) is a bluish white, lustrous, naturally occurring element that people have used almost since the beginning of civilization. Because of its malleability, Pb was one of the first metals that humans began to use for industrial purposes. Plumbism, or Pb poisoning, has been recognized for many centuries and is one of the oldest ailments afflicting humans. Nikander (200 B.C.) was first to describe the symptoms of Pb poisoning, which included colic and pallor. The English aristocracy of the seventeenth and eighteenth centuries suffered from widespread Pb poisoning from consumption of Portuguese wine, transported with submerged Pb bars to enhance flavor and to prevent spoilage. Lancereaux provided the first description of kidney disease and interstitial nephritis by postmortem examination of a Pb poisoned artist.

Anthropogenic activities during the past century have resulted in increased accumulation of toxic metals in soils and natural waters (1). Lead contamination is widespread in urban areas due to industrial emissions, extensive use of alkyl-lead compounds as antiknock additives in gasoline in the past, and lead-based paints and pipes (2), resulting in soil contamination on a global scale with adverse effects on human and environmental health (3).

Lead occurs naturally in low concentrations in all rocks, soils, and dust, usually ranging from 2 to 200 ppm (4). The periodic position of Pb favors the formation of covalent rather than ionic bonds in Pb^{4+} compounds. Lead is similar to certain alkaline earth metals, particularly calcium. Both calcium and Pb form insoluble carbonates and phosphates. However, Pb carbonates and phosphates are less soluble compared to those of calcium. This insolubility of Pb together with its high affinity to biological donors (enriched in oxygen and possibly nitrogen) accounts for its toxicological properties (5).

Here, we provide an overview of the various sources of Pb, its impact on the ecosystem and its effects on human health. Future directions in research related to the effects of Pb on human health are also discussed.

SOURCES OF LEAD

Natural Sources

The average concentration of Pb in the earth's crust is estimated to be 16 mg/kg (4). Lead is mainly found in the form of its sulfide, galena. Some other ores of Pb include cerussite and anglesite. In general, granitic rocks that have high acidic content tend to have more Pb than basaltic rocks. Lead concentrations in soils (farming and city) range from 2 to 200 mg/kg, with most soils having Pb in the range of 5–25 mg/kg (6). Moreover, soils that are underlain by granitic rocks with high acid content have higher Pb concentrations than those overlying basaltic and other alkaline rocks (6). It has been estimated that global natural emissions of Pb to the atmosphere are in the range of $18.6–29.5 \times 10^6$ kg/yr.

Anthropogenic Sources

The major anthropogenic sources of Pb are industrial activities such as mining operations (nonferrous metal, secondary Pb smelters), vehicle emissions, coal burning, refuse incineration, and industrial outdoor paints applied to structural surfaces. However, with the phasing out of Pb in gasoline (which began in the 1970s), Pb in soils and house dusts originating from lead-based paints have become the principal sources of exposure in the United States (7).

In rivers or water bodies, the concentration of Pb mainly depends on local inputs. Since most Pb compounds have low solubility, high concentrations are very rare. However, they are found in acid mine drainage in high concentrations mostly in areas of Pb mineralization (8). Lead shots used for hunting and fishing can also result in significant Pb input to both soil and water and contribute to inputs to surface waters (9), ultimately adding to the Pb burden in the sediments.

MOVEMENT OF LEAD IN THE ENVIRONMENT

The passage of metals through the atmosphere is integral to their biogeochemical cycling. Because of the dynamic nature of the atmosphere, metals can be deposited in areas remote from their initial source. Air is the primary medium for the transport of Pb. Fine particles of Pb generated anthropogenically are transported over long distances until they settle through wet, dry, or cloud deposition (5). Lead transport in the environment depends on the size of the particles. While larger particles (comprising 95% of the emission) settle down after sometime, the smaller Pb particles can travel hundreds of kilometers before they are deposited (4). Lead in the soil and dust is relatively unavailable biologically. It normally reacts with the soil to form insoluble salts. Moreover, Pb also complexes with components of organic matter such as humic acid and fulvic acid, thus making Pb more unavailable (6). The downward movement of Pb from soil by leaching is very slow under most natural conditions (10). Mobility of Pb in the soil is dictated by a number of geochemical process, including oxidation/reduction, precipitation/dissolution, adsorption/desorption, and complexation/chelation. Metallic Pb can be oxidized to more labile forms, the rate of oxidation and the oxidation products being dependent on the site. Once Pb is oxidized, it can be precipitated in the form of hydroxides, sulfates, sulfides, carbonates, and phosphates. The solubility of these precipitates is dependent on factors such as pH and oxidation–reduction conditions. In general, Pb is more soluble under acidic conditions compared to neutral and alkaline conditions. Most of the Pb accumulated in the soil may be directly taken up by grazing animals and microorganisms or may be ingested by children through hand-to-mouth activity. From the grazing animals Pb may enter the food chain (5).

Lead in rivers comes from runoff, erosion, and direct deposition from air. Fresh water generally contains more inorganic and organic suspended material than marine water, and this suspended material has a tendency to adsorb any dissolved Pb. In the case of the oceans, most of the Pb comes from atmospheric deposition rather than from rivers (4).

ECOTOXICOLGICAL EFFECTS OF LEAD

The uptake of Pb in both aquatic and terrestrial ecosystems is determined by its bioavailability. The term "bioavailability" reflects the premise that, for some heavy metals, organisms may be exposed to less than the total amount present in their habitat (11). The extent to which heavy metals react with and affect biological components is immensely influenced by the physicochemical factors of the specific environment (12). In general, the systemic availability of Pb is matrix and chemical species dependent (13–15).

Toxicity to Aquatic Organisms

Dose-related increases in lead concentrations of submerged and floating plants have been observed upon their exposure to dissolved Pb, accumulation being the greatest in the roots, followed by stems and leaves (16). In a study conducted by Kay et al. (17) water hyacinth (*Eichhornia crassipes*) was exposed to solutions containing lead nitrate concentrations of 0–5 mg/L for 6 weeks. The accumulation of Pb was dose-dependent and in the order of roots > stems > leaves. Uptake of Pb from shot-contaminated sediments has been observed in aquatic plants. In an investigation of a skeet target shooting range located on the shores of Lake Merced, California, sediments contained Pb levels up to 1200 μg/g in the shotfall zone, and tule seedheads and coontails growing within these sediments exhibited Pb concentrations averaging 10.3 and 69.2 μg/g dry weight, respectively, compared to concentrations of 2.3 and 11.9 μg/g dry weight, respectively, at control sites (18). However, Van der Werff and Pruyt (19) reported that application of lead nitrate with a Pb concentration of up to 10^{-5} mol/L had no observable toxicity on four aquatic plants, *Elodea gibba, Callitiche platycarpa, Spirodela polyrhiza*, and *Leman gibba*. In the case of fishes, it has been found that *in vivo* sublethal dietary doses of Pb (II) and tributyltin (TBT) induced toxic effects in *H. malabaricus* (20). Davis et al. (21) conducted long-term bioassays with rainbow trout to establish a maximum acceptable toxicant concentration (MATC) limit for inorganic Pb. Fingerling trout were exposed to nominal total Pb concentrations of 0, 40, 120, 360, 1080, or 3240 mg/L. Actual dissolved Pb was measured and results were expressed in terms of dissolved salt. They reported that MATC values between 0.018 and 0.032 mg/L caused the "black tail effect." A similar bioassay with soft water in fishes hatched from exposed eggs suggested MATC values between 0.041 mg/L (where no black tails occurred) and 0.076 mg/L (where 4.7% of fish showed the black tail effect). When fingerlings from nonexposed eggs were used in a soft water bioassay, the MATC for the black tail effect was between 0.072 mg/L (where no black tails occurred) and 0.146 mg/L (where 41.3% of fish had black tails). There were no significant differences between the measured dissolved Pb concentrations in the two tests, indicating that fish from exposed eggs were more sensitive to the effects of Pb than those from nonexposed eggs.

Maddock and Taylor (22) investigated the uptake of organolead by shrimp, mussel, and dab (a flat fish) in short-term experiments and in mussel and dab in long-term experiments. Bioconcentration factors were higher for tetraalkyl Pb than for trialkyl Pb in the short-term exposure. In the long-term experiment conducted on mussels, the greatest tissue concentration of Pb occurred in the gills; with the digestive glands, gonads, and feet containing progressively less Pb (17).

Toxicity to Terrestrial Organisms

Toxicity to Plants. Although Pb is considered to be toxic to plants just like other life forms, sensitivity of plants to Pb and responses of different plant species to Pb vary according to their genetic and physiological makeup (23). The metal remains largely as a superficial deposit or topical aerosol coating on plant surfaces (24,25). Toxicity of Pb to a large extent depends on its absorption, transport, and cellular localization (23). Plants of *Cassia tora* and *C. occidentalis* growing by the roadside accumulated up to 300 mg/g dry weight of Pb (26). Furthermore, accumulated Pb content generally increases with the increase in Pb in the environment, as has been reported for maize and pea leaves and Vigna and sesame roots (23) and leaves (27, 28). Photosynthesis is considered as one of the most sensitive metabolic processes to Pb toxicity (23). Moreover, nitrate reduction is inhibited drastically in roots by the metal, but in the leaves a differential effect is observed in various cultivars (23). Nitrate assimilation is inhibited by 10–100 mM Pb^{2+} in sorghum leaves (29). Lead also inhibits nodulation, N fixation, and ammonium assimilation in the root nodules (23).

Toxicity to Invertebrates. Long-term exposure of terrestrial invertebrates to lead-contaminated soil can result in high tissue concentrations, but one of the detoxification mechanisms within their cells is the subcellular compartmentalization of Pb. This results in only a fraction of the total body Pb burden actually contributing to toxicity (30). Doelman et al. (31) incubated a mixed culture of bacteria in lead nitrate solutions and also grew the fungus *Alternaria solani* on malt agar to which lead nitrate had been added. The cultures were used as food for the nematodes *Mesorhabditus monohystera* and *Aphelenchus avenae,* which were reared for up to 22 days on bacteria and fungus, respectively. Lead was taken up by bacteria to give a range of doses to the nematodes of between 7.6 and 110 μg/g of food. All these exposures had a significant inhibitory effect on the reproduction of *Mesorhabditus monohystera*. However, when woodlice *(Porcellio scaber*) were exposed to treated soil litter containing between 100 and 12,800 mg/kg dry weight of Pb as lead oxide over 64 weeks, no significant effect was found on adult survival, number of young produced, or the survival of the young at exposures up to 6400 mg lead/kg (32).

Toxicity to Birds. In the case of birds, metallic Pb is highly toxic when it is given in the form of Pb shots. Lead poisoning through the ingestion of spent gunshots is a widely recognized waterfowl mortality factor (33). Water fowl ingest spent gunshot when searching for grit (and possibly for food) particles. Once in the bloodstream, Pb is rapidly (but reversibly) deposited in soft tissues, mainly liver and kidney, and (relatively irreversibly) into bone (34). If a large quantity of Pb (e.g., >10 shots) is ingested within a short time, acute Pb poisoning may occur, resulting in death within a few days. However, most of the mortality results from the ingestion of a smaller number of shots, with birds dying of chronic poisoning 2–3 weeks following ingestion (34). The U.S. Fish and Wildlife Service (35) reported that Pb poisoning from ingested sinker and jigs accounts for 10–15% mortality of common loons (*Gavia immer*) with a study revealing that 27% of adult loons had fishing tackle in their stomachs and high Pb levels in their blood. Signs of chronic Pb poisoning include green and watery feces, dropping wings, anemia, weight loss, and atypical behavior; the affected birds die approximately 2–3 weeks after ingesting the shot, often in a very weak condition (36). Secondary Pb shot poisoning can occur when a predator or scavenger consumes animals that have been shot with Pb shot shell ammunition or consumes the gizzard of a bird that has ingested Pb shot (36). Lead also causes a decrease in clutch and egg size, mortality of embryos, depression of growth, and deficits in behavior, thus affecting the survival of birds (37).

EFFECTS ON HUMANS

Lead is present in various forms in the environment, such as free hydrated ions, ion-pair salts/complexes, and organic complexes/chelates (38). Humans are most likely to be exposed to the inorganic forms of Pb such as halides, oxides, sulfides, carbonates, and chromates. Since Pb was phased out as a gasoline additive (tetraethyl Pb) in the 1970s and its use in paint and food containers (e.g., ceramic ware and tin cans) was curtailed, blood Pb concentrations (BLLs) have decreased significantly. However, other sources of Pb and its unknown threshold of subclinical toxicity continue to make Pb an issue of public health concern (39). Lead exposure in the general population (including children) occurs primarily through ingestion, although inhalation also contributes to Pb body burden and may be the major contributor for workers in Pb-related occupations (40). Children's hand-to-mouth activity, increased respiratory rates, and increased intestinal absorption of Pb make them more susceptible to Pb exposure than adults (41,42). Exposure to Pb can result in significant adverse health effects to multiple organ systems. Once Pb is absorbed into the blood plasma, it rapidly equilibrates with the extracellular fluid. More slowly, but within minutes, Pb is transferred from plasma into blood cells (43,44). From the blood plasma, the absorbed Pb is transferred to the liver and the kidneys. Lead tends to accumulate in areas with high levels of calcium; hence, the highest body burden of Pb is found in the bones. In a typical adult, 95% of the Pb is stored in the bones, whereas in children, it amounts to 70% (45,46). During childhood, Pb accumulates predominantly in the trabecular bones. But in the case of adults most of the Pb is found in both cortical and trabecular bones. In both the trabecular and cortical bones there are two physiological compartments, one labile and the other inert for Pb (7). While Pb may be exchanged between the blood and the bone through the labile component, Pb may be stored for years in the inert component (7).

The distribution of Pb in tissues reflects a state of constant, dynamic equilibrium. Any situation that mobilizes the very large, relatively stable pools of Pb within the body, particularly those in the bones, will lead to the redistribution of Pb to a variety of tissues. Redistribution is known to occur during pregnancy, which results in increased risk to the fetus, particularly in women with prior Pb poisoning (5).

The various detrimental human health effects of Pb include:

- Neurological effects including effects on the central and peripheral nervous systems.
- Effects on both male and female reproduction.
- Renal effects.
- Effects on vitamin D metabolism.
- Cardiovascular effects.
- Hematopoietic effects.

Neurological Effects

Lead affects both the central and peripheral nervous systems. An extensive database has provided a direct link between low level Pb exposure and deficits in the neurobehavioral–cognitive performance evidenced in childhood through adolescence (47). Many of the biological aberrations produced by Pb appear to be related to the ability of this heavy metal to either inhibit or mimic the action of calcium. Calcium ions play a special role in the release of neurotransmitters from presynaptic nerve endings (48). A large number of experimental studies have investigated the effects of prenatal and neonatal Pb exposure on central nervous system development and behavior. These studies have shown variable results, forming a spectrum that includes delayed nervous system development, deficits in visual motor function, abnormal social and aggressive behavior, hyperactivity and hypoactivity, as well as no changes in activity (49). The brain and the nervous systems of children and fetuses are generally vulnerable to Pb intoxication because of the incomplete blood–brain barrier and also because both the brain and the nervous system are still developing (40).

Effects on Central Nervous System

In the central nervous system, Pb toxicity is more common in children than adults and may produce either overt symptoms of acute encephalopathy, such as ataxia, headache, convulsions, and coma, or lesser deficits including learning disorders and hyperactive behavior (50,51). Lead disrupts the main structural components of the blood–brain barrier through primary injury to astrocytes with a secondary damage to the endothelial microvasculature. Within the brain, lead-induced damage occurs preferentially in the prefrontal cerebral cortex, hippocampus, and cerebellum (47) Lead enhances the spontaneous or basal release of neurotransmitters from presynaptic nerve endings at low concentrations (48). In addition to enhancing the spontaneous release of neurotransmitters, Pb blocks the release of neurotransmitters normally produced by depolarization of nerve endings. It modulates neurotransmitter release by altering calcium metabolism either by competing with calcium for entry into the cell or by increasing intracellular calcium levels (48). Moreover, high dose exposure to Pb (i.e., BLLs in excess of

4 μM) disrupts the blood–brain barrier (48). In general, blood–brain barrier excludes plasma proteins and most organic molecules and limits even the passage of ions such as sodium and potassium (52). However, at high BLLs large molecules such as albumin, which are normally excluded, freely enter the brain of immature animals exposed to high concentrations of Pb (53,54). Ions and water follow and edema is produced, resulting in the rise of intercranial pressure because of the physical restraint of the skull. When the intercranial pressure approaches the systemic blood pressure, cerebral perfusion decreases and brain ischemia occurs (48).

Children exposed to high levels of Pb suffer from encephalopathy and hyperirritability, ataxia, convulsions, stupor, and coma or death. In general blood, BLLs of about 70–80 μg/dL or greater in children pose a threat (7). However BLLs as low as 10 μg/dL or less can adversely affect the developing nervous system of a child (40). Studies have shown that for every 10 μg/dL increase in the BLL, there is a decrease of children's IQ by about four to seven points (55–60). In the case of adults, Pb encephalopathy may occur at BLLs of about 460 μg/dL (61).

Effects on Peripheral Nervous System

Peripheral neuropathy is a manifestation of Pb toxicity in adults with excessive occupational exposure. Children exposed to high levels of Pb may also suffer from peripheral neuropathy. While in adults the most common manifestation of peripheral neuropathy is wrist drop, in the case of children, general weakness and foot drop are more common (62).

Effects of Lead on Reproduction

Male Reproductive System. An adverse effect of Pb on the male reproductive system has been reported in several epidemiologic studies (63). It has been reported that BLLs below the currently accepted working protection criteria adversely affect spermatogenesis (64). Earlier studies on Pb workers had shown androgenic dysfunction including asthenospermia, hypospermia, and teratospermia that could be produced by direct toxicity to the testis (65). It has been shown that significant levels of asthenospermia and teratospermia were found in workers having BLLs over 500 μg/L (66). The effect of Pb poisoning on the male reproductive system can be seen at BLLs of about 40 μg/dL, with long-term Pb exposure resulting in diminishing sperm counts, sperm concentrations, and total sperm motility (7). Moreover, it was found that the risk of stillbirth or birth defects was elevated for preconception employment in a high Pb exposure environment compared with low Pb exposure jobs (67).

Female Reproductive System. There have been few well-documented reports on reproductive effects of Pb in humans (68). Exposure may result in increased preterm delivery. It was found that preterm delivery was statistically significantly correlated with maternal BLLs in a dose-responsive manner (69). Moreover, due to changes in the bone physiology and mineral metabolism during pregnancy, Pb may move from the bone into the maternal circulation. Lead does cross the human placenta as early as the 12th week of gestation (70). Cord-blood content of Pb shows a high correlation with maternal-blood samples, suggesting that infants are exposed in uterus to BLLs equivalent to those of the mother (71). Recent isotopic speciation studies have demonstrated that the skeletal contribution to BLLs increases from 9% to 65% during pregnancy (72). The maternal Pb burden has been reported to be negatively associated with the birth weight of infants (73). It has been found that prenatal exposure to low Pb levels (e.g., maternal BLLs of 14 μg/dL) may increase the risk of reduced birth weight and premature birth (7).

Effects on the Renal System

Lead affects the renal system in three stages. In the first stage, there is proximal tubular dysfunction (Fanconi's syndrome) manifested by aminoaciduria, glycosuria, and phosphaturia (74). Then chronic exposure results in the second stage that is characterized by gradual tubular atrophy and interstitial fibrosis. There is reduced incidence of inclusion bodies, and glomerular filtration is impaired (75). At the third stage, renal failure occurs and is characterized by renal tubular neoplasia or adenocarcinoma (76). In general, individuals with Pb levels exceeding 60 μg/dL are at a risk of developing renal failure (77,78).

It has been reported that Pb inhibits rBAT-induced amino acid transport in a noncompetitive, allosteric fashion. This blockade of rBAT-induced amino acid transport may be involved in aminoaciduria following Pb intoxication (79). Lead exposure also results in the onset of "saturnine gout" as a result of lead-induced hyperuricemia due to decreased renal excretion of uric acid. Most documented renal effects for occupational workers are observed in acute and high to moderate chronic exposures with BLLs of more than 60 μg dL (40).

Endocrine Effects/Effects on Vitamin D Metabolism

From the studies of children exposed to high Pb levels, it has been found that a correlation exists between BLLs and the level of vitamin D. Lead interferes with the conversion of vitamin D to its hormonal form, 1,25-dihydroxyvitamin D, which is responsible for the maintenance of extracellular and intracellular calcium homeostasis. Thus, impairment by Pb results in impaired cell growth, maturation, and tooth and bone development (40).

Cardiovascular Effects

Lead exposure is one of the factors that may contribute to the onset of hypertension. Other factors contributing to the development of hypertension include old age, increased weight, poor diet, and excess alcohol intake (40). Studies have shown that greater exposure to Pb in occupational environments may increase the risk of hypertensive heart disease and cardiovascular disease. There are several reports that have associated Pb exposure to elevation in blood pressure (80–83).

Hematopoietic Effects

Lead inhibits the body's ability to make hemoglobin by interfering with several enzymatic steps in the heme pathway (40). Heme is the prosthetic group of hemoglobin, myoglobin, and cytochromes. In mammals, heme is synthesized from succinyl-CoA and glycine in eight enzyme-mediated steps (Fig. 1) (84). Enzyme studies of the heme biosynthetic pathway have shown that Pb is an inhibitor of δ-aminolevulinate dehydratase (ALAD), corporphyrinogen oxidase, and ferrochelatase (85). However, the metal has the greatest influence on ALAD, and measurement of ALAD activity can be used as an indicator of Pb levels in the blood (84). Heme synthesis occurs partly in mitochondria and partly in cytoplasm. The three important steps in the synthesis of heme that are influenced by Pb intoxication are:

1. The condensation reaction of two molecules of δ-aminolevulinic acid that is catalyzed by PBG synthase (porphobilinogen synthase) or ALA dehydratase to form porphobilinogen (PBG). ALA-D is the enzyme that is most sensitive to Pb. Inhibition of the enzyme results in the prevention of the utilization of ALA and subsequently a decline in heme synthesis (68).
2. The rate-limiting step in heme biosynthesis is the ALA synthase catalyzed step. The oxidation product of heme is hemin, which acts as a negative feedback inhibitor of ALA synthase and inhibits the transport of ALA synthase from the cytosol to the mitochondria and also represses the synthesis of the enzyme. Lead interferes with the negative feedback control of heme synthesis; ALA synthetase activity is depressed, resulting in increased activity of the enzyme and increased synthesis of ALA (68).
3. The third reaction that is influenced by the intoxication of Pb is the incorporation of the ferrous iron into the porphyrin ring structure that is catalyzed by the enzyme ferrochelatase. Lead inhibits the enzyme ferrochelatase, thus preventing the introduction of iron into the protoporphyrin IX to form heme. The porphyrin chelates with Zn nonenzymatically to form ZnPP, which in turn is incorporated into hemoglobin. It has been found that ZnPP containing hemoglobin has a much lower oxygen capacity than Fe-containing hemoglobin (68). Moreover, iron in the form of ferritin and ferruginous micelles also accumulate in the mitochondria of bone marrow reticulocytes (68) (Fig. 1). In general, Pb induces two types of anemia. While acute, a high Pb level results in hemolytic anemia; chronic Pb exposures result in anemia that is induced by the interference of Pb with heme biosynthesis and also by diminished red blood cell survival. According to the EPA, in the case of occupationally exposed adults, the threshold BLL for a decrease in hemoglobin is 50 µg/dL, whereas in children, the threshold BLL has been observed to be 40 µg/dL (7).

FUTURE DIRECTION

Lead is ubiquitous in nature, but anthropogenic activities have further exacerbated Pb levels in the environment. Although lead-based petroleum has been phased out, Pb is still being used in the industry (such as lead-acid battery manufacturing industry) due to the absence of viable alternatives. Blood lead levels of 10 µg/dL have been associated with adverse health effects in children (86). The treatment of Pb poisoning involves chelation, which accelerates the process of reducing the Pb levels in the circulating blood. In children, chelation therapy is recommended only when the BLLs exceed 45 µg/dL (86). There is an abundance of evidence demonstrating that dietary calcium decreases gastrointestinal Pb absorption,

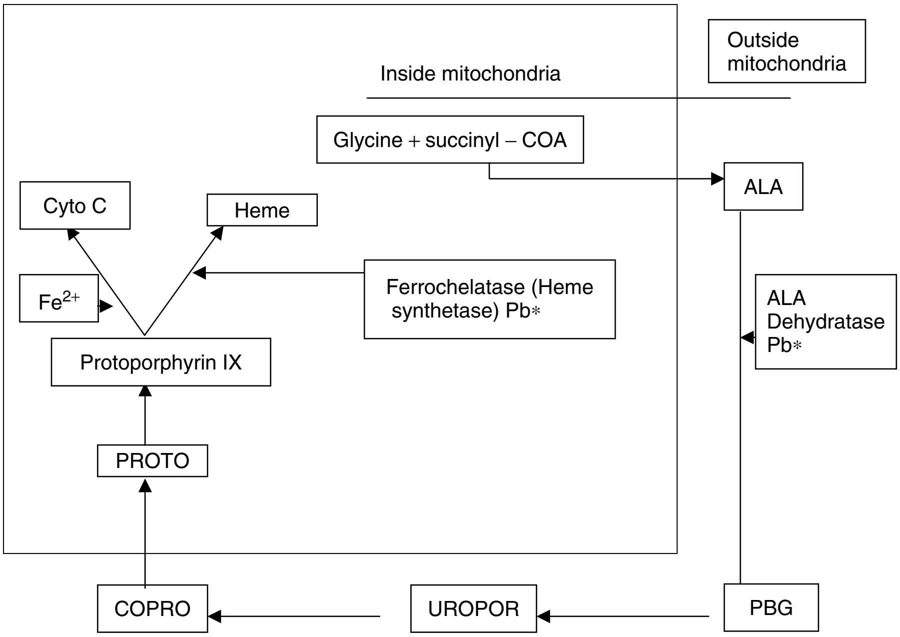

Figure 1. Scheme of heme synthesis showing sites where lead has an effect. PGB, phorbobilinogen; UROPOR, uroporphyrinogen; COPRO, coproporphrinogen; PROTO, protophorphyrinogen; Co A, coenzyme A; ALA, δ—aminolevulinic acid; Pb* site for Pb effect (from Ref. 68).

thereby reducing Pb toxicity (87). Experiments carried out on rats suggest that bone Pb concentrations increased by about fourfold in rats fed with a low calcium diet, compared to rats on a normal calcium diet, although the amounts of Pb ingested were equal (88). Short-term intake of calcium does not alter BLLs, but reports suggest that under conditions of physiological stress, skeletal minerals can be mobilized for calcium and that Pb will also be released along with calcium during this mineral mobilization (72,89,90). Ongoing research is now addressing whether calcium intake will reduce this mobilization.

Epidemiological studies have shown correlations between low levels of Pb contamination in the environment and subtle neurobehavioral effects in children. However, the biochemical mechanisms forming the basis of these subtle neurotoxic effects of low concentrations of Pb in the environment have not been clearly established (5). This is another area where research needs to be focused, to find out the biochemical interactions that may be primarily responsible for the neurotoxic effects of Pb.

MICROBIAL DETECTION OF VARIOUS POLLUTANTS AS AN EARLY WARNING SYSTEM FOR MONITORING OF WATER QUALITY AND ECOLOGICAL INTEGRITY OF NATURAL RESOURCES, IN RUSSIA

GALINA DIMITRIEVA-MOATS
University of Idaho
Moscow, Idaho

GENERAL INTRODUCTION

General

The U.S. Environmental Protection Agency (U.S. EPA) persistently supports programs that monitor water resources using bioassessments and that develop biocriteria for different water bodies throughout the country in accordance with the Clear Water Act, the Watershed Protection Approach, and the National Water-Quality Assessment (NAWQA) Program. Currently, assessments of biological integrity and water quality are based on habitat measurements and also on biosurveys of the status of indicator aquatic communities. In order to evaluate an integrative ecological situation in water resources, the U.S. EPA has established protocols for bioassessments and for developing biocriteria applicable to selected biological assemblages, such as phytoplankton, zooplankton, periphyton, macrophytes, macroinvertebrates, and fish. As the U.S. EPA literature mentions, at the present time, no established protocols exist for other groups of organisms, including bacteria, because the data about those organisms are not sufficiently numerous. However, bioassessments based on the use of currently selected indicator groups of hydrobionts do not indicate the cause of water resource impairment. Also, usually habitat measurements monitor already known impairing factors; therefore, if a new pollutant has appeared, it may remain undetected.

The author of this paper had long-term extensive experience working with water quality control and ecological integrity monitoring using microbial indices. This practice includes eight years of microbial bioassessments and the development of biocriteria implications for the detection of various organic pollutants, a number of heavy metals, and biological contamination in seawaters of Russia, which provided impressive results, demonstrating the advantages of such an approach for monitoring ecological integrity and water quality of estuaries and shallow and pelagic regions of marine coastal zones. The composition alteration of aquatic sediment or plankton microbial assemblages subjected to pollution resulted in an increase of pollutant-resistant (indicator) groups that detected expected and unexpected pollutants and their levels. The analysis of the proportion between all indicator groups assisted us in drawing conclusions about the natural or anthropogenic process or factors causing impairment of water resources.

As monitoring of water quality using microbial indices and habitat metrics can detect many different pollutants at a number of monitoring stations, we gathered sample point data via a Global Positioning System (GPS) and displayed the distribution of each pollutant over the water body on maps employing a Geographic Information System (GIS). Several pollutants have been monitored using microbial assessments and habitat metrics, including measurements of toxic compounds at the reference stations and at the monitoring stations. Microbiological assessments for the evaluation of the biological contamination included controlling fecal and pathogenic bacteria, such as *E. coli, Salmonella, Shigella, and Listeria*, detecting phenol-resistant bacteria as indicators of fecal phenols, and also evaluation of the proportion of proteolytics and lipolytics bacteria in microbial assemblages. In order to monitor the pollution of oil and oil by-products, we studied the percent of microorganisms resistant to those pollutants as well as the concentration of those compounds. The portion of lipolytic bacteria that might contribute to oil biodegradation was also detected and evaluated. We also applied microbiological assessments and habitat measurements in order to detect the presence and the origin of phenols that can appear in the water from point and nonpoint sources. The choice of monitored heavy metal pollution using microbial assessments, and also habitat metrics, was based on the environmental role of heavy metals and their impact. As a primer pool of elements, we controlled Cu, Pb, and Ni as indicators of industrial impact; Cd and Zn as indicators of anthropogenic impact; Co and Cs as detectors of radioactive contamination; and Fe as a marker of terrestrial influence.

Historical Background

Application of Microbial Assessments for Detection of Various Pollutants in the Environment

Response of Indicator Groups of Microorganisms to Pollution in the World Ocean. The concept of microbial indication of organic pollutants in the world ocean has been developed most actively during the last two decades. Progressively increasing anthropogenic load on the marine environment creates tense ecological situations, primarily in coastal areas. As had been established earlier, an increase of anthropogenic pressure on the marine environment influences structural and functional properties of hydrobiont communities (1). Pollutants cause various changes in marine organisms. Organisms that have adapted to new chemical compounds, or increased concentrations of pollutants in the environment, begin to dominate in the structure of biocenosis. The ability to quickly adapt to changing environmental conditions because of high rates of reproduction and growth and versatile enzymatic activity is a unique feature of microorganisms. For this reason, microorganisms are unique tools that scientists have started using to control marine pollution because they have the most direct connections to the surrounding environment, they react quickly by altering population size and composition, and they reflect any environmental changes. On this basis, microbial assemblages are considered indicators of physical, chemical, and biological processes in the world ocean (2–7). As is known, microorganisms are indicators of contamination of various organic substances, because they are destroyers and consumers of those compounds at the same time. The existence and sensitivity of the individual response of the plankton community to variations in the concentrations of metals in contaminated waters, with a complex of metals, are confirmed on the basis of microbiological data and the results of their comparison with the data of chemical analysis (8–11). A number of microorganisms, the composition of main physiological groups, and distinct genera in seawaters and sediments are characteristics of microbial assemblages that researchers used for the purposes of biomonitoring of pollutants in the marine environment (12–15). Biological contamination criteria were developed earlier, historically for fresh waters more than for seawaters. Microbial assessments of other kinds of pollution have longer records in the marine environment, particularly, in Russia.

Detection of Pathogenic Bacteria and Biological Contamination in Surface Waters. Indication of pathogenic microorganisms in surface waters is under the control of environmental services and laboratories. Observed indicator bacteria of biological contamination exist, as well as saprobe indices of waters in freshwater and seawater environments. Freshwater saprobe indices are established on the basis of the ratio between the number of bacteria grown on reach nutrient agar and the number of bacteria grown on pour agar at starving conditions. For barely contaminated sites, the ratio is 1.2–2.8, and for references, the ratio appears as 0.1–0.7 (16). Also, most of the microbial indicators of biological contamination have been studied in fresh waters. In the 1960s, seawaters in Russia were investigated and classified according to their saprobes (17). In the 1970s, indicator microorganisms for biological contamination were determined, and sanitary criteria were established according to international agreement (18,19). According to that classification, in secure waters, the number of *Escherichia coli* cells must not exceed 10 per mL. In 1 mL of dangerous waters that can cause infectious diseases, more than 24 cells were found. The control of biological contamination is also a very highly developed field at the present time.

As seawaters accept an increasing amount of domestic and industrial wastewaters, the biological contamination of seawaters is a subject of the continuing investigation. Distribution of fecal and pathogenic bacteria has been studied in the waters of the Atlantic Ocean (20) and in the benthos coastal zone of the Antarctic Ocean (21). Other regions of the world ocean have been studied in estuarial (22), coastal (13), and pelagic (23) zones. Among the indicators of fecal contamination indicated are such microorganisms as *E. coli, Nitrobacteria* spp., *Clostridium perfringens, Pseudomonas aeruginosa, Vibrio* spp., *Salmonella* spp., *Candida albicans, Klevsiella* spp., *Bacterioides* spp., enterococci, bifid-bacteria, and fecal streptococci (22). Intestinal viruses are also the subject of study in the water environments.

Use of Microorganisms as Indicators of Oil Pollution in Seawaters. Microorganisms were beginning to be used many years ago as detectors of oil pollution and of water quality in the marine environment. One of the first marine microbiologists studying this subject was ZoBell and his coauthors (24). These scientists have found more than 100 species of marine microbes representing 30 genera, which have been able to use hydrocarbons. Those microorganisms have been considered indicators of oil pollution in seawaters. By the present time, researchers have isolated more than 1000 strains of microorganism-oxidizing hydrocarbons (25–28). The most active hydrocarbon-oxidizing marine bacteria were determined to be *Mycobacterium* and *Arthobacter* (29).

In Russia, the first publications devoted to indication of oil contamination in seawaters were published in the 1950s (30,31). The evaluation criteria for oil pollution were based on the ratio of oil-oxidizing heterotrophic bacteria and saprotrophic bacteria or on the ratio of oil-oxidizing bacteria and the total bacterial quantity (29,32). Bacterial criteria for determining acceptable standards for clean water were also established. More recently, data appeared about microbial degradation of not only aliphatic hydrocarbons, but also of polycyclic hydrocarbons (33–35). Their results have demonstrated that indicator groups of microorganisms are developed weakly in noncontaminated pelagic seawaters. In oil-contaminated areas of the world ocean, those groups were very numerous. For this reason, researchers use the activity and a number of hydrocarbon-oxidizing microorganisms as an index of oil pollution in seawaters. Now this is the most heavily investigated field in the study of marine microbiology in Russia and in the world at large.

Microbial Detection of Phenols in Seawaters. Contamination of surface waters by phenols can have different origins. Fecal sterols, polyaromatic hydrocarbons, biphenyls, and Cl-phenols enter water environments from domestic wastewaters, from industrial oil pollution, from oil spills, and from cellulose factories. Contrary to microbial indication of oil pollution in seawaters, indication of phenols does not have long-term records. Over more than twenty years, some articles devoted to microbial detection of phenols in seawaters were published (7,36,37). The microbial detection of fecal sterols (38–40), Cl-phenols, and biphenyls has been studied in more detail (1,15). Microorganisms and degrading aromatic phenols are considered as indicators of phenol pollution in deep-water regions of the ocean (7,36,41). Remarkably, the composition of microbial assemblages from phenol-contaminated seawaters and marine sediments has been found to be close to the composition of the microbial community from active silts of wastewater treatment facilities, which were adapted to phenol by-products (42). Representatives from genera *Bacillus* (25%), *Pseudomonas* (12.5%), *Mycobacterium* (24%), *Micrococcus* (25%), and *Actinomyces* (12.5%) were found there. However, no indices were established to confirm the phenol contamination in the marine environment.

Bacteria-Degrading Lipids, Proteins, and Starch Are Additional Indicators of Organic Contamination in Coastal Waters. Seawater and marine neuston organisms contain considerable amounts of various lipids. The concentration of lipids in seawater varies from 0.01 to 0.12 $\mathrm{mg \cdot mL^{-1}}$, and concentration of lipids in marine plankton appears as 2–25%. Also, three gycerides, fatty acids, and phospholipids are oil by-products during the oil transformation process in the marine environment and bacteria synthesize them as well. As lipids are much lighter than water, they are concentrated on the margin of the surface of seawater and interfere with the gas and temperature exchange process between the ocean and the atmosphere, causing different negative consequences. Many marine bacteria can use lipids as a source of carbon. They possess lipolytic activity and provide self-clearance of lipids from seawaters. Bacterial neuston is particularly important for the biodegradation of lipids in the sea (43). For this reason, some authors suggest considering the appearance of lipolytic activity in the dominant part of neuston microbial assemblages, as confirmation of the presence of oil contamination in seawater.

Determination of a number of lipolytic microflora and measurement of lipolytic activity in marine bacteria serves as a test, characterizing the capability of the marine coastal environment for self-clearance (43,44). Nitcowski et al. (12) presented data in evaluating a portion of the physiological groups of lipolytic microorganisms in aquatic microbial association, as well as a portion of proteolytics, as an indicator of biological contamination. The authors have found that a number of bacteria from those groups were four times as numerous at contaminated sites. Among those physiological groups of microbes, 80% of the population has been identified as pseudomonades and vibrions.

Some marine bacteria, yeasts, and fungi are capable of degrading starch. Such microorganisms were detected among microbial assemblages living on the surface of marine algae and plants (45–47), their remains (44,46), and in the water (45). In our opinion, such microorganisms may also indicate contamination of seawaters by carbohydrates.

Application of Microbial Biosurveys for Detection of Heavy Metal Contamination in the Environment

Practical use of the microbial approach for detection of the presence of metals started in the 1950s in geological survey practice for the metal ore search in Russia. The method was based on the ability of certain bacteria to stimulate or to inhibit their growth in response to the presence of metals of interest in the ground and in the surface waters (48,49). In order to prove that the method of microbial detection can be implicated for metal deposit searches, scientists used the station grid approach, where habitat metrics included measurements of the concentrations of metals. Such field investigations covered extensive areas in different states and republics of the former Soviet Union in Eastern Siberia, Kazakhstan, Ural, and the Caucasus regions. Researchers have found a direct connection between the distribution of metals (Mo, Zn, Cu) and a number of cultured, metal-resistant, or metal-sensitive bacteria. All other similar applications in geological microbiology were reviewed later (50).

In the 1970s, the geochemical ecology of microorganisms was established as a science in Russia. The subject of geochemical ecology of microorganisms is the study of interactions between natural and industrial factors, including metals, in the environment (51,52). At the present time, environmental microbiology studies mechanisms of the interaction between microorganisms and heavy metals. Microorganisms absorb metals for their physiological needs, as do many other organisms, because metals are an important part of biological molecules, including enzymes, hormones, vitamins, pigments, and lipids.

Generated data demonstrate that microorganisms also have a unique system of cell organization and function, responsible for selective binding and absorption of metals by bacteria. The major element of this system is the cell wall. It is remarkable that the adsorptive capability of bacterial cell walls is so high and that it is comparable with the most efficient resins used for ion-exchange chromatography (53). As now established, the selective adsorption of distinct metals by cell walls varies significantly in different bacteria (52–54). In firmicutes, an affinity of cell walls in binding different metals is presented as follows: $La^{3+} > Cd^{2+} > Sr^{2+} > Ca^{2+} > Mg^{2+} > K^{+} > Na^{+} > Li^{+}$ (53). As a result of such high capability of the selective binding of metals, bacteria accumulate metals that greatly exceed the natural concentrations of metals in the environment.

The absorption process involves active and passive transport of metals through the plasma membrane. Specificity of active transport mechanisms is based on ligands selective to individual metals. Those minor membrane protein structures are a second element of the system responsible for selective binding and absorption of metals by bacteria. For example, it has been demonstrated that *E. coli* has three specific systems for transport of iron (55).

Bacteria have a high resistance to heavy metals because of different mechanisms of their detoxification. For this reason, microorganisms are the only live organisms on the Earth that are able to live in environments containing very high concentrations of heavy metals. The detoxification of heavy metals is the system that provides bacterial survival in heavy metal environments. In general, those mechanisms include: limitation or complete blocking of metal internalization into bacterial cells, active removal of absorbed metals from cells, and detoxification of metal ions by binding and transforming them into nontoxic forms or by the resulting intracellular accumulation (56,57). Thus, bacteria possess various mechanisms of self-protection against toxic effects of heavy metals in the environment.

On the basis of presented data, we may conclude that the variety of systems of selective binding and transport of heavy metals, and also the system of detoxification of heavy metals, are real cell functions that provide survival and the specific response of the microbial community to the presence of toxic metals in the aquatic and terrestrial environments. Of course, passive transport and nonspecific transport of metals also take place in microbial cells. Other mechanisms of interaction of bacteria with metals exist as well, but it is not an aim of this entry to discuss all aspects of the interaction of bacteria with metals, including details of detoxification of metals by microbial cells. Those aspects are presented in other papers (56–61). Also, many environmental factors influence the efficiency of the interaction of metal ions with microbial cells, including the pH of various environments, the state of metal ions, and the presence of other ions (56). The information presented above aims to demonstrate a general knowledge that may help in the understanding of the true foundation for the prospective use of microbial assessments for monitoring heavy metals in water environments. However, this powerful tool for environmental monitoring is not yet widely used. Also, since recent times, the technique of microbial survey, employed to indicate different pollutants, their concentrations, and also the ecological state of marine or freshwater environments, was not sufficiently used in Russia, or in the remainder of the world for that matter.

Monitoring Marine Environmental Quality in Russia

The anthropogenic load and its influence on the condition of the world ocean, particularly in the marine coastal zones, continues to grow as a result of population growth and increasing human activity. Such pressure influences qualitative development of sea life and the structural and functional characteristics of hydrobiont assemblages in the ecological, morphological, physiological, biochemical, and genetic levels (1). One of the most important consequences of the pollution of the marine environment is an appearance of indicator forms that can possess harmful characteristics, which is one of the reasons why the methods for biological control of marine environmental quality were developed in the 1960s. Two major different strategic approaches have been applied for biomonitoring of pollution in the marine environment in Russia in the past. These approaches are bioassay and bioindication. Microbial detection of marine pollutants combines the advantages of both methods and gives new possibilities for efficient tracking of pollutants issued from point and nonpoint sources in surface waters.

Bioassay Approach. The bioassay approach is based on the ability of marine organisms to react through their longevity, by the reduction of some life functions, and by alteration of cell structure at the appearance and concentration of toxic compounds in the seawater. These variations are immediately observable and provide information about the degree of toxicity of the environmental samples containing the complex of pollutants for certain kinds of organisms. However, this method does not provide information about the concentration of pollutants or an indication of which pollutant causes this negative effect. The most suitable subjects used for such control are microalgae, larvae of marine invertebrates, young generations of fishes (62,63), sea urchins and molluscs, and also sexual cells of marine organisms and marine polychaete (64). Usually, those subjects are single cell or simply organized forms, which are very sensitive to unfavorable conditions and have short lifespans.

Bioindication Approach. Another technique widely used for the marine environmental quality control is bioindication, which pertains to the study of mature, long-term life forms and requires that organism monitors must be immobile or attached to the marine substrate, and that they must be resistant to pollution and also able to accumulate toxic compounds at a concentration exceeding environmentally acceptable levels to several significant digits. The organisms most often used for bioindication in the marine environment are macroalgae and molluscs (65). These organisms are used particularly to monitor heavy metals in seawaters. In such cases, chemical analysis of the organism's tissues displays every distinct pollutant and establishes the dynamic of its behavior in the marine environment over time. The disadvantage of this approach is that no information about how toxic a certain compound may be and what the concentration of that chemical was during a certain period may be determined.

Use of a Combination of the Bioassay and Bioindication Methods in Russia. The use of both the bioassay and bioindication methods in Russia is mostly applicable to scientific research at the present time. Currently, no state regulation of these methods exists in environmental policy. However, because such approaches are numerous and multidisciplinary, Russian Scientific Institutes always are afforded opportunities to submit results of expertise and to make strong recommendations to any federal government or local state and city organizations and agencies to influence their economical or political solutions. Such scientific investigations are always a subject of consideration for the Environmental Protection Committees and Ministry, and also for the Health Protection Ministry and the local Sanitary Committees of Russia.

It is fortunate to note that most of the time their final decisions are taken with consideration of the recommendations given by Scientific Organizations monitoring the marine environmental quality and condition of marine habitats. For example, several scientific marine institutions conducted long-term and multidisciplinary investigations of the ecological state of the marine environment in the important international economical zone near Vladivostok, Russia during 1996–1998. Named The Tumen River Economic Development Area Project (TREDA), it was planned by the United Nations Organization to help economical and political development of that Pacific Region, involving China, North Korea, Japan, and Russia. The first initiative was considered the only economic side of that project. No detailed information existed about the current complex ecological situation of the area and how the project application could change the surrounding marine environment. The existence of the unique Marine National Reservation in Russia was not considered at all. Subsequently, scientific investigations showed that nobody controlled the flow of wastewater into the Tumen River from China and North Korea; consequently, the pollution at this site has increased tremendously during recent years. The increased flow of domestic, agricultural, and industrial wastewaters into the Sea of Japan caused the appearance of many unhealthy forms among the marine habitats in the Marine State Reservation area. The expertise conducted made responsible persons and organizations plan additional efforts and funding to protect not only the Russian National Marine Reservation but also the marine environment of the Sea of Japan. I am proud to announce that microbial detection results of those dramatic changes were among the first data obtained through these efforts.

MICROBIAL BIOSURVEYS IN FAR EASTERN SEAS OF RUSSIA

Areas of Field Investigations

We began our investigation in this field 12 years ago. The areas that have been investigated in the Russian Pacific region have all involved international, economically, and politically important areas (Fig. 1), such as the Southeast Pacific Ocean coast of the Kamchatka peninsula (1995, 1997, 1999), the southwest (1995, 1997) and the northeast (1996, 1998) of Sakhalin island, and the North (1992, 1996–2000) and South parts of Primorie (1995–2001) (8–11,37,47,66–68). As a matter of background, the Far Eastern seas are influenced by global natural factors such as the Pacific ore "belt," volcanic activity, grand streams, upwelling, and by the action of bringing chemical elements to the surface water in active geochemical zones. As a result, the Far Eastern seas are distinguished as containing the highest level of toxic material, primarily heavy metals, which can provoke ecological stress and cause pollution.

Every water body chosen for our investigation had specific characteristics and was distinguished in the degree of anthropogenic impact, geochemical, geographic, and ecological conditions. In the past, Avachinskaya Guba Bay, Krasheninnikov Bight (Kamchatka peninsula) was known as the biggest Russian Navy base, and because of this status, the area became contaminated with radionuclides. Seawaters surrounding Sakhalin Island are

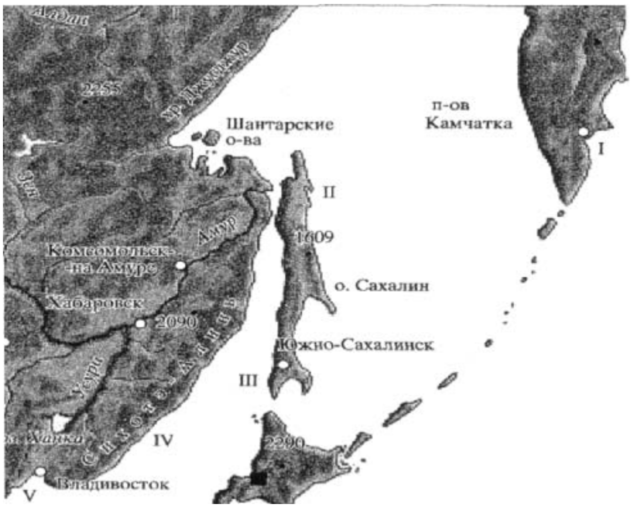

Figure 1. Areas of the studies on microbial indication of pollution of the near-shore waters by heavy metals: I—Kamchatka coast, area of Avachinskaya Guba; II—northeastern coast of Sakhalin Island, Nyiskii, Nabil', and Chaivo Bays; III—southwestern coast of Sakhalin Island, off Kholmsk; IV—Northern Primorie, Rudnaya Bight, and Lidovka Bights; V—Peter the Great Bay, the area of the mouth of the Tumen River Amur and Ussuri Bays, and Nakhodka Bight.

the most biologically productive in the Russian Far East and are used as one of the major international fishery regions. However, this region is affected by a strong anthropogenic impact. The waters near the Kholmsk area (South-West Sakhalin) is under the influence of the Tsushima Current, which carries oil, phenol, and heavy metal pollution from the coast of Japan. The shallow waters of bays of Northeast Sakhalin (Nyiski, Chaivo, and Nabil Bays) undergo oil extraction.

The Russian coast of the Sea of Japan (the Primorie region) is also an important local fishery and an international transportation and trade zone. Rudnaya Bay (Northern Primorie) lies within the region of production and processing of polymetal ores rich in lead, zinc, and also containing a great admixture of copper, cadmium, or rare-earth metals. Traditionally, that aquatic area has been investigated because of its particular characteristic of extensive heavy metal contamination. Kit Bay (Northern Primorie), one of the cleanest parts of the Primorie coast, was used as a reference site for the investigation.

Peter the Great Bay (Southern Primorie) presented itself as a rare type of habitat for aquatic life possessing unique geographic conditions, where the cold water of the Primorie stream mixes with the warm waters of the South Eastern Korean stream (a branch of the Tsushima Current) (69). The bay includes a highly productive shelf with a unique cenosis of aquatics. This area is composed of the only State Marine Reservation of Russia, the mouth of the Tumen River, Amur Bay, Ussuri Bay, Nakhodka Bight, and Golden Horn Bight (1995–2001). At the northwest end of Peter the Great Bay lie Golden Horn Bight, Amur Bay, Ussury Bay, and Nakhodka Bight, which are affected by the severe influence of domestic and industrial wastewaters from Vladivostok, Nakhodka, and other settlements. The ecological situation in the southwest part of Peter the Great Bay, during the longer warm period of the year, is determined by the influence of Tumen River running through industrial zones of China and North Korea. The State Marine Reservation is severely impacted by the pollution carried by that big river.

Parameters Analyzed

In selected aquatoria, a seasonal and monthly microbiological and chemical monitoring of the water quality was conducted. The following parameters were analyzed: (1) the number of colony-forming heterotrophic microorganisms and the proportion of metal-resistant groups of bacteria in the assemblages of colony-forming heterotrophic microorganisms in the near-surface and near-bottom water layers; (2) long-term variations in the number of metal-resistant colony-forming hetertrophic microorganisms; (3) seasonal dynamics in the number of metal-resistant colony-forming hetertrophic microorganisms; and (4) morphological, physiological, biochemichal, and molecular genetic peculiarities of metal-resistant heterotrophic microorganisms. All listed parameters have been investigated at reference sites and at impact sites.

Microbiological monitoring and chemical analyses were performed simultaneously on water samples from areas that had been subjected to a pronounced anthropogenic impact. Special selective media were developed in laboratory experiments and corrected during field observations for the selection of heterotrophic microorganisms that were highly resistant to contaminants. The composition of the pollutant-resistant groups of marine microbial communities was determined under conditions differing in the type of the anthropogenic impact and geochemical features.

Monitoring of Heavy Metal Contamination in Seawaters Using Microbial Biosurveys

The composition of microbial assemblages and also of physiological, biochemical, morphological, and molecular genetic characteristics of bacterial representatives were distinct in the contaminated and reference sites. However, because coastal seawaters usually contained a complex of pollutants, it was difficult to conclude which compound or factor caused that alteration. Only a number of bacteria in the planktonic microbial communities were resistant to each pollutant and seemed to be a clear indicator to characterize the presence of the distinct polluting compound and the degree of contamination. On the basis of the comparisons between the results from the synchronously conducted microbiological and chemical monitoring of the pollution of the near-shore seawaters, a positive correlation was established between the microbial indices of the abundance of resistant forms and the concentrations of each of the metal-treated and organic compounds. The microbial monitoring of heavy metal pollution was the least developed method. Therefore, as an example, I chose to demonstrate the approach of developing a microbial assessment for heavy metal monitoring in seawaters.

Design of Selective Media

The first step needed for the implication of microbial biosurveys was to design selective media that would allow calculation of a number of pollutant-resistant microorganisms in the water. A number of representative bacteria that commonly occur in coastal seawaters have been chosen in order to define the sensitivity of microorganisms to heavy metals. Bacteria of genera *Escherichia, Pseudomonas*, and *Bacillus* from laboratory collections that did not demonstrate a special resistance to metals were grown in nutrient media, containing metal salt at different concentrations. Every species has an individual sensitivity to the toxic metals. The concentration of a compound that completely inhibited any bacterial growth was considered as a selective factor and then used in selective media in order to detect the appearance and the proportion of metal-resistant microorganisms.

As Fig. 2 demonstrates, the reverse correlation took place between the content of metal in the media and the growth of bacteria, if microorganisms did not have the resistance to the introduced toxic compound. However, when metal contamination is present in water, an abundance of microorganisms resistant to contaminating factors appear among the aquatic microbial communities. The illustration below demonstrates a negative correlation between the concentration of heavy metals and number

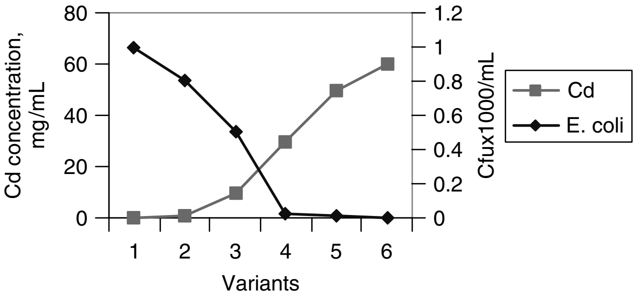

Figure 2. Dependence of bacterial growth on metal concentration in the growth medium.

of surviving microorganisms in the same samples of seawaters.

Chemical and Microbiological Monitoring of Heavy Metals in Seawaters of Peter the Great Bay

The synchronous sampling of heavy metal contents in the northern part of Peter the Great Bay allowed us to compare the results obtained. As graphs demonstrate (Fig. 3a–c), the alteration of a number of the bacteria resistant to heavy metals is an agreement with the concentration of dissolved forms of corresponding metal in the water. We can observe individual response of microbial community to the content of metals in different concentrations in the water under complex pollution conditions in Peter the Great Bay. It points to the existence and sensitivity of the individual response of microbial populations to the content of metals in different concentrations in the water under complex pollution. Moreover, in the case of each heavy metal, the dynamic of that alteration occurs differently within certain intervals of metal concentration. The boundaries between gradual and drastic variations of microbial indices were very clear, which allowed us to formulate microbial criteria that might adequately detect the concentration range of heavy metals in the water.

Average value of the percentage of the metal-resistant forms of bacteria in planktonic and benthal microbial assemblages allows comparison of the water quality from different parts of the large body of water. Moreover, microbial indices indicate from which part of the aquatorium the pollutant enters, from the surface or from the bottom. The next illustration demonstrates such a comparison made on the basis of microbial assessments conducted in several bights and secondary bays of Peter the Great Bay during the summer months of June–August of 1999 (Fig. 4a–d).

Morphological Features of Marine Bacteria Inhabiting Contaminated Waters of Peter the Great Bay

Golden Horn Bight is one of the most impaired water bodies among other bights of Peter the Great Bay. Fishery fleets, trade fleets, the military ship yard, and the city ferry transportation system are among industrial polluters of that aquatorium. Analysis of the morphological characteristics of bacteria in the planktonic assemblages can serve as an indirect characteristic of water pollution. It is a well-known fact that in heavily contaminated marine areas, rod-shaped (over 87%) and gram-negative (over 60%) microflora prevail (70). We conducted microscopic examinations of 117 strains isolated from the near-surface water layer in the central part of Golden Horn Bight, Vladivostok, Russia. Among all microorganisms cultivated, rod-shaped bacteria made up 92%, and 72% of the bacteria were gram-negative.

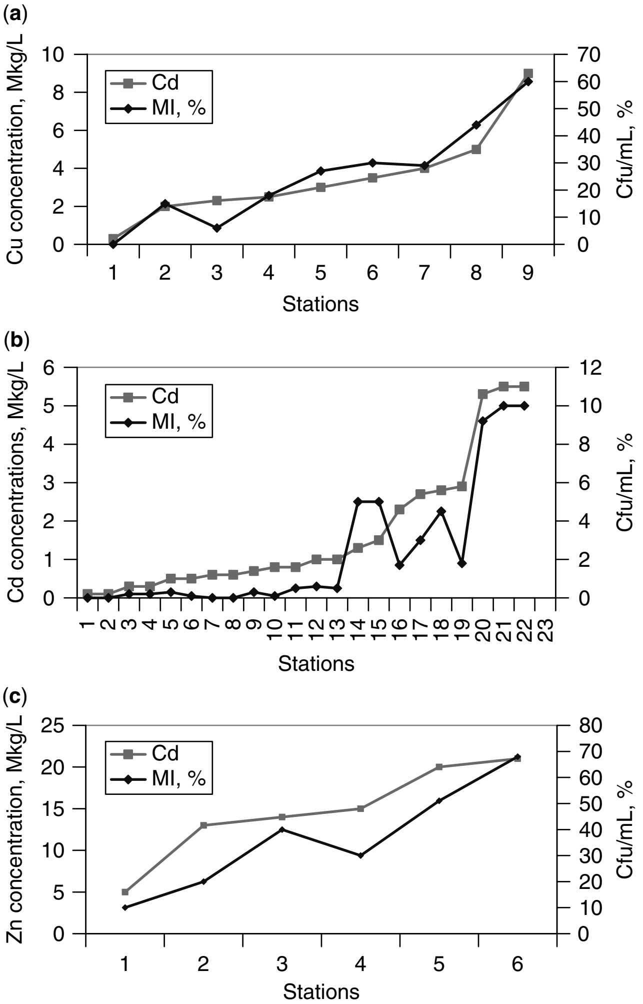

Figure 3. Changes in the values of microbial indices (line MI) and concentration of dissolved forms of metals in the water samples taken from Ussuri Bay: (**a**) copper, (**b**) cadmium, and (**c**) zinc. Along the horizontal axis, the station numbers were sorted with respect to increasing concentrations of heavy metal in the water.

The isolated microorganisms were resistant to several heavy metals at a time, but the combination of metals and the range of bacterial resistance were different, which once again confirms the individual character of microorganism response to the pollutant concentrations in the environment. The use of a transmission electron microscope demonstrated typical symptoms of absorbing specific substances from the environment in both bacilli and cocci and their accumulation both inside the cells and in the cell wall (11). Although these substances were not identified, but based on the electron density of the substances and the detection of multiple metal resistances

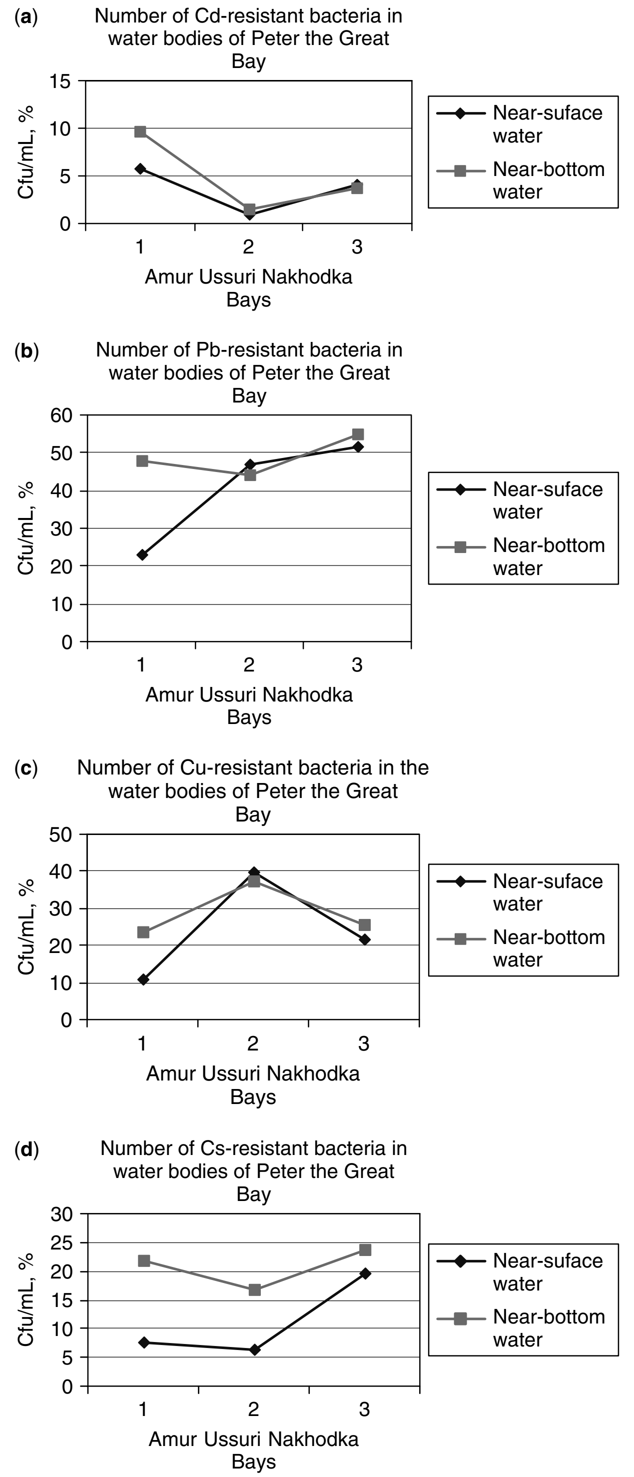

Figure 4. Average value of the number of metal-resistant bacteria in near-surface and near-bottom water samples taken from different water bodies of Peter the Great Bay in June–August of 1999.

in the test bacteria, we assumed that we had observed accumulation of heavy metals by the marine bacteria.

Study of the molecular genetics of Cd-resistant bacteria was also carried out. It was established that all Cd-resistant strains also displayed resistance to antibiotic ampicillin in the concentration of 250 mg/mL (71). Electrophoresis analysis of plasmid DNA from eight strains detected the presence of a small plasmid with a molecular mass of 4 MD in the form of a monomer, dimer, or trimer that were identical to marker plasmid p2728, containing transposon Tn 501 and designed from pUC19 and encoding resistance to Hg and ampicillin (72). Thus, we have demonstrated that marine bacteria, as well as terrestrial bacteria, possess cell mechanisms providing resistance to heavy metals. We assume that numerous bacteria with such morphological and molecular genetic features could serve as indicators of environmental disturbance and contamination in the investigated areas. The presence of such bacteria also suggests the active participation of microbial communities in the process of transformation of substances finding their way into the environment. Depending on the phenomena in question, marine microbial cenoses can act both as indicators of physicochemical and biological processes and as a powerful biotic factor promoting the elimination of pollutants from the marine environment.

Microbial Assessments for Evaluation of Heavy Metal Pollution Level in the Water of Far East Seas

Comparison of Environmental Conditions in Different Regions of Far Eastern Seas Using Microbial Biosurveys. Investigations carried out in a number of regions of Far Eastern seas, having distinguished impacts and ecological situations, resulted in data that confirmed the informative efficiency of the use of microbial assessments for the evaluation of water quality and ecological integrity in the marine environments over geographic and environmental variations taking place in different regions (Table 1).

For example, the data from Table 1 on the microbial detection of heavy metal pollution of Avachinskaya Guba show the presence of a significant portion of cobalt (Co)- and cesium (Cs)-tolerant microorganisms in the microbial associations in the areas where an increased content of radionuclides, such as Co-60 and Cs-137, had formerly been found (73). Krasheninnikov Bay (Fleet harbor), which has been exposed to a pronounced technogenic and anthropogenic impact, is the most contaminated by a complex of heavy metals in this aquatic area. Near the southwestern seaboard of Sakhalin Island (off Kholmsk), the microbial indication confirms the known intense influence of the Tsushima Current on the content of heavy metals in the water (65). In northern Primorie, in Rudnaya Bight, the microbial characteristics reflect the features in the composition of the lead ores mined and the intensity of the technogenic load. The distribution of the metal-resistant groups of microorganisms is the least uniform in Peter the Great Bay, which is caused by the active hydrodynamics and the presence of a large number of sources of heavy metal pollution of both natural and anthropogenic character. Nakhodka Bight, where major commercial, oil, and fishery ports, together with several dockyards are concentrated, is the region most contaminated by complex heavy metals.

Application of Microbial Assessments for Long-Term Monitoring and Evaluation of Water Quality in the Marine Environment. Long-term observation can give very important

Pb	24.5	0.08	10	0.12	0	87.2	0
Fe	0	0	16.1	0	0	41.2	0

environmental information about the intensity of anthropogenic and industrial load on water bodies. Table 2 demonstrates the dynamic of the presence of metal-resistant forms of bacteria in seawater of the port, where Pb-Zn concentrate is transported by sea along the coast, which is located next to the lead smelter in Rudnaya Bight (see Fig. 5). Once again, when microbial indices are compared with the data of chemical analysis, they were in agreement. Moreover, both data of chemical and microbiological monitoring reflected the intensity of the ore processing and the production of the lead concentrate over time.

Years 1997 and 2000 are known as a period of intensive ore processing and the operation of the lead smelter at full production. On the contrary, the situation during 1998–1999 resulted in a drop in the volume of extracted and processed ore because of the general economic recession and long-term forced inactivity of the plant. The dynamics of the microbial assessments remarkably accurately reflect the environmental situation in Rudnaya Bight during that period.

Use of GIS Technology to Indicate Concentrations of Heavy Metals Found in Marine Sediments and to Show the Distribution of Metal-Resistant Bacteria in the Water. In the southwestern part of the bay, the environmental situation is mainly determined by the effect of the Tumen River flowing through the industrialized regions of China and North Korea. From the data of the microbiological analysis of this area, we found that stations located in the zone of riverine runoff waters were characterized in a state where the entire association of microorganisms cultivated showed an increased resistance to the presence of Ni, Zn, and Fe in the environment. In the communities mentioned, there exists a considerable portion of bacteria with an increased resistance to the presence of Cd, Pb, Cu, Co, and Cs in the environment. The data from the chemical analysis and the determination of the content of heavy metals in the tissues of hydrobionts confirm the contamination of the aquatic area by the pollutants listed in the scientific report (74). With a sufficient density in the network of monitoring stations, the data from microbial indication may be applied to preliminary biogeochemical

mapping of the near-shore aquatic areas, which was demonstrated by the example in the area off the mouth of the Tumen River for two of the eight heavy metals analyzed (Fig. 6).

Use of Microbial Biosurveys for Assessments of Organic Pollution in Seawater. Microbial assessments proved to be even more efficient for monitoring organic pollution. This statement is based on the ability of microorganisms to use organic compounds as a source of carbon and energy. As it was reviewed above, the presence of such chemicals results in an increase of bacteria using hydrocarbons for their living needs.

As Table 3 demonstrates, microbial criteria at reference sites are significantly less than at impact areas. Also, microbial assessments give information about sources of the contamination. For example, phenols can be a part of fecal contamination or they can be the result of the waste from cellulose processing. Seawater samples contained phenol destroyers taken either from places where a number of ships are present (Kholmsk, Port; Nyi Bay, exit to the sea), near the domestic wastewater dumping site (in Amur Bay), or next to plants manufacturing products from cellulose (Kholmsk, paper plant). Aside from the case of the paper plant, the number of phenol destroyers was ten times as much in comparison to fecal contaminated sites and correlated with concentrations of phenol in contaminated waters.

A number of microorganisms destroying oil and oil by-products also had a connection with the content of those chemicals in the water. The presence of point or nonpoint contaminating sources close to the beach explains the reason for distribution of those specific microorganisms in the coastal waters. Moreover, the proportion between bacteria resistant to different oil by-products reflected the presence of those particular chemicals in seawaters, which may even explain the origin of the contaminant detected far away from land. For example, it is understandable why the water samples taken from port aquatoria have a significant number of oil and fuel oil microbial destroyers (Kamchatka, Fleet harbor). However, isolation of engine fuel microbial users from the surface of the open ocean water far away from Fleet harbor may cause us to think that bacteria trace the passage of ships that use that kind of fuel.

Example of the Implications of Microbial Criteria for Water Quality Control of Seawater in the Seas of Far East Russia. After years of monitoring the water quality in a large number of water bodies using microbial assessments and chemical habitat metrics, we worked out criteria that can be used for monitoring ecological situations and the quality of seawaters (Table 4). Those criteria can be used during the first evaluation of water samples in order to receive general information about the ecological status of the water body. Then, criteria should be adjusted with respect to all other metrics measured in the water.

Use of criteria, covering a wide number of polluting factors, gives information about the incredible value of

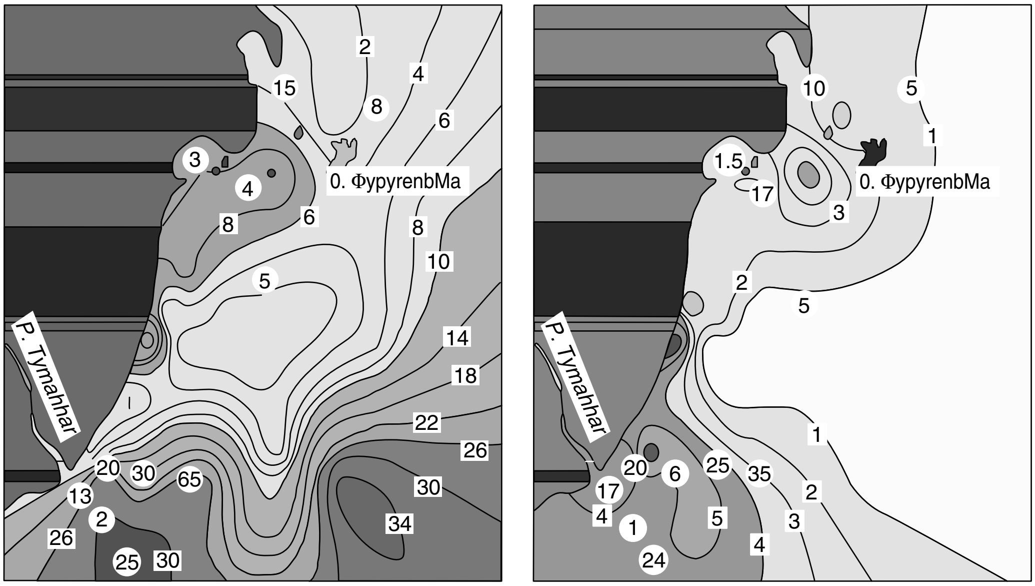

Figure 6. Distribution of the metal-resistant forms of bacteria over the aquatic area adjacent to the mouth of the Tumen River: (left) Cu- and (right) Co-resistant forms. Concentrations of metals in the bottom sediments (in μg/kg of dry mass) are given within the squares; microbial indices (%) are given in the circles.

this global approach, because we can present data on the ecological integrity of a larger system and complete an environmental situation report about the marine or freshwater water body.

Table 4 demonstrates the use and advantage of the microbial assessments for the evaluation of the environmental water quality in the example of data, presented above. The use of symbols better assists in presenting the data on ecological integrity of the marine environment at the moment.

On the basis of data received by a number of scientists over a long-term period, we can conclude that application of microbial criteria and microbial assessments is shown to serve as an operative method of monitoring and short-term forecasting of changes in the environmental conditions of the coastal waters of the sea. This method allows us to

obtain preliminary information, to create biogeochemical maps, preceding labor-intensive and expensive chemical analysis, and, e.g., at the initial stage when we select environmental quality monitoring stations. The microbial biosurvey does indeed permit control of the spread of pollutants in the near-shore waters.

LUMINESCENT BACTERIAL BIOSENSORS FOR THE RAPID DETECTION OF TOXICANTS

Maria B. Davoren
Dublin Institute of Technology
Dublin, Ireland

INTRODUCTION

The need to rapidly screen and assess the potential toxicity of aquatic contaminants has led to the development of several short-term bioassays utilizing bacteria, algae, protozoa, invertebrates, and cell cultures. Bioassays with microorganisms are frequently employed as ecotoxicological screening tools to monitor the hazards of chemical contaminants in the environment. In addition to their ecological importance as decomposers, microbial test systems have several advantages over traditional bioassays, including rapid response times, reproducibility of test conditions, amenability to genetic manipulations, increased sensitivity, and cost saving. Increasingly, luminescent microbial biosensors are being developed and employed for environmental monitoring (1–4). A biosensor integrates a biological sensing component (e.g., bacteria) with a transducer or detection system, which produces a measurable signal (e.g., luminescence) upon exposure of the sensing component to a specific or nonspecific analyte (5). Here the focus is on the use of both natural and genetically engineered luminescent bacterial biosensors for the assessment of toxicity and bioavailability.

BIOLUMINESCENT REPORTER GENES

Bioluminescence, which has been observed in a variety of organisms, is the production of light from living cells by the oxidation of a luciferin (a pigment) in the presence of the enzyme luciferase (6,7). Two frequently exploited bioluminescent reporter systems are the bacterial (the marine *Vibrio fischeri* and terrestrial *Photorhabdus luminescens*) and insect (the firefly, *Photinus pyralis*, and the click beetle, *Pyrophorus plagiophthalamus*) luciferase reactions.

Bacterial bioluminescence is encoded for by *lux* genes and light is produced through the oxidation of fatty aldehydes (8–10). The complete *lux*-gene cassette consists of five structural genes, *lux*CDABE. The *lux*AB genes encode the luciferase enzyme and the *lux*CDE genes encode an enzyme complex that synthesizes the aldehyde substrate for luciferase (3). Bacterial biosensors have been created using either the *lux*AB or the entire *lux*CDABE reporter system, but where the shorter gene construct is employed, an aldehyde substrate (usually *n*-decanal) must be added exogenously before bioluminescence can be measured (11,12).

The *luc*FF and *luc*GR genes encode for firefly and click beetle bioluminescence, respectively. In these eukaryotic systems, light is produced when the luciferase enzyme catalyzes the reaction between the substrate luciferin (which must be added exogenously), adenosine triphosphate (ATP), and oxygen (1,11). Rapid and sensitive detection and quantification of bioluminescence can be achieved using luminometers, liquid scintillation counters, or photographic films (4,13).

BACTERIAL BIOSENSORS BASED ON NATURAL BIOLUMINESCENCE

The naturally luminescent marine bacterium *V. fischeri* (formerly *Photobacterium phosphoreum*) has been extensively employed to generate acute toxicity data. Kaiser and Palabrica (14) published *P. phosphoreum* toxicity data for more than 1300 chemicals. A rapid screening test based on bioluminescence inhibition in *V. fischeri* (NRRL B 11177) has been commercialized as the Microtox test system (Azur Environmental, CA, USA) and is now an internationally adopted bioassay (15,16). The test system measures the light output of the luminescent bacteria after they have been challenged by a sample and compares it to the light output of a control (reagent blank). As bacterial bioluminescence is directly linked to cellular respiration, a difference in light output (between the sample and control) can be attributed to the toxic effect of the sample. The Microtox test has also been widely employed to generate acute toxicity data for environmental samples such as wastewaters (17), industrial effluents (18), and sediment samples (19). For a comprehensive review of the use of Microtox for assessing the toxicity of sediments and soils, the reader is referred to Doherty (20).

In addition to the well established Microtox test system, other toxicity bioassays have been developed which utilize *V. fischeri*. These include BioTox (Aboatox Oy, Finland), LUMIStox (Dr. Lange GmbH, Düsseldorf, Germany), and two portable systems ToxAlert (Merck Ltd., UK) and Deltatox (Azur Environmental, CA, USA). These test systems have been used either individually or in combination with each other in toxicity assessments (21–28). The ToxScreen-II assay (Checklight Ltd., Israel) employs another naturally luminescent marine bacterium, *Photobacterium leiognathii*, as a test organism (29). This test enables discrimination between cationic heavy metals and organic toxicants and has the added advantage of being able to be run at ambient temperatures.

ECOLOGICALLY RELEVANT BACTERIAL BIOSENSORS CONSTRUCTED USING LUMINESCENT-MARKED GENES

Despite the widespread use of Microtox and other test systems utilizing *Vibrio* sp., one frequently cited shortcoming of these assays is the lack of ecological relevance for the testing of freshwater and terrestrial environments (30,31). *Vibrio fischeri* is a marine bacterium and as such is sensitive to pH and osmotic conditions. The genes for bacterial bioluminescence (*lux*AB and *lux*CDABE) have therefore been cloned and inserted using plasmids into environmentally relevant terrestrial and freshwater bacterial test strains (32–35). As with the *V. fischeri* based biosensors, luminescence is dependent on metabolic activity; therefore, any chemical causing metabolic stress will result in a reduction in bioluminescence. Luminescent marking of terrestrial bacteria offers scope for environmentally relevant, whole-cell biosensors that can either be toxin specific or general indicators of pollutant toxicity. These genetically modified bacteria have the added advantage of not being limited by a narrow pH range.

RECOMBINANT LUMINESCENT BACTERIAL BIOSENSORS

Recent advances in reporter gene technology have led to the development of many luminescent marked bacterial biosensors, which have been employed as rapid bioassays to assess the toxicity of a wide range of pollutants. Some of the bacterial biosensors that have been constructed are used for general toxicity testing as they constitutively express luminescence and respond to toxicants in a "lights off" manner, with a decrease in light output related to exposure of the cells to pollutants (Table 1). These bacteria are not toxicant specific and cannot be used to determine the type or the actual concentration of a given toxicant, but rather are general indicators of adverse conditions. As no single biosensor will have a universal sensitivity to all toxicants, multiple luminescent bacteria are increasingly being employed, in a battery style approach to better characterize the toxicity associated with a chemical (50–52). Constitutively expressing biosensors have been used to assess the toxicity of a wide range of pollutants including heavy metals (32), chlorobenzenes (31), chlorophenols (37), industrial effluents (43), and wastewater (53).

In addition to constitutive expression, other biosensors have been developed that react to toxicants in a "lights on" manner, where light production is induced by bioavailable concentrations of toxicants. These recombinant bacteria have been constructed by the molecular fusion of two elements inside a bacterial host, a promoter gene regulated by specific chemical agents or their pathway intermediates, and a promoterless reporter gene (e.g., *luc*FF or *lux*CDABE) inserted as a plasmid. In these toxicant-specific bacterial sensors, a genetic regulatory unit controls the expression of the reporter gene. In the presence of a toxicant this regulatory unit is induced and generates a measurable signal relative to toxicant level, that is, receptor–reporter concept (54). These microbial biosensors offer a powerful new approach to environmental monitoring, providing an indication of the bioavailabilty of specific pollutants in complex environments, rather than the total concentrations obtained by traditional analytical techniques. Biosensors constructed for the detection of specific pollutants in the environment can complement analytical methods by distinguishing bioavailable from immobilized, unavailable forms of contaminants, and frequently an integrated approach using both methods is employed (36,55). In order to assess the overall toxicity of the sample, constitutively expressing reporter biosensors (non-toxicant-specific bioassays) are often run in parallel with toxicant-specific inducible biosensors (36,48,56). Many luminescent bacterial biosensors have been developed for assessing pollutant bioavailability in environmental samples, selected examples of which are presented in Table 2.

Table 1. Selected Examples of Non-Toxicant-Specific Luminescent Biosensor Strains

Bacterial Biosensor Strain	Plasmid	Luminescent Reporter Gene	Tested Compounds[a]	Reference
Bacillus subtilis BR151	pCSS962/pBL1	*luc*FF	Metal-contaminated soils	36
Escherichia coli HB101	pUCD607	*lux*CDABE	2,4-DCP; atrazine, simazine, propazine, mecoprop, MCPA, diuron, paraquat; As, $CuSO_4$, 2,4-DCP, 3,5-DCP, bronopol, TTAB, $ZnSO_4$	37–39
Escherichia coli MC1061	pCSS810	*luc*FF	Metal-spiked water samples	40
Pseudomonas putida F1	pUCD607	*lux*CDABE	Atrazine, simazine, propazine, mecoprop, MCPA, diuron, paraquat; oil-polluted soil	38,41
Pseudomonas fluorescens 10586r	pUCD607	*lux*CDABE	Atrazine, simazine, propazine, mecoprop, MCPA, diuron, paraquat	38
Pseudomonas fluorescens 10586s	pUCD607	*lux*CDABE	Copper in whiskey distillery effluent; papermill effluent; contaminated groundwater; benzene, catechol, phenol; chlorobenzenes; 2,4-DCP; metal-contaminated soils	31,37,42–46
Pseudomonas fluorescens OS8	pNEP01	*luc*GR	Soil-associated arsenite and mercury	47
Ralstonia eutropha ENV307	pUTK2	*lux*CDABE	Polychlorinated biphenyls	48
Staphylococcus aureus RN4220	pCSS810	*luc*FF	Metal solutions	49
Staphylococcus aureus RN4220	pTOO02	*luc*FF	Metal-contaminated soils	36

[a] As = sodium arsenite; bronopol = 2-brom-2-nitro-1, 3-propandiol; 2,4-DCP = 2,4-dichlorophenol; 3,5-DCP = 3,5-dichlorophenol; MCPA = 2-methyl-4-chlorophenoxyacetic acid; TTAB = tetradecyltrimethylammonium bromide.

Table 2. Selected Examples of Toxicant-Specific Luminescent Biosensor Strains

Bacterial Host Strain	Sensor Plasmid	Luminescent Reporter Gene	Inducing Compound(s)	Reference
Bacillus subtilis BR151	pTOO24	*luc*FF	Cadmium, antimony, zinc, tin; metal-contaminated soils	36,49
Escherichia coli AW3110	pTOO31	*luc*FF	Arsenic	40
Escherichia coli MC1061	pTOO31	*luc*FF	Arsenic; arsenic-contaminated sediments; arsenic-contaminated soils	40,47,57
Escherichia coli MC1061	pTOO11	*luc*FF	Mercury	40,58
Escherichia coli MC1061	pzntRluc	*luc*FF	Zinc, cadmium, mercury in spiked soil	59
Escherichia coli MC1061	pmerBR$_{BS}$luc	*luc*FF	Mercury; mercury, cadmium, zinc in spiked soil	59,60
Escherichia coli MT102-PIR	pUT-mer-lux	*lux*CDABE	Mercury	61
Staphylococcus aureus RN4220	pTOO24	*luc*FF	Cadmium, lead, antimony, tin; metal-contaminated soils	36,49
Staphylococcus aureus RN4220	pTOO21	*luc*FF	Arsenic	62
Pseudomonas fluorescens OS8	pTPT31	*luc*GR	Arsenite; arsenite-spiked soil; arsenic-contaminated sediments	47,56,63,64
Pseudomonas fluorescens OS8	pTPT11	*luc*GR	Mercury; mercury-spiked soil	56,63,64
Ralstonia eutropha AE104	pchrBluc	*luc*FF	Chromate	59
Ralstonia eutropha AE2515	pMOL1550	*lux*CDABE	Nickel, cobalt, bioavailable nickel in soils	65
Ralstonia eutropha ENV307	pUTK60	*lux*CDABE	Polychlorinated biphenyls	48

LUMINESCENT BACTERIAL BIOSENSORS FOR ASSESSING POTENTIAL GENOTOXICITY

Bioluminescent assay systems have also been employed to assess the potential genotoxicity of both chemicals and environmental samples. The Mutatox test (Azur Environmental, CA, USA) employs a dark mutant of *V. fischeri* (strain M169) and works in an opposite manner to the Microtox test, in that this strain exhibits increased light production (restoration of bioluminescence) when grown in the presence of sublethal concentrations of genotoxic agents. The Mutatox test is considered a promising tool for detection of genotoxic compounds in environmental samples (66–68). Both the Microtox and Mutatox test have been used in tandem to assess the potential acute toxicity and genotoxicity, respectively, of lipophilic contaminants in aquatic ecosystems (69).

Another test that utilizes a luciferase reporter gene system is the Vitotox assay (Thermo Electron Corporation, USA). This assay, which measures both genotoxicity and cytotoxicity, is based on recombinant *Salmonella typhimurium* TA104 bacteria containing the complete *V. fischeri lux* gene cassette under the control of the *rec*N promoter (70).

Vollmer et al. (71) have also described the construction and initial characterization of bacterial biosensors for the detection of DNA damage. In their research they constructed plasmids in which the DNA damage-inducible promoters *rec*A, *uvr*A, and *alk*A from *Escherichia coli* were fused to the *V. fischeri lux*CDABE operon. They reported that the fusion of the *rec*A promoter to *lux*CDABE yielded the most sensitive response. This recombinant strain (*E.coli* DPD2794) was later employed by Min et al. (72) to detect the genotoxicity of various chemicals and was demonstrated to be capable of distinguishing distinct bacterial responses for direct and indirect DNA damaging agents.

FUTURE DEVELOPMENT OF BIOSENSORS AS RAPID AND ROBUST TOOLS FOR ENVIRONMENTAL MONITORING

There is a growing demand for sensitive and easy to use biological assays for the rapid and cost effective detection of environmentally relevant concentrations of pollutants in soil, sediment, and water ecosystems. Recombinant luminescent bacterial biosensors have recently emerged as promising tools in environmental monitoring for the sensitive and specific quantification of both toxicity and bioavailability. These biosensors possess several of the characteristics of an ideal bioassay system, in that they are relatively inexpensive to conduct, easy to use, ecologically relevant, and amenable for on-line or *in situ* monitoring. In addition, previous research has demonstrated that freeze-drying of luminescent bacterial biosensors has only moderate effects on the performance with respect to sensitivity or induction coefficients (49,59). The availability of bacterial biosensors in a freeze-dried state would negate the need and cost of continuous culturing while ensuring a clonal strain, making reagent-like usage a viable option. Integration of the biosensor constructs into the host chromosome and the creation of stable constructs, which can be maintained even under nonselective conditions, have also been demonstrated (61,73). Optimization of immobilization techniques will advance the exploitation of the commercial potential of these biosensors, by providing a stable and practical system for use in real-time pollutant detection (74–77). A novel automated continuous toxicity test system using a recombinant bioluminescent freshwater bacterium has recently been described (78), giving further promise to the routine utilization of these biosensor systems for real-time biomonitoring of water toxicity in the near future.

DEVELOPMENT AND APPLICATION OF SEDIMENT TOXICITY TEST FOR REGULATORY PURPOSES

Thomas Ángel del Valls Casillas
University of Cadiz
Puerto Real, Spain

INTRODUCTION

Since 1950 there is a growing concern about sediment contamination, and international conventions have been established for the protection of the marine environment (i.e., GIPME, 2000; London Convention, www.Londonconvention.org). Each country has developed particular guidelines for the protection of the environment but even these recommendations have no legislative force; they have been routinely used for characterizing contaminated sediments and for practical purposes such as dredging.

The first approaches to this issue were centered on sediment chemistry and thus the classification was made by comparing the concentration of determined contaminants of concern and sediment quality values established to effectively protect the aquatic environment (1). All these approaches follow the same schema and the same principles starting with an evaluation of the existing information. Contaminants of concern should be evaluated according to the information regarding physical, chemical, and biological properties of the sediments. The principal advantage of using this information is the cost effectiveness of the data collection and, if the data are consistent, decisions can be made to protect the environment without any further assessment.

For those sediments where existing information is not enough for decision-making, further assessments are needed. Traditionally, further assessment included the analysis of a list of contaminants, provided by regulators and assessors, that are to be considered in the evaluation. Concentrations are corrected for the particular characteristics and compared to sediment quality values defined as limit values to classify the sediments. These types of chemical guidelines are used worldwide and can be divided into two different categories depending on how they are derived: the empirical approach is based on statistical analyses of co-occurring chemical and biological effect data (2,3), while the mechanistic approach is based on calculation of equilibrium partitioning between a bound phase and a dissociated phase within pore water (4). Other guidelines use only a measure of the natural background condition or the contaminant concentration that satisfies the different concerns. The use of each one is under debate and new approaches are under development to meet existing regulatory requirements (5,6). One general limitation that applies for all matrices using numerical sediment quality guidelines is that they only address concerns regarding those chemicals for which guidelines have been developed. In addition, the actual availability and thus the effects depend on other factors such as the grain size distribution, composition of the organic matter, or concentration of sulfides in the sediment.

Since the mid-1970s research has focused on the development of sediment toxicity bioassays that could effectively predict potential biological adverse effects and could be used as an effective tool to characterize sediment toxicity. It is widely accepted that there are no chemical measurements that reliably predict sediment toxicity. In addition, sediments are a complex matrix that require complex tests for estimating the actual bioavailability of contaminants (7). Here we review the evaluation process that has been applied in the different initiatives carried out to introduce this new approach in a regulatory context. The design of toxicity tests for the characterization of dredged material in Spain is used as an example.

TEST DEVELOPMENT FOR USE IN REGULATORY PURPOSES

Once the new approach was established and widely accepted, much research was done regarding the selection of the proper battery of tests to include for regulatory purposes. The suitability of a toxicity test for decision-making is determined by the development degree of these tests through research (under academic or private initiatives) and the quantity and quality of the available scientific information. Involvement of the regulatory agencies is fundamental to evaluate the usefulness of the resulting information; they are the entities that should address the uncertainties associated with the different analytical tools used for the decision-making process. Before a bioassay can be included for regulatory purposes, some basic characteristics should be considered. Here we include some of the factors that should be taken into account when evaluating a bioassay for regulatory purposes:

Selection of Organisms

Test species should be autochthon and ecologically relevant in the areas of concern. This extends to those species widely distributed and adapted to the regional aquatic ecosystems naturally or by means of cultures. Their importance in the trophic chain should be established in relation to the geographical zone where the bioassay is going to be applied. It is preferable that they are going to be directly affected by contaminated sediments. Test species are more valuable if they are tolerant over a wide range of environmental variables (i.e., pH, salinity, grain size distribution, or volatile sulfides) and easy to maintain in the laboratory or purchased from commercial cultures. Information regarding the life cycle of the test species, information about its growth and reproduction, and information about the test species' sensitivity for the contaminants of concern are valuable tools for the final selection of the proper test organism. Easy taxonomical identification of the species must be taken into account. For example, the manila clam can be selected as a test organism for sediment toxicity assessment instead of *Macoma nasuta* because although it is not an autochthon species, it is widely cultured and meets all the criteria for its selection.

Selection of Endpoints

Criteria for selecting endpoints in environmental risk assessment processes (ERAs) include susceptibility to the stressor, ease of measurement, unambiguous definitions, and societal and ecological relevance (8). To link sediment quality with ERAs, similar criteria should be employed to select endpoints to assess sediment quality (9). The selection of the endpoint measured in the test must be related to a receptor, process, or effect of concern. The design of the test should pose and answer some questions of the decision-making process and its use should be justified in the followed assessment framework. As stated by Chapman et al. (10), the primary response is mortality, followed by reproductive or growth effects, and finally other sublethal endpoints such as behavior or biomarkers. However, these last ones only provide an indication of exposure and have not yet been linked directly to impacts at the organism level except using histopathology (11). The recommended tests measure mortality and reproductive or growth effects and use ecologically significant taxa similar to or related to resident taxa, which are likely to be exposed and which are appropriately sensitive. Even taking into account all these factors for the selection of the best measurable endpoint, sediment toxicity tests for predicting the effects of contaminants on natural populations, communities, and ecosystems are criticized because they do not take indirect effects into account.

Experimental Design

Two main conditions must be met to properly develop a laboratory toxicity test for regulatory purposes: the test should be designed with a specific goal for the decision-making process and the test must be consistently applied, with its experimental conditions perfectly defined, and should account for the influence of the experimental conditions on test organisms. Standard protocols, including technical reports from government or private organizations, or those endorsed by a standardization group [e.g., American Society of Testing and Materials (ASTM) or Environment Canada (EC)], or published papers in peer-reviewed journals, including interpretive guidance, are available for different species [e.g., amphipods (12,13) or polychaetes (14)]. Another factor affecting the experimental design and application of a test is adherence to standards to ensure the good health of test organisms and to limit the total costs of conducting the test. For example, the commercial bioassay Microtox® has been widely recommended and applied. As a commercial test it is highly standardized after a long period of research for its characterization. Although modifications to the initial protocols have been developed, the oldest design is recommended for use until the new one has been standardized and characterized.

Ruggedness

Test ruggedness is related to the sensitivity of test methods to variations in laboratory conditions such as the feeding regime, light and photoperiod, or grain size distribution. It is important to know the precision in defining features and to establish good quality assurance/quality control guidance.

Ring Tests

Standard methods are required in regulatory programs. In addition to standardization, other important prerequisites are good reproducibility, acceptable interlaboratory variability (defined as multilaboratory precision), and repeatability and intralaboratory precision. While intralaboratory precision reflects the ability of trained laboratory personnel to obtain consistent results repeatedly when performing the same test on the same organisms using the same toxicant (repeatability can include variability related to different operators), interlaboratory precision (also referred to as round-robin or ring tests) is a measure of how reproducible the method is when conducted by a large number of laboratories using the same method, organism, and samples (13). This information is a measure of confidence in the consistency of test performance and application.

Different studies have been successfully completed to evaluate sediment toxicity bioassays (including whole sediment and pore water or elutriate), for example, the whole sediment toxicity test using amphipods (15,16), the bioassay of inhibition of bioluminescence (17,18), and the liquid phase bioassay using sea urchin embryos (17,19).

Validation of the Tests

The validation process of a test can be accomplished through studies to find relationships between sediment toxicity and contaminant concentrations, using a different range of contamination, a different range of sediment conditions, or by means of comparison with other standardized tests. Test validation focuses on comparing data of field impacts to ensure the predictive value of such tools.

Data Management Procedures

When test results are accepted, they must be easily interpreted. The role of the test in the regulatory process is to answer the assessment questions formulated during the sample evaluation. Different approximations have been made to classify sediments according to the biological effects produced. In some countries and for some perspectives, strict guidelines have been established, although it seems more desirable to integrate multiple lines of evidence (terms that define categories of information) and to individuate in this way the process for each particular situation. This approach integrates different categories of information, for example, chemical, toxicological, and benthic community structure. The way in which this information is integrated is going to depend on the project itself and on the information available for each line of evidence.

APPLICATION OF SEDIMENT TOXICITY TEST FOR REGULATORY PURPOSES

In Fig. 1 a general tiered testing scheme to be followed when characterizing contaminated sediments and dredged materials is included as an example of the multiple approaches available. The first tier is accomplished if the available information, including geographical, geological, and pollutant sources, ascertains that the sediment contamination has no effects. If we find fine sediments and important sources of pollutants that result in high concentrations of contaminants, the characterization proceeds to the next tier and information regarding sediment chemistry and the characterization of other parameters, such as microbiology, should be accomplished. Some variables involved in the process are sampling, handling, and storage of the sediment, which influence the bioavailability of contaminants. Each regulatory agency should establish standard procedures that can guarantee the accuracy of the results. The regulatory agencies should also establish the parameters to be characterized, which normally include metals and metalloids, PCBs, PAHs, pesticides, and other compounds such as TBTs. Then the results are compared to the selected sediment quality guidelines for a single species. Such sediment chemical benchmarks have been used as rough limit values or regulatory levels. Depending on how the guidelines were derived (if they were intended to predict toxicity or the absence of toxicity) and what effects were to be assessed, one can judge if the regulatory requirements are met.

For the next tier, a secondary assessment regarding biological tests is used for the characterization. Three different categories can be distinguished according to the exposure routes: tests addressed to measure direct water column effects, those addressed to measure direct effects on benthic organisms, and those that measure the bioaccumulation effect. Because potential effects should include all possible exposure routes, water column effects are characterized by means of liquid phase bioassays and benthic effects by using benthic organisms exposed to the whole sediment. Differences are found when bioaccumulation tests are used. Some countries have included these last bioassays (i.e., Canada) as an important part of the battery of tests. Other countries only recommend them when contaminants accumulated by organisms are present and thus apply these more cost-effective tools to the particular cases where high concentrations of determined substances are present.

Some regulatory agencies have included a list of suitable or recommended bioassays but the final set of tools used for the characterization process is open. Others just include a list of recommendations and factors in selecting the proper battery of tests. The wise use of sediment bioassays is to design a battery of tests that will give a wide range of effects. A good example is the management of dredged materials in Canada (20). In this country, test methods currently used include an acute toxicity test using amphipods, a fertilization assay using echinoids, a solid phase toxicity test using the photoluminescent bacteria, and a bedded sediment bioaccumulation test using bivalves.

During the last decades different sediment toxicity tests have been carried out in Spain as part of a weight of evidence approach using the sediment quality triad (21). These studies used basically acute sediment toxicity tests that covered organisms from a bacterial population to juveniles of commercial species of fish (Table 1). Today, some of these acute toxicity tests shown in the table have been adapted for use in characterizing dredged material quality assessment in Spanish ports and are being considered for incorporation in the new recommendations for the management of dredged material in ports of Spain (RMDM). These tests include the next types and bioassays: screening, the Microtox STP, whole sediment, the amphipod, the polychaeta, the irregular sea urchin tests, and, using elutriates, the sea urchin larvae test (Table 1).

The design and selection of the different tests was carried out under a joint contract between CEDEX and the University of Cádiz and after a practical phase to validate the potential use of standardized tests by other countries but using autochthonous species of organisms in Spain. During this practical phase, different ports were sampled and analyzed using chemical and ecotoxicological tests. Results showed that the mentioned bioassays can be used to characterize dredged material in Spain and some biological guidelines or criteria were developed. These guidelines are similar to others designed and applied for the same purposes by different regulatory agencies, such as the U.S Environmental Protection Agency, Environment Canada, the Dutch Ministry for Commerce and Navigation, and Environment Australia (Table 2). Biological guidelines derived for Spain are shown in Table 3. These values are similar to those proposed by other agencies, although it should be noted that there is a double criteria for classification of toxicity in one sample based on an absolute value together with the demonstration of significant differences by means of statistical tools using a control or reference sediment.

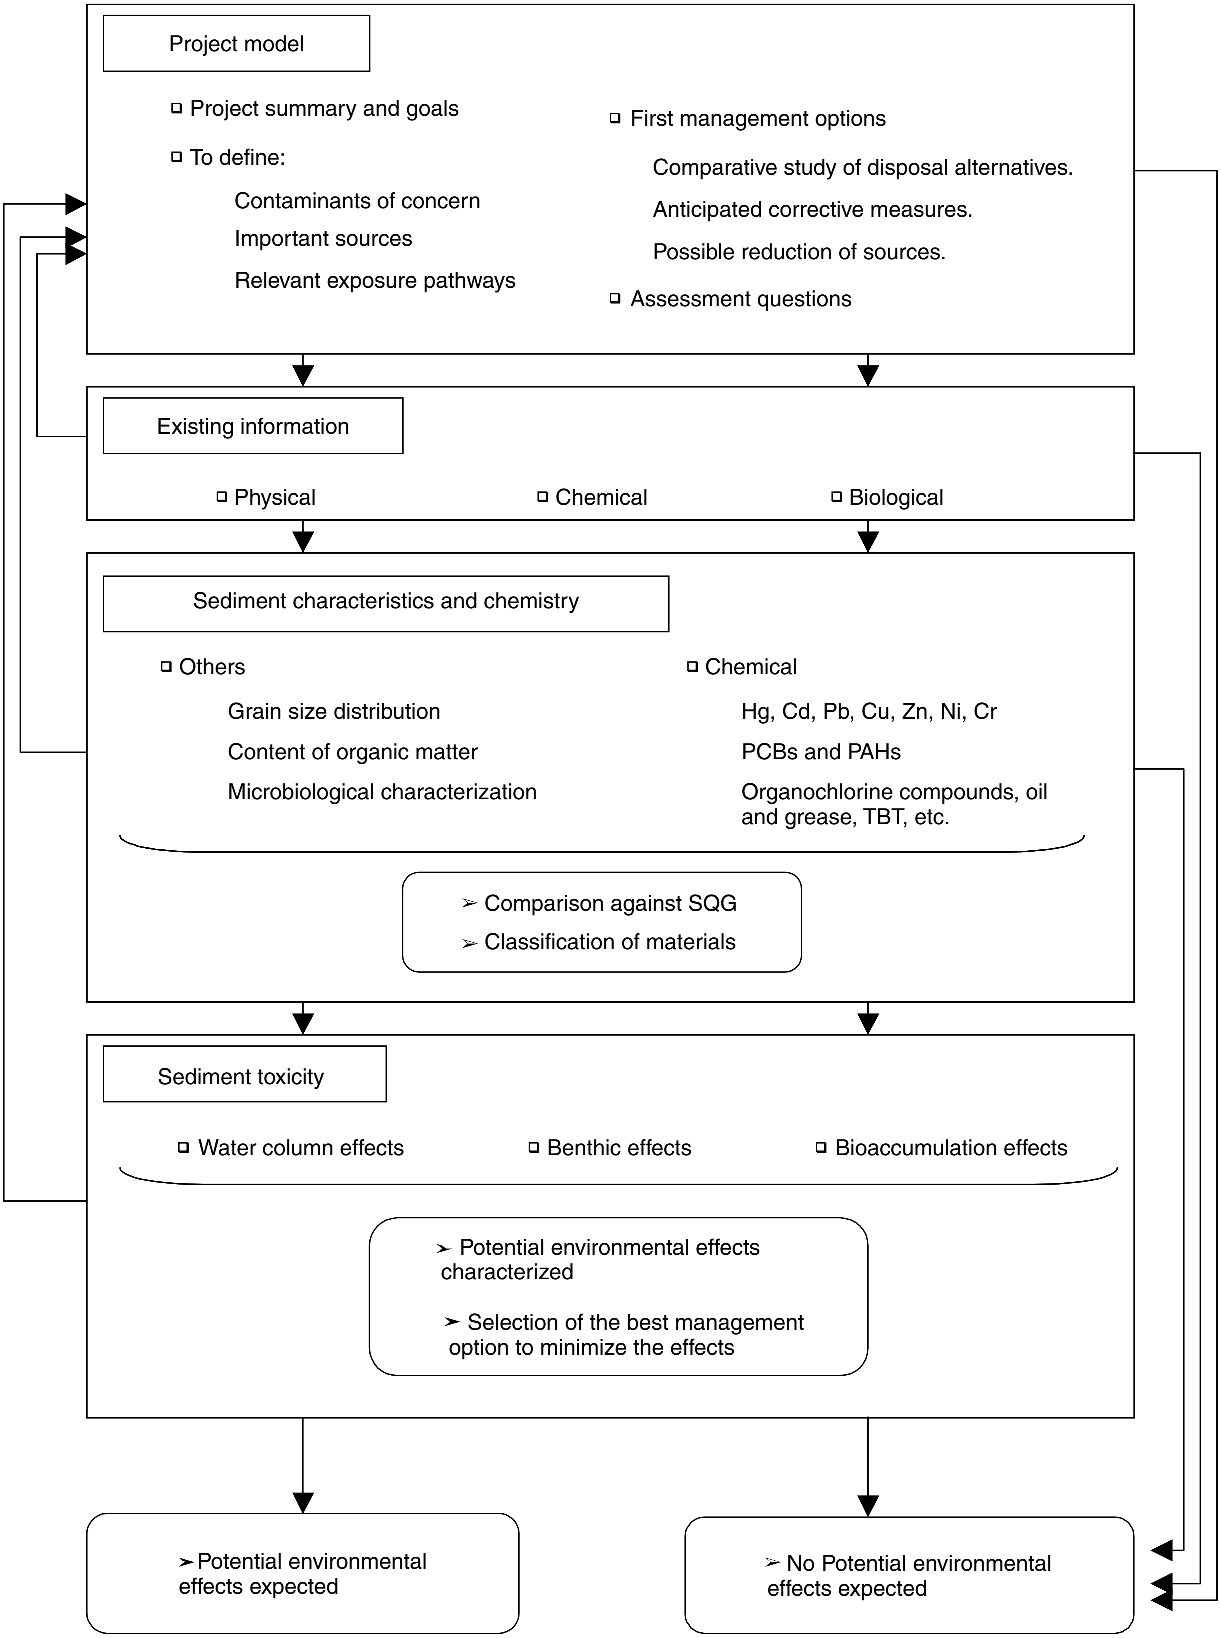

Figure 1. Tiered testing scheme to characterize contaminated sediments and dredged material. It has been adapted from different examples (Basque country, The Netherlands, Canada, or the United States).

Table 1. List of Different Bioassays Checked for Potential Uses in the Battery of Sediment Toxicity Tests Routinely Used to Characterize Dredged Material Disposal Options in Spain

Organisms	Exposure Route	Duration	Temperature, °C	Endpoints	Checked[a]	Acceptable[b]	References
Microtox® (SPT) (*Vibrio fischeri)*	Screening	15 min to 1 h	15	Luminescence inhibition	Yes	Yes	23
Echinoderms (*P. lividus*)	Elutriates	48 h	20	Survival (%)	Yes	Yes	23,24
Rotifer population (*B. plicatilis)*	Elutriates	7d	25	Survival (%)	Yes	?	25
Amphipod (*Corophium volutator, A. brevicornis*)	Whole sediment	10 d	20	Survival (%)	Yes	Yes	21,23
Benthic microalgae (*Cylindrotheca closterium*)	Whole sediment	24–72 h	20	Growth inhibition	0	?	26
Echinoderm (*Echinocardium cordatum*)	Whole sediment	14 d	15	Survival (%)	Yes	Yes	23,24
Polychaetae (*Arenicola marina*)	Whole sediment	10 d	15	Survival (%), bioaccumulation	Yes	Yes	14,23
					Yes	?	
Bivalve (*Ruditapes philippinarum*)	Whole sediment	48 h to 15 d	20	Survival (%); burrowing (TB_{50}) bioaccumulation; histological damage; biomarkers; vitellogenin	Yes	?	27
Crab (*Carcinus maenas*)	Whole sediment	21 d to 3 m	15	Survival (%); burrowing (TB_{50}) Bioaccumulation; histological damage; biomarkers; vitellogenin	Yes/?	Yes/?	28
Fish: benthic and pelagic (*Solea senegalensis; Sparus aurata*)	Whole sediment	1–3 m	20	Survival; bioaccumulation; histological damage; biomarkers	Yes	Yes/?	11

[a] Yes = standardized; ? = in development; 0 = not checked.

[b] Yes means useful for dredged material characterization.

Source: Adapted from Reference 22.

Another important aspect is the use of autochthonous species from Spanish coasts.

FINAL REMARKS AND FUTURE RESEARCH

Research and development are focused on reducing the uncertainties and costs associated with assessing dredged sediment material. Both the number and complexity of environmental questions being posed to port and dredged material managers have steadily increased in recent years, and this trend will likely continue in the future. Ongoing research is being used to provide answers to these questions and to address sources of uncertainty in the assessment and decision-making process. Other confounding factors already discussed must be taken into account when selecting the battery of tests to be applied for characterizing toxicity. Although the effect of some of these factors can be estimated and corrected using a proper reference sediment, others are difficult and the lack of control on some of these variables can have serious implications if test results are used for regulatory purposes.

Acknowledgments
This work has been partially funded by grants from the Spanish Ministry of Development (BOE 13-12-02) and of Education and Science (REN2002_01699/TECNO and VEM2003_-20563/INTER). The design of the acute toxicity tests for dredged material characterization was conducted under joint contract between CEDEX and the University of Cádiz (2001 and 2003).

A reduction–oxidation (redox) reaction involves the transfer of electrons. Thus redox reactions change the oxidation state and affect the speciation, solubility, mobility, and toxicity of elements in the aquatic environment. Major elements involved in redox reactions are O, C, N, S, Mn, and Fe, and the major sensitive redox components include O_2/H_2O, $NO_3^-/(N_2, NH_4^+)$, Mn(III, IV)/(II), Fe(III)/Fe(II), SO_4^{2-}/H_2S, and CO_2/CH_4. In polluted waters, trace elements could include As(V)/(III), Cr(VI)/(III), Hg (II)/(0, −II), Se(VI)/(IV, 0, −II), and U(VI)/(IV). Strong oxidants such as chlorine and ozone are used in water treatment processes too. The theoretical aspects of redox potential (E_h) are based on chemical equilibrium. Redox reactions in nature are driven by chemical and, more importantly, biological processes toward equilibrium, but it is seldom achieved. The traditional method of E_h measurement in water is simple but it is difficult to interpret because redox systems are seldom at equilibrium and multiple redox components coexist. Here we review and summarize theoretical predictions, measurement, and the applications of E_h in aqueous chemistry.

WHAT IS E_h?

E_h is an intensity measure of the reducing or oxidizing conditions in a system, that is, the tendency of a solution to donate to or accept electrons from a chemical species or electrode into the solution (1). E_h is conventionally defined in terms of the potential of a cell composed of two half-reactions: the half-cell of particular interest and the standard hydrogen half-cell. The potential of the hydrogen half-cell $[H^+ + e^- = \frac{1}{2} H_2(g)]$ at standard-state conditions, that is, $(H^+) = 1.0$ M and $P_{H_2} = 1.0$ atm, is set to 0.00 V.

Any redox reaction in nature is completed by two simultaneous half-reactions involving reduction and oxidation of two different chemical species and electrons are transferred from one species (reductant) to another (oxidant). The most important redox reaction, for example, is the microbially mediated oxidation of organic matter (represented by CH_2O) by oxygen (O_2) in an oxic environment (where oxygen is present) (2):

$$CH_2O + O_2 = CO_2 + H_2O \qquad (1)$$

where CH_2O loses and O_2 accepts the electrons, although the number of electrons transferred do not show up in this overall reaction.

Any of the half-reactions in a redox reaction can be generalized as a reduction reaction:

$$\mathrm{Ox} + n\,\mathrm{e}^- + m\,\mathrm{H}^+ = \mathrm{Red} + \mathrm{H_2O} \qquad (2)$$

where Ox and Red represent the oxidized and the reduced species, respectively. Most reduction reactions consume protons while involved in transferring electrons (Table 1).

The reduction potential of Equation 2 is expressed by the Nernst equation,

$$E_\mathrm{h} = E_\mathrm{h}^0 - \frac{2.303RT}{nF}\log\frac{(\mathrm{Red})}{(\mathrm{Ox})(\mathrm{H}^+)^m} \qquad (3)$$

where E_h = reduction potential for the half-reaction (V), E_h^0 = standard-state reduction potential for the half-reaction (V), n = moles of electrons transferred in the reaction, m = moles of protons involved in the reaction, R = natural gas constant ($8.314\ \mathrm{J\cdot K^{-1}\cdot mol^{-1}}$), T = absolute temperature, F = Faraday constant ($96484.56\ \mathrm{C\cdot mol^{-1}}$), and (P) = activity. In dilute solutions, one may assume that activity approximately equals concentration.

The standard state is defined when all activities of redox species are at unity, that is, when $E_\mathrm{h} = E_\mathrm{h}^0$. At 25 °C, Equation 3 becomes

$$E_\mathrm{h} = E_\mathrm{h}^0 - \frac{0.05916}{n}\log\frac{(\mathrm{Red})}{(\mathrm{Ox})(\mathrm{H}^+)^m} \qquad (4)$$

or

$$E_\mathrm{h} = E_\mathrm{h}^0 - \frac{0.05916}{n}\left(m\mathrm{pH} + \log\frac{(\mathrm{Red})}{(\mathrm{Ox})}\right) \qquad (5)$$

Thus, the reduction potential is determined by the ratio of the redox couple and the pH. A high ratio of the reducing species to the oxidizing species yields a low E_h value, indicating the abundance of reducing species (an electron-rich system) and a high tendency of the solution to donate electrons. Thus, E_h is an intensity parameter representing the electron activity of a system.

The standard-state reduction potentials of half-reactions (E_h^0) encountered commonly in aquatic environments are listed in Table 1. The free energy change related to the reduction potential of the reaction is

$$\Delta G_r = -nFE_\mathrm{h} \qquad (6)$$

or

$$\Delta G_r{}^0 = -nFE_\mathrm{h}^0 \qquad (7)$$

The more positive E_h values indicate stronger tendency for the reaction to proceed for the reaction to occur from left to right as it relates to more free energy release (Eqs. 6 and 7). The redox couples with higher positive E_h^0 indicate stronger oxidants (e.g., O_2) and those with lower E_h^0 indicate stronger reductants (e.g., CH_4, H_2S), However, the standard-state conditions do not normally occur in natural systems, where activities of most dissolved redox species including protons are much below unity. The reduction potentials of the important reactions at pH = 7 and at 25 °C, $E_\mathrm{h}^0(\mathrm{w})$, are calculated using Equation 5, and are given in Table 1. These values indicate redox reactions may proceed sequentially in a closed system when electron acceptors are consumed from the strongest to the weakest. It implies that in natural aquatic systems, where organic matter serves as the most abundant reductant, oxidation of organic matter may be accompanied by the consumption of electron acceptors in the sequence of oxygen, nitrate and Mn oxides, Fe oxides, sulfate and carbonate reductions. In reality, these reductions often overlap because microbially mediated reactions can be slow.

In aquatic systems, water reduction to H_2 or oxidation to O_2 sets the boundaries and limits the range of E_h^0. E_h can exceed these boundaries if stronger oxidants than oxygen are added to water, such as chlorine and ozone that are used in drinking water and wastewater treatment. The most important redox couples in natural waters are O_2/H_2O, $NO_3{}^-/N_2$, Mn (III/IV)/Mn(II), Fe

Table 1. Selected Standard-State Reduction Potentials of Half-Reactions Involving Important Elements in Water, Sediments, and Soils

Reaction	E_h^0 (V)[a]	E_h^0(w) at pH = 7.0[b]	pe^0(w) at pH = 7.0[b]
$\frac{1}{4}O_2(g) + H^+ + e^- = \frac{1}{2}H_2O$	1.230	0.816	13.79
$\frac{1}{5}NO_3{}^- + 6/5\ H^+ + e^- = \frac{1}{10}N_2(g) + \frac{3}{5}H_2O$	1.248	0.751	12.70
$\frac{1}{8}NO_3{}^- + 5/4\ H^+ + e^- = \frac{1}{8}NH_4{}^+ + \frac{3}{8}H_2O$	0.881	0.363	6.14
$\frac{1}{2}MnO_2\ (s) + 2\ H^+ + e^- = \frac{1}{2}Mn^{2+} + H_2O$	1.230	0.579	9.79
$\gamma\text{-}MnOOH(s) + 3\ H^+ + e^- = Mn^{2+} + 2\ H_2O$	1.503	0.616	10.41
$Fe(OH)_3(s) + 3\ H^+ + e^- = Fe^{2+} + 3\ H_2O$	0.935	0.048	0.81
$FeOOH(s) + 3\ H^+ + e^- = Fe^{2+} + 2\ H_2O$	0.769	−0.118	−1.99
$\frac{1}{8}SO_4{}^{2-} + \frac{5}{4}H^+ + e^- = \frac{1}{8}H_2S + \frac{1}{2}H_2O$	0.308	−0.210	−3.54
$\frac{1}{8}SO_4{}^{2-} + \frac{9}{8}H^+ + e^- = \frac{1}{8}HS^- + \frac{1}{2}H_2O$	0.254	−0.212	−3.58
$\frac{1}{8}CO_2(g) + H^+ + e^- = \frac{1}{8}CH_4(g) + \frac{1}{4}H_2O$	0.172	−0.242	−4.09
$H^+ + e^- = \frac{1}{2}H_2(g)$	0.000	−0.414	−7.00

[a] Data are from Reference 3.

[b] Calculated based on the E_h^0 and agreeable with data in Stumm and Morgan (6). E_h^0(w) and pe^0(w) apply to the electron activity for unit activities of oxidant and reductant in neutral water (pH = 7.0) at 25 °C; except for the Fe and Mn couples that are based on Mn^{2+} or Fe^{2+} activity of 10^{-6} M because these values are more realistic than the unit activities of standard-state conditions.

(III)/Fe(II), $SO_4{}^{2-}$/HS^-, and CO_2/CH_4. Highly reducing conditions result in methanogenesis and fermentation. Multiple reaction paths result in an array of E_h values for some elements that depend on a particular biological or chemical reaction path (e.g., N, Mn, S, and C). For example, nitrate reduction to N_2 (denitrification) has a higher E_h^0 than reduction to ammonium ($NH_4{}^+$). Various forms of solid phase Mn and Fe oxyhydroxides result in varying reduction potentials.

USE OF pe

In lieu of E_h, electron activity of a system is defined as a pe analogous to pH: $\mathrm{pe} = -\log(\mathrm{e}^-)$.

From Equation 2, at equilibrium, we have

$$K = \frac{(\mathrm{Red})}{(\mathrm{Ox})(\mathrm{e}^-)^n(\mathrm{H}^+)^m} \tag{8}$$

$$\mathrm{e}^- = \frac{(\mathrm{Red})}{n(\mathrm{Ox})(\mathrm{H}^+)^m K} \tag{9}$$

Take the logarithmic form on both sides and rearrange:

$$\mathrm{pe} = \mathrm{pe}^0 - \frac{1}{n}\log\left[\frac{(\mathrm{Red})}{(\mathrm{Ox})(\mathrm{H}^+)^m}\right] \tag{10}$$

or

$$\mathrm{pe} = \mathrm{pe}^0 - \frac{1}{n}\left(m\mathrm{pH} + \log\left[\frac{(\mathrm{Red})}{(\mathrm{Ox})}\right]\right) \tag{11}$$

where

$$\mathrm{pe}^0 = \frac{1}{n}\log K^0 \tag{12}$$

Both Equations 10 and 4 indicate that the activity of electrons can be quantitatively expressed by and directly related to the distribution of redox species and pH. Use of E_h or pe is a matter of preference. There are some advantages in using pe to examine redox phenomenon in some aspects. For example, pe + pH is considered a true variable in representing redox status as it can be used to differentiate the regions of redox species stability (3). When dealing with measured potential, however, it is more straightforward to use E_h than pe; although the conversion shown below is straightforward.

Conversion between E_h and pe at 25 °C is simplified as

$$E_h = 0.05916\ \mathrm{pe}, \tag{13}$$

where E_h is in volts. E_h and pe values change in the same direction and higher values indicate electron-poor systems and lower values indicate electron-rich systems. Table 1 lists the correspondence between $\mathrm{pe}^0(\mathrm{w})$ and $E_h^0(\mathrm{w})$.

E_h MEASUREMENT

Redox potential (E_h) of a solution is the difference in electrical potential measured between a noble metal (e.g., Pt or Au) electrode (also called indicator electrode) that is sensitive to redox couples in solution and a reference electrode that has a fixed potential in reference to the standard hydrogen electrode (SHE). Both electrodes are immersed in the solution and the potential is read on a potentiometer (e.g., pH meter). The noble electrodes are inert and resistant to chemical reactions; that is, they are not involved in the redox reactions and function only to conduct current. Because a standard hydrogen reference electrode ($E_h^0 = 0$) is not convenient for practical use, reference electrodes such as Ag/AgCl or calomel (Hg/Hg_2Cl_2) are commonly used in E_h measurement. Combination ORP (oxidation–reduction potential) electrodes consisting of both the indicator and reference electrodes are commercially available. These electrodes employ a platinum element to measure the potential due to the ratio of two oxidation states or species of an element in solution and each contains its own reference electrode. A commonly used Pt electrode system (electrochemical cell) is illustrated (3) as follows:

Pt electrode **Solution**
Pt | Ox (aq) → Red (aq) |

Reference electrode
KCl (aq, saturated) | Hg(l) : Hg_2Cl_2(s)

In this system, the Pt electrode conducts the electrons from the reduction reaction. The calomel reference electrode consists of a gel composed of liquid Hg^0 and solid Hg_2Cl_2 bathed in a saturated KCl solution. An asbestos fiber connects the saturated KCl solution to the sample by allowing K^+ and Cl^- ions to diffuse from the reference electrode into the sample solution to maintain electrical neutrality. This connection is called a salt bridge or liquid junction and electrically connects the reference electrode to the sample solution. A small and unpredictable liquid junction potential is encountered due to the differences between K and Cl ion diffusion rates, which are affected by the types of ions and the ion concentrations. The junction potential can be minimized by using a concentrated salt bridge and can be corrected to some degree with calibration against a solution with a known redox potential (e.g., ZoBell solution).

ZoBell solution, which contains 0.1 M KCl and an equal amount (e.g., 3.33×10^{-3} M) of $K_4Fe(CN)_6$ and $K_3Fe(CN)_6$, is typically used for testing redox instruments. It is more stable than quinhydrone solution above 30 °C. Quinhydrone solution, however, is much easier to prepare and use. The potential of the ZoBell solution measured by a Pt electrode versus a saturated KCl, Ag/AgCl reference electrode is a linear function of temperature, up to 55 °C (4):

$$E_{h,\,\mathrm{ZoBell}} = 0.428 - 0.0022\,(T - 25), \tag{14}$$

where T is the solution temperature (in °C).

A solution E_h can be obtained from the measurements of the solution and the ZoBell solution by an ORP combination electrode (5):

$$E_{h,\,\mathrm{system}} = E_{\mathrm{observed}} + E_{\mathrm{reference}}$$

where E_{observed} is the sample potential relative to the reference electrode used and

$$E_{\mathrm{reference}} = E_{h,\,\mathrm{ZoBell/reference}} - E_{h,\,\mathrm{ZoBell/observed}}$$

Table 2. Potential of Pt Electrode Versus Selected Reference Electrodes at 25 °C in Standard Zobell Solution[a] (mV)

Calomel Hg/Hg_2Cl_2	Silver/Silver Chloride (Ag/AgCl)			Standard Hydrogen
Saturated KCl	1.00 M KCl	4.00 M KCl	Saturated KCl	
+183	+192	+228	+229	+428

[a] ZoBell solution contains 1.4080 g potassium ferrocyanide ($K_4Fe(CN)_6 \cdot 3H_2O$), 1.0975 g potassium ferricyanide ($K_3Fe(CN)_6$), and 7.4555 g potassium chloride (KCl) in 1 L. The solution should be stored in a dark plastic bottle in a refrigerator.
Source: Reference 5.

where $E_{h,\,ZoBell/reference}$ is the theoretical E_h of the reference electrode and ZoBell's solution, relative to SHE (Eq. 14 for a Pt electrode and a saturated KCl, Ag/AgCl system; others are listed in Table 2) and $E_{h,\,ZoBell/observed}$ is the observed potential of ZoBell's solution relative to the reference electrode.

Care must be taken in measurement of water sample E_h. Proper instrument calibration and electrode testing must be performed. Freshwater samples must be used. Minimizing exposure to the atmosphere during E_h reading is necessary for low E_h samples. Flow-through cells are recommended for use for groundwater or a system with dynamic flow. Detailed procedures for measurement of E_h are available in Clesceri (5) and Nordstrom and Wilde (7).

INTERPRETATION

The concept of E_h measurement is derived based on chemical equilibrium, while the E_h measured in water does not reflect this aspect because redox reactions are seldom at equilibrium in natural waters. Thermodynamics only determines if a reaction is possible. Most redox reactions are mediated by microorganisms with slow kinetics. Lack of equilibrium is particularly prevalent among the various redox couples. Furthermore, many redox species (e.g., O_2, N_2, $NO_3{}^-$, $SO_4{}^{2-}$, $HCO_3{}^-$, and CH_4) are not electroactive; that is, they do not readily take up or give off electrons at the surface of the Pt electrode to contribute to the potential meant to be measured. The only exception is the couple Fe(III)/Fe(II), which are electroactive at low pH and where dissolved Fe is in certain concentrations (e.g., 10^{-5} M). Therefore, the measured E_h using a Pt electrode does not necessarily reflect the distribution of redox couples or species. Because it is a measurement of potential, the Pt electrode responds to changes in pH and other potentials. Comparison among E_h measurements should be based on the same pH and other conditions. Due to the presence of multiredox couples and nonequilibrium status in water, the measured potential is a mixed potential from only those electroactive redox species. Thus, E_h normally does not provide a quantitative measurement of the electron activity of the system measured; that is, it is normally only qualitative. Some authors believe that the measured E_h has no valuable theoretical meaning.

Other factors contributing to the difficulty in using E_h measurement to reflect electron activity of a solution include low concentrations of redox species, which cannot provide enough electron transfers that are detectable by the Pt electrode. The value of junction potential may differ greatly from that in the redox buffer solutions used to calibrate the cell. The Pt electrode can become contaminated by oxides or other coatings; thus, proper cleaning and polishing of the probe are needed before use. Permanently installed probes can be fouled either in high dissolved O_2 solution or strongly reducing conditions. Oxygen can react with Pt to form $Pt(OH)_2$ on the electrode surface. $Pt(OH)_2$ is electroactive and develops a potential with Pt ($\frac{1}{2}Pt(OH)_2 + e^- + H^+ \rightarrow \frac{1}{2}Pt + H_2O$; $E_h^0 = 0.982$ V) and masks the electrode response from electron transport between redox-sensitive solution species (3). Poising of permanent electrodes was also observed in reducing soils (8). The surface of the electrodes became dull after immersing into soil reducing solution for a few days and unable to respond to increased E_h values when nitrate was introduced into the system, while temporary electrodes detected the increase. Thus, a cleaning procedure was necessary to recover the function of the electrodes.

As a result of the discussion above, a large discrepancy is often observed between measured E_h values and predicted E_h values based on the redox couples present in the solution. Figure 1 shows an example of the theoretical E_h values and those observed in soil solutions at neutral pH for some important redox couples (compiled from Refs. 1 and 3). The large discrepancy for the O_2–H_2O, $NO_3{}^-$–N_2, and Mn oxides–Mn^{2+} are partially attributed to the inert behavior of O_2, $NO_3{}^-$, and N_2 at the Pt electrode and inappropriate choice of MnO_2 as electron acceptor as various forms of Mn oxides are present in a number of oxidation states (II, III, and IV) in nature. Similar reasons can apply for the $SO_4{}^{2-}$–H_2S and CO_2–CH_4 couples. The predicted and measured E_h values are closer only for the $Fe(OH)_3$–Fe^{2+} couple. In fact, wider E_h ranges for the same redox reactions than those shown in Fig. 1 were reported under various conditions. This should not be surprising when considering all the factors influencing the E_h measurement as discussed above.

APPLICATION

Although there are practical problems and difficulties in interpretation, E_h is a parameter that can be easily obtained and can be useful for better understanding of water chemistry. A decrease of E_h showed correspondence to sequential reduction of nitrate, Mn, and Fe in soil incubation experiments (9). The critical E_h at which all of the $NO_3{}^-$ was reduced and Mn^{2+} appeared in solution was about 200 mV and the critical E_h at which Fe^{2+} appeared was 100 mV. The qualitative E_h measurement has been used to classify redox regions or zones into different categories in relation to specific redox reactions. For examples, the following zones in soils at pH 7 were defined: oxidized ($E_h > 414$ mV, O_2 present), moderately reduced (120–414 mV, nitrate reduction and Mn reduction), reduced (−120 to 120 mV,

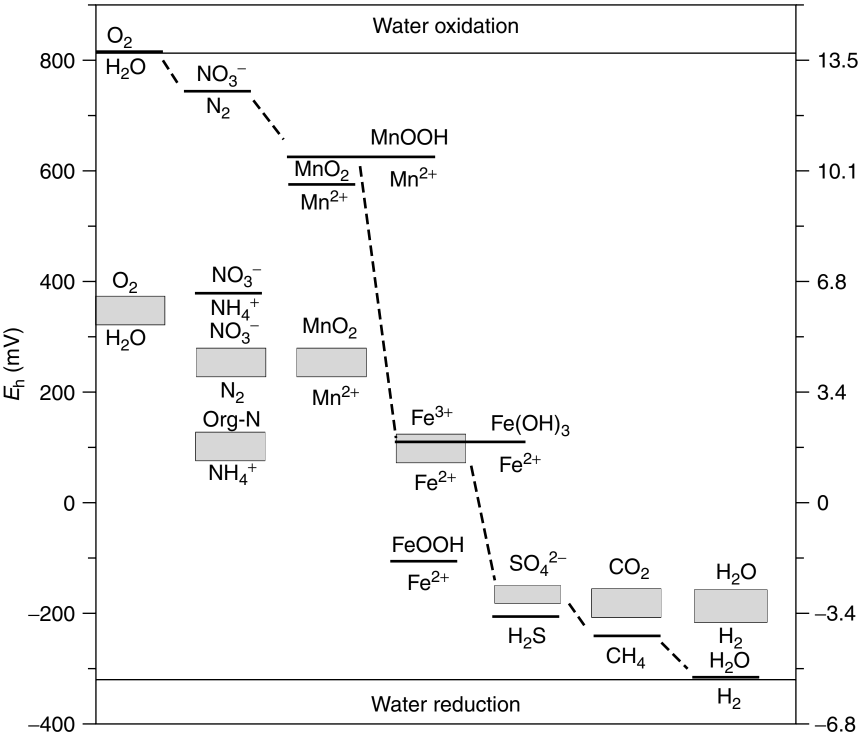

Figure 1. Theoretical and observed E_h for reduction sequences under neutral soil pH solutions. (Modified from Refs. 1 and 3.) The theoretical E_h values for the redox transformations to occur at pH 7.0 are indicated by the horizontal solid line. These values are based on equal activities of reduced and oxidized species unless noted. The activities of dissolved Fe^{2+} and Mn^{2+} are assumed at levels of 10^{-6} M and the pressure of H_2 is arbitrarily set at 10^{-3} atm. The observed E_h ranges for transformation from oxidized to reduced species are indicated by the shaded area. Corresponding pe values are shown on the right y axis.

Fe reduction), and highly reduced ($E_h < -120$ mV, sulfate reduction) (10). The following zones are further proposed at pH 7: oxic ($E_h > 414$ mV, oxygen and nitrate reduction), suboxic (120–414 mV, Mn and Fe oxide reductions), and anoxic ($E_h < 120$ mV, sulfate reduction) (11). Ranges of E_h for redox reactions may vary greatly from one observation to another. In fact, a wide range of E_h for the same redox couple has been reported from the literature (12). These variations originate from the differences among systems observed. Overlapping of redox processes is common especially in an organic matter-rich environment for a complex system such as paddy soil with straw amendment. E_h decrease corresponded to the progressing reducing environment developed upon flooding (13).

Redox buffering capacity (poising) in analogy to pH buffering capacity controls the E_h changes of a system. It is the capability of a system to maintain a redox potential upon addition of oxidizable or reducible materials. In a closed system with abundant organic matter or water near the organic matter-rich sediment (assuming originally equilibrated with oxygen in the atmosphere), oxygen will be quickly depleted due to oxidation of organic matter resulting in an abrupt drop in E_h (13). The E_h level may quickly decrease to and maintain the level indicative of sulfate reduction in most natural waters because nitrate concentrations are usually low and denitrification adds little buffering capacity to the water. In soils or groundwater in contact with oxidizing sediments, however, Mn and Fe oxides in the solid phase can add significant amount of buffering capacity to maintain a relatively higher E_h level for a period of time. The E_h ranges of these sequential redox reactions can be inferred from (Fig. 1).

In conclusion, E_h measurement in water is only a qualitative indication of the electron richness or poorness of a system. E_h measured in a solution is a mixed potential and usually does not quantitatively relate to specific redox reactions or redox couples. The easy measurement of E_h can have some practical use if its determination if handled carefully by following proper procedures (5,7). It can indicate the progressing of a system toward reduction or oxidation and can be used to predict potential redox reactions when comparing similar type systems. This qualitative measurement can assist in further quantitative determinations of redox reactions and chemical species. Nordstrom and Wilde (7) concluded that E_h data can be useful for gaining insights on the evolution of water chemistry and for estimating the equilibrium behavior of multivalent elements relative to pH for an aqueous system. E_h can delineate qualitatively strong redox gradients, such as in stratified lakes and rivers, in an oxidized surface flow that becomes anaerobic after passing through stagnant organic-rich systems, and in mine-drainage discharges.

OTHER APPROACHES

Many other alternative methods in describing and examining redox phenomenon of soil and water have been examined and proposed. A capacity parameter, oxidative capacity (OXC), was defined by Scott and Morgan (14). It integrates all the oxidized and reduced species into a single descriptive parameter. By setting an electron reference level, comparisons among oxidative capacities of various components results in identification of redox classes such as oxic (oxygen present), postoxic (nitrate, Mn, and Fe reduction), sulfidic (sulfate reduction), and methanogenesis. Challenges remain in quantifying the capacity of individual components especially those involving solid phase and organic matter. A nonequilibrium approach to defining the dominant terminal electron-accepting processes (TEAPs) has been applied to groundwater systems (15). This method considers simultaneously the consumption of electron acceptors [dissolved O_2, $NO_3{}^-$–N, Fe(III), $SO_4{}^{2-}$–S, and CO_2], final products [Mn(II), Fe(II), H_2S, and CH_4], and the intermediate product (dissolved hydrogen gas, H_2). A high degree of confidence can be achieved if a combination of all three indicators yields a positive identification of the predominant TEAPs. This is difficult to achieve sometimes because of the incorporation with the solid phase for some electron acceptors and final products. Dissolved H_2 is considered as a master variable in characterizing organic matter degradation or redox chemistry in anoxic conditions (16,17). Molecular hydrogen can be produced by many fermentative microorganisms during metabolism of organic compounds and at the same time consumed by respiratory microorganisms that use different electron acceptors. Molecular hydrogen is a result of the energy threshold for the organisms catalyzing the terminal electron-accepting process. The more electrochemically positive electron acceptors [e.g., nitrate and Mn(IV)] give a greater potential energy yield and reducers of these compounds can obtain their threshold energy yield at lower H_2 concentrations. Thus, a correlation between H_2 concentrations and predominant TEAPs was applied (12,15).

WATER RESOURCE DEVELOPMENT AND MANAGEMENT

WATER RESOURCES CHALLENGES IN THE ARAB WORLD

M.E. Young
Conwy, United Kingdom

THE PROBLEMS

The water shortage in the Arab World (Fig. 1) is severe and worsening. The region receives only 1% of the world's renewable water resources yet contains more than 5% of the world's population. In most Arab states at the start of the twenty-first century, the gross volumetric human and environmental demand for water exceeds natural replenishment. Per capita water availability is worsened by a high regional population growth; a 3% annual population growth rate halves the per capita availability every 24 years.

The paramount need, common to all states, therefore, is to find a sustainable balance between use and replenishment by a combination of measures to increase supply and to reduce demand. Both approaches involve technical (engineering) developments, legal and financial measures, improved water resources management through institutional interventions, and adjustments to national policies of water allocation.

All states need, as a priority, to develop coherent national water resources policies and strategies for the integrated management of water in all sectors—agricultural, municipal, industrial and environmental—in the context of the level of supply that is sustainable and according to sectoral priority. Institutional capacities to assess and manage water resources require development in many countries.

Many states of the region share resources from river flows or aquifers. Protocols that provide for equitable, sustainable and secure sharing must be agreed upon.

Specific water resources problems vary from state to state and include

- low levels of access to safe water supplies;
- inadequate or obsolete supply systems in growing cities;
- waterlogging and salinization of agricultural areas by irrigation (e.g., along the Nile, Tigris, and Euphrates);
- unsustainable groundwater abstraction
- pollution of aquifers and watercourses by human, industrial, and agricultural contamination;
- pollution of overpumped coastal aquifers by seawater intrusion (e.g., Oman, the Gulf States, and Libya); and
- drought and seasonal variability of water supplies.

Most freshwater in the region is used for irrigated agriculture. However, the economic value of water used for irrigation, in terms of the value of food produced, is lower than its value for municipal or industrial use. This situation has been exacerbated in some states by now outdated national policies restricting production to low-value staple food crops that have high water requirements.

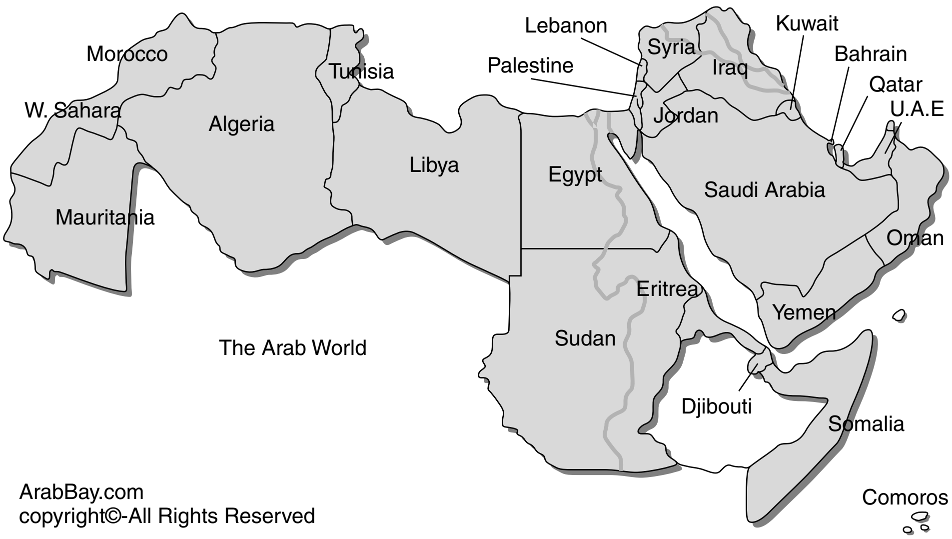

Figure 1. The Arab World.

Reducing water use in irrigation would be the most effective means of reducing the water deficit in most countries. At the same time, reallocating water to higher value sectors would enhance the GDP of all countries of the region. How to effect this transformation with the minimum social disruption in the agricultural sector, while maintaining food supplies, is the central issue of water resources management in the region.

SUPPLY AND DEMAND AT THE START OF THE TWENTY-FIRST CENTURY

Data on water supply and demand from Arab states vary in extent, reliability, and detail. Inventories of water resources are still in progress in most countries, and data on consumption, particularly, are generally inferred rather than measured.

Table 1 shows the estimated volumes of naturally renewable water for the region by state and per capita. Renewable resources comprise internally renewable resources from groundwater recharge and drainage to rivers and the net flows (inflows less outflows) of surface and groundwater from neighboring states. Inflows and outflows agreed to by treaty, or established by political circumstances, are implicit in these data; in the eastern Mediterranean states, particularly, such arrangements are complex and politically uncertain (3). The proportion of the actual renewable resource that comes from outside a state's borders is shown by the dependency ratio.

By 1995, resources per capita had fallen below the level of 1000 m^3 pcpa (per capita per annum) in four states and below 500 m^3 pcpa in 10 more. (An average level of 1000 m^3 is regarded as the level above which a state can be self-sufficient in food; less than 500 m^3 pcpa indicates severe water stress.) At the current rate of population growth, there would be four and 14 states, respectively, in these categories by 2020.

Figure 2 shows how much of this renewable resource is provided by recharge to groundwater, for those states where data exist. Those states that have the highest levels of water stress rely heavily on groundwater.

In many states, groundwater is abstracted faster than it is replenished. Figure 3 shows the proportion of the total annual water supply that is drawn unsustainably ("mined") from nonrenewable ("fossil") groundwater. Figure 4 shows groundwater abstraction as a percentage of renewal; in some states, groundwater is being mined several times faster than it is replenished.

This continued depletion of freshwater resources results from the increasing food demands of growing populations and from agricultural policies that seek national or local food self-sufficiency through irrigation, regardless of the unsustainability of the water supply. Figure 5 shows the proportion of national water supplies allocated to irrigation.

In many states, private well owners hold unrestricted traditional rights to groundwater for irrigation, regardless of the unsustainability of the resource (e.g., Oman, Yemen). Some governments have sought to exploit fossil resources to supply large-scale agriculture (e.g., the Great

Table 1. Renewable Water Resources[a]

Man-made River Project in Libya or for grain production in Saudi Arabia). Access to groundwater has been easier since about 1970, following the introduction of engine-driven groundwater pumps and the availability of deep drilling technology.

Figure 6 shows the volumes of “virtual” water already imported either as processed food, grain, or as live food animals, as a percentage of the total renewable water resource. The high volumes of virtual water show clearly that food self-sufficiency is an unrealistic target for many states.

These data show that the reason underlying the growing shortage of water in the Arab region is the increasing use of water, mainly for irrigation, at rates that exceed rates of replenishment. Historically, governments in the region have sought to address this problem by augmenting water supplies through engineering methods, rather than by encouraging conservation. Augmentation measures considered or implemented include interstate and interbasin water transfer, aquifer development, desalination, and minor processes such as cloud seeding and fog collection. However, the full production and delivery cost of water by all these methods typically exceeds the economic value of the food produced, and most water supplied by these means is now used only to supply higher value urban or industrial demands. The scope for further cost-effective augmentation of supply is limited by technology.

CONSERVATION AND DEMAND MANAGEMENT

Conservation methods used in the region include rainwater harvesting using small structures, recharging flood flows to aquifers, recycling of wastewater to irrigation, and leak reduction in urban networks. The storage of flood flows and treated wastewater in aquifer zones for later recovery and use needs to be further researched and promoted in the region. There is also substantial potential for increasing the conservation and re-use of treated wastewater. However, water can be most effectively conserved by improving farming and irrigation practices, in two ways: by improving food productivity per unit of water used and by reducing water losses in irrigation systems. The former approach includes the introduction of higher yielding and more water efficient (including salt tolerant) crop species and the use of scientific irrigation strategies specific to the crop type and conditions. Water reduction methods include the introduction of drip and sprinkler technology to replace spate irrigation and reduction in transmission and evaporation losses. In most countries of the region, significant savings can still be made by these technical means.

Despite these helpful measures, water resource deficits can be reversed only by fundamental changes in national water and food policies that reduce the water demands of the agricultural sector and gradually divert water to more economically productive sectors, while, at the same time, supporting rural communities in this transition.

POSSIBLE MANAGEMENT SOLUTIONS

It is clearly necessary for each country to develop and implement policies and strategies to produce a new and sustainable balance between supply and demand in irrigation. Most countries continue to pursue supply augmentation by various methods and to promote and subsidize conservation through engineering methods. Nonengineering interventions to promote conservation of water fall into four classes:

- Political
  - Policy revision
  - Water resources assessment, monitoring, and control
  - Pursuit of favorable international agreements for food importation
  - Promoting efficient management of centralized water supplies
- Legal
  - Quotas (limits) on abstraction
  - Water rights—possibly transferable or tradable within a basin
  - Restrictions on water use
- Fiscal
  - Tariffs on water use
  - Taxes on pump fuel
  - Removal of tariffs on cheap agricultural imports
  - Subsidy programs for irrigation and agricultural modernization
- Institutional
  - Expert consultancy
  - Social pressure and public awareness
  - Development of integrated management on a river basin or aquifer scale
  - Outreach and participation, including water users' associations

The combination of approaches that is appropriate for each country depends on the extent and effectiveness of national and local skills and institutions.

Political

Revision of government policy and coherency of policies between ministries and internationally, is paramount. A lack of coordination may result in development plans that cause unsustainable depletion of resources. Some states in the region still actively pursue policies of food self-sufficiency despite the lack of sustainable water resources.

The task of government is first to establish an enabling environment in which government, industry, and non-governmental entities work coherently toward water resource conservation, informed by a good understanding of the extent and quality of the resources. Second, governments and the international community must seek favorable international trade agreements for importing food.

Practical political interventions, whereby centralized governments operate at least primary systems of water-lifting and distribution, are common throughout the region. Great investment is required to upgrade infrastructure and improve efficiency, particularly for the delivery of municipal and rural drinking water. The capital needed is beyond the capacity of some countries but private sector financial participation through public–private partnerships is an alternative. Full privatization of water supply is widely opposed in the region and governments need to develop partnership models that are locally acceptable. To reduce risk and encourage investment, governments need to establish clear water law and robust fiscal regulations, and improve transparency.

International treaties to define shared resources and protocols for sharing information are essential for securing transboundary supplies. The Neil Basin Initiative and the Nubian Sandstone Aquifer System are two vehicles through which several countries consult and collaborate on managing the surface and underground resources of the major resources of northeast Africa. Similar processes are needed for the shared resources of the northern Arabian Peninsula.

International cooperation at a wider level to promote the development and sharing of water technology and information is essential. Recent valuable initiatives and foundations include the Dialogue on Water and Climate in the Mediterranean Region, organized by the World Conservation Union; the Middle East Desalination Research Center, in Oman; and the International Center for Biosaline Agriculture, in Dubai.

Legal and Fiscal

Economists believe that a sustainable water demand will be achieved only by charging the full cost of water to all users. The principle of charging tariffs for water delivery is widely accepted in urban areas of the region, but costs are only partially recovered. Stepped tariff structures that subsidize low-volume users are common. Uncharged-for water losses are abnormally high in some cities of the region.

Other legal and fiscal measures, such as irrigation quotas, water rights, and full-cost pricing are applicable only where water law is clearly defined and where established economic and financial frameworks facilitate the operation of market-based systems. This is not yet the case in most of the Arab region, where volume restrictions on irrigators or fiscal restrictions have been and are likely to be opposed. A cultural perspective that water is a free natural resource is a major obstacle to the introduction of innovative legal and fiscal instruments.

Institutional

Decentralization of water resources management to regional and local management systems is widely regarded as the most effective means of improving water supply services at the level of use, coupled with a well defined water law and integrated water resources management policy at the national level (5).

Institutional approaches are most appropriate where organizations and networks of civil society are amenable to development through training, leadership, and incentives. For example, Egypt, Morocco, and Tunisia have developed water users' associations and basin management organizations that seek to bring all stakeholders together in cooperative and participative operations. They assess the availability and sustainability of the resources; allocate water-use rights based on need, environmental demand, social contingencies, and economic value; control and monitor water distribution and quality; provide training; and collect fees to finance administration and system maintenance.

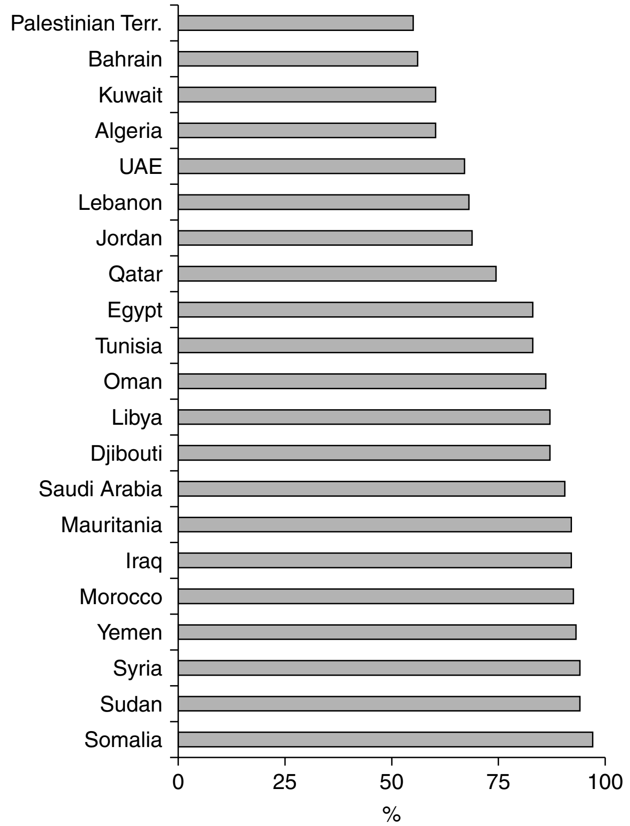

Figure 5. Share of water allocated to agriculture (1).

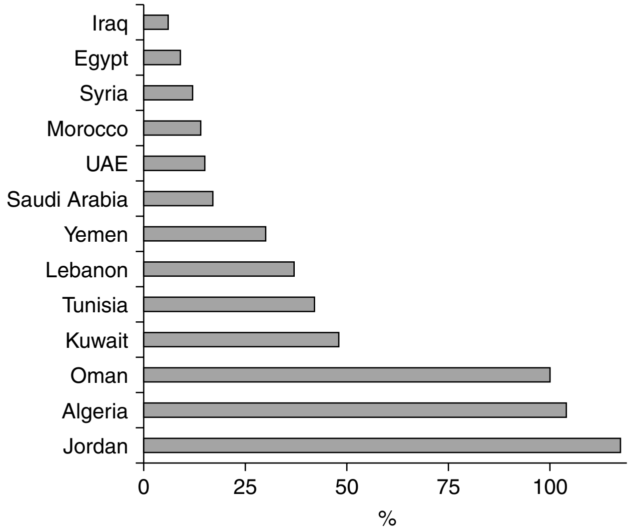

Figure 6. Water embedded in net food imports as a percentage of total renewable resource (4).

The Influence of Islam

Recent international prescriptions for water management, such as the Dublin Principles of 1992 and subsequent pronouncements, have emphasized economic value as a driving criterion for allocating water among sectors. This approach tends to ignore social priorities in rural Arab states and underestimates the practicalities of implementing water management changes in the contexts of Islamic law and, in some states, weak or inflexible political systems.

The holy writings from which Islamic law is derived contain many prescriptions relevant to water management and concur with the Dublin principles regarding community participation. Water is seen as a social good that must be managed sustainably and for the good of all; concepts of payment for delivery, the use of treated wastewater, and privatization of delivery are regarded as permissible (6).

Islam plays a prominent, central, and universally respected role throughout the region and, as an institution distinct from but working with both government and people, wields great influence. Islam has the potential to educate and lead consumers and drive the necessary changes in social attitudes toward water management. Islamic institutions can, therefore, provide leadership in promoting water resource conservation where political and fiscal interventions may fail.

EFFLUENT WATER REGULATIONS IN ARID LANDS

RICHARD MEYERHOFF
CDM
Denver, Colorado

ROBERT GENSEMER
Parametrix
Corvallis, Oregon

JAMES T. MARKWEISE
Neptune and Company, Inc.
Los Alamos, New Mexico

This article addresses the regulation of water resources in arid environments and focuses on the special considerations of effluent-driven ecosystems. Effluent serves as an increasingly important aquatic resource in the arid West, and the application of existing regulations for natural systems to effluent-based bodies of water is receiving greater scrutiny. Issues affecting regulation of effluent include defining appropriate attainable beneficial uses for these created ecosystems, net ecological benefits of effluent discharge, and impacts from the modification of extant flow regimes resulting from effluent addition. The practical application of regulations in effluent-driven ecosystems depends on recognizing these key issues.

EFFLUENT WATERS IN ARID ENVIRONMENTS

Effluent-based waterbodies are an important aquatic resource in arid environments because of the limited availability of alternate sources of water. In addition to general scarcity, water availability is sporadic and unpredictable in dry lands; consequently, effluents from residential, commercial, or agricultural activities are frequently one of the more stable sources of water in the arid West (1). Effluent-driven ecosystems have proliferated, as dams and diversions, groundwater pumping, and the need to dispose of treated effluent in metropolitan areas have modified natural flow regimes.

Three basic natural flow regime types are perennial, intermittent, and ephemeral. Perennial waters flow continuously, intermittent waters flow continuously only at certain times of the year (e.g., because of spring snowmelt), and ephemeral waters flow only in direct response to precipitation. Effluent-based ecosystems are either “dependent” on (effluent is discharged to an ephemeral stream channel) or “dominated” by (effluent is discharged to an intermittent stream channel) treated wastewater effluent discharge.

The discharge of effluent to intermittent or ephemeral streams represents a discontinuity resulting in a disruption to the natural equilibrium as it exists at the time the discharge begins. The natural tendency for the created stream ecosystem is to restructure itself so that a new equilibrium is achieved. This restructuring will take some time; the length will depend on local factors and whether additional stressors are placed on the system (e.g., construction of physical structures in, across, or along the stream, or an increase in effluent flow) (2).

Riparian systems that develop as a result of wastewater discharged into normally dry channels may stand in stark contrast to the adjacent upland vegetation that is not influenced by discharge. In addition, the terrestrial community downstream of the discharge point can be distinctly different from the terrestrial community upstream of the discharge. The expected characteristics of an effluent-based waterway downstream of the effluent discharge can be modeled conceptually (Fig. 1). This conceptual model, which represents a created stream ecosystem where the effluent discharge is the only discontinuity, is based on the physical, chemical, and biological characteristics of 10 effluent-dependent and dominant ecosystems in the arid West (2). From a regulatory standpoint, created or modified stream ecosystems are a class of aquatic environments that are

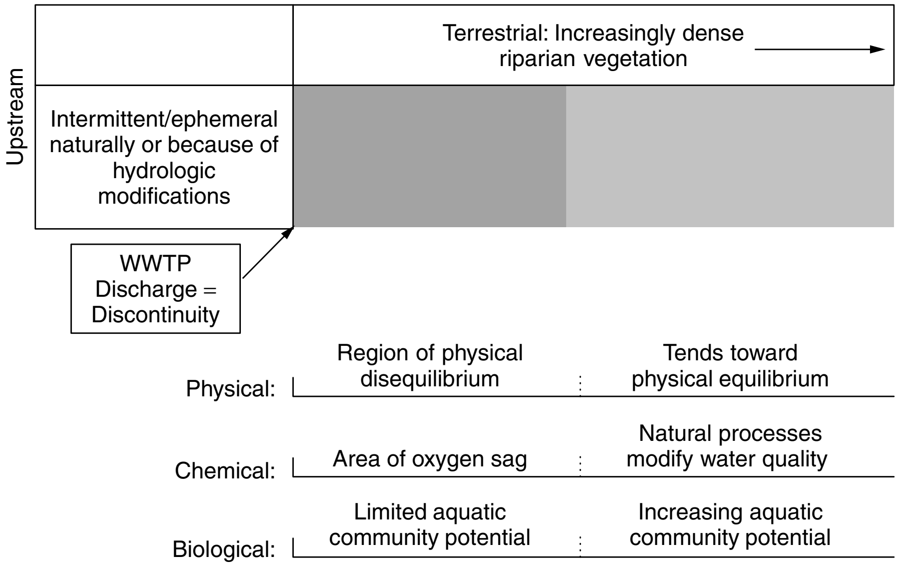

Figure 1. Conceptual model of an effluent-driven stream ecosystem.

typically not distinguished from natural ecosystems. Yet, these ecosystems may have unique attributes that result in different expectations for a "functioning" ecosystem.

Given the unique nature of effluent-based waterbodies, the challenge is to apply the existing regulatory framework in a way that is protective of this resource and still biologically meaningful. Below we address key regulatory issues for protecting effluent-derived ecosystems in arid lands. These considerations include defining "attainable uses" in effluent-driven ecosystems, using net ecological benefit as an alternative end point to measure use attainability, and implications of modifying the flow regime—is wetter better?

ATTAINABLE USES IN EFFLUENT-DRIVEN ECOSYSTEMS

States and tribes are required to establish beneficial uses for surface waters under their jurisdiction. At a minimum, existing uses must be protected (uses actually attained in the waterbody on or after November 28, 1975). States and tribes may go beyond the protection of existing uses and protect designated uses, which are expressed as goals for the waterbody. Designated uses must be protected only if the uses are actually attainable. The EPA defines attainable uses as those beneficial uses that can be achieved (1) when effluent limits under the Clean Water Act are imposed on point source dischargers and (2) when cost-effective and reasonable best management practices (BMPs) are imposed on nonpoint source dischargers. If all appropriate water quality control activities are implemented, then the pertinent question is, "what is the best beneficial use that can be achieved?" Determining what is attainable in a natural ecosystem can itself be difficult; however, when effluent creates the aquatic ecosystem, determining what is attainable is an even greater challenge.

The attainable use may be equal to the designated use or it may be something less. Consider a dry stream bed characterized as an ephemeral flow system. At the point of effluent input (Fig. 1), the water becomes perennial. The addition of water changes the potential of the system and thus what is attainable, especially with regard to the aquatic community. The effects of water addition, physical habitat, water quality, and other stressors define the potentially attainable aquatic community. The result of the interaction of these variables differs with time and also with distance downstream from the point of discharge (Fig. 1). Often, the water quality changes over time as a new technology is installed, new regulations are implemented, or the stream channel is modified. Each change modifies the potential outcome or potential aquatic community. In other words, defining what is attainable is a moving target.

Determining potential or what is attainable is typically defined in the context of the effluent quality, which is related to the degree/type of wastewater treatment. A general belief exists that improved treatment will result in improved aquatic community characteristics. This is likely to be true at low levels of treatment. For example, with the change from primary to secondary treatment, major improvements in the aquatic community are expected and do occur. It is not necessarily realistic, however, to expect the same degree of improvement with more advanced treatment changes, such as with the addition of nutrient removal or filtration, if the limiting factor is habitat-related.

Failing to establish appropriate end points for beneficial uses has significant regulatory and cost implications because the Clean Water Act mandates that states assess water quality in surface waters every 2 years and determine if any of these waters is "impaired." A waterbody is considered impaired if a determination is made that, even after implementing all required effluent limitations (technology and water-quality-based) and BMPs, the water quality still does not meet applicable water quality standards. This analysis presumes that beneficial uses and criteria are appropriately established. However, if the uses and criteria are inappropriate, the basis for the assessment is inaccurate, and the waterbody may be incorrectly assessed as impaired.

Impaired waters must have a total maximum daily load (TMDL) established under the Clean Water Act. A TMDL is the sum of the wasteload allocations for point sources and load allocations for nonpoint sources (including natural background), plus a margin of safety (uncertainty factor). TMDLs are implemented through permits, BMPs, or other water quality management methods. Pollutant allocations are based on meeting the applicable end point or water quality standard. TMDLs can require substantial resources to develop and implement; thus, it is very important to use appropriate end points as the basis for assessing waters correctly.

Under the current method for regulating created or effluent-based ecosystems, states typically establish the same water quality standards or end points for effluent-based waters as established for natural perennial waters. This approach is based on the assumption that the aquatic community in effluent-based waters should be the same as the aquatic community in natural perennial waters; that is, the attainable end point in a natural ecosystem should be the same as the attainable end point in a created ecosystem. When this assumption forms the basis for implementing water quality control programs, the same requirements for effluent limitations are applied to both types of waters.

From a regulatory perspective, establishing appropriate end points in effluent-based ecosystems is especially problematic. The approach outlined above can result in applying substantially more stringent effluent limitations on facilities discharging to effluent-based ecosystems than facilities that discharge to a perennial water. The reason for this difference is that when a facility discharges to a perennial water, credit is given to allow for mixing the effluent with in-stream water. This credit results in less stringent effluent limitations. No such credit is available when the receiving waterbody is dry. This approach results in regulation that is strictly discharge or end-of-pipe based. No consideration (positive or negative) is given to the ecosystem of the receiving water.

The discharge of effluent to dry riverbeds creates an aquatic ecosystem. This ecosystem may be "new," or it may replace an aquatic ecosystem that has been lost because of dams, diversions, groundwater withdrawals, etc. If effluent-based ecosystems are created and if they function differently from natural perennial waters such that what is attainable in the created ecosystem differs from what is attainable in the natural ecosystem, then the use of an alternative regulatory approach to implement a water quality control program might be appropriate.

NET ECOLOGICAL BENEFIT

A concept, called "net ecological benefit," addresses some of the concerns associated with establishing attainable end points for effluent-based waters (3,4). The net ecological benefit methodology is a tool for evaluating whether an alternative end point could be established if it can be demonstrated that the ecological benefits created by the discharge outweigh any identified detriments. A natural progression of this thought process is to consider the use of a "performance-based" approach that considers the functionality of the ecosystem. This approach could lead to establishing alternative success criteria or end points for evaluating ecosystem protection. Examples of net ecological benefit include enhancement of habitat/food for terrestrial native or threatened and endangered (T&E) species, enhancement or restoration of riparian values, preservation of existing habitat that could not be supported without effluent flow, restoration of aquatic and riparian values lost due to human activities, enhancement of water quality resulting in conditions conducive to ecosystem restoration and/or preservation, improvement or creation of habitat capable of supporting fish or allowing migration of anadramous species, and restoration of species diversity in aquatic ecosystems.

EPA (3) guidance notes key issues that should be considered when evaluating whether or not a net ecological benefit exists as a result of an effluent discharge. Foremost among these is that effluent discharges should not produce or contribute to concentrations of pollutants in tissues of aquatic organisms or wildlife that are likely to be harmful to humans or wildlife through food chain concentration. This requirement addresses EPA and USFWS policies to minimize persistent, bioaccumulative chemicals in the environment. Also, a continued discharge to the waterbody should not create or be likely to cause or contribute to violations of other end points, for example, downstream water quality standards or groundwater quality. Finally, all practicable pollution prevention programs, such as pretreatment and source reduction, are operational and the discharger has to be appropriately responsive to previous and ongoing compliance actions. These considerations are designed to ensure that (1) a minimum level of wastewater management and treatment is implemented and (2) pollutants are not exported from the water column into the ecosystem through the food chain.

Use of a net ecological benefit approach as an alternative for setting end points would change the regulatory focus in effluent-driven ecosystems from end-of-pipe based to ecosystem-based. Establishing this nontraditional approach would allow recognizing the environmental benefits of water flow in an otherwise dry channel. Moreover, alternative end points that include terrestrial elements would support efforts to implement permitting on a watershed basis, support ecological restoration efforts, address concerns about the increasing loss of riparian habitat in the arid West, support increased interest in habitat restoration in urban rivers, and potentially benefit threatened and endangered species by maintaining wildlife migration corridors.

MODIFYING THE FLOW REGIME—IS WETTER BETTER?

The addition of effluent to a riverbed has been portrayed as a benefit in the context that any water in a riverbed is better than no water in a riverbed. For sites where the effluent replaces historically natural flows, this thought process makes sense. However, when the effluent discharge creates a flowing river where none previously existed, the question can be asked, "what has been lost or changed by the addition of effluent?" This question is relevant because naturally ephemeral streams have important biological attributes that are as distinct as the biological attributes of a natural perennial river.

The addition of an artificial perennial flow makes the system clearly different from historical conditions (Fig. 1). Biological attributes such as aquatic community richness and diversity are likely to be greater. The increased biological productivity of the aquatic community will provide additional food resources for terrestrial organisms. In addition to these changes in the aquatic community, the terrestrial community will be substantially different, especially in terms of the types of organisms supported. Are these biological changes good? Is having a wetter channel better biologically? These questions have no simple answer. In fact, the answer will depend on public values and local needs. One can easily argue that the number of ephemeral channels, especially in arid regions, far exceeds the number of naturally perennial channels, and thus the creation of a perennial stream in a previously ephemeral stream is a positive benefit. However, in some areas, especially in rapidly developing urban environments, the number of lost ephemeral channels can be significant, and the loss of habitats as a result of effluent discharge can be an important issue for the public to consider.

The creation of effluent-driven ecosystems creates a relatively stable aquatic environment, at least from the standpoint of temperature and flow. Certainly, stormwater runoff will still occasionally cause spikes in flow, but the norm is a relatively constant flow with reduced temperature variation (compared to what might be expected in a natural environment). Native fish species are adapted to the relatively episodic flow regime of natural arid waters. These species have evolved where abiotic factors are the dominant driver in establishing biological communities. Accordingly, these species are better adapted to this environment than nonnative species. Modification of the flow regime removes this driver and if nonnative fish become established (as they have throughout the arid West), they may outcompete the native species.

Similar to fish, the richness and diversity of native riparian vegetation is influenced by the flow regime. For example, the selection of native cottonwoods over nonnative salt cedar can be driven by the distribution and frequency of flows across the floodplain during floods. Under a stable flow regime, native species may be outcompeted. In the end, ecological benefits may result from the discharge of effluent to an otherwise dry or intermittent riverbed, but the modified flow regime is not necessarily a positive benefit for native species.

FINDING A BALANCE IN REGULATING ARID LAND WATERS

Among the general public, a common desire exists to protect beneficial uses, establish water quality criteria to protect uses, and protect riverine habitat and associated wildlife. However, basic agreement on these fundamentals exists, but substantial disagreement may exist over how attainable end points should be defined and how uses should be protected. This disagreement often stems from differences of opinion over how end points should be calculated, what are appropriate assumptions, and how much conservatism or how much of a safety factor should be built into the regulations.

The EPA (4), states, and tribes often take the simplest, most conservative approach when establishing attainable end points because this approach requires the least amount of scientific data. Regulatory institutions cannot be faulted for this. Given the number of different types of aquatic systems (natural or created) and the various and often competing beneficial uses of water (from protection of native species to use of water for industry), the number of factors that could be considered in establishing end points for each waterbody is substantial. Resources are simply not available to establish site-specific uses and criteria for each waterbody. Although regulators are limited in what they can reasonably consider when they establish criteria for an entire state or area, options are available for modifying uses and criteria and establishing appropriate site-specific end points. These tools should be used, when appropriate, because the importance of establishing correct end points cannot be understated. If water quality control efforts are based on unattainable uses or criteria, substantial costs may be incurred with little or no improvement in water quality.

CALIFORNIA—CONTINUALLY THE NATION'S LEADER IN WATER USE

William E. Templin
U.S. Geological Survey
Sacramento, California

In 1950, the U.S. Geological Survey began publishing a series of water-use circulars entitled "Estimated Use of Water in the United States." Every 5 years since then the report has been updated and now provides a valuable, long-term data set of national water-use estimates. Since the inception of this series, California has always reported the largest total fresh and saline withdrawals of all states in the Nation (Fig. 1). The most recent update in this series (1) reports 1995 conditions. California again accounts for the largest withdrawal of water for off-stream uses of all states, which is about 45.9 billion gallons per day, followed by Texas (29.6 Bgal/d), Illinois (19.9 Bgal/d), and Florida (18.2 Bgal/d, Figs. 2 and 3).

The poster demonstrates WHY and HOW California continues to lead the Nation in many withdrawal categories (Figs. 4 and 5). Withdrawals include water removed from the ground or diverted from a surface-water source for use.

WHY? California continues to be the most populous state in the United States, accounting for 12% of its people (more than 32 million in 1995) followed by Texas and New York with about 7% each (Fig. 6). In 1995, California accounted for 5.62 Bgal/d, 14% of the Nation's public supply freshwater use (Fig. 7). Public supply withdrawals are directly related to population supplied, but they also are influenced by withdrawals to supply industrial and commercial water users.

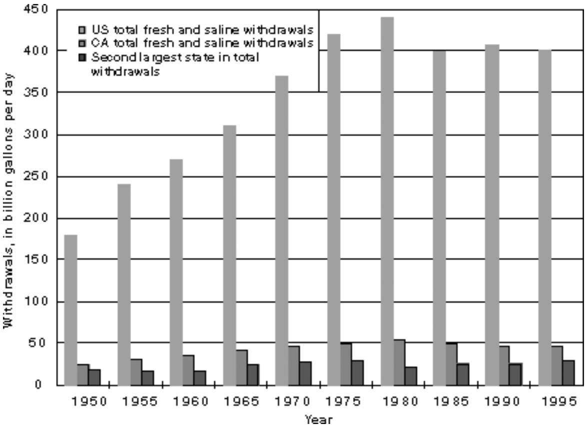

Figure 1. Trends in total fresh and saline withdrawals, 1950–1995.

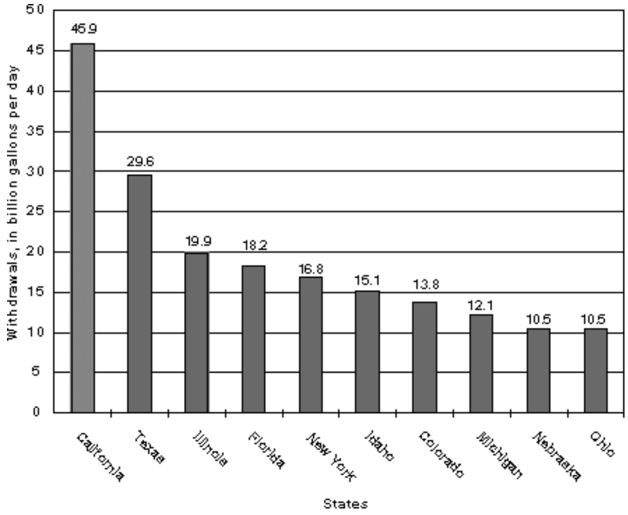

Figure 2. Total fresh and saline withdrawals by top 10 states, 1995.

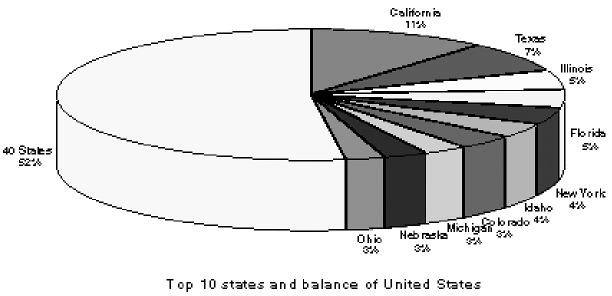

Figure 3. Total fresh and saline withdrawals in the United States during 1995, 402 Bgal/d.

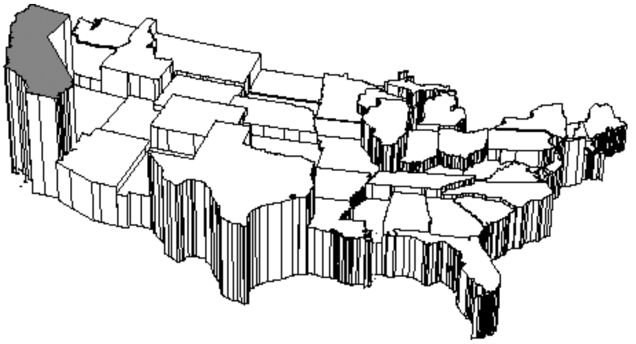

Figure 4. California led all states in freshwater withdrawals followed by Texas, Illinois, and Idaho, 1995.

HOW? Los Angeles County's population exceeded 9.3 million in 1995 and contributed to the county's large public supply withdrawals. Only eight states have more people than Los Angeles County, which accounts for 29% of California's population (Fig. 8).

WHY? California accounted for 28.9 Bgal/d in total irrigation withdrawals in 1995, with 22% of the Nation's total irrigation withdrawals (Fig. 9).

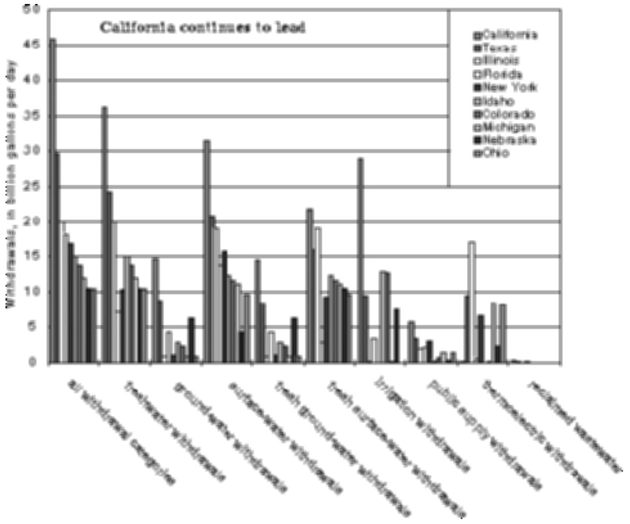

Figure 5. Categories of total withdrawals in the top 10 states, 1995.

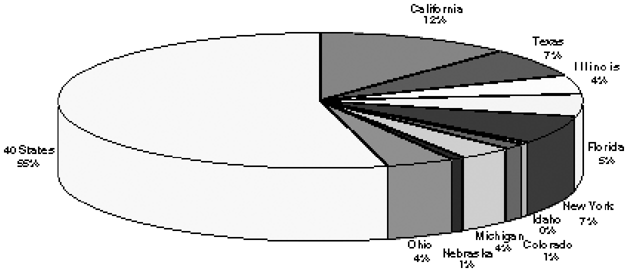

Figure 6. 1995 U.S. population—267 million.

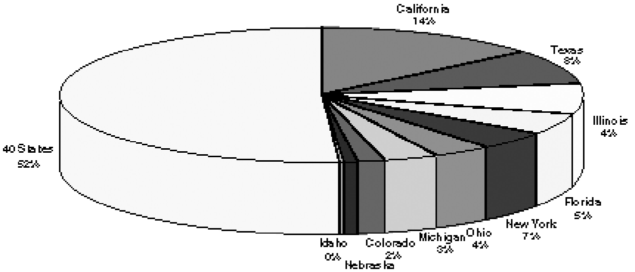

Figure 7. U.S. public supply withdrawals, 40.2 billion gallons per day, 1995.

- GOT MILK? California is the Nation's largest dairy state, producing 26 billion pounds of milk and cheese (2).
- GOT COTTON CLOTHING? California is the Nation's second largest cotton producer.
- HUNGRY? More than half of the Nation's fruits, vegetables, and nuts are grown in California.

HOW? The total withdrawals in the Tulare-Buena Vista Lake Hydrologic Cataloging Unit accounted for more than 8330 Mgal/d in withdrawals for irrigation uses in 1995 (Fig. 10) and 8800 Mgal/d of total freshwater. Only 13 states had more total freshwater withdrawals. This area

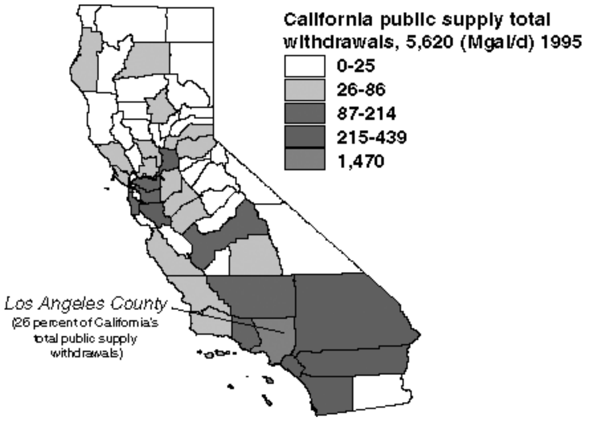

Figure 8. Public supply total withdrawals by county, in California, 1995.

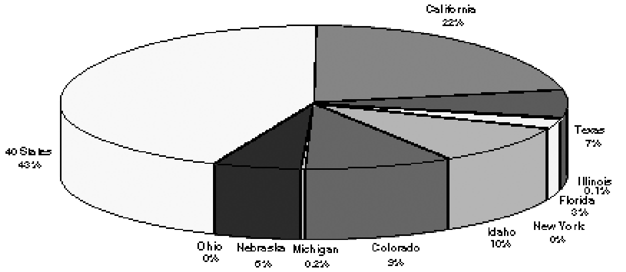

Figure 9. Irrigation withdrawals in the United States in 1995 totals 134 billion gallons per day.

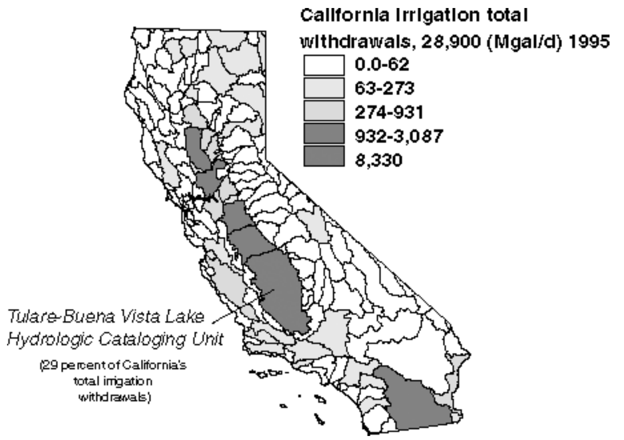

Figure 10. Irrigation total withdrawals by hydrologic cataloging unit, in California, 1995.

contains many of California's dairies and much of our irrigated acreage.

Even though California leads all states in total withdrawals, California's per-capita use rate for total offstream use (1130 gal/d) ranks below the national average (1280 gal/d, Fig. 11).

LESSONS FROM THE RISING CASPIAN*

Igor S. Zonn

INTRODUCTION

The Caspian Sea is the biggest inland body of water in the world. Its surface area is roughly equivalent to the combined area of The Netherlands and Germany (about 400,000 km^2, or 144,000 mi^2). The surface water inflow into the sea is formed by the flow of the Volga, Ural, Terek,

---

*From *Handbook of Weather, Climate, and Water: Atmospheric Chemistry, Hydrology, and Societal Impacts*, T.D. Potter and B.R. Colman (Eds.). John Wiley & Sons, Hoboken, NJ. pp. 885–892.

Sulak, Samur, and Kura Rivers, and small Caucasian and Iranian rivers. The watershed area of the Caspian Sea is 3.5 million square kilometers. The basin of the Volga River makes up nearly 40% of the territory of the catchment of the Caspian Sea, and it supplies about 80% of the total volume of annual water flow into the sea. All components of the Caspian ecosystem, directly or indirectly, to a greater or lesser extent, are influenced by river flow.

The Caspian Sea basin falls into three morphologically different parts: (1) the northern (25% of the sea area), a shallow area (less than 10 m deep; about 20% with depths less than 1 m) extending to a conventional line passing from the Terek River to the Mangyshlak Peninsula; (2) the medium (35%), with an average depth of 170 m (the maximum being 790 m); and (3) the southern (39%), the deepest area, with a maximum depth of 1025 m and an average depth of 325 m. Deep depressions in the northern and southern parts of the sea are divided by an underwater threshold running from the Apsheron Peninsula to Turkmenbashi (formerly Krasnovodsk) (1).

Before the breakup of the Soviet Union in December 1991, the USSR and Iran were the only two independent nations occupying the shores of the Caspian. With the breakup, three additional newly independent nations emerged along the coast: Azerbaijan, Kazakstan, and Turkmenistan. The Russian Federation's Caspian coastline is shared by three of its political units: Astrakhan Oblast, the Republic of Kalmykia, and the Republic of Dagestan.

NATURE OF SEA-LEVEL CHANGES IN CASPIAN SEA

The Caspian Sea is a closed basin in the inland part of Eurasia and this sea's water level is below that of the world ocean. The sea basin stretches almost 1200 km from north to south and its width varies between 200 and 450 km. The total length of the coastline is about 7000 km. Its water surface area is about 390,600 km^2 (as of January 1993). Water salinity in the northern part is 3–6‰ and reaches 12‰ in the middle and southern parts.

Fluctuations in sea level for various lengths of time can be found in the data of geomorphological and historical studies of the record of the Caspian Sea (Fig. 1). Within the last 10,000 years, the amplitude of fluctuations of Caspian Sea level has been 15 m (varying from −20 to −35 m). During the period of instrumental observations (from 1830 onward), this value was only about 4 m, varying from −25.3 m during the 1880s to −29 m in 1977. Annual increases in the level during this period met or exceeded 30 cm on three occasions (in 1867, 30 cm; in 1979, 32 cm; and in 1991, 39 cm). The mean annual increment in the level in the 1978–1991 period was 14.3 cm.

Natural factors are the primary cause of recent Caspian Sea level fluctuations (but not the only cause). Scientists have identified three distinct periods of level changes: 1830–1930, 1931–1977, and 1978 to the present. The first period of 100 years saw sea-level fluctuations not exceeding 1.5 m (5 ft). Researchers considered this period to have been relatively stable. The second period, from 1931 to 1977, is identified by a constant decline in level by 2.8 m (9.1 ft), and in 1977 the Caspian Sea reached its lowest level since the beginning of instrumental record-keeping in the 1830s.

As the sea level declined throughout the 1950s, 1960s, and early 1970s, Soviet scientists forecast that the decline would continue for at least a few decades into the future. Scientists have linked the reason for the decline to the regulation of Volga River flow. During these decades, major engineering activities were undertaken along the Volga, such as the construction of water diversion canals, reservoirs, and dams. The construction of such engineering facilities diverted water away from the Caspian.

In response to this major drop in sea level, human settlements bordering the sea coast began to move toward the receding coastline. Fields and pasturelands were prepared for use, roads and rail lines were constructed, and housing and factories were built on the newly exposed seabed. During the Soviet era, many people emigrated from other parts of the region to settle along the border of the sea. Development of infrastructure along the coast took place to support the increasing population.

In an attempt to save the Caspian from drying out, Soviet scientists and engineers proposed the construction of a dam to block the flow of Caspian water to Kara-Bogaz-Gol Bay, a large desert depression in Turkmenistan adjacent to the sea's eastern shore. Political decisions made in the mid-1970s ordered the construction of the dam, but due primarily to bureaucratic inertia, the dam was not completed until the early 1980s. This was a few years after the Caspian's sea-level change had reversed direction. Before the dam was constructed, the bay took in 40 km^3 (8.6 mi^3) of Caspian water annually. It served as a huge evaporation pond, as well as a natural location for the accumulation of commercially useful mineral salts.

Another Soviet government response to the decline in the Caspian's sea level was a diversion of water into the Volga River from other Soviet rivers that flowed northward into the Arctic Ocean. River water flowing into the Arctic was viewed as wasted and without value to the Soviet Union because it was unused by human activity.

THE CASPIAN RISES

To the surprise of Soviet scientists, the level of the sea began to rise suddenly in 1978, the beginning of its third period of level changes. Since then, the Caspian has risen

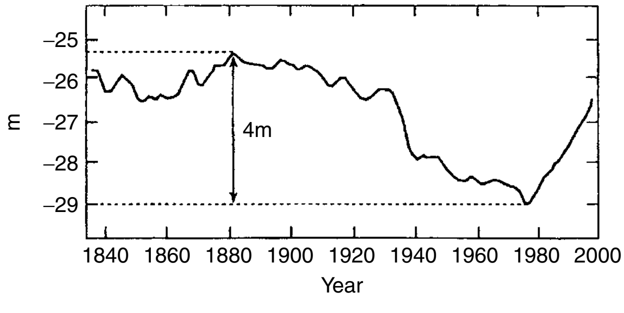

Figure 1. Observed Caspian Sea level, 1835–1999.

steadily by more than 2.5 m. One of the first actions the newly independent government of Turkmenistan took in 1992 was to tear down the dam in order to allow great amounts of water to flow into Kara-Bogaz-Gol Bay again and to replenish the supply of salts.

Scientists have proposed a variety of hypotheses about why the Caspian Sea level had increased so rapidly. These can be clustered into the following categories: tectonic plate movement on the seabed, climate fluctuations and change, and hydraulic construction along the Volga River, or some combination of these factors.

Tectonic Plate Movement Hypothesis

Tectonic movements over periods such as centuries and millennia have been the cause of many geologic changes in the Caspian basin. The region has been subjected to uplift, subsidence, overthrust of landforms, seabed mud-volcanic activity, and landslides, in addition to erosion processes and the accumulation on the Caspian seabed of river-transported sediments. However, it is difficult to see how tectonic movements could cause such sharp fluctuations in the Caspian's sea level over relatively short periods. Thus, it appears that such movements have had an insignificant impact on recent sea-level fluctuations.

Climate Change Hypothesis

Today, most Russian scientists believe that climatic factors are the real cause of the Caspian Sea level rise. Studies by Golitsyn (2) and Golitsyn and McBean (3) indicate that recent changes of the Caspian Sea level are 90% associated with corresponding changes in the water balance components of the sea, as opposed to possible tectonic activity. The volume of inflow from rivers to the sea increased sharply after 1978. During certain years (e.g., 1979, 1985, and 1990), more than 350 km^3 of river water entered the sea. From 1978 until 1990, Volga River flow exceeded 260 km^3/yr. At present, no arguments have challenged the view that the main contribution to seasonal and annual level fluctuations of the Caspian is accounted for by surface inflow and evaporation levels. Within recent decades, the sea's fluctuations have been subjected to anthropogenic impacts as well.

In this regard, climate has two dimensions: climate fluctuations and climate change. Climate fluctuations occur on various time scales, with those of interest to present-day society being on the order of decades and perhaps centuries. Climate-related fluctuation refers to the increase and decrease of sea level over the course of decades. During the past two centuries, the sea has undergone several fluctuations. Those of the twentieth century have adversely affected socioeconomic activities and infrastructure along the sea's coastline.

The view that climatic processes in the Volga basin are the dominant cause of sea-level fluctuations has been recently reinforced. Droughts in this basin and sharply reduced Volga flow into the Caspian from mid-1995 until early 1997 have been associated with a 25-cm (10-inch) drop in Caspian level. Nevertheless, Russian scientists still suggest that the sea level will continue to rise into the first decades of the twenty-first century.

Climate change associated with global warming induced by human activities has also been proposed as the forcing factor behind the Caspian's rise since 1978. Those who see global warming as the forcing factor suggest that the most recent sea-level rise can be associated with intensification of the hydrologic cycle (i.e., more active precipitation-producing processes), an intensification that some scientists have linked to the human-induced global warming of the atmosphere. An increase in precipitation within the Volga River basin would translate into increased sea level.

Hydraulic Construction Hypothesis

Some observers have argued that the recent fall and rise in sea level were the result of human activities. They suggest that the widespread development of hydraulic structures (e.g., dams, reservoirs, irrigation systems) in the Volga River basin, beginning in the 1950s, led to a sharp decline in Volga flow. The filling of many reservoirs built along the rivers flowing into the Caspian, the increase in industrial and municipal water use by several times, and changes in the water regime of the floodplains led to a decrease of streamflow into the sea. Such a hypothesis could be tested by constructing a water budget model for the Caspian. Such a model would need to identify all the inflows into the Caspian Sea (such as from rivers and groundwater) and all outflow from the sea (such as evaporation and water diversions). While it is a seemingly straightforward task, identifying all the sources and sinks of Caspian water is not easy.

There is also a hypothesis about an Aral Sea connection. Yet another suggestion that seems to be made at just about every Aral or Caspian Sea conference is that the decline in the level of the Aral Sea is linked to the rise in level of the Caspian. The reasoning is that water diverted from the Aral basin to the Caspian basin to irrigate the desert sands for cotton production in Turkmenistan ends up either being evaporated into the air or seeping into the groundwater, which eventually makes its way into the Caspian. However, it is important to point out that *both* the recent fall and rise in the Caspian Sea level occurred during three and a half decades of a constant decline in the Aral's level.

SOCIETAL IMPACTS OF SEA-LEVEL RISE

According to a UN Environment Programme estimate, the cost of the impact of the sea-level rise of the Caspian, as of 1994, was $30 to $50 billion (U.S.). Coastal ecosystems have been destroyed, villages inundated and populations evacuated, sea banks eroded, and buildings destroyed. Coastal plains have been invaded by subsurface seawater or have become waterlogged. Fauna have changed, and pasturelands and sturgeon spawning grounds have been destroyed.

Each of the five countries sharing the coasts of the Caspian Sea has suffered losses, and those losses increased until the mid-1990s. They suffer from the different impacts of sea-level rise because the territory along its coastline is neither uniformly settled nor uniformly developed economically. Economic losses in the big cities and villages have been higher than in the rural areas. More specifically, in Astrakhan Oblast (equivalent to an American state), about 10% of its agricultural land was out of production by 1995 because of sea-level rise. The coastline of the Republic of Dagestan (also part of Russia) was affected by the flooding of at least 40 factories in its cities of Makhachkala, Kaspiysk, Derbent, and Sulak. Nearly 150,000 hectares (370,000 acres) of land have been inundated, with a loss of livestock production and breeding facilities. Much of the 650-km (390-mile) Caspian coastline of Turkmenistan is made up of low-lying sandy beaches and dunes that are vulnerable to coastal flooding and erosion. In fact, some Turkmen villages that were once several kilometers from the sea are now coastal communities. Similar adverse impacts of sea-level rise on human settlements and ecosystems are found in Kazakstan, Azerbaijan, and Iran.

The Caspian has been referred to as a “hard currency sea” because of its large oil and natural gas reserves and because of its highly valued caviar-producing sturgeon. Regional reserves contain upward of 18 billion metric tons of oil and 6 billion cubic meters (215 billion cubic feet) of natural gas. Experts suggest that the Caspian is second only to the Persian Gulf with respect to the size of its oil and gas reserves, and that Turkmenistan is a “second Kuwait.” If the sea level were to continue to rise, a large part of the oil and gas mains along the Turkmen coast would become submerged and would also be subjected to corrosion by seawater. Coastal settlements, which include the greater part of Turkmenistan’s oil, gas, and chemical enterprises, would also be threatened. Similar environmental problems would certainly affect other Caspian coastal countries as well (4).

The Caspian Sea is unique in yet another respect: it contains about 90% of the sturgeon that produce the lucrative prized black caviar for export to foreign markets. Sturgeon roe is often referred to as “black gold.” Today, however, Caspian sturgeon is at risk of extinction from overexploitation by illegal poachers and by destitute fishermen desperately seeking funds to buy food for their families. The sea-level rise, with its destruction of sturgeon spawning grounds, adds yet another threat to the endangered Caspian sturgeon.

Poachers hunt sturgeon only for its caviar. Today, they catch sturgeon directly in the open sea. However, in the early 1960s, prohibition was introduced by the former USSR against catching sturgeon in the open sea. Since that time, catching sturgeon has been carried out in the river deltas. Sturgeon reproduce very slowly: the fish do not spawn for the first time until they reach the age of 20–25 years. In 1990, the permissible catch of sturgeon in the USSR was set at 13,500 metric tons. In 1996, permissible (legal) catch was only 1200 metric tons (5).

SEA-LEVEL CHANGE AS A GLOBAL PROBLEM

Given the growing concern about, and possible evidence of, global warming, there has been considerable speculation about the potential impacts on coastal areas of a sea-level rise related to global warming. Scientists who participated in the 1995 Intergovernmental Panel on Climate Change (IPCC) Report (6) suggested that global sea level may well increase by an additional 15–70 cm (6–27 inches) by the end of the twenty-first century. The exact amount of rise would depend on the actual increase in global temperatures. Clearly, any additional increase in sea level could have devastating consequences for coastal communities.

All states that border bodies of water, whether along the global oceans or inland seas, should pay attention to fluctuations in sea level as well as to the rise in sea level linked to global warming. Inland seas, for example, can be viewed as living bodies in the sense that they can expand and can shrink. These changes can occur on different time scales: from daily to seasonally, from a year to a decade, or a century, or a millennium. In fact, they fluctuate and change on all these scales. The same can be said of the open oceans, but they tend to fluctuate on much longer time scales than do the inland seas, over periods of many decades and centuries. Such time scales are difficult to factor into the thinking of economic development planners, whose time frames are on the order of years to a few decades at most.

In essence, one can consider the Caspian as a laboratory of sea-level change and its potential societal and environmental consequences. For the Caspian to serve as a true “laboratory,” its environmental-monitoring network, which collapsed with the breakup of the Soviet Union, must be restored and maintained by regional cooperation among the Caspian states. Impacts on ecosystems that are managed (farms and pastures) and unmanaged (wetlands, forests, deserts) can be identified. Effective human responses to changes in the coastal zone (both land and sea) can also be identified and assessed; environmental engineering proposals to deal with sea-level changes (such as seawall construction, higher oil platforms in the sea, diversion of water from the Caspian to the drying Aral Sea) can be evaluated for effectiveness, taking into consideration the scientific uncertainties surrounding sea-level fluctuations.

Whether the global climate gets warmer, cooler, or stays as it has been for the last several decades, the level of inland seas will likely continue to fluctuate (the mean ocean level has already gone up by 5–6 inches in the twentieth century alone). Societies must learn to cope with both short- and long-term fluctuations. In the Middle Ages, people in the Caspian region were not allowed to settle too close to the sea’s shore, under the threat of death. Apparently, leaders were then aware of the dangers that the Caspian’s fluctuating levels posed to their citizens. Today’s leaders would be well advised to pay attention to traditional wisdom.

INSTITUTIONAL ASPECTS OF WATER MANAGEMENT IN CHINA

Rongchao Li
Delft University of Technology
Delft, The Netherlands

INTRODUCTION

Located in East Asia, on the western shore of the Pacific Ocean, the People's Republic of China (PRC) has a land area of about 9.6 million km^2. China, the most populous country in the world, had 1.25909 billion people at the end of 1999, about 22% of the world's total. The population density in China is 130 people per sq km. A map of China is shown in Fig. 1.

China has a marked continental monsoonal climate characterized by great variety. The summer monsoons last from April to September. The warm and moist summer monsoons last from April to September, bringing abundant rainfall and high temperatures from the oceans, and little difference in temperature between the south and the north. China's complex and varied climate results in a great variety of temperature belts and dry and moist zones.

China has 50,000 rivers that cover catchment areas of at least 100 square kilometers, and 1500 of them cover catchment areas of more than 1000 square kilometers. Most of the rivers flow from west to east to empty into the Pacific Ocean. The main rivers include the Yangzi (Changjiang), the Yellow River (Huanghe), Heilongjiang, the Pearl River, Liaohe, Haihe, Qiantangjiang, and Lancang Rivers. At 6300 kilometers long, the Yangzi is the longest river in China. The second longest is the Yellow River at 5464 kilometers. The Grand Canal from Hangzhou to Beijing is a great water project of ancient China, 1794 kilometers in length. It is the longest canal in the world (*Source*: http://www.chinatour.com/countryinfo/countryinfo.htm#RIVER).

INSTITUTIONAL ASPECTS OF WATER MANAGEMENT IN CHINA

Legislative and Executive Structure

The agencies involved in WRM can be divided into legislative and executive organizations. The legislative structure is organized, in descending order, as follows:

- state level: state congress
- provincial level: provincial congress

Figure 1. Map of China (*Source*: http://www.maps-of-china.com/china-country.shtml).

- city level: municipal congress
- county level: county congress

The legislative structure in China is composed of four levels, shown in Fig. 2.

The executive structure closely relevant to water management is shown in Fig. 3.

Large water projects are managed by Basin Administrative Institutions that are subordinations of the MWR, such as the Yellow River Water Conservation Commission (YRCC). Medium and small water projects are managed by provincial, municipal, and county water administrative institutions, respectively, on the basis of ownership.

FUNCTIONS OF ADMINISTRATIVE INSTITUTIONS

In China, the water resource management organization has traditionally been organized along narrow, subsectoral lines. The national government determines the general legislative and policy framework for water management. The Ministry of Water Resources (MWR) is responsible for the state water management and issues the national water legislation and policies. Other ministries, such as land and agriculture and electronic, are also involved in water management.

The following competent departments under the State Council and local government and their respective functions based on the duty division of the State Council compose the administrative structure of water resource management in China (Table 1).

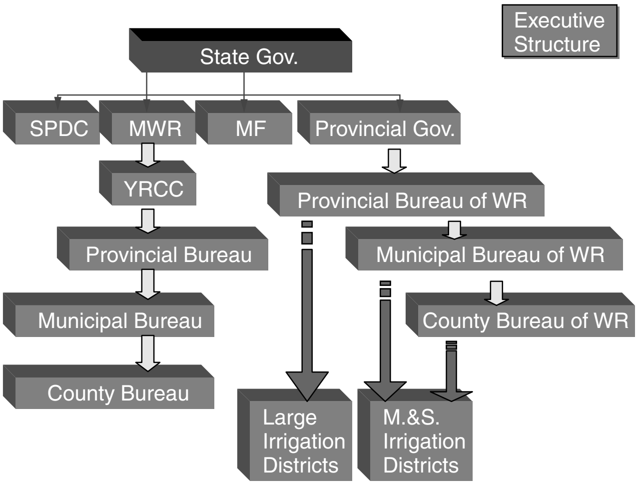

Figure 3. Executive structure of water management.

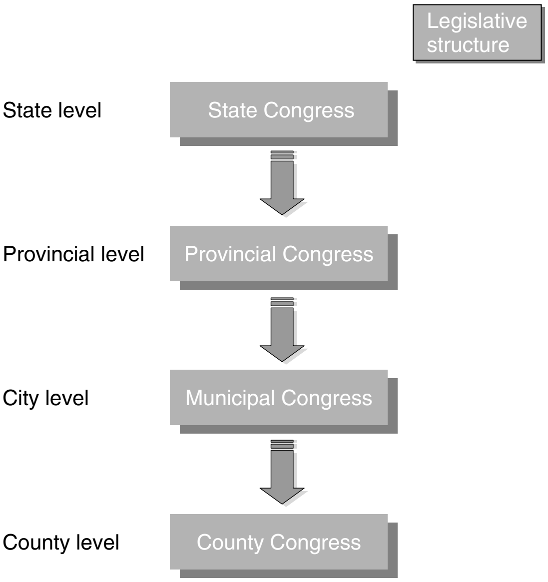

Figure 2. Legislative structure in China.

Ministry of Water Resources

The Ministry of water resources (MWR) is the main department of water resources management under the state council. Its functions are :

- to establish respective regulations of water resources management on water law

Table 1. The 14 Sectors Involved in Water Management in China

Index	Sector	Task
1	Ministry of water resources	Surface water resource management
2	National environmental protection bureau	Water environmental protection
3	Ministry of geomineral	Underground water management
4	Ministry of construction	Construction of city water resource development and protection
5	Ministry of agriculture	Agricultural water management
6	Ministry of energy	Water and electronic construction
7	National planning and development commission	Permits for conservancy projects
8	Ministry of sanitation	Monitor and protect drinking water
9	Ministry of finances	Permits for flood control finance capital
10	National scientific commission	Management of water resource research
11	National meteorological bureau	Prediction and management of precipitation
12	Ministry of transportation	Management of inland navigation
13	Bureau of national land management	Project management of protected basins
14	Ministry of forestry	Protection of river basin forestry

- to carry out a national comprehensive scientific survey and investigation as well as an assessment of water resources
- to draw up the overall planning for the main river basins in China
- to formulate a long-term water supply plan on national and regional scales
- to issue permits for water use
- to construct and maintain water projects such as reservoirs, dikes, and weirs
- to manage the waterways, including rivers, lakes, canals, and flood discharge areas

Generally, there is a department or bureau of water resources under each level of local government which is responsible for local water resources development and management.

To strengthen the development and conservation of water resources in the large rivers in China, the Yangtze, Yellow, Pearl, Huai, Hai, Songhua, and Liao, there are seven river basin commissions established under the leadership of the MWR. These river basin commissions as agencies of the MWR are responsible for the tasks mentioned above in the basin concerned.

National Environmental Protection Agency

The National Environmental Protection Agency, the environmental protection department of the State Council, exercises unified supervision and management for the prevention and control of water pollution. It is in charge of the following responsibilities of water quality management:

- to establish the implementation rules and regulations of water quality management on the basis of prevention and control in the water pollution law
- to establish national water environmental quality standards
- to establish national pollutants discharge standards in accordance with national water environmental quality standards and the country's economic and technological conditions
- to amend national water environment quality standards and national pollutants discharge standards in due time
- to examine and approve the environmental impact statement and inspect water pollution prevention and control facilities of new projects, extensions, or reconstruction projects which discharge pollutants into waterbodies directly or indirectly
- to carry out the task of registration and application for permits for water pollution discharge
- to carry out the task of payment for water pollutant discharge
- to implement elimination and control of water pollution within a certain period
- to exercise the punishment authority of warning and fines on violators of prevention and control in the water pollution law
- to be in charge of pesticide registration

Ministry of Geology and Mineral Resources

The functions of the Ministry of Geology and Mineral Resources are:

- general investigation and exploitation of groundwater
- assessment and unified planning for the development and use of groundwater
- supervision and management of groundwater

Ministry of Agriculture

This ministry is in charge of the management and conservation of farmland irrigation water and fishery waterbodies.

Ministry of Public Health

- supervision and management of drinking water quality in urban and rural areas
- formulation of sanitary standards of drinking water
- monitoring drinking water quality
- definition of sources of drinking water in accordance with other competent departments
- participation in the management of protection zones for drinking water

Ministry of Construction

Construction and management of the water supply in urban, and rural areas and sewerage engineering as well as domestic wastewater treatment plants in cities.

Ministry of Transportation

Supervision and management of water quality for navigation and navigation ways in inland rivers.

In addition to the responsibility of the various Ministries under the State Councils as mentioned above, the responsibility for flood control belongs directly to the State Councils and local governments at various levels as well as the seven large river basin commissions.

LEGAL SYSTEM

In 1988, the Water Law of China was enacted and issued, representing the legal basis for water resources development and management. At present, other relevant laws or regulations have been enacted for effective water pollution control, water and soil conservation, the water-drawing permit system, water conservation in urban areas, flood control, safe management of dams, tariff collection, riverbank management, navigation management, land use for water works, and resident resettlement. A series of laws and regulations related to water resources development and management is also being drafted and processed for enactment, concerning integrated use of water resources, watershed management, flood control, water resources fee collection and management, water pricing of water supply projects, totaling more than 20 (see below).

List of Chinese Laws Related to WRM

Laws

- Constitution of the People's Republic of China (DOE*: 1982, RA**: National People's Congress)
- Forest Law of the People's Republic of China (DOE: 1984, RA: National People's Congress)
- Fishery Law of the People's Republic of China (DOE: 1987, RA: National People's Congress)
- Water Law of the People's Republic of China (DOE: 1988, RA: National People's Congress)
- Environmental Protection Law of the People's Republic of China (DOE: 1989, RA: National People's Congress)
- Water and Soil Conservation Law of the People's Republic of China (DOE: 1991, RA: National People's Congress)
- Mineral Resources Law of the People's Republic of China (DOE: 1994, RA: National People's Congress)
- Water Pollution Control Law of the People's Republic of China (DOE: 1996, RA: National People's Congress)
- Flood Control Law of the People's Republic of China (DOE: 1997, RA: National People's Congress)
- Land Administration Law of the People's Republic of China (DOE: 1998, RA: National People's Congress)

Regulations and Policies

- Working Regulation of Soil Conservancy (DOE: 1982, RA: State Council)
- Price Management Regulation (DOE: 1987, RA: State Council)
- Law on Land Administration (DOE: 1987, RA: State Council)
- Water Extraction Permit System Regulation (DOE: 1993, RA: State Council)
- Urban Water Supply Regulation (DOE: 1994, RA: State Council)
- Method for Management of Irrigation Districts (DOE: 1981, RA: Ministry of Water Resources)
- Method for Construction and Management of Irrigation and Drainage Projects (DOE: 1981, RA: Ministry of Water Resources)
- Technical and Economical Index of Irrigation Management (DOE: 1996, RA: Ministry of Water Resources)
- Industry Policies for the Water Sector (DOE: 1997, RA: Ministry of Water Resources)
- Urban Water Conservation Management Regulation (DOE: 1989, RA: Ministry of Construction)

*DOE: date of enactment;
**RA: responsible agency.

FINANCIAL SOURCES FOR WATER MANAGEMENT IN CHINA

The main financial source for water management is composed of three parts: the infrastructure fund of the water conservancy construction fund, maintenance of projects, and institutional management fees. The sources of the infrastructure fund for water conservancy are:

- the infrastructure fund of the general budget
- the water conservancy construction fund
- loans from domestic banks and other financial organizations
- funds from the sale of bonds
- loans from foreign financial organizations
- other sources approved by state governments

Both the sources for maintenance of projects and institutional management fees are the general budget and the water tariff. Spending of the infrastructure fund for water conservancy is on flood control, drainage, irrigation, water supply, hydropower, navigation, and others. The Financing chart for water management of the YRCC is shown in Fig. 4.

POLICY, LAWS AND REGULATIONS

The Central Government lays the utmost stress on the Yellow River. A series of principles, policies, general water laws, water administration regulations, and basin-oriented water laws have been developed. They involve the water administration of the Yellow River, the management of water resources, management of a water conservancy project and engineering affairs of the Yellow River, management of flood control, water and soil conservation, and protection of water resources. Examples are given below.

Water Laws such as the "Water Laws of the People's Republic of China," "Laws of Water Pollution Prevention of the People's Republic of China," "Laws of Water and Soil Conservation of the People's Republic of China," and "Laws of Flood Prevention of the People's Republic of China"

Laws and Regulations of Water Administration: "Working Regulations of Water and Soil Conservation," "Management Regulations of River Channels of the People's Republic of China," "Management Means of Ratification and Collecting of Water Fees for a Water Conservancy Project," "Regulations of Water and Soil Conservation in Developing the Contiguous Areas of Shanxi, Shaanxi, and Inner Mongolia," "Collecting and Management Means of Water Fees for the Intake of the Irrigation Canal," "Means of Fee Collecting and Management of Sand Mining in River Channels," "Implementation Means of Permit Regulation of Abstracting Water," and "Means of Control and Management of Water Quantity"

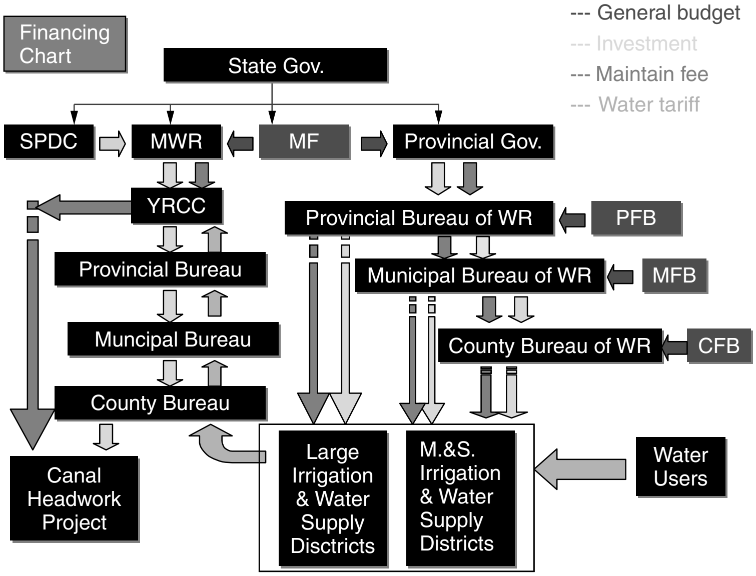

Figure 4. Financial chart for water management of the YRCC.

In addition, there are many local laws and regulations relevant to the management and development of the Yellow River. For example, "Management Means of Water Conservancy Project of the Yellow River of Shandong Province," and "Regulations for Certain Problems in River Channels and Flood Detention Areas in Henan Province."

WILL WATER SCARCITY LIMIT CHINA'S AGRICULTURAL POTENTIAL?

Bryan Lohmar
Economic Research Service,
U.S. Department of Agriculture

Water shortages in important grain-producing regions of China may seriously compromise China's agricultural production potential. Rapidly increasing industrial and domestic water consumption and expanding irrigation have drawn down groundwater tables and disrupted surface-water deliveries. The problem is most severe in north-central China, where most of China's wheat and cotton is produced and irrigation is essential to maintaining high yields. The situation may worsen unless effective water conservation policies can be put into place rapidly.

China is responding to these concerns on several levels. At the national level, the Ministry of Water Resources began promoting water conservation through various measures in the late 1990s, such as strengthening the authority of National River Basin Commissions to enforce water withdrawal limits and promoting irrigation management reforms. Provincial and other local officials are mediating conflicts between users to improve overall water management. In villages, local water managers and farmers are adopting water management reforms and water-saving techniques, such as forming water user associations and alternating wet-dry irrigation for rice. In addition, reforms in the pricing and fee collection system may provide farmers with better incentives to conserve water. Pricing water deliveries to farms based on volume could improve efficiency, but would be costly to monitor since China has over 200 million farm households, each tending several tiny plots of land.

As water for agriculture becomes more scarce, changes in the pattern of crops are more likely than a reduction in cultivated acreage. Wheat is most likely to suffer declines, since wheat is irrigated in much of north China and brings low returns to water. Production of a variety of crops—corn, cotton, and high-value fruits and vegetables—may increase as farmers switch from irrigated wheat. High-value fruits and vegetables are often more water intensive, but are also more suited to water-saving irrigation technologies, such as drip irrigation and greenhouse production.

The success of current efforts to encourage water conservation in China will depend on a variety of factors. Policy reforms will depend critically on the enforcement of withdrawal limits both from surface-water systems and from ground water. Also important is the extent to which policies and local management practices motivate water users and water managers to conserve water resources.

WATER AND COASTAL RESOURCES

U.S. Agency for International
Development (USAID)

Every ecosystem, society, and individual on Earth depends on water. Food security and human health, energy supplies, and industrial production are all dependent on water to a large degree. Water plays an important role in regulating global climate. It is essential for plants and wildlife and ecosystems they inhabit. Water shortages and poor water management can lead to loss of biodiversity and agricultural production, increase in malnutrition and disease, reduced economic growth, social instability, and conflict.

Reliable water supply has been a fundamental component of the increased agricultural productivity achieved by the green revolution. Irrigated agriculture currently uses 70% of the world's developed water supplies. With increasing competition for water to meet domestic and industrial needs, and for servicing essential ecosystems, agriculture is faced with producing more food with less water.

Water resources are not distributed uniformly across the globe—nor are they necessarily located where the largest concentrations of people reside. Demand for water outstrips supply in a growing number of countries, and the quality of that supply is rapidly declining: 450 million people in 31 countries already face serious shortages of water. These shortages occur almost exclusively in developing countries, which are ill-equipped to adopt the policy and technology measures needed to address the crisis. By the year 2025, one-third of the world's population is expected to face severe and chronic water shortages.

Exacerbating the problem, human activities often contaminate the world's limited freshwater resources, making them unavailable for further human use and threatening the health of the lake, river, and wetland ecosystems they support. Likewise, coastal and ocean systems are under threat from the impact of a broad range of human activities. Coastal systems are particularly vulnerable to degradation from land-based activities, climate change, over-fishing, and damage to coral reefs, and they require active intervention to ensure their continued survival.

The U.S. Agency for International Development has made the preservation and environmentally sound development of the world's water resources a top priority. The Agency's investments have helped improve access to safe and adequate water supply and sanitation, improve irrigation technology, enhance natural environments, and develop better institutional capacity for water resources management in countries around the world (Fig. 1). This has supported the Agency's underlying goals of reducing conflict and improving the welfare of people across the globe.

Figure 1. USAID worked with local partners to improve water resources management in Morocco's Nakhla region of the Rif Mountains.

WATER USE CONSERVATION AND EFFICIENCY

WATER USE AND USERS ON GLOBAL AND REGIONAL SCALES

Water has many uses and users, ranging from fluvial navigation to employing water as a component in a chemical experiment. On a global level, the four most water demanding human activities are energy—hydroelectricity—generation, irrigation for agriculture, urban supply, and nonurban industrial production. Each of them requires huge quantities of water; and in its usage at least some water characteristic is affected, which limits the options of the remaining users to profit from that same water. This causes a competition in which each user would like to have exclusive rights to manage and exploit the resource. Hydroelectricity affects the potential energy of water (topographic elevation), and the other three basically affect water quality. There is a fifth user, frequently neglected by humans, which has the most ancient right to benefit from water, nature. The natural world needs water in lakes, forest, woods, floods, and climate regulation and has been greatly affected by the human desire to conquer and transform and to grow and expand.

Worldwide, the agricultural sector is the biggest water consumer, although this balance is not equal in every continent or country. For instance, nations that have benign and frequent rains that allow good direct agricultural production may have no need for irrigation; others that are very dry or have an uneven distribution

---

of water and rain require huge irrigation works to get reasonable crop yields. Figure 1 depicts the distribution of volumes among the three human uses that most affect water quality.

WATER SCARCITY, CONFLICTS, TECHNOLOGY, AND CONSCIOUSNESS

Water scarcity, which is rapidly growing in most countries, creates serious conflicts, competition for water, and evidently great unfairness in many cases. Figure 2 is a clear and simple illustration of why there is growing scarcity in most nations. Of course, its severity differs widely, depending on regional natural resources and demographic pressure. In general, there are growing crises in the whole world.

Legal rules establishing some priorities for water usage, or simply the legal support to historical privileges, sometimes help in attenuating real or apparent conflicts among users. Other regulatory mechanisms are water markets, where users can trade their water rights to other users. This last has advantages, but also great disadvantages when the market and the world economy (usually a totally artificial issue subject to political fancies and fashions) send erroneous signals about the value of things.

Competition among users is not absolute; water used upstream can later be freely used downstream, provided the residual water discharges from the first consumers are not dangerous enough to inhibit their later usage. Anyway, there always is some technological possibility of treating and reusing water. If there were enough money to apply technology, conflicts would be eliminated, but technology is costly, and most of the world is poor. This is worsened by the low value given to water by traditional economies and by the unequal competition for globalized trade in agricultural products. So unfairness and crises still have a long way to go.

An often misconceived economics paradigm suggests that water should be used where it renders the greater rate of return. This is a kind of taboo to be seriously questioned and reviewed because it leads us to accept the idea that uses in services such as tourism, electronics, and industry in general are more important than use in agriculture and food. A better approach is to accept that the latter use is greatly undervalued by the market and the others are exaggeratedly overvalued. The same situation occurs in ecological water use.

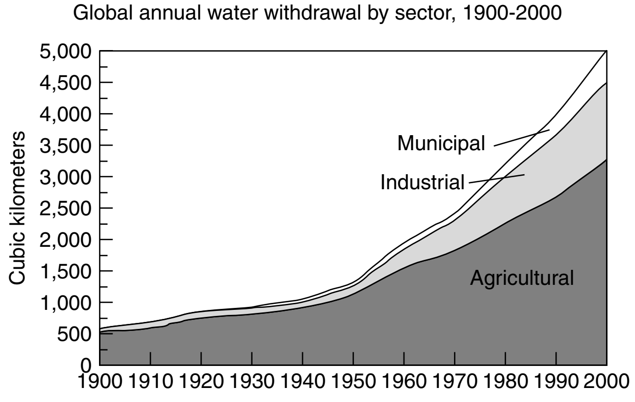

Figure 1. Rising water use. Global annual water withdrawal by sector, 1900–2000 (from Ref. 1).

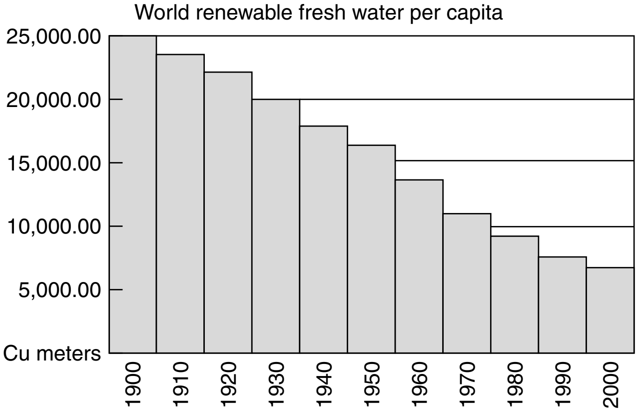

Figure 2. A century of changes in water availability: clear signs of scarcity and conflicts.

The mid-twentieth century vision of dealing with water needs and scarcity problems was to increase the supply by means of big dams and similar huge engineering works. They have proved insufficient and merely made the demand disproportionately grow, so the vision for this century must be radically changed. The approach now must be "water demand management" respecting natural limits and boundaries. Scarcity must be directly dealt with, by conservation and "efficient water use." These options also have a technological component but rather rest mainly on human habits and consciousness. They are radically different from options that rely on huge engineering works for water transfers and treatment.

WATER USERS AND DEMAND ON AN URBAN SCALE

Water users in cities are mostly the people who live and work there; they can be represented by existing houses, buildings, shops, offices, parks, hotels, schools, and factories. There are many types of cities and ample variations in these components. Tourist and recreational cities have lots of hotels and almost no factories; in industrial cities, it is the opposite. Housing for families usually is the greater component in any city and evidently the sector demanding more water.

The water demand in a city can be expressed in liters/person/day; it is comprised of the water used directly or indirectly by an average citizen and the leaks in the piping network. People use water directly in their houses, but also in their jobs or at school, and indirectly by others serving them, as in restaurants where they eat, by shops or services visited, and in general by every industry in the city. Leaks unavoidably occur so the water may arrive in the consumption area. The previous reasons explain why if the average in-house *consumption* is 300 L/capita/day, the full *demand* may be around 500 L/capita/day. Figure 3

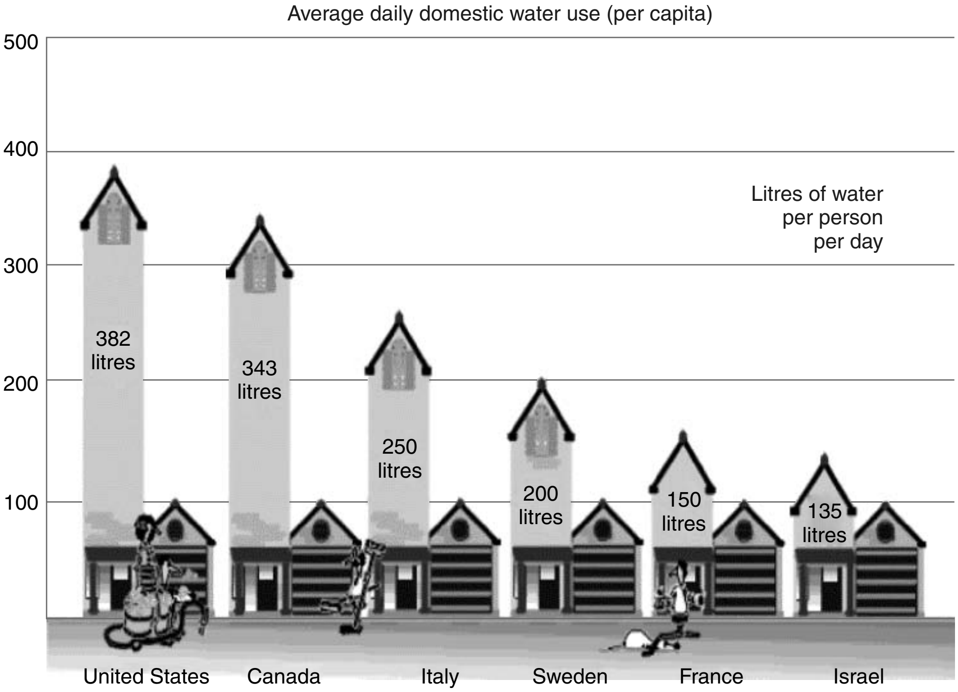

Figure 3. House water consumption in some countries (from Ref. 2).

contrasts some international statistics about in-house consumption. There are big variations, of course, even within a nation and even among different zones and persons in the same city. Figure 4 is a sample of in-house water usage distribution.

CONSERVATION OF WATER AND OTHER RESOURCES

Water emphasizes many conflicts and scarcities, although water may not be the real issue considering that there is plenty of water on our planet. Water quantities may not be the problem, but its quality, or its location in time or in space. Infrastructure, investments, and technology are always essential for actions such as water treatment, storage for other seasons, or transport to other places. Therefore, the real restrictions may not be water volumes or qualities, but those regarding energy resources, financial sources, and managerial capabilities to transport it or to preserve its purity. Energy is one important inhibitor; if it were freely available, water could be pumped from far away flood zones to deserts (this does not consider possible negative ecological impacts).

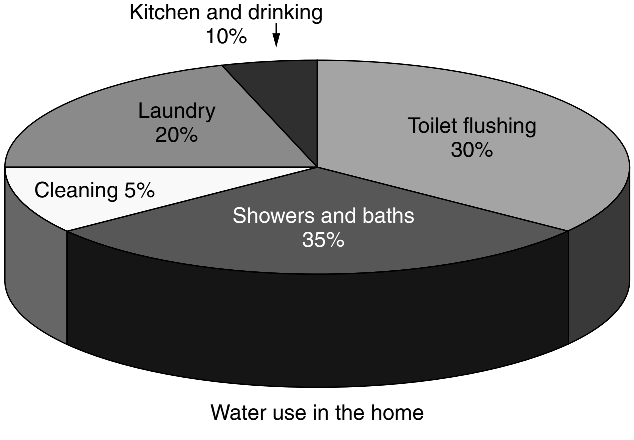

Figure 4. Typical household water use in Canada (from Ref. 2).

When institutions request people to save water, they do not merely think of saving water volumes, but rather of saving energy expenditures by eliminating the need for larger pipes and, mainly, by diminishing pollution caused by the water usage and discharge. Many propose conservation plans, so the volume saved is used to support demographic and demand growth. In this case, there are no real savings and compensations for previous damage and overexploitation, but merely variants of the twentieth century backing of human expansionism.

The need for conservation and for “efficient water use” has a much broader scope than merely using less water. The real purposes and issues may be protecting the whole environment, our economy, and the quality of life of future generations. They can have a rather dark side when used as a political and demagogic argument simply to maintain inertias for growth and expansionism, which require less money investments but possibly greater human and environmental sacrifices and discomforts that are not taken into account.

MEASURING THE EFFICIENCY OF URBAN SERVICES

Even in something as specific as public water supply, efficiency has many angles and goals. Simultaneously, it is important to save water volumes, to avoid pollution, to diminish unnecessary expenditures, and to distribute water more fairly among different users. For instance, if there were an optimal amount of water to be given to people, considering health, welfare, and other aspects (for example, 150 L/person/day), anything above or below such a quantity could be considered inefficient.

One common type of inefficiency occurs in water transportation because there always is some degree of leakage caused by breaks in the piping system. This efficiency is computed as the ratio of the volume delivered to clients, measured by micrometers, divided by the total volume extracted from the water source. The operating or "revenue efficiency" is the total money collected through bills paid by clients, compared to the total amount in issued bills. The "unaccounted for water" (UFW) indicator is a measure of the overall inefficiency of a water supplier, considering physical and commercial losses. Another strategic indicator is represented by the ratio of total expenditures to total income during a certain period.

Yet another important way to assess performance is by comparing the initial water quality at the source against the quality returned after discharge. An increasing degree of recycled or reused water within a city evidently is also a desirable way to demonstrate improvements.

It would be extremely expensive and totally impractical to have a system without inefficiencies, that is, 100% efficiency in all aspects. What is done by developed water utilities is to work simultaneously using an ample set of "performance indicators" and to apply several benchmarking rules and comparisons with other utilities, as suggested by the International Water Association (3).

Just as any water utility may have various types of efficiencies to be confronted routinely and evaluated, the private home owner, or any factory or hotel manager, may have many parameters by which to assess performance in water usage and its impact on the environment. Water audits (Fig. 5) are appropriate as systematic procedures for assessing performance and to detecting failures as well as opportunities for improvement.

CONSERVATION AND EFFICIENCY, THE NEED AND THE HOW

The need for conservation and efficient water use comes from scarcity and competition for the resource, each time more evident in many places. In this regard, many national and international institutions advise how to save water. The most classical are to take shorter showers, not to leave the faucet open while shaving, or changing the old toilet for one of newer design (maximum 6 liters/flush, see Fig. 6). There are lots of these recommendations, which are not bad at all, but maybe at sites of severe crises and scarcities, recommendations should be even more daring and definitive, to attack the roots of problems, not their symptoms. Some of these newer counsels are: use dry latrines instead of toilets, shower just once a week, and use perfumes; be a vegetarian and not a meat eater (meat production demands much more water than vegetables); family planning; bicycles instead of cars; reuse, recycle, rethink; charge "green taxes" for many environmentally damaging products or packaging.

The importance of systematically assessing and measuring efficiency lies in finding improvement opportunities. Performance or efficiency indicators should be compared against reference values to detect failures, changes, and trends. The reference standards should be carefully discussed and selected, because if not, some incongruence and evident mistakes may occur. One pitiable flaw would be to report efficiencies greater than 100% when abstaining from using water in certain industrial process or eliminating a superfluous water need. For instance, when comparing the change to dry latrines after using traditional toilets, it evidently does not mean infinite efficiency, although doubtlessly it is great environmental progress.

Excessive, wasteful, and polluting water uses should be restricted. However, how these restrictions should be

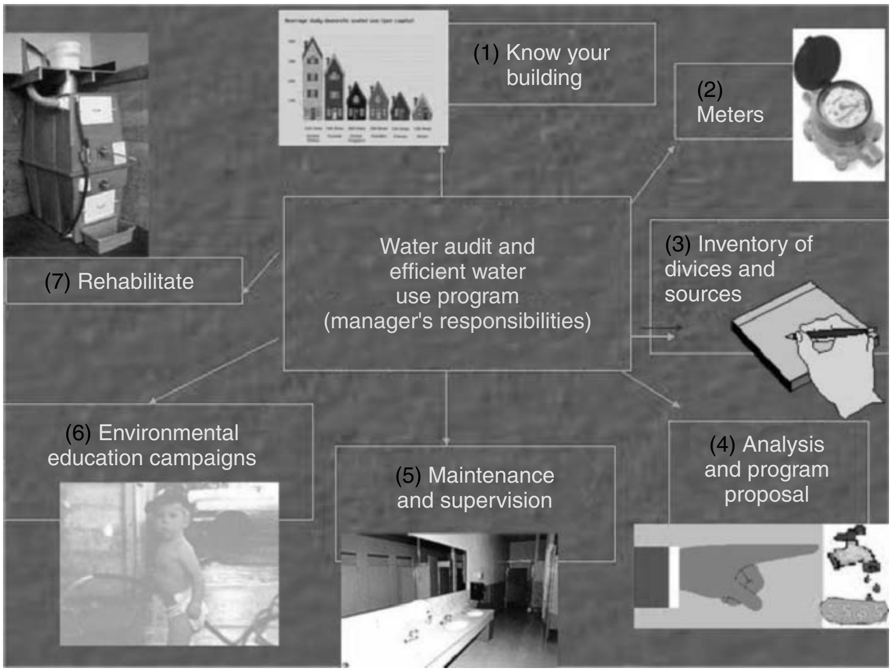

Figure 5. Seven stages for water-saving programs in buildings.

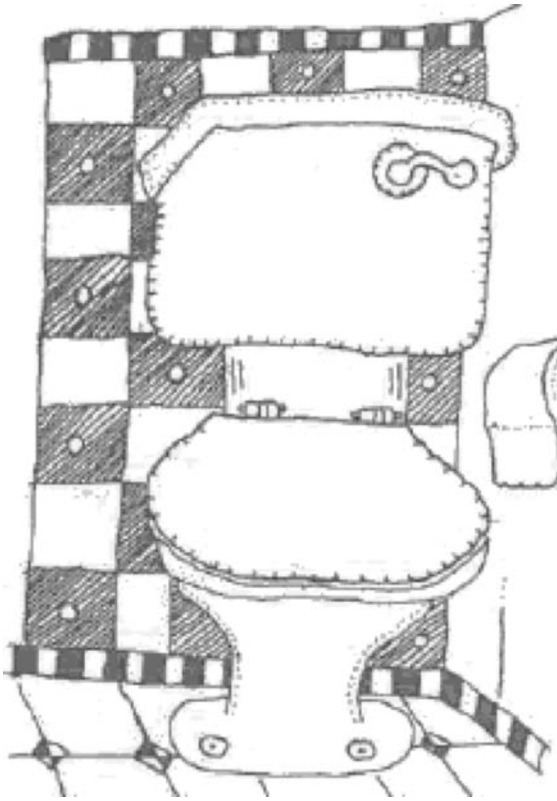

Figure 6. Toilet bowl: friend and foe. The most frequent cause of water consumption, leakages, and pollution.

attained is an interesting issue. The least desirable options would be laws for direct prohibitions. There are better choices, for instance, measuring water and contaminant loads in discharges and applying tariffs high enough to discourage those uses and encourage the search for better technologies and processes.

Besides metering and tariffs, there are many programs and actions that any water supplier must consider, which contribute to efficient water use in a city. Among them are user education and water culture, macrometering, information systems, client census, demand forecasting, automation of operations, leak detection and control, materials testing and quality control, employee training, improved maintenance procedures, bylaws, aquifer recharge, rain harvesting, water audits, improved domestic water-saving devices, water treatment, water reuse and recycling, and desalination. Each of these programs and tasks has different degrees of importance depending on the local conditions, and together make up a desirable set of simultaneous actions to be considered and used.

This article supplies only a list of these programs without further details. Each one deserves a specific and detailed explanation, which hopefully may appear in other sections of this Encyclopedia of Water. All of them are important and strategic for efficient water use and resource conservation.

LIMITS TO GROWTH AND EFFICIENCY

The options for solving water scarcity, along with the crises and conflicts it causes, rest mainly in the social, moral, and economic realm, rather than in the technical one, although at first glance, it may appear the other way.

Most likely, technology can always find a way to improve efficiency, but also it implies that costs sometimes are not apparent. Solutions often have clear and immediate economic components but often also may have vague, but possibly important, environmental, quality of life, and long-term consequences. Unfortunately, traditional economic and technical models merely deprecate and do not consider such impacts because they do not know how to deal with them.

Technological options for improving water efficiency sometimes are clear and simple, and can be adopted without much questioning and doubt; however, in many other cases, it is important to have broader vision. Here is a brief list of arguments to reflect on and consider:

— Efficient water use is not simply “using less water.” There are many other options for managing demands. Reuse is an important one.

— Efficient water use depends more on the efficient use of resources other than merely on water saved. Energy, money, technology, people’s willingness, forests, and climate are some of these other resources.

— Urban water scarcity is not a water availability problem. It may be a symptom and reflection of other problems so that, when confronted, the scarcity issue will be immediately relieved.

— Scarcity problems could be “easily” solved by stopping consumption and population growth.

— Urban water scarcity is a “moral and ecological problem,” not a technical one.

— More severe and urgent laws are required for sites suffering extreme scarcity, particularly, where aquifers present continued water table drawdown.

— Scarcity is referred to as a problem of shortages but is a situation of “longages” (excesses) of bad habits and population or industrial growth in inappropriate zones.

Technology can succeed in allocating population increases by using and reusing the fixed available water volume more intensely. However, this style of technology application merely justifies expanding the coverage, without a clear improvement in the quality of life. Reuse, treatment, and desalination, are desirable options up to certain limits, but should never be used indiscriminately to justify further growth. On the contrary, they must promote diminishing human impacts to make more natural space available. Theoretically, it is possible to have houses or factories with zero water discharge, and almost zero water demand by intensive treatment and reuse.

Water desalination is an interesting option for increasing the supply of water. It has a history as ancient as the hydrologic cycle, its basis. Humans have used desalination techniques for survival on long ocean journeys and for supplying isolated islands for centuries. Nowadays, desalination processes use reverse osmosis that demands huge energy input, which mainly comes from thermoelectric power plants; so the process is equivalent to exchanging petrol for water. In that sense, besides being a rather expensive choice not for every one, it is not a sustainable option because fossil energy is a nonrenewable resource. It would be more desirable and sound to research and promote technology using solar energy for these processes.

Now that the failures and flaws of traditional economic models that cheer growth and expansion are evident, there is need for a new paradigm. Efficient water use and conservation should be seen as a route to reach this new paradigm, not as a means for reinforcing the old one.

When continuous, long lasting, and growing sacrifices or "improved efficiencies" are the alternative to make available water to increasing populations and when there is not a clear end to these situations, serious questioning must be done about the risk of failure of this route (plagued by decreasing safety levels) and of the worth of such sacrifices. It could be that opting to limit growth and technology would be more appropriate, sound, and simple.

CONSERVATION OF WATER

Mukand Singh Babel
Asian Institute of Technology
Pathumthani, Thailand

Water is the main component of the natural ecosystem and an essential element for human life. It is also fundamental for the social and economic development of a country. Water is needed for drinking, washing, and sanitation at personal, domestic, and municipal levels; for agricultural purposes such as irrigation, livestock, and fisheries; for industrial development, navigation, hydropower production, recreation, and so on. In addition, there is increased realization that water is needed for maintaining ecosystems.

The higher rate of population growth associated with several anthropogenic activities leading to increased pollution of water resources has augmented critical situations worldwide related to scarcity of water resources either in quantity or quality to meet the vital necessities of humankind.

When the ratio of water availability to demand exceeds certain limits, the stress on resources becomes noticeable, and the conflicts among users intensify and increase in frequency. A region that have water availability of about 1700 m^3 per capita/year faces periodic water scarcity, and this is considered a warning if the population continues to grow. Below this limit, “water stress” is periodic. If this limit is even lower, about 1000 m^3 per capita/year, the region is under “chronic water scarcity.” Economic development, well-being, and health are affected at these levels. The situation is “extremely scarce” if the per capita availability is below 500 m^3 per year. Many countries that used to have plentiful water resources are facing water scarcity, that is likely to be aggravated in coming years.

On one hand, there is the problem of scarce availability in relation to increasing demands; on the other hand, there is poor resources management and wasteful and inefficient use of freshwater. To address these water problems, it is necessary to control the overuse and pollution of water resources by improved management of water resources through conservation and water saving concepts and practices.

The main water-use sectors are agricultural, industrial, and domestic. At a global level, agricultural water use accounts for 70%, industrial use 21%, and 9% for domestic consumption. Though industrial water demand is much smaller than agricultural demand in low- and middle-income countries, it exceeds domestic and agricultural demands in developed and industrialized countries, as shown in Table 1.

Water is wasted nearly everywhere; there is great potential for better conservation and management, no matter how water is used. The term water conservation is associated mainly with the policy, managerial measure, or user practice aiming at conserving or preserving water resources and taking care of the degradation of water resources; water saving aims to limit or control water demand and avoid wastage and misuse. Both perspectives are complementary and interrelated in managing scarce water resources.

Table 1. Distribution of Water Use[a]

	Agricultural Use	Industrial Use	Domestic Use
World	70%	22%	8%
High-income countries	30%	59%	11%
Low- and middle-income countries	82%	10%	4%

[a] Reference 1.

AGRICULTURAL SECTOR

Most water is used for agriculture (Table 1). Efficient agricultural water management, therefore, is a major conservation option. It is common to find that more than half of the water drawn from a source does not even reach the fields being irrigated. Generally, less than 40% system efficiency prevails in many irrigation schemes. Such an appalling situation should be tackled by pursuing better systems of farm water management—improving irrigation efficiency by reducing water distribution losses, changing cropping patterns, improving irrigation scheduling, and adopting irrigation efficient technologies. Deterioration of irrigation network systems due to lack of proper and adequate maintenance are the main causes of increased losses through leakage and percolation. Rehabilitation of existing irrigation schemes is, therefore, required to alleviate the situation. It is also equally important, when implementing new irrigation schemes, to give sufficient attention to adequate operation and maintenance. Active participation by the users is vital for sustainable management of irrigation systems. Several governments are in the process of transferring management functions to farmers or developing joint (government agency and water users) management systems.

In gravity irrigation methods such as basin, furrow, and flooding, a large quantity of water is lost by leaching down the root zone and as runoff at the end of the field. Land leveling, along with other technical measures, provides conditions for reducing the advance time and water volumes required to complete the advance, for better water distribution as well as application efficiencies. For moderate to high infiltration soils, where system automation is possible, water can also be saved by adopting surge irrigation which consists of intermittent cycling of water applied to furrows and borders, thereby producing changes in the soil surface conditions which favor a faster advance of water.

Sprinkler irrigation methods have higher system efficiencies than gravity irrigation. Water in sprinkler irrigation can be conserved by improving the distribution uniformity—optimizing the overlapping of sprinkler jets, minimizing discharge variations, minimizing wind drift and evaporation losses, maximizing infiltration of applied water, and avoiding surface runoff losses. Microirrigation has the least loss of water among irrigation methods. It can be classified in two general categories: drip or trickle irrigation, where water is slowly applied through small emitter openings from plastic tubing; and microspray irrigation or microsprinkling, in which water is sprayed over the soil surface. Water conservation in microirrigation can be improved by using a single drip line for a double crop row, using microsprayers in high infiltration soils, adjusting the duration and timing to soil and crop characteristics, controlling pressure and discharge variations, adopting automation and fertigation, and chemigation (application of fertilizers and herbicides or other chemicals with irrigation water).

Water conservation measures are also very important in dry-land agriculture because crop growth depends solely on the moisture retained by the soil from rain. Conservation measures in rain-fed agriculture are carried out mainly by appropriate crop and soil management practices. Crop management techniques consist of managing crop risks, such as selecting the cropping pattern to suit the available seasonal rainfall; controlling water stress, such as adaptation of crop rotation to environmental constraints, including covered fallow for grazing; and water conservation cropping techniques, such as by employing conservation tillage, windbreaks to decrease wind impacts on evaporation, etc. Soil management practices are broadly categorized as runoff control, such as contour tillage, using mulches, furrow diking, etc; improvement of soil infiltration rates, such as application of organic matters and mulching; increasing soil water storage holding capacity, such as deep tillage; control of evaporation from soil by crop residue and mulching; runoff control in sloping areas by terracing, contour ridges, and strip cropping; and water harvesting.

Reuse of water, such as using wastewater (graywater) for agriculture, is considered a conservation option to increase the availability of water either currently or in the future. More than 500,000 ha of farmland are currently being irrigated with treated wastewater in 15 countries around the world. However, the use of such wastewater, if not treated well, may threaten the public health by spreading bacteria, viruses, and parasites. For example, the outbreak of typhoid fever in the mid-1980s in Santiago, Chile, was attributed to the use of wastewater, with unsatisfactory sanitary quality, to irrigate 16,000 ha of horticultural farms (2).

The major challenge to water planners and managers is that physical availability of water is fixed, but demand will increase to cater to the needs of an ever increasing population. The tendency today is to shift from water policies based on water supply management to those based on demand management. Agricultural water demand management consists of reducing crop irrigation requirements, adopting irrigation practices that lead to higher irrigation performance and water saving, controlling system water losses, and increasing yields and income per unit of water used. It works with agronomic, economic, and technical management decisions for decreasing irrigation water demand and recovering the costs of irrigation water supply. An agricultural water demand management program should consider the interaction between the quantity, quality, and biological aspects of both groundwater and surface waters; the sustainability of irrigation and drainage schemes; and environmental sustainability. Water demand management necessitates establishing structural incentives, regulations, and restrictions that help to bring about efficient water use in irrigation by farmers while encouraging innovations and saving technology.

INDUSTRIAL SECTOR

Water is used in industries in power generation, temperature control, manufacturing processes, and washing. The principal water users in industry are thermal and atomic power generation, chemistry and petroleum chemistry, ferrous and nonferrous metallurgy, wood pulp and paper industry, and machine building.

The quantity and quality of water required by industry vary with the type of industry and the industrial processes. The effluents produced by the industry are also of different qualities, which may require different treatment processes. Water recycling and reuse are the main water saving strategies in industry. Industrial water recycling, which began on a large scale in the 1970s to help cope with antipollution regulations, has also become an effective conservation measure. American steelmakers, which once consumed 280 tons of water for every ton of steel made, later needed to use only 14 tons of new water; the rest was recycled. Similarly, in Japan and western Germany, for example, a large increase in the number of factories has been accommodated without a considerable increase in total industrial water use (2).

The most common conservation measures in industrial water use are water-use monitoring, recycling, reuse, cooling tower use, equipment modification, and employee education. Of all industrial water use, cooling water accounts for a very large share. Replacement of once-through cooling processes with recirculating systems can provide some of the largest water savings. Often, cooling water can be reused for landscape irrigation and cleanup. The physical and chemical properties of water may change after use, requiring some simple treatment before being used again. Treated water can be reused for heating processes; water from washing raw food material can be reused for cooling, heating, or indoor washing.

DOMESTIC SECTOR

In urban areas, water supplies are used in households and for services such as city washing, fire fighting, and maintenance of swimming pools or recreational parks and lakes. A considerable amount of water is lost by leakage in the water distribution network. The unaccounted for water (UFW) comprises system leakages, illegal tapping, theft, incorrect meter reading and billing, and overflowing reservoirs. System monitoring and metering should be done in appropriate intervals to obtain information on the system state variables to prepare plans for water conservation measures as well as for estimating water losses, their location, and causes so as to prepare for appropriate corrective measures. Typical water losses as a percent of water supplied are 8–24% for developed countries, 15–24% for newly industrialized countries; for developing countries, it is 25–45%, as surveyed in 1991 by the International Water Services Association (IWSA). Examples of typical water losses for developing countries are well portrayed by Arequipa, Peru, with a 45% loss, and Hanoi, Vietnam, with a 68% loss (43% nonbilled, 20% leakage, 5% company use) (3). Between 20 to 40% of the supply was UFW in Indian cities and towns (4). On the municipal level, cities have saved from 10 to 25% of their water by repairing leaky pipes (2). Preventive as well as corrective maintenance can play a major role in water conservation.

Water pricing and billing can induce water saving habits in users if price increases with the volume used, particularly when the differential increases in price are large enough to encourage water savings. The reclamation of wastewater for nonpotable purposes has become a proven measure to help meet increasing demand. Where extreme water scarcity exists, a feasible but expensive solution is to have a dual distribution network for high quality water which is needed for uses such as drinking, food preparation, and bathing, and for treated reusable water which can be used for landscape and recreational ground irrigation, toilet flushing, and floor washing. Such reusable water can be available from, for example, treated urban drainage stormwater. Such examples of dual systems can be found in Australia, Hong Kong (China), Japan and the United States, to name a few. In Japanese cities, for example, such reclaimed water finds greatest use in toilet flushing (40%), compared with only 15% for irrigation in urban landscaping; in Hong Kong, seawater has been used extensively for decades for toilet flushing in commercial and multifamily residential buildings. However, a dual distribution system is difficult to implement because it requires very large investments from the public sector as well on the part of users in their homes. Financial incentives such as subsidies may be required for such investments in additional infrastructures and to implement other high-cost water conservation technologies.

In the domestic sector, most water is used for gardens and for bathrooms and toilets. In a typical household that has outdoor facilities, nearly 50% of the water is used for gardening; of the total indoor water use, 33% is spent on showers and bath, 24% for toilet flushing, and 22% in laundry (5). Water saving plumbing fixtures and appliances are cost-effective and provide permanent long-term economic advantages. Replacing traditional toilets which use 16 to 20 liters per flush with low-flow toilets (such as 6 liters per flush) or placing containers or bags filled with water in the tanks of large volume toilets can save a lot of water by reducing their capacity. A minor repair to control toilet leaks can be of immense help in conserving water. These leaks can be detected by adding a few drops of food coloring to water in the toilet tank and observing if the colored water appears in the bowl. Showers take second place in domestic water demand. Reducing the time for showering and preferring showers to immersion bathing can be very effective in conserving water. Low-flow showerheads and faucet aerators save water as well as energy used to heat water (where warm water is needed).

When washing clothes and dishes by machine, operating clothes washers and dishwashers with full loads can economize on water used. Outside the home, water can be saved by avoiding unnecessary spillage of water. Simple practices like using a broom, not a hose, to clean driveways, steps, and sidewalks; washing the car with water from a bucket; and irrigating plants either in the early morning or the late evening can save a lot of water. In landscaping, use of native plants that require less care and water than ornamental varieties can save a large quantity of water. While mowing the lawn, the lawn mower should be adjusted to a higher setting to provide natural ground shade and to promote water retention by the soil. In swimming pools, water can be continuously recycled, clarified, and purified by means of portable equipment and appropriate chemicals. Evaporation losses can be minimized by covering the pool when not in use.

INSTITUTIONAL MEASURES

Educational programs are very important in instilling water conservation awareness among users. Conservation literature can be distributed along with regular bills to water users. Local service organizations can also play a big role in disseminating water conservation information. An excellent time to provide this information to customers is just prior to the summer season when demand normally peaks. Local newspaper articles, radio and television public service announcements, information centers at local fairs and shopping centers, etc. can also be used to promote conservation awareness and education. Local schools can be a very good place to offer conservation knowledge to young people by means of water education activities such as water conservation posters, slogans, essays, or exhibit contests for children. High-use facilities such as schools and colleges, hospitals and institutions, country clubs, and health clubs are appropriate places to initiate water conservation programs.

Water laws provide a general framework for water use and conservation and are complemented by regulations. They can help water conservation by restricting excessive water use, for example, establishing standards for indoor plumbing fixtures, maximum volumes per flush in toilets, or making it compulsory for filtering, treating, and recycling the water in swimming pools, etc. The provision of incentive and penalties helps in enforcement of regulations as well as in the adoption of water saving technology by customers.

THE DEVELOPMENT OF AMERICAN WATER RESOURCES: PLANNERS, POLITICIANS, AND CONSTITUTIONAL INTERPRETATION

Martin Reuss
Office of History Headquarters
U.S. Army Corps of Engineers

To understand the development of American water resources, one must first look at American political and social values and at American governmental institutions. Even a cursory examination shows the lasting influence of decisions and attitudes molded as the country took its first hesitant steps as a republic. Historian Joyce Appleby has argued that the first generation of Americans bequeathed "open opportunity, an unfettered spirit of inquiry, [and] personal liberty" to future generations—qualities, we might note, that often introduce an element of uncertainty into public administration. But if we extend the analysis a bit, we might not only gain an appreciation of the many challenges facing water resource developers, but also illuminate a fundamental question facing democratic nations: To what extent should human liberty be constrained in order to provide and manage a human necessity—water?

Beyond Appleby's observations, one notes at least pervasive elements woven into American political behavior. The first, the inescapable, element is distrust of powerful governments. Power corrupts, the first Americans agreed without much hesitation, and the challenge was how to minimize that corruption, how to ensure that good men will not be enticed to do evil, and how to disperse power to minimize oppression. Loudly over the years, Americans continue to proclaim their distrust of big government; even popular presidents generate skepticism when they appear to reach for increased power and authority.

Only as a last resort, and then with resignation, not enthusiasm, as during the Great Depression, do Americans turn to the national government to solve their problems. The result can be truly impressive: Grand Coulee and Bonneville dams, locks and dams on the Upper Mississippi, the California Central Valley Project, and the Los Angeles flood control system all came out of depression-era politics, but arguably all are aberrations in the story of American water resources.

The second element, almost as pervasive as the first, is that power and liberty are fundamental antagonists. The dispersion of power among the three branches of government purposely sets power at war with itself rather than with "life, liberty, and the pursuit of happiness." Each branch would be allowed only sufficient power to discharge official duties, and a system of checks and balances would guard against abuse. Recoiling from British monarchism, the constitutional drafters took special care to try to prevent executive branch intrusions into the duties of the other two branches. This was a system that, regardless of its merits, made implementation of rational planning enormously difficult, as water developers soon appreciated.

Political attitudes one thing; government structure was another. And here the Founding Fathers developed a system that guaranteed further complications. They fashioned a republican form of governments within the government. A century later, young political scientist Woodrow Wilson thought that this structure posed the principal challenge to American administration. Few water resource planners would disagree. Republican government, it must be remembered, began in the states, not in the new national capital; delegates to the Continental Congress delayed business so they could go home and participate in state constitutional conventions. The formation of these state governments may have excited Americans more than the latter formation of the union itself, and the American Constitution explicitly guaranteed to each state a republican form of government (Article IV, Section 4). Once the United States achieved its independence, many Americans pondered how citizens could owe allegiance to two governments, two legislatures, simultaneously. Were the states and national government partners or were the states meekly to accept national supremacy? No one at the Constitutional Convention quite knew what to expect from this layer-of-powers (or was it a marble-cake, twentieth century political scientists later debated), and numerous, contrary explanations emerged of what the delegates had actually achieved. In no area did the confusion become more manifest or disruptive than in internal improvements, especially in water projects that crossed state lines.

The term "internal improvements" came to mean many things to the citizens of the young republic. It included roads, canals, schools, lighthouses, fortifications, and even technological innovations-most anything that seemed to provide security and promote the economy. Gradually, it came to mean something a bit more specific, though still covering (pardon the pun) a large amount of ground: it applied to what we now call "infrastructure," and water transportation was a central concern. Benjamin Franklin had proposed at the Constitutional Convention that Congress have the power to construct canals, but opponents won the day, fearing that Congress would become too powerful. In fact, the term "internal improvements" cannot be found in the American Constitution, an obstacle for those seeking affirmative authority for federal involvement in public works. But neither did the Constitution proscribe the activity, which meant to internal improvement advocates that the function lay legitimately within federal authority. This ambiguity not only produced a constitutional quagmire for internal improvements, but it provided a platform upon which larger issues of the role of government and the nature of liberty could be debated. In short, the internal

---

improvements issue amplified and sharpened the debates about the very nature of American republicanism. By any other name, it continues to serve that function to the present day.

Given Americans' distrust of government and emphasis on personal liberty, America's first politicians, and all the generations following, confronted the difficulty of promoting economic growth without expanding governmental authority. One answer was the corporation, a device that actually predated the Constitution but in the age of internal improvements became much favored. As presumed promoters of the public good, they effectively became agencies of government. In this way, legislatures could support economic and political development without necessarily involving tax monies. The fact that individual incorporators might thereby profit aroused little concern. The more important point was that corporations brought together sufficient capital to launch an enterprise, whether a canal or a municipal water system. Even if a number of these ventures brought forth charges of corruption, internal improvement advocates ceaselessly trumpeted the moral and intellectual gifts stemming from public works, as though canals were spiritual as well as economic enterprises. To complaints that corporations disenfranchised people and led to the inequitable distribution of wealth, champions argued-somewhat quaintly in light of what subsequently emerged corporations were nothing more than little republics eminently suited for the United States. For better or worse, the victory of the corporation in American life was almost as revolutionary as the victory of republicanism itself, and the alliance between government and corporations became a hallmark of American economic development. Government was not to replace business, but was to support and, within certain limits, protect it.

George Washington and other Federalists had ardently hoped that corporations might provide the capital and means to build internal improvements to bind the nation together and transcend local interests, perhaps leaving overall planning to the national government. But the chance slipped through their hands. The structure of Congress assured that state interests in internal improvements would prevail over national interest. There would be no national board, no national planning. Rather, Congress would periodically pass rivers and harbors acts that generally reflected parochial politics. To stimulate states and the private sector, Congress also provided a percentage of funds obtained from the sale of public lands in new states to finance roads and canals (the three and five percent funds dating back to 1802) and voted to turn over certain lands to states for reclamation (Swampland acts of 1849 and 1850). In a few cases, too, Congress might vote to subscribe to canal stock or even grant land to a company-a practice that presaged the enormous land grants given to railroad companies as they extended their presaged the enormous land grants given to railroad companies as they extended their lines across the continent later in the century.

Caught in a congressional quagmire that appeared to offer no rational plan for the development of the country's infrastructure, succeeding presidents attempted to develop some orderly process, but at the same time they worried over possibly unconstitutional intrusions into areas beyond federal authority. We turn our attention to the Executive Branch in part two of this series.

WATER MARKETS: TRANSACTION COSTS AND INSTITUTIONAL OPTIONS

Terence R. Lee
Santiago, Chile

The costs involved in the transfer of property, or transaction costs, can significantly affect the capacity of any market to operate efficiently. If water marketing is to achieve its full potential, markets must be designed to minimize transaction costs. Water marketing may lead, however, to efficiency gains, even if transaction costs are high. Moreover, increasing water scarcity will raise the welfare gains from trade relative to these costs, as the value of water rights increases. Transaction costs can be lowered by technological advance and by institutional design. It can also be expected that transactions costs will fall as the market matures, as learning by doing has its effect.

TRANSACTION COSTS

Transaction costs can be defined as those resources dedicated to establish, operate, and enforce a market system. They may take one of two forms, the services which buyers or sellers must provide from their own resources; the differences (margins) between the buying price and the selling price of a water right, for example, due to the direct financial cost of any brokerage services.

In a water market, there are three potential sources of transaction costs:

the costs of finding trading partners, of verifying ownership of water rights, and of describing the right for purposes of the proposed transfer;

the costs involved in reaching an agreement to trade, such as negotiating the price; arranging financing and other terms of transfer; drawing up contracts; consulting with lawyers and other experts; paying fees for brokerage, legal and insurance services; and transferring legal titles;

the costs of setting up a legal, regulatory and institutional framework, mitigating possible third-party effects, and ensuring compliance with applicable laws.

Water markets tend to be highly regulated, so many transaction costs arise from public policies governing water transfers. The burden imposed by policy-induced transaction costs comes from the direct costs of a transfer and also from the delays due to waiting for regulatory approval. These costs can be high. For example, in the western United States, waiting periods for state agency decisions, vary from 4–6 months in New Mexico, to 5–9 months in Utah, and to an astonishing 20–29 months in Colorado (1,2). It is possible to place institutional restraints on such regulatory induced delays. In Chile, the Water Code regulates the maximum time periods permitted for each stage of any recourse to regulatory intervention (3). This type of institutional requirement, at least, reduces the arbitrariness inherent in regulatory delays.

Transaction costs prevent markets from operating efficiently and reduce the overall economic benefits of water marketing. They increase the cost of water rights and decrease the incentive to trade. Transaction costs introduce inefficiencies, which block equalization of marginal values among different uses, users, and locations. In extreme cases, transaction costs can prevent markets from forming altogether.

These considerations imply that transaction costs usually reduce welfare and that public policies to reduce costs will be welfare improving. This does not mean, however, that all regulation of water markets is bad. Some costs arise from justifiable efforts to protect third-party interests. Such policy-induced transaction costs are not necessarily wasteful or inefficient if they provide real protection for third parties that may be affected by water transfers.

Transaction costs can be independent of the quantity of water rights transferred. The title search, filing fees, and other similar costs are often fixed. This penalizes smaller trades and favors larger trades. Other transaction costs, such as brokers' commissions, may be proportional to the amounts or values traded. More extensive water infrastructure and highly developed user institutions can lower costs. A recent empirical study indicates that, in Chile, transaction costs are particularly low in the areas that have more modern infrastructure and well-developed water users associations (4).

Variations in transaction costs can affect the spatial concentration of market activity. In Texas, for example, the major market activity is concentrated in the Lower Rio Grande Valley where transaction costs are low (5). Transaction costs can also affect the choice of the type of transaction. For example, usually the transaction costs for a permanent transfer exceed those for a lease.

MARKET-RELATED TRANSACTION COSTS

The efficiency of any competitive markets rests on the assumption that good, reliable, and easily accessible information is available. In practice, such information is not always available for water markets, partly because producing and disseminating information is often costly and difficult and, partly, because the means to redistribute risk are incompletely developed due to uncertainty about the nature of the risk and the asymmetry of information between market participants. Altogether, however, the information requirements for efficient water marketing are no greater than those needed for effective administrative allocation of water.

A study of water markets in the western United States concluded that all markets studied were characterized by varying degrees of uncertainty and incomplete access to market information on water commodities, prices, and market opportunities (6). Where there is no ready means for buyers and sellers to obtain information, they face legal, hydrologic, and economic uncertainties. These constitute a substantial cost disincentive to engage in water marketing.

INSTITUTIONAL OPTIONS

Efficient construction of any market requires the existence of the necessary conditions for trading to occur: (1) well-defined property rights, (2) public information on the supply of and the demand for water rights, and (3) the physical and legal possibility for trading to take place. Of these three necessary conditions, by far the most important is the existence of well-defined property rights. In the case of water, property rights define and limit the rights and duties of their holders relative to one another and to the rest of society to the use of a certain amount of water, which may be defined either volumetrically or in terms of shares of a stream or canal flow. If rights are poorly defined, market processes cannot be relied upon to allocate water resources efficiently. It is a basic responsibility of governments, as far as markets are concerned, to define, allocate, and enforce property rights in water. Government policies play a critical role in defining the institutional setting for market operation and provide the basis for market activity by defining, allocating, and enforcing water rights.

The way property rights are defined will structure the incentives and disincentives that members of society face in their decisions regarding water ownership, use, and transfer. For market participants to estimate the value of a water right, they must be able to form secure expectations about the benefits and costs of owning and transferring it and the degree to which it is protected from impairment by others (7).

So, there is a need for a reliable and trusted means of registering rights. Hydrologic information is also required to permit the right to be defined. Various types of information are essential for rational decision-making by water rights holders: the legal and hydrologic characteristics of water rights and the costs of alternative means of obtaining water. This implies the existence of good data and monitoring systems, which can be provided only by public agencies.

The public availability of information on the supply of and the demand for water rights must also include the means to identify willing buyers, sellers and intermediaries or brokers and the means for entering into enforceable contracts. Such information is better provided by the market rather than by public agencies.

In addition, a clearly defined set of transfer rules is necessary to permit market transactions to take place when buyers and sellers determine. Transactions should be contingent only upon compliance with a known set of trading rules or transfer criteria. This is an essential prerequisite for a continuous water market. There must also be information ensuring that the physical possibilities for the transfers produced through trade can actually happen. This may require the legal possibility of easements or the purchase of rights of way across the property of third parties.

AVERTING WATER DISPUTES

Jody W. Lipford
PERC
Bozeman, Montana, and
Presbyterian College
Clinton, South Carolina

INTRODUCTION

At midnight on August 31, 2003, time ran out on a proposed agreement among the states of Alabama, Florida, and Georgia to allocate water in the Apalachicola-Chattahoochee-Flint (ACF) River Basin. The deal had been 13 years in the making, but it ended in failure. "It's a true shame that we were as close as we were and couldn't get an agreement," said Alabama's chief negotiator (1).

It was a shame. The collapse of these lengthy negotiations sends the matter to the courts, and the Supreme Court may ultimately decide how the disputed water will be divided. More broadly, the failure of the state governments to reach agreement reveals that water, long considered plentiful in the southeastern United States, is in danger of becoming a subject of intractable conflict. The failure signals that a water crisis may well emerge in the region unless new approaches to allocating water are adopted.

As the population of the Southeast increases, competing demands for water—for municipal use, for recreation, and for hydropower, to name just a few—are growing. Today the problem surfaces in the form of occasional interstate disputes such as this one, but the failure to resolve them casts an ever-longer shadow over the future of water resources in the region. When demands of competing users outstrip supply, there must be ways to ensure that water goes to the users who value it most and that the waterways of the Southeast are not roiled by unending conflict.

This article explains the reasons behind the conflict in the Apalachicola-Chattahoochee-Flint River Basin, why attempts at resolving it failed, and what alternatives should be considered. It explains how to allocate water to its most productive uses, restore peace to the areas around these waterways, and avert other conflicts that are emerging, not only in these states but elsewhere in the South.

THE BACKGROUND

As shown on the map in Fig. 1, the ACF Basin drains an area of 19,800 square miles in the states of Georgia, Alabama, and Florida. The Basin starts in the headwaters of the Chattahoochee River in northern Georgia, above Atlanta. The Chattahoochee flows through Georgia's Piedmont before turning sharply south, forming the southern half of Georgia's border with Alabama and a notch in Georgia's border with Florida. At the border, it meets the Flint River to form the Apalachicola River, which flows through the Florida panhandle into the Gulf of Mexico (2).

Historically, in the ACF basin, as in most of the southeastern United States, water has been abundant and has met the many demands for it. The demands include water for domestic, commercial, industrial, hydroelectric, navigational, and recreational uses.

Under riparian water rights—the system of water rights in the eastern part of the United States—landowners can use water that flows adjacent to their property as long as they do not appreciably diminish the quantity or quality of water available to downstream users. But riparian rights were effectively overridden in 1946, when Congress authorized the U.S. Army Corps of Engineers to construct dams for flood control, navigation, and hydroelectricity along the Chattahoochee River.[1] Later,

---

[1] The Army Corps of Engineers has long played a role in the ACF River Basin. To facilitate commercial traffic, the Corps began dredging the Chattahoochee River in the 1880s. At present, five Army Corps dams dot the ACF River Basin: the Buford Dam, which forms Lake Sidney Lanier; the West Point Dam, which forms Lake West Point; the Walter F. George Dam, which forms Lake Walter F. George; the George W. Andrews Dam; and the Jim Woodruff Dam, which forms Lake Seminole. Authorization and construction of these dams began in the 1940s, 1950s, and 1960s, and by the 1970s they were all operational (3, pp. 151, 155).

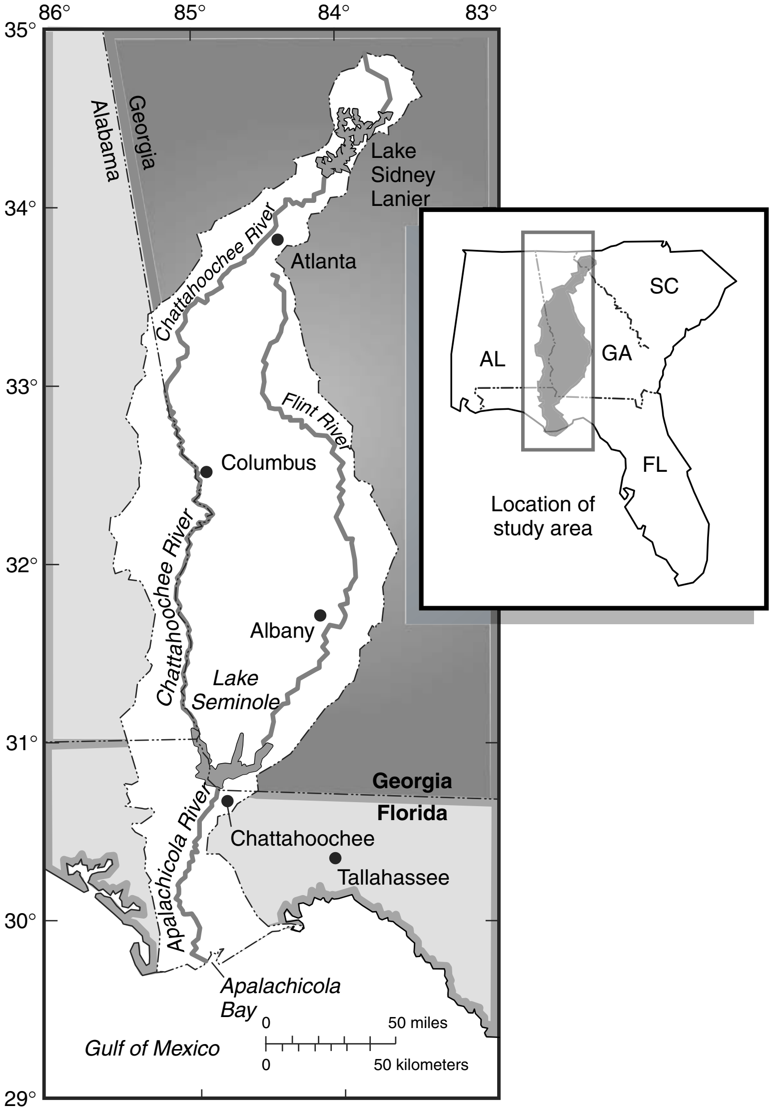

Figure 1. Apalachicola-Chattahoochee-Flint (ACF) River Basin. Courtesy of Mandy-Scott Bachelier.

the Corps added water supply and recreation as purposes of the dams and the reservoirs they created (4,p.2; 5). These projects transformed the waters of the basin from private property governed by the riparian doctrine to public property.

Today, the waters of the ACF River Basin continue to be owned and managed by the federal government through the Army Corps of Engineers. The Corps' managers meet weekly to consider various water needs, such as hydroelectric production, recreation, navigation, and environmental quality (6). In addition, all requests to increase water withdrawals must be approved by the Corps (7, p. 993).

Except for flood control, each of these purposes requires a minimal lake level or river flow rate. Electricity cannot be produced, nor can barges navigate, without sufficient water. Similarly, fish populations require stable lake levels during spawning season. Sufficient flow also dilutes pollution, helping to ensure water quality (6). The Corps also commonly provides recreational facilities, such as parking areas, boat ramps, and public restrooms. Response to the recreational amenities of the lakes has been heavy; millions of user-days are tallied each year (3, p. 158). The Basin also supplies water for public use. All these competing demands limit the amount of withdrawals that can be made.

Conflicts Over Increasingly Scarce Water

For a long time, the system of riparian doctrine and public management through the Army Corps of Engineers worked well. In the 1980s and 1990s, however, rapid population growth, particularly in metropolitan Atlanta, combined with recurrent drought led to increased pressure on the ACF River Basin's resources.

Atlanta's population grew from 2.2 million in 1980 to 3.0 million in 1990, and then to 4.1 million in 2000. Of 126 metropolitan statistical areas listed by the Census Bureau, only 17 had higher population growth rates from 1980 to 1990, and only eight had higher population growth rates from 1990 to 2000.[2]

---

[2] See Table 30 of U.S. Census Bureau (8, pp. 32–34).

Demand for water to satisfy this growing population increased dramatically. Metropolitan Atlanta's water use increased from 289 million gallons per day in 1980 to 459 million gallons per day in 1990, and then to 606 million gallons per day in 2000.[3] Metro Atlanta relies almost exclusively on surface water; over 70% comes from the Chattahoochee River and Lake Sidney Lanier, the lake formed north of Atlanta by the dam at the headwaters of the Chattahoochee.

Yet, the Chattahoochee River and Lake Lanier are ill suited to supplying Atlanta's water needs. The Chattahoochee is the smallest watershed in the country to supply a metropolitan area with the majority of its water (9). The largest share of Atlanta's water use—53.8%—is for residential use; commercial, government, and industrial users take 22.8%, 5.6%, and 4.2%, respectively (10).

A preliminary study by the Army Corps of Engineers indicates that Atlanta is already approaching, and at times exceeding, water use levels that were not expected until 2030. Whether these findings are accurate or not—the Georgia Environmental Protection Division says that the Chattahoochee River and Lake Lanier are sufficient to supply Atlanta through 2030—there is no doubt that future demands on the Chattahoochee River and Lake Lanier will be heavy and growing (11).

Drought has worsened this pressure on the River Basin's waters. During the 1980s and 1990s, the Southeast experienced recurrent and severe droughts. In the most severe drought, rainfall in Atlanta fell by as much as 25%, and annual average streamflows along the Apalachicola River fell to less than half their historical norms.[4]

The Crisis Begins

In 1989, recognizing that Atlanta's "finite supply of clean water is looming as a barrier to growth" (12, p. 68), Atlanta and the Army Corps of Engineers proposed to approximately double the water Atlanta drew from Lake Lanier, to 529 million gallons per day. Without sufficient water, Georgia officials feared the loss of 680,000 jobs and $127 billion in wages through 2010 (13, p. 26).

The proposal by Georgia and the Army Corps alarmed the citizens of Alabama. Increased withdrawals from Lake Lanier would reduce flows along the segment of the Chattahoochee River that forms the southern half of Alabama's border with Georgia and would stunt economic development there. So, in 1990, Alabama sued the Army Corps to keep it from allocating more of the ACF River Basin's waters to Atlanta.

The state of Florida quickly joined the lawsuit on the side of Alabama, fearing that reduced water flows would harm the oyster-rich Apalachicola Bay farther downstream and lead to deterioration of the Apalachicola's water quality. The state of Georgia then joined the lawsuit on the side of the Army Corps of Engineers to defend its withdrawal. The stage was set for 13 years of studies, proposals, counterproposals, and extended deadlines.

These actions reflected unique concerns in each state. Alabama officials worried that Atlanta's withdrawals would stifle Alabama's economic development by limiting water needed for domestic, industrial, and commercial use. Water quality would also suffer because reduced downstream flows would mean less dilution of polluted upstream water. Atlanta not only uses a large amount of water, but also discharges heavily polluted water back into the Chattahoochee (7, p. 996; 12, p. 68–69).[5] If dirtier water came from Atlanta, Alabama might have to raise water cleanup standards for industrial and municipal users, which would be costly and would put Alabama at a competitive disadvantage in attracting economic development (14, p. 3).

From Florida's perspective, the chief problem was oyster beds. Reduced flows, especially at critical times, and heavier pollution could threaten the Apalachicola Bay's oyster industry, which supplies approximately 10% of the country's oysters and employs over 1000 people. The river is also a commercial source of shrimp, blue crab, and finfish, as well as the home of an important sport fishery and the only commercial source of Tupelo honey. It has been recognized as an Outstanding Florida Water (15, p. 34; 16).

Other factors exacerbated the conflict. For example, recreational users want lakes kept full or nearly full; however, the competing objectives of hydropower and flood control require that lakes be drawn down, typically during summer and winter. Similarly, navigation requires minimal flows that reduce the water in lakes when river levels become too low for barge traffic. Finally, ecosystem preservation requires a pattern of flows that mimics nature's seasonal cycle and may conflict with other demands (4, p. 2; 14, p. 3).

Despite years of negotiation, the states never agreed how to allocate the basin's waters. Because these negotiations failed, the matter is now likely to be settled by the Supreme Court.

Constitutional Paths to Solution

Once Alabama took the Corps to court in 1989, the states had several constitutional options to choose from to settle the conflict over water allocation. They could go to Congress for a decision, their suits could reach the Supreme Court, or they could negotiate their own agreement or compact. Neither Congress nor the Supreme Court likes to get involved in interstate water disputes. Moreover, suits reaching the Supreme Court are costly, usually require lengthy negotiations, and yield uncertain outcomes.

For these reasons, the states opted for an interstate water compact. Alabama agreed to deactivate its lawsuit during the negotiation period, the Army Corps of Engineers agreed not to allocate additional water from Lake Lanier to Atlanta, and all parties agreed to a comprehensive study of the water resources in the basin (4,

[4] For data on streamflow of the Apalachicola River at Chattahoochee, FL, see waterdata.usgs.gov/fl/nwis/annual/calendar_year/?site_no=02358000.

[5] In response to federal consent decrees to stop spills of untreated wastewater into the Chattahoochee and to comply with the Clean Water Act, Atlanta is currently trying to raise over $3 billion to renovate its antiquated sewage treatment system.

pp. 3–4).[6] In early 1997, all three state legislatures ratified legislation authorizing the negotiation of an ACF River Basin Compact to allocate the basin's waters. These acts were subsequently signed by the three state governors. The U.S. Constitution requires congressional approval of interstate compacts, so in November 1997, Congress approved and President Clinton signed federal authorizing legislation. The goal of the compact was to assign property rights to water fairly and avoid future conflicts. This goal proved elusive, however.

The Failure of the Compact

The federal legislation set an initial deadline of December 31, 1998 for compact negotiations, unless the states agreed unanimously to extend that deadline.[7] This deadline proved much too optimistic, as each state presented proposals reflecting its parochial interests. To begin with, Alabama and Florida wanted consumptive uses of water defined and limited.[8] Georgia resisted this approach in favor of one that focused on reservoir levels. Specifically, Georgia wanted the ACF River Basin's reservoirs to be kept full or nearly full (19, p. 8), so that Georgia would have enough water to supply Atlanta (4, p. 14). In return, Georgia offered Alabama and Florida minimum flow guarantees. But Alabama and Florida rejected Georgia's proposal, fearing that the minimum flows might become the norm, in essence reducing the water flowing downstream.

To ensure adequate flows along its border, Alabama argued that the ACF River Basin's water should be allocated to meet the original objectives of dam construction. These included navigation (i.e., barge traffic), flood prevention, and hydroelectric production—but not water supply to municipalities or recreation (4, p. 2; 19, p. 9). Florida agreed with Alabama in opposing minimum flows, but also wanted downstream flows to be adjusted to mimic natural flow cycles. Additional problems plagued the negotiations, from definitional questions (e.g., how to define "severe drought") to the choice of the computer model for forecasting river flows and lake levels (19, pp. 9–10).

No agreement was forthcoming, so the states agreed to extend the deadline till January 1, 2000. Yet, the passing of another year did not appreciably advance the negotiations. Once again, the states set a 1-year deadline, establishing a pattern of deadline extensions that continued until July 22, 2003. At that point, progress seemed to have been made. The three governors signed a Memorandum of Understanding that set a blueprint for water allocation in the ACF River Basin. The memorandum authorized water supply for Atlanta from Lake Lanier at 705 million gallons per day and left open the possibility of greater future withdrawals. The memo also established minimum flow requirements downstream from Atlanta; the most important was a flow of 5,000 cubic feet per second on the Apalachicola River at Chattahoochee, Florida. The deadline for final agreement on the memorandum was August 31, 2003 (20).

Although Florida Governor Jeb Bush signed the memorandum, he and other Florida officials had reservations, which they expressed in an accompanying statement (21). They insisted that minimum flows must not become targets, that Lake Lanier must be managed to deal effectively with drought, and that the governing ACF Commission must have authority to approve any withdrawals from Lake Lanier that exceeded the amount specified in the memorandum.[9]

Ultimately, the states could not agree. Florida feared that minimum flows, which had been less than 5000 cubic feet per second only twice during the recent droughts (on a mean monthly basis), might become the norm. Thus, Florida officials again raised the issue of Georgia's withdrawals from Lake Lanier. Georgia officials responded by agreeing either to limit Atlanta's withdrawals or to promise minimum flows through the basin, but not both, and accused Florida of trying to micromanage its waters (23,24). As a result, Florida officials refused to accept the Memorandum of Understanding, and the deal collapsed. The states have now reactivated their original lawsuits (1,5,24).[10]

THE ALLOCATION OF WATER

Economists recognize the scarcity of valuable resources. Without prices on these resources, there is not enough to satisfy all who want to use them. In most settings, however, market prices allocate resources and allow them to move to those users who value them the most. This market process allocates resources to their most productive uses and maximizes society's wealth. In the case of the ACF River Basin water, however, market prices do not currently allocate water; it is allocated politically.

Economists also recognize that resources have multiple uses. Water, for example, may be used to generate

---

[6] Until the compact was completed, the states agreed to "freeze" water at current use levels. Should increased withdrawals be needed, the states agreed to notify other states in advance (17, p. 202). For further details, see Public Law 105-104, Article VII (c).

[7] [Public Law 105-104, Article VIII (3)].

[8] Consumptive use, also known as water consumed or water depleted, may be defined as the "part of water withdrawn that is evaporated, transpired, incorporated into products or crops, consumed by humans or livestock, or otherwise removed from the immediate water environment." The definition also includes "any water withdrawn in the basin and transferred out of the basin for use" (18).

[9] Sixty-four percent of the ACF River Basin's reservoir capacity is held in Lake Lanier (22).

[10] Complicating the legal proceedings is a deal struck by Georgia and the Army Corps of Engineers in January 2003 in which metropolitan Atlanta governments agreed to pay the Corps $2.5 million per year toward the operation of Lake Lanier's Buford Dam in exchange for greater withdrawals from the lake. With this deal, metropolitan Atlanta sought not only to obtain additional water, but also to mollify hydropower customers who pay for the dam and who had filed suit against the Corps in 2000 because the Corps had already allocated water from hydropower to supply metropolitan Atlanta. Georgia and the Corps negotiated this deal without informing Alabama or Florida and set it aside only when Alabama and Florida found out about it and threatened to withdraw from the compact negotiations. This deal, like the initial lawsuits between the states and the Corps, has been reactivated and will have to be settled by the courts (5,25).

electricity; aid oyster production; provide wildlife habitat; produce industrial products; provide channel depth for barges; provide recreational opportunities for boaters, skiers, and fishers; or supply households with water for drinking, watering lawns, or filling swimming pools. In the ACF Basin, some water is used in each of these ways.

Whether allocation occurs through market prices or other methods, it is rarely all-or-nothing. In the Southeast (and the United States generally), there is ample water to supply basic human needs, such as drinking water. Where conflicts occur, as in the ACF Basin, it is over shifting some water, not all water, from one use to another. Simply put, the ACF Basin issue is whether more water should be allocated to Atlanta, presenting Alabama and Florida with the prospect of less water but not complete deprivation.

Although compacts have some advantages over congressional or judicial apportionment, they are poorly suited to allocate water in ways that maximize water's productive value to society. Compacts are highly political and confront intractable information problems, and such was the case with the negotiations over the ACF Basin's waters.

Interest Groups

Groups with a vested interest in the outcome of the compact influenced the ACF River Basin negotiations. Each tried to get more water allocated in its favor, irrespective of water's most productive uses. The influence of these groups introduced conflict, making a workable agreement difficult to achieve. Industrial, environmental, municipal, and political interests all made their voices heard (19, p. 8). The *Atlanta Journal-Constitution* identified political and business leaders of metropolitan Atlanta, environmentalists, and Florida's shellfish and fishing industries as uncompromising interest groups who refused to yield to the demands of other users (1).

The Apalachicola Bay's oyster industry serves as an example of a small, well-organized interest group with strong influence; its employment of approximately 1000 people is minimal in a state with total employment of approximately 7.2 million.[11] Note, however, that the industry had support throughout the state of Florida from citizens who wanted the environmental amenities of their state's river preserved.

After the agreement failed, some interests, such as the Atlanta Regional Commission and homeowners and businesses on Lakes Lanier and West Point, seemed just as happy. They feared that Georgia had compromised too much already.

Informational Problems

Even if negotiators could be insulated from interest group influence, they would still face important informational questions. If their goal is to allocate the water to its most productive uses, negotiators must first know how much total water can be allocated and how that will vary over years of normal rainfall and drought. Perhaps most important, they need to determine whether society will benefit more from allocating water to Atlanta's developers, say, or to Florida's oyster producers. And, if they can decide objectively to allocate more water to Florida's oyster producers, they would still have to decide whether the extra water should come from Lake Lanier (thereby maintaining levels at downstream reservoirs) or from downstream reservoirs (thereby maintaining levels at Lake Lanier).

By making these decisions, policy makers are implicitly choosing who will benefit and who will be harmed. A decision to allocate more water to Atlanta lessens development in eastern Alabama and reduces Florida's seafood production. A decision to allocate more water to Alabama and Florida benefits the economies of these states, but curbs Atlanta's economic development. Similarly, a decision to supply downstream users from Lake Lanier diminishes recreational opportunities for users of that lake and maintains those opportunities for users of downstream reservoirs; the opposite decision would benefit Lake Lanier's recreational users but harm those who use downstream reservoirs. And even if policy makers could determine water's most productive uses, their decisions would soon be rendered obsolete by changes in the total supply of water, changes in the total demand for water, and marginal changes in allocation necessary to maximize the total productive value of the basin's water resources.

Negotiators did try to obtain answers to some of the technical questions through the use of computer software that forecast future river flows and reservoir levels based on consideration of "historic rainfall patterns over the last fifty-five years" and "anticipated water uses within the basin in a future year, typically 2030 or 2050" (19, p. 8). But repetition of historical rainfall patterns is not guaranteed. Nor are anticipated water uses easily forecast. Atlanta's rapid population growth and commensurate water use have been dramatically underpredicted by the experts.[12] To compound matters further, different software programs give different estimates, and, not surprisingly, the states have used different modeling programs (19, p. 10).

Practical Problems

Negotiators confronted two other factors that made agreement less likely: (1) The ACF River Basin's waters were already fully allocated, and (2) the drought was expected to end soon. That the water wealth of the ACF River Basin is already fully allocated made bargaining more contentious because changes will force redistribution of existing allocations. In contrast, for example, the country's first interstate water compact, the Colorado River Compact of 1922, was negotiated in the arid West, and more water was anticipated from the Boulder Canyon Project Act, which authorized the Hoover Dam and created Lake Mead. Moreover, negotiators knew that the 1998–2002 drought was unprecedented and would likely come to an end, reducing pressures on the ACF River Basin's waters. These expectations were borne out;

---

[11] The employment figure is taken from table 602 of U.S. Census Bureau (8, p. 393).

[12] The *State and Metropolitan Area Data Book, 1997–98* predicted that metropolitan Atlanta's 2000 population would be 3.682 million (26). The actual figure was 4.112 million, an error of 430,000 for a prediction published only 2 years in advance.

abundant rain fell during the latter half of 2002 and during 2003.[13]

PROPOSALS FOR MARKETING WATER

With compact negotiations now in disarray, policy makers must look to other alternatives. An obvious proposal is for Atlanta (and other municipalities in the basin) to charge a price for its water that at least approximates its market value. Ample evidence shows that higher water prices reduce consumption (27, p. 12–13). At present, water is underpriced in Atlanta, leading to overuse. Even in the most recent drought, the city of Atlanta raised its price to residential users by only 3%. For the average residential user, the monthly water bill rose from $16.55 to $17.05. The city plans additional rate hikes through 2004, but these will raise average residential bills by a mere $1.00 per month (28). During the drought, rather than raising the price of water further, officials imposed restrictions on outdoor water use that continue in effect (29,30).

Raising water prices to market levels is apparently not politically feasible. This means that the states of Alabama, Florida, and Georgia and the federal government should consider basinwide proposals to create water markets. Experience with markets in water has shown that they can overcome some of the most difficult challenges of water allocation. They can ensure that water is allocated to its most productive uses and can prevent conflicts among users.

To some, marketing water is still a strange idea. Long accustomed to the notion that water is a commonly owned resource, many readers may doubt that it is feasible to "trade" water and thereby satisfy various interests more readily than through political negotiations. Yet, there is a strong precedent for marketing of water. Much of the American West is arid; it receives less than 17 inches of precipitation a year. With water always precious, the West evolved a system of private property rights to water, and with it, water markets. This system, known as the prior appropriation doctrine, resulted from the need to divert water for mining and agriculture. In simplest terms, it allowed a person to divert water from a river or stream on the basis of seniority (or "first in time, first in right"); the right remained as long as the individual continued to use the water ("use it or lose it"). Water users could transfer their rights to others. The private provision of water flourished (31, p. 31–45), and continues to do so, although laws that guide the transfers of water are somewhat antiquated, and restrictions on transfers that made sense in the past do not necessarily encourage efficient use today.

In spite of these restrictions, water trades occur among agricultural users, between agricultural users and cities, and between agricultural users and environmentalists. Even interbasin and interstate trades are common (27, p. 14–21). In Texas, where both riparian and prior appropriation doctrines are recognized, a system of marketable permits similar to that described below allocates water along the Rio Grande River (32).

In a fully functioning water market, users pay a market price for water consumed, and that price serves as a rationing mechanism. Those who can put the water to the most productive use and demonstrate this by willingness to pay, will purchase the water, be they residential developers or oyster producers. Market prices motivate those with relatively less productive opportunities to sell the water to more productive users. Through markets, groups can work out slight or marginal changes that maximize the total value from all uses.

Markets also yield peace among transacting parties. In markets, only the parties considering buying or selling a resource take part in the negotiations. Outside influences from politicians, bureaucrats, or interest groups do not guide the negotiations, as they do in the political process. The terms of exchange, such as the price, must be voluntarily agreed upon for exchange to occur. Any would-be buyer or seller who does not like the price does not have to buy or sell.

In contrast, in the political sphere, resource users often do not pay a price for a resource they consume, or they pay less than the resource's market value. This encourages them always to want more and leads to conflicts among users and a state of perpetual unhappiness for all.

As economists often point out, the foundation for markets is private property rights that are defined—that is, rights with a clearly specified ownership claim; enforced—that is, rights with a claim that is secure; and transferable—that is, rights that may be sold to others. Clearly defined, enforced, and transferable property rights are necessary for exchange. Buyers will not purchase resources if the rights to those resources are uncertain or insecure, but when rights to property are certain, secure, and transferable, markets flourish. Market-based allocation of the ACF River Basin's waters would encourage allocation of the basin's waters to their most productive uses and foster peace among users.

The Army Corps' Role

To understand how markets might work, it is appropriate to begin with the Army Corps of Engineers, which is the effective owner of the water in the ACF Basin. At present, the Corps almost entirely depends on congressional appropriations. In the Mobile District in which the ACF River Basin is located, the Corps receives some fees for its services, but they represent a small part of the Corps' budget. The fees it receives are either insufficient to cover the costs of its services (as in recreation fees), the Corps does not retain the revenues (as in the case of revenues from hydropower), or it simply does not charge for the services it provides (as for navigational services, although commercial vessels do pay a fuel tax that is used to fund inland waterway projects).

The Corps is supported by taxpayer dollars and cannot receive financial benefit from the services it provides, so it has no incentive to determine which competing uses are most productive and thus to adopt market exchange as the

---

[13] From July 2002 to August 2003, rainfall exceeded normal levels in Atlanta, Columbus, and Albany, Georgia, by 9.64 inches, 12.21 inches, and 6.57 inches, respectively (data supplied by Pam Knox, assistant state climatologist, Georgia State Climatology Office, University of Georgia, Athens, e-mail correspondence, October 15, 2003).

way to allocate water in the Basin. In an ideal world, the Corps' financing and function would be changed to give it an incentive to allocate scarce water resources to their most productive uses, thereby raising the total wealth generated from the Basin's waters. This would happen if the Corps were to retain property rights and management authority over the Basin's waters, but taxpayer support of the Corps and its projects were reduced. In exchange, the Corps would be given the authority to charge whatever fees it deemed appropriate for the services it provided and to retain the revenues. For example, the Corps could implement or change fees it charges for hydropower, dredging, water supply, and recreational services. If drought or increased demand raised the relative scarcity of water, the Corps would have the authority to raise fees. Some taxpayer support is justified because the Corps also provides flood control that benefits all users.

Although the Corps is extremely powerful in Congress and therefore such a change in the financing of the Corps is unlikely, there is some precedent for this kind of institutional reform of a public agency. In 1996, the Fee Demonstration Program allowed the National Park Service, the Forest Service, the Bureau of Land Management, and the Fish and Wildlife Service each to choose 100 sites that could raise or implement new fees and retain 80% of the revenues. Although the Fee Demonstration Program does not intend self-sufficiency for the participating agencies or individual sites, the results from changed incentives are evident, as these agencies have improved services to visitors of public lands by allocating more funds to badly needed repair and maintenance of some of the country's most-valued natural and recreational resources (33). Like the Fee Demonstration program, reform of the Army Corps of Engineers could begin on a short-term, experimental basis.

With a mandate to balance its budget and the authority to set fees and retain revenues, the Corps would have an incentive to allocate water resources to their most productive uses. If Atlanta developers wanted more water, they would have to pay a price that reflected the value of the water to other users. If it did not, those other users would outbid it. The Corps would also have to take into account the costs of its services. If barge traffic was insufficient to generate revenues to cover the costs of dredging, the Corps would cease to dredge the basin. Through this system, those with the most productive opportunities for the water would be the ones to obtain it. Such allocation would also maximize the Corps' net revenues. Unfortunately, this outcome is not very likely to occur in a political setting.

A System of Marketable Permits

Under current political arrangements, marketable permits seem to be the most promising approach to creating a water market. Marketable permits depend on the assignment of property rights to water. To implement them in the ACF River Basin, the Army Corps of Engineers could first establish a daily "water budget," consisting of the total net withdrawals allowed from the basin, based on average daily withdrawals from some past period of consumption. After this global budget is established, the Army Corps of Engineers could grant water allocations to each user based on average daily use, again from some period of past consumption. Even though hydropower producers, barges, and oyster producers do not strictly divert water, the water they use is "diverted" from the Basin into the Gulf of Mexico and therefore should be measured for the allocation. By making the allocations daily, the Corps would allow for seasonal variations in demand and flood control. Permit allocations would be divisible and transferable. And, of course, under no condition could water be allocated in a way that violates federal water use laws.

When the supply of rainfall was abundant, so that water in the Basin exceeded the global daily budget, all users could be satisfied without the need to transfer water among users. However, in the case of drought, the Army Corps of Engineers could cut daily permit allowances by an equal percentage for all users. The Corps could then serve as a water broker, facilitating transactions among users by matching buyers and sellers and helping to negotiate terms of exchange, while charging a fee to cover administrative costs. Similarly, if the demand for water rises to the point that it exceeds the global daily budget, users who want more water would have to purchase that water from other users.

To see how this might work, consider a simplified example with two users, a lake, and a river running downstream from the lake. Suppose the two users are Atlanta developers and Florida oyster producers, the lake named Lake Lanier, and the river the Chattahoochee. Suppose that for a given day, the water budget for this river basin is 1000 gallons, allocated between 800 gallons for Atlanta developers and 200 gallons for Florida oyster producers. (Actual quantities would, of course, be in the millions of gallons per day.)

If rainfall allows greater net withdrawals, say to 1100 gallons, each user's allotment can rise by 10%. A drought, however, might reduce net withdrawals to 900 gallons, forcing cuts in permitted allotments to 720 gallons for Atlanta developers and 180 gallons for Florida oyster producers. This is where trading comes in. If Atlanta's developers want to restore their allocation, they must offer to purchase an additional 80 gallons from Florida's oyster producers. If the contracting parties agree, the Army Corps will release less water from Lake Lanier, increasing the amount available to Atlanta's developers and reducing the downstream flow for Florida's oyster producers.

If, in contrast, Florida's oyster producers want to retain a flow of 200 gallons, they will offer to purchase an additional 20 gallons from Atlanta developers. If the parties agree, this time the Army Corps of Engineers will release more water from Lake Lanier, reducing the amount available for Atlanta's developers but increasing the flow for Florida's oyster producers.

One can envision associations of users with similar wants, such as an upstream association of developers and recreational users and a downstream association of hydroelectric utilities, barges, environmentalists, and oyster producers. At times, association members would benefit by combining funds and sharing costs.

Purchasing water allotments to retire (i.e., not use) them should also be allowed. For example, if electric utilities want to increase downstream flows to generate electricity at the same time that recreational users want lake levels held high, as on a summer holiday weekend, the recreational users could purchase water rights from the electric utilities, if the utilities agreed, and retire those rights. Instead of producing revenues through hydropower, the electric utilities would receive payments from recreational users. Similarly, environmentalists might want to purchase and use or retire rights during seasons when fish spawn.[14]

In each of the exchanges described, the amount of water traded would be a small portion, not all of the total allowances. For example, recreational users would be likely to purchase some, but not all, of the electric utilities' water. Lake levels would fall enough to generate some electricity, but not as much as they would fall if recreational users did not purchase some of the water rights.[15]

To be effective, these marketable permits must have the key characteristics of property rights: They must be clearly defined, so that each user knows its allocation for each day; enforced, with the Army Corps of Engineers serving as enforcer of the permit allowances through its monitoring of lakes and dams; and transferable, with transfer facilitated by the Army Corps of Engineers serving as broker. With defined, enforced, and transferable property rights, a water market could develop that would ensure an allocation of water to its most productive uses and peace among contracting parties.

As an alternative to water transfers among users at mutually agreed upon prices, the Corps could advance market allocation by establishing a water bank. The Corps could serve as an underwriter that buys and sells water at specified prices, with the spread between these prices used to cover the costs of administering the bank. Such banks have been used in times of drought. For example, water banks were used successfully in 1977 and 1991 in California to cope with drought. In 1991, California offered to purchase water at a price of $125 per acre-foot and to sell water at a price of $175 per acre-foot. The state purchased and sold 400,000 acre-feet of water, mostly to municipal and agricultural users (31, pp. 11–12, 102–103).

In the ACF River Basin, the Army Corps of Engineers could assign to users daily property rights to flows of water, based on historic use patterns, and then serve as a water banker, standing ready to buy and sell water at specified prices. Depositors could leave water in the Basin, and withdrawers could buy it. With price playing an allocative role and with voluntary transactions, the Basin's waters would be allocated more efficiently, and relations among the ACF River Basin's users would become more harmonious.

Implications for the Southeast

Making these kinds of changes in the ACF River Basin is critical because water conflicts are brewing throughout the Southeast. Along Georgia's border with South Carolina, a request by Habersham County, Georgia, to withdraw 12.5 million gallons per day from the Savannah River Basin provoked the South Carolina state legislature to introduce resolutions calling on Congress to stop the Army Corps of Engineers from granting the request, which would have transferred water from the Savannah River Basin to the ACF Basin.[16] In addition, Georgia is involved in a dispute with Alabama over water in the Alabama-Coosa-Tallapoosa River Basin. And North Carolina and South Carolina have disputed the flow of water in the Yadkin-Great Pee Dee River Basin (35–37). By establishing water markets in the ACF River Basin, the states of Alabama, Florida, and Georgia could serve as an example to other southeastern states to help them avoid the conflicts that have for so long plagued the attempts to allocate that Basin's waters.

WHAT CHANCE FOR CHANGE?

Market reforms offer great potential, but when government is in control, change typically comes about only with crisis. Higher rainfall since the summer of 2002 has diminished the sense of crisis. Does this mean that all hope is lost for market allocation of water in the ACF River Basin or elsewhere in the Southeast? Not at all.

By failing to achieve compact resolution, the states of Alabama, Florida, and Georgia have embarked down the risky path of judicial apportionment. The risk is that the Supreme Court could allocate the ACF River Basin's waters in a way that is unsatisfactory to each or all of the states (17, p. 226). Because these allocations are not transferable, states with an unsatisfactory allocation would have no way, short of further litigation, to change the allocation. As the states contemplate this possibility, they may find it prudent to drop their lawsuits and pursue a means of allocating water that relies on markets, such as one of the proposals offered in this article.

Once demand permanently outstrips supply under current arrangements, water in the Southeast will be rationed. The question will be how. Will water be rationed by markets, which promote productive use and harmony among users? Or will it be rationed by political processes that are likely to result in misallocation and conflict? As economic development continues, perhaps plagued by drought, the citizens of the Southeast may choose the efficiency and harmony of markets over the misallocation and contention of politics.

[14] Retiring rights requires some ranking among users. If hydropower users have the higher ranking, recreational users would have to purchase rights from them to keep lake levels up. On the other hand, if recreational users had the higher ranking, hydropower users would have to purchase rights from them to drop lake levels. Coase (34) argues that clearly defined property rights and sufficiently low transaction costs will lead to allocating resources to their most productive uses.

[15] With less water for hydroelectric production, utilities might have to raise prices to their customers.

[16] Before this conflict could escalate, Habersham County withdrew its permit request.

WATER SUPPLY AND WATER RESOURCES: DISTRIBUTION SYSTEM RESEARCH

Mark C. Meckes
Roy C. Haught
U.S. Environmental
Protection Agency

Two water distribution system simulators (DSS) are in operation at the U.S. EPA Test and Evaluation (T&E) Facility in Cincinnati, Ohio. The T&E Facility is a multifaceted research resource in which a wide variety

---

of water treatment and other environmental protection technologies are conceived, designed, and evaluated in the laboratory, bench, and pilot plant scale. The EPA designed and fabricated the DSS systems to evaluate and understand the dynamics which influence water quality within water distribution infrastructure systems in the United States and abroad. The first distribution system simulator (DSS-1) has continuous flow conditions. There are six individual 75 ft (25 meter) lengths of 6 in (15 cm) diameter ductile iron pipe arranged into "pipe loop" configurations to simulate a distribution system. This pipeloop system can be configured to operate as; independent/individual loops, collectively as one unit, or in various experimental configurations to complement EPA's experimental research. DSS-1 is equipped with two 1500 gallon reservoir tanks to simulate a comprehensive distribution infrastructure system. This unique engineering design permits operating any combination and configuration of the six loops under various experimental operating parameters (Table 1). Each loop is insulated and fitted with a heat exchanger to maintain constant temperature conditions during operation. The DSS is interfaced with a Supervisory Control and Data Acquisition (SCADA) system, which is used to monitor, control, and archive operating conditions and collected data continuously. Bioflim samples are collected on coupons [View1–View2] which are set flush with the interior surface of the pipe wall. The coupons may be removed for sampling and analysis without disrupting water flow.

The second distribution system (DSS-2) is over 300 feet long and is a once through system composed of six inch diameter PVC pipe. This unit is being utilized to evaluate water quality in a dead end branch of a distribution system and to develop design models for water distribution. Both DSS units are located above ground to permit easy access to the entire pipe network. Experimental studies (Table 2) are ongoing to understand the physical, chemical, and biological activities that occur in drinking water distribution systems.

Table 1. Operating Parameters Of The Distribution System Simulator

Parameter	Normal Operation	Experimental Test Conditions
Distribution system simulator	Parallel (6 individual distribution system simulators)	Parallel or series in groups of 6, 3, 2, or 1
Housing	Ductile iron (Non-lined)	Ductile iron (Non-lined)
Flow	88 gpm or 1 ft/s	No Flow to 140 gpm or 0 to 1.6 ft/s
Temperature	60 °F (15.5 °C)	35 °F (1.6 °C) to Ambient
Chemical control	Free chlorine 1.0 ppm	Chemical control as needed
pH	7.0 to 7.5	Control/monitor as needed
Turbidity	< 0.5 NTU	Control/monitor as needed
Water supply	Cincinnati—tap water (Chlorinated)	Dechlorinated, deionized, tanked, surface water (River)

OBJECTIVES

The DSS provides researchers with a mechanism to study how water quality is affected during distribution. Results from research studies (Table 2) will be used to provide guidance on how to maintain a high level of water quality during distribution. A secondary objective to this project is to develop, evaluate, and demonstrate real time monitoring of water quality parameters within distribution systems using remote telemetry. Results from research will be used to provide guidance on how to utilize remote monitoring of water quality to detect changes in water quality within distribution systems.

RELEVANCE

Throughout the world there are millions of miles of water distribution pipe lines which provide drinking water for use by individuals and industry. Although these distribution systems provide drinking water to the world, very little is known about the physical, chemical, and biological activities that occur within them. Some of these water distribution systems have been in service well over one hundred years. DSS-1 has been in operation for over three years, as water moves through distribution systems, it comes into contact with a wide range of material some of which can cause significant changes to the quality of the finished water supply. Suspended solids in finished water can settle out under low flow conditions and can be suspended during high flow. Various disinfection agents and water additives react with organic and inorganic materials within a distribution system generating by-products which may be undesirable in the water supply. Oxidant resistant microorganisms colonize pipe surfaces producing a complex micro environment known as "biofilm". Biofilms are highly resistant to many disinfection methods and techniques. Our research looks at the various experimental test parameters which influence biofilm growth. This work will also help EPA

Table 2. Proposed DSS Studies

No	Title of Proposed Study
1	Preliminary Studies of Biofilm Formation in Pilot-Scale Distribution Systems
2	Opportunistic Pathogens in Biofilms
3	Effect of a Pollution Event on a Simulated Water Distribution System
4	Impact of Nutrient Removal on Growth Potential for Bacteria
5	Impact of Alternative Treatment on Biofilm Growth
6	Real-Time Monitoring and Control of Distribution Systems
7	Effects of pH Changes on Biofilm Growth in a Distribution System
8	Bacterial Growth in Distribution Systems

develop a better understanding of the dynamics inside distribution systems.

RESEARCH GOALS

Fabricate aboveground water distribution system simulator's which permit easy access and can be operated under controlled conditions. Conduct studies to develop a better understanding of the dynamics that occur in drinking water distribution systems. Determine what physical, chemical, and biological factors influence biofilm growth within such systems. Develop and test mechanisms for the enhancement and control of biofilm growth within a simulated distribution system. Additionally, develop and evaluate real time monitoring, data collection, and archiving of water quality parameters within water distribution systems using remote telemetry. Results will be used to develop and provide guidance on ways to maintain high levels of water quality through distribution systems.

DROUGHT IN THE DUST BOWL YEARS

National Drought Mitigation Center

INTRODUCTION

In the 1930s, drought covered virtually the entire Plains for almost a decade (1). The drought's direct effect is most often remembered as agricultural. Many crops were damaged by deficient rainfall, high temperatures, and high winds, as well as insect infestations and dust storms that accompanied these conditions. The resulting agricultural depression contributed to the Great Depression's bank closures, business losses, increased unemployment, and other physical and emotional hardships. Although records focus on other problems, the lack of precipitation would also have affected wildlife and plant life and would have created water shortages for domestic needs.

Effects of the Plains drought sent economic and social ripples throughout the country. For example, millions of people migrated from the drought areas, often heading west, in search of work. These newcomers were often in direct competition for jobs with longer-established residents, which created conflict between the groups. In addition, because of poverty and high unemployment, migrants added to local relief efforts, sometimes overburdening relief and health agencies.

Many circumstances exacerbated the effects of the drought, among them the Great Depression and economic overexpansion before the drought, poor land management practices, and the areal extent and duration of the drought. [Warrick et al. (2) and Hurt (3) discuss these issues in greater detail.] The peculiar combination of these circumstances and the severity and areal coverage of the event played a part in making the 1930s drought the widely accepted drought of record for the United States. To cope with and recover from the drought, people relied on ingenuity and resilience, as well as relief programs from state and federal governments. Despite all efforts, many people were not able to make a living in drought-stricken regions and were forced to migrate to other areas in search of a new livelihood. It is not possible to count all the costs associated with the drought of the 1930s drought, but one estimate by Warrick (1) claims that financial assistance from the government may have been as high as $1 billion (in 1930s dollars) by the end of the drought. Fortunately, several lessons were learned that were used in reducing the vulnerability of the regions to future droughts.

THE GREAT DEPRESSION AND OVERCAPITALIZATION

In the early 1920s, farmers saw several opportunities for increasing their production. New technology and crop varieties were reducing the time and costs-per-acre of farming, which provided a great incentive for agricultural expansion. This expansion was also necessary to pay for expensive, newly developed equipment (such as listers and plows) that was often purchased on credit, and to offset low crop prices after World War I.

When the national economy went into decline in the late 1920s because of the Great Depression, agriculture was even more adversely affected. In addition, a record wheat crop in 1931 sent crop prices even lower. These lower prices meant that farmers needed to cultivate more acreage, including poorer farmlands, or change crop varieties to produce enough grain to meet their required equipment and farm payments.

When drought began in the early 1930s, it worsened these poor economic conditions. The depression and drought hit farmers on the Great Plains the hardest. Many of these farmers were forced to seek government assistance. A 1937 bulletin by the Works Progress Administration reported that 21% of all rural families in the Great Plains were receiving federal emergency relief (4). However, even with government help, many farmers could not maintain their operations and were forced to leave their land. Some voluntarily deeded their farms to creditors, others faced foreclosure by banks, and still others had to leave temporarily to search for work to provide for their families. In fact, at the peak of farm transfers in 1933–34, nearly 1 in 10 farms changed possession, with half of those being involuntary (from a combination of the depression and drought).

POOR LAND MANAGEMENT PRACTICES

A number of poor land management practices in the Great Plains region increased the vulnerability of the area before the 1930s drought. Some of the land use patterns and cultivation methods in the region can be traced back to the settlement of the Great Plains nearly 100 years earlier. At that time, little was known of the region's

---

climate. Several expeditions had explored the region, but they were not studying the region for its agricultural potential, and, furthermore, their findings went into government reports that were not readily available to the general public (5). Misleading information, however, was plentiful. "Boosters" of the region, hoping to promote settlement, put forth glowing but inaccurate accounts of the Great Plains' agricultural potential. In addition to this inaccurate information, most settlers had little money or other assets, and their farming experience was based on conditions in the more humid eastern United States, so the crops and cultivation practices they chose often were not suitable for the Great Plains. But the earliest settlements occurred during a wet cycle, and the first crops flourished, so settlers were encouraged to continue practices that would later have to be abandoned. When droughts and harsh winters inevitably occurred, there was widespread economic hardship and human suffering, but the early settlers put these episodes behind them once the rains returned. Although adverse conditions forced many settlers to return to the eastern United States, even more continued to come west. The idea that the climate of the Great Plains was changing, particularly in response to human settlement, was popularly accepted in the last half of the 19th century. It was reflected in legislative acts such as the Timber Culture Act of 1873, which was based on the belief that if settlers planted trees they would be encouraging rainfall, and it was not until the 1890s that this idea was finally abandoned (6). Although repeated droughts tested settlers and local/state governments, the recurrence of periods of plentiful rainfall seemed to delay recognition of the need for changes in cultivation and land use practices.

Several actions in the 1920s also increased the region's vulnerability to drought. Low crop prices and high machinery costs (discussed above) meant that farmers needed to cultivate more land to produce enough to meet their required payments. Since most of the best farming areas were already being used, poorer farmlands were increasingly used. Farming submarginal lands often had negative results, such as soil erosion and nutrient leaching. By using these areas, farmers were increasing the likelihood of crop failures, which increased their vulnerability to drought.

These economic conditions also created pressure on farmers to abandon soil conservation practices to reduce expenditures. Furthermore, during the 1920s, many farmers switched from the lister to the more efficient one-way disc plow, which also greatly increased the risk of blowing soil. Basically, reductions in soil conservation measures and the encroachment onto poorer lands made the farming community more vulnerable to wind erosion, soil moisture depletion, depleted soil nutrients, and drought.

DROUGHT DURATION AND EXTENT

Although the 1930s drought is often referred to as if it were one episode, there were at least four distinct drought events: 1930–31, 1934, 1936, and 1939–40 (7). These events occurred in such rapid succession that affected regions were not able to recover adequately before another drought began. Historical maps of U.S. climate divisions and graphs of U.S. river basins reflect this situation.

COPING WITH AND RECOVERING FROM DROUGHT

During the 1930s, many measures were undertaken to relieve the direct impacts of droughts and to reduce the region's vulnerability to the dry conditions. Many of these measures were initiated by the federal government, a relatively new practice. Before the 1930s drought, federal aid had generally been withheld in emergency situations in favor of individual and self-reliant approaches. This began to change with the development of the Great Depression in the late 1920s and the 1933 inauguration of President Franklin Delano Roosevelt. The depression helped "soften deep-rooted, hard-line attitudes of free enterprise, individualism, and the passive role of the government", thus paving the way for Roosevelt's New Deal programs, which in turn provided a framework for drought relief programs for the Great Plains (1).

Warrick et al. (2) describe these drought relief programs, which are credited with saving many livelihoods throughout the drought periods. The programs had a variety of goals, all of which were aimed at the reduction of drought impacts and vulnerability:

- Providing emergency supplies, cash, and livestock feed and transport to maintain the basic functioning of livelihoods and farms/ranches.
- Establishing health care facilities and supplies to meet emergency medical needs.
- Establishing government-based markets for farm goods, higher tariffs, and loan funds for farm market maintenance and business rehabilitation.
- Providing the supplies, technology, and technical advice necessary to research, implement, and promote appropriate land management strategies.

As important as these programs may have been, the survival of a majority of the families and enterprises undoubtedly rested solely with their perseverance and integrity. Whether they stayed or moved into the drought regions or migrated to other areas in hopes of a better life, families encountered new hardships and obstacles that would require ingenuity, resilience, and humility. Those who remained in the drought regions were forced to endure severe dust storms and their health effects, diminished incomes, animal infestations, and the physical and emotional stress over their uncertain futures. Humor helped; tales about birds flying backward to keep from getting sand in their eyes, housewives scouring pots and pans by holding them up to keyholes for a sandblasting, and children who had never seen rain were among the favorite stories of Dust Bowl inhabitants. In the end, it was a combination of willpower, stamina, humor, pride, and, above all, optimism that enabled many to survive the Dust Bowl. These qualities are succinctly expressed in the comments of one contemporary Kansan: “We have faith in the future. We are here to stay” (quoted in Ref. 3).

The 1930s drought and its associated impacts finally began to abate during spring 1938. By 1941, most areas of the country were receiving near-normal rainfalls. These rains, along with the outbreak of World War II, alleviated many of the domestic economic problems associated with the 1930s. In fact, the new production demands and positive climatic conditions brought the United States into a rapid economic boom.

Even though short-term conditions seemed to be relatively stable, there were some drawbacks to this production growth. One drawback (described in Ref. 3) was that the start of World War II shifted remaining funds and priorities away from drought-related programs. Men were taken off work programs to enter the armed forces and to produce for the war effort. Moreover, items such as gasoline and replacement parts were redirected from federal drought and conservation programs to the war efforts. This meant that conservation programs and research were significantly reduced during this period. Another drawback was that with the return of the rains, many people soon forgot about conservation programs and measures implemented during the 1930s droughts. This led to a return to some of the inappropriate farming and grazing practices that made many regions so vulnerable to drought in the 1930s.

1930s DROUGHT COSTS

Although the 1988–89 drought was the most economically devastating natural disaster in the history of the United States (7), a close second is undoubtedly the series of droughts that affected large portions of the United States in the 1930s. Determining the direct and indirect costs associated with this period of droughts is a difficult task because of the broad impacts of drought, the event’s close association with the Great Depression, the fast revival of the economy with the start of World War II, and the lack of adequate economic models for evaluating losses at that time. However, broad calculations and estimates can provide valuable generalizations of the economic impact of the 1930s drought.

Overall Drought Costs

In 1937, the Works Progress Administration (WPA) reported that drought was the principal reason for economic relief assistance in the Great Plains region during the 1930s (4). Federal aid to the drought-affected states was first given in 1932, but the first funds marked specifically for drought relief were not released until the fall of 1933. In all, assistance may have reached $1 billion (in 1930s dollars) by the end of the drought (1).

According to the WPA, three-fifths of all first-time rural relief cases in the Great Plains area were directly related to drought, with a disproportionate amount of cases being farmers (68%) and especially tenant farmers (70% of the 68%). However, it is not known how many of the remaining cases (32%) were indirectly affected by drought. The WPA report also noted that 21% of all rural families in the Great Plains area were receiving federal emergency relief by 1936 (4); the number was as high as 90% in hard-hit counties (1). Thus, even though the exact economic losses are not known for this time period, they were substantial enough to cause widespread economic disruption that affected the entire nation.

LESSONS LEARNED: THE LEGACY OF THE 1930s DROUGHT

The magnitude of the droughts of the 1930s, combined with the Great Depression, led to unprecedented government relief efforts. Congressional actions in 1934 alone accounted for relief expenditures of $525 million (8); the total cost (social, economic, and environmental) would be impossible to determine.

If the Roosevelt era marked the beginning of large-scale aid, it also ushered in some of the first long-term, proactive programs to reduce future vulnerability to drought. It was in these years, for example, that the Soil Conservation Service (SCS)—now the Natural Resources Conservation Service—began to stress soil conservation measures. Through their efforts, the first soil conservation districts came into being, and demonstration projects were carried out to show the benefits of practices such as terracing and contouring (for a discussion of the activities of the SCS during this period, see Ref. 3).

Warrick et al. (2) note that the proactive measures continued in the years following the drought: conservation practices and irrigation increased, farm sizes grew larger, crop diversity increased, federal crop insurance was established, and the regional economy was diversified. Many other proactive measures taken after the 1930s drought also reduced rural and urban vulnerability to drought, including new or enlarged reservoirs, improved domestic water systems, changes in farm policies, new insurance and aid programs, and removal of some of the most sensitive agricultural lands from production (7).

Problems remained, but these programs and activities would play a fundamental role in reducing the vulnerability of the nation to the forthcoming 1950s drought. Although a larger area was affected during the 1950s drought, the conservation techniques that many farmers implemented in the intervening years helped prevent conditions from reaching the severity of the 1930s drought.

DROUGHT MANAGEMENT PLANNING

Neil S. Grigg
Colorado State University
Fort Collins, Colorado

It is impossible to "manage" a naturally occurring drought, so "drought management" refers to managing resources, including water, to mitigate the adverse effects of droughts, which are certain to occur. Other resources that can be managed are food supplies, including animal feed, public facilities of various kinds, and economic resources to aid businesses, farmers, and citizens.

As "creeping disasters," droughts are easy to ignore until too late, thus presenting a significant risk to water resources managers. The dilemma is that to prepare for them might be expensive and require seldom-used facilities, but without preparation, water supplies might run out on rare occasions. For this reason, drought management planning presents a challenge to water agencies, as well as to other governmental and private sector organizations.

Drought has two forms: a period without enough rain and a period of shortage: each requires drought management planning. A period without enough rain is a "meteorologic drought," and leads to shortages, which are called by names such as "hydrologic," "agricultural," and "socioeconomic" drought.

Drought management planning is a form of contingency planning that answers the question "what do we do if a drought occurs?" As in other forms of contingency planning, the process is to assess the threat, identify the vulnerable parts of systems, and take measures to prepare, mitigate, respond, and recover from the impact of a drought, should one occur.

Failures in water supply can have serious consequences for cities, industries, and other water users such as irrigation, hydropower, recreation, and wildlife. The primary impact of drought is due to real or feared interruption of supplies because water supply is critical to the economy and the natural environment. This risk increases with the interdependence and vulnerability of water systems, environmental stakes are also high. Drought is a serious threat to food supplies and farm income, especially in nations where food supplies are marginal.

Assessing the threat of drought requires knowledge of the security of supplies or the probability that a raw water supply system will run out of water. This is usually estimated for individual water agencies in terms of the return period of the drought planned for or the annual probability of running short. The concepts of return period and failure probability are in wide use, but for droughts they are complex because drought duration, system yield, and return period must be considered.

The concept of "safe yield" is used to describe the reliability of a water system, another measure of security. To estimate safe yield requires analysis of components and the systems that deliver water to users. Vulnerability analysis requires assessing of all possible modes of failure, not only hydrologic failure. For example, if a dam requires emptying for repair, supplies may run short from lack of storage, even when they are available from precipitation.

Examples of measures to prepare, mitigate, respond, and recover from drought impacts are shown in Table 1 (1).

Drought response plans are usually prepared by water management organizations to anticipate drought and plan activities to take place after a drought occurs. These are custom-tailored to the needs of each

Table 1. Drought Planning

Supply Augmentation	Demand Reduction	Impact Minimization
New sources	Legal restrictions	Forecasting
Water storage	Pricing	Mutual aid
Reuse of water	Devices to limit use	Insurance

organization but generally include the usual contents of emergency response plans, such as assessment of the hazard, identification of vulnerable components, mitigation measures, plans to meet critical water needs, arrangements for mutual aid, team organization and roles, and special conditions.

DROUGHT AND WATER SUPPLY MANAGEMENT

Neil S. Grigg
Colorado State University
Fort Collins, Colorado

Drought is a normal, albeit extreme, aspect of hydrologic variation, so it should be considered when making plans for water. Planning for water supply management involves both supply augmentation and demand management. Supply augmentation can involve new supplies or extending use of existing supplies.

During drought, making water available to meet requirements of people, business, and the environment is critical. As explained in the article on "Drought Management Planning," preparing for drought requires contingency planning to assure adequacy of water supplies, and management of available water supplies during drought is the key element of drought response. Thus, effective water resources management requires actions that assure water availability during drought as well as normal times.

Technologies and methods for providing water supplies go back to early Rome, which brought in water supplies by aqueducts. Water supply systems in the United States date from early settlements, which used spring water pumped through bored logs. Some early pumps were horse-driven, followed later by steam power.

Water supply systems have three subsystems: source of supply, treatment and distribution, and delivery of enough water of high quality at sufficient pressure for intended uses. A percentage of the water is normally unaccounted for, mainly through leakage and other losses. Water for fire fighting must also, be provided. Providing enough water requires volumes of delivery to meet needs reliably during peak demand periods and during drought.

The required quantities of water can be estimated from statistics of water use for domestic, commercial, and industrial uses. These vary widely, depending on many socioeconomic factors. Average per capita use of water in the United States, including all uses, varies from about 100–200 gallons per capita per day (gpcd) (378–756 liters per capita per day). The highest rates are normally in dry regions, where water supplies are used for lawn irrigation. In highly concentrated urban areas, water uses may be mostly inside apartment buildings and in commercial facilities and may be close to 100 gpcd (378 liters per capita per day), without any requirement for lawn irrigation. In other countries, water demands may be less, depending on socioeconomic variables. In a developing country city, use might be much less than levels in the United States, and water may not be available to all residents.

Sources of freshwater supply include surface water, groundwater, and reclaimed waters. Surface water can include stored water in reservoirs or direct diversions from streams. Typical infrastructure components include dams, tunnels, outlet tubes, canals, gates and controls, spillways, and support structures. Groundwater sources include springs, wells, infiltration galleries, and aquifers that store recharged water. Infrastructure components include wells, casings, pumping systems, piping, housing, and other support facilities. Given the increasing restrictions on the development of surface water, groundwater development is receiving more attention, including the implementation of aquifer storage and recovery (ASR) systems.

In special cases, rainwater can be caught on roofs and stored in cisterns. This type of local supply system is found mostly in developing countries and in special, remote locations where centralized systems are not possible. Bottled water is an increasingly popular source, and point-of-use treatment systems are becoming more popular.

Demand reduction can be legal, physical, or voluntary. Drought plans normally contain provisions to restrict use during times of shortage. Physical controls can include reduced pressures and requirements for devices to impose water conservation. Voluntary systems rely primarily on education and calls for citizenship.

As population increases and environmental water needs are more recognized, it becomes more difficult to find new sources of supply. Therefore, innovative approaches being studied include

- dual use of water where reclaimed and impaired waters are used for nonpotable applications
- conservation systems, where "new" sources are created by saving water
- innovative storage systems, such as aquifer–storage–recovery (ASR) systems

- conjunctive use, where water from different sources, such as surface and groundwater, are managed jointly
- reuse, where wastewater is treated and used again in one form or another
- point-of-use treatment systems
- bottled water

ASSESSMENT OF ECOLOGICAL EFFECTS IN WATER-LIMITED ENVIRONMENTS

Randall T. Ryti
James T. Markweise
Neptune and Company, Inc.
Los Alamos, New Mexico

We consider that water-limited environments include arid lands that have less than 250 millimeters (10 inches) of annual precipitation and semiarid lands that have annual precipitation between 250 and 500 millimeters (1). This paper discusses the characteristics of arid and semiarid environments, approaches for evaluating the potential ecological impacts from anthropogenic contaminant sources, and the issues that make such assessments complex in arid and semiarid environments.

Precipitation defines water-limited environments, and plants and animals have developed specialized adaptations to the paucity/lack of water. For example, avian adaptation to desert environments is characterized by decreased metabolic rates and minimized water loss (2). Organisms have adapted to more efficient use of limited water quantities by behaviorally and/or physiologically optimizing their ability to acquire and retain water. For example, some beetles meet all their water needs by drinking the dew that collects on their bodies. Another strategy for surviving in dry environments includes adaptations to exploit periodic monsoons that are characteristic of arid and semiarid regions and involves rapid population growth to exploit periods of abundant resources (3).

Precipitation can be large, but it is infrequent. The spatial scale for precipitation also varies from thunderstorms that may impact a portion of a watershed to larger storm systems that impact an entire region. The predictability of storms varies widely between seasons or years for water-limited environments. Terms like intermittent or interrupted have been used to describe flow in water-limited environments. The pattern and intensity of flow change as a result of prolonged periods of wet or dry conditions in these environments.

Effluent and surface water runoff from residential, commercial, or agricultural activities are frequently more predictable sources of water in dry environments. Effluent/runoff is typically laden with metals and organic chemicals, and, it has been demonstrated, affects the composition and abundance of aquatic organisms in receiving streams (4). Wastewater effluent from anthropogenic sources may be inserted as a point source (i.e., an outfall pipe), or runoff may originate from nonpoint sources (e.g., distributed spatially from agricultural application). These types of contaminant sources frequently overlap and confound the interpretation and mitigation of ecological effects.

Directly related to effluent/runoff is the source of water used by people in water-limited environments. Two common water sources are impoundments along major river systems or pumping of groundwater. When dams are introduced, flow regimes in these water-limited environments change and lead to dramatic changes in the species in areas of modified flow regimes (5).

In addition to anthropogenic influences on water availability and water quality, the physical environment of arid/semiarid land potentially affects water resources. In the arid southwest United States, closed hydrologic basins exist; salt flats are one resultant landscape feature of closed basins. Surface depressions may also accumulate water during intense precipitation, and evaporation concentrates chemicals in these ponds during dry periods. This is in contrast to moist environments, where water transport of contaminants generally leads to diluted concentrations. Wind-driven contaminant transport is also more important in dry environments where the soil and rock lie exposed to wind erosion because of limited plant coverage.

Dry environments are also more susceptible to disturbance due to several factors. One is decreased resilience to stressors because of the extreme nature of the environment. Aridity in itself can be a stressor for plants and animals, and, it has been shown, influences species composition (6) and population characteristics (7). Adding anthropogenic stressors to this environment (e.g., through pollution) may decrease a population's viability if it is already near the individual tolerance limits for surviving in the dry environment. For example, Sjursen and others (8) showed that exposure to organic chemicals could reduce drought tolerance in soil invertebrates. In addition, populations depending on rainfall for reproduction could be locally exterminated if their source of water (e.g., an ephemeral rain pool) were impacted with chemical toxicants. Soils in arid environments also develop more slowly than in moist areas, recover from stress slowly (9), and are more susceptible to erosion after physical disturbance.

Adverse effects contributing to impacts can be defined as "Changes that alter valued structural or functional attributes of ecological entities ..." (10). Effects can be assessed for ecological entities on any scale of biological organization, including genetic, individual, population, community, and ecosystem levels. "An evaluation of adversity may include a consideration of the type, intensity, and scale of the effect as well as the potential for recovery" (10). These evaluations are typically categorized as either stressor-based or effects-based assessments. Stressor-based assessments are initiated to evaluate physical, chemical, or biological entities that can induce an adverse response (11). Effects-based assessments are initiated to determine the cause(s), once an adverse impact is observed.

Tools to evaluate and manage environmental effects come from a number of disciplines. Resource management fields (e.g., forestry, wildlife management) develop plans to manage or mitigate effects of logging, hunting, and fishing. Conservation biology develops plans to mitigate more general human impacts on the environment. For regulatory agencies, ecological risk assessment has been the tool used to evaluate ecological effects of planned or historic actions (10).

The U.S. Environmental Protection Agency (EPA) Office of Solid Waste and Emergency Response (a.k.a. Superfund) started developing guidance on ecological risk assessment in the late 1980s. This process culminated in the Risk Assessment Forum process for ecological risk assessment (12). Parallel to these efforts was the Ecological Risk Assessment Guidance for Superfund or ERAGS (11).

ERAGS starts by identifying the ecological entity that needs to be protected (the assessment endpoint). By defining an adverse effect, the measures used to evaluate effects will be identified. ERAGS encourages using multiple lines of evidence, including field information, laboratory studies, and literature studies for each measure. Effects are characterized through lines of evidence (13,14), and the weight of the evidence dictates how one manages adverse effects.

The complications from assessments in water-limited environments are often related to the spatial and temporal scales of the assessment. For example, one may be concerned about potential adverse ecological impacts on aquatic and terrestrial receptors of effluent releases to a stream from an industrial facility. One set of considerations is the physical environment and other anthropogenic impacts on the stream. As discussed before, flow in the stream may be expected to change dramatically as seasonal and annual changes in precipitation occur. Altered flow regimes and other anthropogenic impacts on this stream are also expected. These considerations may help select appropriate assessment endpoints.

The abundance of bats in roosts near a stream near an industrial facility could be selected as an assessment endpoint. However, bats have large foraging ranges and are likely to be impacted by contaminants from multiple sources. In addition, bats are migratory and could be exposed to contaminants from distant locations. Another assessment end point for this example could be abundance of benthic macroinvertebrates. This choice has the advantage of greater site fidelity and thus minimizes confounding effects from neighboring anthropogenic releases. Benthic macroinvertebrates also lend themselves to direct experimentation as a line of evidence without some of the ethical and logistical problems of vertebrates.

Another complication of adverse effects assessments in water-limited environments is the availability of appropriate toxicity bioassays for taxa commonly found in such environments (15). This problem is more obvious for terrestrial receptors. For example, earthworms are the most commonly used soil animals in soil toxicity bioassays. However, earthworms are not representative of the more important detritivores in arid/semiarid environments (mites). This is an area of active research for more biologically relevant toxicity testing organisms for water-limited environments.

Last, variation in timing and amount of precipitation complicates some empirical evaluation of ecological effects. For example, the phenology of most organisms in arid and semiarid environments is tied to precipitation, and most studies of adverse effects are tied to government funding cycles. This is why some empirical studies of biota abundance and diversity are dismissed for practical reasons and laboratory studies of toxicity are emphasized. In some cases, a field experiment where precipitation is artificially simulated is another option, if time represents a logistical constraint.

Acknowledgments

We thank two peer reviewers, R. Mirenda and M. Tardiff, for their constructive comments on an earlier draft of this paper.

REACHING OUT: PUBLIC EDUCATION AND COMMUNITY INVOLVEMENT IN GROUNDWATER PROTECTION

Jennifer Nelson
The Groundwater Foundation
Lincoln, Nebraska

INTRODUCTION

Throughout its existence, The Groundwater Foundation (TGF) has identified public education and community involvement as vital ingredients to successful groundwater protection activities. TGF is an international nonprofit organization based in Lincoln, Nebraska, with a mission to educate and motivate the public to care about and for groundwater. Groundwater provides drinking water to nearly half of the U.S. population (1) and is critical for other economic uses such as irrigation, agriculture, and industry. Unfortunately, because it is a hidden resource, the general public knows comparatively little about groundwater or how to protect it. Providing education to stakeholders about the value of groundwater is an excellent way to illustrate how individual and group decisions and activities can have a direct impact on the quality and quantity of local groundwater resources.

TGF was founded in 1985 and since has held that people could learn about groundwater in ways that were both scientifically accurate and user friendly. TGF works to make groundwater science accessible to and understandable by people everywhere, allowing these educated people to become active partners in protecting the environmental and economic vitality of their communities by protecting local and regional groundwater resources.

Groundwater Guardian is a program of TGF that provides a framework for community action and groundwater protection by providing recognition, support, and lessons learned. Over 300 communities from the United States and Canada have participated in Groundwater Guardian since the program began in 1994. Groundwater Guardian relies on voluntary efforts spearheaded at the local level to effectively address local groundwater-related concerns and issues through the creation of a diverse local team, which focuses the interests and resources of a community on the importance of long-term groundwater protection.

Groundwater Guardian serves as both an organizing and planning tool for communities interested in groundwater protection. A community within the program is broadly defined—it can be a city, county, watershed area, school, or other area where there are people committed to learning about and protecting groundwater. To enter the program, communities first form a team of diverse stakeholders, including citizens, local government, educators, business, and/or agriculture. The team is the heart of the program and is designed to be broad-based to draw on the different resources and expertise of various sectors of the community. These stakeholders who represent key local groups are in an excellent position to identify a community's groundwater problems, develop an education/action plan to address these issues, and document their progress and success.

After a team is formed, local issues of concern are identified and then addressed through activities addressing public education and awareness, pollution prevention, public policy, conservation, and best management practices. Teams submit plans for these activities in the beginning of the year and report back to TGF at the end of the year on progress made. Groundwater Guardian designation is awarded based on the information provided in these plans and reports.

USING EDUCATION AS A STARTING POINT FOR GROUNDWATER PROTECTION

Groundwater Guardian teams generally start with some sort of public education campaign to build awareness for future protection activities. This education may take the form of a youth festival, newspaper column, water bill insert, public service announcement, website, brochure, seminar, public meeting, or other means. Education is a popular starting point for most Groundwater Guardian teams because:

- Education is viewed as an accessible, common activity that invites broad community participation.
- Goals and objectives can easily be set and achieved and give community efforts valuable success to build upon.
- Awareness and understanding are the basis for future activity, for adults and children alike.
- Children are likely to communicate with and involve parents, relatives, neighbors, and friends with successful and memorable education experiences (2).

Public education allows a progressionary approach to groundwater resources protection. It first engages community residents to know that their individual actions and practices, like disposing of motor oil properly, using only appropriate amounts of fertilizer, and taking shorter showers, can have an impact on local groundwater quality and quantity. It then also builds a base of knowledge for future support of protection activities. Residents who know that their drinking water is supplied by groundwater, pumped from wells in a specific area, are more likely to support efforts such as wellhead protection and the implementation of best management practices that protect that source than a resident who simply thinks that drinking water comes from the tap. Education creates a foundation for action.

VALUE OF COMMUNITY INVOLVEMENT IN GROUNDWATER PROTECTION

In TGF's experiences, community involvement is necessary to successful, meaningful, and long-lasting groundwater protection, which provides numerous benefits to all community residents, including:

- *Protecting Natural Resources*. Groundwater is sometimes referred to as the environmental "bottom line" as an indicator of how successful all environmental protection activities are. By monitoring groundwater quality and quantity, communities can see the impacts of their groundwater and other natural resource protection activities. By protecting groundwater resources, communities are often also protecting a variety of other natural resources, such as wildlife habitat and wetlands.
- *Safeguarding Public Health*. Safe groundwater is directly related to good health. Contaminated drinking water can cause illness, disease, or even death. By protecting groundwater supplies that are used for drinking water, communities are protecting their own health.
- *Developing Economic Vitality*. Communities depend on local groundwater supplies not only as a source of drinking water but to provide businesses and agricultural producers with an input to create a market good. Without clean, safe and plentiful groundwater supplies, communities across the country would face serious challenges to their long-term sustainability.
- *Building Community Capacity*. Communities that make the commitment to groundwater are the very same communities who are working to be innovative and strive for long-term growth and sustainability of their community. Because of the variety of effective groundwater protection activities and options available, communities working to protect groundwater are also building their capacity to address other community issues, such as growth, strategic planning, solid waste, transportation, and economics.
- *Sustaining Supplies*. As populations continue to grow, increased demand is placed on groundwater supplies. Communities that are educated about the value of local groundwater resources are much more likely to manage those resources in a sustainable way.
- *Sharing Responsibility*. Whether it is for drinking or as an economic input, all those within a community use and benefit from groundwater. Consequently, protecting groundwater supplies is best done by a diverse team of community representatives who share a variety of viewpoints but are working toward a common goal. By sharing the responsibility for groundwater protection, strong communities will protect groundwater supplies for generations to come.

STRATEGIES FOR PUBLIC EDUCATION AND COMMUNITY INVOLVEMENT IN GROUNDWATER PROTECTION

There are numerous options for public education and community involvement for local groundwater protection. Protection efforts implemented by Groundwater Guardian communities often begin with public education activities, including:

- Organizing a community or school water festival
- Launching a public awareness campaign
- Distributing educational materials about local groundwater issues
- Holding public meetings
- Planning field trips

Communities often find success with these relatively easy to implement, yet high impact, public education activities and can then move on to more challenging efforts, such as:

Conservation

Endorse and encourage the use of water-saving devices
  Encourage sustainable lawn care and gardening practices
  Work with the local water department to foster conservation awareness

Pollution Prevention

Inventory local pollution sources
  Properly close abandoned wells
  Recognize local pollution sources and identify possible solutions

Public Policy

Establish and manage wellhead protection areas
  Support compliance with the Safe Drinking Water Act
  Encourage federal, state, and local interagency coordination
  Develop a community comprehensive plan

Best Management Practices (BMPs)

Encourage the adoption of BMPs in rural, urban, and commercial areas
  Adopt land use protection measures
  Provide voluntary management options

PUBLIC EDUCATION + COMMUNITY INVOLVEMENT = GROUNDWATER PROTECTION

Groundwater protection in small, groundwater-dependent communities is reliant on a high level of citizen involvement to be successful. These communities may lack the financial resources and/or professional expertise to ensure the protection of groundwater resources that are vital to the human and economic health of the community. Instead, they rely on an educated and empowered citizenry acting responsibly on behalf of the community. When citizens understand the fundamental importance of groundwater to their environmental and economic future, they are motivated and able to develop innovative and cost-effective strategies for its protection.

TGF has found that no matter how diverse communities are, those that are successful begin the groundwater protection process in generally the same way: by involving local stakeholders. The involvement of a diverse group of stakeholders is the most important part of the Groundwater Guardian program because a credible, broad-based team effectively represents community interests and therefore shares the responsibility for groundwater protection among community groups.

As is the case for any issue that depends on community involvement for its success, groundwater protection needs a long-term commitment that is continuously rejuvenated by creativity, new ideas, and leadership. The same ingredients that contribute to sustaining meaningful groundwater education and protection activities also apply to other beneficial community activities. By starting with public education and stressing diverse community involvement, communities are on the path to sustainable groundwater protection. As TGF has learned, “it is because of people that groundwater must be protected, but it is only through people that we can do so.”

INTEGRATION OF ENVIRONMENTAL IMPACTS INTO WATER RESOURCES PLANNING

Mehmet Ali Yurdusev
Celal Bayar University
Manisa, Turkey

Nature is so complicated that we need to idealize or simplify to understand, interpret, and benefit from it. Simplifications are carried out by modeling natural events. Models give us the opportunity to input values representing the observed values of natural phenomena to see what the possible outcome would be. Water is one of the few natural substances without which human beings cannot survive. Water use, therefore, is much more complicated because it has to reconcile an irregular or random natural phenomenon and humans' attitudes toward it, which is not less complicated than water in nature itself. Therefore, it has to be managed by employing complicated computer-based mathematical models. The spatial and temporal dimensions of this complicated issue can then be handled. These modeling studies are generally referred to as water resources planning (WRP). WRP can be defined as matching future demands to potential resources, satisfying some preset objectives such as cost-effectiveness or environmental quality. The end product of water resources planning is a development plan for some future period, normally 20 to 30 years. As such, WRP mainly encompasses three types of activities:

- assessment of available water resources,
- assessment of future water requirements, and
- matching between available resources and forecast demands.

In the third phase of water resources planning, what is primarily involved is identifying the most appropriate development strategy for meeting projected demands at minimum cost, over the planning horizon. On a national scale, the planning process is characterized by the need to screen a large number of potential options (1) to determine

- which resources should be developed,
- the timing and order of that development, and
- the areas of demand to which each new resource should be assigned.

Typically, this has required information relating to future demand, the performance of different size sources at various locations, the possible links between sources and demand centers, together with all associated construction and operating costs. Faced with an enormous choice of possibilities for matching resources to needs, a systematic search procedure is normally required to achieve an objective assessment. The objective function of the procedure would be minimization of total discounted costs. To that end, various forms of mathematical programming have been used (2) to identify the minimum net present value of a development program. Alternatively, heuristic search techniques can be used which, although not as rigorous, provide a practical solution (3).

In the past, scant attention would have been given to environmental considerations within the water resources planning process until a scheme had already been selected. Then, detailed environmental assessment would be undertaken. At that stage, some attempts would be made to identify and ameliorate damaging environmental impacts. In contrast, the environmental considerations can be incorporated from the outset and included in selecting the scheme to be promoted. This is achieved by weighting the costs of the various options (both construction and operating) to reflect their environmental impacts, before including them in the economic evaluation. The objective function of the combined methodology is to minimize the total monetary and environmental discounted cost of meeting the projected demands. Quantification of such considerations is achieved by running an appropriate model with and without the environmental factors. Such a model should integrate an environmental impact assessment (EIA) and economic planning (EP) models. The EIA model develops what might be called environmental impact factors (EIF) to weigh the costs of schemes, and the EP model is to undertake the scheme selection and timing process using environmentally adjusted costs. The EIF is a weighting function whose role is to raise the cost of a water resource option if its environmental impact assessment indicates that it is environmentally damaging and to decrease it otherwise. Using such a factor in an economic planning model has the effect of influencing the solution toward selecting environmentally friendly schemes at the expense of environmentally damaging ones. In mathematical terms, an EIF is

$$0 < \text{EIF} < 1 \text{ and } 1 < \text{EIF} < 2$$

where 0 is the best possible outcome and 2 is the worst. Using such factors, environmental gain can be expressed by the former and the environmental loss by the latter: a value of 1 indicates neutrality.

A multicriterion decision-making technique referred to as composite programming (CP) can be used to derive the EIFs. The output from CP is a measure of the composite distance resulting from the aggregation of a series of basic indicators (4). For a given L, the composite distance from a so-called ideal point, where 0 represents the best possibility and 1 represents the worst possibility, the main features of CP are (1) $0 < L < 1$ and (2) the larger L, the worse the associated scheme. The real values of basic indicators are weighed to obtain a further indicator value. The procedure continues until it reaches a final indicator value that will represent the performance of the option according to the indicators considered. A simple mathematical function which deliberately exaggerates the extreme values can be used to transform L into EIF as follows:

$$\mathrm{EIF} = 1.4907\sqrt{L} \qquad \text{if } 0 < L < 0.45 \tag{1}$$

$$\mathrm{EIF} = 2 - 1.4907\sqrt{1-L} \qquad \text{if } 0.45 < L < 1 \tag{2}$$

In this way, it is possible to convert a series of basic indicators covering both detrimental and beneficial impacts to a corresponding EIF within the range of 0 to 2. When evaluating an impact, assessment values range from negative significant to positive significant with a central point at neutral. The impacts of water projects can be grouped according to their resource use, quality, ecosystem, and social implications. For example, the aggregation structure given in Table 1 can be considered as assessing the overall construction impact of a groundwater development scheme. The assessment values in Table 1 are assigned within a range between 1 and 8; 1 is the worst situation, 8 is the best, and 4 is neutral. The values in parenthesis show the normalized ones.

The values of second level indicators are calculated from the weighted sum of the associated basic impacts. The value of resource implications is directly taken as neutral because there are no associated basic impacts from which its value can be obtained. The overall value is, then, calculated as 0.41, and the EIF as 95% from Equation 1. This value indicates that the project is somewhat environmentally friendly and, therefore, the associated cost will be reduced accordingly during the optimization process.

Clearly, different types of resources/links will affect the environment in different ways, and therefore, each has its own specific set of considerations. Similarly, there are different considerations for each type of resource/link during the construction and operational phases. All these different impacts can be accommodated within the EIA model (5).

The economic planning model is intended to undertake the scheduling process to determine when the resources are to be built. Therefore, an existing model should be adopted for this purpose. Such a model would perform the planning process using the costs of water schemes contained in the case study under consideration. The objective is to find the least-cost solution for the whole exercise. As previously mentioned, the idea is to use the outputs of an EIA model (EIFs) in the economic planning model selected to reflect the environmental performance of each scheme. The two-way usage of an economic planning model would give the user the opportunity to compare results with and without environmental impacts. This may even be used to quantify the cost of environmental impacts in the form of additional investment required to apply environmentally friendly solutions (with environmental impact solutions). There are several economic water resources planning models that can be used for this purpose. The models can be based on unit costs (6), integer linear programming (2,7), heuristic programming (8), and genetic algorithms (9). The selection of an economic planning model depends on the availability of models, the amount to be invested, the nature of the exercise, and the capability of the models. Unfortunately, most of the models mentioned may not be commercially available. However, the owners may lend the models on request.

Combining economic planning and EIA models produces an overall environmentally-influenced economic planning system in which EIFs are used to weigh the real construction and operating costs for various development options to reflect their positive or negative environmental

Table 1. Constructional Environmental Impact Assessment for a Groundwater Scheme

Basic Impacts	Assessment Values	Weights	Second-Level Indicators	Indicator Values	Weights
			Resource use implications	0.50	0.18
Lack of visual intrusion	6(0.18)	1.00	Quality implications for physical system	0.18	0.29
Effect of construction on surface ecosystem	4(0.50)	0.44			
Pipeline laying impact on vegetation and wildlife	3(0.66)	0.56	Ecosystem implications	0.59	0.25
Impact of infrastructure construction; noise, mud, etc.	4(0.50)	0.27			
Landscape/land use impact of pipeline/structures	4(0.50)	0.27	Social implications	0.35	0.29
Implementation benefits	6(0.18)	0.45			

impacts. The coupling can be achieved simply by an economic model using the cost figures modified by the EIFs produced by the EIA model.

Such a methodology was applied to the whole of England and Wales using the National Rivers Authority's (NRA) data (3). The exercise was undertaken using the same economic planning model used by NRA coupled with an independent code for the EIA model (8). The environmentally sensitive solution was repriced in real terms by the model and therefore, the additional cost of preferring such a plan was estimated (5).

THE EXPANSION OF FEDERAL WATER PROJECTS

Martin Reuss
Office of History Headquarters
U.S. Army Corps of Engineers

Instead of national planning, Congress settled on a piecemeal approach to public works development in the early nineteenth century and, with rare exceptions, has clung to this approach ever since. In May, 1824, President Monroe signed legislation appropriating $75,000 to improve navigation on the Ohio and Mississippi rivers—major routes to the western part of the country. The act empowered him to employ "any of the engineers in the public service which he may deem proper" and to purchase the "requisite water craft, machinery, implements, and force" to eliminate various obstructions. Along with the General Survey Act, signed a month before, the Mississippi-Ohio rivers legislation initiated the permanent involvement of the Army Corps of Engineers in rivers and harbors work. However, each act focused on one activity: the General Survey Act on planning; the other on construction. Two years later, Congress combined surveys and projects in one act, thus establishing a pattern that lasts until the present. The 1826 act, therefore, can be called the first true rivers and harbors legislation.

By the time of the Civil War, the federal contribution to river, harbor, and canal improvements amounted to about $17 million in appropriated monies. Some 4.6 million acres of public lands were given for canal improvements and another 1.7 million acres for river improvements. Land grants under the 1849 and 1850 Swamp Land acts and the 1841 land grant act totaled some 73 million acres. While these grants and appropriations were significant, they represented a modest amount of aid compared with state and private sector contributions, which by 1860 totaled well over $185 million for canals alone. Corporations and public agencies spent many millions more on the construction of urban water systems.

Many of the canal companies incorporated by the states ran into trouble. The 1837 depression had driven a number into bankruptcy; others survived, but only with a healthy influx of state money, state guaranteed bonds, and occasional federal and state land grants. Often, too, the national story was repeated at the state level, with rationally planned canal routes sacrificed to local political pressures to extend canals to uneconomical out-of-the-way villages. The one major exception to this sad story was the Erie Canal, whose success had spurred the canal boom that increasingly appeared more like a dismal bust, especially with new competition from the railroads. From Pennsylvania to Ohio to Indiana to Illinois and on into the states of the old Northwest, canal fever turned to canal panic, and the public lost faith in both the companies and the politicians who had supported the enterprises.

The American Civil War (1861–1865) also affected the development of water projects. Military action and wartime budgetary constraints took their toll on many of the nation's ports and navigable waterways, and after the war commercial development accelerated demands for waterway improvements. A business-oriented Republican Congress responded by authorizing a great deal more money for rivers and harbors. The federal government also took over many of the bankrupt canal companies, and the Corps of Engineers became the custodian of former private or state waterways. This, as one author put it, was the "Golden Age of the Pork Barrel". Between 1866 and 1882, the Presidents signed 16 rivers and harbors acts. The 1866 act appropriated $3.7 million for 49 projects and has been described as the first omnibus bill, so called because like a horse-drawn omnibus of the time,

---

the legislation provided room for a great many people boosting various projects. Sixteen years later, though, the 1882 act appropriated five times more money. By that year, the federal government had spent over $111 million on rivers and harbors projects. "Willingness to pay"—the primary test of project implementation before the Civil War—now included unprecedented federal largess. In the so-called "Gilded Age," lack of federal or non-federal funds was about the only thing that prevented construction.

By the 1880s, the basic working relationship between Congress and the Army Corps of Engineers was set. Congress directed the Corps to survey potential projects, make recommendations, and provide cost estimates. Rivers and Harbors acts funded both the surveys and the projects that Congress chose to authorize. Also in the early 1880s, Congress mandated that the Corps of Engineers use more contractors and less hired labor. By the end of the century, contractors did nine-tenths of all waterways construction, and no Corps officer could use hired labor without the express authority of the Chief of Engineers. Increasingly, then, the Corps became a funding conduit to the private sector. This pattern did not stop private sector engineers from calling for the complete elimination of the Corps from public works, but Congress rejected all bills that leaned in that direction.

Fear of railroad competition and questions about federal aid to projects of apparently local benefit moved the Senate in 1872 to create a Select Committee on Transportation Routes to the Seaboard. Composed of nine senators, the committee was headed by Senator William Windom of Minnesota and known popularly as the Windom Committee. Its 1873 report promoted waterway over railway transportation wherever waterways were properly located. Of more relevance here is the committee's conclusion (on a five to four vote) that the sum of local rivers and harbors projects contributed to the national interest. Generally accepted by Congress, this conclusion justified federal contributions for waterway improvements. The result was the authorization of dozens of dubious projects. By 1907, the cumulative total for rivers and harbors appropriations was more than four times the 1882 figure; the federal role in navigation improvements continued to grow.

Meanwhile, the issue of constitutional authority had somewhat changed focus. In 1870, the Supreme Court ruled in The Daniel Ball case that the common law doctrine that navigability depended on tidal influence, a doctrine accepted in British courts, did not fit the American situation. However, the definition the Court substituted was extraordinary. The test of navigation was to be the river's "navigable capacity." That meant, the Court went on:

> Those waters must be regarded as public navigable rivers in law which are navigable in fact. And they are navigable in fact when they are used, or are susceptible of being used, in their ordinary condition, as highways for commerce over which trade and travel are or may be conducted in the customary modes of trade and travel on water.

In short, American rivers were navigable if they were, are, or could be navigable. This decision, in combination with the earlier 1824 Gibbons v. Ogden Court ruling, made the federal government the clear guardian and ultimate decision-maker on tens of thousands of miles of waterways in the United States. In practice it sufficed to show that a stream had the capacity to float logs to declare it navigable. However, with this issue more or less settled, another appeared: flood control.

Rivers always flood, but the floods do not always damage life and property. In the United States, we can trace floods as far back as 1543, when Mississippi River floods stopped Hernando De Soto's expedition. Naturally, as settlers moved into the floodplains and built villages, then cities, the damages increased. By the mid-nineteenth century, the problem was becoming critical along the lower Mississippi. Most people put their faith in technology to protect them. Indeed, the then popular term "flood prevention" testifies to an extraordinarily unrealistic idea when one thinks about it a bit. In the twentieth century, the term became "flood control," a somewhat more modest formulation. Nowadays we speak of "flood damage reduction," which probably comes closest to the mark. In any case, in the 1870s calls came for repairing and raising the levees on the Mississippi River. In 1879, Congress created a joint military—civilian Mississippi River Commission to develop and implement plans to improve navigation and flood control on the lower Mississippi. However, once again some Congressmen raised constitutional objections, expressing doubts that flood control was an appropriate federal activity. Until 1890, no appropriation could be used for repairing or constructing any levee in order to prevent damage to lands from overflow, or for any purpose other than deepening and improving the navigation channel. The 1890 floods along the lower Mississippi resulted in the removal of this restriction, which, in any event, had had little practical effect other than satisfying congressional scruples.

Floods in 1912, 1913, and 1916 along the Ohio and Mississippi rivers eventually led to passage of the 1917 Flood Control Act, the nation's first act dedicated solely to flood control. It provided funds on a cost-shared basis for levee construction along the lower Mississippi and another appropriation to improve the Sacramento River in California. While an important step towards federal involvement in flood control, it was comparatively modest compared to what followed in the coming decades, when flood control became intertwined with multipurpose development—the subject of the next essay.

FLOOD CONTROL HISTORY IN THE NETHERLANDS

RONGCHAO LI
Delft University of Technology
Delft, The Netherlands

The traditional flood control approach in The Netherlands is fighting against natural dynamics or, restricting the natural dynamics of a river system by canalization and embankments. However, such an approach results in destruction of river scenery, damage to nature and cultural values, as well as continuous dike raising and strengthening. Changing societal views in The Netherlands have aroused discussion of alternative flood management strategies. Around the beginning of the for twenty-first century, new visions appeared such as "living with floods" and the "room for the river" policy.

FLOOD CONTROL HISTORY IN THE NETHERLANDS

The Netherlands is a small country in Western Europe. The delta of the Rhine, Meuse, and Schelde Rivers lie within the country. One-third of The Netherlands needs and has artificial protection against floods from the sea or major rivers (see Fig. 1). Millions of people live, and large industries have settled in this area. In the western coastal area, the major cities such as Amsterdam, The Hague, and Rotterdam are situated. Large parts of the western coastal area lie below sea level. Also in the area along the rivers, cities and industries have settled. Therefore, flood risk management is an important issue for The Netherlands.

Figure 1. Almost 75% of The Netherlands is threatened by floods (1).

The Rhine and Meuse Rivers are the largest and most important rivers in The Netherlands. The Rhine River has a large catchment stretching from the high Alps in Switzerland, Germany, and France. The Meuse River flows through France and Belgium. Only the most downstream parts of these rivers are situated in the Netherlands. Therefore, flood risk management focuses on the discharge of water. Nowadays, after a long history of coping with floods, a high safety standard has been reached.

Before 1000 A.D., floods occurred very frequently. Mainly the higher parts in The Netherlands were inhabited, and in the lower parts, people lived on mounds, so no real disasters occurred in that period. Because people had no technological options to prevent flood then, they had no other option but to live with the floods and to avoid the floodwaters. They adapted their lives and land use to the rivers and sea.

About 1000 A.D., the inhabitants of The Netherlands started to build the first dikes around relatively small polders. The flood risk management strategy changed from living with floods to a strategy where the river and its floods were more controlled. This trend of increasing the control of the river continued, and by 1400 A.D., an almost completely closed dike system already existed along the rivers (2). Furthermore, huge changes in the course of the river and the riverbed in the form of regulation and canalization took place (3). The river was harnessed into a small area and now the people and land use did not adapt to the river any longer, but the river was adapted according to the wishes of the inhabitants. The main flood management strategy consisted of preventing floods. This strategy continued unchanged until 1953. After each dike breach, the broken dikes were reconstructed, raised, and improved resulting in increasingly higher and stronger dikes. The last great flood of the Rhine River occurred in 1926, after which the dikes were improved again (2). Since then, the rivers seemed controlled, and people feel safe.

In 1953, a major flood from the North Sea took place that killed more than 1800 people. This flood resulted in new safety regulations for the coast and also for the river area. Previously, dike heights were based on the maximal recorded water level, but after 1953, a more scientific base has been used. The optimal level of safety was defined as the accepted probability of flooding for the different areas in The Netherlands. To be able to use this new norm, it was simplified to the demand that dike levels should exceed water levels related to a discharge with a chosen return time. After several years of discussion, one safety level was chosen for the whole area threatened by river floods: a discharge with a probability of once in 1250 years (the design discharge). Flooding by causes other than overtopping of dikes and uncertainties in nature and in the calculations were considered by adding 0.5 m to the required height and some regulations for the design of the dikes. Every 5 years, the design discharge is calculated anew based on the recorded discharges.

Nowadays, the Dutch rivers are thus strongly human-influenced. Figure 2 shows a cross section of a typical

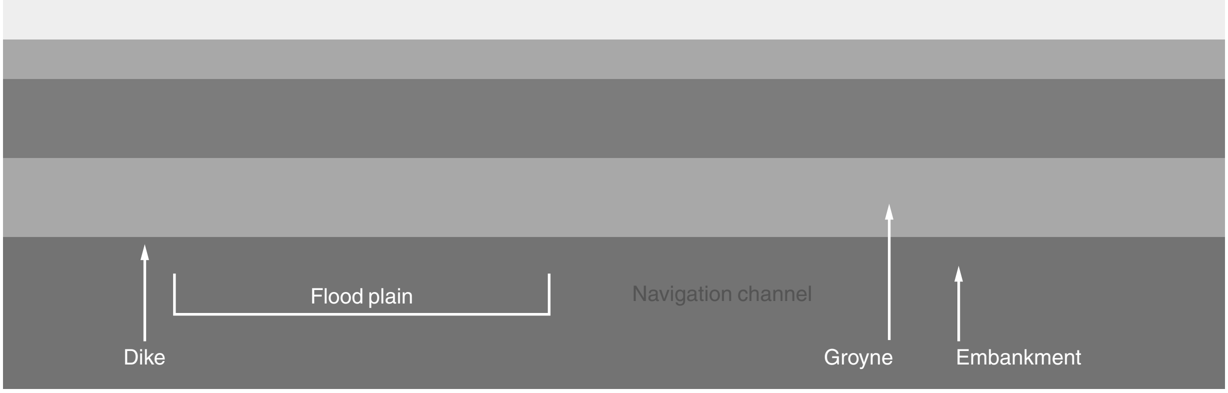

Figure 2. A cross section of a typical river in The Netherlands (4).

Dutch part of a river. The rivers consist of a small mainstream that has to enable navigation all year round. Next to this mainstream, are floodplains which carry water during peak flows, about twice each year in wintertime. These floodplains are used for agriculture and recreation in the summertime during lower discharges. The area outside these floodplains is protected from floods by huge embankments. The unprotected floodplains sometimes lie higher than the surrounding area due to sedimentation in the floodplains and subsidence of the surrounding area. To prevent the area along the rivers from becoming flooded at once, this area is subdivided into dike circles, which are areas surrounded by embankments or natural higher areas.

In 1993 and 1995, extremely high river discharges occurred in the Meuse and Rhine Rivers. Because of these extreme peak discharges, the design discharge with a probability of once in 1250 years increased from 15.000 m^3/s to 16000 m^3/s at the Dutch–German border. Using the traditional approach of flood risk management, this would lead to a further increase of dike heights. However, new solutions have developed nowadays creating room for the rivers (5).

NEW VISIONS AND IDEAS IN FLOOD RISK MANAGEMENT

Due to changes in the values of society and available technology in The Netherlands, flood risk management is changing. Some of these changes and the resulting ideas on flood risk management are mentioned here (1):

- The current strategy based on *one design discharge for the whole* area threatened by river floods leads to the same level of protection for different areas with different potential flood damage. Cities, agricultural areas, and nature reserves all have the same probability of flooding in The Netherlands. The question arises whether this is economically sensible. It also means that it is unknown which area will become flooded first when an extreme discharge occurs. Because all areas theoretically have the same probability of flooding, a large area has to be evacuated.
- Due to the fact that this strategy *focuses on preventing floods*, little attention has been paid to the consequences of possible floods. Relatively little attention is paid to plans for emergency situations, evacuation plans, flood mitigation measures, etc. which also might lower flood risks. New technology has increased the possibilities for good flood forecasts, of communication technology, and flood warnings. Also the possibility to anticipate peak flows by lowering a structure and using a detention pond has grown. These technologies make it easier to allow controlled floods and therefore reduce the need to prevent floods in all circumstances.
- By looking only at the probability of a design discharge, risks are not clearly visualized. The uncertainties in, for example, the design discharge, the translation of the discharge to water levels, the diversion of the peak flow through the different river branches, the strength of dikes and structures, and human behavior are not clearly considered. This results in a false sense of safety in the area and thus in rapid economic development and increasing potential flood damage.
- Another disadvantage of the strategy is that it includes an endless need for raising and improving the water defense structures. *Restricting* the natural dynamics of a river system by canalization and embankments requires continuous maintenance and improvements, otherwise the river dynamics will damage these works, and the river will try to return to its own natural behavior.
- The current strategy results in destruction of the river scenery and damages nature and cultural values. Recently, these values have become more important. A new strategy should consider these values and not focus only on reaching a “safe” situation by technical solutions.
- In these modern times, disasters are not accepted any longer. The government and water managers would be held responsible for a disaster, even if the event that caused the disaster is extreme and rare.

In The Netherlands, consciousness has increased that absolute safety cannot be guaranteed and that floods will always occur. However, disasters are not accepted any longer. Therefore, and because of the disadvantages of the current strategy, as mentioned above, new ways to deal with uncertainties and flood risks have to be found.

In 1990, the policy report "Room for Rivers" was published. This policy wants to create room for rivers to stop the continuous cycle of dike raising, increased feelings of safety, increased investments, increased flood risks, and needs for further dike raising. By moving the dikes away from the river, digging out the floodplains, removing obstacles from the floodplains and sometimes constructing bypasses for peak flows, room for the river is created. The purpose of this policy is to interrupt the continuous dike raising and lower the water levels in the river by giving the river more space. In reality, this policy has been applied at different locations. Numerous obstacles, such as roads to bridges, roads to ferries, and brick factories in the floodplains have been removed or have changed to permit water flow. At Nijmegen near the Dutch–German border, a dike has been moved to increase room for the river. The inhabitants of the area normally opposed these projects because the room for the river is taken from other functions. However, they are mostly also against dike raising because it deteriorates their scenery and sometimes it destroys houses and restaurants built on or near the dike.

Another new policy is the indication of so-called "emergency areas." These are areas that must be flooded first to protect other, more vulnerable areas. Officially these areas should be used only for discharges that exceed the design discharge, thus with a frequency of less than once in 1250 years. Official research has been published, but until now, no governmental decision has been made about the indication of such areas, the location of these areas, or the regulations for the inhabitants of these areas. It is unclear whether the villages in these areas will be protected by dikes and what damage compensation they will receive. The purpose of this policy is to limit the emergency measures to smaller areas and to know what area will become flooded and not leave the choice to the river.

Other new concepts are introduced in the National Policy on Water Management. According to this policy we should "aim at resilient and healthy water systems." Resilient water systems are systems that may be disturbed or show temporary change but will easily recover. To discuss resilience and resistance, a systems approach to flood risk management has to be adopted. The system on which flood risk management focuses can be defined as the whole area threatened by floods including the society, ecosystems, and the river itself in this area. Optimal flood risk management depends on the society and culture of the inhabitants, not only on the discharge regime of the river. Furthermore, the whole system should be studied, not just a small river stretch, because measures as well as floods downstream and upstream interact with each other. Measures may transport the flood problems downstream, and upstream floods may prevent downstream inundations. In resilience strategies for flood risk management, floods are not necessarily prevented, but the flood impacts are limited, and recovery after the flood is enhanced. Resilience strategies focus on the whole discharge regime, not on a certain design discharge or design event. These strategies are still only a subject of research and an option for the long term. For more information, see De Bruijn and Klijn (1) or Vis et al. (6).

CONCLUSIONS

One-third of The Netherlands needs and has artificial protection against floods from the sea or the major rivers. In this area, millions of people live and large industries have settled. This proves the importance of flood management for The Netherlands. After centuries of coping with floods, research and reconsideration of flood management strategies are still needed because society is changing and thus the optimal flood management strategy must also change.

FOOD AND WATER IN AN EMERGENCY

Federal Emergency
Management Agency

INTRODUCTION

If an earthquake, hurricane, winter storm or other disaster strikes your community, you might not have access to food, water and electricity for days, or even weeks. By taking some time now to store emergency food and water supplies, you can provide for your entire family. This brochure was developed by the Federal Emergency Management Agency in cooperation with the American Red Cross and the U.S. Department of Agriculture.

WATER

Having an ample supply of clean water is a top priority in an emergency. A normally active person needs to drink at least two quarts of water each day. Hot environments can double that amount. Children, nursing mothers and ill people will need even more.

You will also need water for food preparation and hygiene. Store a total of at least one gallon per person, per day. You should store at least a two - week supply of water for each member of your family.

If supplies run low, never ration water. Drink the amount you need today, and try to find more for tomorrow. You can minimize the amount of water your body needs by reducing activity and staying cool.

HOW TO STORE WATER

Store your water in thoroughly washed plastic, glass, fiberglass or enamel-lined metal containers. Never use a container that has held toxic substances.

Plastic containers, such as soft drink bottles, are best. You can also purchase food-grade plastic buckets or drums. Seal water containers tightly, label them and store in a cool, dark place. Rotate water every six months.

EMERGENCY OUTDOOR WATER SOURCES

If you need to find water outside your home, you can use these sources. Be sure to purify the water according to the instructions listed below before drinking it.

- Rainwater
- Streams, rivers and other moving bodies of water
- Ponds and lakes
- Natural springs

Avoid water with floating material, an odor or dark color. Use saltwater only if you distill it first. You should not drink floodwater.

THREE WAYS TO PURIFY WATER

In addition to having a bad odor and taste, contaminated water can contain microorganisms that cause diseases such as dysentery, typhoid and hepatitis. You should purify all water of uncertain purity before using it for drinking, food preparation or hygiene.

There are many ways to purify water. None is perfect. Often the best solution is a combination of methods. Two easy purification methods are outlined below. These measures will kill most microbes but will not remove other contaminants such as heavy metals, salts and most other chemicals. Before purifying, let any suspended particles settle to the bottom, or strain them through layers of paper towel or clean cloth.

1. *Boiling*
   Boiling is the safest method of purifying water. Bring water to a rolling boil for 1 minute, keeping in mind that some water will evaporate. Let the water cool before drinking.
   Boiled water will taste better if you put oxygen back into it by pouring the water back and forth between two clean containers. This will also improve the taste of stored water.
2. *Disinfection*
   You can use household liquid bleach to kill microorganisms. Use only regular household liquid bleach that contains 5.25 percent sodium hypochlorite. Do not use scented bleaches, color-safe bleaches or bleaches with added cleaners.
   Add 16 drops of bleach per gallon of water, stir and let stand for 30 minutes. If the water does not have a slight bleach odor, repeat the dosage and let stand another 15 minutes.
   The only agent used to purify water should be household liquid bleach. Other chemicals, such as iodine or water treatment products sold in camping or surplus stores that do not contain 5.25 percent sodium hypochlorite as the only active ingredient, are not recommended and should not be used.
   While the two methods described above will kill most microbes in water, distillation will remove microbes that resist these methods, and heavy metals, salts and most other chemicals.
3. *Distillation*
   Distillation involves boiling water and then collecting the vapor that condenses back to water. The condensed vapor will not include salt and other impurities. To distill, fill a pot halfway with water. Tie a cup to the handle on the pot's lid so that the cup will hang right-side-up when the lid is upside-down (make sure the cup is not dangling into the water) and boil the water for 20 minutes. The water that drips from the lid into the cup is distilled.

HIDDEN WATER SOURCES IN YOUR HOME

If a disaster catches you without a stored supply of clean water, you can use the water in your hot-water tank, pipes and ice cubes. As a last resort, you can use water in the reservoir tank of your toilet (not the bowl).

Do you know the location of your incoming water valve? You'll need to shut it off to stop contaminated water from entering your home if you hear reports of broken water or sewage lines.

To use the water in your pipes, let air into the plumbing by turning on the faucet in your house at the highest level. A small amount of water will trickle out. Then obtain water from the lowest faucet in the house.

To use the water in your hot-water tank, be sure the electricity or gas is off, and open the drain at the bottom of the tank. Start the water flowing by turning off the water intake valve and turning on a hot-water faucet. Do not turn on the gas or electricity when the tank is empty.

Food

Short—Term Supplies. Even though it is unlikely that an emergency would cut off your food supply for two weeks, you should prepare a supply that will last that long.

The easiest way to develop a two-week stockpile is to increase the amount of basic foods you normally keep on your shelves.

Storage Tips

- Keep food in a dry, cool spot-a dark area if possible.
- Keep food covered at all times.
- Open food boxes or cans carefully so that you can close them tightly after each use.
- Wrap cookies and crackers in plastic bags, and keep them in tight containers.
- Empty opened packages of sugar, dried fruits and nuts into screw-top jars or air-tight cans to protect them from pests.
- Inspect all food for signs of spoilage before use.
- Use foods before they go bad, and replace them with fresh supplies, dated with ink or marker. Place new items at the back of the storage area and older ones in front.

Nutrition Tips

During and right after a disaster, it will be vital that you maintain your strength. So remember:

- Eat at least one well-balanced meal each day.
- Drink enough liquid to enable your body to function properly (two quarts a day).
- Take in enough calories to enable you to do any necessary work.
- Include vitamin, mineral and protein supplements in your stockpile to assure adequate nutrition.

Food Supplies

When Food Supplies Are Low. If activity is reduced, healthy people can survive on half their usual food intake for an extended period and without any food for many days. Food, unlike water, may be rationed safely, except for children and pregnant women.

If your water supply is limited, try to avoid foods that are high in fat and protein, and don't stock salty foods, since they will make you thirsty. Try to eat salt-free crackers, whole grain cereals and canned foods with high liquid content.

You don't need to go out and buy unfamiliar foods to prepare an emergency food supply. You can use the canned foods, dry mixes and other staples on your cupboard shelves. In fact, familiar foods are important. They can lift morale and give a feeling of security in time of stress. Also, canned foods won't require cooking, water or special preparation. Following are recommended short-term food storage plans.

SPECIAL CONSIDERATIONS

As you stock food, take into account your family's unique needs and tastes. Try to include foods that they will enjoy and that are also high in calories and nutrition. Foods that require no refrigeration, preparation or cooking are best.

Individuals with special diets and allergies will need particular attention, as will babies, toddlers and elderly people. Nursing mothers may need liquid formula, in case they are unable to nurse. Canned dietetic foods, juices and soups may be helpful for ill or elderly people.

Make sure you have a manual can opener and disposable utensils. And don't forget non-perishable foods for your pets.

SHELF-LIFE OF FOODS FOR STORAGE

Here are some general guidelines for rotating common emergency foods.

- Use within six months:
  - Powdered milk (boxed)
  - Dried fruit (in metal container)
  - Dry, crisp crackers (in metal container)
  - Potatoes
- Use within one year:
  - Canned condensed meat and vegetable soups
  - Canned fruits, fruit juices and vegetables
  - Ready-to-eat cereals and uncooked instant cereals (in metal containers)
  - Peanut butter
  - Jelly
  - Hard candy and canned nuts
  - Vitamin C
- May be stored indefinitely (in proper containers and conditions):
  - Wheat
  - Vegetable oils
  - Dried corn
  - Baking powder
  - Soybeans
  - Instant coffee, tea and cocoa
  - Salt
  - Non-carbonated soft drinks
  - White rice
  - Bouillon products
  - Dry pasta
  - Powdered milk (in nitrogen-packed cans)

IF THE ELECTRICITY GOES OFF

FIRST, use perishable food and foods from the refrigerator.

THEN, use the foods from the freezer. To minimize the number of times you open the freezer door, post a list of freezer contents on it. In a well-filled, well-insulated freezer, foods will usually still have ice crystals in their centers (meaning foods are safe to eat) for at least three days.

FINALLY, begin to use non-perishable foods and staples.

HOW TO COOK IF THE POWER GOES OUT

For emergency cooking you can use a fireplace, or a charcoal grill or camp stove can be used outdoors. You can also heat food with candle warmers, chafing dishes and fondue pots. Canned food can be eaten right out of the can. If you heat it in the can, be sure to open the can and remove the label first.

Disaster Supplies

Emergency Supplies. It's 2:00 a.m. and a flash flood forces you to evacuate your home-fast. There's no time to gather food from the kitchen, fill bottles with water, grab a first-aid kit from the closet and snatch a flashlight and a portable radio from the bedroom. You need to have these items packed and ready in one place before disaster strikes.

Pack at least a three-day supply of food and water, and store it in a handy place. Choose foods that are easy to carry, nutritious and ready-to-eat. In addition, pack these emergency items:

- Medical supplies and first aid manual n Money and matches in a waterproof
- Hygiene supplies container
- Portable radio, flashlights and n Fire extinguisher extra batteries n Blanket and extra clothing
- Shovel and other useful tools
- Infant and small children's needs (if appropriate)
- Household liquid bleach to purify drinking water.
- Manual can opener

WATER DEMAND FORECASTING

Steven J. Renzetti
Brock University
St. Catharines, Ontario, Canada

INTRODUCTION

People who are involved with planning, constructing, and operating water supply facilities frequently must have an idea of the current state of water use and also what future water demands are likely to be. This need is made all the more important when water use is rising rapidly and when the cost of major water infrastructure projects is considered. These factors imply that there is a need for accurate forecasts of water demands so that infrastructure projects are correctly sized and scheduled. The purpose of this article is to examine briefly the concepts and methods for forecasting water demands (for a more detailed discussion, see Refs. 3–5). We begin by considering the general nature of water demand forecasts.

ISSUES IN FORECASTING WATER DEMANDS

There are several issues surrounding the general practice of water demand forecasting. Boland (1) points out that any forecast has two essential components: explanation and prediction: "Explanation of water use usually takes the form of a model that relates the past observed level of water use to various variables. Replacing past values of the explanatory variables with those expected in the future produces a prediction of future water use" (pp. 162–163). Historically, the first of these two tasks—explaining water use—has been done by using 'fixed-coefficient' models. In this approach, it is assumed that water use is related to a single explanatory factor such as population and, further, that the relationship between water use and population is a fixed, proportional one. Dziegielewski (2), for example, provides a brief review of the history of urban water demand forecasting and demonstrates that, in the 'traditional' method of forecasting, total future demand is predicted as the product of expected population growth and a fixed per capita water use coefficient. This method was subsequently refined by disaggregating total water use by user classes, area, and time period. The fundamental forecasting method remained the same, however; 'unit water use coefficients' is multiplied by the projected growth in a particular user group in a specific location. The fundamental shortcoming of the fixed coefficient approach is that it fails to anticipate changes in the relationship between water use and the dominant explanatory variable that may arise from changes in other, neglected variables. For example, forecasts of residential water use that are based on the number of households in an area may overstate future water demands if they neglect the impacts of rising water prices. More recently, more complex models have sought to estimate statistically the relationship between water use and a set of explanatory variables, including water prices.

Estimated relationships form the basis for demand forecasts. Dziegielewski (2) describes how a computer model commonly used to forecast urban water demands (IWR-MAIN) is evolving to incorporate more complex models of water use.

Another feature of water demand forecasts is that they have different time horizons and that these different time horizons reflect, in part, the different uses to which water demand forecasts are put. These may be roughly categorized into short-, medium-, and long-term forecasts (3,6). Short-run forecasts are conducted by water utility managers and water supply agencies to anticipate daily peak loads and other seasonal features of water use. Medium-term forecasts often examine user group investment decisions (such as the locations of new housing developments and manufacturing facilities) to establish anticipated changes in water demands during the next 5–10 years. These forecasts are then used to guide water agency investment decisions. Finally, long-term forecasts can investigate the impacts of structural and technological changes in the economy (such as the shift in employment from manufacturing to service-based industries) as well as the impacts of major policy changes (such as water quality legislation).

CASES OF WATER DEMAND FORECASTING

As mentioned earlier, water demand forecasts can be conducted on a variety of geographic scales. This section draws on chapter 11 of Renzetti (5) and considers examples of water demand forecasts conducted on municipal, regional, and national scales. Boland (1) summarizes a forecasting exercise where the IWR-MAIN water demand model was combined with predictions of climate change to predict water use in Washington, DC. Boland combines the predictions of five climate change models with forecasts of other explanatory variables such as prices, incomes, and housing stock. These are then fed into IWR-MAIN, and the model provides predicted water use levels for 2030 under different climate and policy scenarios. In the absence of any change in climate patterns, summer water use in the region is expected to grow 100% by 2030. Once the impacts of climate change are incorporated, the predicted growth ranges from 74% to 138%, assuming no change in policies. However, implementing relatively modest nonprice conservation efforts (such as adopting a revised plumbing code) reduces the range of forecasted growth in summer water use to between 40 and 92%. Adding a 50% increase in real water prices reduces expected water use growth even further: predicted growth in summer water use between 1985 and 2030 in this case ranges from 26.6% to 73.6%.

Planners often also forecast the water demands of major water-using sectors within a region. Representative of this type of exercise is the California Department of Water's recent effort to forecast urban, agricultural, and in-stream water use in California to the year 2020 (7). Urban water use is assumed to be the product of population growth and changes in per capita water use the latter is modeled as determined by a number of factors such as income, water prices, and conservation measures. Statewide urban per capita water use in 1995 was 229 U.S. gallons/day; the forecasted level of per capita water use in 2020 is 243 gallons/day without new conservation measures and 215 gallons/day using new conservation measures. The California Department of Water adopts a sophisticated and multifaceted approach to forecasting irrigation water demands. Each crop's aggregate irrigation water use is calculated as the product of the crop's water "requirements" and the statewide irrigated acreage for the crop. Individual crop's water requirements are estimated using agronomic and climate data. Expected statewide acreage for each crop is a function of forecasted market conditions and expected government policies. The final type of water use to be factored into the Californian forecasts is in-stream needs. It turns out that these are largely determined by legislation and future climate conditions. After summing across sectors, total Californian water use in 1995 was 79,490 thousand acre-feet and, assuming a continuation of past climatic conditions, total Californian water use in 2020 is forecast at 80,500 thousand acre-feet. The prediction of constant total water use masks the fact that several sectors and regions are expected to exhibit different rates of growth. For example, total projected urban water use will rise from 8770 thousand acre-feet in 1995 to 12,020 thousand acre-feet in 2020, and agricultural water use is expected to decline from 33,780 thousand acre-feet to 31,500 thousand acre-feet for the same period.

Finally, there have been considerable efforts expended to forecast water demand growth on a national and even global scale. Gleick (8) critically surveys researchers' efforts to project global water use into the twenty-first century. Gleick points out that early projections were essentially extrapolations of current water use patterns under 'business as usual' assumptions regarding technology, water pricing, and water use efficiency. The extrapolations are then based on projections of expected growth in population, agricultural, industrial, and energy output. Gleick contends, however, that almost all of the projections based on fixed-coefficient models of water use have significantly overstated actual water use in the past because they cannot anticipate the extent to which water's growing scarcity induces technological and institutional innovation, changes in sectoral composition, and slowing rates of population growth. For example, Gleick compares a number of projections of global water use in 2000 with actual recorded water use and finds that actual withdrawals in the mid-1990s were only half of what most forecasters in the 1960s and 1970s projected.

A representative example of this type of effort is Seckler et al. (4). The authors project per capita and total withdrawals for 118 countries for the period 1990–2025. Projections of per capita residential withdrawals are based on population or GDP growth, and per capita irrigation water use is assumed constant ("business as usual") or declines due to improved technology ("high efficiency"). The impact of improved efficiency is dramatic. In the first scenario, global irrigation water use grows 60% for the period; in the second scenario, irrigation water use grows by only 13%. Similarly, global water withdrawals increase by 56% in the "business as usual" scenario and by 26% in the 'high efficiency' scenario.

CONCLUSIONS

The rapid growth in water demands that has been observed in many regions and sectors and the costs of servicing these demands highlight the need for accurate water demand forecasts. This article has demonstrated that researchers and utility operators have developed techniques to conduct forecasts for different time periods and different geographic scales. Historically, the fixed-coefficient method of explaining and predicting water demands has dominated, but experience with this model has demonstrated that it neglects many factors (such as prices, incomes and, water conservation programs) that influence demands. This shortcoming has typically led fixed-coefficient models to overstate expected water demand growth. It is expected that more sophisticated models that account for a wider range of factors that influence water use and that allow for feedback between water use and economic conditions will provide more accurate forecasts of water demands.

REMOTE SENSING AND GIS APPLICATION IN WATER RESOURCES

SANJAY KUMAR JAIN
National Institute of Hydrology
Roorkee, India

Water resources are essential for human life, agriculture, and hydroelectric power generation. Remote sensing and the Geographic Information System (GIS) help in creating an appropriate information base for efficiently managing these resources. The synoptic view provided by satellite remote sensing and the analytical capability provided by the GIS offer a technologically appropriate method for studying various features related to land and water resources.

Remote sensing is a tool that permits accurate and real-time evaluation, continuous monitoring or surveillance, and forecasts of inland water resources. Remote sensing systems are used to observe the earth's surface from different levels of platforms, such as satellites and aircraft, and make it possible to collect and analyze information about resources and environment across large areas. Remote sensors record electromagnetic energy reflected or emitted from the earth's surface. Different kinds of objects or features such as soils, vegetation, and water reflect and emit energy differently. This characteristic makes it possible to measure, map, and monitor these objects and features using satellite or aircraft-borne remote sensing systems. Satellite imagery offers a number of advantages over conventional survey techniques:

- areal synoptic coverage (gives areal information as against point information through conventional techniques)
- repetitive global coverage (for monitoring change)
- real-time processing
- sensing of surrogates rather than the desired specific observation
- multispectral coverage
- more automation, less human error

For many water related studies, remote sensing data alone are not sufficient; they have to be merged with data from other sources. Hence a multitude of spatially related (i.e., climatic and geographic) data concerning rainfall, evaporation, vegetation, geomorphology, soils, and rocks have to be considered. In addition, information is also required such as locations and type of tube wells and rain and river gauges. Thus, the fast storage, retrieval, display, and updating of map contents are important functions. A system that can store data, select and classify stations, and perform mathematical and sorting operations is called a database, and information can be extracted from it for a given purpose. If this information can also be displayed in the form of maps, we can speak of geographic information. So this complete set of information forms the Geographic Information System (GIS). The GIS is an effective tool for storing, managing, and displaying spatial data (Fig. 1) often encountered in hydrology and water resources management studies. The GIS technology integrates common database operations, such as queries and statistical analysis, with the unique visualization and benefits of geographic analysis that maps and spatial databases offer. The use of remote sensing data in the GIS is shown in Fig. 2.

One of the capabilities of the GIS most important to water resources management studies is describing the topography of a region. A digital elevation model (DEM) provides a digital representation of a portion of the earth's terrain across a two-dimensional surface. DEMs have proved to be a valuable tool for topographic parameterization of hydrologic models, especially for drainage analysis, hillslope hydrology, watersheds, groundwater flow, and contaminant transport.

Problems of water resources development and efficient use such as frequent floods and droughts, waterlogging and salinity in command areas, an alarming rate of reservoir sedimentation due to deforestation, and deteriorating water quality and environment are varied and numerous in nature. All must be tackled by systematic approaches involving a judicious mix of conventional methods and remotely sensed data in the GIS environment. The availability of remotely sensed data and the use of the GIS has provided significant impetus to hydrologic analysis and design and their use in water resources

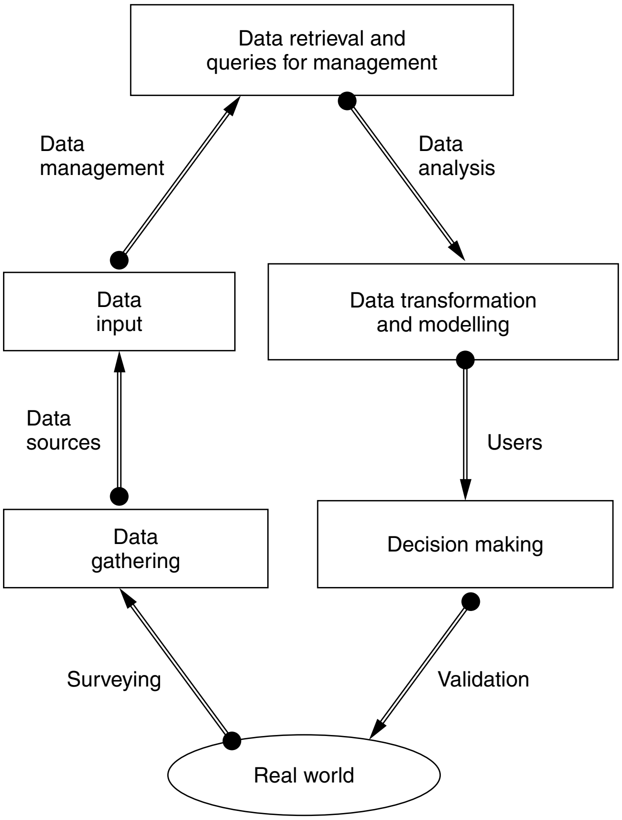

Figure 1. The GIS, a management tool.

planning and development. Remote sensing and GIS techniques have been extensively used in various areas of water resources development and management, such as land use/cover classification, precipitation, snow cover, floodplain management, command area studies, waterlogging and soil salinity, sedimentation in reservoirs, and hydrologic modeling, which are defined below in brief.

LAND USE/LAND COVER CLASSIFICATION

Multispectral classification of land cover types was one of the first well-established remote sensing applications for water resources. Numerous investigators have used a classification of land cover from satellite data as input to various water resources studies. Land use features can be identified, mapped, and studied on the basis of their spectral characteristics. Healthy green vegetation has considerably different characteristics in the visible and near-infrared regions of the spectrum, whereas dry bare soil has a relatively stable reflectance in both regions of the spectrum. Water shows very low reflectance in the visible part of the spectrum and almost no reflectance in the infrared part of the spectrum. Thus, by using multispectral data suitably, different ground features can be differentiated from each other, and thematic maps depicting land use can be prepared from satellite data. Land use data devised from remote sensing are an ideal database for distributed hydrologic modeling changes. In many hydrologic models, the parameters of vegetation related model components (e.g., for interception and evapotranspiration) are chosen, dependent on land use.

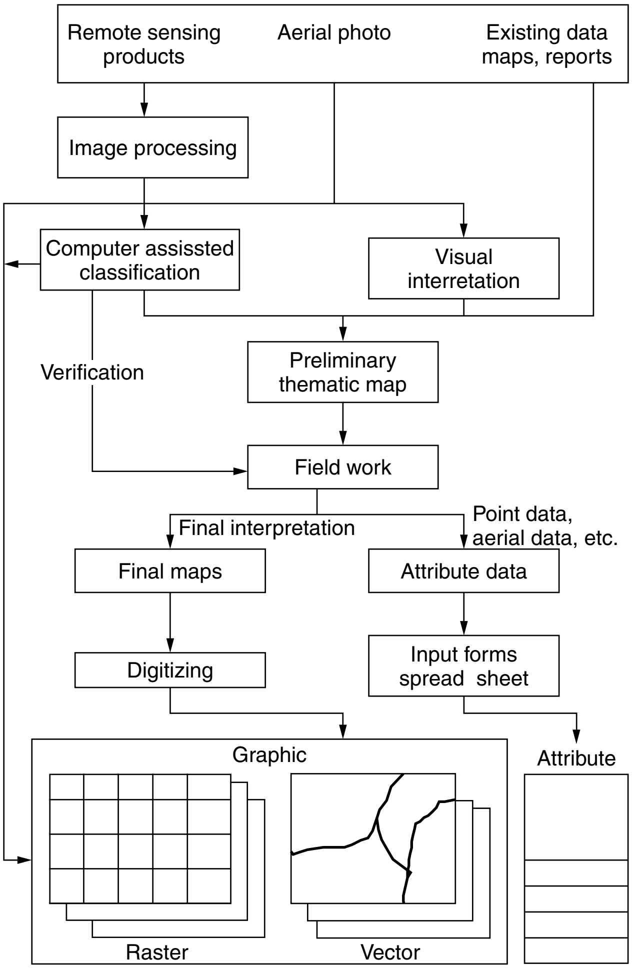

Figure 2. Remote sensing products in a GIS.

PRECIPITATION STUDIES

Precipitation, one of the driving forces in the hydrologic cycle, is a prime candidate variable for remote sensing measurement. There are many remote sensing possibilities, including ground based radar, visible and thermal infrared satellite imagery, and microwave satellite data. The use of ground based radar has been successful especially when used with an integrated rain-gauge network and in areas of low relief. Visible and thermal infrared techniques using measurements of cloud top reflectance and temperature have been used in a variety of ways by meteorologists and other scientists to estimate monthly, daily, and storm precipitation totals. Visible and infrared measurements represent observations only of the upper surface of clouds. In contrast, it is often believed that microwave radiation is not affected by the presence of clouds. Measuring rain from a spaceborne radar is very attractive because it can discriminate in range (altitude when operated from space), and radar reflectivity is directly related to rainfall rate.

SNOW COVER STUDIES

Measurement of the area of a basin covered by snow is similar to land cover measurement. Conventional methods have limitations in monitoring the snow covered area in mountainous basins because of inaccessibility.

Very little information on snow is collected regularly in mountainous areas, so remote sensing remains the only practical way of obtaining some relevant information on the snow cover in the large number of mountain basins. At present the visible, near IR, and thermal IR data from various satellite (Landsat, IRS, NOAA) are being used operationally for mapping the areal extent of snow cover in mountainous basins. Visible and near-infrared wavelengths do not penetrate far into the snowpack, so they provide information mainly about the surface of the snowpack. Microwave remote sensing is promising because of its ability to penetrate the dry snowpack and its capability of acquiring data in cloudy or nighttime conditions. Snow cover data extracted by satellite remote sensing is immediately usable in snowmelt runoff models. In addition to the extent of snow cover, satellite data are useful in computing snow water equivalent from microwave data.

SOIL MOISTURE ASSESSMENT

Remotely sensed data have great potential for providing areal estimates of soil moisture rather than point measurements. Quantitative assessment of soil moisture regime is essential for water balance models, irrigation scheduling, crop management, and surface and subsurface flow predictions. Remote sensing of soil moisture can be accomplished to some degree in all regions of the electromagnetic spectrum. The use and application of remotely sensed data for soil moisture depends on measuring the electromagnetic energy that is reflected or emitted from the surface. Thus, either direct observations of the soil by remote sensors or indirect estimates using plant condition are useful in soil moisture observations. The soil moisture beneath microwave remote sensing can directly measure the dielectric properties of the earth's surface, which in turn is strongly dependent on moisture content.

FLOODPLAIN MANAGEMENT

Reliable data on river morphology, river meandering, the extent of flooding, and duration are required for proper planning of flood control projects. In conventional methods of flood risk zoning, the flood discharge is routed through a river reach to estimate the likely inundation due to spilling over banks/embankments based on topographic contour maps available and the configuration of the river geometry obtained from land surveys. Continuous availability of satellite based remote sensing data has made understanding the dynamics of floods much easier. Satellite remote sensing techniques provide wide area coverage, repetitiveness, and consistency, which enables collecting reliable information on all major floods.

Remote sensing can provide information on flood inundated areas for different magnitudes of floods, so that the extent of flooding in floodplains can be related to flood magnitude. The duration of flooding can be estimated with the help of multiple coverage satellite imagery of the same area within 2–3 days by satellites. High-resolution satellite data provide information on the floodplain and effectiveness of flood control works. The extent of inundation for specific flood return periods can be estimated. Using close contour information, the extent of inundation for a given elevation can be estimated, this is a vital input for risk zone mapping.

The GIS provides a broad range of tools for determining the area affected by floods and for forecasting areas that are likely to be flooded due to the high water level in a river. Spatial data stored in the digital database of the GIS, such as a digital elevation model (DEM), can be used to predict future floods. The GIS database may also contain agricultural, socioeconomic, communication, population, and infrastructural data. This can be used in conjunction with flooding data to adopt an evacuation strategy, rehabilitation planning, and damage assessment in a critical flood situation.

MAPPING AND MONITORING OF WATERSHEDS

Proper planning of watersheds is essential for conservation of water and land resources and their productivity. Characterization and analysis of watersheds are a prerequisite for this. Watershed characterization involves measuring parameters of geologic, hydrogeologic, geomorphological, hydrologic, soil, and land cover/land use. Remote sensing via aerial and spaceborne sensors can be used for watershed characterization, assessing management requirements, and periodic monitoring. The various physiographic measurements that can be obtained from remotely sensed data are size, shape, topography, drainage pattern, and landforms. Quantitative analysis of drainage networks enables relationships among different aspects of the drainage pattern of a basin to be formulated as general laws and to define certain useful properties/indexes of the drainage basin in numerical terms. The laws of stream numbers, stream length, and stream slopes can be derived from measurements made in the drainage basin. Remote sensing along with ground based information in the GIS mode can used for broad and reconnaissance level interpretations of land capability classes, irrigation suitability classes, potential land users, responsive water harvesting areas, monitoring the effects of watershed conservation measures, correlation for runoff and sediment yields from different watersheds, and monitoring land use changes and land degradation.

COMMAND AREA STUDIES

Water management in command areas requires serious attention in view of the disappointing performance of our irrigation projects, despite huge investments. The command area is the total area lying between drainage boundaries, which can be irrigated by a canal system.

Remote sensing can play a useful complementary role in managing the land and water resources of command areas to maximize production. Management of water supplies for irrigation in command areas is a critical problem to tackle with limited quantities. This requires information on total demand and the distribution of demand for irrigation in command areas. Moreover, the vastness of the areas involved, time constraints, and yearly changes demand fast inventories of conditions. As more area is brought under irrigation, crop monitoring also becomes essential for estimating agricultural production and efficient planning of water management. In all these, remote sensing can be looked upon as an aid in planning and decision making. The usefulness of remote sensing techniques in inventorying irrigated lands; identifying crop types, their extent, condition; and production estimation has been demonstrated in various investigations. Conjunctive use planning of surface and groundwaters can be done using remotely sensed information on surface water in conjunction with ground based data on groundwater availability. This would permit development of conjunctive use models for water allocations in a GIS environment.

WATERLOGGING AND SOIL SALINITY

Waterlogging and soil salinity are some of the major land degradation processes that restrict the economic and efficient use of soil and land resources in command areas. To assess waterlogging in command areas, multispectral and multitemporal remote sensing data are very useful. The satellite data thus provide a quick and more reliable delineation of waterlogged areas and standing water. The spatial distribution of soil affected by “positional waterlogging” (i.e., that due to its location in the landscape) can be modeled from digital topographic data using the concept of contributing area. This waterlogging depends on two topographic factors: (1) the local slope angle and (2) the drainage area. The probability of waterlogging increases with the contributing drainage area and decreases with increasing local slope angle. The waterlogging phenomenon is related to topography, so digital terrain modelling (DTM) can aid in detecting waterlogged areas. DTM provides information regarding slope and aspect, which in turn provide information about the areas that are susceptible to waterlogging.

One of the common practices for observing waterlogged areas in command areas is to take observations in existing open wells at regular intervals, twice a year in the pre- and postmonsoon seasons. Data are also collected on water quality. The information thus collected is used to draw hydrographs and the depth of the water table to prepare maps subsequently. So preparation of these maps can help a lot in identifying waterlogged zones in a command area. Using field data, which is available as point data, groundwater depth distributional maps can be prepared in the GIS. With the help of these maps, shallow GW areas, areas susceptible to waterlogging, can be identified. The areas falling within the 0–1.5 m range generally indicate waterlogged or salt-affected patches depending primarily on the soil characteristics, particularly texture.

RESERVOIR SEDIMENTATION

Most common conventional techniques for sedimentation quantification are (1) direct measurement of sediment deposition by hydrographic surveys and (2) indirect measurement of sediment concentration by the inflow–outflow method. Both methods are laborious, time-consuming, and costly and have their own limitations. Sampling and measurement of suspended sediments is a tedious and expensive program for either *in situ* or laboratory work.

The introduction of remote sensing techniques in the recent past has made it very cheap and convenient to quantify sedimentation in a reservoir and to assess its distribution and deposition pattern. Remote sensing techniques, offering data acquisition over a long time period and broad spectral range, are superior to conventional methods for data acquisition. The advantage of satellite data over conventional sampling procedures include repetitive coverage of a given area every 16–22 days, a synoptic view which is unobtainable by conventional methods, and almost instantaneous spatial data across the areas of interest. Remote sensing techniques provide a synoptic view of a reservoir in a form very different from that obtained by surface data collection and sampling.

WATER QUALITY STUDIES

Recently, the alarming proportions of water quality deterioration have necessitated rapid monitoring for efficient checks to prevent further deterioration and to cleanse our polluted water resources. Moreover, surveillance of water quality is an important activity for multiple uses such as irrigation and water supply. Water quality is a general term used to describe the physical, chemical, thermal, and/or biological properties of water.

A combination of ground (water) and remote sensing measurements are required to collect the data necessary to develop and calibrate empirical and semiempirical models and validate the more physically based models. Water samples analyzed for substances of interest (i.e., suspended sediment, chlorophyll) should be collected at the same time (or on the same day) that the remote sensing data are collected. Location of sample sites should be determined by GPS (or other available technique) so that the correct data (pixel information) can be extracted from remote sensing for comparison. Remote sensing applications to water quality are limited to measuring those substances or conditions that influence and change the optical and/or thermal characteristics of the apparent surface water properties. Suspended sediment, chlorophyll (algae), oil, and temperature are water quality indicators that can change the spectral and thermal properties of surface waters and are most readily measured by remote sensing techniques.

GROUNDWATER STUDIES

A remote sensing system is quite helpful in groundwater exploration because remotely sensed data provide a synoptic view of high observational density. The common current remote sensing platforms record features on the surface. Most of the information for groundwater, as yet, has to be obtained by qualitative reasoning and semiquantitative approaches. Remotely sensed information is often surrogate and has to be merged with geohydrologic data to become meaningful. Vegetation can be used as an indicator if local knowledge is available and the types can be identified on the satellite data. Apart from the contribution that remote sensing can make to understanding regional hydrogeology—necessary for managing groundwater resources—perhaps the strongest application for management is the evaluation of recharge, groundwater drafts for irrigation, and identification of flow systems in areas where there is a paucity of geohydrologic data. Surface conditions, soils, weathered zones, geomorphology, and vegetation determine recharge, suitability for artificial recharge, and soil and water conservation measures that can affect recharge.

Groundwater vulnerability to pollution is also directly related to surface conditions. Indexing methods for group depth to water table, net recharge, topography, impact of vadose zone media, and hydraulic conductivity of the aquifer (leading to the acronym DRASTIC) into a relative ranking scheme use a combination of weights and ratings to produce numerical values.

HYDROLOGIC MODELING

In the early days, the GIS was used mainly as a hydrologic mapping tool. Nowadays, it plays a more important role in hydrologic model studies. Its applications span a wide range from sophisticated analyses and modeling of spatial data to simple inventories and management tools. The GIS has evolved as a highly sophisticated database management system to put together and store the voluminous data typically required in hydrologic modeling. The application of the GIS has enhanced the capacity of models in data management, parameter estimation, and presentation of model results, but the GIS cannot replace hydrologic models in solving hydrologic problems.

Due to its data handling and manipulation capabilities, the GIS is increasingly being used as an interface and data manager for hydrologic models. There are four levels of linkage of hydrologic model with the GIS. These levels vary from considering the GIS and the model as separate systems to fully integrating the model and the GIS.

One typical application of a GIS in watershed analysis is predicting the spatial variability of surface erosion from spatial data sets obtained from maps of the vegetative cover, soils, and slope of the area. Solutions of a surface erosion (soil loss) prediction model, for example, the universal soil loss equation (USLE) or its modifications, combine spatial data sets, their derivatives, and other information necessary to predict the spatial variability of surface erosion on a watershed. This analysis can determine areas of potentially severe surface erosion and provide an initial step in the appraisal of surface erosion problems.

GIS FOR DECISION MAKING

The GIS is derived from multiple sources of data of different levels of accuracy. Though a single piece of data can be assigned an accuracy value, information derived from multiple sources of inaccurate data can also be assigned a level of accuracy. In any pictorial representation of data, uncertainty can be brought in as one of the dimensions to guide final decision making. Any decision today has to depend on a variety of factors, which are available in an information system like the GIS. However, weighting as well as the proper use of such data is still problematic.

The decision support system (DSS) can be designed as an interactive, flexible, and adaptable computer based information system (CBIS), especially developed to support the solution of a management problem for decision making. It uses data, provides an easy interface, and allows for decision-makers' own insights to illustrate the objectives and information characteristics of the various levels of decision making. DSS provides a framework for incorporating analytical modeling capabilities with a database to improve the decision-making process. Currently available DSS provides primarily for well-structured problems. It are also being used for decision making in water resources planning and management.

CONCLUSIONS AND FUTURE NEEDS

Many water resources applications can profit from the use of remote sensing and the GIS. The reason for adopting GIS technology is that it allows displaying spatial information in integrative ways that are readily comprehensible and visual. Remote sensing is now being widely regarded as a layer in the GIS. Although remote sensing is a specialized technique, it is now being accepted as a basic survey methodology and as a means of providing data for a resource database. The GIS provides a methodology by which data layers can be interrelated to arrive at wider decisions (1).

The research needs in the area of water resources are as follows:

- A first and very important aspect is data availability and compatibility in any GIS related study. Spatial information required for water resources studies should be readily available for timely execution. The data banks should provide digitized maps and their spatial data compatible with various systems. Such data availability could significantly speed up the analysis.
- One difficult task in incorporating the GIS in water resources modeling is interfacing water system models with the GIS. Automation of interfacing tasks is one of the areas to be researched in incorporating the GIS and available models.
- The recent development of the decision support system (DSS) to assist in water resources decision making holds the key for integrating the GIS and water resources models.

- Another area of potential research to enhance the modeling process further is the integration of expert systems and the GIS. Expert GIS systems can be used to provide regulatory information by linking regulatory facts stored in a database to sites located in a GIS through an expert system query interface.
- Further research is needed for comparing the GIS packages available on the market and their positive and negative aspects, providing check lists for GIS users.

GLOBALIZATION OF WATER

A.Y. Hoekstra
UNESCO–IHE Institute for
Water Education
Delft, The Netherlands

WHY WATER IS A GLOBAL RESOURCE

People in Japan can affect the hydrological system in the United States. People in Europe can affect regional water systems in Thailand or Brazil. There are basically two mechanisms that make global connections between seemingly local water systems. First, the climate system connects different places on earth, because evaporation in one place results in precipitation in another place. The climate system is inherently global: local emissions of greenhouse gases contribute to a changing global climate, thus affecting temperature, evaporation, and precipitation patterns elsewhere. In this way, human activities in the economic centers of the world affect base and peak flows in rivers throughout the world. There is, however, a second mechanism through which people can affect water systems in other parts of the world. A European consumer of Thai rice raises rice demand in Thailand and subsequently the use of water for rice irrigation in Thailand. Globally, roughly one-fifth of the water used in agriculture is applied in areas used for producing export commodities. This fraction is increasing in line with the increase of global trade. Scientists have known for several decades that human activities within a river basin strongly impact on the water flows and water quality in such a river basin. It is more recent that scientists have started to realize that local water problems are often, in their roots, problems that cannot be solved locally or regionally, because the driving forces lay outside the region. The gradual disappearance of the Aral Lake in Uzbekistan–Kazakhstan, for instance, is directly linked to the global demand for cotton.

EFFICIENT USE OF THE GLOBAL WATER RESOURCES

According to international trade theory, countries with abundant water resources might have a comparative advantage in producing water-intensive goods if compared to water-poor countries. Since water resources are quite unevenly distributed over the world, one should not be surprised that under conditions of free trade water-intensive production processes get concentrated in the water-rich parts of the world. A water-scarce country can thus aim at importing products that require a lot of water in their production (water-intensive products) and exporting products or services that require less water (water-extensive products). This is called *import of virtual water* (as opposed to import of real water, which is generally too expensive) and will relieve the pressure on the nation's own water resources. For water-abundant countries an argument can be made for *export of virtual water*. Import of water-intensive products by some nations and export of these products by others results in international "virtual water flows."

The idea of achieving "global water use efficiency" through virtual water trade between countries is relatively new. Traditionally, water managers have focused on achieving "local water use efficiency" at user level and "water allocation efficiency" at river basin level. "Local water use efficiency" can be increased by creating awareness among the water users, by charging prices based on full marginal cost, and by stimulating water-saving technology. "Water allocation efficiency" can be improved by allocating the water within a catchment or river basin to those types of use where water creates the highest added value. A key question today is which level—the user, river basin, or global level—will be most relevant in increasing overall water use efficiency and reducing overall impact on the globe's water systems.

THE CONCEPT OF "VIRTUAL WATER"

The volume of virtual water "hidden" or "embodied" in a particular product is defined as the volume of water used in the production process of that product (1,2). Not only agricultural products contain virtual water: most studies to date have been limited to the study of virtual water in crops. Industrial products and services also contain virtual water. As an example of virtual water content, one often refers to the virtual water content of grains. It is estimated that for producing 1 kg of grain, grown under rain-fed and favorable climatic conditions, we need about 1–2 m^3 of water, which is 1000–2000 kg of water. For the same amount of grain, but growing in an arid country, where the climatic conditions are not favorable (high temperature, high evapotranspiration), we need up to 3000–5000 kg of water.

If one country exports a water-intensive product to another country, it exports water in virtual form. In this way, some countries support other countries in their water needs. Worldwide both politicians and the general public increasingly show interest in the pros and cons of "globalization" of trade. The tension in the debate relates to the fact that the game of global competition is played with rules that many see as unfair. Knowing that economically sound water pricing is poorly developed in many regions of the world, this means that many products are put on the world market at a price that does not properly include the cost of the water contained in the product. This leads to situations in which some regions in fact subsidize export of scarce water.

METHOD TO CALCULATE VIRTUAL WATER FLOWS

Calculation of the Virtual Water Content of a Product

The virtual water content of a product is a function of the water volumes used in the different stages of the production process. The virtual water content of a particular crop in a particular country can, for instance, be calculated on the basis of country-specific crop water requirements and crop yields (3):

$$\mathrm{VWC}[n, c] = \mathrm{CWR}[n, c]/Y[n, c] \qquad (1)$$

Here, VWC denotes the virtual water content (m^3/ton) of crop c in country n, CWR the crop water requirement (m^3/ha), and Y the crop yield (ton/ha). The crop water requirement can be calculated from the accumulated crop evapotranspiration ET_c (in mm/d) over the complete growing period. The crop evapotranspiration ET_c follows from multiplying the "reference crop evapotranspiration" ET_0 with the crop coefficient K_c:

$$\mathrm{ET}_c = K_c \times \mathrm{ET}_0 \qquad (2)$$

The crop coefficient accounts for the actual crop canopy and aerodynamic resistance relative to the hypothetical reference crop. The crop coefficient serves as an aggregation of the physical and physiological differences between a certain crop and the reference crop. The concept of "reference crop evapotranspiration" was introduced by FAO to study the evaporative demand of the atmosphere independently of crop type, crop development, and management practices. The only factors affecting ET_0 are climatic parameters. The reference crop evapotranspiration ET_0 is defined as the rate of evapotranspiration from a hypothetical reference crop with an assumed crop height of 12 cm, a fixed crop surface resistance of 70 s/m, and an albedo of 0.23. This reference crop evapotranspiration closely resembles the evapotranspiration from an extensive surface of green grass cover of uniform height, actively growing, completely shading the ground, and with adequate water (4). Reference crop evapotranspiration can be calculated on the basis of the FAO Penman-Monteith equation (4,5).

The calculation of the virtual water content of livestock products is a bit more complex. First, the virtual water content (m^3/ton) of live animals is calculated, based on the virtual water content of their feed and the volumes of drinking and service water consumed during their lifetime (6). Second, the virtual water content is calculated for each livestock product, taking into account the product fraction (ton of product obtained per ton of live animal) and the value fraction (ratio of value of one product from an animal to the sum of the market values of all products from the animal).

Calculation of International Virtual Water Flows and Drawing a National Virtual Water Balance

Virtual water flows between nations can be calculated by multiplying international product trade flows by their associated virtual water content. The latter depends on the water needs in the exporting country where the product is produced. Virtual water trade is thus calculated as

$$\mathrm{VWT}[n_e, n_i, p, t] = \mathrm{PT}[n_e, n_i, p, t] \times \mathrm{VWC}[n_e, p, t] \qquad (3)$$

in which VWT denotes the virtual water trade (m^3/yr) from exporting country n_e to importing country n_i in year t as a result of trade in product p. PT represents the product trade (ton/yr) from exporting country n_e to importing country n_i in year t for product p. VWC represents the virtual water content (m^3/ton) of product p in the exporting country.

The gross virtual water import (GVWI) to a country is the sum of all product-related virtual water imports. The gross virtual water export (GVWE) from a country is the sum of all product-related virtual water exports. The virtual water balance of country x for year t can be written as

$$\mathrm{NVWI}[x, t] = \mathrm{GVWI}[x, t] - \mathrm{GVWE}[x, t], \qquad (4)$$

where NVWI stands for the net virtual water import (m^3/yr) to the country. Net virtual water import to a country has either a positive or a negative sign. The latter indicates that there is net virtual water *export* from the country.

GLOBAL VIRTUAL WATER FLOWS

The global volume of international virtual water flows is roughly 1000 billion m^3/yr (7). For comparison, the total water use by crops in the world has been estimated at 5400 Gm^3/yr. These figures show that a substantial volume of water serves the global market. Countries with a large virtual water export are the United States, Canada, Thailand, Argentina, and India. Large importers of virtual water are Europe (except France), Japan, China, and Indonesia.

National virtual water balances over the period 1995–1999 are shown in Fig. 1. Full data on virtual water imports and exports are provided in Table 1. Some countries, such as Brazil, Syria, Pakistan, Tajikistan, and Uganda, have net export of virtual water over the period 1995–1999, but net import of virtual water in one or more particular years in this period. There are also countries that show the reverse, such as the Philippines, the Russian Federation, Uzbekistan, Kyrgyztan, Mongolia, Nicaragua, and Mexico. Developed countries generally have a more stable virtual water balance than the developing countries.

Countries that are relatively close to each other in terms of geography and development level can have a rather different virtual water balance. While European countries such as The Netherlands, Belgium, Germany, Spain, and Italy import virtual water in the form of crops, France exports a large amount of virtual water. In the Middle East we see that Syria has net export of virtual water related to crop trade, but Jordan and Israel have net import. In Southern Africa, Zimbabwe and Zambia had net export in the period 1995–1999, but South Africa had net import. (It should be noted that the balance of Zimbabwe has recently turned due to the recent political and economic developments.) In regions of the former Soviet Union, countries such as Kazakhstan and the Ukraine have net export of virtual water, but the Russian Federation has net import.

Net virtual water flows between thirteen world regions in the period 1995–1999 are shown in Fig. 2. The largest virtual water flows have been indicated with arrows. Regions with a significant net virtual water import are

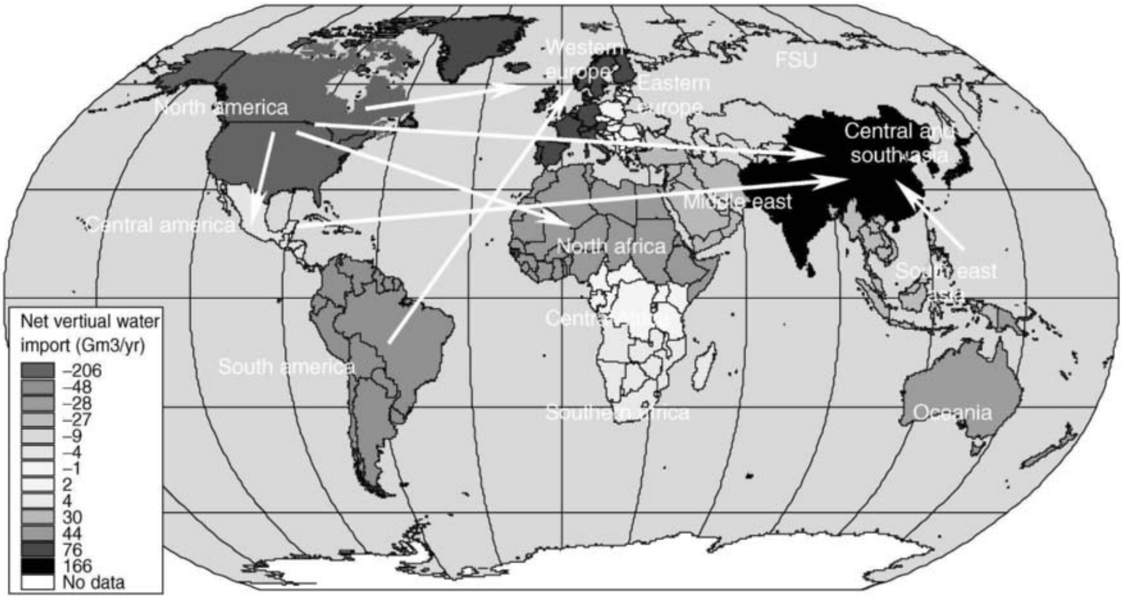

Figure 2. Virtual water balances of thirteen world regions over the period 1995–1999. The arrows show the largest net virtual water flows between regions (>20 Gm^3/yr).

Central and South Asia, Western Europe, North Africa, and the Middle East. Two other regions with net virtual water import, but less substantial, are southern Africa and Central Africa. Regions with substantial net virtual water export are North America, South America, Oceania, and Southeast Asia. Three other regions with net virtual water export, but less substantial, are the former Soviet Union, Central America, and Eastern Europe. North America is by far the biggest virtual water exporter in the world, while Central and South Asia is by far the biggest virtual water importer. Central and South Asia is the largest region in terms of population, so food demand is higher than in the other regions. This explains why the region is the biggest virtual water importer. The virtual water flows between countries within the region are also high, thus the countries within the region highly depend on both countries outside and countries within the region. Western Europe is the region with the biggest volume of internal virtual water flows. Besides, the volume appears to be rather stable over the years.

WATER SCIENCE GLOSSARY OF TERMS

U.S. Geological Survey

Here's a list of water-related terms that might help you understand our site better. It is compiled from a number of sources and should not be considered an "official" U.S. Geological Survey water glossary. A detailed water glossary is kept by the Water Quality Association, and an **extremely detailed** water dictionary is offered by the Nevada Division of Water Planning.

A

acequia–acequias were important forms of irrigation in the development of agriculture in the American Southwest. The proliferation of cotton, pecans and green

---

chile as major agricultural staples owe their progress to the acequia system.

acid–a substance that has a pH of less than 7, which is neutral. Specifically, an acid has more free hydrogen ions (H^+) than hydroxyl ions (OH^-).

acre-foot (acre-ft)–the volume of water required to cover 1 acre of land (43,560 square feet) to a depth of 1 foot. Equal to 325,851 gallons or 1,233 cubic meters.

alkaline–sometimes water or soils contain an amount of alkali (strongly basic) substances sufficient to raise the pH value above 7.0 and be harmful to the growth of crops.

alkalinity–the capacity of water for neutralizing an acid solution.

alluvium–deposits of clay, silt, sand, gravel, or other particulate material that has been deposited by a stream or other body of running water in a streambed, on a flood plain, on a delta, or at the base of a mountain.

appropriation doctrine–the system for allocating water to private individuals used in most Western states. The doctrine of Prior Appropriation was in common use throughout the arid west as early settlers and miners began to develop the land. The prior appropriation doctrine is based on the concept of "First in Time, First in Right." The first person to take a quantity of water and put it to Beneficial Use has a higher priority of right than a subsequent user. Under drought conditions, higher priority users are satisfied before junior users receive water. Appropriative rights can be lost through nonuse; they can also be sold or transferred apart from the land. Contrasts with Riparian Water Rights.

aquaculture–farming of plants and animals that live in water, such as fish, shellfish, and algae.

aqueduct–a pipe, conduit, or channel designed to transport water from a remote source, usually by gravity.

aquifer–a geologic formation(s) that is water bearing. A geological formation or structure that stores and/or transmits water, such as to wells and springs. Use of the term is usually restricted to those water-bearing formations capable of yielding water in sufficient quantity to constitute a usable supply for people's uses.

aquifer (confined)–soil or rock below the land surface that is saturated with water. There are layers of impermeable material both above and below it and it is under pressure so that when the aquifer is penetrated by a well, the water will rise above the top of the aquifer.

aquifer (unconfined)–an aquifer whose upper water surface (water table) is at atmospheric pressure, and thus is able to rise and fall.

artesian water–ground water that is under pressure when tapped by a well and is able to rise above the level at which it is first encountered. It may or may not flow out at ground level. The pressure in such an aquifer commonly is called artesian pressure, and the formation containing artesian water is an artesian aquifer or confined aquifer. See *flowing well*

artificial recharge–an process where water is put back into ground-water storage from surface-water supplies such as irrigation, or induced infiltration from streams or wells.

B

base flow–streamflow coming from ground-water seepage into a stream.

base–a substance that has a pH of more than 7, which is neutral. A base has less free hydrogen ions (H^+) than hydroxyl ions (OH^-).

bedrock–the solid rock beneath the soil and superficial rock. A general term for solid rock that lies beneath soil, loose sediments, or other unconsolidated material.

C

capillary action–the means by which liquid moves through the porous spaces in a solid, such as soil, plant roots, and the capillary blood vessels in our bodies due to the forces of adhesion, cohesion, and surface tension. Capillary action is essential in carrying substances and nutrients from one place to another in plants and animals.

commercial water use–water used for motels, hotels, restaurants, office buildings, other commercial facilities, and institutions. Water for commercial uses comes both from public-supplied sources, such as a county water department, and self-supplied sources, such as local wells.

condensation–the process of water vapor in the air turning into liquid water. Water drops on the outside of a cold glass of water are condensed water. Condensation is the opposite process of evaporation.

consumptive use–that part of water withdrawn that is evaporated, transpired by plants, incorporated into products or crops, consumed by humans or livestock, or otherwise removed from the immediate water environment. Also referred to as water consumed.

conveyance loss–water that is lost in transit from a pipe, canal, or ditch by leakage or evaporation. Generally, the water is not available for further use; however, leakage from an irrigation ditch, for example, may percolate to a ground-water source and be available for further use.

cubic feet per second (cfs)–a rate of the flow, in streams and rivers, for example. It is equal to a volume of water one foot high and one foot wide flowing a distance of one foot in one second. One "cfs" is equal to 7.48 gallons of water flowing each second. As an example, if your car's gas tank is 2 feet by 1 foot by 1 foot (2 cubic feet), then gas flowing at a rate of 1 cubic foot/second would fill the tank in two seconds.

D

desalinization–the removal of salts from saline water to provide freshwater. This method is becoming a more popular way of providing freshwater to populations.

discharge–the volume of water that passes a given location within a given period of time. Usually expressed in cubic feet per second.

domestic water use–water used for household purposes, such as drinking, food preparation, bathing, washing clothes, dishes, and dogs, flushing toilets, and watering lawns and gardens. About 85% of domestic water is delivered to homes by a public-supply facility, such as a county water department. About 15% of the Nation's population supply their own water, mainly from wells.

drainage basin–land area where precipitation runs off into streams, rivers, lakes, and reservoirs. It is a land feature that can be identified by tracing a line along the highest elevations between two areas on a map, often a ridge. Large drainage basins, like the area that drains into the Mississippi River contain thousands of smaller drainage basins. Also called a "watershed."

drip irrigation–a common irrigation method where pipes or tubes filled with water slowly drip onto crops. Drip irrigation is a low-pressure method of irrigation and less water is lost to evaporation than high-pressure spray irrigation.

drawdown–a lowering of the ground-water surface caused by pumping.

E

effluent–water that flows from a sewage treatment plant after it has been treated.

erosion–the process in which a material is worn away by a stream of liquid (water) or air, often due to the presence of abrasive particles in the stream.

estuary–a place where fresh and salt water mix, such as a bay, salt marsh, or where a river enters an ocean.

evaporation–the process of liquid water becoming water vapor, including vaporization from water surfaces, land surfaces, and snow fields, but not from leaf surfaces. See transpiration

evapotranspiration–the sum of evaporation and transpiration.

F

flood–An overflow of water onto lands that are used or usable by man and not normally covered by water. Floods have two essential characteristics: The inundation of land is temporary; and the land is adjacent to and inundated by overflow from a river, stream, lake, or ocean.

flood, 100-year–A 100-year flood does not refer to a flood that occurs once every 100 years, but to a flood level with a 1 percent chance of being equaled or exceeded in any given year.

flood plain–a strip of relatively flat and normally dry land alongside a stream, river, or lake that is covered by water during a flood.

flood stage–The elevation at which overflow of the natural banks of a stream or body of water begins in the reach or area in which the elevation is measured.

flowing well/spring–a well or spring that taps ground water under pressure so that water rises without pumping. If the water rises above the surface, it is known as a flowing well.

freshwater, fresh water–water that contains less than 1,000 milligrams per liter (mg/L) of dissolved solids; generally, more than 500 mg/L of dissolved solids is undesirable for drinking and many industrial uses.

G

gage height–the height of the water surface above the gage datum (zero point). Gage height is often used interchangeably with the more general term, stage, although gage height is more appropriate when used with a gage reading.

gaging station–a site on a stream, lake, reservoir or other body of water where observations and hydrologic data are obtained. The U.S. Geological Survey measures stream discharge at gaging stations.

geyser–a geothermal feature of the Earth where there is an opening in the surface that contains superheated water that periodically erupts in a shower of water and steam.

giardiasis–a disease that results from an infection by the protozoan parasite Giardia Intestinalis, caused by drinking water that is either not filtered or not chlorinated. The disorder is more prevalent in children than in adults and is characterized by abdominal discomfort, nausea, and alternating constipation and diarrhea.

glacier–a huge mass of ice, formed on land by the compaction and recrystallization of snow, that moves very slowly downslope or outward due to its own weight.

greywater–wastewater from clothes washing machines, showers, bathtubs, hand washing, lavatories and sinks.

ground water–(1) water that flows or seeps downward and saturates soil or rock, supplying springs and wells. The upper surface of the saturate zone is called the water table. (2) Water stored underground in rock crevices and in the pores of geologic materials that make up the Earth's crust.

ground water, confined–ground water under pressure significantly greater than atmospheric, with its upper limit the bottom of a bed with hydraulic conductivity distinctly lower than that of the material in which the confined water occurs.

ground-water recharge–inflow of water to a ground-water reservoir from the surface. Infiltration of precipitation and its movement to the water table is one form of natural recharge. Also, the volume of water added by this process.

ground water, unconfined–water in an aquifer that has a water table that is exposed to the atmosphere.

H

hardness–a water-quality indication of the concentration of alkaline salts in water, mainly calcium and magnesium. If the water you use is "hard" then more soap, detergent or shampoo is necessary to raise a lather.

headwater(s)–(1) the source and upper reaches of a stream; also the upper reaches of a reservoir; (2) the water upstream from a structure or point on a stream; (3) the small streams that come together to form a river. Also may be thought of as any and all parts of a river basin except the mainstream river and main tributaries.

hydroelectric power water use–the use of water in the generation of electricity at plants where the turbine generators are driven by falling water.

hydrologic cycle–the cyclic transfer of water vapor from the Earth's surface via evapotranspiration into the atmosphere, from the atmosphere via precipitation back to earth, and through runoff into streams, rivers, and lakes, and ultimately into the oceans.

I

impermeable layer–a layer of solid material, such as rock or clay, which does not allow water to pass through.

industrial water use–water used for industrial purposes in such industries as steel, chemical, paper, and petroleum refining. Nationally, water for industrial uses comes mainly (80%) from self-supplied sources, such as a local wells or withdrawal points in a river, but some water comes from public-supplied sources, such as the county/city water department.

infiltration–flow of water from the land surface into the subsurface.

injection well–refers to a well constructed for the purpose of injecting treated wastewater directly into the ground. Wastewater is generally forced (pumped) into the well for dispersal or storage into a designated aquifer. Injection wells are generally drilled into aquifers that don't deliver drinking water, unused aquifers, or below freshwater levels.

irrigation–the controlled application of water for agricultural purposes through manmade systems to supply water requirements not satisfied by rainfall. Here's a quick look at some types of irrigation systems.

irrigation water use–water application on lands to assist in the growing of crops and pastures or to maintain vegetative growth in recreational lands, such as parks and golf courses.

K

kilogram–one thousand grams.

kilowatt-hour (KWH)–a power demand of 1,000 watts for one hour. Power company utility rates are typically expressed in cents per kilowatt-hour.

L

leaching–the process by which soluble materials in the soil, such as salts, nutrients, pesticide chemicals or contaminants, are washed into a lower layer of soil or are dissolved and carried away by water.

lentic waters–ponds or lakes (standing water).

levee–a natural or manmade earthen barrier along the edge of a stream, lake, or river. Land alongside rivers can be protected from flooding by levees.

livestock water use–water used for livestock watering, feed lots, dairy operations, fish farming, and other on-farm needs.

lotic waters–flowing waters, as in streams and rivers.

M

maximum contaminant level (MCL)–the designation given by the U.S. Environmental Protection Agency (EPA) to water-quality standards promulgated under the Safe Drinking Water Act. The MCL is the greatest amount of a contaminant that can be present in drinking water without causing a risk to human health.

milligram (mg)–One-thousandth of a gram.

milligrams per liter (mg/l)–a unit of the concentration of a constituent in water or wastewater. It represents 0.001 gram of a constituent in 1 liter of water. It is approximately equal to one part per million (PPM).

million gallons per day (Mgd)–a rate of flow of water equal to 133,680.56 cubic feet per day, or 1.5472 cubic feet per second, or 3.0689 acre-feet per day. A flow of one million gallons per day for one year equals 1,120 acre-feet (365 million gallons).

mining water use–water use during quarrying rocks and extracting minerals from the land.

municipal water system–a water system that has at least five service connections or which regularly serves 25 individuals for 60 days; also called a public water system

N

nephelometric turbidity unit (NTU)–unit of measure for the turbidity of water. Essentially, a measure of the cloudiness of water as measured by a nephelometer. Turbidity is based on the amount of light that is reflected off particles in the water.

non-point source (NPS) pollution–pollution discharged over a wide land area, not from one specific location. These are forms of diffuse pollution caused by sediment, nutrients, organic and toxic substances originating from land-use activities, which are carried to lakes and streams by surface runoff. Non-point source pollution is contamination that occurs when rainwater, snowmelt, or irrigation washes off plowed fields, city streets, or suburban backyards. As this runoff moves across the land surface, it picks up soil particles and pollutants, such as nutrients and pesticides.

O

organic matter–plant and animal residues, or substances made by living organisms. All are based upon carbon compounds.

osmosis–the movement of water molecules through a thin membrane. The osmosis process occurs in our bodies and is also one method of desalinizing saline water.

outfall–the place where a sewer, drain, or stream discharges; the outlet or structure through which reclaimed water or treated effluent is finally discharged to a receiving water body.

oxygen demand–the need for molecular oxygen to meet the needs of biological and chemical processes in water. Even though very little oxygen will dissolve in water, it is extremely important in biological and chemical processes.

P

pH–a measure of the relative acidity or alkalinity of water. Water with a pH of 7 is neutral; lower pH levels indicate increasing acidity, while pH levels higher than 7 indicate increasingly basic solutions.

View a diagram about pH.

particle size–the diameter, in millimeters, of suspended sediment or bed material. Particle-size classifications are:

[1] *Clay* 0.00024–0.004 millimeters (mm);
[2] *Silt* 0.004–0.062 mm;
[3] *Sand* 0.062–2.0 mm; and
[4] *Gravel* 2.0–64.0 mm.

parts per billion–the number of "parts" by weight of a substance per billion parts of water. Used to measure extremely small concentrations.

parts per million–the number of "parts" by weight of a substance per million parts of water. This unit is commonly used to represent pollutant concentrations.

pathogen–a disease-producing agent; usually applied to a living organism. Generally, any viruses, bacteria, or fungi that cause disease.

peak flow–the maximum instantaneous discharge of a stream or river at a given location. It usually occurs at or near the time of maximum stage.

per capita use–the average amount of water used per person during a standard time period, generally per day.

percolation–(1) The movement of water through the openings in rock or soil. (2) the entrance of a portion of the streamflow into the channel materials to contribute to ground water replenishment.

permeability–the ability of a material to allow the passage of a liquid, such as water through rocks. Permeable materials, such as gravel and sand, allow water to move quickly through them, whereas unpermeable material, such as clay, don't allow water to flow freely.

point-source pollution–water pollution coming from a single point, such as a sewage-outflow pipe.

polychlorinated biphenyls (PCBs)–a group of synthetic, toxic industrial chemical compounds once used in making paint and electrical transformers, which are chemically inert and not biodegradable. PCBs were frequently found in industrial wastes, and subsequently found their way into surface and ground waters. As a result of their persistence, they tend to accumulate in the environment. In terms of streams and rivers, PCBs are drawn to sediment, to which they attach and can remain virtually indefinitely. Although virtually banned in 1979 with the passage of the Toxic Substances Control Act, they continue to appear in the flesh of fish and other animals.

porosity–a measure of the water-bearing capacity of subsurface rock. With respect to water movement, it is not just the total magnitude of porosity that is important, but the size of the voids and the extent to which they are interconnected, as the pores in a formation may be open, or interconnected, or closed and isolated. For example, clay may have a very high porosity with respect to potential water content, but it constitutes a poor medium as an aquifer because the pores are usually so small.

potable water–water of a quality suitable for drinking.

precipitation–rain, snow, hail, sleet, dew, and frost.

primary wastewater treatment–the first stage of the wastewater-treatment process where mechanical methods, such as filters and scrapers, are used to remove pollutants. Solid material in sewage also settles out in this process.

prior appropriation doctrine–the system for allocating water to private individuals used in most Western states. The doctrine of Prior Appropriation was in common use throughout the arid West as early settlers and miners began to develop the land. The prior appropriation doctrine is based on the concept of "First in Time, First in Right." The first person to take a quantity of water and put it to beneficial use has a higher priority of right than a subsequent user. The rights can be lost through nonuse; they can also be sold or transferred apart from the land. Contrasts with riparian water rights.

public supply–water withdrawn by public governments and agencies, such as a county water department, and by private companies that is then delivered to users. Public suppliers provide water for domestic, commercial, thermoelectric power, industrial, and public water users. Most people's household water is delivered by a public water supplier. The systems have at least 15 service connections (such as households, businesses, or schools) or regularly serve at least 25 individuals daily for at least 60 days out of the year.

public water use–water supplied from a public-water supply and used for such purposes as firefighting, street washing, and municipal parks and swimming pools.

R

rating curve–A drawn curve showing the relation between gage height and discharge of a stream at a given gaging station.

recharge–water added to an aquifer. For instance, rainfall that seeps into the ground.

reclaimed wastewater–treated wastewater that can be used for beneficial purposes, such as irrigating certain plants.

recycled water–water that is used more than one time before it passes back into the natural hydrologic system.

reservoir–a pond, lake, or basin, either natural or artificial, for the storage, regulation, and control of water.

return flow–(1) That part of a diverted flow that is not consumptively used and returned to its original source or another body of water. (2) (Irrigation) Drainage water from irrigated farmlands that re-enters the water system to be used further downstream.

returnflow (irrigation)–irrigation water that is applied to an area and which is not consumed in evaporation or transpiration and returns to a surface stream or aquifer.

reverse osmosis–(1) (Desalination) The process of removing salts from water using a membrane. With reverse osmosis, the product water passes through a fine membrane that the salts are unable to pass through, while the salt waste (brine) is removed and disposed. This process differs from electrodialysis, where the salts are extracted from the feedwater by using a membrane with an electrical current to separate the ions. The positive ions go through one membrane, while the negative ions flow through a different membrane, leaving the end product of freshwater. (2) (Water Quality) An advanced method of water or wastewater treatment that relies on a semi-permeable membrane to separate waters from pollutants. An external force is used to reverse the normal osmotic process resulting in the solvent moving from a solution of higher concentration to one of lower concentration.

riparian water rights–the rights of an owner whose land abuts water. They differ from state to state and often depend on whether the water is a river, lake, or ocean. The doctrine of riparian rights is an old one, having its origins in English common law. Specifically, persons who own land adjacent to a stream have the right to make reasonable use of the stream. Riparian users of a stream share the streamflow among themselves, and the concept of priority of use (Prior Appropriation Doctrine) is not applicable. Riparian rights cannot be sold or transferred for use on nonriparian land.

river–A natural stream of water of considerable volume, larger than a brook or creek.

runoff–(1) That part of the precipitation, snow melt, or irrigation water that appears in uncontrolled surface streams, rivers, drains or sewers. Runoff may be classified according to speed of appearance after rainfall or melting snow as direct runoff or base runoff, and according to source as surface runoff, storm interflow, or ground-water runoff. (2) The total discharge described in (1), above, during a specified period of time. (3) Also defined as the depth to which a drainage area would be covered if all of the runoff for a given period of time were uniformly distributed over it.

S

saline water–water that contains significant amounts of dissolved solids.

Here are our parameters for saline water:

Fresh water. Less than 1,000 parts per million (ppm)
Slightly saline water. From 1,000 ppm to 3,000 ppm
Moderately saline water. From 3,000 ppm to 10,000 ppm
Highly saline water. From 10,000 ppm to 35,000 ppm

secondary wastewater treatment–treatment (following primary wastewater treatment) involving the biological process of reducing suspended, colloidal, and dissolved organic matter in effluent from primary treatment systems and which generally removes 80 to 95 percent of the Biochemical Oxygen Demand (BOD) and suspended matter. Secondary wastewater treatment may be accomplished by biological or chemical-physical methods. Activated sludge and trickling filters are two of the most common means of secondary treatment. It is accomplished by bringing together waste, bacteria, and oxygen in trickling filters or in the activated sludge process. This treatment removes floating and settleable solids and about 90 percent of the oxygen-demanding substances and suspended solids. Disinfection is the final stage of secondary treatment.

sediment–usually applied to material in suspension in water or recently deposited from suspension. In the plural the word is applied to all kinds of deposits from the waters of streams, lakes, or seas.

sedimentary rock–rock formed of sediment, and specifically: (1) sandstone and shale, formed of fragments of other rock transported from their sources and deposited in water; and (2) rocks formed by or from secretions of organisms, such as most limestone. Many sedimentary rocks show distinct layering, which is the result of different types of sediment being deposited in succession.

sedimentation tanks–wastewater tanks in which floating wastes are skimmed off and settled solids are removed for disposal.

self-supplied water–water withdrawn from a surface- or ground-water source by a user rather than being obtained from a public supply. An example would be homeowners getting their water from their own well.

seepage–(1) The slow movement of water through small cracks, pores, Interstices, etc., of a material into or out of a body of surface or subsurface water. (2) The loss of water by infiltration into the soil from a canal, ditches, laterals, watercourse, reservoir, storage facilities, or other body of water, or from a field.

septic tank–a tank used to detain domestic wastes to allow the settling of solids prior to distribution to a leach field for soil absorption. Septic tanks are used when a sewer line is not available to carry them to a treatment plant. A settling tank in which settled sludge is in immediate contact with sewage flowing through the tank, and wherein solids are decomposed by anaerobic bacterial action.

settling pond (water quality)–an open lagoon into which wastewater contaminated with solid pollutants is placed and allowed to stand. The solid pollutants suspended in the water sink to the bottom of the lagoon and the liquid is allowed to overflow out of the enclosure.

sewage treatment plant–a facility designed to receive the wastewater from domestic sources and to remove materials that damage water quality and threaten public health and safety when discharged into receiving streams or bodies of water. The substances removed are classified into four basic areas:

[1] greases and fats;
[2] solids from human waste and other sources;
[3] dissolved pollutants from human waste and decomposition products; and
[4] dangerous microorganisms.

Most facilities employ a combination of mechanical removal steps and bacterial decomposition to achieve the desired results. Chlorine is often added to discharges from the plants to reduce the danger of spreading disease by the release of pathogenic bacteria.

sewer–a system of underground pipes that collect and deliver wastewater to treatment facilities or streams.

sinkhole–a depression in the Earth's surface caused by dissolving of underlying limestone, salt, or gypsum.

Drainage is provided through underground channels that may be enlarged by the collapse of a cavern roof.

solute–a substance that is dissolved in another substance, thus forming a solution.

solution–a mixture of a solvent and a solute. In some solutions, such as sugar water, the substances mix so thoroughly that the solute cannot be seen. But in other solutions, such as water mixed with dye, the solution is visibly changed.

solvent–a substance that dissolves other substances, thus forming a solution. Water dissolves more substances than any other, and is known as the "universal solvent."

specific conductance–a measure of the ability of water to conduct an electrical current as measured using a 1-cm cell and expressed in units of electrical conductance, that is, Siemens per centimeter at 25 degrees Celsius. Specific conductance can be used for approximating the total dissolved solids content of water by testing its capacity to carry an electrical current. In water quality, specific conductance is used in ground water monitoring as an indication of the presence of ions of chemical substances that may have been released by a leaking landfill or other waste storage or disposal facility. A higher specific conductance in water drawn from downgradient wells when compared to upgradient wells indicates possible contamination from the facility.

spray irrigation–a common irrigation method where water is shot from high-pressure sprayers onto crops. Because water is shot high into the air onto crops, some water is lost to evaporation.

storm sewer–a sewer that carries only surface runoff, street wash, and snow melt from the land. In a separate sewer system, storm sewers are completely separate from those that carry domestic and commercial wastewater (sanitary sewers).

stream–a general term for a body of flowing water; natural water course containing water at least part of the year. In hydrology, it is generally applied to the water flowing in a natural channel as distinct from a canal.

streamflow–the water discharge that occurs in a natural channel. A more general term than runoff, streamflow may be applied to discharge whether or not it is affected by diversion or regulation.

subsidence–a dropping of the land surface as a result of ground water being pumped. Cracks and fissures can appear in the land. Subsidence is virtually an irreversible process.

surface tension–the attraction of molecules to each other on a liquid's surface. Thus, a barrier is created between the air and the liquid.

surface water–water that is on the Earth's surface, such as in a stream, river, lake, or reservoir.

suspended sediment–very fine soil particles that remain in suspension in water for a considerable period of time without contact with the bottom. Such material remains in suspension due to the upward components of turbulence and currents and/or by suspension.

suspended-sediment concentration–the ratio of the mass of dry sediment in a water-sediment mixture to the mass of the water-sediment mixture. Typically expressed in milligrams of dry sediment per liter of water-sediment mixture.

suspended-sediment discharge–the quantity of suspended sediment passing a point in a stream over a specified period of time. When expressed in tons per day, it is computed by multiplying water discharge (in cubic feet per second) by the suspended-sediment concentration (in milligrams per liter) and by the factor 0.0027.

suspended solids–solids that are not in true solution and that can be removed by filtration. Such suspended solids usually contribute directly to turbidity. Defined in waste management, these are small particles of solid pollutants that resist separation by conventional methods.

T

tertiary wastewater treatment–selected biological, physical, and chemical separation processes to remove organic and inorganic substances that resist conventional treatment practices; the additional treatment of effluent beyond that of primary and secondary treatment methods to obtain a very high quality of effluent. The complete wastewater treatment process typically involves a three-phase process: (1) First, in the primary wastewater treatment process, which incorporates physical aspects, untreated water is passed through a series of screens to remove solid wastes; (2) Second, in the secondary wastewater treatment process, typically involving biological and chemical processes, screened wastewater is then passed a series of holding and aeration tanks and ponds; and (3) Third, the tertiary wastewater treatment process consists of flocculation basins, clarifiers, filters, and chlorine basins or ozone or ultraviolet radiation processes.

thermal pollution–a reduction in water quality caused by increasing its temperature, often due to disposal of waste heat from industrial or power generation processes. Thermally polluted water can harm the environment because plants and animals can have a hard time adapting to it.

thermoelectric power water use–water used in the process of the generation of thermoelectric power. Power plants that burn coal and oil are examples of thermoelectric-power facilities.

transmissibility (ground water)–the capacity of a rock to transmit water under pressure. The coefficient of transmissibility is the rate of flow of water, at the prevailing water temperature, in gallons per day, through a vertical strip of the aquifer one foot wide, extending the full saturated height of the aquifer under a hydraulic gradient of 100-percent. A hydraulic gradient of 100-percent means a one foot drop in head in one foot of flow distance.

transpiration–process by which water that is absorbed by plants, usually through the roots, is evaporated into the atmosphere from the plant surface, such as leaf pores. See evapotranspiration.

Tributary–a smaller river or stream that flows into a larger river or stream. Usually, a number of smaller tributaries merge to form a river.

turbidity–the amount of solid particles that are suspended in water and that cause light rays shining through the water to scatter. Thus, turbidity makes the water cloudy or even opaque in extreme cases. Turbidity is measured in nephelometric turbidity units (NTU).

U

unsaturated zone–the zone immediately below the land surface where the pores contain both water and air, but are not totally saturated with water. These zones differ from an aquifer, where the pores are saturated with water.

W

wastewater–water that has been used in homes, industries, and businesses that is not for reuse unless it is treated.

wastewater-treatment return flow–water returned to the environment by wastewater-treatment facilities.

water cycle–the circuit of water movement from the oceans to the atmosphere and to the Earth and return to the atmosphere through various stages or processes such as precipitation, interception, runoff, infiltration, percolation, storage, evaporation, and transportation.

water quality–a term used to describe the chemical, physical, and biological characteristics of water, usually in respect to its suitability for a particular purpose.

water table–the top of the water surface in the saturated part of an aquifer.

water use–water that is used for a specific purpose, such as for domestic use, irrigation, or industrial processing. Water use pertains to human's interaction with and influence on the hydrologic cycle, and includes elements, such as water withdrawal from surface- and ground-water sources, water delivery to homes and businesses, consumptive use of water, water released from wastewater-treatment plants, water returned to the environment, and instream uses, such as using water to produce hydroelectric power.

watershed–the land area that drains water to a particular stream, river, or lake. It is a land feature that can be identified by tracing a line along the highest elevations between two areas on a map, often a ridge. Large watersheds, like the Mississippi River basin contain thousands of smaller watersheds.

watt-hour (Wh)–an electrical energy unit of measure equal to one watt of power supplied to, or taken from, an electrical circuit steadily for one hour.

well (water)–an artificial excavation put down by any method for the purposes of withdrawing water from the underground aquifers. A bored, drilled, or driven shaft, or a dug hole whose depth is greater than the largest surface dimension and whose purpose is to reach underground water supplies or oil, or to store or bury fluids below ground.

withdrawal–water removed from a ground- or surface-water source for use.

X

xeriscaping–a method of landscaping that uses plants that are well adapted to the local area and are drought-resistant. Xeriscaping is becoming more popular as a way of saving water at home.

HARVESTING RAINWATER

Ganesh B. Keremane
University of South Australia
Adelaide, Australia

INTRODUCTION

Water is the genesis and continuing source of all life on the earth, and we all completely depend on this renewable source. According to the United Nation's World Water Development Report (1), "Mankind's most serious challenge in the 21st century might not be war or hunger or disease or even the collapse of civic order; it may be the lack of fresh water," which justifies the present scenario that freshwater is a scarce resource. Although it is the commonest and the most critical stuff on the earth, water has been always an undervalued resource. There are more than 1.4 billion cubic kilometers (km^3) of water—enough to give every man, woman, and child more than 230 million cubic meters (m^3) each if we were to divide it evenly (2). However, more than 98% of the world's water is saltwater, and for our basic vital needs, we have to depend on freshwater, most of which is locked in the polar ice caps. This leaves less than 1% of the earth's freshwater to be accessed in lakes, rivers, and groundwater aquifers. The major portion of the water diverted for human needs is drawn from this renewable, readily accessible part of the world's freshwater resources, thus making it a scarce resource.

NEED FOR WATER HARVESTING

The prevailing water scarcity experienced by most of the water-scarce countries (arid and semiarid) of the world can be attributed to high water stress and unsustainable rates of withdrawal. Dupont (3) attributes this widening gap between freshwater demand and supply to three main factors: a limited global supply of freshwater, increased water consumption, and poor water management. The global supply of freshwater is limited and unevenly distributed as against the demand for freshwater, which increased sixfold between 1900 and 1995 (4,5). Moreover, the exponential increase in the consumption of water from population growth, rapid industrial development, and the expansion of irrigated farmland (6) contributes to added pressure on the water supply. Of these, the trend toward irrigating farmland, which provides one-third of the world's harvest from just 17% of its cropland, is responsible for much of the pressure on the water supply and has risen from 50 million hectares to 250 million hectares since 1990 (7). Poor water management and conservation practices have contributed to the decline in the quality and availability of water in addition to overlogging and deforestation that are destroying water tables and causing siltation and salinization. Wasteful and environmentally destructive farming techniques, overuse of pesticides and chemical fertilizers, and expansion of urban areas are other factors that have further reduced freshwater supplies. The statistics provided in the United Nations World Water Development Report (1) support this:

- World population is likely to increase by half as much again, to about 9.3 billion by 2050.
- One liter of wastewater is sufficient to pollute about eight liters of freshwater, and every day about 2 million tons of wastes are dumped into rivers, lakes, and streams.
- As of today, it is estimated that across the world there are about 12,000 cubic kilometers of wastewater, which is more than the total amount in the world's 10 largest river basins at any given moment.
- At present, 48% of the earth's population lives in towns and cities; this will increase to 60% by 2030.

For these reasons, water has become a scarce resource in many parts of the world. About 80 countries containing 40% of the world's population suffer from serious shortages, mostly in the developing world (4). Despite widely available evidence of the crisis, ways to help ensure adequate water supplies for household, agricultural, and other uses are available to farms and communities. Rudimentary conservation measures, application of new technology, and sensible conservation practices could do much to stabilize water withdrawals (3). Water harvesting is one such technology.

WATER HARVESTING—TO MAKE EVERY DROP COUNT

Providing irrigation to crops in hot, dry countries (arid and semiarid) accounts for 70% of the water use in the world (8). Further, the rise in land pressure has resulted in using more and more marginal areas for agriculture. Much of this land is located in the arid and semiarid belts characterized by scanty, uneven distribution of rainfall, where much of the precious water is soon lost as surface runoff. Recent droughts have highlighted the risks from the failure of monsoons to all life on the earth. Irrigation may be the most obvious response to drought but has proved costly and can benefit only a fortunate few (9). Lately this has gained popularity for an old technology in a new way, and that technology is water harvesting.

Water harvesting is no new concept for humankind. Though its importance in mitigating the water scarcity problem has been highlighted much in the recent past, it traces its history to biblical times. Extensive water harvesting apparatus existed 4000 years ago in Palestine and Greece (10). Critchley and Chapman (9), while discussing the history of water harvesting systems, mentioned that the earliest evidence of the use of water harvesting is the well-publicized systems used by the people of the Negev Desert, where the hillsides were cleared of vegetation and smoothed to provide as much runoff as possible; the water was then channeled in contour ditches to agricultural fields and/or to cisterns. In the New World, about 400–700 years ago, people living in Colarado (North America) and Peru (South America) also employed relatively simple methods of water harvesting for irrigation (11). The practice of collecting water from rooftops is also a very ancient type of water harvesting, practiced since the earliest times up to the present. However, renewed interest in the technology of water harvesting arose in the 1950s in Israel, Australia, and the United States. Since then, this technology has developed manifold through experimentation and demonstration projects.

WHAT IS WATER HARVESTING?

Prinz (12) opines, "There is no generally accepted definition of water harvesting." But the term water harvesting in its crudest form can be understood as, *catching rain as it falls*. However, many experts have defined water harvesting and some of them are mentioned for reference: Critchley and Chapman (9), in their manual on water harvesting, define water harvesting in its broadest sense as the collection of runoff for its productive use. Thames (11) defines water harvesting systems as "artificial methods whereby precipitation can be collected and stored until it is beneficially used. The system includes a catchment area and a storage facility for the harvested water, unless the water is to be immediately concentrated in the soil profile." "Water harvesting is collecting and using precipitation from a catchment surface" (10).

Though defined differently, it is clear from the definitions that water harvesting is the practice of collecting and storing water from various sources for beneficial use; the catchment area, runoff, and the storage area are the central elements or components of any water harvesting system. These elements are briefly explained in Box 1.

Box 1: Components of Water Harvesting[a]

Catchment Area. An area that is reasonably impermeable to water which can be used to produce runoff. It may include natural surfaces such as rock outcrops, surfaces developed for other purposes such as paved highways or roof tops, and/or surfaces prepared with minimal cost and effort such as those cleared of vegetation.

Runoff. That portion of precipitation which is not intercepted by vegetation, absorbed by the land surface, or evaporated, and thus flows overland into a depression, stream, lake, or ocean. Runoff may be classified as direct runoff or base runoff according to the speed of appearance after rainfall or melting snow, and as surface runoff, storm interflow, or groundwater runoff, according to its source.

Storage Area. Based on where the water is stored, the storage area can be the soil profile, excavated ponds, or any underground structure.

1. *The Soil Profile*: Simple arrangements are made to direct water from hillsides onto cultivated areas to store the water immediately in the soil for plant use. Whether sufficient water can be stored to offset a prolonged drought is a disadvantage.
2. *Excavated Ponds*: Ponds excavated in the ground surface are used for storing large quantities of water. These are often economical means of storage, but evaporation and seepage are serious drawbacks.
3. *Underground Structures*: Can be in the form of aquifers (an underground layer of porous rock, sand, or gravel containing large amounts of water) or cisterns (man-made underground construction to store water). In the light of the disadvantages/drawbacks of the other two types, it is an interesting alternative.

^{a}*Source*: Reference 13.

FORMS OF WATER HARVESTING

As mentioned before, water harvesting has been practiced for ages and is still relevant worldwide. A great number of forms exist with various names. Prinz and Singh (14) group water harvesting techniques into three broad groups: rainwater harvesting, floodwater harvesting, and groundwater harvesting. A brief description of these techniques along with subtypes is given below.

Rainwater Harvesting

Defined as a method for inducing, collecting, storing, and conserving local surface runoff for agriculture or other beneficial use (15). This can be further grouped into three subtypes:

- Water collected from roof tops, courtyards, and similar compacted or treated surfaces that is used for domestic purposes or garden crops.
- Microcatchment water harvesting is a method of collecting surface runoff from a small catchment area (catchment length usually between 1 and 30 meters) and storing it in the root zone of an adjacent infiltration basin. The basin is planted with a tree, a bush, or with annual crops.
- Macrocatchment water harvesting, also called harvesting from external catchments, is done where runoff from a hillslope catchment (catchment length usually between 30 and 200 meters) is conveyed to a cropping area located at the hill foot on flat terrain.

Floodwater Harvesting

Defined as the collection and storage of creek flow for irrigation use. According to Critchley and Chapman (9), floodwater harvesting is also known as “large catchment water harvesting” or “spate irrigation” and may be further classified as

- *Floodwater harvesting within a steambed* in which case the water flow is dammed and, as a result, inundates the valley bottom of a floodplain. The water is forced to infiltrate and the wetted area can be used for agriculture or pasture improvement.
- *Floodwater diversion* wherein the wadi water is forced to leave its natural course and is conveyed to nearby fields.

Groundwater Harvesting

A rather new term employed to cover traditional as well as unconventional ways of groundwater extraction. Subsurface dams and sand storage dams are some fine examples of groundwater harvesting. They obstruct the flow of temporary or short-lived streams in a riverbed, and store the water in the sediment below the ground surface, which is useful for aquifer recharge.

WATER HARVESTING STRUCTURES

All the previously mentioned forms of water harvesting are done with the aid of different permanent or temporary structures. There are several structures by which water can be harvested for aquifer recharge. A few most widely used and cheapest structures are described below. Barton (16) ranks them among the most popular methods for two main reasons: low construction cost and ease of operation and maintenance.

- *Contour trenches* are excavations parallel to contours on slopes to conserve water and prevent soil erosion and thus help water to infiltrate.
- *Gully plugs* are stone barriers built across gullies and deep rills that trap sediments eroded from higher up a slope and impound runoff, encouraging infiltration.
- *Check dams* are temporary structures constructed from locally available material such as brushwood, loose rock, or woven wire to impede the soil and water removed from the catchment. The impeded water collects behind the dam and infiltrates the soil, recharging the aquifer. The cost of construction ranges from US $200–400 (for temporary structures) to US $1000–2000 (for permanent structures), depending on the material used, the size of the gully, and the height of the dam (16).

- *A percolation tank* is a dam built on permeable ground so that floodwater is held back long enough to percolate into the ground, hence, the name "percolation tank." This is constructed by excavating a depression to form a small reservoir or by constructing an embankment in a natural ravine or gully. The construction cost is estimated at approximately US $5,000–10,000.
- *Groundwater dams* are structures that intercept or obstruct the natural flow of groundwater. These are often built within riverbeds to obstruct and detain groundwater flow so as to sustain the storage capacity of the aquifer and meet demands during high periods. These may be either a subsurface dam that is constructed within the aquifer itself or a sand storage/silt trapping dam that is constructed above ground to trap sand transported with floodwater.
- *Rooftop harvesting* is a method that can be adopted by individuals. Several techniques to harvest rainwater from the roof tops are in use: abandoned dug well, abandoned/running hand pump, gravity head recharge, and recharge pit (16). Though in use mainly to harvest water for household and domestic use, there are evidences of groundwater recharge using this technique. CGWB (10) has observed additional recharge to groundwater by dug wells to the extent of 6.6 TCM with a benefited area of 1.3 hectare in the Jalgaon district of Maharashtra, and, also, a rise in water level from 1.43 to 2.15 m has been recorded in Delhi from the adoption of rooftop harvesting techniques.

CHOICE OF WATER HARVESTING AREA AND TECHNIQUES

Planning is an important process involved in implementing any water harvesting project by an individual or community. It starts with the identification of the area for water harvesting, followed by selection of the techniques/forms/structures. While doing so, it is of utmost importance to consider the following parameters (11,12).

- *Amount and Seasonal Distribution of Rainfall*: Knowledge of the intensity and distribution of rainfall for a given area is necessary for designing a water harvesting system.
- *Topography*: Knowledge of the landform along with the slope is the next important parameter to determine the system for harvesting water and also the structures to be included.
- *Soil Type and Depth*: Important for designing a water harvesting system, the characteristics of soils determine the water movement and the quantity of water that can be stored and also influence the rainfall runoff process.
- *Provisions for Maintenance*: A maintenance program, even when the water collected is not being used (off season), is a must. Failure to provide for maintenance will result in early failure of the system.
- *Acceptance by the Local Community*: Last but not the least, to be successful water harvesting requires local capacity building, cooperation, and extensive participation. The users must believe that the system proposed is the best for their needs. Hence, before implementing any system, acceptance by the end or final user is a must to ensure the sustainability of the system. Only then can it be a success.

CONCLUSIONS

The water harvesting concept used to be more applicable to arid and semiarid regions where rainfall is either not sufficient or precipitation is erratic. But, lately, due to ever increasing population, growing urbanization, unsustainable withdrawal of groundwater accompanied by erratic monsoons, other regions of the world are also facing the problem of water scarcity. Hence, water harvesting is being looked into as an effective method to mitigate this problem of water scarcity all over the world because it offers a method of effectively developing scarce water resources by concentrating the rainfall/runoff in parts of the total area. These systems have the potential to increase the productivity of arable and grazing land by increasing the yields and by reducing the risk of crop failure. As studied by Kakade et al. (17), they also facilitate afforestation, fruit tree planting, and agroforestry. Using harvested rainwater helps decrease the use of other valuable water sources such as groundwater, and helps in groundwater recharge (18). It is also a relatively inexpensive method of water supply that can be adapted to the resources and needs of the rural poor. As such, there is no "the best" system of water harvesting. However, the system can be designed to fit best within the constraints of a given location taking into account technical, social, physical, and economic factors. Thus, learning from the past experiences and adopting new technological developments that take place, any water harvesting system can be considered a successful or an ideal system if it is

- technically sound, properly designed and maintained,
- economically feasible for the users, and
- capable of being integrated into the social traditions and abilities of the users.

URBAN WATER RESOURCE AND MANAGEMENT IN ASIA: HO CHI MINH CITY

Hiep N. Duc
Environment Protection
Authority, NSW
Bankstown, New South Wales
Australia

INTRODUCTION

Ho Chi Minh City, the largest city in Vietnam, has a current population of about 5 million that is increasing rapidly due to internal migration and natural growth. The water demand and the stress on the environment due to increasing waste and pollution pose a serious challenge to the people and the authority administering the city.

The Ho Chi Minh City Service of Communication and Public Works (SCPW) admitted in September 1998 that the city's decades-old water supply system cannot meet the growing demand. According to the SCPW, the water consumption is estimated at 800,000 m^3 per day, but the combined daily capacity of its two water plants at Thu Duc and Hoc Mon and underground wells stops short at 750,000 m^3. But just only 500,000 m^3 is available to users each day after water loss in delivery is taken into account (the proportion of water loss is as high as 32% in some areas). However, in 2000, the daily demand jumped to 1,250,000 m^3/day but the Water Supply Company can provide only 850,000 m^3/day.

Ho Chi Minh City is situated next to the Saigon River, which joins the Dong Nai River to form the northern and eastern boundaries of the city. This means that the waterways can be both potential water sources and receivers of polluted wastes.

The Dong Nai River has a minimum flow of approximately 100 m^3/s. It originates in the Central Highlands of Vietnam and flows through Dong Nai and Ho Chi Minh City with tributaries from other provinces. The total catchment area is 42,665 km^2, and the total flow volume is 30.6 km^3/year (1). Forests cover approximately 30% of the basin. The upstream area in the lowland part of the river is the present Cat Tien National Park. The Tri An reservoir and hydropower plant are located downstream nearby.

WATER ENVIRONMENT AND POLLUTION

One of the important aspects of water resource usage management is the prevention and mitigation of sources of pollution going into the watercourses.

Sources of Pollution

The majority of industries are located in industrial zones around Ho Chi Minh City. In addition to old industrial zones such as Bien Hoa zone 1 built in 1963, a large number of new industrial zones were set up recently in the neighboring provinces of Dong Nai, Song Be, and Ba Ria-Vung Tau. They were established to attract foreign investment to set up factories to produce goods for domestic and export markets. The industrial zone in Bien Hoa (Dong Nai) is upstream from Ho Chi Minh City. The foremost concern is that the wastewater discharge from this zone to the Dong Nai River is near the Hoa An pumping station that supplies water to the residents of Ho Chi Minh City (2).

Altogether, it was estimated that about 200,000 m^3/day of wastewater are discharged into the Dong Nai–Saigon River from the industrial zones. Industrial source discharges are located mostly in the Thu Duc and Bien Hoa areas, but they can also be found scattered along many canals in and around Ho Chi Minh City. There are five main canal systems that receive direct wastes from various sources: Nhieu Loc-Thi Nghe, Tau Hu-Ben Nghe, Doi-Te, Tan Hoa-Lo Gom, and Tham Luong-Vam Thuat. The total length of these canal systems is about 56 km with about

100 km of smaller tributaries. According to statistical data from the Water Supply Company, there is 461.291 m^3 of wastewater discharge into the canal systems daily (2).

Water pollution is more visible during the rainy season when the inadequate drainage system cannot cope with the water volume. In many areas of the city, traffic cannot move due to extensive flooding after a rain.

Pollution Management

Wastewater treatment facilities are required for new and established industrial zones. In Binh Duong province, a wastewater treatment plant was built in 1998 for the Vietnam–Singapore Industrial Park and adjacent areas. The system includes an 8-km canal to drain rain and treated wastewater from the zone into the Saigon River. In Bien Hoa II Industrial Park, a plant for treating wastewater from factories was put into operation in 1999. The plant has an initial daily capacity for treating 4,000 m^3, and 20 of the 76 factories had been connected to the plant since it started operating. The 2-hectare plant has four reservoirs for biological, chemical, and physical treatment of liquid waste before it is conveyed to another reservoir for final treatment.

Another issue regarding the management of water pollution is the storm water system. In 2001, the municipal Communication and Public Works will spend VND101 billions to upgrade and improve the storm water drainage system. It is part of a 5-year plan to reduce flooding during the rainy season. To partly finance the maintenance and upgrading of the drainage system, the city authority decided in early 2001 to allow the Water Supply Company to collect a water drainage levy from water users starting in July 2001. The rest of the capital is in the form of loans from international bodies such as foreign governments or the World Bank.

The most significant plan for improving water quality and the environment is the Urban Drainage and Sewer Master Plan. This plan was prepared and developed in 1999 with assistance from the Japanese Government. The Nhieu Loc–Thi Nghe canal basin has been identified and given the highest priority to improve the water environment and associated infrastructure (3). The shoreline improvement via house clearance, relocation, and parkland development as well as canal dredging has been done since 1996 but without capital investment in the drainage and sewer infrastructure. Street flooding and traffic jams during the rainy season are a frequent phenomenon. The Nhieu Loc–Thi Nghe Project was started in early 2001; part of the financing came from a World Bank loan. The Project is managed and implemented by the Urban Drainage Company.

The city Urban Drainage and Sewer Master Plan conforms to the national Urban Wastewater Collection and Sanitation Strategy Study and the Government Decision No. 35/1999/QD-TTg of March 5, 1999 (3).

WATER SUPPLY AND DISTRIBUTION

Government and City Organizations

In 1977, the city People's Committee established the Environmental Protection Council to oversee the environment. In 1992, the Environment Committee was formed. In 1994, the Department of Science, Technology and Environment (DOSTE) was established as part of national body run by the Ministry of Science, Technology and Environment (MOSTE) when the Environment Law was passed by the National Assembly.

The Department of Transport Communication and Public Works is the city government body in charge of planning the water supply network and other infrastructures. HCM Water Supply Company is the city operating enterprise in charge of supplying water to the city. The Urban Water Drainage Company is another city authority that oversees the operation of the wastewater and storm water network. The Waste Treatment Company of Ho Chi Minh City is concerned with the disposal of solid wastes, including household and hospital wastes, produced in the city. It owns several landfill waste sites in and around the city. These three public service enterprises report to the city's Director of Transport Communication and Public Works.

All the above companies are city government enterprises. The first private water treatment plant in Vietnam was built on a build-operate-transfer (BOT) basis under a 20-year contract with the city People's Committee and the Water Supply Company of Ho Chi Minh City. The plant was built and run by Binh An Water Corporation, a consortium of Malaysian companies that has a loan from the International Finance Corporation (IFC) (4). The Binh An treatment plant will provide 100,000 m^3/day (about 10% of the current demand) to the Ho Chi Minh City and Bien Hoa industrial zone (5).

Water Supply Network

The main water supply plant for Ho Chi Minh City is the Thu Duc Water Station. It currently supplies 650,000 m^3/day to the city using water from the Dong Nai River. The Dong Nai Water Supply Project will increase the plant capacity to 750,000 m^3/day (6). Part of the project cost is funded by a loan from the Asian Development Bank (ADB). Lyonaise des Eaux is building another water plant at the existing Thu Duc Water station to supply 300,000 m^3 each day to districts 2, 7, 9, Thu Duc, and Nha Be. This is a 25-year joint BOT venture with the Water Supply Company.

In 1991, there was a project planned to build a new water supply plant using water from the Saigon River with funding aid from the Italian government. The planned supply plant has a capacity of 300,000 m^3/day and would provide water to District 12, 6, Tan Binh, and Binh Chanh. But as the project was underway in 1995, the aid was stopped by the Italian government due to faults in timing management. Since then, the HCM People Committee has tried to use various schemes to get it restarted, first as a joint venture with foreign companies, then as a BOT project, and finally in April 2000 as a total sale package including equipment and project works to private investors. But so far none was successful.

In surrounding areas of the city, the water demand was alleviated by some new projects. In 1997, the Hoc Mon Underground Water plant was upgraded to a capacity of 50,000 m^3/daily using a loan from the Asian Development

Bank (ADB). In Dong Nai province, construction of a new water supply plant is being carried out at Thien Tan. The US $25 million Thien Tan water project is funded by aid from the government of the Republic of Korea to provide clean water to more residents of the province. The plant will have a capacity of 100,000 m^3/day.

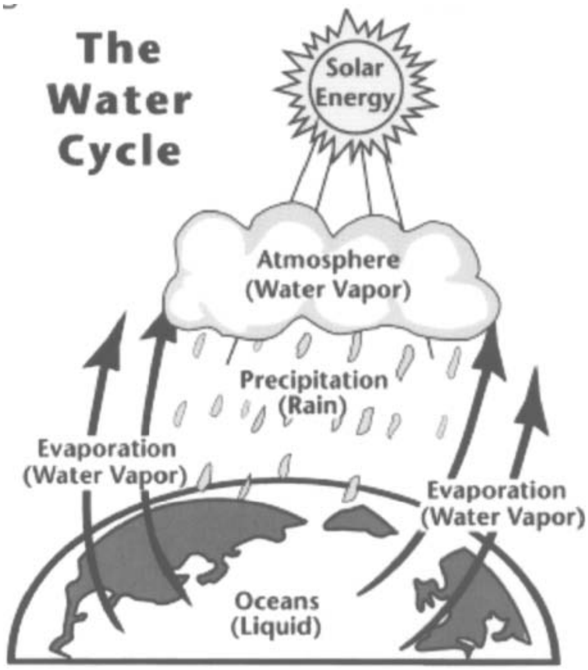
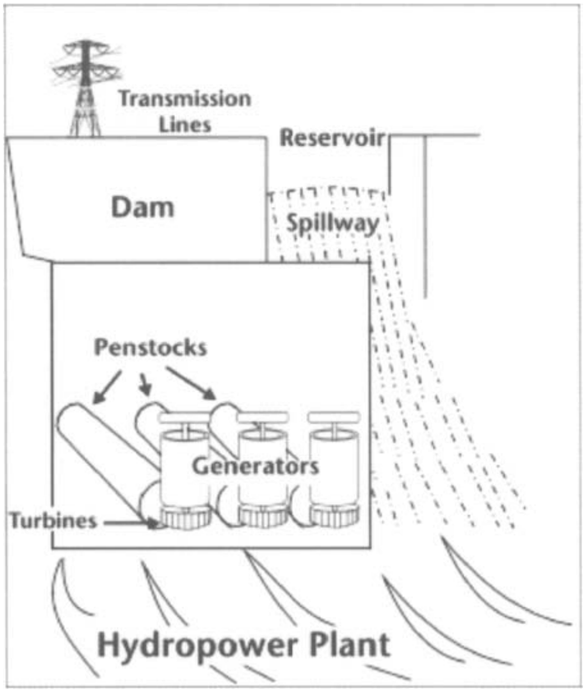
HYDROPOWER—ENERGY FROM MOVING WATER

Energy Information Administration—Department of Energy

Of the renewable energy sources that generate electricity, hydropower is the most often used. It accounted for 6 percent of U.S. generation and 42 percent of renewable generation in 2001. It is one of the oldest sources of energy and was used thousands of years ago to turn a paddle wheel for purposes such as grinding grain. Our nation's first industrial use of hydropower to generate electricity occurred in 1880, when 16 brush-arc lamps were powered using a water turbine at the Wolverine Chair Factory in Grand Rapids, Michigan. The first U.S. hydroelectric power plant opened on the Fox River near Appleton, Wisconsin, on September 30, 1882. Until that time, coal was the only fuel used to produce electricity. Because the source of hydropower is water, hydroelectric power plants must be located on a water source. Therefore, it wasn't until the technology to transmit electricity over long distances was developed that hydropower became widely used.

Mechanical energy is derived by directing, harnessing, or channeling moving water. The amount of available energy in moving water is determined by its *flow* or *fall*. Swiftly flowing water in a big river, like the Columbia River along the border between Oregon and Washington, carries a great deal of energy in its flow. So, too, with water descending rapidly from a very high point, like Niagara Falls in New York. In either instance, the water flows through a pipe, or *penstock*, then pushes against and turns blades in a turbine to spin a generator to produce electricity. In a *run-of-the-river system*, the force of the current applies the needed pressure, while in a *storage system*, water is accumulated in reservoirs created by dams, then released when the demand for electricity is high.





Meanwhile, the reservoirs or lakes are used for boating and fishing, and often the rivers beyond the dams provide opportunities for whitewater rafting and kayaking. Hoover Dam, a hydroelectric facility completed in 1936 on the

---

Colorado River between Arizona and Nevada, created Lake Mead, a 110-mile-long national recreational area that offers water sports and fishing in a desert setting.

Over one-half (52 percent) of the total U.S. hydroelectric capacity for electricity generation is concentrated in three States (Washington, California and Oregon) with approximately 27 percent in Washington, the location of the Nation's largest hydroelectric facility—the Grand Coulee Dam.

It is important to note that only a small percentage of all dams in the United States produce electricity. Most dams were constructed solely to provide irrigation and flood control.

Some people regard hydropower as the ideal fuel for electricity generation because, unlike the nonrenewable fuels used to generate electricity, it is almost free, there are no waste products, and hydropower does not pollute the water or the air. However, it is criticized because it does change the environment by affecting natural habitats. For instance, in the Columbia River, salmon must swim upstream to their spawning grounds to reproduce, but the series of dams gets in their way. Different approaches to fixing this problem have been used, including the construction of "fish ladders" which help the salmon "step up" the dam to the spawning grounds upstream.

WATER MARKETS IN INDIA: ECONOMIC AND INSTITUTIONAL ASPECTS

Halanaik Diwakara
University of South Australia
Adelaide, Australia

BACKGROUND

Historically, India's water resources have been perceived as an important input to production in agriculture for regional and economic development. India is an agrarian economy. Therefore, water is the elixir of life for millions of farmers in the country. Water markets are not akin to commodity markets. Because of ambiguous property rights to both surface and groundwater, informal selling and buying are popping up in different parts of India. These are not legal; surface water structure is built by government funding, so farmers have no right to sell it. In addition, electricity pumping costs are not borne by farmers and a major portion of groundwater pumping is through electricity; so farmers have no right to sell groundwater also.

The water markets are prominent because of the profit from the sale of water for nonagricultural purposes. Electricity is virtually free, so selling groundwater for agriculture is not as profitable as it is for nonagricultural purposes. Even though nonagricultural purposes such as domestic water needs are not as large as for agriculture, consumer demand for domestic water is apparent, and consumers are willing to pay more than farmers who buy water for agriculture. Groundwater is reckoned as a poverty reduction tool in rural India, and its contribution to rural wealth is more than that of surface water (1).

Increasing demand for groundwater in India on account of the Green Revolution and commercial farming has led to enormous pressure on groundwater resources. Because of the growing population and expanding economy, the demand for water is surpassing the supply. Further, development of water resources is constrained by investment bottlenecks, environmental concerns, and political and legal snags inherent in interregional water transfers (3). Though the onus of achieving effective use of water falls on water markets, unless the true cost (value) of water is reflected in terms of actual electricity cost, any attempt by the government would be futile.

Reallocation of water through marketing is a response to growing demands on limited supplies of water (4). Neoclassical economic theory tells us that a market increases efficiency by allocating resources to their most valuable use. However, in the case of natural resources, the economic theory of markets may not always be true, for example, in central California, where the water market is immature (5). This is precisely true for India as well.

This article explores the nature and extent of water markets in India and focuses on groundwater markets and relevant economic and institutional (legislative) aspects. In the next section, the nature and extent of water markets in India are provided, followed by some economic aspects of water markets. In the following section, institutional aspects focusing on regulation of groundwater resource are discussed in the context of water markets. Finally, some water policy (institutional) issues under which water markets can be improved by a water reform process in India are discussed.

NATURE OF WATER MARKETS

Recent literature on water markets in India indicates that markets for groundwater are one of the ways of accessing irrigation (6). These water markets are niche markets, highly location-specific and endemic, at least in south India. In India, water markets are informal; the transfer of water takes place among farmers (between irrigators). In informal water markets, enforcement of contracts does not occur by recourse to legal and institutional measures but rather on personal trust (4). Some markets for water resemble close to perfect competition. Each seller is offering an identical product, so there is free entry and exit of farmers, no single buyer and seller can influence the price, and there is enough information as well (for instance, water markets in Gujarat). These water markets are seasonal and not permanent. Though the water transfer takes place mainly between irrigators, in some pockets like in periurban areas of Bangalore, a southern city of India, water is traded between irrigator and nonirrigators, water markets are localized, and the nature of competition resembles an oligopoly (7). Similar findings are reported by Palanisami (8) and Janakarajan (9). Nevertheless, the demand for groundwater remains large for agriculture.

EXTENT OF WATER MARKETS

The extent of the area irrigated through water markets, which is often considered a proxy of water trading, varies across regions as well as over time, depending on a number of factors such as rainfall, groundwater supply, cropping patterns, and the cost and availability of electricity (3).

It is estimated that 20% of the owners of the 14.2 million pump sets in India are likely to be involved in water trading (10); this indicates that water markets are providing water for about 6 million hectares, or 15% of the total area irrigated by groundwater (4). This is on the high side and therefore it cannot be a reliable estimate. Still, there is a lack of systematic estimates of the magnitude of water trading on the macrolevel. Using a methodology based on pump set rental data, Saleth (10) estimated that 6 million hectares or 15% of the total area under groundwater irrigation is on account of water trading. Further, by a net addition to output of $230/ha/year (based on the difference between the average irrigated and rain-fed yields, as reported by Government of India), the total value of output due to water sales is estimated at $1.38 billion per year (11). According to the irrigation and electricity acts, water selling is illegal, but it persists in niches.

ECONOMIC ASPECTS

The thesis behind the economics of groundwater use is that *water is used most efficiently when it is extracted at rates that maximize net benefits over time*. Hence, the benefit–cost calculus matters. The cost components include the cost of extracting and delivering the groundwater, and the opportunity or the uses to which the water is put determines user cost and benefits. For example, Diwakara and Nagaraj (7) indicated that the benefit–cost ratio for groundwater sales to an urban area in an informal setting is 2.67:1 for the construction and hotel industries compared to 1.35:1 for paddy crops. This signals that water transfer to nonagriculture is a lucrative business. The costs of extraction are primarily a function of pumping technology, the depth from which the groundwater can be pumped, and the costs of energy (mainly electricity in India). These costs increase with pumping depth and costs of energy and decrease as pump efficiency is improved. Thus the water market for agriculture is different from the water market for nonagriculture. Farmers selling water for nonagricultural purposes are relatively more efficient than farmers selling for agriculture because the marginal value product (MVP) of the former is higher than that of the latter.

In India, the cost of energy used to pump the water is charged on a flat rate (fixed) basis, $30.55 per horsepower (in Gujarat), indicating that the marginal extraction cost of pumping groundwater is zero; this encourages farmers to use water to the point where the marginal value of production is close to zero.

The appropriators and policy makers largely ignore the user pays principle, so water markets are inefficient and illegal because user costs are not borne either by the buyer or seller. This has encouraged water sellers to use electric motors to their full capacity at no marginal cost. Further, the cost of extraction also includes the value of the opportunity foregone by extracting and using the water immediately rather than at sometime in the future (opportunity cost). The user cost is a measure of the economic consequences of pumping now and thereby lowering the water table and increasing the cost of extraction for all future periods, that is, increasing negative economic effects that are not internalized. Therefore, sellers are more into a neoclassical return through water rates and interlocked markets.

INSTITUTIONAL (LEGAL) ASPECTS

So far in India, there has been little or no effort to devise appropriate water institutions to cope with the increasing demand for water in a dynamic agrarian economy. Solutions to the technical problems of groundwater resources are well known and are enforceable. However, efficient allocation and use of water resources depend on institutions, which have received lip service. An influential article, “The Tragedy of the Commons” by Garrett Hardin (12) encouraged scholars to hold the view that lack of private property rights to the resource has led to degradation and overexploitation of common pool resources (13). The solution is to promote self-governing institutions (14,15).

Albeit there has been an attempt to regulate groundwater resources through the “Model Bill to Regulate and Control the Development of Groundwater” in 1992, but it failed to address the groundwater extraction and use issues; rather, more emphasis was given to administrative control mechanisms. This misses the potential management opportunities represented by water markets (16). The National Water Policies of 1987 and 2002 have also failed to address regulatory issues to govern the private extraction of groundwater resources.

The issue of property rights has fueled the recent debate on groundwater ownership. It is believed that assigning property rights to groundwater and permitting competitive markets to function can finesse most of the inefficiencies of the common pool problem (17), but this neglects the fact that the appropriative activities by which individuals create effective property rights are themselves an alternative use of scarce resources (18). The priority for exclusive private ownership may be an obstacle to incompletely defining resources situations where some collective ownership may be more appropriate (19). The main function of property rights is to encourage greater internalization of effects (20,21). The rights to extract groundwater are by and large in the hands of private individuals who own land. So, the landlords are also water lords in India, provided the groundwater is available from the vulnerable aquifers. Groundwater is a common pool resource unit, so its yield is subtractable and its exclusion is not an issue of rivalry (22). Hence, defining the rights to use is a challenging task.

Current energy pricing (flat rate) is not desirable for India's groundwater sustainability. Even though some big farmers use high-energy diesel pumps to lift groundwater, the water extraction will not be and cannot be as much as that in the use of electrical pumpsets because farmers have to pay for diesel and not for electricity. Hence, groundwater mining and overuse of energy are interlinked and necessitate a high opportunity cost in water-scarce regions. In Gujarat State, energy pricing is US $37 per year per pump horsepower (23). Therefore, marginal cost pro-rata pricing for electricity could be one of the welfare-improving institutional measures that could be considered. However, as Zilberman (24) notes, these welfare measures would be felt only when the efficiency benefits from reform are more significant and apparent.

On the one hand, groundwater is treated as a "free good," and on the other, it is exploited competitively. This underscores the importance of well-defined, clearly enforceable rights to extract groundwater. Groundwater resources are largely extracted by individual well owners in India. In the absence of well-defined and enforceable rights to extract water, the availability of groundwater is determined and subject to the law of capture, that is, whoever taps the groundwater first gets to use it. In such a situation, pumpers have an incentive to extract as much water as possible, subject to the constraints imposed by pumping costs (25).

Access to groundwater, a fugitive (dynamic) resource, is largely a function of rights to extract. Though a legal framework that ties rights to groundwater to land ownership governs groundwater use in India, there is no legal limit on the amount of water a landowner can draw. Hence, markets for groundwater in India are informal and illegal and fluctuate in pricing as well as in pricing methods. For example, if a farmer is selling groundwater to his neighbor, it is also in return for some labor shortage situations or may be some interest payments and so on. These, too, are subsumed in the water charge paid by the buyer.

In the absence of a limit on the volume of groundwater extracted, farmers are tapping the resource with myopic behavior ignoring the fact that one's extraction is a function of the neighboring well's extraction at a time and over time leading to cumulative interference of wells that affects the lives of the wells (26). The lack of quantity regulation of groundwater extraction might lead to the *tragedy of the water law*. Hence, quantity regulations are common practices around the world and are preferred to taxes (27).

CONCLUDING REMARKS

Though water policy has generally been considered an important issue, its rational formulation and implementation have received lip service, and the water policies of the twenty-first century have to be significantly different from the past policies because of several changes that have already occurred in the water sector (28). India is gearing up to meet the challenges of the millennium with a fast developing economy. Throughout history, institutions have been a panacea for managing natural resources. Without suitable water institutions, the dream of achieving sustainable use of water resources will be in vain. Recognizing water markets as informal institutions that tackle the problem (access) and efficiency (high value use), appropriate measures through regulation of groundwater are the need of the hour for India. It is indicative that markets and states are now seen not as competing but as complementary institutions in the quest to "*get the rules right*," and many formulations see a broader range of institutions of economic governance as essential in this task, including small scale communities-neighborhoods, nongovernmental associations, and the like (29). In this regard, a blend of regulatory and economic measures applicable to Indian situation is suggested herewith.

There is a lack of explicit policy on water markets in India. Keeping in view the reckoned benefits of formal water markets, an attempt could be made to devise a set of rules focusing on property rights (tradable), quantity regulation, energy pricing, well-spacing norms, water laws to promote self-governing institutions that manage groundwater, and establishing an oversight commission to settle disputes between users and water authorities.

PROPERTY RIGHTS

Groundwater in India is largely developed by private investment, as in many parts of the world. However, the rights to extract water are still chattel to the land. The potential benefit of well-defined property rights is that it reduces transaction costs, and assuming access to credit, small farmers can have water rights. Considerable consensus exists that, for markets to be effective, legally defining property rights to water as private and transferable should be in place (4,30,31) along with a declaration of rights for efficient use of the resource (32). As the sovereign power and guardian of the nation's resources, as well as the protector of the law and rights, the government has the power to define necessary property rights and then dispose them to individuals (33). However, the third party effects of water markets need attention because the effects of water transfers and the costs of administering efficient and fair solutions to these third party effects could lead to restricting trade (34). In this regard, quantity regulation would be a suitable strategy.

QUANTITY REGULATION

The groundwater resource is extracted in unlimited quantities in India without regard to its impact on neighboring wells and environmental consequences. Evidence indicates that, in a variety of situations, governments regulate undesirable activities by controlling quantity rather than charging taxes (27). So, simply defining property rights is not a sufficient condition. It should be blended with quantity regulation. If quantity regulation is opted for and implemented, still, the access to groundwater resources is a function of number of users across time and space. Hence, to facilitate efficiency (physical and economic), the resource has to be priced to reflect its true value. This could be done through marginal cost pricing of electricity and groundwater.

MARGINAL COST PRICING

The energy used to lift the groundwater from the deeper layers of the aquifer in many parts of India is electricity and diesel to some extent. Electricity is priced on a fixed (flat rate) basis. Hence, the marginal cost of extraction is zero, and there is no incentive for users to conserve the resource. In a true economic sense, users extract groundwater until the marginal value product becomes zero. The value of groundwater needs to be reflected through marginal cost pricing of electricity and groundwater as well. This could be achieved by pricing electricity on a pro-rata basis.

WELL-SPACING NORMS

In the absence of well spacing norms, the well interference problem poses serious threats to sustainability and equity in well irrigation, especially in water-scarce regions in India. The withdrawal of groundwater without regard to recharge efforts goes unabated, and the resource itself becomes unsustainable by reducing the lives of wells. So, to avoid the well interference problem, which underscores sustainability, there is a need for spacing norms between wells.

PROMOTING SELF-GOVERNING INSTITUTIONS

The community should accept a law to allocate water rights, regulate quantities of water, implement marginal cost pricing, and impose well-spacing norms. Evidence indicates that, if the economic rents from water trading are concentrated in the hands of a few individuals or the negative effect on third-party users is large and unmitigated, the community is not likely to obey the law (4). Therefore, self-governing institutions, such as water users' cooperatives, associations, or small private well organizations need to be promoted by enacting a suitable water law. In any society, there is no guarantee that all stakeholders obey the law. To settle disputes between violators of the rules, there is a need for an oversight commission with representatives from users, local, state, and federal governments.

In conclusion, emphasis should be on collective action through user groups and cooperatively managed irrigation systems for sustainable use of water resources. Therefore, a combination of local water rights and user organizations should be encouraged. Nevertheless, the institutional linkage between water markets and rental markets for irrigation assets needs attention because the rental market allows farmers to irrigate their farms by renting irrigation assets from neighbors, and they contribute both to equity in water use and better use of irrigation assets, especially when groundwater rights are not defined (35).

These are some of the measures that are believed to be possible in the Indian scenario and could be incorporated into legislation, provided that the sociopolitical economy realizes the need and accepts them. Further, there shall not be any underenforced water law, especially in the context of the economic and environmental damage that has been created and unaccounted for largely due to policy failure.

WATER RESOURCES OF INDIA

Sharad K. Jain
National Institute of Hydrology
Roorkee, Uttranchal, India

India occupies an important place in Southeast Asia. Its geographic area of 3.29 million square kilometers extends from 8° 4′ N and 37° 6′ N latitude and between 68° 7′ E and 97° 25′ E longitude. The country is bounded by the Himalayas in the north and has a large peninsular region tapering toward the Indian Ocean. The coastline of India extends for more than 6000 km. This unique combination of location and topography, a large peninsula, very high mountains followed by wide river plains, and the ocean in the south, create a complex climate and hydrology in the country.

From the physiographical point of view, India can be divided into seven broad regions: (1) northern mountains; (2) Plains of Indus and Ganga Basin; (3) Central Highlands; (4) peninsular plateau, the east coast region; and (5) the west coast region. Two chains of islands, the Andaman and Nicobar in the Bay of Bengal and Lakshadweep in the Arabian Sea, are also part of India.

The Himalayas in the north are one of the major mountain ranges of the world. In India, they extend over 2500 km from east to west, and the width varies from 250 to 400 km. Topographically, the Himalayas can be subdivided into three major ranges, the Greater Himalayas, the Middle Himalayas, and the Shivaliks whose average heights are 6000, 4000, and 1000 meters, respectively. The Himalayas are home to many of the highest peaks of the world and have large permanently snow-covered areas. Geologically, the Himalayas are comparatively young mountain chains that are formed by sedimentary rocks. This coupled with steep slopes and intense monsoon rainfall yields high sediment loads in the rivers. The other prominent mountains include the Aravalis, the Vindhyachals, the Satpuras, the Eastern Ghats, and the Western Ghats. The mountains are the primary source of rivers that derive their flow from rainfall and snow and glacier melt (Himalayan rivers). Plateaux, another striking feature of the topography in India, range in elevation from 300 to 900 meters. The major plateaux are the Malwa, the Vindhyas, the Chota Nagpur, the Satpura, and the Deccan.

India is traversed by a number of mighty rivers that can be broadly divided into two groups: the rivers of the Himalayan region and the peninsular rivers. The snow-fed Himalayan rivers are mostly perennial, whereas many small rivers of the peninsular region remain dry during the summer months.

CLIMATE OF INDIA

The mighty mountains, extensive plateaux, and the ocean in the south have an important bearing on the climate of India that can be described as a tropical monsoon climate. India is a country with extremes of climate. The climate varies from extremely hot to extremely cold, from extremely arid to extremely humid, and from continental to oceanic. Here, temperature varies from more than 47° C at some places in summers to below −40° C at many places in the Himalayas; rainfall varies from almost negligible to about 1100 cm. The eastern state of Meghalaya is the home to Cheerapunji, which is famous for the most rainfall in the world—on the order of 1142 cm in a year. Rainfall amounting to nearly 104 cm has been recorded at this place in a day. The potential evapotranspiration over the country varies from 150 to 350 cm. This wide range of climatic conditions working in conjunction with a range of topographic and soil/rock properties produces a complex and interesting pattern of water resource distribution across the country.

In India, rainfall is received through southwest and northeast monsoons, cyclonic depressions, and western disturbances. Most of the rainfall in India takes place under the influence of the southwest monsoon between June and September, except in Tamil Nadu where it occurs under the influence of the northeast monsoon from October–November. The rainfall in India shows great variations, unequal seasonal distribution, unequal geographic distribution, and frequent departure from the normal. The flow of monsoon winds is significantly influenced by high mountains in the north which are an effective barrier. The peninsular shape of the southern part that is close to the ocean provides a big source of moisture.

Monsoons

The southwest monsoon starts from the equatorial belt and hits the Indian subcontinent in two distinct currents. The Bay of Bengal branch sets in the northeastern part of the country, and the Arabian sea branch hits at the southern part of the peninsula. The first branch moves westward, and the second northward; together they cover the whole country. Normally, the monsoon sets in over the entire country by the beginning of July. The monsoon withdraws in September.

As the southwest monsoon withdraws, a northeasterly flow of air begins. This air picks up moisture from the low-pressure areas in the Bay of Bengal, hits the coastal areas of Orissa and Tamil Nadu, and causes rainfall. During this period, severe tropical cyclones are also formed in the Bay of Bengal and the Arabian Sea. These cyclones are responsible for intense rainfall in the coastal areas.

The water vapor carried by the monsoon from June–September amounts to about 11,100 km^3. About 3000 km^3 (= 27% of the total) of this moisture precipitates as rainfall. During the remaining 8 months of the year, precipitation is of the order of 1000 km^3. In South Indian states such as Tamil Nadu, Andhra Pradesh, and Kerala, the northeastern monsoon also contributes significantly to precipitation.

At the beginning of December, weather disturbances originating in extratropical regions enter India from Afghanistan and Pakistan. These are known as western disturbances and cause moderate to heavy rain and snowfall in the northern mountainous region. Light to moderate rainfall is also experienced in the northern plains.

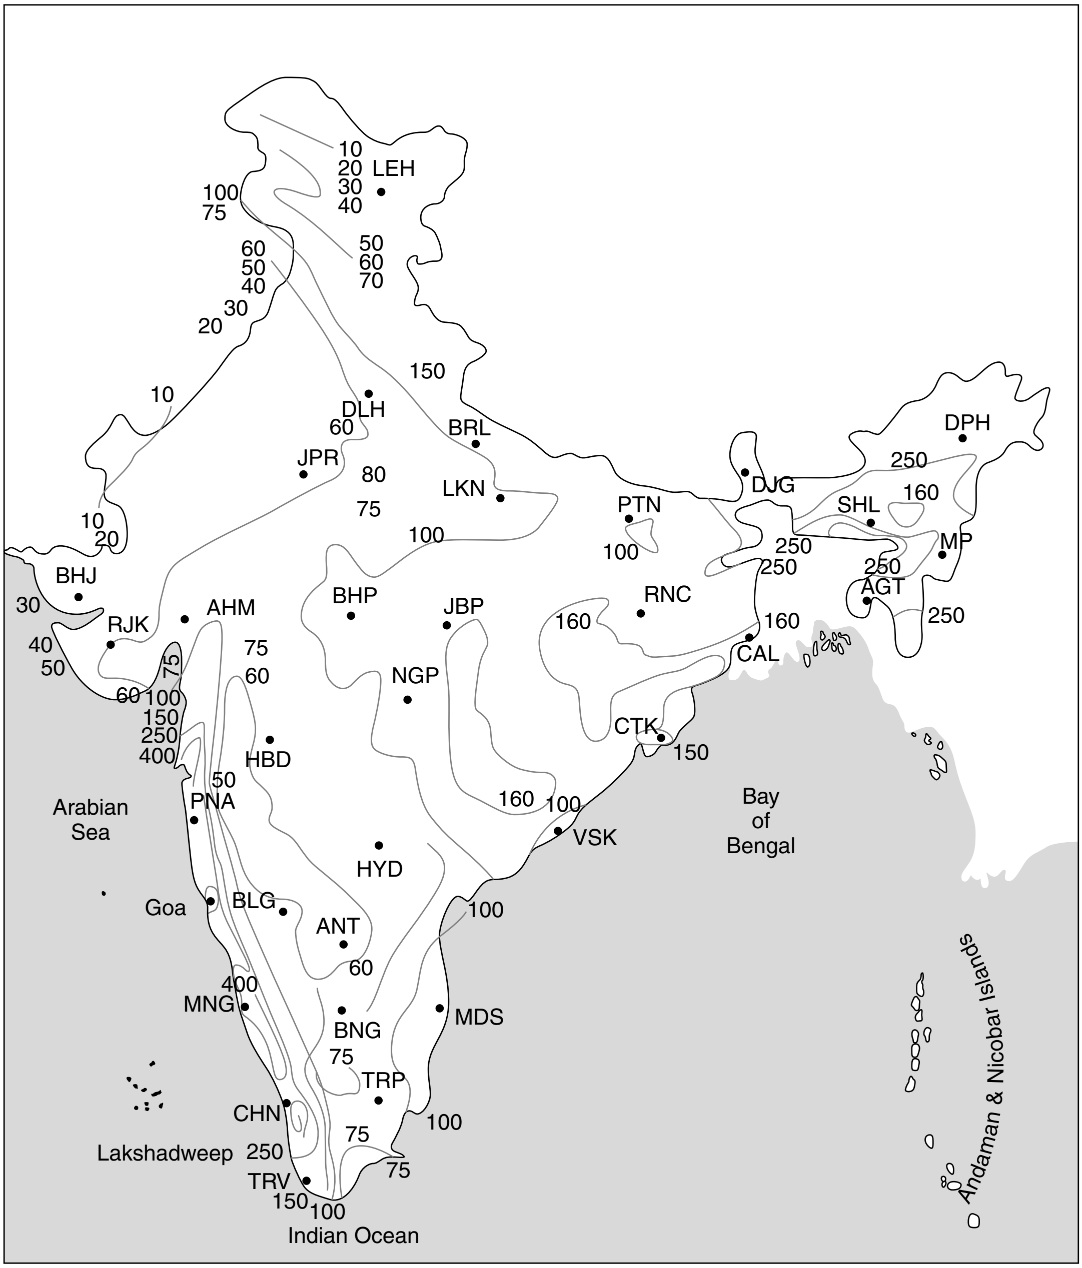
The annual precipitation over the country, including snowfall, is about 4000 km^3 which is equivalent to about 120 cm of depth. The variation of average annual rainfall over the country is shown in Fig. 1. As seen from the figure, there is a considerable amount of areal variation in the annual rainfall in India. The annual rainfall varies from about 10 cm in western deserts to about 1100 cm in northeastern parts of the country. More than half of the precipitation takes place in about 15 days and that too in about 100 hours in a year. The number of rainy days varies from about five in western deserts to 150 in the northeast. Such a wide variation makes the task of water resource engineers very challenging.

River Basins of India

A river basin, the natural context in which water occurs, is the most appropriate unit for planning, development, and management of water resources. The Ganga–Brahmaputra–Meghna basin, the largest basin in India, receives waters from an area that comprises about one third of the total area of the country. The second largest basin, that of Godavari, covers about 10% of the total area of India. The rivers are well spread over the entire country except for the Thar desert in Rajasthan. The catchment areas of the major river basins and the states through which they flow are given in Table 1. A map of India showing important rivers is given in Fig. 2.

Based on topography, the river systems of India can be classified into four groups: (1) Himalayan rivers, (2) Deccan rivers, (3) coastal rivers, and (4) rivers of the inland drainage basin. The Himalayan rivers receive input from rain as well as snow and glaciers and, therefore, are perennial. During the monsoon months, the Himalayas receive very heavy rainfall, and these are the periods when the rivers carry about 80% or more of the annual flow. This is also the period when floods are commonly experienced. The Deccan rivers are rain-fed and therefore have little or no flow during the nonmonsoon season. The coastal streams, especially on the west coast, have limited catchment areas and are not lengthy. Most of them are nonperennial. The streams of the inland drainage basin of Western Rajasthan are few and far between. They flow for a time only during the monsoon.

The main river systems in the Himalayas are those of the Indus and the Ganga–Brahmputra–Meghna. The River Indus rises near Mansarovar Lake in Tibet. Flowing through Kashmir, it enters Pakistan and empties into the Arabian Sea near Karachi. A number of important tributaries of the Indus, the Sutlej, the Beas, the Ravi, the Chenab, and the Jhelum, flow through India. The Bhagirathi and Alakhnanda are two important rivers that originate in the Garhwal Himalayas. These join at Dev Prayag to form the Ganga, the most sacred river of India. It traverses Uttranchal, Uttar Pradesh, Bihar, and West Bengal and thereafter enters Bangladesh. Some important tributaries of the Ganga are the Yamuna, the Ramganga, the Ghaghra, the Gandak, the Kosi, and the Sone. Many of these tributaries are mighty rivers themselves. For example, River Yamuna has its own mighty tributaries, Chambal and Betwa. The Brahmaputra rises in Tibet (where it is known by the name Tsangpo). It enters India in Arunachal Pradesh and after traversing Assam, enters Bangladesh. Its important tributaries are the Dibang, Luhit, Subansiri, Manas, and Tista. The Ganga and Brahmputra Rivers meet at Goalundo in Bangladesh. The Barak river, the head waters of the Meghna rises in the hills in Manipur. The Meghna is part of the Ganga–Brahmaputra–Meghna system. The combined Ganga–Brahmaputra River meets the Meghna in Bangladesh, and this combined system flows into the Bay of Bengal.



(i) Based upon survey of India map with the permission of the surveyor general of India

(ii) © Government of India copyright 1990.

(iii) The territorial waters of India extend into the sea to a distance of twelve nautical miles measured from the appropriate base line.

Figure 1. Annual rainfall across India (1).

The Deccan rivers can be further classified in two groups: west flowing rivers and east flowing rivers. The Narmada and the Tapi Rivers flow westward into the Arabian Sea. The important east flowing rivers are the Brahmani, the Mahanadi, the Godavari, the Krishna, the Pennar, and the Cauvery. These rivers flow into the Bay of Bengal. The rivers on the west coast are important because they contain as much as 14% of the country's water resources and drain only 3% of the land.

SURFACE WATER RESOURCES OF INDIA

The water resources of a basin are based on stream flow measured at a terminal site on the river. The average annual flow at the terminal point of a river is normally denoted as the water resource of the basin. Note that this refers to availability of water with a probability of 50%. To plan a water resource project, dependability at other levels such as 75% and 90% is needed. Most Indian rivers

	Total	3,287,260	

[a] Reference 1.

carry large flows during the monsoon season (June to September). The average annual flow in important Indian rivers is given in Table 2.

Usable Surface Water Resources

Though the estimated surface water availability is of the order of 1869 km^3, the amount of water that can be put to beneficial uses is much less because India experiences monsoon climate, implying that nearly 80–90% of the annual runoff occurs during monsoon months. As enough storage capacity is not available, a large part of this flow goes to waste, and some of it also causes flood damage.

As is clear from Table 2, the storage space available from the projects completed by 1995 is about 174 km^3; the projects under construction would provide 76 km^3, a total of about 250 km^3 of storage space, ignoring small structures. This is about 36% of the possible storage space of 690 km^3. To harness the usable surface water, about 400 km^3 of additional live storage needs to be created. Thus, the development of surface water has a long way to go to achieve full potential.

GROUNDWATER RESOURCES ASSESSMENT

Groundwater resources can be classified as static and dynamic. The static resource can be defined as the amount of groundwater available in the permeable portion of the aquifer below the zone of water level fluctuation. The dynamic resource is the amount of groundwater available in the zone of water level fluctuation. The usable groundwater resource is essentially a dynamic resource which is recharged annually or periodically

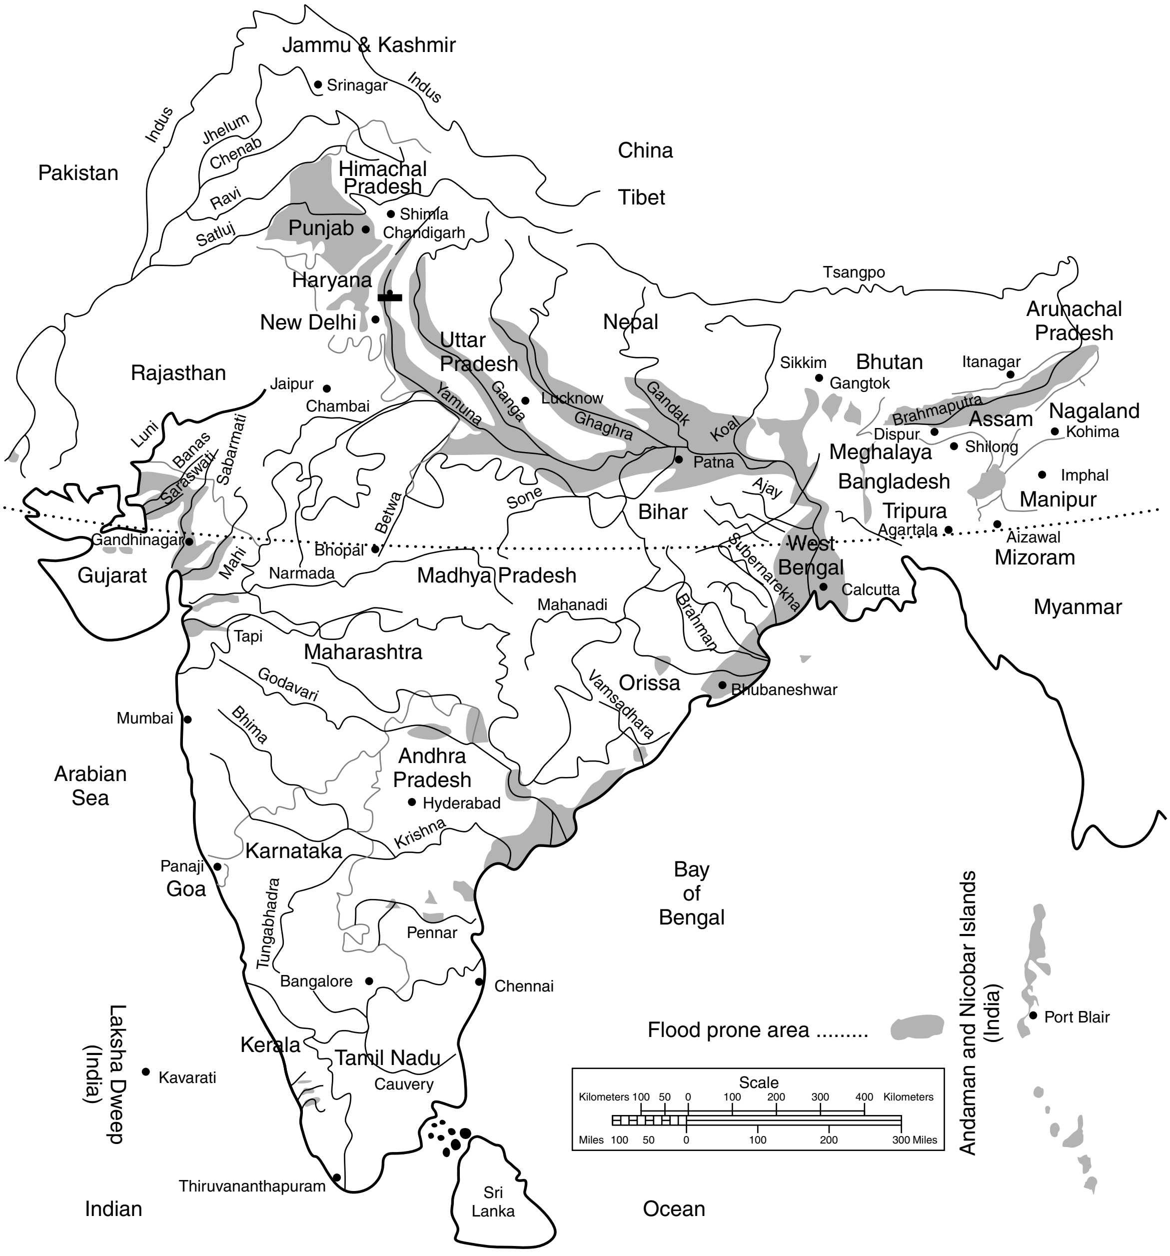

Figure 2. Important rivers of India and flood-prone areas (1).

by rainfall, irrigation return flows, canal seepage, and influent seepage.

Due to diversified meteorologic, topographic, and geologic features, the groundwater distribution is quite divergent across the country. Rock formations vary from Archean to Recent, and the topography ranges from the mountain terrain of Himalayas to the flat alluvial plains and coastal tracts. The northern plains in the Indus–Ganga–Brahmputra Basins that extend over a distance of 2400 km from east to west constitute one of the largest groundwater reservoirs in the world. Almost the entire peninsular part is covered by a variety of hard and fissured rock formations. The coastal and deltaic tracts form a narrow strip around the peninsula; some of them contain highly productive aquifers. The basin-wise groundwater potential of the country is given in Table 3.

The groundwater resources available for irrigation are about 360.3 km^3; out of this, the usable quantity (90% of potential) is about 324.27 km^3. Thus the total usable groundwater resource is $324.27 + 71.08$(domestic and other uses) $= 395.35$ km^3. The present level of development is about 32%.

The water that is present in the aquifer below the zone of water level fluctuation is known as static groundwater. The static groundwater resource of the country is estimated at 10, 812 km^3.

To summarize, the usable volume of water from surface resources is 690 km^3, and from groundwater sources 396 km^3, giving total annual usable water resources of

	Total	1869.00	690.00	173.73	75.42	132.30

1086 km^3. In addition, about 10–15% of this quantity will be available as return flow from irrigation and domestic uses. As against this, the total withdrawal for all uses in the year 1990 was 552 km^3. The irrigation sector accounted for about 83% of this use.

Most of the groundwater development in India is up to a depth of about 50 meters and is financed mainly by institutional and private sources. In the shallow region, the wells include dug wells, dug and bore wells, and shallow tube wells. The exploitation in the deeper zone (50 m and more) is usually through the public sector for community irrigation, water supply, or industrial purposes. Groundwater development has been intensive in the plains of the Indus–Ganga basin of Punjab, Haryana, and Uttar Pradesh.

WATER RESOURCES REQUIREMENT

The increase in population and expansion of economic activities inevitably lead to rising demands for water for diverse purposes. Surface water is either used in-stream for hydropower and navigation or is diverted for off-stream use. A small part of diverted water returns to streams or aquifers, and the rest is consumed. Groundwater is used mostly for irrigation or for domestic requirements.

The Indian economy has traditionally been agriculturally based. At independence, it was of crucial importance to develop irrigation to increase agricultural production to make the country self-sustaining and to alleviate poverty. Accordingly, the irrigation sector was assigned a very high priority in the 5-year plans. Giant schemes such as the Bhakra Nangal, Hirakud, Damodar Valley, Nagarjunasagar, and Rajasthan Canal project were undertaken to increase irrigation potential and maximize agricultural production.

Long-term planning has to take into account the growth of population. A number of individuals and agencies have estimated the likely population of India by the year 2025 and 2050. According to the estimates adopted by NCIWRD(1), by the year 2025, the population is expected to be 1,333 million in the high growth scenario and 1,286 million in the low growth scenario. In the year 2050, the high rate of population growth is likely to result in about 1,581 million people, whereas the low growth projections place the number at nearly 1,346 million. Keeping in view the level of consumption, the estimated food grain requirements per capita per year would be 218 kg for the year 2025 and 284 kg for the year 2050. After considering factors such as feed requirement, losses in storage and transport, seed requirements, and buffer stock, the projected food-grain and feed demand for 2025 would be 320 million tonnes (high demand scenario) and 308 million tonnes (low demand scenario). The requirements for the year 2050 would be 494 million

tonnes (high demand scenario) and 420 million tonnes (low demand scenario).

Irrigation

The irrigated area in the country was only 22.6 million hectare (Mha) in 1950–1951. Food production was much below the requirement of the country, so due attention was paid to expansion of irrigation through surface and groundwater projects. The ultimate irrigation potential of India has been estimated at 140 Mha. Out of this, 76 Mha would come from surface water and 64 Mha from groundwater sources.

The quantity of water used for irrigation in the last century was of the order of 300 km^3 of surface water and 128 km^3 of groundwater. The estimates indicate that by the year 2025, the water requirement for irrigation would be 561 km^3 for a low demand scenario and 611 km^3 for a high demand scenario. These requirements are likely to increase to 628 km^3 for a low demand scenario and 807 km^3 for a high demand scenario by the year 2050.

Domestic Use

Water for the community water supply is the most important requirement, and it is about 5% of total water use. It is estimated that about 7 km^3 of surface water and 18 km^3 of groundwater are being used for community water supply in urban and rural areas. Along with the increase in population, another important change in water supply is a higher rate of urbanization. Per the projections, the higher the expected growth, the higher would be urbanization. It is expected that nearly 61% of the population will be living in urban areas by the year 2050 in a high growth scenario as against 48% in a low growth scenario.

Different organizations and individuals have given different norms for water supply in cities and rural areas. The figure adopted by NCIWRD (1) was 220 liters per capita per day (lpcd) for class I cities. For cities other than class I, the norms are 165 for the year 2025 and 220 lpcd for the year 2050. For rural areas, 70 lpcd and 150 lpcd have been recommended for the years 2025 and 2050. Based on these norms and the projection of population, it is estimated that by the year 2050, the water requirements per year for domestic use will be 90 km^3 for a low demand scenario and 111 km^3 for a high demand scenario. It is expected that about 70% of the urban water requirement and 30% percent of the rural water requirement will be met by surface water sources and the remaining from groundwater.

Hydroelectric Power

The hydropower potential of India has been estimated at 84,044 MW at a 60% load factor. At independence (1947), the installed capacity of hydropower projects was 508 MW which was about 37% of the total installed capacity. By the end of 1998, the installed hydropower capacity was about 22,000 MW which was 24.85% of the total installed capacity of 88,543 MW. The status of hydropower development in major basins is quite uneven. For example, the hydropower potential of Brahmputra Basin is about 34,920 MW which is 41.5% of the total potential of the country. Only 1.3% of this was developed by the year 1998. The percentage development in Indus was about 14.7% and 17.26% in Ganga. The major hydroelectric projects (above 750 MW) in India are Bhakra, Dehar, Koyna, Nagarjunasagar, Srisailam, Sharavarthy, Kalinadi, and Idukki.

Table 4. Annual Water Requirement for Different Uses in km^3

Uses	Year 1997–1998	Year 2010			Year 2025			Year 2050		
		Low	High	%	Low	High	%	Low	High	%

Industrial Water Requirement

Rough estimates indicate that present water use in the industrial sector is of the order of 15 km^3. The water use by thermal and nuclear power plants with installed capacities of 40,000 MW and 1,500 MW (1990 figures), respectively, is estimated at about 19 km^3. In view of the shortage of water, the industries are expected to switch over to water efficient technologies. If the present rate of water use is continued, the water requirement for industries in the year 2050 would be 103 km^3, and if water saving technologies are adopted on a large scale, the requirement is likely to be nearly 81 km^3.

Water Quality

Water quality issues are gaining recognition as river waters are getting heavily polluted in many places and groundwater quality at many places is beginning to deteriorate. Among the main concerns for water quality are (1) arsenic in drinking water in West Bengal (affecting about 5 million persons); (2) fluoride levels are high in Andhra Pradesh, Gujarat, Haryana, Karnataka, Punjab, Rajasthan, Tamil Nadu, and Madhya Pradesh (affecting 14 million persons); (3) iron levels are high in the northeastern and eastern parts of the country (affecting 29 million persons); and (4) salinity is high in Gujarat, Haryana, Karnataka, Punjab, Rajasthan, and Tamil Nadu.

Total Water Requirements

Based on the various studies, the total annual requirement for freshwater from various sectors is estimated at about 1050 billion m^3 by 2025 A.D. The breakdown is shown in Table 4. Estimates show that this demand will be met by harnessing 700 billion m^3 of surface water and 350 billion m^3 of groundwater.

FLOODS AND DROUGHTS

Floods and drought are two water-related natural calamities that are recurrent phenomena in India.

Floods

Floods are the most frequent natural calamities faced by India in different magnitudes, year after year. About 80–90% of the annual precipitation in India takes place during 4 months of monsoon; this is also the season when floods are mostly experienced. The main causes of floods in India are inadequate capacity of river sections to contain high flows, silting of river beds, and drainage congestion. Floods are also caused by cyclones, cloud bursts, and snow/glacier melt. Based on the causes of floods, the country can be divided into four basins/regions. In the Brahmaputra and Barak Basin, the main problems in the state of Assam are inundation caused by overflow of the Brahmaputra and its tributaries and erosion along the river bank. In the Ganga Basin, the flooding problem is confined to small portions in the middle and terminal reaches. In general, the severity of the problem increases from west to east and from south to north. The worst flood affected states in the Ganga Basin are Uttar Pradesh, Bihar, and West Bengal. In Uttar Pradesh, flooding is confined to the eastern districts: the rivers that cause flooding include the Sarada, the Ghagra, the Rapti, and the Gandak. The major causes here are drainage congestion and bank erosion. North Bihar is in the grip of floods almost every year due to spillage of rivers. In West Bengal, floods are caused by drainage problems as well as tidal effects. Flood problems are not very severe in the rivers in the northwest part of India, and here the cause of floods is inadequate drainage capacity. Flash floods are also experienced here. Flash floods are characterized by a sharp rise and recession of river flow, and the damage is mainly due to the sudden rise of the river, leaving a very short time for evacuation. In the central and southern part of the country, floods occur in the Narmada, Tapi, Godavari, Mahanadi, and Krishna Rivers. The coastal regions of Orissa, Andhra Pradesh, and Tamil Nadu also face problems due to cyclones.

According to the estimates, the average area annually affected by floods is 7.52 Mha of which the agricultural area is 3.52 Mha. According to NCIWRD (1), during the second half of the twenty-first century, on average, 1515 lives and 95,285 head of cattle were lost every year. The area liable to floods was assessed at 40 Mha which is about one-eighth of the geographical area of the country.

Drought

Normally, the term drought is used for a shortage of precipitation or water at a place when it is expected. Meteorologic drought is said to occur at a place when there is more than a 25% decline in rainfall from the normal value. Meteorologic drought over an extensive area triggers hydrologic drought which is the condition of significant depletion of water resources in rivers, reservoirs, lakes, and springs. A marked depletion of soil moisture and precipitation leads to agricultural drought. Based on detailed drought studies for the country, 99 districts have been identified as drought prone. The total geographic area of these districts is about 1,081,131 sq. km.

WATER INFRASTRUCTURE AND SYSTEMS

NEIL S. GRIGG
Colorado State University
Fort Collins, Colorado

Water infrastructure is the set of constructed elements that operate within water resources systems and interact with environmental elements, or natural systems, such as watersheds, streams, lakes, and aquifers (see article on WATER RESOURCES MANAGEMENT). Table 1 gives examples of structures used in constructed systems for different purposes of water management.

In a watershed, sets of these structures may control water for different purposes. Most apparent might be a multiple-purpose reservoir, that has a dam and hydroelectric plant connected to electric transmission lines. Below might be a diversion dam to enable a canal to take irrigation water from the stream, if it is located in a dry region. There might be a re-regulating reservoir with locks for navigation. Dams are a special class of hydraulic structure, and they provide barriers to the flow to enable reservoirs to store water.

Dams have a number of special components, including service and emergency spillways, outlet structures,

Table 1. Structures for Water Resources Management

Purpose	Conveyance	Storage	Treatment[a]	Pump or Generate	Control
Water supply	Water pipes	Reservoir	WTP	Pumps	Valves
Water quality	Sewer pipes	Tanks, ponds	WWTP	Sewage pumps	Gates
Flood control	Channels	Detention ponds	SWTP	Flood pumps	Inlets
Hydropower	Penstocks	Reservoir	–	Turbines	Gates
Navigation	Locks	Reservoir	–	–	Valves
Environment	Rivers	Natural storage	Wetland	–	–

[a] WTP = water treatment plant; WWTP = wastewater treatment plant; SWTP = stormwater treatment plant.

and drains. Outlet works might discharge to a municipal water supply treatment plant, and further downstream a wastewater treatment plant might discharge to the stream.

A reservoir is a lake where water is stored, either natural or dammed artificially. Reservoirs require special management attention because they control flow throughout river systems. As a consequence, they tend to be both strategically important and controversial. Great dams such as Hoover Dam on the Colorado River, Aswan Dam on the Nile River, and Three Gorges Dam on the Yangtze River in China influence whole regions and even nations.

To control flows, there will be valves, gates and spillways, but they are mostly invisible. Wells might provide water for users such as farming operations or irrigation of golf courses.

Diversion structures on a stream change its direction or flow patterns. They might include intakes, boat chutes, or river training structures. A fish ladder is a special kind of diversion structure meant to provide migrating fish species with methods for swimming upstream, usually around a dam.

The structures and components that are associated with conveyance systems include natural open channels and canals, pipelines, pipe networks and sewers, bridges, and levees. Open channels are either natural or man-made. A river is an example of a natural open channel. Levees are part of conveyance systems that form the banks of channels to protect land areas from flooding. A canal or lined drainage ditch would be an example of a man-made channel. A lock raises or lowers boats and ships up or down a river.

Pipes, or closed conduits, can be classified as tunnels, transmission pipelines, pressure pipe networks, or sewer networks.

A bridge is part of a conveyance system in the sense that it provides a method for separating a stream bed from a road, a rail line, or some other structure crossing a stream. A culvert has a function somewhat like a bridge that enables a separation of grades between a small stream and a roadway or other embankment above.

Hydroelectric plants are facilities that generate electric energy from water discharge. They include turbines, generators, and associated hydraulic components.

Pumps impart energy to water and raise it in elevation or pressure. There are several different types of pumps, built mainly around the centrifugal or turbine pump format, and they have numerous applications.

Valves, gates and spillways are control devices for conveyance systems or dams. Spillways are used as emergency overflow devices to protect dams. There are a number of types, normally classified as the service spillway or emergency spillway. Water flowing over a spillway normally flows into some type of energy dissipation device to avoid erosion downstream.

Coordinating the operation of these components places the focus on the water resources *system*, as opposed to individual pieces. A water resources system is a combination of constructed water control facilities and environmental elements that work together to achieve water management purposes (see article on WATER RESOURCES MANAGEMENT). A constructed system consists of structural facilities that control water flow and quality, and a natural water resources system comprises environmental elements such as watersheds, stream channels, and groundwater systems.

OVERVIEW AND TRENDS IN THE INTERNATIONAL WATER MARKET

RANDY T. PIPER
Dillon, Montana

OVERVIEW AND TRENDS

The term "water market" is a slippery concept. Like water, the term water market is free flowing and can take a variety of forms, depending on the cultural environment and who invokes the term. In "The Importance of Getting Names Right: The Myth of Markets for Water," Joseph Dellapenna argues for greater precision when using the language of water markets (1). Consequently, when we speak of water markets, we need to identify specifically the rules that governments employ and the roles that governments play in defining, divesting, and defending water markets. In most geographic settings, water markets do not exist without some formal role for government administration.

In Brazil, local water markets have evolved with minimal government oversight. Dating from 1854 in the Cariri region of northeast Brazil, sugar cane farmers established a water market. The farmers themselves defined the amount of water for each farm. Moreover, farmers developed water measuring devices and monitoring rules independent of formal government administration. However, this water market limits who can own the water, that is, water is neither auctioned to the highest bidder nor sold to nonfarmers who would divert the water for fisheries or for nonagricultural urban consumption (2).

Technology can and does play an important role in water markets. For example, technology can make bottled water more affordable to consumers and more aesthetically appealing to consumers. In 2001, Norwegian water in American markets gained fame and market share largely because of the package design. Technology can improve the quality of water, from wastewater treatment plants to desalination. For example, 120 countries now employ some form of desalting equipment (3). At the 2001 Bahrain meeting of the World Congress of International Desalination Association, the primary focus was on the technologies of water markets, not the institutions of water markets (4). Technology can improve the institutions of water markets and make it more cost-effective for governments and nongovernments to define and enforce the boundaries of water markets and to monitor the consumption and transactions of water markets (5).

Technology in the narrow sense can and does improve the product and package of water and water markets. Technology in the broad sense can and does improve the institutions of water markets. However, the technology and science of water markets per se are not the paramount challenges in many international markets. In 2000, the 10th Stockholm Water Symposium reached this conclusion: “Long-term challenges in water management are not so much linked to classical scientific and technical aspects as to institutional innovations” (6).

In “Water Challenge and Institutional Response,” R. Maria Saleth and Ariel Dinar reviewed the institutional innovations of 11 countries: Australia, Brazil, Chile, China, India, Israel, Mexico, Morocco, South Africa, Spain, and Sri Lanka. These World Bank researchers found several commonalities among the 11 countries. For example, countries have reached a supply limit of water resource development and are now focusing on the rules of allocation of their supplies. Countries have also begun to experiment with decentralization and privatization. Among the countries (Australia, Israel, Mexico, and Spain) that have national water plans, Israel and Mexico delegate much of the allocation administration to subnational levels that are organized primarily along hydrogeologic lines in the form of basins (7). These river basin organizations then may develop rules of participation and the roles of market-oriented institutions for allocation. According to R. Maria Saleth and Ariel Dinar, “Countries have begun to recognize the functional distinction between centralized mechanisms needed for coordination and enforcement and decentralized arrangements needed for user participation and local level solutions” (8).

In the urban water subsector, another institutional innovation is privatization or corporatization of water and water infrastructures. Privatization can take a number of forms, from management, service, and lease contracts to build, own, operate, and transfer contracts to full private ownership under a regulatory regime. In the 1990s, several transnational corporations acquired water firms and/or formed subsidiaries to compete in international markets. This trend is illustrated by noting the home country’s parent company followed by its water subsidiary: England’s Kelda and Alcontrol, France’s Vivendi and Vivendi Environment, Germany’s RWE and Bovis Thames, and America’s Enron and Azurix. In comparison to the 1990–1994 period, during the 1995–1999 period, the monetary value of water and sanitation privatization projects increased by 100% to approximately $9 billion in Latin America and approximately $9 billion in East Asia and Pacific regions, by more than 1000% to approximately $1 billion in sub-Saharan Africa and approximately $2 billion in Europe and Central Asia regions, and by more than 2000% to approximately $5 billion in the Middle East and North Africa regions (9). The ownership and names of the transnational corporations will change based on the ebb and flow of supply–demand interactions. However, the role of any newly named corporation will remain the same: to maximize its returns on equity for various privatization projects.

Some institutional analysts consider the two trends of decentralization and privatization innovative and preferable to centralized national ownership and management. However, other institutional analysts view these trends as less than innovative and undesirable. A statement from the conclusions of the 10th Stockholm Water Symposium captures this sentiment: “The economically based approach that dominates at present, and has the market as a recommended mode of interpretation, was seen as having severe limitations when it comes to acceptable ways of coping with the emerging water crisis” (10).

Even when countries can overcome the cultural and linguistic barriers to crafting water market-oriented institutions, these countries still encounter other barriers, primarily cost-effective technology. Cost-effective technology exists for the defining, defending, and divesting of water *quantity*. For example, affordable geographic information systems (GIS) allow governments and nongovernments to monitor whether water users are “rustling water” and consuming illegal quantities. However, when the focus turns to water *quality*, the costs of technology for measuring and monitoring pollution trespassers increase dramatically (11). The wealthier countries of the European Union, South America, Asia, and Middle East can afford some of these emerging technologies—both for water quantities and qualities—but less affluent countries cannot allocate sufficient resources to create water markets, whether for quantities or qualities.

SUMMARY

Generalizations remain precarious. Institutional successes at one national level may not transfer to other national levels within the same region. Institutional successes at one national level may not transfer to subnational levels within the same country. The barriers to diffusion of institutional innovations are numerous and varied, flowing from economic, political, and social to technological and linguistic barriers.

Governments will continue with cross-country agreements that more clearly define their respective rights, rules, and roles. National governments may play a more active role in achieving hydrosolidarity among themselves, but this external hydrosolidarity does not preclude internal hydrosolidarity in the form of denationalization and water-market-oriented institutions. In a few countries, governments may well continue to finance, manage, and own water resources and view water as a nationalized “means of production.” However, as the World Bank’s R. Maria Saleth and Ariel Dinar observe, “But nowhere, even in China, is the state’s absolute ownership of water established to exclude private use rights” (8).

Many governments will still continue to denationalize and privatize water resources. In urban areas, private corporations will continue to build and manage water systems, while the government finances the construction and capital costs, and consumers finance the operating costs via user fees. When urban consumers cannot finance the full capital and operating costs, governments will experiment with full-cost pricing mechanisms, transparency of subsidies, and “water vouchers.” In rural areas, national governments may allocate some of the financing, managing, and owning to local governments. In turn, localized governments may experiment with a variety of market-oriented institutions. The structure of these institutions could include allowing current owners and users to sell their water for nonagricultural uses.

During the next few decades, it is unlikely that many governments will permit the following scenario for international water markets to develop. Both national and local governments give full private property rights to agriculture and/or urban "owners." With full rights, these owners could then sell their water to whomever they wanted. Willing higher and highest bidding buyers and consumers would include rural and urban residents, transnational corporations, environmental groups, and even water speculators (12). Once governments and nongovernments have experimented with internal hydrosolidarity and learned the lessons from the multiple forms of water-market-oriented institutions such as water banks and water vouchers, governments and nongovernments may well transfer this knowledge to the realm of external hydrosolidarity.

Finally, when we interpret "international water markets" and we more precisely speak in terms of water-market-oriented institutions, our language and logic must accurately reflect the multiple roles that governments play in the creation and evolution of international water markets.

BEST MANAGEMENT PRACTICES FOR WATER RESOURCES

Mohammad N. Almasri
An-Najah National University
Nablus, Palestine

Jagath J. Kaluarachchi
Utah State University
Logan, Utah

INTRODUCTION

Best management practices (BMPs) for water resources are affordable, practical, and effective methods for eliminating or reducing the movement of pollutants from the ground surface to groundwater or surface waterbodies. Such pollutants include nutrients and pesticides, among others, that may have adverse effects on human health. In addition, BMPs can be viewed as methods to ensure a sustainable and safe yield of water resources through optimal conjunctive management of these resources. The main premise in developing BMPs is to achieve a balance between the goal of protecting water resource quality, for instance, and the economic and social ramifications of adopting these BMPs. Before adopting BMPs for a specific site, it is essential to understand the BMPs thoroughly and to ensure their technical feasibility through research, experience, field pilot studies, and surveys. In addition to technical feasibility, BMPs should be economically well founded through cost-effectiveness analysis and acceptable via adopting and maintaining them. BMPs may consist of single practices or combinations of them based on the problem at hand and the social and economic ramifications. BMPs for groundwater resources are important because they preserve and protect groundwater quality and quantity. Preservation of groundwater resources minimizes public health problems and maintains the social and economic values of groundwater. For instance, the cost of mitigating polluted groundwater can be extremely high and by adopting effective BMPs, such mitigation costs can be reduced dramatically.

This document focuses on BMPs to protect and preserve groundwater resources from nitrate contamination.

NITRATE CONTAMINATION OF GROUNDWATER

Groundwater is the primary source of drinking water in many parts of the world and the sole supply of potable water in many rural communities (1). There is increasing could include allowing current owners and users to sell their water for nonagricultural uses.

During the next few decades, it is unlikely that many governments will permit the following scenario for international water markets to develop. Both national and local governments give full private property rights to agriculture and/or urban "owners." With full rights, these owners could then sell their water to whomever they wanted. Willing higher and highest bidding buyers and consumers would include rural and urban residents, transnational corporations, environmental groups, and even water speculators (12). Once governments and nongovernments have experimented with internal hydrosolidarity and learned the lessons from the multiple forms of water-market-oriented institutions such as water banks and water vouchers, governments and nongovernments may well transfer this knowledge to the realm of external hydrosolidarity.

Finally, when we interpret "international water markets" and we more precisely speak in terms of water-market-oriented institutions, our language and logic must accurately reflect the multiple roles that governments play in the creation and evolution of international water markets.

INTRODUCTION

Best management practices (BMPs) for water resources are affordable, practical, and effective methods for eliminating or reducing the movement of pollutants from the ground surface to groundwater or surface waterbodies. Such pollutants include nutrients and pesticides, among others, that may have adverse effects on human health. In addition, BMPs can be viewed as methods to ensure a sustainable and safe yield of water resources through optimal conjunctive management of these resources. The main premise in developing BMPs is to achieve a balance between the goal of protecting water resource quality, for instance, and the economic and social ramifications of adopting these BMPs. Before adopting BMPs for a specific site, it is essential to understand the BMPs thoroughly and to ensure their technical feasibility through research, experience, field pilot studies, and surveys. In addition to technical feasibility, BMPs should be economically well founded through cost-effectiveness analysis and acceptable via adopting and maintaining them. BMPs may consist of single practices or combinations of them based on the problem at hand and the social and economic ramifications. BMPs for groundwater resources are important because they preserve and protect groundwater quality and quantity. Preservation of groundwater resources minimizes public health problems and maintains the social and economic values of groundwater. For instance, the cost of mitigating polluted groundwater can be extremely high and by adopting effective BMPs, such mitigation costs can be reduced dramatically.

This document focuses on BMPs to protect and preserve groundwater resources from nitrate contamination.

NITRATE CONTAMINATION OF GROUNDWATER

Groundwater is the primary source of drinking water in many parts of the world and the sole supply of potable water in many rural communities (1). There is increasing awareness that groundwater is vulnerable to contamination from domestic, industrial, and agricultural wastes (2). Sources of groundwater contamination are widespread and include accidental spills, landfills, storage tanks, pipelines, agricultural activities, and many other sources. Of these sources, agriculture activities produce nonpoint source pollution in small to large watersheds especially due to nitrogen in fertilizers and various carcinogenic substances found in pesticides. Due to its high mobility, nitrate is the primary nitrogen species lost from soils by leaching (3). Groundwater contamination by nitrate has been confirmed throughout the United States (4,5) and worldwide (6). Elevated nitrate concentration in drinking water can cause *methemoglobinemia* in infants and stomach cancer in adults (7–9). Therefore, the U.S. Environmental Protection Agency (U.S. EPA) has established a maximum contaminant level (MCL) of 10 mg/L NO_3-N (10). Nitrate may indicate the presence of bacteria, viruses, and protozoa in groundwater if the source of nitrate is animal waste or effluent from septic tanks. Likewise, nitrate contamination of surface water has health and environmental effects. Transport of nitrate to surface water occurs mainly via discharge of groundwater during baseflow conditions (11). Hence, prevention of groundwater contamination protects surface water quality as well.

Agricultural activities are probably the most significant anthropogenic source of nitrate contamination in groundwater. Nitrogen is a vital nutrient for plant growth. Nevertheless, when nitrogen-rich fertilizer application exceeds the plant demand and the denitrification capacity of the soil, nitrogen can leach to groundwater usually in the form of nitrate (12). Many studies have shown high correlation between agricultural land use and nitrate concentration in groundwater (6,13,14). Agricultural practices result in nonpoint source pollution of groundwater and the effects of these practices accumulate over time (7). Nonpoint sources of nitrogen from agricultural practices include fertilizer, dairy farms, manure application, and leguminous crops (15). Point sources of nitrogen such as septic tanks and dairy lagoons contribute to nitrate pollution of groundwater.

BMPs TO MINIMIZE NITRATE CONTAMINATION OF GROUNDWATER

Identification of areas with heavy nitrogen loadings from point and nonpoint sources is important for land use planners and environmental regulators. Once such high-risk areas have been identified, BMPs can be implemented to minimize the risk of nitrate leaching to groundwater. The knowledge of the spatial distribution of nitrogen loading can identify the areas where groundwater needs to be protected. This assessment is of great importance in designating areas that can benefit from pollution prevention and monitoring programs. In large areas such as large watersheds or basins, proper understanding of on-ground nitrogen loading from different sources and corresponding transformations in the soil are needed before areas can be designated for future protective measures (16).

BMPs developed to protect groundwater quality are improvements in agricultural practices and land use patterns (17). Improving agricultural practices focuses on tillage practices, crop rotation, rational fertilizer and manure applications, vegetation cover, and irrigation management (18). For instance, on-ground application of manure should be in accordance with agronomic requirements and the nitrogen mass in the soil (19). Land use changes include reevaluation of land use distribution and changes in the land use in areas that are vulnerable to contamination. However, this option may not be feasible in many instances due to competing stakeholder concerns arising from economic constraints and these constraints may, sometimes, override environmental concerns. BMPs imply conflicting objectives. On the one hand, the main aim of a BMP is to reduce nitrate concentrations in groundwater below the MCL. On the other hand, a protection alternative should consider the minimization of economic losses incurred from implementing the protection alternatives. Therefore, a multicriteria decision analysis might be developed to determine the most viable BMP that accounts for the different decision criteria.

Fertilizer and manure applications are required to replace crop land nutrients that have been consumed by previous plant growth. They are essential for economical yields. However, excess fertilizer and manure use and poor application methods can lead to nitrate pollution of groundwater and surface waterbodies. Therefore, it is important to match nitrogen applications to crop uptake to minimize nitrate leaching. This is the core of the BMPs that address the problem of nitrate contamination of groundwater resources.

Effective BMPs limit movement by minimizing the quantity of nutrients available for leaching below the root zone. This is achieved by developing an inclusive nutrient management plan that uses field studies, soil and groundwater models, uses only the types and amounts of nutrients necessary to produce the crop, applies nutrients at the proper times and by proper methods, implements additional farming practices to reduce nutrient losses, and follows proper procedures for fertilizer storage and handling. In the following, the main BMPs pertaining to fertilizer and manure applications for reducing nitrate occurrences in the groundwater are summarized based on the work provided by Waskom (20), the EPA (21), Almasri (22), and Almasri and Kaluarachchi (23), among other studies listed in the references.

Application Rates and Fertilizer Types

One component of a comprehensive nutrient management plan is determining proper fertilizer application rates (24). The objective is to limit fertilizer application to an amount sufficient to achieve a realistic crop yield. Allowing for other nitrogen sources in the soil is also part of the concept. Previous legume crops, irrigation water, manure, and soil organic matter all contribute nitrogen to the soil. Along with soil samples and fertilizer credits from other sources, nitrogen fertilizer recommendations are based on yield goals established by crop producers. Yield expectations are established for each crop and field based on soil properties, available moisture, yield history, and management level.

Applying the appropriate form of nitrogen fertilizer can reduce leaching.

Nitrate forms of nitrogen fertilizer are readily available to crops but are subject to leaching losses. Nitrate fertilizer use should be limited when the leaching potential is moderate to high. In these situations, ammonium nitrogen fertilizers should be used because they are not subject to immediate leaching. However, ammonium nitrogen transforms rapidly into nitrate via the nitrification process, especially when soils are warm and moist. More slowly available nitrogen fertilizers should be used in these conditions. Nitrification inhibitors can also delay the conversion of ammonium to nitrate under certain conditions (23).

Fertilizer Application Timing

Nitrogen fertilizer applications should be timed in periods of maximum crop uptake. Fertilizer applied in the fall causes groundwater quality degradation. Partial application of fertilizer in the spring, followed by small additional applications as needed, can improve nitrogen uptake and reduce leaching risk.

Fertilizer Application Methods

Fertilizer application equipment should be checked at least once a year and should be properly calibrated to ensure that the recommended amount of fertilizer is applied. Fertilizer placement in the root zone can greatly enhance plant nutrient uptake and minimize leaching losses. Subsurface applied or incorporated fertilizer should be used instead of surface broadcast fertilizer. An efficient application method for fertilizer is to place dry fertilizer into the ground in bands closer to the seed, so that it can be recovered by the crop very efficiently. To reduce losses through surface runoff and volatilization, all fertilizers should be mechanically incorporated into the soil. Fertilizer application to frozen ground should be avoided and limited on slopes and areas with high runoff or overland flow.

Irrigation Water Management

Irrigation water should be managed to maximize efficiency and minimize runoff or leaching. Irrigated crop production has the greatest potential for source water contamination because of the large amount of water applied and the movement of nutrients via irrigation flux. Nitrate can leach into groundwater when excess water is applied to fields. Irrigation systems, such as sprinklers, low-energy precision applications, surges, and drips, allow producers to apply water uniformly and with great efficiency. Efficiency can also be improved by using delivery systems such as lined ditches and gated pipe, as well as reuse systems such as field drainage recovery ponds that efficiently capture sediment and nutrients. Gravity-controlled irrigation or furrow runs should be shortened to prevent overwatering at the top of the furrow before the lower end is adequately watered.

Manure Application Reduction

Manure is an excellent source of plant nutrients, especially nitrogen. Nevertheless, excessive applications of manure lead to nitrogen buildup in the soil that eventually leads to groundwater pollution. Prior to application, manure should be analyzed to determine its nutrient content. The application of increasing quantities of manure to the same land area may result in groundwater quality problems and adverse environmental consequences. If it turns out that the land base is insufficient for manure application, then BMPs should be introduced. In the following subsections, BMPs pertaining to dairy manure such as reducing herd size, composting/exporting manure, or implementing feeding strategies to reduce nutrient content in the excrement are summarized (25).

Dairy Herd Size Reduction. Manure production and loading are functions of dairy herd size, so downsizing the dairy herd is apparently the most straightforward and effectual BMP that minimizes manure loading (25). Nonetheless, such an option has serious economic ramifications that may prohibit the adoption of this alternative.

Manure Composting/Exporting. Manure exporting is a viable alternative because it does not involve herd size reduction. For manure to be exported, it should be composted. Composting is a biological process that converts organic manure to a more stable material such as humus. Composting is the aerobic decomposition of organic matter by certain microorganisms such as bacteria that consume oxygen and use nutrients such as carbon, nitrogen, phosphorus, and potassium as they feed on the organic waste. They produce heat, carbon dioxide, and water vapor. Heat destroys pathogens and weed seeds. The resulting composted manure is humus-like organic material, fine-textured, low in moisture, and has a nonoffensive earthy odor. Because of the carbon dioxide and water vapor that escape during the process, the resulting compost can be approximately half the volume and weight of the original material. Efficient composting requires maintaining proper temperatures and oxygen levels in the composting material (26). Warm temperatures help microorganisms to grow best. Elevated temperatures are needed to destroy pathogens and weed seeds. Bulking materials can be mixed with manure to provide structural support when manure solids are too wet to maintain air spaces within the composting pile. Composting is best accomplished by placing the manure in windrows. The windrows can be turned and mixed periodically to maintain oxygen levels for proper composting. The windrows may be 3 to 6 feet high and 10 to 20 feet wide, depending mostly on the type of machinery used in turning them. The width of the windrow must allow air movement into the manure to introduce oxygen. Composting reduces spreading costs, facilitates land application, eliminates manure odors, and promotes manure transporting and marketing. Composted manure can be used mainly on lawns and gardens to keep and add organic matter in the soil. Organic matter provides good aeration porosity, holds more water, and releases important nutrients.

Improve Dairy Cow Diets. The future challenge for dairy producers and nutritionists will be to formulate rations properly for high milk production levels while simultaneously minimizing the environmental impact of excessive nitrogen content in the excrement. A properly formulated ration that precisely meets the cow's requirements for milk production, maintenance, and growth minimizes excessive nitrogen in the manure. Many dairy producers overfeed crude protein to support high levels of milk production. However, this results in excessively high nitrogen in the excrement. The protein that is not used for milk production or maintenance and growth is excreted as urea or organic-N. This practice has an adverse effect on the environment. Feeding strategies can be adopted to minimize manure nitrogen content while maintaining the same milk production levels. Van Horn (27) showed that when cows are precisely fed to meet the National Research Council recommendations (28), the nitrogen content in manure dropped by 14%.

INTEGRATED WATER RESOURCES MANAGEMENT (IWRM)

MUKAND SINGH BABEL
Asian Institute of Technology
Pathumthani, Thailand

TODAY'S WATER PROBLEMS

Population and economic growth has led to rising demand for water for human consumption, food production, industrial uses, and other development activities, and opportunities for increasing the supply are becoming prohibitively expensive. The growing concern for maintaining natural ecosystems is exerting further pressure on water resources. The threatening environmental problems originating from unsustainable use of water resources are of great concern. Pollution of water is connected with human activities. Proliferation of development activities and modern living styles has also contributed to the worsening of water quality. Adverse conditions such as social inequity, economic marginalization, and lack of poverty alleviation programs in many countries also force people living in extreme poverty to overexploit soil and forestry resources, which often results in negative impacts on water resources. Deteriorating water quality caused by pollution makes safe use difficult for downstream users and threatens human health and the functioning of aquatic ecosystems.

In most countries, water policies have been largely dominated by a supply-oriented and compartmentalized sector mentality. Top-down approaches have prevailed in development and management of water resources without participation by stakeholders in decision making. In these traditional approaches, the important distinction between managing water as a commonly owned natural resource and providing services for water users has not been fully recognized, leading to a confusion of roles and responsibilities of different organizations dealing with water. Thus, inefficient governance and increased competition for finite water resources are the root cause of water problems.

Balancing and compromising the need for water by people, different economic sectors, and nature is the main challenge faced by the water sector. About 1 billion people in the world are without access to safe drinking water, and about 3 billion people do not have access to adequate sanitation. Securing water for people is a prime concern in many countries. According to the UN medium projections, the population on earth in 2025 will reach about 7.8 billion, a 38% increase over present levels. Providing water to meet the needs of food and fiber for the world population in years ahead is another main challenge. Even with improved irrigation management and water productivity, it is estimated that 17% more water will be required for this population (1). Ecosystems are sources of various benefits to society such as providing timber, fuel, wildlife habitats, aquatic resources, etc. Ecosystem security through maintenance of the natural environment and proper management of land and water resources is therefore essential.

Variation of precipitation over time and space leads to the classical problem of too much or too little water. The variations in water flow and groundwater recharge, whether of climatic origin or due to land mismanagement, can add to drought and floods, which can have catastrophic effects in terms of large-scale loss of human life and damage to economic, social, and environmental systems. Managing the variability of water in time and space and the associated risks are other challenges.

CONCEPTS OF IWRM

Compared to traditional approaches to water resources problems, integrated water resources management (IWRM) takes a broader holistic view and examines a more complete range of solutions. It looks outside the narrow water sector for policies and activities to achieve sustainable water resources development. It also considers how different actions affect and can reinforce each other. IWRM has attracted particular attention since the International Conferences on Water and Environmental in Dublin in 1992. IWRM can be defined as follows:

"IWRM is a process which promotes the coordinated development and management of water, land and related resources in order to maximize the resultant economic and social welfare in an equitable manner without compromising the sustainability of vital ecosystems" (2).

IWRM principles place its overriding importance over economic, social, and natural facets. It draws its inspiration from the Dublin principles, culminating from the International Conference on Water and the Environment in Dublin, 1992. These are the four Dublin principles:

- Freshwater is a finite and vulnerable resource, essential to sustain life, development and the environment.
- Water development and management should be based on a participatory approach, involving users, planners, and policy makers at all levels.
- Water has an economic value in all its competing uses and should be recognized as an economic good.
- Women must play a central part in the provision, management and safeguarding of water.

In the traditional approach, the planning and operation of water systems is usually fragmented, causing a lack of coordination, wastage of resources, and conflict among stakeholders. Water issues are also generally neglected when decisions are made about crop patterns, trade and energy policies, and urban design and planning, all of which are critical determinants of water demand. For the sustainable use of water resources, there is a need to create institutions and frameworks that can transcend these traditional boundaries and involve a variety of users and stakeholders. IWRM promotes a holistic view and looks at the entire hydrologic cycle and the interaction of water with other natural and socioeconomic systems. IWRM focuses on integration, participation, consultation, gender awareness, and consensus.

Integration among different stakeholders and different domains of water resources is one of the highlights of IWRM. At its most fundamental level, IWRM is as concerned with the management of water demand as with its supply. Thus, integration can be considered in two basic categories—the natural system and the human system. The natural system puts critical importance on resource availability and quality; the human system fundamentally determines the resource use, waste production, and pollution of the resource. Integration of the natural system implies a concern with upstream–downstream water-related interests, integration of land and water management, integration of freshwater management and coastal zone management, a unified management of surface water and groundwater, a shift to management at a river basin level, integration of quantity and quality, and matching water management with other sectoral policies with a collateral impact (trade, housing, energy, agriculture, etc.). Human system integration involves mainstreaming of water resources, cross-sectoral integration in national policy development, analyzing macroeconomic effects of water development on overall economic development, influencing economic sector decisions, and integrating all stakeholders in the planning and decision-making process.

As one of the principles of the IWRM, the concept of water as an economic good introduces a wholly new model to water resources management. Therefore, it differs from the traditional approach in that it invariably associates economic aspects of water with water resources management issues. It distinguishes between the value of water and its pricing. The concept of the value of water is used in assisting allocation processes; the pricing concept is used as part of the cost recovery issue. The economic value of water is highlighted through greater stress on demand management rather than supply-side management, a recognition (and estimation, where possible) of the economic value of water in different uses, acceptance of the notion of opportunity cost (what is lost to other uses from taking it for a particular purpose), and attention to cost recovery, though with concern for affordability and securing access for the poor.

Water conservation is another critical aspect of IWRM. Freshwater ecosystems face enormous threats, directly and indirectly, from human activities. Conserving freshwater systems is essential for the future survival of all living species on the earth. Water conservation and management call for the protection, improvement, and use of water according to principles that will assure their highest economic and social benefits. Maintaining the delicate and sustainable balance of demand and supply of water is a critical element of any sound water strategy.

To fulfill desirable social, economic, and natural conditions, IWRM places its overriding criteria on economic efficiency in water use, equity and access for all, and sustainability of vital ecosystems. The increasing scarcity of water as well as financial resources, under increasing pressure from the excessive demands upon it, demands that water be used with maximum possible efficiency. The "social equity and access for all" criteria recognize the basic human right to access to water of adequate quantity and quality. The third criterion (ecological sustainability) is about ensuring that the present use of the resource does not undermine ecological stability and that future generations are not adversely affected.

Three basic elements highlight the IWRM framework: the enabling environment, the institutional roles, and the management instruments, as shown in Fig. 1.

The enabling environment refers to the general framework of national policies, legislation, and regulations. The

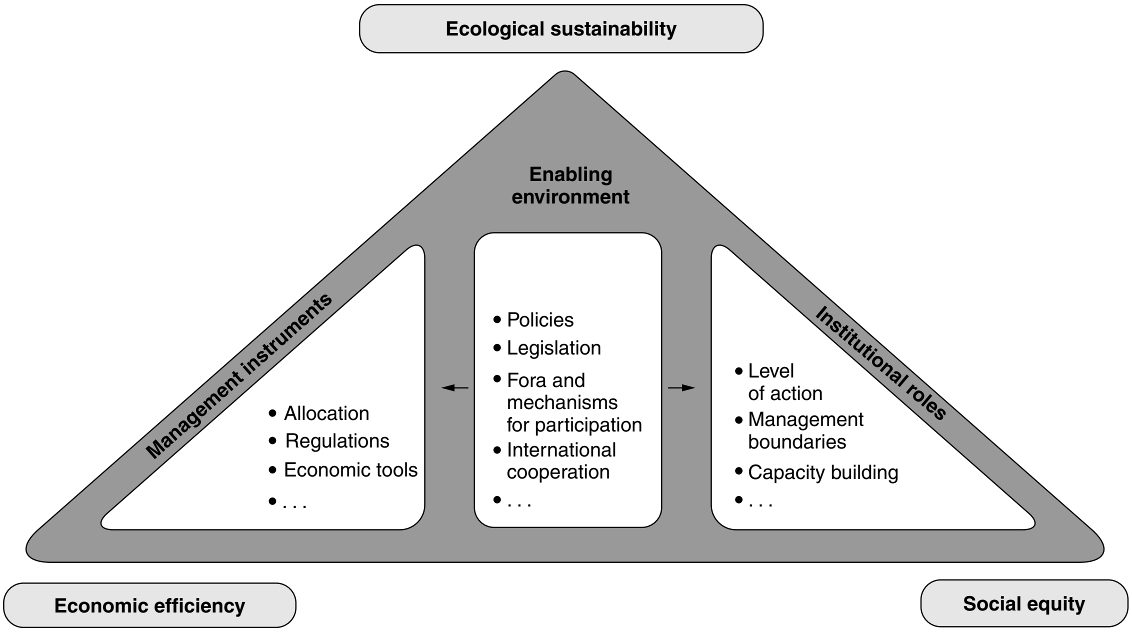

Figure 1. General framework for IWRM (2).

institutional framework defines the roles and responsibilities of government agencies at different levels and other stakeholders. The management instruments include water resources assessment, communication and information systems, allocation, economic tools, technology, and so on.

In spite of considerable advantages in IWRM, its implementation requires a much greater commitment from all stakeholders. There are many challenges, which have to be overcome for successful implementation. The short-term costs and disadvantages may seem more apparent than tangible benefits in the pursuit of longer term advantages. Integration is difficult to implement at first and may not guarantee equity for all; simply involving a wider range of stakeholders in decision making may not automatically ensure fair treatment for them.

MANAGEMENT OF WATER RESOURCES FOR DROUGHT CONDITIONS*

INTRODUCTION

Droughts have been a part of our environment since the beginning of recorded history, and humanity's survival may be testimony only to its capacity to endure this climatic phenomenon. According to Yevjevich and others (1, p. 41), one of the earliest records of efforts to plan for droughts is found in the biblical story of Joseph. The pharaoh of Egypt gave Joseph the authority to plan and implement the world's first recorded national drought strategy. One can ask if improvements in society's planning capability over the past several millenniums have increased our ability to deal with droughts in other than catastrophic terms. Certainly, droughts will continue to be a randomly occurring climatic phenomenon. Have we built on any past successes pertaining to the planning for droughts and managing water resources during droughts; have we learned from past actions or inactions; or are we doomed to repeat our mistakes? The evidence indicates that society tends to be unwilling to plan for droughts.

To better understand why society is still reacting to droughts rather than planning for their eventuality, the activities of various levels of government in planning for droughts must be examined. Until very recently, the policies of most State governments for dealing with drought have been to "wait 'til it rains" and in the meantime provide some form of emergency assistance to localities and hope a catastrophe can be avoided. Many States also, as a matter of implicit policy, place primary responsibility for drought action with the Federal Government and local governments who, throughout the Nation's history, have been the primary levels of government involved when droughts occur. The policies of both the Federal Government and the local governments also have been to provide emergency relief and to try to reduce water demand to match the available supply. This governmental approach, however, has not reduced the economic losses or the level of inconvenience and suffering of the Nation's citizens. With each succeeding drought, the cycle repeats itself. As a result, the following questions arise: Do the States have a responsibility for planning for droughts? If the States do have such a responsibility, what type of planning should take place? Is there a possibility that drought-related activities of the Federal Government and the local governments are likely to change in the future, and if so, how and why?

In strictly climatic terms, a drought can be defined as an interval of time, generally months or years in duration, during which the actual moisture supply at a given place consistently is less than the climatically expected or climatically appropriate moisture supply (2, p. 3). Drought generally is defined as being meteorological, hydrological, or agricultural. However, the ultimate consequences of droughts have to be placed in the context of the effects on the social and economic activities of a given region (Evan C. Vlachos, Colorado State University, written commun., January 1988). Thus, the climatic attributes of drought also need to be defined in social and economic terms because it is in these contexts that water management becomes important (Evan C. Vlachos, Colorado State University, written commun., January 1988). Yevjevich and others (1, p. 32) have suggested that we think in terms of "sociological drought," which is defined as the meteorological and hydrological conditions under which less water is available than is anticipated and relied on for the normal level of social and economic activity of the region.

---

*This article is reproduced in its entirety from Walker, W.R., Hrezo, M.S., and Haley, C.J. (1991). Management of water resources for drought conditions. In: *National Water Summary 1988-89—Hydrologic Events and Floods and Droughts*. Paulson, R.W., Chase, E.B., Roberts, R.S., and Moody, D.W., (Compilers). U.S. Geological Survey Water-Supply Paper 2375, pp. 147–156.

Due in part to our agrarian heritage and because water deficiencies can develop rather quickly in the root zone, most droughts are thought of as agricultural droughts. This characterization can be confusing, however, because an agricultural drought can occur in the midst of a hydrological wet period. The distribution of precipitation during a year can be such that there is a shortage of moisture (drought) during a critical growing period for a variety of crops, yet the total precipitation for the year can be greater than the historical yearly average. In this discussion of institutional and management aspects, droughts are considered as moisture shortages that seriously affect the established economy and the quality of life of a region.

The following analysis of the roles of government in planning for droughts begins with an examination of the traditional activities of government during a drought. If the traditional approach by government seems less than desirable, then the obstacles to greater involvement need to be identified and evaluated to determine if they can be removed or circumvented. The suggestions by King and others (3) in their "Model Water Use Act" for managing water resources during droughts are examined in some detail to determine if they provide a minimum approach for States to consider in developing a plan for managing water resources for drought conditions. To better assess the status of State involvement, the drought programs and drought-related actions of the 48 conterminous States are reviewed in terms of the minimum criteria recommended by King and others (3). Lastly, the expanded role that the Federal Government might have in planning for and mitigating the effects of droughts pursuant to existing Federal water-quality legislation is considered.

TRADITIONAL GOVERNMENT APPROACH TO DROUGHTS

Droughts have two components—climatic (decrease in precipitation) and demand (use of water). In responding to droughts, governments tend to concentrate most of their activity on reducing the demand for water, although they might have limited options for controlling the climatic component. Cloud seeding, for example, might make increasing the snowpack possible and, in some instances, obtaining a limited summer rainfall. Because climatic control, however, generally is less reliable, most measures focus on management, reallocation, and distribution of existing water sources and on establishing priorities accordingly for different uses (4, p. 41).

LOCAL GOVERNMENT

Traditionally, managing water resources during droughts has been based on immediate reactions to a current crisis. The focus of most action is to reduce the daily demand for water, and local governments usually are responsible for reducing water demand within their jurisdictions. Broader issues that impinge on their programs to reduce water demands are not within their purview; for example, local governments are not permitted to allocate surface water and groundwater among competing users. Local governments, however, do not covet the existing authority for reducing water demands. Even in times of impending crisis, there is a great reluctance to impose water-conservation measures, if there is any hope that rain will fall in time to save officials from having to do so. Decision makers are not popular when they must halt or reduce industrial activity, curtail domestic use, or prohibit "nonessential" services. As a result, timely action rarely is achieved (Evan C. Vlachos, Colorado State University, written commun., January 1988).

The local approach to the management of water resources during droughts is not responsive to other drought-induced issues such as minimum instream flows because these issues are not within the purview of local government. Yet water for wildlife, increased contamination due to low flows, and decreased navigation and hydroelectric-power generation are issues equally as important as the ones being addressed by local government. Water shortages cause low streamflows that have an adverse effect on fish and wildlife habitat. If there are no limits as to how much flows can decrease or for how long (the longer the period of low flow, the greater the stress), the recovery time for a habitat can be extremely long, or a habitat can be lost permanently. Low flows can increase salt-water intrusion, increase health hazards because of increased concentration of toxic substances and pathogens, decrease hydroelectric-power generation, and curtail recreational opportunities. Decreased precipitation also increases the potential for brush and forest fires and wind erosion of topsoil.

With a few exceptions, the response of government at any level to the shortages caused by decreased precipitation has been to react rather than to adopt a proactive approach to minimize the effect of droughts. Drought planning at the local level in many areas appears to be given a low priority because of the randomness of droughts, the limited resources for planning, the limited jurisdiction (local government might not be able to control streamflow levels), and the programs of the Federal Government to provide disaster relief in time of crisis. As a result, local governments are encouraged to accept an implicit policy of doing only what can be done after a crisis has occurred.

A notable exception to inaction at the local level to plan for drought conditions occurred in the Washington, DC, area. The leadership role in this case was taken by the Interstate Commission on the Potomac River Basin (ICPRB), but the implementation of the water resources plan was by local government. The plan finally adopted saved between $200 million and $1 billion compared to longer scale structural solutions previously proposed (5, p. 106). Implementation of the plan was through eight separate but interlocking contracts executed in 1982 (5, p. 106).

STATE GOVERNMENT

With the exception of eight States—Arkansas, California, Connecticut, Delaware, Florida, Minnesota, New Jersey, and South Carolina—the activities of the State governments in managing water resources during droughts have been minimal. Most State governments have not passed legislation providing for additional drought planning beyond slight modifications in their water laws. Governors, on occasion, will declare counties or designated areas as disaster areas in order to make individuals eligible for Federal relief.

FEDERAL GOVERNMENT

The Federal Government generally has limited its activities to providing direct relief to drought victims and to farmers in general. For example, the Federal response to the 1976-77 drought, which affected about two-thirds of the country, was to enact the Emergency Drought Act of 1977 (Public Law 95-18), the Community Emergency Relief Act of 1977 (Public Law 95-31), and certain provisions of the Supplemental Appropriations Act of 1977 (Public Law 95-26) to bolster existing emergency-assistance programs. As the result of these laws, 40 Federal programs, administered by 16 agencies, offered drought relief in the form of loans, grants, indemnity payments, and other forms of assistance to State and local governments, households, farms, and private businesses (6, p. 1–2). The overriding objective was to reduce impending damage by implementing short-term actions to augment existing water supplies. Other Federal programs available to drought victims were designed to provide assistance after damage had occurred (6, p. 2). Typical of these were the disaster loan programs of the Farmers Home Administration. Four Federal agencies—the Departments of Agriculture, Commerce, and Interior and the Small Business Administration—were responsible for implementing emergency drought programs at a cost of $5 billion, which included an additional $1 billion for short-term emergency actions to augment existing water supplies (6, p. 11). The Comptroller General of the United States (6, p. 11) concluded that:

- Some drought programs were enacted or implemented too late to have much effect in augmenting water supplies.
- Inadequate standards for determining the worthiness of projects meant that many projects were funded that had little, if any, effect in mitigating the effects of the drought.
- Drought victims were treated in an inconsistent, inequitable, and confusing manner.
- Inadequate coordination among the agencies resulted in inefficient and inequitable distribution of funds.

The report (6, p. 21) also recommended that a national plan be developed for providing assistance in a more timely, consistent, and equitable manner. Issues to be considered in the development of such a plan are:

- Identification of respective roles of agencies involved to avoid overlap and duplication of activities.
- Need for legislation to more clearly define agency roles and activities.
- Need for standby legislation to permit more timely response to drought-related problems.

In 1988, in response to another severe drought, Congress passed the Disaster Assistance Act of 1988 (Public Law 100–387). This legislation is less comprehensive than the 1977 legislation in that its primary purposes are to protect farm income in an efficient and equitable manner, protect the economic health of rural communities affected by the drought, and help assure a continued adequate supply of food for American consumers. Little in this legislation reflects the major recommendations of the Comptroller General of the United States (6) regarding the development of a national plan for providing future assistance in a more timely, consistent, and equitable manner. Although the Secretary of the U.S. Department of Agriculture is authorized to make grants and provide other assistance to combat water shortages, the Disaster Assistance Act of 1988 is primarily an agricultural-relief act. Thus, to date, the Federal Government has limited its involvement in droughts to the provision of water-resources information, technical assistance, and financial relief to mitigate the costs incurred once a drought has occurred.

OBSTACLES TO EFFECTIVE PLANNING FOR DROUGHTS

Although governments can plan effectively for droughts, fundamental problems that deter action need to be examined and understood before drought planning can become a reality. Five obstacles to planning for droughts—specificity, randomness, drought phenomenon, cost of droughts, and political considerations—are discussed here.

SPECIFICITY

Planning for and management of hazardous events presuppose that those events are well defined and discernible to all. The planning necessary to reduce the effects of most natural hazards is difficult because the intensity and frequency of the events are unknown, although there is never any question as to their eventual occurrence. Although no technical expertise is required to determine when floods, volcanic eruptions, or earthquakes have been experienced, considerable uncertainty exists as to when droughts start and end. A drought is almost a “non-event” (Evan C. Vlachos, Colorado State University, written commun., January 1988). Any discussion about planning for drought conditions and management of water resources, therefore, requires some definition as to what constitutes a drought. This lack of specificity can be a major contributing factor, although unstated, as to why the planning for droughts and the managing of water resources during droughts have received less attention than they deserve.

RANDOMNESS

Droughts, when placed in historical perspective, have not received much attention from governments at any level until severe water shortages occur. What most inhibits the planning for water shortages associated with droughts is their random nature. It is this inherent variability that makes "reacting" to a water-shortage crisis and instituting relief efforts when the shortages occur appear to be more rational than does "planning" for droughts. People tend to overlook that droughts are a normal part of the climatic regime and that they will recur. Droughts remain a certainty; only their frequency and severity are unknown. Thus, it makes good sense to plan to reduce both the costs that result from droughts and the associated personal hardships.

DROUGHT PHENOMENON

Another obstacle to planning for droughts is inherent in the drought phenomenon. Although droughts do affect individuals, in reality droughts are a community problem having characteristics of Hardin's famous "Tragedy of the Commons" (1, p. 34). The self-interest of each individual using communal property is to maximize it for immediate gain. The net result can well be the destruction or deterioration of the communal property. In Hardin's example, the overgrazing and destruction of the common pastures occurred because each person sought to graze all the animals possible. The sum of the actions by each individual was not "best" for the sum of the individuals. This phenomenon makes the best policy infeasible unless the individuals reach a consensus themselves or are compelled to do so by a government.

Droughts produce the same type of situation. For individuals experiencing a drought, options to deal effectively with water shortages are limited. Collective action by all the individuals provides the best solution. The use of groundwater during times of drought in many Eastern States provides a comparable situation to the one described by Hardin in the case of common pastures. The common law in many Eastern States deals with groundwater as a common resource that is appropriated under the Rule of Capture (7, p. 115). What you capture is what you get, and those having the deepest wells and the largest pumps get the most water. Given these circumstances, the solution for an individual during drought conditions might be to drill a well. If all individuals act in the same manner, a variety of consequences can occur to the detriment of each. A shallow aquifer eventually can be depleted, the individuals can be competitors for water and cause larger and larger cones of depression as deeper wells and larger pumps are utilized, or the increased pumping can cause saltwater intrusion, which will destroy the quality of the water in the aquifer for all. The best solution for all parties might be an agreement between the individual well owners, or restriction by the local government, to curtail the time and rate of pumping. Under these circumstances, an individual who pumps water from a common aquifer cannot plan effectively for droughts. If an individual well owner seeks to conserve groundwater or plan for a water shortage, he or she needs to be aware that the water he or she does not pump will probably be pumped by others.

Because droughts affect larger geographic areas than those occupied by single communities, the ability of an individual community to respond effectively is affected by the actions of similar communities in the drought area. The position of each community in this larger arena can be analogous to that of the individual in the community. Individual actions by each community can be counterproductive to the policy best for the region as a whole. For one community, the solution may be the building of a reservoir on a stream that is the water source for other communities downstream. As each community opts to resolve its water needs without regard to its neighbors, the stream can become an inadequate water source for all. The development of a regional water supply for all communities might be the best solution, but this will require the consensus of all the communities.

COST OF DROUGHTS

The lack of information about the cost of droughts is another reason why only marginal interest exists in planning for droughts, especially at the State level. The magnitude of drought costs is assumed to be less than that of other natural hazards because the losses associated with other natural hazards are more evident and generally are incurred during short periods of time. In contrast, drought losses generally are distributed over longer time periods. When the true costs of drought are known, drought losses can dwarf the losses from other natural hazards. For example, Australia determined that, for the period 1945–1975, the costs of droughts were four times the costs of other natural hazards (8, p. 226). In addition, all the costs associated with droughts are not clearly defined. The social effects of droughts and the associated costs, how the effects propagate throughout society, and who is ultimately affected need to be better understood. Human suffering is less likely to be factored into the cost assessment even though these costs are real and can continue for years, long after other costs have been absorbed. The aggregated indirect costs probably are far greater than the direct costs, but because of their diffused nature they are difficult to identify and quantify and, thus, generally go unrecognized (1, p. 32). These indirect costs, which are disbursed among large groups and throughout large geographic areas, nevertheless constitute a major proportion of the total costs resulting from droughts (1, p. 32). Again, the random nature of droughts, coupled with the rapid decrease of public interest in droughts after normal precipitation resumes and the limited resources available for planning, make the determination of in-direct costs associated with the droughts less urgent. As long as these indirect, diffused costs remain undisclosed, decision makers will have incomplete knowledge of the costs of drought. If the past is any guide, the total costs of droughts probably never will be reliably assessed.

The length of a drought also has a significant effect on the total costs; long droughts are more costly than shorter droughts. A sustained drought, such as the one in the 1930s, can have economic and social costs that are never quantified. During the 1930s drought, for example, agriculture was abandoned in some sections of the Nation; this abandonment, in turn, caused dislocation of people and severe impairment of the economic substructure that supported agriculture. The 1930s drought had an effect on a whole generation of Americans, wherever they lived and however they made their living (4, p. 34). Even if the value of human life is ignored, the total economic losses from droughts can be staggering.

POLITICAL CONSIDERATIONS

Lastly, political considerations affect action that might lessen the effects of droughts through better planning and management. The randomness of droughts induces the public to believe that little can be done to reduce the costs of droughts before they occur. In addition, the public's memory of past tragedies usually is short, and political attention shifts quickly to new political problems. The public, lacking an analysis of the total costs associated with a drought, has the illusion that droughts are affordable, although inconvenient. Thus, decision makers lack the public support needed to take aggressive action in planning for droughts and managing water resources during droughts. This is not strictly an American phenomenon, as witnessed by the inaction of the British Parliament during the mid-1970s when the country experienced its worst drought in 500 years (9, p. 51). Early in the drought, efforts were made to have Parliament enact legislation to extend the responsibilities of the river authorities to mitigate the effects of the drought. Before responding, Parliament waited until there was widespread public awareness of the need for the legislation; thus, the damage factor was increased substantially compared to what it would have been had Parliament acted earlier.

In contrast to a lack of public support, special-interest groups at the State level might oppose activities that are essential for an effective water-management plan applicable to droughts. For example, farm groups in Virginia strongly oppose any Federal, State, or regional water-management plan because they believe there should be no regulation of water apart from the Riparian Doctrine (Mark Tubbs, Virginia Farm Bureau, commun., 1981). Water management, of necessity, must be at the core of any program to mediate the effects of water shortages that occur during droughts, but political factors can substantially dampen the interest in managing water resources even during droughts.

FRAMEWORK FOR STATE ACTION

The "Tragedy of the Commons" phenomenon, which characterizes the problems associated with any management plan to mitigate the costs associated with droughts, illustrates that, in the absence of agreement among all the parties affected by the drought, the management responsibility needs to be at the lowest possible level of government that will permit the attainment of management's objectives (1, p. 34). The State, in most situations, represents the unit of government that has the authority to allocate water, to set policy objectives that are concerned with water-use efficiency and equity, to consider interboundary issues and externalities associated with matters such as minimum instream flows, and to coordinate the activities of local governments in meeting water-supply needs during times of severe water shortages.

The responsibility for managing water resources during droughts, once assumed by the State, needs to be vested in such a manner as to require timely action and not be vulnerable to legal challenges by groups who do not favor an approach taken by the State. Although expanding the Governor's powers to deal with disasters by including droughts might be expeditious, the action taken by most States generally is to group management activities with the authority primarily designed to respond to disasters after they have occurred rather than to undertake planning activities to reduce the cost of droughts in advance of their occurrence. Colorado, Delaware, New Jersey, and North Carolina are examples of States that have used executive power to develop statutory guidelines that define droughts and delineate interaction among State agencies responsible for water resources (10, p. 162–163).

PLANNING TOOLS

The authors of the "Model Water Use Act" (3, 1958) developed five planning tools—identification of drought indicators, designation of government authority, notification of the public, curtailment of water use and maintenance of revenues, and monitoring of water-user compliance—to cope with planning for water shortages associated with droughts. These tools addressed the following fundamental questions:

- How does a State know when there is a drought?
- If there is a drought, who is in charge?
- How is the public informed?
- How are current allocations and uses of water to be modified?
- How is compliance assured?

The answers or responses to these fundamental questions need not be identical for each State having a functioning water-management plan applicable to droughts. Each State, however, needs to address each question in terms of its own circumstances. Failure to address each of the questions will detract seriously from the effectiveness of a water-management plan. Each of these planning tools is now examined in detail.

IDENTIFICATION OF DROUGHT INDICATORS

Because of the difficulty of deciding when droughts start and end, specific drought indicators must be used to decide when to implement a water-management plan.

When such indicators have been identified, water users can formulate contingency plans and make decisions on future economic investments (11, p. 47). The drought indicators must be precise and susceptible to little, if any, subjective decision making. The latter makes the indicators vulnerable to court action by those who oppose advanced planning.

A variety of drought indicators can be used, including the Palmer Index (a drought-severity index), in stream flows, historical data on the present and anticipated needs for water, the degree of subsidence or saltwater intrusion, the potential for irreversible adverse effects on fish and wildlife, and reservoir or groundwater conditions relative to the number of days of water supply remaining (11, p. 47). Usually it is desirable to select a number of drought indicators to reflect the seasonal relation of supply versus demand. The Delaware River Basin Commission (11, p. 51) relies on five drought indicators—precipitation, groundwater levels, reservoir storage, streamflow, and the Palmer Index. Ranges of values for each of these indicators are assigned to one of four drought stages—normal, drought watch, drought warning, and drought emergency (11, p. 51). To activate any one of the drought stages, three of the five drought indicators must indicate a given drought stage (12, p. 34). The drought indicators should not be so complex as to cause uncertainty about whether some stage of the water-management plan should be activated; for example, if precipitation and reservoir storage are two drought indicators, the decision to activate the plan will be unclear if the precipitation is less than normal while reservoir storage is normal.

When there is only one source of water supply, one drought indicator may be sufficient; for example, when a city's only source of water is a reservoir, the water-management plan can be activated if reservoir storage, expressed as a percentage of normal seasonal capacity, decreases below a specified percentage. The phasing criteria used by Manchester, Connecticut, are an example (Table 1): a drought watch goes into effect when reservoir storage is at 70 percent of normal seasonal capacity, and stage I of the water-management plan becomes operational when reservoir storage is 57 percent of normal seasonal capacity.

A sliding scale for drought indicators also can be shown graphically in terms of the storage in a reservoir, as shown by the operation curves for three reservoirs in New York that also are part of the Delaware River basin (Fig. 1). When the actual reservoir level drops below the drought-warning zone or drought zone, schedule of reduced diversions from the basin to the various localities takes effect. The Pennsylvania Drought Contingency Plan for the Delaware River Basin is based on these criteria. Where groundwater is one of the main sources of water supply, drought indicators based on groundwater levels can be used; the Alameda County Water District in California has such a plan (12, p. 38).

Most water-management plans have correlated successive stages of a drought strategy to certain deficit-reduction goals (12, p. 39). Fewer than three stages in a plan can result in marked differences in the actions to be implemented between the first and the second stages. More than five stages in a plan, however, can cause frequent transitions between stages, which can decrease the effectiveness of the plan. An example of a workable plan is the Seattle Water Department five-stage plan for reducing water use (Table 1). Agencies having water-management

Table 1. Drought-Contingency-Plan Phasing Criteria Used By Two Cities in the United States

MANCHESTER, CONNECTICUT
(South System)

Drought Stage	Drought Stage Initiating Conditions	Demand-Reduction Objective
Drought watch	Reservoir water levels at 70 percent of normal seasonal capacity.	Informational only, raise public awareness
Stage 1	Reservoir water levels at 57 percent of normal seasonal capacity.	Cut back withdrawals from reservoirs by 5 percent or reduce total system use by 3.8 percent.
Stage 2	Reservoir water levels at 40 percent of normal seasonal capacity.	Cut back withdrawals from reservoirs by 30 percent or reduce total system use by 20 percent.
Stage 3	Reservoir water levels at 0 percent of normal seasonal capacity	Eliminate withdrawals from reservoirs and reduce total system use by 70 percent.

Source: Data from Reference 12, pp. 33, 35, and 36.

SEATTLE, WASHINGTON, WATER DEPARTMENT
(Deficit reduction objective is based on demand levels in a l-in-50-year
drought, which are expected to be above normal averages due to warm, dry conditions)

Summer-Shortage Response Plan

		Demand-Reduction Amount, in Million Gallons Per Day	
Stage 1 Minor shortage potential	Total system storage is not filled to capacity as of June 1. Streamflow and snowmelt forecasts indicate that inflows will be inadequate to fill storage facilities before the beginning of the peak-use season.	Water-system management Customer Total	3.0 0.0 3.0
Stage 2 Moderate shortage potential	Total system storage is predicted to fall below the level required to meet expected demands during a 1-in-50-year drought. System inflows continue to be low. Weather forecasts predict a continuing trend of warmer, drier than normal conditions.	Water-system management Customer Total	3.0 4.7 7.7
Stage 3 Serious shortage	Total system storage drops below the level required to meet expected demands during a 1-in-50-year drought. System inflows continue to be low. Weather forecasts predict a continuing trend of warmer, drier than normal conditions.	Water-system management Customer Total	5.0 15.0 20.0
Stage 4 Severe shortage	Conditions described for stage 3 occur near the end of the peak-use season.	Water-system management Customer Total	5.0 16.1 21.1
Stage 5 Critical emergency	Customer demands and system pressure requirements cannot be met.	Not applicable.	

Fall-Shortage Response Plan

		Demand-Reduction Amount, in Million Gallons Per Day	
Stage 1 Minor shortage potential	Total system-storage levels are dropping due to the increased use associated with a warm, dry summer. Weather forecasts predict a continuing trend of warmer, drier than normal conditions.	Water-system management Customer Total	3.0 0.0 3.0
Stage 2 Moderate shortage potential	Total system storage is expected to fall below the level required to meet expected demands during a 1-in-50-year drought.	Water-system management Customer Total	5.0 2.4 7.4
Stage 3 Serious shortage	System inflows continue to be low.	Water-system management Customer Total	5.0 6.2 .11.2
Stage 4 Severe shortage	Weather forecasts predict a continuing trend of warmer, drier than normal conditions.	Water-system management Customer Total	5.0 19.6 24.6
Stage 5 Critical emergency	Customer demands and system pressure requirements cannot be met.	Water-system management Customer Total	5.0 52.4 57.4

plans have determined that fall droughts have a lesser probability of occurrence, but if they do occur, they are likely to develop more quickly and be more severe.

DESIGNATION OF GOVERNMENT AUTHORITY

The designation of a governmental unit or agency having specific drought-planning authority in advance of a drought is one of the critical aspects of providing for managing water supplies during droughts (10, p. 162). For a water-management plan to be effective, the designated agency needs to have authority to declare that a drought exists and to alter water-use patterns. The location of a unit or agency that has this authority within the State's administrative structure will vary. Statutory authority needs to be detailed and specific. If discretionary authority is given, well-defined guidelines for its use need to be given. Failure to adequately delineate the limits wherein action needs to be taken can create situations where administrators postpone action in order to avoid conflict with user groups. This postponement lessens the protection afforded to both water quantity and quality (10, p. 164).

NOTIFICATION OF THE PUBLIC

When drought conditions activate the implementation of the water-management plan, the public needs to be notified. The notice needs to contain information about the provisions to curtail use, when conservation measures become effective, the availability of variances, and the procedures for obtaining a variance. The exact notification procedure can be developed to reflect local conditions. Examples of States having well-defined notification procedures include Florida, Georgia, North Carolina, and South Carolina (10, p. 165).

CURTAILMENT OF WATER USE AND MAINTENANCE OF REVENUES

A system of priorities of water-use categories needs to be in place before droughts occur, so that each user knows, in advance of a drought, in what order water restrictions will be applied. If industries and commercial establishments know, in advance of a drought, the procedures to be used in reducing water availability, they can establish their own contingency plans for those reductions; for example, they can arrange for alternative water supplies or plan reductions in production schedules. Unlike most Western States, the majority of Eastern States, which allocate water according to the riparian doctrine, do not have a water-use-priority system to deal with water shortages caused by droughts. Some attempt, however, has been made in most States to show a preference for certain uses (10, p. 162).

A reduction in water use will cause a reduction in the revenues of the water suppliers. The reduced revenues come at a time when costs are greater because of expenditures made to deal with the drought. In the absence of a water-revenue reserve or a drought-emergency account, water suppliers need to either increase water rates or impose a drought surcharge (12, p. 49). The use of a drought surcharge has several advantages compared to a simple increase in water rates. For example, the drought surcharge is easier to administer, and the amount of revenue to be generated is more predictable. This surcharge probably is more acceptable to the customer because it is a one-time charge that is understandable and allays the fear that a water-rate increase to make up revenues lost during droughts will continue when the drought is over.

MONITORING OF WATER-USER COMPLIANCE

Experience has indicated that reductions in water use greater than 20–25 percent cannot be obtained with a request for voluntary conservation (12, p. 29). There does not seem to be general agreement as to whether mandatory conservation regulations or water-rate increases and drought surcharges are the most effective means of reducing water use to a volume less than that obtained by voluntary conservation. Utah determined that price increases to reduce water use were not as effective as mandatory conservation regulations for a short drought (12, p. 28). New Jersey, in contrast, recently enacted a "water emergency price schedule" in preference to mandatory restrictions (New Jersey Administrative Code, title 7, section 19B-1.5(a)). Some utilities managers argue that the availability of enforcement mechanisms is the important feature of the plan and that their application is rare (12, p. 29). Much of the monitoring of customers for compliance comes from peer-group pressure, but governmental employees, such as supervisors of streets and wastewater departments and inspectors for buildings, plumbing, electric, construction, and health services, can be empowered to issue citations (12, p. 29). This is an effective method of monitoring a service area with a minimum of expense and with minimal disruption of employees' regular work schedules.

SYNOPSIS OF PLANNING AND MANAGEMENT ACTIVITIES OF THE STATES

The planning tools suggested by King and others (3) in their "Model Water Use Act" provide a minimum set of criteria for evaluating the activities of States in the area of water management during droughts. A survey in 1983 and its update in 1986 by the Virginia Water Resources Research Center (10) determined that, of the 48 conterminous States, only 8 States have comprehensive water-shortage plans, 27 States have emergency drought provisions within their water-rights system, and 13 States do not appear to have plans in place for managing water resources during droughts (Fig. 2).

The eight States that have comprehensive water-management plans incorporate all of the basic concepts suggested in the "Model Water Use Act." However, the approach by each State has been different and reflects individual State needs and existing water-allocation systems. The drought indicators that are used

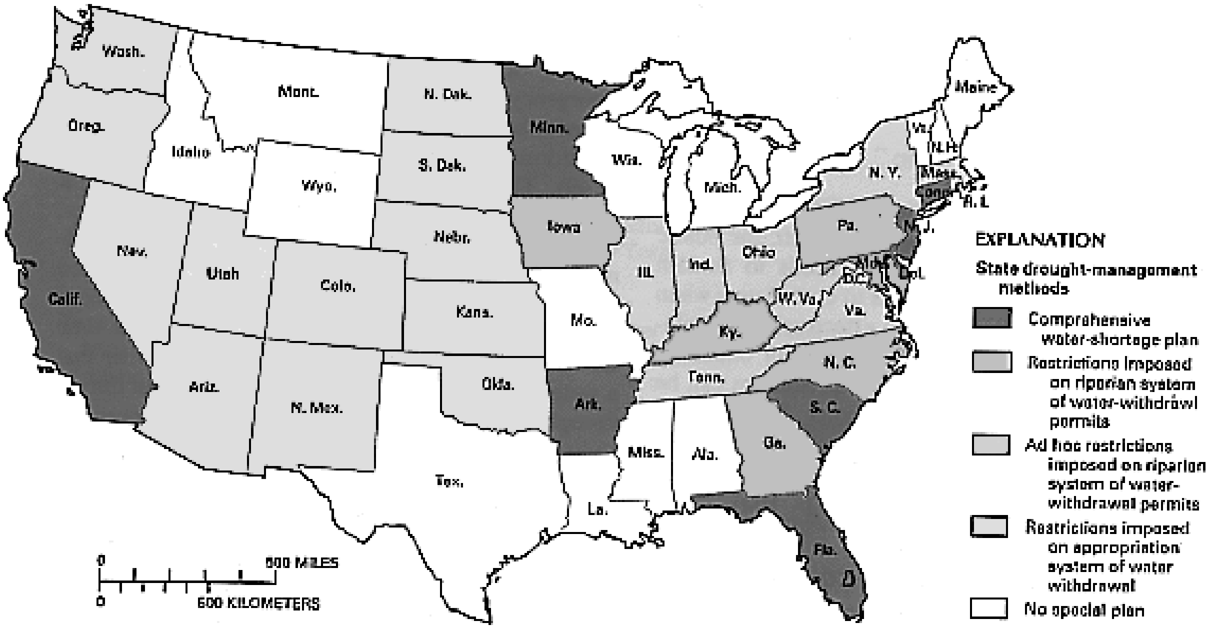

Figure 2. State-level methods for managing water resources during drought conditions (From Ref. 10, p. 146).

to determine when the plans are to begin and to end probably were the least precise component in the plan of each of the eight States. All the water-management plans are activated at the State level except in Florida, where activation is the responsibility of existing water-management districts, and in California, where activation is in the charge of the intrastate districts mandated by statute.

Water laws of 27 States have been modified to establish systems of water-use categories (Fig. 2). Although having these systems in place eases the management of water supplies once a drought occurs, most of the changes are designed to meet emergency water shortages rather than to provide a strategy to mitigate the effects of droughts before an emergency develops (10, p. 149). These 27 States can be subdivided into those that have modified the riparian doctrine with some form of a permit system; that use a modified appropriation system; or that rely on civil-defense, disaster, or emergency legislation that incorporates droughts within its definitions (10, p. 148). A description of these subdivisions follows.

Six States (Fig. 2) in the East have modified then common-law riparian doctrine by requiring water-use permits for some uses. Many of the permits are subject to water-use restrictions during times of severe water shortages. Georgia has water-use restrictions that are implemented during water emergencies. Iowa has made all use of surface and groundwater subject to a statewide permit system; permit users are denied water whenever the minimum instream-flow standard is reached. In Kentucky, permits give no guarantee of a water right during droughts. Conservation programs are required under all permits in Maryland when the safety is threatened by existing or projected water demand. North Carolina's permit system is limited to designated capacity-use areas; other laws in North Carolina grant water-emergency powers that affect the capacity-use areas and the rest of the State. Pennsylvania requires permits only of public water suppliers using surface water; permits are conditioned on there being an emergency water plan in place. All these States have taken some initial steps to manage their water resources during droughts, but they utilize few of the planning tools suggested by King and others (3) in their "Model Water Use Act" for water management (10, p. 155).

Twelve States (Fig. 2) in the West have attempted to deal with severe water shortages by modifying the appropriation doctrine for allocating water. Under this doctrine only the most senior appropriation in time will receive water during water shortages. All these States have modified the appropriation doctrine to some degree to accommodate water shortages caused by droughts. New Mexico, for example, provides for changing the place of diversion, storage, or use of water if an emergency exists (10, p. 152). In Oregon, the Director of Water Resources can order State agencies and political subdivisions to develop water-conservation and water-use-curtailment plans that encourage conservation, reduce nonessential water use, prevent waste, provide for reuse of water, and allocate or rotate the supply to domestic, municipal, and industrial uses (10, p. 152). Utah allows its State Engineer to use regulatory authority to prevent waste in order to mandate rotation of irrigation water where no use will benefit from a diversion of the water supply (10, p. 152). In these 12 States, legislation provides some management tools to assist in decreasing the effects of a water-shortage crisis. Little of the modifying legislation includes the planning tools suggested by King and others (3) in their “Model Water Use Act” to manage water shortages due to droughts in a comprehensive way.

Nine States (Fig. 2) in the Midwest and Mid-Atlantic region have left the management of droughts, from a State perspective, almost entirely to the Governor. These States perceive water shortages as primarily the responsibility of local government. The State has a role when the shortage becomes extensive in terms of time and scope and affects such a large area of the State that the water shortage is perceived as a severe crisis approaching a disaster. These States choose to deal with water shortages due to droughts on an ad hoc basis. New York passed a law that took effect in 1990 and requires a conservation plan for surface withdrawals.

INTRASTATE REGIONAL AUTHORITIES AND INTERSTATE COMMISSION COMPACTS

Intrastate regional authorities can perform the water-management function during droughts if droughts are less than statewide in scope. Politically, such authorities are difficult to create because of the rivalry that exists among local units of government. If intrastate regional authorities are established, such regional grouping must be done carefully to avoid possible constitutional challenge as unlawful delegation of legislative authority (10, p. 162). The water-management districts in Florida are examples of this approach.

When droughts affect more than one State but are not national in scope, interstate commissions and compacts can provide the management function to mitigate drought effects. Their effectiveness is predicated on having well-publicized plans and specific rules for planning purposes so that all users know how they will fare when the river flows cannot accommodate all the withdrawal demands (10, p. 164). The Delaware River Basin Compact (Public Law 87–328, 75 Stat. 688, 1961) and the 1978 Potomac River Low Flow Agreement are examples of interstate compacts that have been used to plan for the problems associated with droughts. Such commissions or compacts require, however, the approval of all of the involved State legislatures, which could be a difficult task politically. The fact that the number of such entities is small is ample evidence of the difficulty and time required to establish them.

FEDERAL RESPONSIBILITIES FOR WATER QUALITY AS RELATED TO DROUGHTS

Since 1972, with the passage of the Water Pollution Control Act Amendments (Public Law 92–500), the Federal Government has assumed a more dominant role on water-quality issues related to surface water. Because droughts and the resulting low flows have a substantial effect on water quality, it is possible, on the basis of existing legislation and regulations, that the Federal Government might become more interested in drought management. For example, Section 208(b)(2)(1) of the Clean Water Act (Public Law 92–500) provides:

> Any plan prepared under such process shall include, but not be limited to, (1) a process to (i) identify, if appropriate, salt water intrusion into rivers, lakes, and estuaries resulting from reduction of fresh water flow from any cause, including irrigation, obstruction, groundwater extraction, and diversion, and (ii) set forth procedures and methods to control such intrusion to the extent feasible where such procedures and methods are otherwise a part of the waste treatment management plan.

The legislative history amplifies on this point (1972 U.S. Code Congressional and Administrative News, p. 3706) (emphasis added):

> Salt water intrusion no less than point sources of discharge, alters significantly the character of the water and the life system it supports. Salt water intrusion often devastates the commercial shellfish industry. It must be accounted for and controlled in any pollution control program. It makes no sense to control salts associated with industrial or municipal waste point sources and allow, at the same time, similar effects to enter the fresh water as a result of intrusion of salt water. *Fresh water flows can be reduced from any number of causes. The bill requires identification of those causes and establishment of methods to control them so as to minimize the impact of salt water intrusion.*

Droughts can be one of the major causes for reduced freshwater flows, and the law requires that methods be established to control or to minimize the causes of reduced freshwater flows that allow saltwater intrusion.

The Siting Requirement under the Safe Drinking Water Act (Public Law 93–523) contains language(emphasizes added) that can be construed to include drought conditions and, thus, impose on States the requirement to adapt siting criteria that include drought conditions:

> Before a person may enter into a financial commitment for or initiate construction of a new public water system or increase the capacity of an existing public water system, he shall notify the State and, to the extent practicable, avoid locating part or all of the new or expanded facility at a site which: (a) Is subject to a significant risk from earth-quakes, floods, fires *or other disasters which could cause a breakdown of the public water system or a portion thereof.*

Droughts could conceivably be “other disasters” provided for in the Safe Drinking Water Act. A combination of these water-quality considerations might, in the future, cause the Federal Government to give greater consideration to managing the effects of droughts, at least with respect to those effects that impinge on water-quality issues.

Lastly, the quality of surface-water bodies is affected markedly by the runoff that occurs when precipitation increases after a drought. During the drought, pollutants accumulate on the land surface and on other surfaces, such as pavement and structures. It is not uncommon for droughts to be followed by a period of abnormally high precipitation that tends to aggravate the already existing water-quality problems by rapidly flushing large loads of pollutants into surface-water bodies. After the drought in England in the 1970s, the nitrate concentration in the Thames River increased to the point where the public-supply intakes had to be closed (9, p. 54). This kind of post drought problem may be reflected in what the Federal Government requires States to do to meet water-quality standards. Some drought planning may occur at the State level as a byproduct of the action taken to address this water-quality problem.

CONCLUSIONS

The planning for and the management of the effects of droughts appear to have a low priority in all but a few States, although all have experienced severe water shortages. For the most part, accommodating the inconvenience caused by droughts is considered a local-government responsibility. The Federal Government's role has been to provide financial assistance to citizens after the droughts have occurred. Water-quality legislation may cause the Federal Government to take a more proactive approach to managing the effects of droughts. Several factors will have to coexist before many States will undertake development of plans to mitigate the effects of droughts. Such factors may be the occurrence of a drought that is long and extensive, thereby increasing demands on a fixed water supply, and a public awareness of the economic costs of droughts. As water demands continue to grow, even minor droughts will become more serious, and States will be compelled to become leaders in developing water-management plans.

WATER RESOURCES MANAGEMENT

Neil S. Grigg
Colorado State University
Fort Collins, Colorado

Water is an essential asset for all life and economic activity, and the term "water resources management" describes activities necessary to balance supplies and demands of water. It involves applying structural and nonstructural measures to control natural and man-made water resources systems to achieve beneficial human and environmental purposes, which may be listed as water supply, wastewater service, flood control, hydropower, recreation, navigation, and environmental protection (1). Along with these, water resources management deals with mutual impacts between water and other systems, such as land, wildlife, and economic systems.

Water resources management controls *water resources systems*, that are combinations of constructed water control facilities and natural, or environmental elements that work together to achieve water management. A constructed water resources system, consisting of structural facilities, provides control of water flow and quality and includes facilities for water supply and wastewater management; for drainage of land and control of floods; and for water control in rivers, reservoirs, and aquifers. Examples include conveyance systems (channels, canals, and pipes), diversion structures, dams and storage facilities, treatment plants, pumping stations and hydroelectric plants, wells, and all appurtenances.

Natural water resource systems comprise sets of environmental or hydrologic elements in nature that include the atmosphere, watersheds, stream channels, wetlands, floodplains, aquifers and groundwater systems, lakes, estuaries, seas, and the ocean.

In addition to structural measures to control water flow and quality, nonstructural measures are used for programs or activities that do not require constructed facilities. Examples of nonstructural measures include pricing schemes, zoning, incentives, public relations, regulatory programs, and insurance.

Water resources management takes place within a "water industry" that consists of water service organizations, regulators, coordinators, and support organizations. This industry places great value on public involvement in decisions because water affects all people and activity in interdependent relationships.

Water supply serves four categories of water users: people, industries, farms, and the general environment. Thus, we speak of water supply for people (domestic water supply), for cities (urban water supply), for farms (irrigation), for industries (industrial water supply), and for cities and industries (municipal and industrial or M&I water), or we can speak of water for the environment (water for natural systems and habitat). Wastewater management serves the same categories, as urban wastewater, industrial wastewater, and drainage for farms.

In-stream uses of water include hydropower generation, navigation, recreation, and sustenance of fisheries and ecological systems.

Stormwater and flood control are different types of water management activities that handle excessive water. As "protective" services, they do not provide water, but remove or store the excess water.

Given its many facets, water resources management should be comprehensive, coordinated, and integrated. Comprehensive water resources management includes all purposes and stakeholders in its activities. When water management is coordinated, there should be linkages between activities so that they occur with due consideration of each other. Integrated water resources management is a term that includes aspects of comprehensive and coordinated water management, and it has been explained in several ways; usually the goal is describing a holistic management process.

For example, a working group of the Awwa Research Foundation (2) used the term "Total Water Management" to explain the integrated nature of water resources management:

> "Total Water Management is the exercise of stewardship of water resources for the greatest good of society and the environment. A basic principle of Total Water Management is that the supply is renewable, but limited, and should be managed on a sustainable use basis. Taking into consideration local and regional variations, Total Water Management
>
> - encourages planning and management of natural water systems through a dynamic process that adapts to changing conditions;
> - balances competing uses of water through efficient allocation that addresses social values, cost-effectiveness, and environmental benefits and costs;
> - requires the participation of all units of government and stakeholders in decision-making through a process of coordination and conflict resolution;
> - promotes water conservation, reuse, source protection, and supply development to enhance water quality and quantity; and
> - fosters public health, safety, and community good will."

In the past, water resources management was primarily an engineering arena for building dams, laying pipelines, installing pumps, and operating systems. Now, managing water resources requires skills and approaches that go beyond pure engineering, science, management, and law. Water resources managers must deal with complexity and conflict to unravel interdependency of systems and resolve political and legal dilemmas. Skills from several disciplines are required, including law, finance, and public administration, along with engineering and science.

Greenbelt, Maryland

To do their jobs, water resource managers in the Columbia River Basin have mostly relied on data from sparsely located ground stations among the Cascade Mountains in the Pacific Northwest. But now, NASA and partnering

agencies are going to provide United States Bureau of Reclamation water resource managers with high resolution satellite data, allowing them to analyze up-to-date water-related information over large areas all at once.

The pilot program is now underway with the Rio Grande and Columbia River basins where water is scarce while demands range from hydropower, to farming, fishing, boating and protecting endangered species (Fig. 1). Water resource managers in these areas grapple with the big money stakes of distributing a finite amount of water to many groups. NASA satellite data offer to fill the data gaps in mountainous and drought-ridden terrain, and new computer models let users quickly process that data.

Land Surface Models (LSMs) from NASA, other agencies and universities, and NASA satellite data can be used to determine snowpack, amounts of soil moisture, and the loss of water into the atmosphere from plants and the soil, a process known as evapotranspiration. Understanding these variables in the water cycle is a key to managing water in such resource-limited areas.

"The latest satellites provide so much up-to-date and wide-ranging data, which we can use in the models to monitor and better understand what is happening with the water cycle in these areas," said Kristi Arsenault, research associate for the Land Data Assimilation System (LDAS) team at NASA's Goddard Space Flight Center, and Research Associate at University of Maryland, Baltimore County.

"These efforts are designed to improve the efficiency of the analysis and prediction of water supply and demand using the emerging technologies of the Land

Rainfall is one of the main variables that drive land surface models used by water resource managers and scientists. *Credit*: Images by Robert Simmon, NASA GSFC Earth Observatory, based on data provided by Kristi Arsenault, NASA GSFC and Univ. of Maryland-Baltimore County.

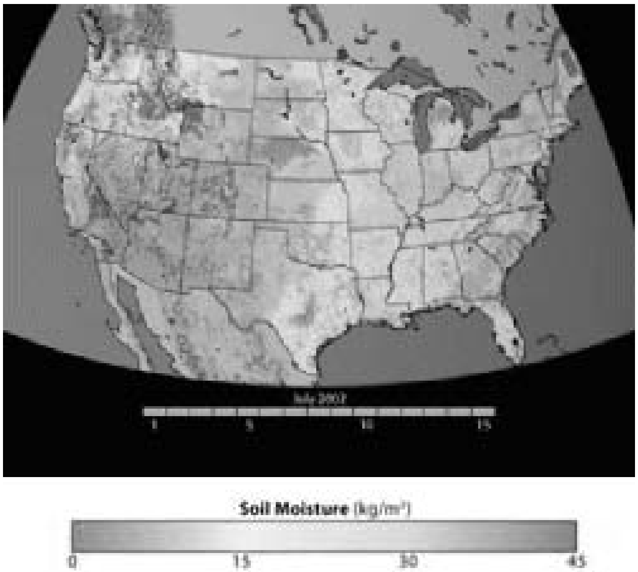

Figure 6. U.S. soil moisture (July 1 to 15, 2002). This animation shows changes in soil moisture from July 1 through 15, 2002, derived from a land surface model. Soil moisture is important for knowing how much water is contained in the soil, which is vital for crop production, flood prediction, and evapotranspiration estimates. *Credit*: Images by Robert Simmon, NASA GSFC Earth Observatory, based on data provided by Kristi Arsenault, NASA GSFC and Univ. of Maryland-Baltimore County.

Data Assimilation System," said Dr. Dave Matthews, manager of the River Systems and Meteorology Group of the Technical Services Center, U.S. Bureau of Reclamation (Reclamation). Computer models, known as decision support systems, that factor in ecological, human, and legal restrictions are vital to managing and allocating water, Matthews added. These systems will incorporate NASA satellite and model data.

NASA's tools may be of vital use in the Rio Grande and Columbia River basins where the disparate and numerous water demands have enormous economic implications. In the Rio Grande Basin, for example, water managers dole out water to farmers so they can irrigate their land. At the same time, under the Endangered Species Act, states are required by law to maintain river water levels to protect the habitat of the endangered silvery minnow. A recent seven-year drought has exacerbated these demands.

Similarly, the Columbia River Basin provides water for the Coulee Dam, the largest concrete dam in North America, and a means for controlling floods. This hydroelectric dam is the third largest producer of electricity in the world. At the same time, the basin is a source of water for a billion dollar agricultural area.

To help make big decisions of allocating water, NASA's special technologies can provide a unique perspective from space. For example, satellites can classify vegetation, a task that is essential to calculating evapotranspiration, which accounts for up to 60 percent of water loss into the air in a region like the Rio Grande Basin. Some managers have been relying on vegetation maps that dated back to 1993, in areas where wild-lands, crops and farming practices are subject to change.

Landsat data can provide highly detailed spatial information, but these images may only be available once a month, and are very expensive. The newer technologies of the Moderate Resolution Imaging Spectroradiometer (MODIS) instrument on the Terra and Aqua satellites provides more frequent passes and day-to-day and week-to-week changes in vegetation production (Fig. 2). In addition, other variables of interest, like snow cover and land surface temperatures, are updated more regularly by MODIS, which can aid in identifying areas with potential flooding and help with the daily management of the water resources (Figs. 3 and 4).

LDAS has also begun to evaluate soil moisture data from NASA's Advanced Microwave Scanning Radiometer (AMSR-E) aboard the Aqua satellite and 3-hour rainfall estimates from NASA's Tropical Rainfall Measuring Mission (Figs. 5 and 6). All this data helps determine how much water is being absorbed into the ground, versus how much is evaporating into the atmosphere. These observations will then be assimilated into Land Surface Models so that water managers can assess flood risks and other factors and act accordingly in a timely manner.

Reclamation brings water to more than 31 million people and provides one out of five Western farmers with irrigation water for 10 million acres of farmland.

One mission of NASA's Earth Science Enterprise is to expand and accelerate the realization of economic and societal benefits from Earth science information and technology.

TRANSBOUNDARY WATER CONFLICTS IN THE NILE BASIN

Rongchao Li
Delft University of Technology
Delft, The Netherlands

WATER SCARCITY IN THE NILE

The Nile, the longest river in the world, has nourished livelihoods, supported a vast array of ecosystems, and played a central role in a rich diversity of cultures. As shown in Fig. 1, from its major source, Lake Victoria in east central Africa, the White Nile flows generally north through Uganda and into Sudan where it meets the Blue Nile at Khartoum, which rises in the Ethiopian highlands. From the confluence of the White and Blue Nile, the river continues to flow northward into Egypt and on to the Mediterranean Sea. From Lake Victoria to the Mediterranean Sea, the length of the Nile is 5584 km (3470 mi). From its remotest headstream, the Ruvyironza River in Burundi, the river is 6671 km (4145 mi) long. The river basin has an area of more than 3,349,000 sq km (1,293,049 sq mi) (source: http://www.nilebasin.org/IntroNR.htm).

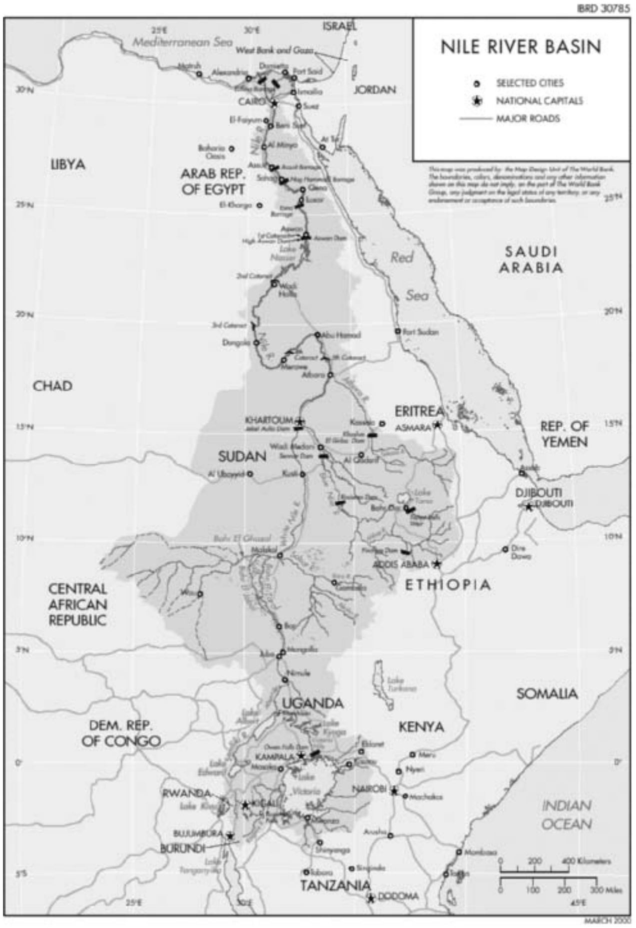

Figure 1. Nile basin map. (*Source*: http://www.nilebasin.org/nilemap.htm.)

As a typical transboundary case, the Nile River Basin is shared by ten countries: Burundi, Democratic Republic of Congo, Egypt, Eritrea, Ethiopia, Kenya, Rwanda, Sudan, Tanzania, and Uganda.

Since the early 1970s, water scarcity has become a matter of concern for the downstream states of the Nile. The engagement of the two downstream states (Egypt and the Sudan) in effective development of irrigated agriculture marked the beginning of real scarcity. The 1960s, in particular, marked the beginning when the two countries engaged in constructing large-scale water projects; by the end of the decade, three dams (Roseires and Khashm Al-Girba in Sudan and the High Dam in Egypt) were constructed. Large-scale agricultural schemes have become dependent on these dams.

In addition to damming the river and increasing demand for irrigation, population growth is considered a major cause of water scarcity in the Nile Basin. Since the late 1940s, probably all Nile Basin countries started to witness steady population increases. In the 1990s, the Nile Basin region experienced one of the highest population increments among the world's regions. Striking evidence of this is that 6 out of the top 20 countries in the world in population increments in 1991 were Nile riparians. The population of Ethiopia, Sudan, and Egypt will double from 157 million to 388 million by the year 2050. The total population of the Nile Basin will more than double when it increases from its 1992 figure of 259 million (1, p. 82) to 607 million by the year 2025. The Nile riparians will remain, well into the first half of this century, among those with the highest growth rate in the world; their rates range from 2.4% to 3.6% (1, p. 82). The most important conclusion to be derived is that more significant increases are taking place in upstream than in downstream countries (2, p. 2). Moreover, it is observed that the countries that have large populations are increasing their population faster than those that have smaller populations. Thus, except for the Democratic Republic of Congo, all large-populated countries will be in dire need of Nile waters as irrigated agriculture increases.

The 1980s witnessed yet another driving force in the region that contributed to water scarcity, the recurrent droughts and their consequential population concentration along the banks of the Nile and its tributaries. The 1980s and 1990s seem to provide new causes that have turned migration into "displacement." Referring to the Nile, Mageed (3, p. 159) stated that "The arid and semi-arid regions of the Basin are experiencing a serious breakdown of the environmental fabric and the spread of desertification along with the collapse of socio-economic systems." The part of the Nile Basin that is crossed by the Sudano–Sahelian zone has scored the highest rate (88%) of desertification in the early 1980s compared to the African average (84%) and the world average (61%). The consequences of drought and land degradation surfaced soon after the 1980s decade started and reached their peaks in famines in Ethiopia and the Sudan simultaneously in 1984. The effect of these, however, has hit all the Nile riparians in different degrees. These consequences have led/will lead to radical changes in the population map in Ethiopia and the Sudan. These famines have pushed large groups of population to the Nile River zone and thus contributed to real population concentration along the banks of the Nile and cultivable irrigable lands in its vicinity. Computations from population census data reveal that the river zone in central Sudan has increased its relative population size by 5.61% between 1983 and 2000, and similarly, in Ethiopia, the relative size of the population inside the Nile Basin increased by 6.5% in just a decade between 1984 and 1994. The same census data show that the population of urban areas in both countries is increasing along the banks and tributaries of the Nile/inside the Nile Basin. The population of Egypt has always been concentrated along the borders of the Nile except for some small oases in the deserts. Although the government of Egypt is developing urban areas outside the Nile valley, most of these developments still depend on Nile water for their water supply.

Unlike population concentration on a regional scale, population concentration in urban areas generates scarcity of a much higher magnitude (4, p. 90). This concentration generates water scarcity in several ways, including high demand for safe water for drinking and sanitation and high pollution rates, which render some water useless, or even harmful. However, as no further facilities have been installed, the concentrating of population has negatively affected the provision of safe water for urban dwellers; in Sudan, the rates decreased from 100% in 1980 to 86% in 2001. In all Nile Basin countries, except for Egypt, provision of safe water has been very limited. Water scarcity caused by population concentration is increased by the in-stream demand for hydropower generation, by the evaporation of reservoirs developed for hydropower generation, by increasing demand due to agricultural development, and by climate change due to global warming.

WATER ALLOCATION AND DISPUTES IN THE NILE BASIN

In reality, water scarcity already causes violence and conflict within and between nations, which is a threat to social and political stability. Peter Gleick, who makes an ongoing effort to understand the connections between water resources and international conflict and security issues, points out that "disputes over control of water resources may reflect either political power disputes, disagreements over approaches to economic development, or both. It is evolving as international and regional politics evolves..." (5). Water disputes typically are erupting within countries in the downstream regions of stressed river basins. Even if water disputes between countries do not lead to war directly, they have fueled decades of regional tensions and thwarted economic development before eventually giving way to cooperation. The Nile is an example in this respect.

Legal arrangements for the Nile in the nineteenth century were much more comprehensive than today in terms of legal obligations abided by all governments ruling over almost all the territory of the Nile Basin. Britain had been the main party to all these agreements; it signed agreements with Italy, Congo Free State, Ethiopia and Egypt. These agreements remained intact until independence. The decolonization process left the Nile with colonial agreements that were not respected by all newly independent riparians other than Egypt.

Immediately after acquiring its independence, the Sudan sought a new deal with Egypt over the Nile water to replace the 1929 agreement signed between the Sudan government (British administration) and Egypt. Conflicts arising at the postindependence stage, unlike the previous conflict, which was basically for securing the flow of rivers, were about the allocation of specified quotas of the now known as large quantities of water, yet scarce to meet the heightening demand. Hence, the Sudan started to confront the unfair division of water; it considered that Egypt's share was more than it actually should be, given that all the Nile water flows into Egypt, save 4 billion m^3 allocated to the Sudan by the 1929 agreement. For the Sudan, a new deal was thus seen as necessary. The challenge of the Sudan did not stem from preserving rights to the future realization of its agricultural potential; rather it was the obstruction of its already developed policies for bringing on board this competent potential. "The Sudan, to prove its case, embarked on drawing up the 'Nile Valley Plan'. The main object of the plan was to provide for the irrigation needs of Egypt and the Sudan and the assumed needs of the other riparian states for irrigation, together with the full development of hydro-electric potential in Uganda, Ethiopia, the Sudan and Egypt" (6, p. 73). The whole exercise was challenging Egypt's monopoly of the Nile by adding an element of egalitarian multilateralism. What made this grow to a challenge was that Sudan was seeking to mobilize the other riparians behind its plan. Egypt, however, was striving to start the implementation of the High Dam at Aswan. The Sudan, while opposing the Aswan Dam project in principle, had put forward three principles for resettling the water question. First, that Sudan's share should be determined before work began on the High Dam. Second, that Egypt must provide for the resettlement and "adequate alternative livelihood" of the people of the Wadi Halfa town and district who would be removed by the High Dam construction. Finally, that the Sudan should have the right in the future to build whatever works were deemed necessary for using her share of the Nile waters (7, pp. 173–174).

Upon accepting these conditions, the conflict between Egypt and the Sudan was bilaterally settled by the Full Utilisation of the Nile Waters Agreement in (1959). The 1959 agreement "established a joint committee (PJTC) and specifies quantitative allocations for the two countries: assuming an inflow of 84 billion m^3 from the Blue Nile and the White Nile sources, the agreement allocates 55.5 billion m^3 to Egypt and 18.5 billion m^3 to Sudan" (8, p. 17; 9).

The deliberations leading to the signing of the 1959 agreement, however, had created a serious conflict with Ethiopia. In 1957, Ethiopia sent a note to Egypt and Sudan in which it asserted its "natural rights" to use the water originating in her territory and in which it also referred to Ethiopia's projected water needs and requirements. These projected needs would certainly decrease the discharge of the Nile (10). The 1959 agreement was considered to favor the Sudan (11,12), dismember Ethiopia (12), and neglect the other upstream countries. The outcome of the 1959 Agreement had effectively put Egypt and the Sudan in one camp against the camp of all other riparians. The newly independent upstream states—individually, but sharing the same view—started to criticize Egypt and the Sudan's monopoly of the Nile waters. Egypt seemed to have accepted the idea that the upstream states are bound by agreements signed during the colonial time, but Sudan's position was different, namely, recognizing the rights of upstream states (10, p. 12).

In the eyes of the Egyptians, Ethiopia has always represented a potential threat to the Nile water. According to Hultin (13, p. 37): "It is not so much what Ethiopian governments—or other riparian governments for that matter—have done with regard to the waters of the Nile, but rather what they might be doing, that is the cause of anxiety in Cairo." Repeatedly, the Ethiopian governments asserted that they are not bound by any agreements on the Nile and that those agreements that were signed during colonial rule were either not signed by them or they were forced to sign by a colonial power. An important element in the dispute is the difference between the states in their starting argument. Egypt and the Sudan, bound by an agreement, based their contest for the Nile waters on real needs, but Ethiopia is driven by the awareness of its future needs and, therefore, is not ready to risk her unused resources (12). Egypt and the Sudan see that their 1959 Full Utilisation of the Nile Waters agreement can be the foundation for any future agreement among all riparians, but the other riparians, especially Ethiopia, want new arrangements.

FORMULATION OF A BASIN-WIDE WATER SHARING FRAMEWORK

The current environmental condition in general and the water scarcity issue in particular require new regimes of thinking and social organization or reorganization. As stated above, there are a variety of driving forces in water scarcity. For instance, until recently, the quarrel over the Nile waters was driven by the states' ambitions to develop economically. In the last two decades, this necessity to develop, in the Nile riparian, is being replaced by a much more urgent need—food security. Two conditions in this respect can be illustrated: one is a condition of abundance that allowed states to expand their irrigated large-scale agriculture endlessly to engage more and more in the market and the second is the condition of scarcity which brought new pressures that affect political stability and necessitate responses from states to groups demands. The condition of scarcity makes it a necessity that states adopt certain regulations to cater to the pressures arising.

The first attempt at cooperation among the Nile countries took place in 1960 through what is referred to as the Hydromet Survey Project, basically aiming to build a database for the Basin. In 1992, Hydromet was replaced by TECCONILE (Technical Cooperation Committee for the Promotion of the Development and Environmental Protection of the Nile Basin). TECCONILE continued until 1999 when it was replaced by the Nile Basin Initiative (NBI) as a wider framework with different operating organs to pave the way for final legal and institutional arrangements.

When competition reaches the crisis stage that the likely win–lose balance turns into a lose–lose balance, the contestants are likely to cooperate to survive the ordeal (14). Developments in Nile Basin politics in the last half of 1999 indicate that the co-Basin states have already reached the situation indicated above. Unlike the first half of the 1990s of national assertiveness and unilateral approaches to use of the Nile waters, the co-Basins now have (in the second half of the 1990) a new initiative, using the Technical Advisory Committee as its technical arm. The objective of the initiative is to reach a solution through the equitable use of the Nile waters. The conference of the Nile riparians in Addis Ababa in May 1999 moved further in this direction, and the Nile co-riparians have emphasized the sustainable development of the river. Thus, already the issue of equitable water use has been expressed together with the issue of sustainability.

Out of these initiatives, the shared vision of the NBI arose that is meant "to achieve sustainable socio-economic development through the equitable utilization of, and benefit from, the common Nile Basin water resources." The initiative as a comprehensive cooperative framework provides for significant changes in the old formula that would protect the co-riparians from inflicting harm on each other. Significant harm is always the consequence of competition, whereas equity and reasonableness can be attained through cooperation. The first is often defined by ideological and political imperatives, whereas the latter is for calculating mutual benefits or avoiding mutual losses—the economic imperatives. In this regard, the request of the Nile-COM for the World Bank and its partners to host a consultative group (ICCON) as a forum for seeking funds is a significant move toward emphasizing the economic imperatives. The Ethiopia entry into the debate on legal arrangements is likely to cool down the previous tension and create a condition conducive to cooperation.

The emphasis on sustainability is what makes the NBI different from the previous initiatives. Moreover, unlike the previous ones, it is a vision shared by all riparians. It means, in short, that awareness of the current environmental problems that affect all riparians is finally on its way toward institutionalization. It is the emphasis on sustainability that gives way to the newest part in the Initiative: the subsidiary action subprogram. The principle of subsidiary is considered "an important approach to cooperative action within a Basin-wide framework" and is meant "to take decisions at the lowest appropriate level, to facilitate the development of real action on the ground." It is this part which gives place to alternative developments by decentering the definition-making and decision-making about the Nile waters, which has been always the monopoly of central governments or bodies representing them. Building the pillars of the temple of cooperative framework (confidence building and stakeholder involvement; socioeconomic, environment and sectoral analysis; development and investment planning; and applied training) in itself involves a necessary learning process in which different levels will contribute. It, thus, informs the new priorities to be set for the Nile Basin countries as it translates to "capacity building and human resource development." As well, it makes place for priorities depending on the needs and specific problems facing each country or a sub-Basin that combines more that one country. It caters to the communities dwelling in the Basin that would be affected by the grand policies to be launched.

Another important aspect of NBI is that it will also consider measures outside the basin when this will ease the problems in the basin, in particular, measures with respect to population and agriculture. Their approach will be based on equitable regional economic development to ensure the balance between upstream and downstream *and* between inside and outside the basin.

What complicates the issues of water scarcity in the future is that the Nile Basin countries are far from providing water efficient alternatives. Thus, the development of the river, necessarily sustainable, is an urgent necessity.

PLAUSIBLE SOLUTIONS

Despite the fact that the Nile River is viewed as the archetype for any future conflict over international water, recent developments show that through cooperation, the Nile riparians can overcome many of the hurdles and establish a peaceful and sustainable solution to the problems of water scarcity in the Nile. What is needed, therefore, is:

1. Principle of equity. Egypt and the Sudan must accommodate the position and demands of Ethiopia and other upstream countries in an institutional manner (15). Ethiopia which views itself as being dismembered by the 1959 Nile water agreement will likely offer greater cooperation should the downstream riparians recognize its right to development of its part of the Basin and facilitate it. If Ethiopia is allowed to go ahead with its Blue Nile basin plan, Egypt and the Sudan would benefit from it (see also Infrastructure Solutions). Governments and international organizations must act early and constructively. Tensions among the Nile basin countries are finally easing, thanks in part to unofficial dialogue among scientists and technical specialists that have been held since the early 1990s and more recently at a ministerial level in the NBI. The key is establishing a process of early cooperation before serious hostilities erupt that make it difficult for nations to sit around a negotiating table together.
2. Strong institutions. Treaties that provide for effective monitoring and enforcement are often remarkably resilient, holding even when the signatories are engaged in hostilities over nonwater issues. Long-term programs of joint fact-finding, technical cooperation, and other initiatives that establish a climate of cooperation among countries can pave the way for resolving disputes when they do arise.
3. Effective rural development. To our understanding, the major problems that the Nile Basin countries are facing now are not merely the need for sharing water; rather they have to do with what makes the quest for sharing more feverish. In other words, environmental degradation and population concentration makes the quest for more water endless. So dealing with these problems and similar ones is what is urgent for all Nile riparians. The NBI can be seen as a framework which allows overcoming some of the factors contributing to water scarcity, including rural development. The multiple billions of dollars that are expected for the development of the Nile basin should be spent on large-scale hydraulic constructions and should also partly be spent on rural development in the territory of the co-riparians—not necessarily inside the Basin.
4. The import of "virtual water" represents one important element in how states could solve their water scarcity problems. In the Nile, this virtual water importation can be thought of in a more innovative way. The Nile Basin countries differ in climate; therefore, crops produced as well as the natural hazards, solutions, and therefore cooperation should consider these differences. Ethiopia faces severe soil erosion due to deforestation, and this very soil erosion, among others, is what pushes Ethiopia toward using Nile water. A fund for forestation and then benefiting from forest products (service for the ecosystem, fruits and other products which become part of the livelihood of rural population, and products for exportation) would thus produce a double advantage. Downstream as well as upstream Nile riparians can import virtual water from Ethiopia necessary for the rehabilitation of the latter. The Sudan, viewed as the breadbasket of Africa and the Middle East, could import virtual water from Ethiopia and export virtual water too. The difference, however, is that virtual water from Ethiopia, in the form of afforestation products, would help rehabilitate this country's highlands, therefore, decrease its demand for Nile water. Similarly Egypt can import virtual water from Ethiopia and the Sudan, through a formula of less virtual water from downstream and more virtual water from upstream—less water-consuming products versus more water-consuming products (rice).
5. Infrastructure solutions. Establishment of reservoirs on the Blue Nile in Ethiopia is suggested as "the greatest opportunity over the long term for dramatic improvement in the overall management of Nile resources" (16, p. 152). What is interesting in this regard is that the water savings so made, which could be of the order of 12–21.4 billion m^3 per year (17), would quadruple Ethiopia's irrigated area without reducing supplies to Egypt and the Sudan. Some other solutions are transfer of storage from reservoirs in Egypt and the Sudan to Lake Tana and the Blue Nile basin combined with water conservation in the Ethiopian highlands (by way of reducing evaporation and annual flooding losses) and will provide regulated flow to downstream countries. Similar schemes could be implemented in the equatorial lake regions of the upper White Nile riparian countries,

resulting in additional water saving construction of a bypass canal (the Jonglei diversion canal) in southern Sudan reducing the enormous evaporation losses and increasing the contribution of the White Nile to the main Nile appreciably. The Machar Marsh and Bahr El Ghazal in southern Sudan can contribute 11 billion m^3 (18, p. 139; also see 1, p. 92).

6. Water saving technologies. In all cases, maximum use should be made of water saving technologies (more crop per drop). This includes water saving options in the surface water system (reduction of losses of seepage and evaporation), more efficient irrigation techniques (land leveling, drip irrigation, etc.), and other management techniques (reuse, nightirrigation, etc.).

PLANNING AND MANAGING WATER INFRASTRUCTURE

Neil S. Grigg
Colorado State University
Fort Collins, Colorado

Water infrastructure consists of the constructed elements that control water for water supply, wastewater service, flood control, hydropower, recreation, navigation, and environmental protection (see articles on Water Resources Management and Water Infrastructure and Systems). Generally, these constructed elements involve conveyance systems, including channels, canals, pipes, and bridges; diversion structures; dams; reservoirs; locks; treatment plants for water supply and wastewater management; pumping stations; hydroelectric plants; spillways, valves, and gates; and wells. Planning and managing water system capital assets require provisions for capital investment, operations, and maintenance.

Capital investment in water facilities requires a careful process that begins with planning them, preparing the designs, and constructing the systems. The goal of capital investment is to obtain a maximum return over the project’s “life cycle.” This means considering costs and management needs over the full life of the facility and requires that operations and maintenance, including corrective maintenance, be carefully conducted to gain maximum usage and life from the investment.

The planning process involves a series of steps that include identifying the need; searching out alternative ways to meet the need; evaluating economic, environmental, and social costs and benefits; making decisions about the alternatives to pursue; and implementing the plan. The steps in planning drive the process, but they involve many complex issues and substeps. Each project has unique features and stakeholders, political issues in gaining approval for infrastructure often control the pace and agenda. Traditional planning processes now incorporate sophisticated environmental, social, and economic investigations and are now much more complex than in the past. For example, the United States’ experience with environmental impact statements required by the National Environmental Policy Act shows that it costs more to add environmental impact analysis to planning, and the decision process becomes more complex.

In an attempt to rationalize complex criteria, the concept of "multiobjective evaluation" was developed to consider economic development, social benefits, and environmental enhancement when planning for water purposes such as water supply, power, and flood control. This concept was included in the "Principles and Standards" that emerged from the Water Resources Planning Act. These later were changed to "Principles and Guidelines."

For a minor component, such as a new pump station, the process may be straightforward and short term. For major facilities such as dams, the process may take many years and, in some cases, ultimately not succeed at all. In addition to the planning steps cited, practical assessments such as how to pay for facilities and identifying legal obstacles are required. Also, stakeholders must be involved at each step of the process through public involvement and consultation.

The design process involves creative decision-making about the configuration and details of projects. Design includes drawings, documents, and plans necessary to initiate construction. Construction begins with preparing contract documents and involves bidding, review, award, organization, construction itself, inspection, and acceptance. Keeping all of the phases going in the proper direction and order is the task of the "project management process." Designing and constructing major water resources projects require high levels of skill and organization involving risk to the public and environment. For example, dam construction may require control of an entire river over several seasons when floods might occur. A wastewater treatment plant might involve large-scale and sensitive biological processes.

After construction is completed, the project enters the "operations and maintenance" or "O&M" phase. Large water systems such as dams and reservoirs are subject to special operating rules. Water treatment plants require trained operators who can monitor chemical and biological parameters while adjusting operating controls. Far-flung systems extending over several watersheds may have sophisticated supervisory control and data acquisition (SCADA) systems, consisting of instruments, wireless and wired communications, computers, and control systems.

Decisions about water system operation are controlled by complex sets of rules and guidelines. In some cases, regulatory controls are very stringent, and violations result in heavy penalties. Operations may be based on computer simulations and multiobjective criteria, as in following rule curves for reservoir operation. A science of *water resources systems analysis* has emerged to provide tools and techniques for operating complex systems.

Maintenance management is also required in a capital management system. Without adequate maintenance, water resources infrastructure systems will usually not perform well and will wear out sooner than planned. The maintenance management system brings activities together for investment, organization, scheduling, and monitoring. Its general functions are inventory, condition assessment, preventive maintenance, and corrective maintenance.

An inventory of facilities, components, and equipment is the cornerstone of maintenance management. Inventory methods differ for real property, fixed assets, and equipment. An inventory can be as simple as, for example, a set of drawings indicating where sewer pipes are located in a section of a city. These drawings, with annotations, are used by maintenance forces to locate and service pipes. On a more sophisticated level, the drawings could indicate other, nearby facilities, such as water and electricity lines, and can also be used to coordinate between services. Even more sophisticated would be coordinated data in a GIS and database format, available on a common basis to different sections of the organization whose work involves shared data, processes, facilities, and staff.

Condition assessment requires inspection and analysis of condition so that maintenance activities can be planned and scheduled. It is used to plan and schedule capital management activities, such as maintenance, needs assessments, budgeting, and capital improvement programs.

Preventive maintenance (PM) is the ongoing program of care given to equipment or components. In general, PM requires consistent, timely completion of tasks prescribed by documented procedures according to set schedules that include regular follow-up. Information sources for PM are O&M manuals, product information, and experience of workers. PM records include equipment data, the preventive maintenance record, the repair record, and a spare parts stock card.

Generally speaking, corrective maintenance means to repair equipment or components that have failed or deteriorated. It can range from minor to major repair and drives the "3 R's" of infrastructure—repair, rehabilitation, and replacement. Corrective maintenance requires a decision if the deficiency is minor or major enough to require capital budgeting. If the problem is major, the capital plan and budget incorporate information about new standards and growth forecasts to lead to decisions about rehabilitation and/or replacement.

When a water resources facility has reached the end of its useful life, it must be removed, rehabilitated, or replaced. Many dams around the world are now 50 or more years old and will face these decisions in the future. Wastewater treatment plants built during the 1970s in the United States are now three decades old. In addition to new investment to handle population growth, a discussion will occur in the future about strategies for reinvestment and modernization of these key infrastructure components.

APPLICATION OF THE PRECAUTIONARY PRINCIPLE TO WATER SCIENCE

Leonard I. Sweet
Engineering Labs Inc.
Canton, Michigan

Discussions of applying the precautionary principle have received new momentum from several highly contentious policy issues, including the bovine spongiform encephalopathy crisis, blood donor screening, genetically modified foods, antibiotic feed additives, and phthalates in baby toys. The level of precautionary interpretation and its application to "decision-making under ambiguity" has wider ramifications for waste policy, ecological toxicology, and especially water science. A balanced debate is warranted over the merits of the two seemingly rival environmental risk management paradigms—risk assessment and the precautionary principle.

The basic definition of the precautionary principle has three elements: threat of harm, scientific uncertainty, and the precautionary action. As such, the principle questions whether scientific knowledge is strong enough to permit reasonably confident decision-making, and it favors preventive action in the face of uncertainty as well as a participatory public in decision-making. The precautionary principle can be applied in general on two fronts, the *ex ante* side that reflects a desire to avoid or prevent undesirable adverse effects in policy frameworks and legislation, and on the *ex post* side, reflecting the fact of having to live with consequences of past decisions, side effects, or accidents (e.g., historical liability or natural resource damage assessments).

The relative constraints and uncertainties of risk assessment suggest to some that risk managers should abandon the risk framework in favor of the precautionary approach. In water science, it is not prudent to propose one as an alternative to the other. An immediate concern is that the precautionary-based approach fails to account for risk transfers, priority substances, and costs versus benefits. It is proposed that a variety of precautionary initiatives and decision analysis tools in risk management (e.g., life cycle assessment, weight of evidence, cost–benefit), as well as the open exchange of information and rational thinking, will aid in bridging the dichotomy between risk assessment and the precautionary principle.

INTRODUCTION

The momentum toward a paradigm shift to precautionary approaches will be faced globally by government and industry, and those in water science will have to rethink radically their current safety, risk management, and regulatory control schemes. The premise of precautionary decision-making is that environmental or human health threats are challenging to comprehend and resolve and that it is necessary to establish an environmental management paradigm to regulate suspect activities before they cause harm. Although originally intended for environmental management issues, the precautionary principle has now expanded to address human health and safety issues (i.e., toxicology, epidemiology, industrial hygiene, medicine). For example, it is likely that a precautionary approach was used in addressing the health and safety risks of using thalidomide because the precise mechanism by which thalidomide impacts the fetus was not characterized until the late 1980s.

In general, precautionary approaches instruct environmentally protective decisions before any potentially harmful effects of a given action or technology are fully proven. There are varying degrees of interpretation of the precautionary principle, including the most stringent or maximally precautionary versus the most permissive or minimally precautionary: (1) strong precaution (where the scientific evidence is uncertain but the public is informed and the evidence indicates that the worst case is the most probable outcome), (2) strong precaution (where the evidence is too weak to justify abrupt changes, given costs, but policymakers take a holding pattern and halt further intervention until more risk evidence is available), and (3) weak precaution (where the evidence is overly weak to justify change in public policy, given costs and other factors, and the public is informed of possible risk).

It can be seen that a regime based strictly on the precautionary principle places the burden of proving the harmlessness of a given action on the party who would engage in that action. This version of the burden of proof policy is a departure from the traditional toxic tort approach in which no harm is presumed to result from the activity of another until a party can demonstrate damage and causation. In the environmental arena, the tort-oriented nonprecautionary approach postpones the regulation of activities until harm occurs and compels a response to potential degradation. Consistent with this continuum of approaches is the presumption that precautionary action is acceptable as an interim measure because, as the scientific evidence accumulates, it is only a matter of time until an adequate level of certainty is reached.

It is apparent that in the governance of risk, the risk-based and precautionary approaches are divergent with regard to scope, risk, and how best to handle uncertainties and values (Table 1).

Rather than seeing that precaution is in conflict with science-based regulations, some suggest that the precautionary approach is consistent with sound scientific practice: (1) in acknowledging and responding to difficult problems in risk assessment such as ignorance (we don't know what we don't know) and incommensurability (we have to compare apples and pears) and (2) in critically thinking about the "use" of scientific knowledge.

GLOBAL SCOPE

Reflecting the divergent values of risk management, the precautionary principle has been defined, and the relative importance weighted differently by various nations (e.g., lack of firmly established international or legal meanings of the precautionary principle). The inconsistency in the precautionary approach is further complicated because actions within one state may cause identifiable harm to another state's environment, which in turn may create international responsibilities.

In a global economy, there are certainly different country-specific circumstances for interpreting the precautionary principle, including the level of industrialization, governance, economic and technical contexts, and human resources available for monitoring and evaluating problems connected with chemical risks. The current perception is that Europe believes that the earlier one exercises precaution, especially when cumulative pollution and diverse chemical risks do not respect boundaries, the more effectively it can be done.

Table 1. Highlights of Risk-Based and Precautionary Frameworks

Risk Framework	Precautionary Framework
Scope: • origins in quantification and hypothesis testing • premise of threshold and assimilative capacity • focus on individual and population risk • methods (i.e., hazard identification and characterization, appraisal of exposure, risk characterization) • adheres to tenets of toxicology (i.e., Paracelsus, Pare's, Haber's, Arndt–Schulz)[a]	Scope: • origins in subjectivity and emotion • does not support assimilative capacity or threshold in environmental/human health • focus on values and a unifying perspective of precaution • methods not well defined; no cause–consequence chain • adheres to caveat of *primum non nocere* or "first do no harm"
Chemical innocent until proved guilty: • "prove harm" regulatory approach • burden of proof on regulatory agency, customer, or public • pollution prevention/minimization opportunity if established threat • focus on preventing false positives	Chemical guilty until proved innocent: • "prove safety" regulatory approach • burden of proof on innovator or manufacturer • ensure safety or ban agent/activity before established threat • focus on avoiding false negatives
Optimistic view of • best available data • default values • analytical techniques • modeling methods • margins of error • statutory time constraints • reasonable estimates	Pessimistic view of • data (inaccuracies, gaps, unsuitability) • modeling (overly complex, nonrandom) • analytical (detection limits, interference) • timescales (inadequate for decision-making and legislation) • uncertainty (e.g., smokescreen vs. scientific indeterminacy)
Risk recommendations viewed as • entrenched in model and method uncertainty • carried out on product versus process • subject to cost/benefit analysis	Risk recommendations viewed as • proactive and adaptive in the face of new information or the unforeseen • not subject to cost/benefit analysis

[a] Paracelsus: dose–response contains the notion of threshold of effect; Arndt/Arndt–Schulz: predicts continuum of physiological mode of action dependent on strength of stimuli, that is, from hormesis/stimulation at low levels to retardation at high levels; Haber's: includes the variables of time and dose as a function of exposure to compare hazards better and formulate thresholds of toxicity; Pare's: the specificity and toxicity of chemicals are due to their unique structure and the laws of biology that govern the response interaction.

Regardless of the geographical complexities, however, there appear to be two consistent global elements of the precautionary principle: first, insufficient scientific information and second, significant but uncertain risks.

Consider the European policy on chemicals and the environment. Europe regards the precautionary principle highly, and erring on the side of caution when knowledge is limited and prediction speculative is viewed as a sensible and sound approach to good governance. The European community has also adopted a variety of principles that are directly or indirectly also designed to improve implementation of the precautionary principle, including the following: (1) polluter pays, (2) preventive principle, (3) sustainable development, and (4) inter-/intragenerational equity. Taken together, the core direction of these principles suggests that liability, at a minimum, should enhance incentives for more conservative, proactive, preventive, future-oriented, and responsible actions.

The European community's approach to the "polluter pays" principle could lead to a structure of environmental liability based on increased levels of precaution and prevention. Such an approach may also introduce new damage assessments, such as environmental damages to nature or biological diversity (e.g., due to the discharge of hazardous substances into waterways) when polluters are identifiable, where the damages are quantifiable and concrete, and where a causal link is established between polluters and damage.

Although there is no fully agreed upon version of the precautionary principle, it is being embraced extensively in international articles, treaties (International Joint Commission on Great Lakes; EU Institutional Treaty), summits (Rio Earth Summit), laws (e.g., German Vorsorgeprinzip legislation; Dutch wildlife laws), conventions (e.g., United Nations' Convention on Law of the Sea, Climate Change, and Biodiversity; UN General Assembly World Charter for Nature), conferences (e.g., 1998 Wingspread Conference Center), and other policy-making formats (e.g., Communication from the European Commission about guidelines for EU research activities; Expert Advisory Board on Children's Health and the Environment). The precautionary principle is clearly viewed as a logical corollary of the established international law norm that no state has the right to engage in activities within its borders that cause harm to other states.

Although the various interpretations of the role and application of the precautionary principle revolve around science and policy, the issue is steadily subjected to political motivations in administration and legislation. In particular, precautionary action has elevated such issues as genetically modified organisms, acid rain, radio-frequency fields, toxic waste disposal, and climate change. However, the precautionary principle is currently lacking in providing evidentiary standards for safety, (e.g., with medicines it revolves around quality, efficacy, and dose–response constancy), as well as criteria for obtaining regulatory approval. This is a serious shortcoming because it is conceivable that practitioners of precaution could be overcautious or unscientific in considering whether new technologies pose unique, extreme, or unmanageable risks, without properly characterizing the many new aspects that may confer net benefits and total hazard reduction. Such a discriminatory policy could inflate the costs of research or remedies, result in high taxation of products, waste resources, inhibit the development of new technologies, restrict consumer choice, and result in zero hazard reduction, all potentially for theoretical risks.

DRIVERS TO ADOPT

Proponents of the precautionary principle believe that existing environmental regulations and other decisions based on risk appraisal techniques have failed to protect environmental and industrial health. Recognized drivers for adopting the precautionary principle include the following:

- risk aversion
- reduced reliance on the quantitative risk in favor of qualitative techniques and participative deliberation
- strong commonsense appeal to general public
- working to safe minimum standards
- adopting sustainability efforts
- following a win–win/least regrets regime with regard to costs and benefits
- primary prevention
- data deficiency or uncertainty challenges, modeling difficulties, analytical difficulties, and insufficient time for adequate research
- commonsense appeal of having the polluter pay
- those in risk governance are frequently asked to provide the final word of advice on safety or risk before they have sufficient proof
- concern that too much focus on risk assessment could delay needed protections
- provides additional rationale for environmental and public health surveillance efforts, to use indicators, and detect the probability of adverse consequences as early as possible.

But in practice or in policy implementation, the precautionary approach is not very popular among experts in the risk arena because the potential benefits from the drivers may not warrant the cost and it is a challenge to make the principle a unified perspective that addresses many of the concerns.

ANTIDRIVERS

Clearly, however, there are antidrivers to adopting the precautionary principle. The main ones include:

1. the reverse onus that shifts the duty of care to be placed on the developer's actions to "prove safety," which may ignore the tenets of toxicology that demonstrate a need to regulate chemicals based on both the beneficial as well as adverse; the other concern is that this is potentially counter to notions of liberty and freedom by shifting the burden of proof from government onto innovators
2. the apparent advocating of controversial measures, including bans or phaseouts, clean production, alternatives assessments, organic agriculture, ecosystem management, health based occupational exposure limits, and a requirement for premarket testing
3. the apparent lack of cost–benefit analyses, in that for many cases that call for precautionary action, the marketplace does not necessarily play a critical role and good cost–benefit information is not available
4. the belief that the precautionary principle allows controlling important resource allocation issues by fear, emotion, and politics and that becoming more "safe" in some areas may involve spending resources that cannot be used doing more 'good' in other areas
5. the continuing challenge for proponents to frame an adequate and harmonized version of the principle. This is a reflection that the principle is still evolving—to some, it is already part of the risk appraisal arsenal, to others it is not yet on the radar screen, and to still others it is the antithesis of risk assessment.

Other concerns in adopting precautionary approaches revolve around the implications for the relationship between environmental protection and economic development, the economic consequences. Technologists and scientists are concerned that the precautionary principle is irrational and potentially based on nonobjective science and that it is anti innovation/antibusiness. The concern is that the precautionary principle is biased toward noncorporate and nonindustrial opinions, is susceptible to manipulation with regard to trade and equality, and may become an excuse for arbitrary restrictions that may stifle progress, prevent the use of newer and safer technologies, and possibly create more risk or uncertainty. Not every action or technology that has associated uncertainty should trigger precautionary action, and furthermore, every chemical should not be a presumed or preestablished carcinogen or endocrine disruptor.

The reticence to implement precautionary approaches fully is likely to remain until a more wise and balanced approach to chemical risk management is established. Most would agree that uncertainties in major decisions need to be weighed, analyzed, and communicated to impacted parties, but a combination of options in addition to the precautionary principle may prove most effective in managing risk (e.g., perhaps prioritized precautionary thinking in tandem with risk characterization and the use of current and better/best control technologies). It is also clear that the growing interest in precautionary approaches is more likely a reflection of shifting values on risk tolerance and governance versus a preference for subjective versus objective problem-solving techniques. Herein lies much of the controversy around its implementation—what constitutes sufficient proof, proof of safety, or proof of negligence?

RISK TOLERANCE

One certainly must consider that the tolerability of individual risk and the regulation of societal risk are integral to our government and culture. Yet the concepts of safety and risk are relative and subjective. In some areas of regulation, an explicit treatment of risk is warranted, whereas in other areas, risk appraisal is more implicit and reliant on best professional judgment. But how safe is safe enough with regard to personal, national, or international risk criteria in water science?

To address this question practically, one must characterize the time frame and magnitude of the hazard and decide on a common language—the language of risk analysis or the precautionary principle.

- *Risk Analysis.* Risk-based target levels, health-based criteria, standards as low as reasonably practicable, reasonable probability of no harm, an adequate margin of safety, proportionality, weighing costs and benefits, virtually safe doses, allowable daily intakes, benchmarks, maximum allowable tissue concentrations
- *Precautionary Principle.* Common sense, an ounce of prevention is worth a pound of cure; better safe than sorry; a stitch in time saves nine; if in doubt, don't pump it out; sentence first, verdict afterward

Apparently lacking in the language of the precautionary principle are a cost–benefit analysis, risk communication issues (e.g., regarding whether the hazard is imposed upon, entertained voluntarily, controllable, inequitable, and to what level the public is averse to the issue), and a good characterization of the boundaries and dimensions of uncertainty (i.e., ignorance, systemic, indeterminacy).

Risk informed decision-making must involve some level of cost–benefit analysis to focus resources and set priorities so that the greatest social benefits are achieved at the lowest cost. Some practitioners may strive to make a formal cost–benefit analysis the determining factor for risk tolerability. However, a formal cost–benefit analysis seemingly contradicts the precautionary principle, as it assumes certainty where, by definition, certainty does not exist. Furthermore, there are some concerns that requiring a cost–benefit analysis would render the precautionary principle less effective, cumbersome, and bureaucratic. Cost–benefit analysis may not be an appropriate methodology for managing uncertainty, as it can be applied only if there is full knowledge of the cost of that damage—and this is challenging because precautionary actions are not based on demonstrated risk, but rather on anticipated risks that are considered plausible.

UNCERTAINTY

Uncertainty refers to the failure to address fully a standard of proof/safety required by decision-makers and to the recognition that one cannot fully characterize the extent and potential seriousness of the consequences of not meeting that standard. In the face of inherent and irreducible uncertainty, it is clear that risk management and precautionary principle paradigms need to be adaptive and consider statistical significance (i.e., power, probability of type I or type II error), as well as environmental significance.

What level of causation, threshold of confidence, or lack of proof is required to trigger use of the precautionary principle to link an exposure to some possible harm? Various trigger criteria have emerged, including reasonable suspicion, potential damages are serious or irreversible, scientific certainty, cost-effectiveness, a single complaint, a single case, a single animal study, a combination, only where the probability and cost of impacts are completely unknown, or some gradient or level lower than the balance of probabilities or prevailing probability. Whatever the trigger, the precautionary principle should be subject to review and assigning responsibility, as well as subject to the European Commission criteria of proportionality, nondiscrimination, consistency, and cost–benefit analysis. The precautionary measures must also be proportionate to the benefits to be achieved. Hence, there is a need for an open and transparent procedure to identify the best options for harm avoidance.

Uncertainty in detecting and evaluating chemical hazards leads to challenges when conducting risk analyses (e.g., robust estimates of exposure and risk for pharmaceuticals in drinking water are not available). In the absence of a scientifically rigorous approach to evaluating the risk potential, actions may be guided by societal perceptions of risk or safety (e.g., refractory pharmaceuticals in wastewater) and may lead to malignment, restriction, or banning of chemical agents. One has to balance carefully the perceived reduction in health risks to society from precautionary action and the denial of public access to materials or technologies that, under appropriate conditions of safe handling and use, would not result in notable risks and may have substantial net benefits.

In the end, one must recognize that the scientific basis of modern water policy involves varying degrees of uncertainty. But it is more certain that risk analysis and precaution converge at the level where they are issue driven and that, regardless of the paradigm or language agreed upon, risk informed decision-making in water science must be efficient and rational, even when data are uncertain and the lines of evidence are imperfect.

POTENTIAL RELEVANCE TO WATER AND ENVIRONMENTAL SCIENCE ISSUES

The precautionary principle can be applied to emerging public concerns, such as large-scale environmental and health issues, and to the associated changes in regulatory frameworks. Most notably, issues include major industrial accidents, agricultural and food sector (e.g., mad cow disease), dioxin exposure and long-range transport, the irreversibility of global issues (e.g., ozone layer depletion, enhanced greenhouse effect), and biotechnologies (e.g., cloning and genetic modification). For watersheds, management decisions based on the relationship between stressors and resources may include act now, protect, restore, or watch.

These are current examples of the precautionary principle in action in the regulatory and environmental arenas:

- *DDT Use to Combat Malaria.* The precautionary principle demands no risk taking when there are unpredictable consequences—the potential environmental and health risks posed by future use of DDT—and hence there is a strong push not to allow it to be used or manufactured. The millions of people suffering from malaria that could have benefited from using DDT simply do not understand the argument of focusing only on potential future risks versus present and clear benefits: the economic benefits of the chemical if the threat of malaria were reduced, health care costs reduced, needless morbidity and mortality reduced, that is, the need to balance the potential risks against the certainties and benefits.
- *Global Climate Change.* With climate change, proof will be validated only after many years of data collection. Given the scope, potential injury, and irreversible consequences, the available information should be given great deference.
- *Biodiversity and Wetlands Loss.* Consider unforeseen circumstances with regard to the Endangered Species Act in the United States; it does not require landowners to protect unlisted but declining species on their lands.
- *Fisheries Sustainability (Disease, Transgenics, Overfishing, etc.).* The use of transgenic salmonid fish that are reproductively sterile. Aquatic organism risk analysis is proposed to evaluate the environmental safety of transgenic aquatic organisms, but its primary weakness is that the probabilities and consequences are based on subjective evaluations and opinions. There is no requirement for scientific analysis or collection of experimental data in support of the risk analysis process. The role of risk analysis as a basis for fish health management is questioned, given the uncertainties, including unrealistic expectations of the ability to identify the right fisheries management decision, stakeholder participation, inadequate predictive ability of models, lack of integration of management and science, and a tendency to overestimate possible versus likely hazards. There are also considerations of failing to account for the unknown, unexpected, or synergistic impacts.
- *Substances of Concern.* California's Proposition 65 assumes that a listed chemical of concern is released to waterways and that it is "guilty before proven innocent."

  Banning persistent, bioaccumulative, toxic substances. Sweden is considering banning substances that persist in the environment and accumulate in living tissue, regardless of whether they are proven significantly toxic such as lead in leaded glass. Under the current system, regulations are aimed at controlling rather than preventing end of pipe versus upstream pollution.

  Restricting pesticide use. Canada is moving closer to adopting the precautionary principle based on a year 2001 Supreme Court ruling that upholds the right of local governments to restrict pesticide use to essential uses to protect human health and the environment. Northern Ireland is banning many pesticides used for food production amid rising consumer concerns about impacts on human health and the environment due to chemical residues. This, of course, involves a ban on any pesticide where there is doubt about its safety, even if the weight of scientific evidence is insufficient or inconclusive.

  Potential bans on antibiotics, given the uncertainties and risk of microbial resistance in the environment.
- *Ocean Shipments or Dumping.* Ocean shipments of radioactive materials and the reprocessing of nuclear wastes and acquiring stockpiles of plutonium. Proponents may want to cite explicitly the precautionary principle as a framework to regulate such shipments. The principle might require users of the ocean to exercise precaution, alertness, and effort by undertaking relevant research, developing nonpolluting technologies, and avoiding activities that present uncertain risks to the marine ecosystem—and further it would reject the current notion of a measurable ability of the environment to assimilate wastes.

  Proposals to dump sewage sludge on the seemingly barren areas of the deep seabed. There is little known about the ecology of this region, the harm to the seabed and interconnected ecosystems. A traditional tort approach would allow dumping until harm is recognized, but a precautionary regime would require the dumping state to prove that the dumping is harmless before engaging in that activity.
- *Water Reuse, Reclamation, and Safety.* A precautionary approach might stipulate that climate change and increased urbanization may threaten to dry up wetlands, pushing species of those habitats to extinction. The fix may be to increase the efficiency of water use and stop wasteful irrigation practices where water losses are highest. The principle might also stipulate that all types of water abstraction and water transfers should be controlled. Certainly economic instruments and regulation can provide a flexible means of improving water resource issues.

  The events of 9/11 may warrant conducting a security sweep of the nation's drinking water systems or for facilities to develop specific security plans based on vulnerability assessments.
- *Sewage Sludge.* In the United States, the biosolids rule imposes limits on molybdenum and alkylphenol. Some critics claim that the risk assessment process is inadequate and does not address all potential or foreseeable risks. Environmentalists, farmers, and scientists have encouraged the U.S. EPA to adopt a more protective program that uses the precautionary principle to determine the safety of applying water to land.
- *Habitat Conservation.* Involves dealing with data deficiencies in species status and magnitude of impacts in a manner that guards target species from irreversible habitat loss yet does not preclude development.
- *Biotechnology.* Consider genetically modified organisms or foods. The benefits of genetically modified

plants include reduced use of fertilizer and pesticides, increased yields, better adaptation to extreme environmental conditions, and reduced allergenicity versus the cost of impacts that may include allergenicity and exotic species that outcompete native and nonmodified organisms.

- *Antidegradation.* Antidegradation and antibacksliding rules are likely to become increasingly important in water policy because the intention of the Clean Water Act is to prevent perceptible downgrading of designated water uses. The protection of high-quality waters under the antidegradation rule might be interpreted differently by risk analysis versus the precautionary principle: For example, the precautionary principle might interpret the rule as an absolute prohibition on lowering water quality. The risk-based approach would consider that avenue a no-growth interpretation and propose a structure that provides systematic evaluation of all available information regarding the social, environmental, and economic impacts of lowering water quality.
- *Sustainable Development.* Some would argue that to achieve sustainable development, policies must be based on the precautionary principle. Environmental measures must anticipate, prevent, and attack the causes of environmental degradation. Science alone cannot determine the appropriate focus of the management inquiry or how to define a just or politically acceptable solution. Setting standards is the confluence of science and policy determination.

Consider the example of applying the precautionary approach to the risks of contaminants in surface and groundwater, including biological, chemical, and radiological agents. Certainly, on a global scale, pathogenic contamination of drinking water can be considered a significant health risk due to disease outbreaks, but there are also exposures to nonpathogenic toxicants. Water pollution comes from many routes, sources, and in various forms; in each case, there are incomplete or lacking data, certainly in the exposure, probability, and effects stages.

In contrast to the precautionary principle, risk-based objectives in water science are typically technology-based (e.g., best available technology, or best available technology economically achievable). One clear advantage of an approach based on technology includes national consistence in treatment level, predictable economics, and relative ease of enforcement—although it does not guarantee improved environmental performance because some areas may be under or overmanaged.

For some environmental practitioners, the precautionary principle appears to focus only on the risk from the agent or technology versus the clear benefits that may result from its use or from the risk trade-offs or transfers that may result from an alternative. Because the risks of a new technology are often not apparent until the technology is in use, some suggest it is then too late to undo the harm (e.g., various case studies in the Great Lakes have suggested to some investigators that the length of time between the introduction of a new technology and the discovery of its deleterious effects and the regulatory action to reduce exposure is typically greater than 25 years). Certainly, unpredictable consequences are not new to water science, considering the unanticipated challenges caused by the use of asbestos and PCBs. The concepts of risks and benefits in water science are not as clearly etched as some may think.

RECOMMENDATIONS FOR BALANCING PROOF VERSUS PRECAUTION

Proponents should proceed cautiously with the precautionary principle. Potential problems in abandoning the risk assessment framework in favor of following the precautionary principle are highlighted in Table 2:

There are certainly some refractory questions to consider, such as:

1. What grounds justify applying the precautionary principle, and what will be the trade-offs? Stifle new technology and associated benefits (e.g., genomic understanding of microbes, plants, animals) from which there is little experience and lots of uncertainty; increase the costs of developing and marketing; threaten freedom and trust of basic research.
2. Who will trigger use of the precautionary principle, and how will they interpret the volume and breadth of data generated from such areas as genomics and proteomics in a positive manner? Risk related data are increasingly in the form of biological markers, gene expression, and protein level change, for which there is an abundance of data generated; yet these are possibly laden with uncertainty and lack of validation. How will this data be processed by the precautionary principle in characterizing new products and assessing efficacy, safety, and so on?
3. What is "sustainable" about the precautionary principle? If we apply the recognized working definition that sustainability is "a challenge that economic growth and development must take place and be maintained over time within the limits set by the physical, chemical, biological, social, and political environments," it follows that environmental protection, product stewardship, and economic development are complementary rather than antagonistic processes, as the precautionary principle would suggest.
4. What is the role of scientific evidence, and to what extent can the precautionary regulatory approach be thought of as without factual or scientific justification, arbitrary and irrational, defensible or enforceable in court, and vulnerable to scientific, legal, and constitutional challenges?
5. To what extent can the precautionary regulatory approach for setting risk standards be flexible enough to consider site-specific conditions in which it is applied (i.e., natural and anthropogenic factors, chemical agent, receptor type and size, exposure conditions, bioavailability, and cost)?

In the end, the relative strength and quality of the precautionary policy will depend on legitimacy, degree of

Table 2. Issues and Risks

Issue	Recommendation
• Process and structure not costless and likely has high expenditures associated given uncertainties	• Utilize cost–benefit and regulatory flexibility analyses • Rational decisions should account for the impact of benefit reduction
• Chemical use does not equal chemical risk	• Account for the way chemical is used, materials handling, exposure sources, potency to receptors • Adopt guidelines to ensure chemical risk and substitution are balanced and not harmful
• Potential risk transfers	• Do not trade a known manageable risk for an uncertain alternative • Actions to remove hazard may remove benefits; loss of benefits introduces new risks • Brainstorm unforeseen risk potentials, such as danger of responding to wrong threat • Utilize a "total hazard" approach
• Undefined and arbitrary methods or interpretation	• Rigorous, prioritized; avoid overregulation that may lead to loss of potential benefits
• Technological stagnation	• Cessation or phaseout of regulatory prescription threatens to kill the patient while inventing a cure for a disease that does not necessarily exist; it may lead to arbitrary unscientific rejection of beneficial technologies
• Lack of prioritization	• Final assessment should involve prioritization of substances and relative risk; should consider impacts of cessation or phaseout on international legislation, production and use, economics, and alternatives
• No zero risk in a technology-based society	• Neither risk assessment nor the precautionary principle can eliminate all risks; these paradigms can only be refined to reduce the relevant risks to a perceived acceptable level; proving no risk is a difficult if not impossible task
• Risks of no action	• The precautionary principle must include a full range of options, including no action
• Tools for precautionary thinking	• Life cycle analysis, waste-free product goals, cleaner production, green building, environmental justice, ecoefficiency, benchmarking, best practices
• Tolerability and meaningful restraints	• Need to define and quantify risk acceptability criteria • The margins of safety for descriptions of low risk must be defined and should consider factors of uncertainty, cost–benefits, and lack of knowledge • Goal is to introduce reasonable/plausible conservatism
• Politicization	• Balance technical, scientific, economic, and political
• Codes of ethics	• Practitioners should adhere to a code of ethics that re-iterates the need for validity of data and sound scientific approaches that are transparent, systematic, subject to peer review, accountable, and independent

public trust, and actual quality of products and decisions. Whether by traditional risk analysis or by precautionary thinking, risk management should be determined case by case and population by population, with a full and transparent accounting of the bigger picture, the consequences of different actions including no action, and the public values surrounding those actions; even if the details are obscure.

WATER PRICING

Steven J. Renzetti
Brock University
St. Catharines, Ontario, Canada

INTRODUCTION

The price of water is measured by the value of the economic resources that must be sacrificed to acquire potable water. In many cases, this price is easily understood as the number of dollars and cents that must be paid to obtain a specific volume of water. In other cases, often in low-income countries, the price of water is best understood as the combination of out-of-pocket expenses plus the time required for travel to and from a water source.

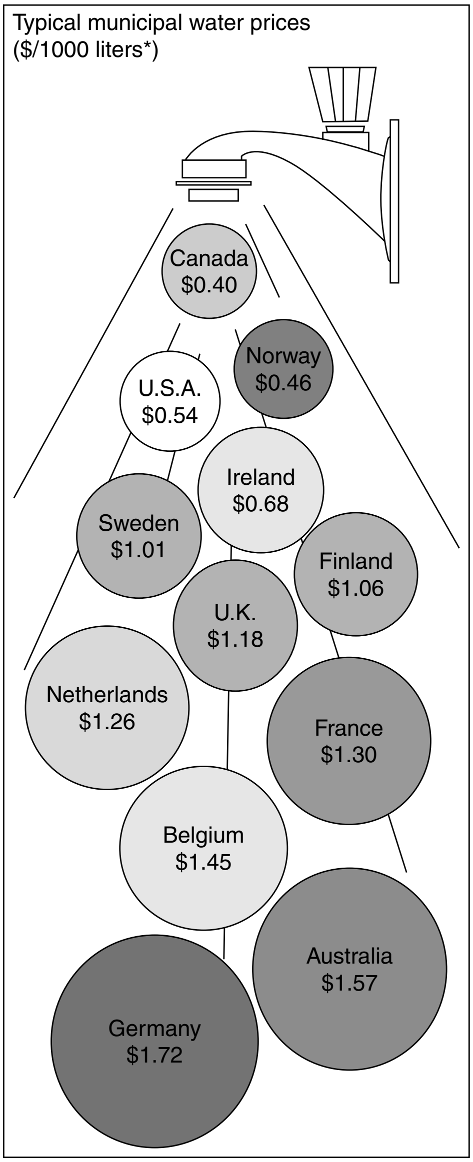
The purpose of this article is twofold. First, it describes the nature and range of water prices around the world. Second, it explains the significance of the price of water for decisions regarding the supply of water and the demand for water. The article concludes that, despite the potentially important role of water prices, a lack of attention to water pricing has been a major contributing factor to worldwide problems of water allocation and water quality.

WATER PRICES AROUND THE WORLD

The level and form of water prices vary widely around the world. Figure 1 gives an indication of the range of residential water prices across a number of countries. The form or structure of water prices also varies across countries and across sectors (agricultural, residential, commercial, and industrial). On the one hand, there are many examples where users face a price of zero for their water. This occurs in municipalities where household water use is not metered and in rural areas where households rely on, but do not pay for, groundwater. There is also another way in which the price of using water can be said to be zero in many cases. If a factory or sewage treatment plant discharges wastes into a waterbody without paying for that right, then these facilities are using water free. It is important to remember, however, that a zero price for water does not mean that there is no cost for using it. This cost may come in the form of the infrastructure needed to purify and transport the water to users, in the form of reduced water quality, or it may come in the form of foregone benefits that would have been enjoyed by other water users had they access to another's water.

On the other hand, water prices can be quite complex and have several components: a one-time connection charge, a recurring fixed charge, a volumetric charge, and supplemental charges for sewage treatment and environmental protection. Further, the volumetric component of the price of water can, itself, vary in structure. It can be a constant amount (such as $0.76 U.S. per cubic meter in Toronto, Canada in 2002) or it can be variable in the sense that the price charged on the last unit of consumption either rises or falls with consumption (these are termed increasing and decreasing block rate structures, respectively). The City of Los Angeles, for example, has a very complex rate structure for residential consumers; the volumetric component varies by season, the household's location, and the quantity of water consumed (2).

Table 1 provides a snapshot of water prices in different sectors and countries. There are a number of noteworthy features of the information presented. First, the information is somewhat fragmentary because information for a number of sectors is not included. Most national governments do not collect data on water prices in their countries. Second, in many sectors and countries, the price of water is very low. The implications of this observation for the viability of water supply systems and for the level of water use are discussed in the next



*All amounts are in 1992 Canadian dollars. In most countries, these prices are increasing from year to year. These figures do not include the cost of waste treatment.

Source: *National Utility Service International Water Price Surveys* as published in World Water and Environmental Engineer.

Figure 1. International comparison of water prices. (*Source*: Reference 1. Note that 1 Canadian dollar in 1992 is the approximate equivalent of $0.75 U.S. in 2001).

section. As Dinar and Subramanian (3) point out, within any sector, prices may vary by the quantity consumed, by the type of water use (e.g., what type of crop is grown), by the time of consumption, and by location. Prices also vary significantly across sectors; industry typically faces the highest prices. Interestingly, prices appear to differ less across countries than they do across sectors within a given country. This may be due to some sectors' political power that has allowed them to avoid facing the full costs of their water use. Finally, there does not appear to be a strong connection between a country's water prices and the scarcity of water in that country. Canada's low water prices might be explained, in part, by its abundant water supplies, but low water prices are also observed in water-scarce countries such as Australia and Spain.

THE FUNCTIONS OF WATER PRICES

In principle, the price of water can play several important roles. From the viewpoint of society as a whole, the price of water informs users and suppliers of the value and scarcity of water. From the viewpoint of the agency supplying water, water prices generate the revenues needed to ensure the financial viability of the agency. From the viewpoint of an individual household, farm, or business, water prices inform decision-makers what they must give up in exchange for getting water. Thus, it can be seen that water prices play many roles and that they have the potential for influencing the demand for water, the supply of water, and the allocation of water among competing users (4,5).

To see how the price of water plays these multiple roles, consider the impact of rising water prices (for

United States	0.0124–0.438	NA	NA

[a] Prices refer only to the volumetric component. They do not include any connection fees or other charges not related to the volume of water consumed.

[b] A cubic meter is approximately 220 Imperial gallons or 264 U.S. gallons.

[c] "NA" means that no number was reported in the original source.

Source: Adapted from Table 1.2 in Reference 3.

example, that might be brought on by the increased energy needed to pump water from shrinking aquifers). Water users see increased prices as a signal of the increased costs that result from using an increasingly scarce (and, thus, valuable) resource. Users can then be expected to reconsider their planned water uses with an eye to conservation and/or substitution toward less expensive alternatives. These types of responses can include changing landscaping practices, retrofitting plumbing fixtures, introducing water recycling, and investing in more efficient water-using equipment. It is important to notice that changing water prices, then, can have an influence on water-use practices and also on the use of other goods and services.

From the perspective of water suppliers, rising prices are a signal that alternative sources of supply are now more attractive options than previously thought. Securing additional water can take the form of reducing system losses, investing in new technologies (perhaps more efficient pumps or water meters), extending the water collection network, or purchasing or leasing water rights.

Rising water prices also provide valuable signals to other decision-makers in society. Rising water prices (and their signal of growing water scarcity) indicate to government that there is an increasing possibility of heightened conflicts among competing water users. As a result, that there may be a need to review the adequacy of water rights laws and water allocation regulations. In addition, rising water prices are a signal to those firms who design and build equipment that delivers or uses water. These firms will see that there is a stronger incentive to innovate and design improved forms of water-related technologies and equipment.

ASSESSING WATER PRICES

The preceding section indicates that water prices, in principle, play a variety of roles, including raising revenue for water utilities and signaling relative scarcity to both suppliers and demanders. Water prices are best able to play these roles when they are free to rise and fall according to changes in supply and demand. Furthermore, the signal they send will be most informative when prices accurately reflect the full costs to society of water use (including any environmental damage). This section briefly examines how well prices perform these roles.

Many researchers and analysts (6,7) are critical of the history and current state of water pricing and argue that, in most cases throughout the world, water prices fail either to reflect accurately the full social costs arising from water use or to fulfill their other functions. Renzetti (8) demonstrates that municipal water prices in Ontario, Canada, often understate the incremental cost of supply by a factor of 2. Munasinghe (9) examines water pricing in Manila and finds that it underestimates the cost of supply by failing to reflect declining groundwater levels. Underpricing water is hardly limited to municipal water supply systems. Research indicates that low prices for irrigation water have historically provided significant subsidies to the agricultural sector. Roodman (7) asserts that "The U.S. government spent an estimated $45–93 billion more than it earned on public irrigation projects between 1902 and 1986 (in 1995 dollars)" (p. 37). These researchers believe that inadequate water prices are a major factor in many of the problems relating to water management (6,10). These problems include overuse of water, poor system reliability, reduced water quality, and the diversion of productive capital to subsidized water projects.

It is sometimes thought that low water prices benefit low-income farmers and households. Unfortunately, this is unlikely to be the case. First, low water prices are an inefficient way to assist the poor because water generally makes up a relatively small share of total household expenditures. In any case, a better option is to design water prices so that families who use relatively little water can be given a free allowance of a specific quantity of water. Second, low water prices often translate into water agencies that do not have adequate financial resources to maintain water quality and system reliability. Middle and high-income households may be able to shield themselves by finding alternative sources of water supply, but the poor can rarely do this. Thus, the general principle is to set prices so that they may reflect, as fully as is politically and administratively feasible, the forces of supply and demand.

CONCLUSIONS

This article has examined the nature of water prices and has demonstrated that the price of water can play an important role in many decisions related to the supply and demand of water and to the allocation of other scarce resources such as investment capital. Despite this potential, water prices have not played an important part in the history of water management. For example, many people remember the building of the Grand Coulee and High Aswan dams, but how many know the prices charged for water in these projects? This lack of attention to water pricing has had important consequences. These include prices that are far below the cost of supply, overuse of water, reduced water quality, and the delayed development of water-conserving technologies. Perhaps because of these conditions, a growing amount of attention is being directed toward water pricing.

SPOT PRICES, OPTION PRICES, AND WATER MARKETS

Terence R. Lee
Santiago, Chile

Markets in water rights do not operate only for buying and selling permanent water rights. Using a market makes available a variety of other tools for increasing the efficiency of water use. Among the most interesting of these tools is the use of spot markets and water use options or future markets. Both alternatives lead to a broadening of the market and to an increase in the number of participants on both the buyer and the seller sides of the market. Their use also results in more stable demand and supply conditions as the market has a larger number of buyers and sellers. They also permit water users to hedge against changes in the price and availability of water rights and thus eliminate the need to hoard as a hedge against this risk. On the other hand, the use of spot and option or future markets requires developing storage facilities and interconnected conveyance systems if their full benefits are to be obtained.

Spot markets involve the leasing, not the sale of water rights. The sale of rights is replaced by the sale of water. In a spot market, the water right remains with the owner. The temporary sale of water in a spot market is a preferred market response to short-term changes in demand and supply.

Water users may find it advantageous to engage to engage in a spot market for a variety of reasons. The seller has an opportunity to earn revenue in the temporary trade of surplus water but does not give up any water rights. This is particularly useful for accommodating a short-term demand for additional water for any use that has a predictable and fixed life span or for a use of uncertain duration. For example, a farmer facing an unexpected variation in normal supplies may buy on a spot market when it is not economical to transport water in periods of sufficient water supply. There are, however, examples of the longer term use of spot markets when a water user is unable or unwilling to commit the resources necessary to buy a water right.

One example of a permanent spot market, where farmers always pay spot prices for water, is found in the community of Huerta in Alicante, Spain. Here the ownership of water is separate from the ownership of land. Water is distributed by rotation at a fixed rate, approximately the same quantity of water in each successive rotation, and the proportion of water available to any water right holder varies for each rotation, depending on the water rights acquired. Before each rotation, a notice is posted that announces the date on which the rotation will commence and informs water rights holders that, within a prescribed period, they should claim their "*albalaes*" or tickets for this rotation. Once allocated, tickets, available in twelve denominations for a constant supply of water from 1 hour to 1/3 minute, are freely tradable in a public auction and an informal market. The community makes a genuine effort to provide information to farmers so they can buy and sell water intelligently; there are brokers who facilitate trading. A simulation model comparison of this system with those found elsewhere in Spain, where trading is not permitted, indicated that the spot market approach adopted in Alicante is the most efficient in terms of net increases in regional income. The differences are not great for moderate water shortages but are significant in conditions of severe water shortage (1).

In a typical spot market contract, the buyer pays the owner of the water right, generally in periodic installments, but there can also be an up-front payment to initiate the sale. Such contracts are often renewable. The length of a contract in irrigation districts is typically a single season. Contracts can be, however, very short, sometimes for as little as a few hours. In the short run, spot prices usually provide a source of water cheaper than the purchase of a permanent water right, but water on a spot market can and will fluctuate in price. The supply is secure only for the period of the contract. There is also an expense in the constant renewal costs for those who depend on short-term purchases in a spot market.

By providing immediate access to water, spot markets can, however, accommodate the most varying needs. The flexibility of spot markets makes them an attractive option for many users, and they are often very active, particularly among neighboring water rights holders in irrigation districts, even where markets in permanent rights have not been established. Spot purchases, often informal, are usually the predominant form of market transactions, whether or not a formal market exists.

In Chile, seasonal spot purchases of water have been a much more active form of water reallocation than water rights sales (2). The most common transaction is an arrangement between neighboring farmers whose water requirements differ through the cropping cycle (3,4). Spot trading between neighbors is easier because it does not require investment in storage facilities or elaborate systems of interconnection between canal systems. In California, as well, water marketing is characterized by an emphasis on seasonal spot markets, although there are good facilities for transferring water over very large distances (5).

Option prices are based on longer term agreements to lease, or sometimes, but less commonly, to sell a water right. The option is taken up when a given event occurs, typically a drought. There are examples of the use of options in both the United States and in Chile. A typical arrangement in Chile is the payment by a fruit farmer of a prenegotiated fee to a farmer growing annual crops for an option on water supply in the case of drought (6).

Options can be and are also used to transfer water from agricultural to nonagricultural users; this has been common practice in the western United States. Dry year option contracts are an attractive alternative when supplies are normally adequate. Options provide supplies during droughts at a cost lower than purchases or leases of water rights.

Options are particularly attractive because the buyer secures long-term water supplies and the seller receives compensation for the option, including the income lost when the option is exercised. For the buyer of an option, the contract also provides a means of obtaining additional water supply, under predetermined conditions, and at a specified price.

Option contracts are, however, complex. The contract must address the risk to the buyer that the water right will not be available when the time comes to exercise the option. The establishment of an option contract limits the rights of the owner of the water right to sell. This issue can be addressed by including in the contract the "right of first refusal" which allows the seller to retain the option of selling the right, but gives the option holder the right to match the offered price (7). Moreover, to produce the greatest benefits, options require long-term contractual commitments, up to 20 or more years, which can introduce many uncertainties into the arrangement.

Option contracts can include payments adjusted over time to allow for changes in water use, production costs, technology, and other conditions. Alternative methods of charging can be used; a lump sum, annual payments, or a combination of annual payments with a lump sum when the option is exercised. The latter is a particularly attractive alternative, because neither party needs to anticipate fully the number of times the option will be exercised over the contract period (8). The holders of water rights on which option contracts have been agreed to can also be compensated in kind, for example, by lower rates for the option holder's production; as in irrigation to hydroelectricity generation transfers, farmers can be compensated by lower electricity rates.

WATER MANAGED IN THE PUBLIC TRUST

Laurel Phoenix
Green Bay, Wisconsin

Managing water in the public trust requires considering the water demand of current and future citizens as well as that of ecosystems, fish, and wildlife. This presumes that water will be managed sustainably for human and ecosystem benefit, despite the fact that ecosystems have no voice in the political process. To understand how complicated it is to accomplish this, the definition and history of the public trust is examined. Next, water management is briefly described to contrast current water management methods with the finesse that managing water in the public trust would require. Finally, some of the difficulties of achieving this in a world of rising demand and finite resources are highlighted, followed by a set of principles describing government obligations to uphold human rights.

WHAT IS THE PUBLIC TRUST?

The public trust is an enduring doctrine obligating government to manage natural resources in the best interests of its citizens. Because some vital natural resources like oceans, air, and wildlife cannot be owned in the same way a person can hold a property interest in land, it is the responsibility of government to hold ownership over these common resources in trust for its citizens, so that their use may be regulated to ensure universal access and prevent their overuse or degradation.

HISTORY OF THE PUBLIC TRUST

The common law doctrine in European history is first attributed to the Roman Emperor Justinian, who declared in 533–534 B.C.E. that running water, seas, and wildlife were part of a "negative community" of things that could not be owned but could be used under regulation to ensure vital common resources were not exploited (1). A later example is the Magna Carta signed in 1215, granting guaranteed liberties to the people that not even King John or future kinds could overrule. Because of its importance to fisheries, commerce, and navigation, the public trust doctrine in America was initially used at federal and state levels only to apply to waterways, but court rulings since then have expanded the public trust to include many other environmental issues, such as protection of ecosystems, recreation like swimming and boating, preservation of views (scenic values), habitat (wildlife values), open space, and beaches (2). Some states have taken a step further to apply the public trust to nonenvironmental issues, such as historical sites; civic sites or economically important areas, such as aging downtown districts; or economic development such as tearing down old, low value single homes to be replaced with many more valuable units, such as expensive condos.

Consequently, the public trust has evolved from rules for equitably sharing the natural "commons" of the land to case law expanding the multiple uses of water resources, as well as rules looking at any social or economic good that could be said to advance the public welfare.

HOW IS WATER "MANAGED"?

Water resources management has been defined as "the application of structural and nonstructural measures to control natural and man-made water resources systems for beneficial human and environmental purposes" (3). Structural facilities include wells, dams, diversion structures, pipes, pumps, treatment plants, and hydroelectric plants. Nonstructural measures are economic incentives, regulations, public education, and planning. Numerous individuals, agencies, and jurisdictions are involved in these structural and nonstructural components. Beyond this complexity, water managers must concomitantly address needs for navigation, municipal water supply, irrigation, fishing, industrial use, hydropower, recreation, public access, and traditionally sacred sites, among others. Water must also be managed to protect ecosystems, fish, and wildlife and should not be unsustainably used to the detriment of future generations.

In America, water resources management is a fragmented collection of federal, state, and local laws managed by numerous and sometimes competing agencies, water districts, ditch companies, acequias, and so on. There are a haphazard mix of treatment and pollution laws at the federal level, water allocation laws at the state level, and sporadic conservation laws at some local levels when supplies run low. It is complicated further by outdated international treaties and interstate compacts. Some states permit, measure, and track individual water use, and others do not.

Two reasons for this lack of a more organized and efficient water management system are (1) a long history, until recently, of having enough water to meet the needs of most users and (2) a variety of political influences on water management decisions. First, competing human uses will have great influence in politics, whereas ecosystems or future generations have few advocates. Second, of the current competing uses, some interest groups have more political power than others, so water may be inequitably or inefficiently managed, allocated, and used. Third, of the current competing uses, some are mutually exclusive in that they cannot happen at the same time in the same location, causing more conflict and subsequent pressure on water managers. For example, building a dam on a prime salmon run damages their ability to spawn, reducing their populations by 80–90%. Another incompatible use of a stream or lake is jet skiing and fishing. Fourth, political influences can cause the best science to be ignored, so, for example, irrigators will get the water they want even after biologists predict large fish kills will result (e.g., Klamath River fish kills of 2002–2003). Fifth, politicians and other decision-makers will be pressured to make decisions with short-term benefits, ignoring long-term solutions. Finally, land use decisions, usually made at a local level, rarely are made with the goal of preserving/protecting water resources. Thus, there are small but cumulative negative effects on surface and ground water everywhere.

MANAGING WATER IN THE PUBLIC TRUST

Managing water in the public interest, therefore, would be a complex and deliberate allocation of water resources to meet the requirements of as many uses as possible, consistent with protecting the resources from pollution and allocating some water for users with no political voice (e.g., ecosystems and future generations)—a Sisyphean task. (Punished for his misdeeds, the Greek Sisyphus was condemned by the gods to rolling a large boulder up a hill for eternity, only to have it roll back down again and force him to start over.) This is complicated enough, but how is this to be done in a world with a fixed amount of water but rapidly growing and often impoverished populations? Already there is evidence of a current global crisis of not enough water to meet human demand. If over 1.1 billion people have no access to safe drinking water today (4), and water conflicts have already been mapped over a large part of the world (5), how can water be wisely managed to provide for the larger populations predicted for the future? There are 6.4 billion people on the Earth now, and by 2050 there will be 9.3 billion (6). Can technological and regulatory improvements produce enough water for these future generations? Besides the inevitable greater demand from additional people, water managers will also have to prepare for climate changes that could alter the historic precipitation and evaporation rates of different regions. Set with such a task, where do we start?

GOVERNMENTAL OBLIGATIONS TO MANAGE WATER IN THE PUBLIC INTEREST

The United Nations has set some guidelines for how governments can fulfill their obligations to their people to support their human rights. These directives of "respect, protect, fulfill" were applied to water to give examples of these governmental obligations (7):

1. The obligation to respect means no interference with anyone's current access to water. Nations could no longer be:

   "engaging in any practice or activity that denies or limits equal access to adequate water;
   artibrarily interfering with traditional arrangements for water allocation;
   unlawfully polluting water;
   limiting access to, or destroying, water services and infrastructure."

2. The obligation to protect means protecting citizens' access to water from third parties, such as warring clans or multinational water companies. Nations would need to:

   "adopt the necessary and effective legislative and other measures to restrain third parties from denying access to adequate water and from polluting and inequitably extracting from water resources;
   prevent third parties from compromising equal, affordable, and physical access to sufficient and safe water where water services are operated or controlled by third parties."

3. The obligation to fulfill means government would need to institute laws and policies to ensure that *every* citizen finally had equal access to water. This could be, for example, "legislative implementation, adoption of a national water strategy and plan of action to realize this right while ensuring that water is affordable and available for everyone."

This framework of respect, protect, and fulfill would use structural and nonstructural measures, but the goals and responsibilities would be more clearly defined than they are now, driving the laws, policies, and choices for governmental expenditures.

FUTURE CHALLENGES

A world where water is managed in the public trust will require major changes. First, it will need governments responsive to and under the control of their citizens, where there is full public participation and transparency in decision-making regarding equitable allocation of water and effective pollution control. Prioritization will then need to be established in advance to deal with a triaged allocation strategy in times of scarcity. Nonpoint and point sources of pollution will need to be far more rigorously monitored to prevent drinking water and habitat degradation. We will no longer be able to pollute with impunity. And finally, inefficient consumption across all human uses, domestic, municipal, industrial, and agricultural will need to be replaced with the most careful consumption, as water becomes increasingly precious.

WATER RECYCLING AND REUSE: THE ENVIRONMENTAL BENEFITS

Environmental Protection
Agency

The Experience at Koele Golf Course, on the Island of Lanai, has used recycled water for irrigation since 1994. The pond shown is recycled water, as is all the water used to irrigate this world-class golf course in the state of Hawaii.

> "Water recycling is a critical element for managing our water resources. Through water conservation and water recycling, we can meet environmental needs and still have sustainable development and a viable economy."
>
> —*Felicia Marcus, Regional Administrator*

WHAT IS WATER RECYCLING?

Recycle: verb 1.a. To recover useful materials from garbage or waste, b. To extract and reuse.

While recycling is a term generally applied to aluminum cans, glass bottles, and newspapers, water can be recycled as well. Water recycling is reusing treated wastewater for beneficial purposes such as agricultural and landscape irrigation, industrial processes, toilet flushing, and replenishing a groundwater basin (referred to as groundwater recharge). Water is sometimes recycled and reused onsite; for example, when an industrial facility recycles water used for cooling processes. A common type of recycled water is water that has been reclaimed from municipal wastewater, or sewage. The term water recycling is generally used synonymously with water reclamation and water reuse.

Through the natural water cycle, the earth has recycled and reused water for millions of years. Water recycling, though, generally refers to projects that use technology to speed up these natural processes. Water recycling is often characterized as "unplanned" or "planned." A common example of unplanned water recycling occurs when cities draw their water supplies from rivers, such as the Colorado River and the Mississippi River, that receive wastewater discharges upstream from those cities. Water from these rivers has been reused, treated, and piped into the water supply a number of times before the last downstream user withdraws the water. Planned projects are those that are developed with the goal of beneficially reusing a recycled water supply.

HOW CAN RECYCLED WATER BENEFIT US?

Recycled water can satisfy most water demands, as long as it is adequately treated to ensure water quality appropriate for the use. Figure 1 shows types of treatment processes and suggested uses at each level of treatment. In uses where there is a greater chance of human exposure to the water, more treatment is required. As for any water source that is not properly treated, health problems could arise from drinking or being exposed to recycled

The Palo Verde Nuclear Generating Station, located near Phoenix, Arizona, uses recycled water for cooling purposes.

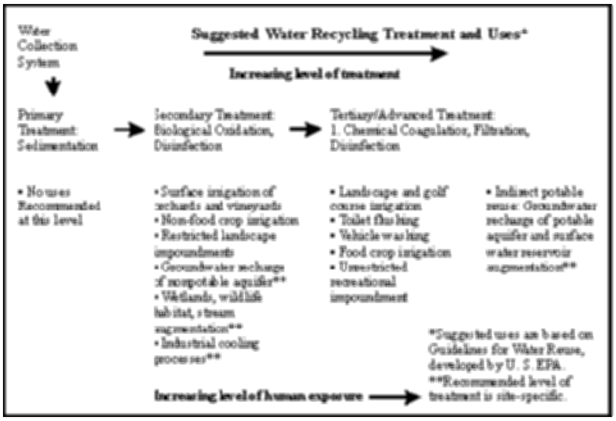

Figure 1. While there are some exceptions, wastewater in the United States is generally required to be treated to the secondary level. Some uses are recommended at this level, but many common uses of recycled water such as landscape irrigation generally require further treatment.

The Irvine Ranch Water District provides recycled water for toilet flushing in high rise buildings in Irvine, California. For new buildings over seven stories, the additional cost of providing a dual system added only 9% to the cost of plumbing.

water if it contains disease-causing organisms or other contaminants.

The U.S. Environmental Protection Agency regulates many aspects of wastewater treatment and drinking water quality, and the majority of states in the United States have established criteria or guidelines for the beneficial use of recycled water. In addition, in 1992, EPA developed a technical document entitled "Guidelines for Water Reuse," which contains such information as a summary of state requirements, and guidelines for the treatment and uses of recycled water. State and federal regulatory oversight has successfully provided a framework to ensure the safety of the many water recycling projects that have been developed in the United States.

Recycled water is most commonly used for nonpotable (not for drinking) purposes, such as agriculture, landscape, public parks, and golf course irrigation. Other nonpotable applications include cooling water for power plants and oil refineries, industrial process water for such facilities as paper mills and carpet dyers, toilet flushing, dust control, construction activities, concrete mixing, and artificial lakes.

Although most water recycling projects have been developed to meet nonpotable water demands, a number of projects use recycled water indirectly for potable purposes. (Indirect potable reuse refers to projects that discharge recycled water to a water body before reuse. Direct potable reuse is the use of recycled water for drinking purposes directly after treatment. While direct potable reuse has been safely used in Namibia (Africa), it is not a generally accepted practice in the United States.) These projects include recharging groundwater aquifers and augmenting surface water reservoirs with recycled water. In groundwater recharge projects, recycled water can be spread or injected into groundwater aquifers to augment groundwater supplies, and to prevent salt water intrusion in coastal areas. For example, since 1976, the Water Factory 21 Direct Injection Project, located in Orange County, California, has been injecting highly treated recycled water into the aquifer to prevent salt water intrusion, while augmenting the potable groundwater supply.

While numerous successful groundwater recharge projects have been operated for many years, planned augmentation of surface water reservoirs has been less common. However, there are some existing projects and others in the planning stages. For example, since 1978, the upper Occoquan Sewage Authority has been discharging recycled water into a stream above Occoquan Reservoir, a potable water supply source for Fairfax County, Virginia. In San Diego, California, the Water Repurification Project is currently being planned to augment a drinking water reservoir with 20,000 acre-feet per year of advanced treated recycled water.

WHAT ARE THE ENVIRONMENTAL BENEFITS OF WATER RECYCLING?

In addition to providing a dependable, locally controlled water supply, water recycling provides tremendous environmental benefits. By providing an additional source

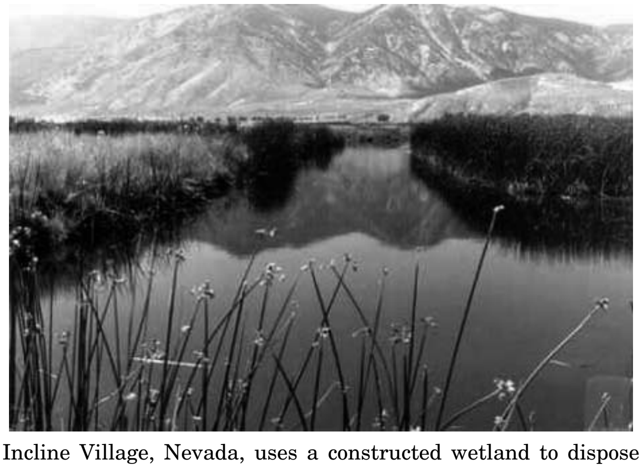
For over 35 years, in the Montebello Forebay Groundwater Recharge Project, recycled water has been applied to the Rio Hondo spreading grounds to recharge a potable groundwater aquifer in south-central Los Angeles County.

In California, Mono Lake's water quality and natural resources were progressively declining from lack of stream flow. In 1994, the Los Angeles Department of Water and Power was required to stop diverting one-fifth of the water it historically exported from the basin. The development of water recycling projects in Los Angeles has provided a way to partially offset the loss of Mono Basin water, and to allow the restoration of Mono Lake to move ahead. Copyright 1994, Mono Lake Committee.

of water, water recycling can help us find ways to decrease the diversion of water from sensitive ecosystems. Other benefits include decreasing wastewater discharges and reducing and preventing pollution. Recycled water can also be used to create or enhance wetlands and riparian habitats.

WATER RECYCLING CAN DECREASE DIVERSION OF FRESHWATER FROM SENSITIVE ECOSYSTEMS

Plants, wildlife, and fish depend on sufficient water flows to their habitats to live and reproduce. The lack of adequate flow, as a result of diversion for agricultural, urban, and industrial purposes, can cause deterioration of water quality and ecosystem health. Water users can supplement their demands by using recycled water, which can free considerable amounts of water for the environment and increase flows to vital ecosystems.



Incline Village, Nevada, uses a constructed wetland to dispose of wastewater effluent, expand the existing wetland habitat for wildlife, and provide an educational experience for visitors.

Recycled water has been used for a number of years to irrigate vineyards at California wineries, and this use is growing. Recently, Gallo Wineries and the City of Santa Rosa completed facilities for the irrigation of 350 acres of vineyards with recycled water from the Santa Rosa Subregional Water Reclamation System.

WATER RECYCLING DECREASES DISCHARGE TO SENSITIVE WATER BODIES

In some cases, the impetus for water recycling comes not from a water supply need, but from a need to eliminate or decrease wastewater discharge to the ocean, an estuary, or a stream. For example, high volumes of treated wastewater discharged from the San Jose/Santa Clara Water Pollution Control Plant into the south San Francisco Bay threatened the area's natural salt water marsh. In response, a $140 million recycling project was completed in 1997. The South Bay Water Recycling Program has the capacity to provide 21 million gallons per day of recycled water for use in irrigation and industry. By avoiding the conversion of salt water marsh to brackish marsh, the habitat for two endangered species can be protected.

RECYCLED WATER MAY BE USED TO CREATE OR ENHANCE WETLANDS AND RIPARIAN (STREAM) HABITATS

Wetlands provide many benefits, which include wildlife and wildfowl habitat, water quality improvement, flood diminishment, and fisheries breeding grounds. For streams that have been impaired or dried from water diversion, water flow can be augmented with recycled water to sustain and improve the aquatic and wildlife habitat.

WATER RECYCLING CAN REDUCE AND PREVENT POLLUTION

When pollutant discharges to oceans, rivers, and other water bodies are curtailed, the pollutant loadings to these bodies are decreased. Moreover, in some cases, substances that can be pollutants when discharged to a body of water can be beneficially reused for irrigation. For example, recycled water may contain higher levels of nutrients, such as nitrogen, than potable water. Application of recycled water for agricultural and landscape irrigation can provide an additional source of nutrients and lessen the need to apply synthetic fertilizers.

At West Basin Wastewater Treatment Plant in California, reverse osmosis, an advanced treatment process, is used to physically and electrostatically remove impurities from the wastewater.

WHAT IS THE FUTURE OF WATER RECYCLING?

Water recycling has proved to be effective and successful in creating a new and reliable water supply, while not compromising public health. Nonpotable reuse is a widely accepted practice that will continue to grow. However, in many parts of the United States, the uses of recycled water are expanding in order to accommodate the needs of the environment and growing water supply demands. Advances in wastewater treatment technology and health studies of indirect potable reuse have led many to predict that planned indirect potable reuse will soon become more common.

While water recycling is a sustainable approach and can be cost-effective in the long term, the treatment of wastewater for reuse and the installation of distribution systems can be initially expensive compared to such water supply alternatives as imported water or groundwater. Institutional barriers, as well as varying agency priorities, can make it difficult to implement water recycling projects. Finally, early in the planning process, agencies must implement public outreach to address any concerns and to keep the public involved in the planning process.

As water demands and environmental needs grow, water recycling will play a greater role in our overall water supply. By working together to overcome obstacles, water recycling, along with water conservation, can help us to conserve and sustainably manage our vital water resources.

STATE AND REGIONAL WATER SUPPLY

Timothy J. Downs
Clark University
Worcester, Massachusetts

INTRODUCTION

Integrated watershed management (IWM) seeks to combine interests, priorities, and disciplines as a multistakeholder planning and management process for natural resources within a watershed ecosystem, centered on water quantity and water quality. Driven bottom-up by local needs and priorities and top-down by regulatory responsibilities, it must be adaptive, evolving dynamically as conditions change (1). Water resource spatial and political scales range from local/municipal, subregional, state, regional (multistate), national, multinational (“regional” in a global sense) to continental and global. Large watersheds occupy state and regional spatial scales, presenting considerable challenges for IWM and water supply, in particular, because of the number and diversity of human consumers and biodiverse habitat needs.

A watershed spatial scale is often used by ecologists to analyze species distribution and biogeochemical cycling. Watersheds can be characterized by the proportions of land area taken up by five main land use/land cover categories (2): urban land, agricultural land, rangeland, forestland, and water. It is arguable whether a watershed or ecoregion scale (region of relative homogeneity based on soil, climate, and vegetative criteria) is most appropriate for managing water quality and aquatic habitats (2). Even in terms of water stocks and flows, the differences between precipitation and evapotranspiration in one watershed that determine the runoff and infiltration that can be used for water supply are influenced by regional climatic and hydrological processes.

Water has many users and uses: drinking, industrial processing, irrigation, hydroelectricity, cooling water for power plants, and recreation (swimming and fishing). It also satisfies the needs of nonhuman species and participates in hydrogeochemical cycles and climate. Competing uses can be sources of conflict, especially when supplies are scarce or degraded by pollution. For example, using a river for industrial processing upstream may conflict with its use as a drinking water supply downstream if toxic discharges are significant. On a state and regional scale, the number of users and competing uses increases, and successful water supply depends on effective communication and negotiation among constituencies. Just as in small watersheds, conflicts in one portion can affect other portions.

The state and regional hydrographic area becomes an operational unit of analysis when water supply and wastewater sanitation are administered on this scale; this means that policies and practices are carried out on a geopolitical scale larger than a municipality or a subregional watershed. Such is the case in many countries, like France, Mexico, parts of the United States, and the United Kingdom. Examples of regional approaches are (1) in France, six water agencies administer the six large hydrographic regions of the country; (2) in the United States, examples of regional management include the Great Lakes Commission and the Ohio River Valley Water Sanitation Commission; and (3) in Mexico, Watershed Councils administer 26 hydrographic regions; several have portions of two or three states.

Much of the emphasis on regional watershed protection in the United States focuses on pollution and water quality, which directly impacts water supply sources and calls for an approach based on risk assessment. For example, in the Mid-Atlantic region (consisting of 18 U.S.

Geological Survey hydrologic units), the Environmental Protection Agency (EPA) is coordinating efforts to identify watersheds that make the most significant contribution to pollution (2). The GIS is employed to model the relationships between water quality indicators and land use/land cover. Water resources management on a state or regional scale is sensitive to the resolution of data gathered and the spatial scale on which predictive models are run and boundaries for analysis set. The pollution of lakes and rivers by nutrients and sediment from nonpoint sources (NPS), it has been shown, is well predicted by land use/land cover patterns (2). Two management strategies are employed to manage NPS pollution: (1) planning and source reduction, for example, limiting impervious surfaces, keeping grazing animals out of streams; and (2) structural and best management practices (BMPs), for example, vegetative borders, conservation tillage.

Water supply on a state and regional hydrographic scale requires drawing up plans that address the following (3): inter- and intra-agency coordination, technical assistance to local agencies and the public, public participation, and program boundaries (e.g., coastal zones must include watersheds contributing NPS pollution). And specifically NPS pollution control programs must address (3) urban sources of pollution, marinas and boats, agricultural sources of pollution, forestry, hydromodification, and wetlands.

INSTITUTIONAL STRUCTURE

Howe (4) has identified key water management requirements for a watershed/multiwatershed scale: (1) coordinated management of surface water and groundwater resources, (2) coordinated management of both water quantity and water quality, (3) provision of incentives for greater economic and technical efficiencies in water use, and (4) protection of public values associated with water service (e.g., reliable, safe, clean, affordable supply). To achieve this, the water institutions must develop the following characteristics (after Ref. 4):

- the capacity to coordinate water plans with other agencies (e.g., urban planning, agriculture, public health, environment, industrial);
- the capacity to solve water problems creatively using a variety of options and approaches (e.g., laws, pricing, taxes, tradeable supply and/or pollution permits, subsidies);
- the foresight to separate roles and responsibilities for water resource planning and management activities from construction activities (i.e., avoid conflicts of interest);
- the multidisciplinary capacity to undertake multicriteria/multiobjective planning and evaluation of alternatives;
- devolve decision-making power to the lowest level—national, state/regional (provincial), local or municipal—consistent with the scale of the water issue;
- capacity and willingness to use appropriate participatory methods involving different stakeholders at different stages of a project (preplanning/conceptual, planning and design, implementation, maintenance, monitoring, and evaluation);
- ability to reward innovation and adapt to changing conditions and priorities.

Federal, state, and regional laws and regulations are crucial instruments that help us respond to the challenge of water sustainability. Such responsive legal instruments should do the following (after Ref. 5):

- Encourage administration at the appropriate hydrological scale: watershed, multiwatershed or aquifer system.
- Foster internalization of the values and ethics of sustainable resource development.
- Encourage integrated approaches to water supply and sanitation, ecology, and public health.
- Prevent water allocation and usage policy making from fragmenting among agencies.
- Promote integrated appraisals, notably environmental, economic, and sociopolitical impacts assessment of alternative actions.
- Encourage integrated capacity strengthening of governmental institutions, NGOs, community associations, and businesses to transition into more sustainable policies and practices and work collaboratively.
- Enforce reward and penalty incentives that encourage sustainability.

WATER SUPPLY PLANNING AND MANAGEMENT

These are the five categories of human consumption (6):

1. domestic (in-house and out-of-house);
2. industrial (e.g., factories, power stations), commercial (e.g., shops and hotels), and institutional (e.g., hospitals, schools);
3. agricultural (e.g., farms, crops, livestock);
4. public (e.g., parks, fire fighting, sewer flushing;
5. Losses—distribution losses, consumer wastage, metering errors, and/or unrecorded consumption.

Table 1 shows the water supply categories used by the U.K. National Rivers Authority for watershed and regional multiwatershed planning and the principal demand considerations.

For state and regional water supply that may include several watersheds and aquifers, coordinating the forecasting of demand is essential for sustainable supply. Forecasting beyond 15 years is highly uncertain; so for longer time frames, we employ scenario projections that ask the question: If these conditions or assumptions apply (e.g., a certain population growth rate, unit demand, supply losses), then what will the future water demand be? The estimation of demand involves (6):

Table 1. Regional Water Use Categories Employed by the U.K. National Rivers Authority and Demand Considerations

Use Category	Typical Uses	Demand Considerations
Drinking water supply	Municipal water supply (surface and/or groundwater; private wells)	Population levels, growth rates and consumption patterns, pricing and wastage
Industrial water supply	Process water supply; cooling waters	Production process technologies and efficiencies
Agricultural water supply	Irrigation waters; livestock watering; milkhouse wash water; livestock housing wash water	Cropland area and crop types and cultivation methods; livestock populations; dairy production
Flood control	Impoundment of high flows for controlled release; construction of dams, reservoirs, levees, channel protection	Flood risks, especially in the floodplain; seasonality and intensity of rainfall and snowmelt; vegetative buffers
Thermal power generation	Cooling waters; settling pond waters; water for pipe flushing and maintenance	Thermal cycle efficiency; power demand and scheduling; capacity
Hydroelectric power generation	Impoundment of water for power generation; construction of dams and reservoirs; pumping and drawdown of water levels	Minimum head required for expected power generation
Navigation	Recreational boating; commercial transport shipping; commercial tourist shipping	Minimum depths and flows required for safe passage
Water-based recreation	Recreational fishing; boating; swimming; hiking, picnicking; nature enjoyment (e.g., bird watching); aesthetic enjoyment	Cultural values, including water odor and color, nature appreciation; seasonality of recreation; numbers of recreators; laws
Fish and wildlife habitat	Aquatic and riparian habitats; protection of community structure; protection of rare and endangered species	Sensitivity of species to disturbance; ecosystem type; types and intensities of stressors (e.g., water loss, pollution)
Water quality management	Protection of minimal flows for water quality preservation; low-flow augmentation from reservoirs; assimilation of waste discharges from municipalities and industries; assimilation of storm and combined sewer discharges	Magnitude, duration and frequency of waste flows; point or nonpoint sources; types and toxicities of contaminants; health risks to humans and other species

Source: After References 7 and 8.

1. plotting the population trend for the past 10–20 years and estimating the proportion likely to be due to immigration and that due to natural increase (births minus deaths);
2. dividing the supply area into different socioeconomic classes of domestic use;
3. estimating the typical domestic consumption per capita in each class;
4. seeking values of future immigration and natural increase for the different classes of housing;
5. Estimating distribution pipe loss rates, consumer wastage, and unsatisfied demand;
6. Estimating the growth in industrial, commercial, and service demands (a function of population growth);
7. Estimating growth in agricultural demand, hydroelectric demand, and public and ecosystem maintenance demand.

Equation 1 is the general supply equation for any bounded area (6).

$$\begin{aligned}\text{Total supply} &= \text{total legitimate potential demand} \\ &\quad + \text{consumer wastage} + \text{distribution} \\ &\quad \text{losses} - \text{unsatisfied demand} \\ &= \text{water supply unreturned} \\ &\quad + \text{wastewater return} \end{aligned} \tag{1}$$

Water can be supplied, and demand can be met by one or a combination of the following options: (1) surface freshwater withdrawal (lakes, reservoirs, rivers and streams), (2) saltwater desalination, (3) groundwater withdrawal (springs and aquifers), (4) rainfall harvesting, (5) wastewater reuse, and (6) demand management (efficiency measures and absolute reduction). For the latter, pricing water equitably is an important consideration, and it has been postulated that there is a inverse power relationship between demand (Q) and price (P), such that (6)

$$Q = k\,P^{-x} \tag{2}$$

where k is a constant and x is the elasticity between Q and P.

In addition, in developing countries, the price of water must be tiered according to ability to pay, such that the poorest people (those at a subsistence level without surplus income) are fully subsidized, whereas high-end consumers (more than 300–400 liters/person/day) pay the most and have a financial incentive to reduce their consumption.

REGIONAL WATER TREATMENT AND DISTRIBUTION

Water treatment technologies seek to produce adequate and continuous supplies of water that are of sufficient quality—chemically, microbiologically, and aesthetically—for their intended uses. Treatment consists of a series of physical and chemical unit processes that are designed as a function of the source and quality of the raw water, the required water quality produced, and the throughput (or flow rate). A typical full water treatment system consists of eight stages (9): (1) intake, (2) pretreatment (e.g., screening, neutralization, aeration); (3) primary treatment (e.g., coagulation, flocculation, sedimentation); (4) secondary treatment (rapid and slow sand filtration); (5) disinfection (e.g., chlorination or ozonation); (6) advanced treatment (activated carbon, membrane diffusion); (7) fluoridation; and (8) distribution.

On a state and regional scale, sufficient water treatment capacity must be built and planned for using regional demand forecasting. The location of water treatment plants depends on the location of the source of raw water, the location of the users, and whether or not it is more cost-effective to build a few large plants to serve the region or a network of smaller local plants. This treatment plant spatial configuration will also determine, and be determined by, the distribution system design. The distribution system consists of a network of pipes (9): (1) trunk mains that bring large flows from the source to the treatment plant and then to storage reservoirs or towers; and (2) distribution mains that deliver water from the service storage to the users, a highly branched network. Service reservoirs and water towers cope with the diurnal variation in demand by satisfying peak demand, supplementing the average daily flows. Service reservoirs must be able to satisfy the population for at least 24–36 hours and provide enough pressure to reach the storage tanks of individual users, perhaps more than 50,000 households (9). The hydraulic head for fire fighting is at least 30m, and maximum head is about 70m (above this, leaks and bursts are common). In flat areas, water is fed by gravity from water towers, which can incur high pumping costs. High-rise buildings require their own pumping. Typically, each user has a supply pipe that connects to the communication pipe at the property boundary, which in turn connects to the service main. Water distribution networks serve different zones, each one supplied by a service reservoir and/or tower (9). On a regional and state scale, the planning and management of such an infrastructure must be carefully coordinated to meet the growing demands of a diverse set of users. In times of drought, regional water supply is severely tested, and the risk of drought must be addressed with a careful regional provision of adaptive reserve storage and aggressive water conservation strategies that penalize nonessential use.

WATER SUPPLY IN DEVELOPING COUNTRIES

Table 2 summarizes the sources, decision criteria, delivery methods, and levels of service for water supply in developing countries. Three main factors affect the choice of water supply in developing countries (11):

- institutional—land tenure, administrative structure, finance level;
- population—demography, size, growth rate, socioeconomic levels, attitudes, and behaviors;
- technical—scale, geophysical conditions, urban layout, alternatives, resources.

For the rural subsistence poor, the main water supply problem is stable access to safe water. For the urban poor and periurban marginalized communities, the main problem of water supply is that the connection and supply costs are too high.

On a state or regional scale, these water supply issues become magnified, and it is no surprise that the most controversial aspect of water supply in developing countries is selling of water administration concessions to private water companies by a central government. Recognizing water as an economic good is essential for efficient management, but it should be priced equitably according to users' ability to pay. For subsistence communities, a full

Table 2. Key Aspects of Water Supply in Developing Countries

Sources	Selection Factors	Delivery Methods	Levels of Service
• Springs • Rivers • Lakes • Aquifers • Rainfall • Snowmelt • Recycled wastewater • Desalinated saltwater	• Distance from source to user • Water quality at source • Cost of raw water and delivery • Scale of supply • Alternatives available • Sanitation method • Return drainage method • Preferences of users • Land and water rights • Risk of shortfall, outage, pollution	• Hand transport in containers • Vehicular transport • Pipelines (gravity, pumped) • Pipelines to troughs, reservoirs, standpipes, communal ablutions, households, businesses, public places, fields of crops • Channels	1. Simple source with disinfection 2. Pump and supply line to reservoir or standpipe 3. Household standpipes or connections 4. Individual household supplies

Source: After Reference 10.

public subsidy is appropriate for basic needs (1): overprivatization risks occur when water services are run purely for profit and marginalized communities unable to pay incur crippling water debts (12). This has occurred in South Africa and touches a nerve in many other places where water is viewed as both a public good and a human right that should not be controlled by commercial interests. We should also recognize that the problem with user willingness to pay is cultural (habits of free water) and also one of poor service quality: Why should a person pay for water that is not clean and comes only intermittently?

WATER POLLUTION AND HEALTH RISKS

Pollution produced in one part of a watershed or regional hydrographic area poses potential health risks to other parts. Microbiological water pollution causes many persistent water-related diseases worldwide, whereas chemical water pollution adversely affects humans and other species, especially sensitive aquatic organisms. Much of the serious chemical pollution stems from runoff of agricultural chemicals (fertilizers containing nutrients and pesticides such as DDT) and industrial wastes such as solvents and heavy metals. For example, many tributaries of the Amazon Basin have been contaminated by mercury from mining waste, resulting in methylmercury levels in fish well above the World Health Organization (WHO) standard (13). Another dramatic example of regional mercury contamination occurred in Canada in 1984, where 64% of all Cree Indian residents of Chiasabi had levels above the WHO standard (13). Nash (14) claims that the main obstacles to effective water quality management are cost and a lack of information. Downs argues that the problems go much deeper to cultural obstacles and weak societal capacity (15).

AQUATIC ECOSYSTEMS

Freshwater lakes, ponds, rivers, streams, wetlands, and aquifers are inextricably linked by hydrologic cycles acting on watershed, multiwatershed, regional hydrographic, and continental scales. A mere 1% of land surface is covered by freshwater, but it contains 12% of the animal species (16). Conservationists claim that freshwater biota are being destroyed by anthropogenic impacts faster than they can be studied or protected: overconsumption by human populations, cultural eutrophication, acidification, dam construction and hydromodification, the introduction of invasive species, habitat loss from development, and climate change. Examples are all too plentiful (16): (1) the invasion by lampreys (an ocean parasite) of the Laurentian Great Lakes after the construction of the Erie Canal, resulting in the decimation of salmonid species; (2) the invasion of the same system by the zebra mussel and spiny water flea, upsetting native invertebrates and zooplankton; and (3) the massive diversion of river water to the Aral Sea on the border of Kazakhstan and Uzbekistan to irrigate cropland, leading to a 65% decrease in volume from 1926–1990, destruction of the fisheries, economic collapse, and health problems.

The Aral Sea is a dramatic example of the need to take a regional approach to water supply and wastewater sanitation and to account for the coupled needs of humans and other species. Covitch (16) argues that technology alone—such as GIS monitoring and remote sensing—cannot hope to address the pace or complexity of freshwater ecosystem degradation. Rather, institutional reforms must provide water to aquatic habitats and minimize adverse impacts, while enabling multidisciplinary research is done on regionally representative biotas and hydrologic regimes (16).

WATER SUPPLY FOR AGRICULTURAL PRODUCTION

The twentieth century's Green Revolution boosted agricultural production and was made possible in large part by doubling the amount of irrigated land from 1950–1980 (17). In 1989, a third of the world's food harvested came from the 17% of the cropland that was irrigated, and two-thirds of the freshwater supply is used for irrigation (17). Clearly, on a state and regional scale, for example, California, agricultural demands are often the largest of all demands, and so savings derived from more efficient irrigation technology and/or diversions to other uses can have a huge impact on water supply sustainability. There is concern that growing populations, especially in water-scarce developing countries, will overwhelm the capacity of irrigated cropland to provide sufficient food and that water stress will become even more acute. The cost of adding to land currently irrigated is high in places such as Africa because of weak capacity and the need to build supporting infrastructure. In addition, many rivers are seasonal.

There is great scope for improving the efficiency and management of irrigation water: (1) using much less water per hectare [often less than half the water applied benefits the plant (17)] and (2) ensuring that water is delivered at the right time in sufficient quantities. Many schemes that involve massive irrigation cause fields to become waterlogged and soils to become salinized, leach nutrients, and lose fertility. Grossly inefficient schemes also contribute directly to the overexploitation of aquifers and surface waters and the degradation of aquatic ecosystems. Postel (17) has estimated that about 20% of the irrigated land in the United States relies on overexploited groundwater and causes major state and regional water supply impacts. Similar problems exist in many other countries, such as China, India, and the Middle East. Already, in the Great Plains of the United States, farms have been abandoned because of falling water tables; in the Texas High Plains Region, irrigated land area shrunk by 34% from 1974–1989 because the cost of overpumping the Ogallala Aquifer System exceeds the value of crops grown there (17).

Diversions of irrigation water to other uses, especially urban areas, is becoming a more common practice; some farmers sell water for more than they would earn from using it to grow crops. Los Angeles, Mexico City, and Beijing are just three examples of megacities that rely on importing water from rural farming zones. Unless laws and regulations adequately compensate the regions that lose the water to thirsty cities, serious issues of environmental justice exacerbate rural poverty.

WATER SUPPLY FOR ENERGY PRODUCTION

Water supply and energy supply are closely related, and conflicts over access, costs, pricing, and the overarching sustainability challenges for both resources invariably run parallel (18). Energy production relies on reliable water supplies: fossil fuel, geothermal, and nuclear power plants draw vast amounts of water from lakes, rivers, or the ocean for cooling. In water-scarce regions, either withdrawals alter hydrologic regimes and impact ecosystems, water scarcity places absolute limits on energy production, or scarcity forces interbasin water transfers. Droughts in Africa and Asia and even California have significantly impacted hydroelectric production, causing shortfalls that either go unmet or must be met by scaling up other energy sources (18). For example, a decade of drought in Egypt severely reduced the capacity of the Aswan Dam that supplied half of Egypt's power. The massive investment worldwide in dams, aqueducts, and reservoirs was made to overcome both the uneven distribution of freshwater for water supply and to provide hydroelectricity for development. Cheap energy has allowed water resources to be superexploited, that is, pumping of deep fossil groundwater and pumping of interbasin water transfers over mountains in water-stressed regions. In this way, just as coal and oil allowed industry to escape the solar budget, cheap energy also allows settlements to escape the immediate constraints of local hydrology. But on a regional scale, such constraints are not escaped, merely reconfigured temporarily. Sustainable regional water and energy supply must be considered as coupled resources and managed accordingly.

WATER SUPPLY POLITICS AND LAW

All regional issues impacting water supply—urban demand, public health, ecosystem integrity, agricultural demand, energy needs—can be effectively addressed only by state and regional institutions that design and apply the aforementioned responsive regulatory instruments and allow the participation of regional stakeholders in water supply planning and management. McCaffrey (19) states that there are two major principles that underpin most international water treaties: (1) the principle of equitable utilization—the apportionment of uses and benefits of a shared watercourse should be made in an equitable way; and (2) that a country, through actions that affect an international watercourse, may not significantly harm other countries. The key to successful comanagement is sharing of information and communication, especially about development plans. These same ideas should be applied to state and regional water supply within a country.

CLOSING REMARKS

Water supply on a state and regional scale poses special challenges for planning and management because of the large number and wide diversity of users and habitats to support; the related uncertain forecasting of demand; the need to provide a reliable, affordable service; and the number of potential multisectoral priority issues (energy, agriculture, health, ecology) to address. In practice, the success of this depends on communication and coordination on three levels: (1) between each village, town, city, farm and industry of the region; (2) among the water, industrial, energy and agricultural development sectors of the state or region; and (3) among the water utility companies, their customers, and local and state government regulators. Responsive institutions and regulations are vitally important to achieve this, to mitigate the risks of drought and pollution, and to meet the growing demand, especially in water-scarce/water-stressed regions where the competition for safe water is increasingly intense.

RIVER BASIN DECISIONS SUPPORT SYSTEMS

Charles D.D. Howard
Water Resources
Victoria, British Columbia,
Canada

The interacting components of water resource systems incorporate physical, biological, chemical, and institutional constraints and objectives (Fig. 1). Water projects are difficult to manage efficiently within potentially conflicting objectives and constraints on water quality, river flows, and lake levels. There are many types of decisions, and these must be made on a timely and reliable basis. Decisions vary from timescales of minutes for assigning loads to hydroelectric generating units to weeks and months for managing water quality, reservoir levels, and pumping from groundwater. On shorter timescales, decisions are based on deterministic analyses. On longer timescales, decisions are dominated by consideration of probabilities.

Planning can benefit from decision support systems developed for actual operations. Sound plans require realistic analysis that these systems provide for changes

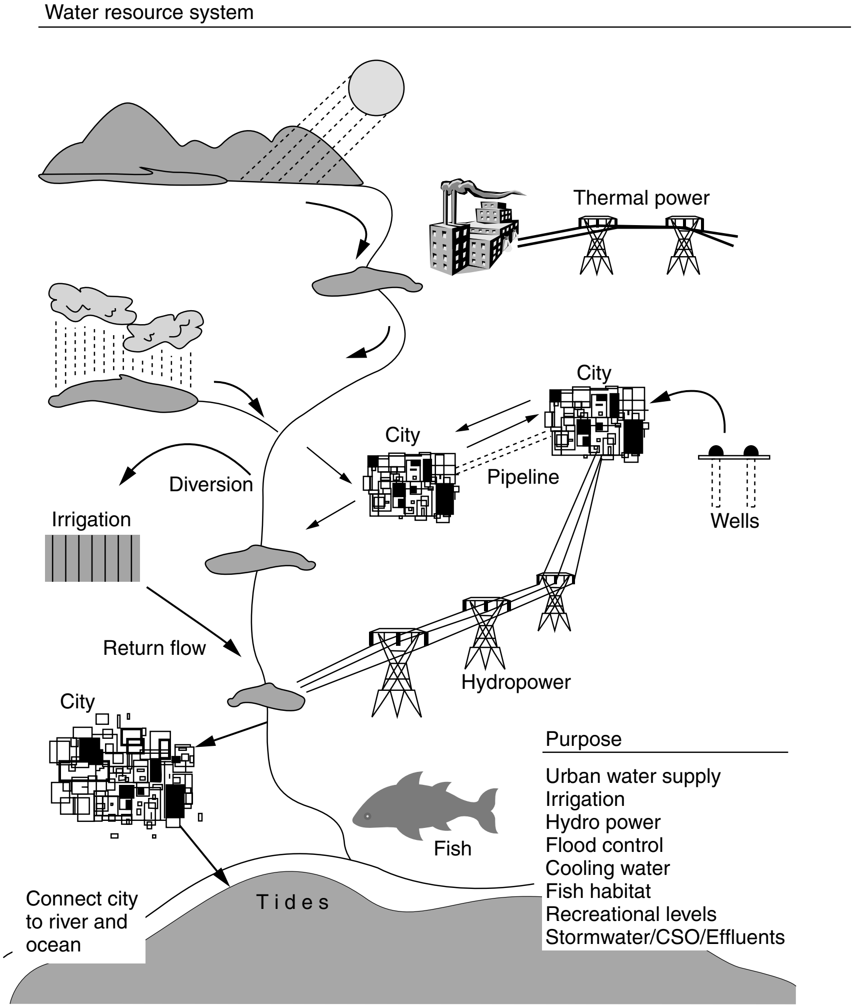

Figure 1. Water resource systems are complex.

in operating parameters, capacity expansion, and the benefits and costs of potential new environmental objectives. Figure 2 illustrates how many of the same program modules and data are used for planning studies and for actual operations.

Until recently, the data and computer simulation analysis behind water management decisions simply supported experience and judgments. In the latter half of the twentieth century, *decision support systems* based on optimization techniques were developed to recommend the best possible decisions. These software systems develop recommendations by continuous analysis of constantly changing data and evolving priorities. The key components of decision support systems are data, computer models of processes, and trained people.

The purpose of a decision support system is to acquire data and to increase its informational content. To be effective, a decision support system should execute rapidly in response to changing data. Computer input and output should be in a form that is most convenient for the person making the decisions. Modern computer systems minimize the manual input required and automatically suggest optimal operating decisions that recognize all current factors.

COMPUTER MODELS FOR WATER MANAGEMENT

There are two related, but fundamentally different types of water resource models—scientific models and management models. Scientific models are used primarily to investigate physical relationships in some detail. They provide a surrogate for extensive field monitoring by using available field data and scientific principles to interpolate and to extrapolate. They in-fill missing information on how the physical system is operating. A secondary purpose for scientific models is to test how different assumptions about future or past physical conditions would affect the system.

Management models are used primarily to suggest water management decisions—they are the main tools of decision support systems. They include a description of the scientific, institutional, and economic factors that bear on the decision-making process. To accomplish this, they must be comprehensive in modeling the interactions among components of these systems. For some types of decisions, an approximate description of the physical processes is adequate; for most types of decisions, the institutional and economic factors must be comprehensively described because they make up the key objectives in water management decisions.

Scientists should not expect management models to be absolutely accurate in scientific matters. Managers should be prepared to have recommendations from management models reality-checked by scientists.

SPREADSHEETS IN DECISION SUPPORT SYSTEMS

Spreadsheets can be the engine of a decision support system for planning studies but are unsuitable for supporting short-term operating decisions for data-intensive water resource systems. They are used routinely for hydrologic studies and for economic analysis of water resource systems. A spreadsheet can model operation of reservoirs, aqueducts, treatment plants, and water quality. The sensitivity of decisions to data

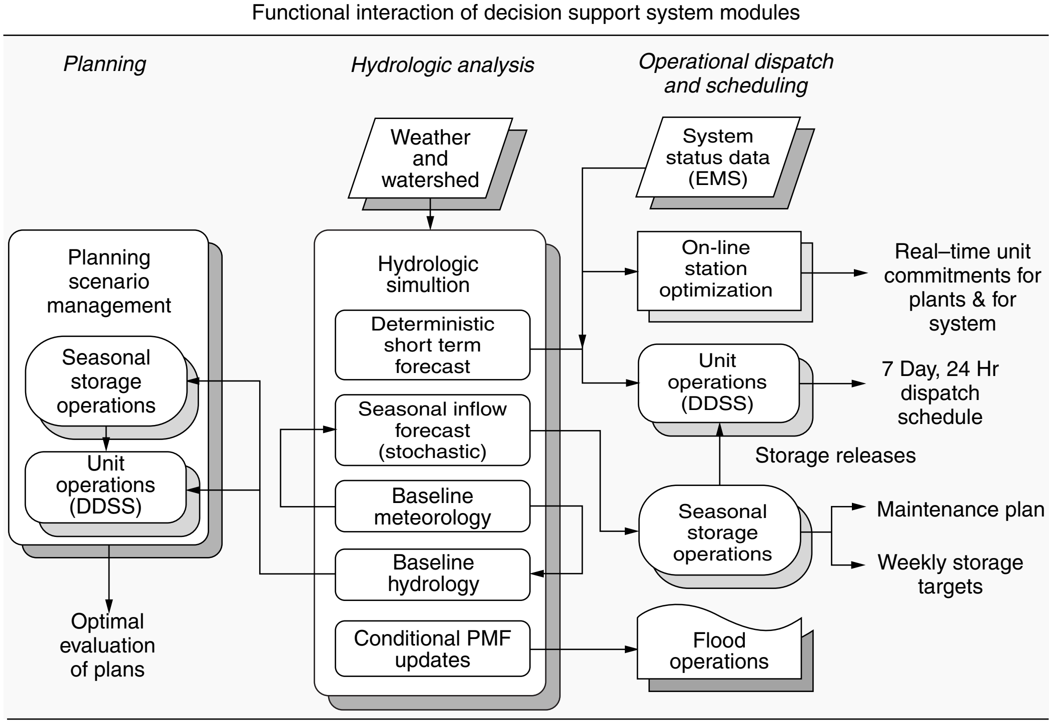

Figure 2. A decision support system for hydroelectric planning and operations.

can be examined, and specific recommendations for improvements in other models can be developed with the aid of spreadsheets.

Macro capabilities in spreadsheets are used for managing data files, displaying and printing graphs and tables, and for eliminating the need for others to be experts in programming. Macros can readily merge spreadsheets and acquire data from servers without user interaction. The detailed logic for water planning can be examined to determine how it might be structured for optimization routines in a more complex model.

Spreadsheet add-ons provide routines that can be very useful for optimizing water management decisions. A spreadsheet SOLVER function deals with nonlinear constraints and automatically drives the spreadsheet to maximize objectives within specified constraints. This eliminates trial and error in using the spreadsheet, reduces the number of explicit logical operators, and simplifies technology transfer and user training. Aftermarket optimization routines from third-party vendors extend this capability to larger more complex management issues.

A spreadsheet offers the following advantages: It can be a platform for quickly trying out new ideas, other computer models and their output can be conveniently evaluated, spreadsheets are widely used and upgradeable as computer technology advances, and output tables and graphics can be readily tailored to different needs. A spreadsheet is an easy link with past methods of operating a water resource system, and it can be carried forward into the future with minimal risk of obsolescence.

Spreadsheets are not a good choice for large complex systems that require comprehensive data management and quality control, a high degree of automation, and rapid execution. Special purpose water management computer programs are more effective for large water resource systems if they are structured conveniently for the specific application. But, as part of an overall decision support system, the spreadsheet format offers advantages in rapid implementation, capabilities for data manipulation, flexibility in presentation of results, and ease of understanding.

DEALING WITH UNCERTAINTY IN HYDROLOGIC DATA

On longer timescales, allowances for uncertainty may be intuitive—primarily colored by recent experience or based on hydrologic ensembles. A hydrologic ensemble is a set of inflow records used in a computer model to test river and reservoir operations across a range of possible inflow conditions. The ensemble members are input to simulation or optimization routines that model the operating constraints and objectives and provide information that supports actual decisions.

In some applications, hydrologic ensembles are developed with a calibrated hydrologic forecasting model from initial hydrologic conditions and historical weather data. Meteorologic ensembles generated by medium-range weather forecasting models offer the potential for conditioning future weather on current atmospheric conditions, and they eventually may replace historical weather data for forecasting hydrologic ensembles.

Hydrologic ensembles also may consist of the records of river discharge or synthetic streamflow sequences based on the autocorrelation and cross correlation characteristics of basin discharge records. Ensembles based on historical discharges are missing the atmospheric and basin moisture conditioning information that limits the range of likely future discharges. It can be observed that historical stream flow records contain a wider range of inflow possibilities than it is realistic to expect for the current conditions that are faced during operations. Heuristic methods may consider that each member of an ensemble is equally likely or some members of the ensemble may be given more weight, for example, if an El Niño condition is relevant or there is a heavy snow cover. Uncertainty of hydrology is reduced to some extent in forecasts that realistically deal with the initial watershed state and with improved future medium-range weather forecasts.

The realities of water project operations are often avoided in project planning. Postconstruction project evaluations and benefits seldom, if ever, relate back to the projections made during planning. Part of this difficulty can be avoided if the planning methodology simulates how actual operating decisions will be made. It is unrealistic to plan a system without considering the forecasted inflows during actual operations and how the operators will respond. Deterministic optimization does not consider uncertainty at all, and simulation studies based on rule curves and historical flow data lack both the finesse of optimization and a realistic expectation of near-term inflows. Water resource planning studies should include some measure to simulate the forecasts of water supply and demand that are updated at each decision point during actual operations.

EXAMPLE OF A HYDROELECTRIC DECISION SUPPORT SYSTEM

With the advent of market competition, there are clear advantages to being in position to provide quickly an optimum generation schedule based on projections of market prices and the availability and value of water. For a cascade of dams, this is a complex decision process. When water is in short supply, maximizing revenue or ensuring that all generating stations are loaded so that overall system generation is as efficient as possible will optimize the 168-hour generating schedule. This requires allocating load so that plants operate at the relatively few discrete points of maximum efficiency determined by optimal use of the generating units within each plant while meeting operational constraints (Fig. 3). Water movement between plants is considered in the optimization so that head is maximized, spill is minimized, and generation takes advantage of time of day variations in loads and energy prices.

Additional considerations include very short-term adjustments to generation and longer term plans for the most effective use of reservoir storage. Planning for maintenance of the machinery considers availability of crews, seasonal variability of hydrology, environmental constraints, and energy prices. The decision support

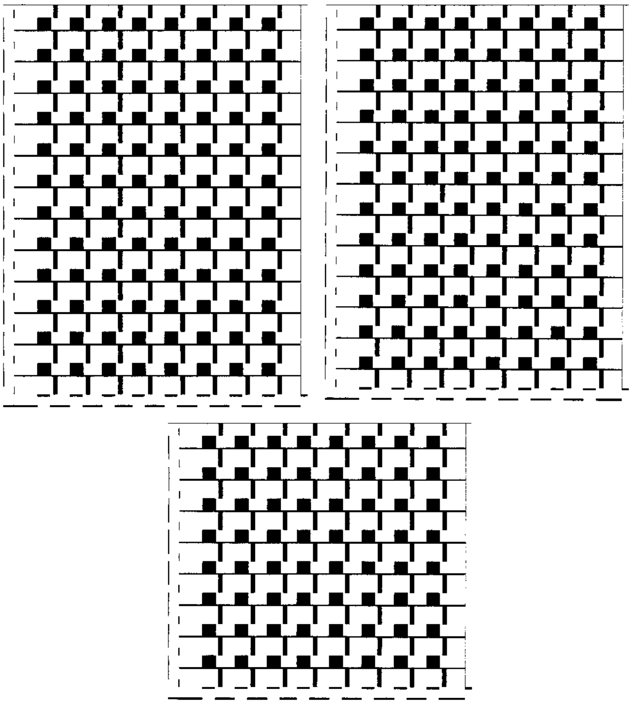

Figure 3. Hydroelectric plants have discrete points of maximum efficiency.

system recommends the optimum decisions by considering hydrologic probabilities and risks.

Each decision support system is slightly different, depending on the requirements for water management and the date when the software was developed. For a hydroelectric decision support system, the following functions are now supported by software (1):

- water management through reservoir release scheduling,
- systemwide maintenance planning for generators,
- forecasting hourly and seasonal local unregulated inflows,
- near-real-time unit loading optimization,
- hourly schedules for all generators in the system, and
- convenient data acquisition, quality control, archiving, and retrieval

Each of these functions requires access to a common pool of consistently reliable data. Static data describe the physical facilities and operational constraints such as minimum river flows and allowable ramping of river and reservoir levels. Dynamic data include hydrometerologic data, weather forecasts, discharge throughout the river system, projected hourly value of energy, the state of generating machinery, reservoir and tailwater levels, spill, current system electrical load, and special operating goals and constraints.

Some of these data are current, some are not—some have been previously checked, and some are in a raw form and may contain errors. The software provides quality control that takes data from several sources, on different time steps, of different quality, and concatenates it to provide currently useful information.

Recent installations are PC-based; local workstations use the Windows operating system. Data are stored on dedicated central servers with an SQL or Oracle database. The database sends and receives data from various servers and workstations around the system via an internal network. An archive of historical operating data supports projections and comparisons with past conditions.

REQUIREMENTS FOR A WATER RESOURCES MANAGEMENT DECISION SUPPORT SYSTEM

A customized modeling and database system will provide convenient graphical current and historical information and operating recommendations that are automatically optimized by the system. Data handling must be convenient with minimal opportunities for introducing human error and maximum flexibility for editing storing, retrieving, and displaying data and model results. There should be an emphasis on realistically designed graphical user interfaces and interactive graphical editing that reflect the preferences of the intended operators.

The data management model consists of a database system and site-specific capability for editing and displaying data in a manner that is keyed to the basin mapping. The model will be informative and practical for routine quality control, storage, retrieval, and graphic display. The database will provide a home for the monitoring data and an integrated backbone for all of the modeling software. The data will probably come from more than one source, so the database must be compatible with the communications facilities.

The hydrologic forecasting model establishes local inflow forecasts for all of the reservoirs. Two types of forecasts are necessary: deterministic hourly forecasts for one week that support daily operating decisions and weekly conditional probability forecasts for 1 year that support longer term management strategies. Both types are driven by weather data and weather forecasts. Initial conditions for each forecast reflect the computed or measured current moisture state of the basin, including soil moisture and water in storage as snow. Conditional probabilities are derived from historical weather data and the current initial moisture conditions of the basin. Deterministic forecasts include hydrodynamic routing in river systems.

An effective implementation often uses a combination of a calibrated conceptual model of the hydrologic cycle and field monitoring of river discharges, soil moisture, and snow cover. River discharge measurements provide forecast verification and information for model readjustment during operation. The local inflow forecasts are routinely updated daily and more frequently when there is concern for floods.

The water demand forecasting model considers the planning objectives, past demands, current demands and forecasts, and hydrologic forecasts. The model includes individual subarea requirements that place significant demands on the system. This is an important component for ongoing water management planning in response to changing circumstances, including water and energy demand management during drought.

The reservoir operations models must be practical, fast, and provide comprehensive optimizations that reflect complex site-specific physical and institutional details and prioritized or multiple objectives. River basin operation may be simulated by suitably constraining the optimization model(s) or by a special simulation model. Generic river and reservoir models used for planning are unsuitable for operational scheduling within a decision support system if they lack features that minimize manual data input and have excessive execution time during optimization.

The river and reservoir operations optimization model(s) use forecasts of local unregulated inflows to recommend the best long-term and short-term strategies. The objective function may include water supply for irrigation and cities, hydroelectric production, and flood management within environmental and facilities management constraints, specific discharge and water level targets, and physical limitations of the system of reservoirs and river channels. All components and operating constraints of important facilities are represented in the optimization modeling system. A simulation capability can be used to test the viability of operating plans developed by judgments that do not follow the recommendations from deterministic and probabilistic optimization models.

When there are several operating objectives, optimization can be accomplished in the software by using a set of prioritized objectives. For example, in flood management, the first priority might be to protect downstream property from flooding. With this as the objective, the software determines an operating sequence for spillway gate operations. Then, with the resulting minimized downstream flood damage as a constraint, a new objective function is used to determine the gate operations that will minimize upstream flooding. Finally, with both the upstream and downstream previously optimized flood damages as constraints, a third optimization minimizes the number of nighttime gate changes. This last step determines the sequence of gate operations actually recommended for managing the flood with available reservoir storage. With a suitable optimization model, the method is quick because each successive optimization uses the feasible solution from the previous analysis as a starting point.

The method of prioritized objectives also may be useful as a practical procedure for defining trade-offs for other types of water management decisions that require considering multiple objectives. Revising the priorities and reoptimizing can examine trade-offs. This application of a decision support system has the advantage of avoiding the difficult and often confusing task of assigning relative weights to objectives. The significance of priorities may be more readily grasped than the relative value of objectives that may be incommensurate.

BASIC REQUIREMENTS

The entire system of software must run on an operating system that is compatible with standard word processing and spreadsheet software. Maintenance for the entire system should be minimal. The software and data should be capable of being maintained and upgraded by computer specialists readily available to the owner of the decision support system. The water management models, operating system software, and computer hardware should have sufficient redundancy to provide a high level of reliability. The entire modeling system must run on the owner's computer network and must provide remote access to the database by users who are not connected to the network. The system must have levels of password security to control access to various portions of the database and modeling modules.

WHY HAVE A DECISION SUPPORT SYSTEM?

A common bottom line question among water resource system managers is: What is the value of a decision support system? The benefits are not uniform for all systems because of the relative importance of uncertainties and the multitude of institutional and physical constraints on operation. The value of a specific decision support system can be estimated by reconstructing the actual operating history and optimizing at each step as each operating decision was made. The decision support software can be designed to automate such an audit as a routine business practice aimed at raising overall efficiency within an enterprise.

Since 1987, a decision support system has been used to guide weekly reservoir release decisions at two hydroelectric plants in the coastal mountains of British Columbia, Canada. Studies of 1970–1974 operations (a period before the decision support system became operational) showed that, compared to operation with perfect foresight, as determined by a deterministic optimization model, the rule curve based operation had produced 83.4% of the maximum attainable energy compared to 95.1% with the full decision support system. Without the hydrologic forecast component, the optimization component would have produced 92.8% by simply using long-term average monthly inflows in place of the forecast. The actual energy produced by operating with the DSS in each year between 1989 and 1993 was 100, 93, 98, 94, and 96% compared to the maximum possible. The decision support system provides accessible data and a consistent framework for improving operating decisions.

Decision support systems can be expensive, but they bring improvements through more effective management to achieve objectives, reduced personnel requirements, fewer violations of environmental constraints, more effectively trained personnel, and objective technical performance evaluations. For a complex river system with many control points and reservoirs, a team of operators is trained to use the software modules and to interpret their output. For systems with only two or three major facilities, one or two trained operators can manage a highly automated, complex decision support system.

WATER RESOURCE SUSTAINABILITY: CONCEPTS AND PRACTICES

Timothy J. Downs
Clark University
Worcester, Massachusetts

INTRODUCTION

The most famous definition of sustainable development is "development that meets the needs of the present without compromising the ability of future generations to meet their own needs" (1). This unifying concept was the theme of the 1992 Earth Summit in Rio de Janeiro that produced the so-called Blueprint for Sustainable Development, *Agenda 21* (2). At the core of the sustainability paradigm is the desire to reframe the perceived competition between development and environment (economy vs. ecology) into new forms of development ethics, thought, practice, and policy, reconciling enhancement of the quality of (human) life and social well-being with the conservation of ecological integrity. Underpinning this lofty goal was the ethical pursuit of a more equitable society both today (intragenerational equity) *and* in the future (intergenerational equity). The term *sustainable development* is somewhat of an oxymoron because it implies stability, yet change, and begs the coupled questions: What to sustain, for how long, and for whom? This has led to confusion and a plethora of debate over the conceptual validity of the model. A useful working definition of a sustainable project, program, practice, or policy is one that yields a steady stream of benefits (or positive impacts) that exceed costs (negative impacts) over intergenerational timescales (25 years and beyond), while conserving ecological integrity.

Too much talk of "achieving" sustainable development has led to some disenchantment with the concept when it is not delivered, or even approximated. The real power of the sustainable development idea lies in its ability to change the way we think about intra- and intergenerational equity and our responsibility as custodians of biodiversity (3). It is much more helpful to view sustainability as a *relative*, dynamic state of development practice, one that can be degraded or improved substantially, but never reached absolutely. Sustainability becomes very useful when we work with stakeholders to explore development alternatives that are compared against the status quo, business-as-usual baseline state. So, one key criterion for comparison is the relative sustainability of an option compared to others, for example, one water supply alternative versus others. In practice, this criterion is broken down into social, economic, and ecological subcriteria, the comparative evaluation of alternatives is done by a multicriteria method such as environmental and social impacts assessment (ESIA).

Viewing development in terms of helping people help themselves, finding alternative policies, plans, programs, and actions, and comparing them for positive and negative impacts is a useful simplifying approach that cuts through skepticism about sustainability and its inherent complexity. This is exactly what lawmakers had in mind when they enacted the landmark U.S. National Environmental Policy Act (NEPA) in 1969, the law that gave birth to environmental impact assessment (EIA). But in few cases has compliance with this law led to more sustainable solutions, and the public is skeptical that it is merely a technical process that endorses preconceived actions (3).

The fact that Earth Summit 2002 in Johannesburg was oriented strongly toward understanding why the plans and lofty goals of Earth Summit 1992 have not been reached, even approximated,—prospects are worsening for sustainability according to global trends (4–6)—adds considerable impetus to our quest to understand what makes the sustainability concept operational. What are the underlying concepts and philosophies that describe

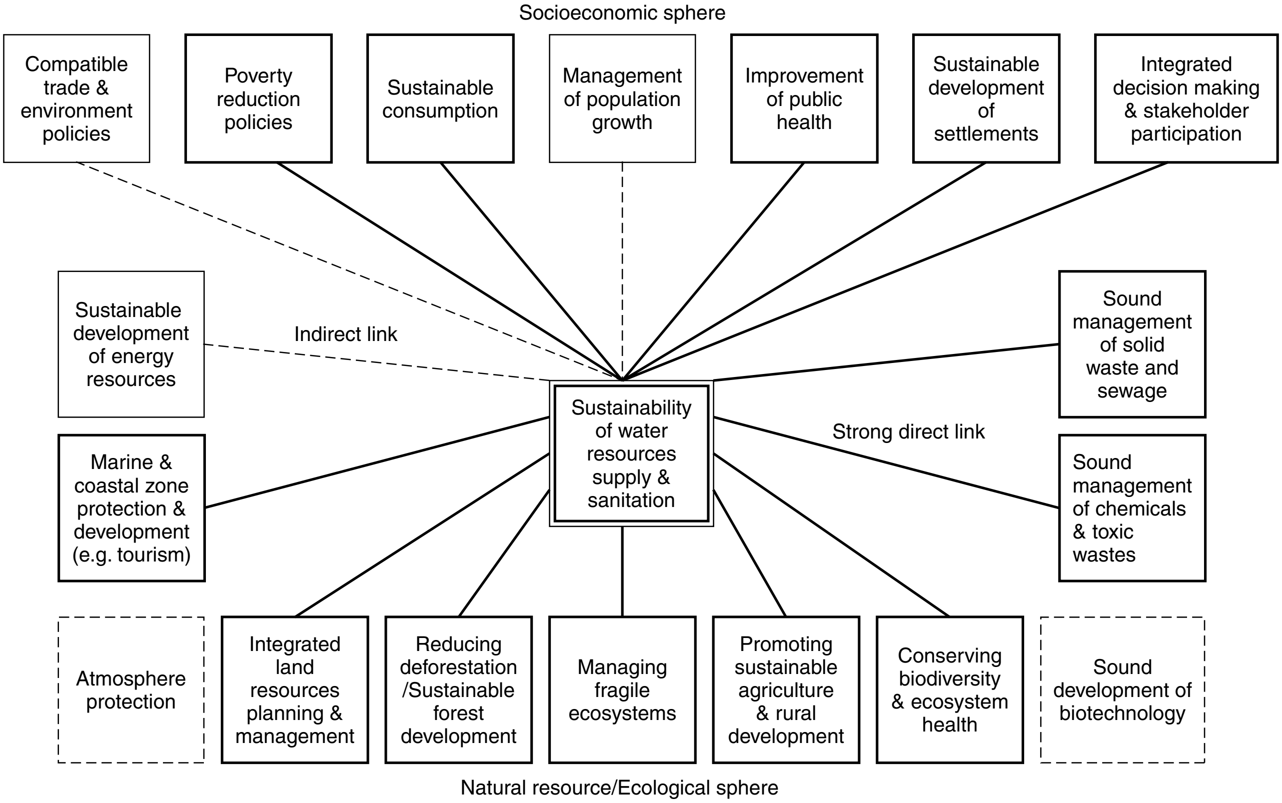

Figure 1. Agenda 21 components of sustainable development. Water resource sustainability influences many sectors and is a strategic operational focal point (7) (permission of University of Newcastle–upon-Tyne).

sustainability, and how can these be put into practice? Notably, freshwater resource sustainability is of great strategic importance to sustainable development as a whole because it has by far the highest degree of structural and functional interdependency with the other sectors/topics considered in *Agenda 21* (Fig. 1). This means, in theory, if we can solve water problems, many others will follow.

SUSTAINABILITY CONCEPTS

Human activities—agriculture, industry, urban development, and the like—stress environment and ecological health (including human health) in three main ways that often overlap and magnify each others' effects (3):

- through overexploitation of natural capital/resources (soils, water, plants, animals),
- through overproduction of wastes beyond the assimilative/attenuative capacity of ecosystems, and
- through land use/land cover changes that alter ecological structure and function.

The literature of the late 1980s and early 1990s is replete with discussions of sustainability as a concept, model, idea, paradigm, and philosophy. Hardin's seminal article called "The Tragedy of the Commons" in 1968 (8) was an important work that provoked discussion and raised awareness of the risk of overexploiting common natural resources without property rights. Hardin's theory held that individuals who have access to a common resource would seek to overexploit the resource to maximize their benefits and that the aggregate cost of overexploitation borne by the population as a whole would exceed the benefits. Such a scheme would be neither optimal for the society nor sustainable. The field of Common-Pool Resources (CPR) seeks to find governance solutions to sustainable natural resource management (9,10), investigating institutional predisposing conditions for successful governance of common natural resources, a partial refutation of Hardin's theory. Critics of CPR state that it is predicated on a single resource concept isolated from the ecosystem context of many resources, that studies are about self-governance that excludes the state, and that it is based on assumptions that resources and people do not change (11).

Another seminal publication was *The Limits to Growth* (12), which predicted the collapse of natural resources such as fossil fuel, metals, timber, and fish from overexploitation. This "crisis" scenario proved largely erroneous because of a gross underestimation of available reserves. Initially, it heightened concern over the sustainability of development, but then it undermined these same concerns by exaggerating the risks of collapse and losing legitimacy.

In 1987, the United Nations Commission on Environment and Development produced a report called *Our*

Common Future (1), widely known as the Bruntland Report after the chairperson, Norwegian Prime Minister Gro Harlem Bruntland. Focusing on satisfying basic human needs—water, food, shelter, energy, health—the Commission promoted seven strategic imperatives for sustainability and seven preconditions (Table 1). The report went on to suggest that the transition to sustainability will be driven by industrial wealth and that wealth creation be made more equitable and environmentally responsible. Its value has been to stimulate activity, though it has been criticized for failing to fully consider the dependence of industrial economic growth on natural resource exploitation (13).

The physical thermodynamic aspects of sustainability have been addressed by the Natural Step philosophy, set up in Sweden, based on a set of four systemic principles (14):

1. Substances from the earth's crust may not be extracted at a rate faster than their slow redeposit into the earth's crust.
2. Substances must not be produced by society faster than they can be broken down in nature or deposited into the earth's crust.
3. The physical basis for nature's productivity and diversity must not be allowed to deteriorate.
4. There must be fair and efficient use of energy and other resources to meet human needs.

Despite the obvious difficulty of meeting the first three principles, the World Business Council for Sustainable Development (WBCSD), a coalition of 125 companies worldwide, endorses *Natural Step*, as do conservation groups such as the International Union for the Conservation of Nature (IUCN) (14). The interests of the business sector are addressed by the concept of *triple bottom line*, the three dimensions being economic, social, and environmental. The main issues among these three are as follows (after Ref. 14):

- Economy–environment issues: How to promote ecoefficiency, clean production, and waste prevention and minimization? How to employ ecotaxation and create a market for tradable environmental permits? How to account for nonmarket costs and benefits?
- Society–environment issues: How to raise awareness and environmental literacy? How to counter environmental injustice and foster generational equity?
- Economy–society issues: How companies consider social costs and benefits of their investments? How wealth generation can address human rights and business adhere to an ethical code of practice.

Pearce and Turner (15) have defined sustainable development as "maximizing the net benefits of economic development subject to maintaining the services and quality of natural resources over time." They state several sustainability rules: (1) use renewable resources at rates less than or equal to the natural rate at which they can regenerate; (2) always keep waste flows to the environment at or below the assimilative capacity of the environment; and (3) optimize the efficiency with which nonrenewable resources are used, subject to substitutability between resources and technological progress. The first two are absolute physical thermodynamic sustainability criteria readily applicable to water quantity and water quality, whereas the third is an economic criterion. Examples of violations of rule 1 and 2 are the depletion of aquifers by withdrawing more water than is being recharged and the degradation of water quality, respectively.

Table 1. Sustainability Imperatives and Preconditions

Strategic Imperatives	Preconditions[a] (Capital Needs)
1. Economic growth must be revived in developing nations to alleviate poverty and reduce pressure on the environment.	1. A responsive political decision-making process (S).
2. Equity and nonmaterial value must be included in the consideration of growth.	2. More efficient economic systems that use less natural resources (N, S, H, F, P)
3. Basic human needs for food, water, shelter, energy must be met, accepting that changing (more equitable) patterns of consumption are needed.	3. Responsive social systems that redistribute the costs and benefits of development (S, H, F).
4. Reduce population growth by reducing economic pressures to have children.	4. Production processes that operate within ecological limits (N, S, H).
5. Conserve and enhance the natural resource base.	5. Technology development that supports efficient energy and resource solutions (N, S, H, F, P).
6. Environmental risk management technology must be developed and made available to the developing world.	6. International order that maintains cohesion globally (S).
7. Decision making should consider ecological and economic criteria.	7. Responsive, flexible, self-correcting government institutions (S, H).

[a] S: social capital; H: human capital; F: financial capital; P: physical capital; N: natural capital.

Source: After Reference 1.

Sustainability fundamentally challenges cultural norms, values, and behaviors. Using a historical cultural evolution argument, Downs (16) argues strongly that a combination of ethics, productive social interaction, and knowledge integration are cultural prerequisites for improving sustainability. Professionals and academics in the environmental field are now (and for the foreseeable future) centrally concerned with the pursuit of 'sustainable solutions' to priority problems of natural resource degradation. Reflecting the triple bottom line, sustainable solutions are those that are at the same time ecologically viable, economically feasible, and socially desirable (Fig. 2).

The International Union for the Conservation of Nature (IUCN) has actively promoted *green accounting*,

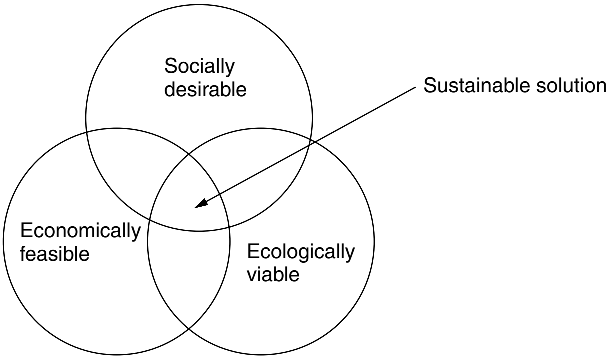

Figure 2. Sustainable solutions must satisfy three sets of criteria: social, ecological, and economic (17).

a process by which the economic costs and benefits of natural environment exploitation are measured (14). Norway has institutionalized this process to track the state of natural resource stocks and pollution rates. The United States has developed a supplement to normal economic accounting called the Integrated Economic and Environmental Satellite Account (IEESA) that seeks to account for the economic impact of environmental changes in water quantity, water quality, mineral stocks, forest stocks, and fish stocks (14). To do this will require new concepts, methods, and data, and impetus that can counter lobbying against such policies by special interests.

Spearheading what has been called the *Blue Revolution* for water sustainability (14) is the method of integrated watershed management (IWM)/integrated water resources management (IWRM). IWM/IWRM seeks to combine interests, priorities, and disciplines as a multistakeholder planning and management process for natural resources within the watershed ecosystem, centered on water quantity and water quality. Driven bottom-up by local needs and priorities and top-down by regulatory responsibilities, it must be adaptive, evolving dynamically as conditions change (3). Two global institutions play a key role in strengthening the social capital to sustain water resources: (1) the Global Water Partnership (GWP, founded 1996) that seeks to translate principles into practice through partnerships based on integrating knowledge and experience and (2) the World Water Council (WWC, founded 1996) that seeks to raise awareness of water problems and promote solutions (14).

IWM/IWRM is new and still evolving: “IWRM has neither been unambiguously defined nor has the question of how it is to be implemented been fully addressed. What has to be integrated and how is it best done? Can the broad principles of IWRM be operationalized in practice—and, if so, how?” (18). There are four broadly accepted IWRM principles, as set down by the 1992 *International Conference on Water and the Environment* in Dublin (19):

- Fresh water is a finite and vulnerable resource, essential to sustain life, development, and environment.
- Water development and management should be based on a participatory approach, involving users, planners, and policy-makers at all levels.
- Women play a central part in the provision, management, and safeguarding of water.
- Water has an economic value in all its competing uses and should be recognized as an economic good.

Building on these principles, water resource analysis, planning and management must be (after Ref. 3)

- holistic—incorporate the governing aspects of the “whole ecosystem” (watershed links to other watersheds, aquifer systems, bays, and estuaries), including interrelated natural resources (air, water, soil, biota), and humans as an integral, supermodifier of the ecosystem;
- integrated and participatory—incorporate relevant knowledge from the natural sciences, engineering, social sciences, and humanities, and accommodate the diverse set of interests, concerns, roles, and responsibilities of different stakeholders (including marginalized groups like periurban poor and rural subsistence farmers);
- strategic—identify and focus primarily on governing dynamics (the few drivers and responses that govern the way the system behaves), gather priority data, identify and address priority problems most cost-effectively;
- adaptive—adapt to changing geophysical and sociopolitical conditions; and
- sustainable—provide a steady stream of use benefits (or positive impacts) to present and future populations of humans and other species that exceed costs (negative impacts), while conserving ecosystem integrity and environmental quality.

Laws and regulations are crucial instruments that help us respond to the challenge of water sustainability. Such responsive legal instruments should do the following (after Ref. 20):

- Encourage administration at the appropriate hydrological scale: watershed, multiwatershed, or aquifer system.
- Foster internalization of the values and ethics of sustainable resource development.
- Encourage integrated approaches to water supply and sanitation, ecology, and public health.
- Prevent water allocation and usage policy making from fragmenting among agencies.
- Promote integrated appraisals, notably environmental, economic, and sociopolitical impacts assessment of alternative actions.
- Encourage integrated capacity strengthening of governmental institutions, NGOs, community associations, and businesses to transit into more sustainable policies and practices, and work collaboratively.
- Enforce reward and penalty incentives that encourage sustainability.

SUSTAINABILITY PRACTICES

The numerous rules and principles that populate the concepts of sustainability can be translated into indicators that can be measured quantitatively (e.g., waste flows are being assimilated/waste accumulation is zero) or qualitatively (e.g., the quality of stakeholder collaboration). These ecological, economic, and social sustainability indicators should be used to assess existing conditions and identify priorities for action, comparing action alternatives (impact assessment), and monitoring/evaluating the performance of the chosen alternative.

Earth Summit 2002 in Johannesburg tried to come to grips with ways to make the concept operational, how to put into practice the aspirations of Rio 1992. Howe (21) identified key water management requirements for a watershed/multiwatershed scale: (1) coordinated management of surface water and groundwater resources, (2) coordinated management of both water quantity and water quality, (3) provision of incentives for greater economic and technical efficiencies in water use, and (4) protection of public values associated with water service (e.g., reliable, safe, clean, affordable supply). And to achieve this, water institutions must develop the following characteristics (21):

- the capacity to coordinate water plans with other agencies (e.g., urban planning, agriculture, public health, environment, industrial);
- the capacity to solve water problems creatively using a variety of options and approaches (e.g., laws, pricing, taxes, tradable supply and/or pollution permits, subsidies);
- the foresight to separate roles and responsibilities for water resource planning and management activities from construction activities (i.e., avoid conflicts of interest);
- the multidisciplinary capacity to undertake multicriteria/multiobjective planning and evaluation of alternatives;
- devolve decision-making power to the lowest level—national, state/regional (provincial), local, or municipal—consistent with the scale of the water issue;
- the capacity and willingness to use appropriate participatory methods involving different stakeholders at different stages of a project (preplanning/conceptual, planning and design, implementation, maintenance, monitoring, and evaluation).
- the ability to reward innovation and adapt to changing conditions and priorities.

It is clear that to do most of what sustainability challenges society to do requires us to strengthen our *capacity to respond* to those challenges and opportunities. “Capacity building is the sum of efforts needed to develop, enhance and utilize the skills of people and institutions to follow a path of sustainable development” (22). A UNDP program *Capacity 21* (22), seeks to build capacity to implement *Agenda 21*.

Considerable community-based water management experience worldwide provides empirical evidence of what works on the community scale and why (see 23–26 among many others). IRC (23) found that the following are major factors for success in community water projects: baseline community capacity, community demand, donor and government support (financial and as policy), sufficient water resources, and the capacity of implementation agencies. But work has tended to focus on one population context alone (e.g., rural subsistence), and on one aspect (water supply and/or sanitation, or irrigation, or land degradation), instead of the more integrated watershed management approach advocated for sustainability. A considerable body of knowledge exists on participatory methods, methods include participatory rural appraisal (PRA), participatory action research (PAR), rapid rural appraisal (RRA), and participatory action development (PAD); all have been applied to strengthening community water management. But calls have been made to move beyond traditional participatory methods to more integrated analysis and planning methods with community and government stakeholders (27).

How do we make sustainability progress in a field that builds on successes, learns from failures? From 1998–2000, local working groups in collaboration with the Mexican National Water Commission (CNA), coordinated by Downs (7), developed a participatory integrated capacity-building (PICB) approach to water sector sustainability. Following an analysis comparing relatively sustainable development projects worldwide during the past 10–15 years (those yielding a steady stream of benefits *after* external support was removed) with a much larger number of *un*sustainable projects, six broad synergistic levels of capacity building emerged as critical components for success: (1) strengthening political and financial commitment; (2) strengthening human resources, including education, training, and awareness-raising; (3) strengthening information resources for policymaking (e.g., monitoring and GIS tools for data integration); (4) strengthening policies, regulations, enforcement, and verification; (5) applying appropriate technology and basic infrastructure (e.g., for water and wastewater treatment); and (6) stimulating local enterprise development (i.e., support products and services providing socioeconomic sustainability). Each one builds on those before it with positive feedback. Crucially, we see that operational sustainability is a function of participation and integrated capacity building (7).

Figure 3 shows a desirable participatory project sequence. On the analytical (science) side, we need strategic information on watershed conditions, especially water quantity, water quality, and use requirements (present and future users are humans and other species). On the policy and management sides, we need strategic planning methods that accommodate stakeholder inputs, evaluate options, choose a preferred option (by multiple criteria), and support the implementation and sustainable operation of this option. PICB is used to make the selected preferred management option (PMO) sustainable (for more

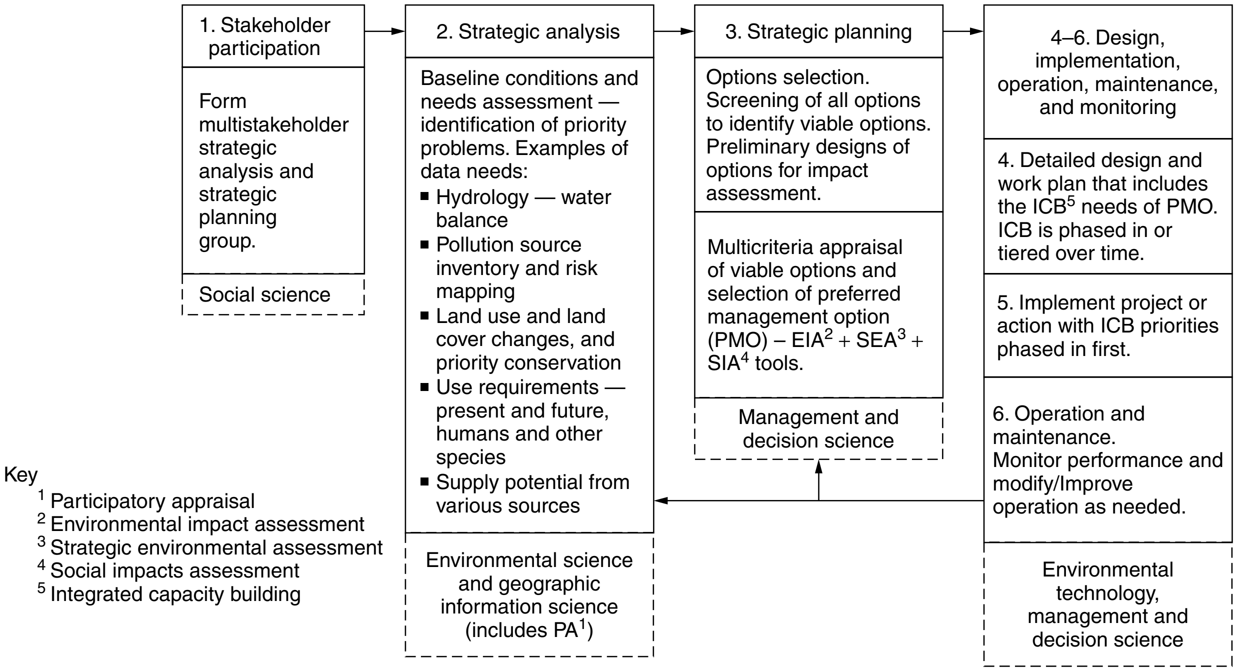

Figure 3. Six stages of operational water sustainability. Strategic participatory planning selects an alternative using sustainability criteria (impact assessment), and integrated capacity building sustains it (after Ref. 3).

information, see the article INTEGRATED CAPACITY BUILDING NEEDS FOR WATER SUPPLY AND WASTEWATER SANITATION).

An integrated, sustainable watershed management plan must be based on reliable information (PICB Level 3) about baseline geophysical, hydrologic, water quality, pollution source, ecological and socioeconomic conditions. Identifying key indicators, integrating data on them, interpreting and disseminating information to watershed–bay stakeholders informs policy and raises awareness of priority issues. It also facilitates collaborative actions to mitigate those issues. This strategic data can be fed into a GIS database that can be manipulated for decision-making. The GIS format can be used to engage community, NGO and government stakeholders in the *strategic analysis* process that must underpin the watershed–bay planning, design, implementation, and maintenance/monitoring stages (Fig. 3). A web-accessible GIS can also provide actors with a powerful means to understand how their interests fit into the wider multi-interest context of a watershed ecosystem. Such visualization and information is conducive to multistakeholder participation and dispute mediation: Actors internalize the stakes of others and can better negotiate compromises to meet common goals (3). Such information resource/planning tools do not yet exist, data are scattered, of varied formats, and have significant gaps that flag primary data gathering needs. Close collaboration with watershed NGOs engaging in community capacity building and state and local environmental agencies will ensure that results have the greatest impact and utility (3).

The term *strategic* is stressed: We must choose to collect data of the highest information value for our objectives and only this data (3). In this way, what appears to be a huge project scope is reduced to its critical components, is manageable, and most importantly, effective. This also keeps volunteer data gatherers engaged because they see the impacts of their efforts on policy. We already know what most of these key data are (priority pollutants, use data, hydrologic balance, etc.); often some exists, though dispersed and must be integrated. Other priority data needs emerge as part of the analysis.

Empirical evidence points strongly to community-based natural resource management as a key to social sustainability. But how can this be done on the watershed scale required for hydrologic sustainability? The answer lies in strengthening the social capital of the watershed by forming collaborative networks of communities. Often in developing countries, marginalized rural agroforesters occupy the upper reaches of the watershed and become, *de facto*, producers of water resources for downstream users. Evidently, both producers and users share the common interest of watershed sustainability, and both must be involved in strategic planning. By networking and through capacity building coordinated by NGOs, marginalized communities can gain the power they need to negotiate with influential user groups and government agencies.

CLOSING REMARKS

Integrated watershed management and integrated capacity building seem to confirm that the challenges of sustainability are primarily cultural and sociopolitical, not economic, scientific, or technical. Echoing the cultural prerequisites of Downs (16), any sustainability process, method, or approach—certainly IWM, PICB, EIA—will ultimately depend for its success on two cultural determinants:

- *an ethical core*—values and attitudes respectful of intra- and intergenerational equity and natural resource conservation; and
- *a participatory culture*—swapping "win–lose" for "win–win"; choosing the philosophy of collaboration and mutual gains over conflict negotiation and trade-offs.

Providentially, international case studies reveal that water sustainability challenges and opportunities are similar across cultures and geographical contexts and yield significant economies of scale in the development of theory and practice.

THE PROVISION OF DRINKING WATER AND SANITATION IN DEVELOPING COUNTRIES

Terence R. Lee
Santiago, Chile

Few die from a lack of water, but many die from water. Despite all the resolutions made at international congresses and all the pledges from governments and international organizations, more than 3 million people die each year from water-related diseases (Fig. 1). These deaths occur in circumstances where safe water and sanitation would have cut by at least one-third the number of diarrhea cases (currently at 4 billion worldwide every year) which result in 2.2 million of those deaths (1).

The U.S. National Academy of Engineering includes drinking water supply as one of the great engineering achievements of the twentieth century. For those fortunate to live in a developed country, it was. However, the failure to provide universal safe drinking water and adequate sanitation is amongst the gravest contradictions of our world at the beginning of the twenty-first century. The necessary technology has existed for at least two millennia, but there remain serious obstacles to its application. The result is that at least 1 billion people remain without access to a reliable and safe source of water, and more than 2.5 billion lack safe sanitation. This population is concentrated in countries at the lowest levels of development.

The deficits in services are greatest in Africa where 38% of its population remains without safe water and 40% without sanitation; Asia has 19% of its population without access to safe water, 52% without adequate sanitation; and in Latin America and the Caribbean, 15% of the population is without a potable water supply and 22% without adequate sanitation. Although, it has been estimated that a large number of additional people obtained access to services in the 1990s (800 million to water and 750 million to sanitation), population migrations and growth have meant that the proportion of the urban population with access to a safe water supply actually decreased, whereas the absolute number of people without access to water and sanitation remained the same (3).

An example of what these statistics can mean in reality for the population of a city can be illustrated by the situation in Dakar, the capital of Senegal in West Africa. In Dakar, the urban area can be subdivided into three zones:

- The first zone is completely laid out in lots and endowed with water supply and sanitation. It corresponds to the area of the colonial city founded in the second half of the nineteenth century. Today, it is the commercial and administrative center.
- The second zone is the formal suburban area, which is partly parceled in legally constituted lots. However, only part of this area has public water supply and sanitation. In the rest, where the majority of houses have been built on public land without permission, the inhabitants eliminate domestic wastes *in situ*. Of the inhabitants, 40% use latrines, 40% use abandoned wells, and 20% use dug holes.
- The third zone is entirely without any public water supply or sanitation (4).

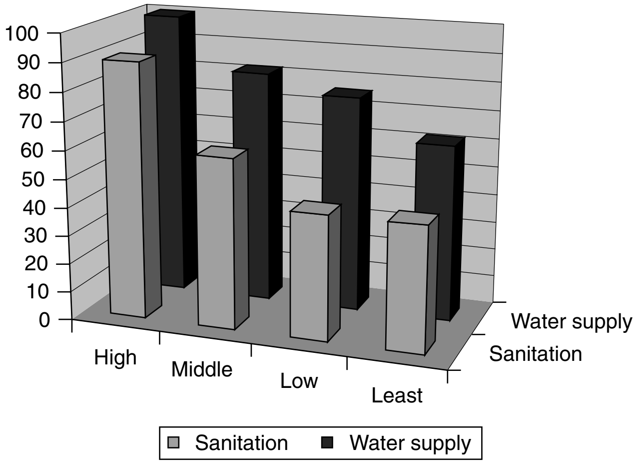

Figure 1. Percentage of population with access to improved water source and sanitation, by level of development. (*Source*: Reference 2.)

In the suburbs of Dakar, only 40% of the population receives drinking water from a protected source, usually public taps; the remainder of the population relies on water from shallow wells, running the risk of contracting diseases as the groundwater quality is menaced through the existence of poor quality latrines and of excreta deposited directly on the soil.

The menace of well contamination is present even in rural areas that have much lower population densities than those of the suburbs of Dakar. The problem is the reliance on shallow wells when excreta are also disposed of into the shallow aquifer. Problems due to contamination are compounded by the restrictions on water consumption imposed by the need to carry water over long distances (Table 1). People will go a very long distance to get water, even more than 2000 meters, but consumption drops drastically when water has to be carried so far. It has been estimated by the World Health Organisation that something of the order of 50 liters per person a day is needed to live safe from disease, which, the data in the table suggest, means a tap in the dwelling.

For the rural population, water may be free, even if not close by. In urban areas, even for low levels of supply, water has to be paid for. It has long been known that the poor pay more when the source is not a public utility (Table 2).

Rural water supply service can be extended through the successful change to a demand-led provision of both technologies for the individual household (hand dug wells, hand pumps, roof catchments) and community technologies (gravity flow and simple pumped systems manageable by community members). The main issue is to overcome the operations and maintenance problems, which, in the past, have made up to one-third of even such

Table 1. Water Consumption in Rural Areas

Type of Water Supply	Average Daily Consumption, Liters per Person
Communal source	
Well or tap farther than 1000 meters	7
Well or tap between 250 and 1000 meters	12
Well less than 250 meters	20
Tap less than 250 meters	30
Tap in yard	40
Tap in house	
Single tap	50
Multiple taps	150

relatively low technology systems out of order soon after installation (7). Any improvement will require continuing support once the systems are installed. It is now accepted that increased private sector involvement and the transfer of many water points from community to private household management can improve performance. For example, a World Bank survey in the 1980s showed that 60% of the public hand pumps in rural India were out of order, compared to only 10% of privately owned pumps (8).

Rural sanitation normally takes the form of on-plot sanitation, which does not impose high external investment costs or significant operation and maintenance responsibilities outside the household. Public support is required for the critical tasks of health and sanitation education and promotion, and there is a need for effective provision of small-scale credits to allow the purchase of components, such as latrine slabs. Some of these activities could be successfully delegated to the private sector, as has been done with both rural water supply and sanitation installation and maintenance support in Chile (9).

In urban areas, self-help solutions have limited application. Urban water supply systems, even where they exist, commonly do not cover the entire population, have not expanded to keep pace with population growth, and fail to provide either adequate pressure or a continuous supply. The shortfall in coverage always means the absence of service for lower income groups. In addition to the failure of systems to expand or provide continuous supply, demand for water grows as industrial and commercial demands rise with economic growth. At the same time, increased household demand for drinking water is in part driven by higher living standards resulting from economic growth and by the use of conventional waterborne sewerage, which significantly increases per capita water use.

Because of economies of scale and the low value of the product supplied, urban water supply has been considered a 'natural' monopoly. It is certainly not practicable or economical to have direct competition in the provision of network services at the household level. Traditionally, providing water supply and sewerage services has been a local responsibility where services are overwhelmingly run through municipal governments. One consequence of local municipal ownership and management of services has been the creation of serious difficulties for the transfer of successful experience. In the nineteenth and early twentieth centuries, technological and administrative transfers, even if restricted, did occur through colonial governments. Now, transfer has been largely left to international aid organizations which, whether governmental or nongovernmental, have failed to provide continuity in commitment over the long term.

Even where historically services have been provided by private companies, these too have tended to be small and local. Water supply and sewerage services have largely resisted globalization and even today foreign operation and investment in services is very limited. There has been, therefore, little transfer of the ways and means of providing service from the successful to the rest of the world.

Where transfers have occurred, advances and innovation in water supply and sewerage have been related mainly to the technical aspects of the operation and administration of large organized urban systems. There has been little or no innovation for the provision of services to the informal suburbs of the large cities in developing countries, and this is why the use of the shallow well for water supply and the latrine for excreta disposal remain the methods of choice.

Moreover, it has been the conventional wisdom that a large and relatively sophisticated institution is required to plan, organize, and control this monopoly provision. However, there is considerable potential for private sector involvement in managing, or supporting the management of, all or parts of a system, as well as in contributing to the capital requirements in middle-income metropolitan areas.

Dar-es-Salaam, Tanzania, presents an example of one possible alternative approach. Residents of Dar-es-Salaam face chronic water shortages and often have to combine several sources of water at different costs and quality to fill their needs. The Dar-es-Salaam Water and Sewerage Authority provides most of the bulk water supplies to the city. The Authority is relatively efficient; some 80% of the water produced is billed, although only 50% of the bills is collected. However, only one-third of households receive their water directly from the utility, creating a large niche for the private sector in water distribution. Large parts of the distribution system—both the piped system and nonpiped supply—are in private hands (10). This "privatization by default" is manifested in two ways:

- through the private redistribution of water, that is, water vending, ranging from home-based, quasi-legal resellers and informal low-income pushcart vendors to more formalized and regulated distributors delivering water to people's homes by tank truck; and
- by the "spaghettization" of the piped water network, where privately financed individual service lines are, in practice, directing investments and expansion of the distribution system.

Urban sanitation needs may be met through on-plot systems, communal facilities, or traditional sewerage systems. Privatization by default of network sewerage services is rarely, if ever, found. On-plot systems involve households in providing their own facilities through different types of latrines, but contamination of the groundwater results in densely populated communities. Communal facilities economize on investment and water but may not be acceptable in all cultures, however. Alternative systems to traditional sewerage systems can reduce costs and could be provided communally. The provision of simplified sewers is one alternative. Simplified sewerage is essentially conventional sewerage without any of its conservative design requirements. It can be considered as the latter stripped down to its hydraulic basics. It is also called shallow sewerage, and its in-block variant is often called backyard or condominial sewerage. Under this system, the sewers are laid on private rather than public land, household labor is accepted as partial payment for the connection, and smaller bore sewers are used. It is estimated that the costs of service delivery can be reduced by 30% using this system.

The provision of sewerage through conventional waterborne sewers has considerable economies of scale leading to monopolistic provision and needs complex institutional support. However, smaller scale provision is possible with simplified sewerage systems. This means that the private sector and local communities could become more involved in supplying and servicing such systems as well as in providing on-plot sanitation, where this is possible, and also in providing and managing communal sanitation facilities.

The provision of services to the rural population, or even to less dense urban areas, should not and does not require such high levels of investment, and the same technology can be applied that has existed for milennia. However, a serious obstacle to improving water supply and sanitation in large third-world cities is the cost of modern centralized water supply and waterborne sewage systems. These require a capital investment of, at least, US$ 1000 per connection even without sewage treatment. It is in the cities that innovation is required and alternative systems must be sought.

SUSTAINABLE MANAGEMENT OF NATURAL RESOURCES

Lucas Reijnders
University of Amsterdam
Amsterdam, The Netherlands

INTRODUCTION

It is easier to agree on what is *un*sustainable than on what is sustainable. The once great Newfoundland cod fishery collapsed in 1992, causing 20,000 people to lose their jobs (1). It is uncontroversial to call the fishing practices that led to this collapse unsustainable. Similarly, it is uncontroversial to call mining of fossil water for corn production in Saudi Arabia unsustainable. However, by now there are probably more than 100 definitions of sustainability. Such definitions include environmental and often also social and economic aspects of human activities. They may either stress matters that can in principle be objectively established (such as fish stocks) or be social constructivist, emphasizing divergent views of stakeholders, different world views, or procedures to come to agreement about what sustainability means in a specific social context.

Here sustainability will be defined according to the World Conservation Strategy (2) that introduced the concept among policy makers. This definition fits a steady-state economy (3)—an equilibrium relation between human activities and the physical environment. The definition is also in line with long-standing approaches to safeguard the long-term productivity of forestry and fisheries (4). The main underlying principle of so defined sustainability is that of justice between the generations. This principle comes back in the most famous of later definitions of sustainability, given in the report *Our Common Future* (5): "meeting the needs of the present without compromising the ability of future generations to meet their needs."

"Natural resources" is a concept less controversial than sustainability. It includes all that we use or take from nature to provide for our existence. Mineral oil, river water, North Atlantic cod, and iron ore all belong to our natural resources. Efforts are needed to obtain these resources. They can be considered natural capital and are not technologically replaceable by other forms of capital, such as social or financial capital (6). There is also a category of services of nature that we use, whether or not we are aware of it. These include degradation of toxic substances, maintenance of atmospheric composition, sequestration and cycling of minerals, and structuring services. Many of these services are ecosystem services. There is no reason to believe that financial or social capital can be an effective substitute for nature in producing ecosystem services (7).

In this article, sustainable management of natural resources comes down to maintaining natural capital so that it can be used by all future generations of humans. This is based on a production level that can be sustained indefinitely without threatening the living conditions of future generations (8).

First, sustainability is discussed in the context of four different types of natural resources. Thereafter, three aspects of sustainability are discussed in more detail:

- sustainable management of fresh water resources,
- sustainable management of fisheries, and
- sustainable management of ecosystems.

TYPES OF NATURAL RESOURCES AND THEIR SUSTAINABLE USE

In the context of resource management, several important types of natural resources can be distinguished. First, there are flux-type natural resources. These can be used without any impact on future availability. Examples of such flux-type natural resources are wind and solar radiation. Second, there are renewable natural resources. In this case, there are currently substantial additions to the stock. Such resources include freshwater in rivers and fish in the seas. Aquifers that are replenished, mostly at a rate of 0.1–0.3%/year (9), also belong to the category of renewable resources.

A third type of natural resource is the product of slow geological processes. This is the category of the (virtually) nonrenewables and includes metal ores, fossil water, and fossil carbon compounds. Compared with the total stock, there are no or relatively small additions to these resources. Total stocks may vary strongly. For instance, stocks of iron ore are large, but the stocks of, for instance, Ag (silver), Sn (tin), or Pt (platinum) ores and fossil water are relatively small. A fourth type of resource covers living nature, which provides for ecosystem services.

From the viewpoint of sustainable resource management, flux-type resources may be freely used. This is not so for the other three types of resources.

To conserve renewables over long periods of time, the usage of renewables should not exceed the addition to stock. Moreover, the quality of the stock should be maintained. For instance, as to groundwater, the condition should be met that water tables do not fall, and also pollution that negatively affects the future value of the resource should be prevented.

The concern for (virtually) nonrenewable natural resources is mainly with geochemically scarce natural resources that are currently being depleted rapidly. In this category belong fossil water resources in North Africa and Southwest Asia that are currently "mined" (10). Fossil carbon compounds and ores for phosphates and metals such as silver, platina, tin, and nickel are other examples. If the stocks that are formed by slow geological processes are to last during the normal lifetime of a primate species ($\sim 10^6$ years), losses from stocks (including stocks in the economy) due to dissipation should be kept small. When substitutes that are dependent on flux-type or renewable resources are made available in a sustainable way, relatively large reductions of the stock that was formed by geological processes are defensible (11).

In ecosystem functions that are important to us, both the area available to natural ecosystems and species composition ("biodiversity") of ecosystems matter. Moreover, for proper functioning, a number of conditions regarding the abiotic aspects of the ecosystem should be met. Requirements as to the quantity and quality of water available function, often prominently, among such conditions (12).

SUSTAINABLE MANAGEMENT OF FRESHWATER RESOURCES

Freshwater is a vital natural resource for humankind. Only 3% of the world's water is fresh, and of that over 98% occurs as groundwater and less than 2% in surface water such as rivers and lakes. Desalinized seawater is used to a very limited extent as a resource. This is closely related to its high price (9).

To meet the criterion of sustainability, as defined here, the usage of renewable freshwater resources should not exceed additions to stocks. Withdrawal of seawater is by itself insignificant in view of sustainability, but desalinization should be powered by energy from flux-type resources (wind solar) or by sustainable biomass chains. The use of fossil freshwater stocks may be considered to bridge gaps temporarily on the way to sustainability.

Traditionally, management of freshwater resources has been strongly focused on the supply side: trying to supply adequate amounts of good-quality water and limiting the negative impacts of excessive water. Interest in sustainable management has shifted the focus. Demand-side management, reuse of water, and water conservation have become important. Though there is substantial scope for improvement at current price levels, it has rightly been argued that sustainable management of water resources is dependent on major changes in economic arrangements for dealing with water resources. A number of proposals for such changes have focused on rationing, where the sum of rations reflects sustainable management. Most proposals, however, argue in favor of water pricing that reflects the true full cost, including external costs.

In demand-side management, providing for freshwater-based services with less water ("improving efficiency") matters. As agriculture is the most important consumer of freshwater, requiring an estimated 65–75% of all water use, agriculture is a useful primary focus for efforts to improve water efficiency and reuse (9,12,13). This is especially so in semiarid areas that are currently "water starved" or where current practices cannot be sustained. Moreover, the share of agriculture in water withdrawals in such areas is often >85% (14). Water losses from agricultural systems in semiarid areas due to leakage during storage and conveyance (in case of irrigation), and to runoff, drainage, and evaporation are usually of the order of 70–85%. In some parts of sub-Saharan Africa, the loss for rain-fed agriculture may be 95% (13). Though a substantial part of these losses is unavoidable, there is also scope for improvement. For instance, when current water efficiency in sub-Saharan Africa is 5%, an increase to 10% (doubling vegetation yield) can often be achieved by the introduction of dwarf shrubs and improved tillage and nutrient management (13).

In irrigated agriculture, now responsible for about one-third of worldwide food and fiber harvests, better efficiencies are also possible. Options for efficiency improvement include better provisions for storage and conveyance, better scheduling, furrow diking, direct seeding, land leveling, microirrigation systems (drip irrigation and microsprinklers), and better regulation of the groundwater table (12,13).

Reuse of water in agriculture is a way to limit water withdrawals. In practice, both water from wastewater treatment plants and drainage water are reused (10,13–16). In the latter case, such water is often used to irrigate relatively salt-resistant crops. In managing reuse, the quality of water is important. The salinity and sodicity of water may negatively affect the future productivity of agricultural land. Excessive levels of nitrate, pesticides, and the presence of agents causative of infectious diseases may pose a direct threat to animal and human health. Receiving soils may, furthermore, act as a "sink" for hazardous compounds that may subsequently enter human and animal food chains. When persistent hazardous pollutants enter deep groundwater, they can result in long-term contamination of this important freshwater stock. Negative aspects of the secondary water supply may be influenced by pollution prevention ("source reduction") and treatment. Often there are possibilities for source reduction that are profitable at current prices (18).

Though both improvements in agricultural water efficiency and reuse offer scope for a more sustainable management of resources, it should be realized that in an increasing number of countries, especially due to increasing population pressure, such improvements will not be sufficient to feed the population in a sustainable way. This leads to the need for such countries to import "water-intensive" food from countries that have no water shortages.

Improvements in efficiency and reuse are also possible outside agriculture. An obvious object for improved efficiency is excessive loss and illegal withdrawal from distribution systems. In industrialized countries, losses of the order of 6% to more than 25% are common (17,19). Higher percentages have been noted elsewhere. In Jordanian cities, for instance, 55% and more of the input in distribution systems is "unaccounted for water" (10).

Water-efficiency improvement in industry and households has advanced. In industry, much of the improvement has come from internal reuse and process optimization, and there is still scope for further reductions in industrialized countries. For instance, a detailed study in the United Kingdom (20) suggested that industrial water consumption can be cut by 30% in a profitable way at current price levels. When water prices for industry increase to reflect true costs, profitable efficiency gains may increase considerably (17,21). Studies pertinent to developing and emerging industrial countries also tend to show a large potential for profitable water efficiency improvements (22–24).

Substantial improvements are underway in household water efficiency. Water use by water closets has been reduced by 75% or more, and major improvements in water efficiency have also been achieved in showers and appliances such as (dish and clothes) washing machines. Such efficiency improvements are usually profitable if current lifetime costs of appliances are considered (12,25). Internal reuse of household water, for instance, by using gray water for flushing water closets is practiced to a limited extent.

Finally, stocks of water may be improved by better water conservation. An eye-catching example of water conservation is in Sun Valley in the Los Angeles basin (USA). This valley was beset by floods from periodic winter rains. This led to regular press coverage showing vehicles driving in heavy (rain) water. To solve this problem, the County's Public Works Department initially opted for a storm drain to carry surplus water to the ocean. However, public discussion led to another solution. Water from winter rain is now increasingly collected in Sun Valley to recharge groundwater. In Europe, new urban developments increasingly rely on keeping rainwater out of the sewer systems and allowing it to infiltrate to add to groundwater stocks.

SUSTAINABLE MANAGEMENT OF FISHERIES

Fisheries catch renewable natural resources. When catches systematically exceed additions to stock, such resources can be depleted. If catches that exceed additions to stock are stopped, in a number of cases, the population rebounds. However, there are also cases where stocks do not rebound and remain at low equilibrium populations.

To be sustainable, catches should not exceed additions to stock in quality and quantity. Regarding cod, for instance, it is not only important to maintain a constant number of fish but also to safeguard that such fish are in the right age and size classes to maintain predation and reproduction (8). Moreover, for economic, biological, and social reasons, fisheries should manage stocks toward the higher end of abundance (1).

Sustainable management of fisheries is a long-standing issue. At least since the thirteenth century, European kings and other people in high places are on record opposing unsustainable fishing in their realms. The earliest recorded government-sponsored efforts to manage fisheries in a sustainable way in Europe date from the same time (26).

There is evidence that a number of traditional management systems have operated sustainably while managing stocks toward the higher end of abundance. Such systems have usually been characterized by ownership and controlled access; closed seasons during which fishing was prohibited; a taboo on fishing in refuge areas; and gear, size, and species restrictions (27,28). By present standards, fishing effort has been low under such traditional arrangements. When efforts increase (usually linked to financial pressures, population pressure, and technological development), stocks tend to decrease—especially when there is open access. The unregulated dynamic of fisheries is to deplete a stock as far as markets and technology will allow and then move on to the next stock (1,29).

A variety of approaches have been tried to counter the tendency of fisheries to deplete stocks. In many cases, such efforts have failed. Consequently, prices paid for the produce of fisheries are now often much higher than they would have been under conditions of sustainable management (8). Moreover, it has been estimated that the revenues of the worlds fishing fleets are approximately US\$20–40 $\times 10^9$ below their operating costs (30,31).

Against this sobering background, there is no shortage of suggestions for improvement, all focusing on the supply side. Some have argued in favor of a revival of traditional arrangements that have worked well, such as the community-based fisheries management systems in the Pacific Islands and Japanese inshore fisherman's traditional user rights (28,32). Whether such a revival can be successful is dependent on meeting a number of conditions (28). Current developments are not necessarily conducive to this (27).

Recently, based on an initiative of the Worldwide Fund for Nature (WWF) and the company Unilever, a nongovernmental initiative emerged to certify sustainable fisheries. This is the Marine Stewardship Council that, by March 2004, had certified eight fisheries as sustainable. There is considerable favorable consumer interest in this approach (33), but it is too early to offer a verdict on the success of this scheme.

Most proposals for improving management practices have focused on government intervention. The use of incentive-based price instruments, such as landings and vessel taxes, has been advocated (31). Though, in the case of freshwater, adapting prices is increasingly popular as a means to attain sustainable management, this is different for fisheries. To the extent that efforts have been undertaken by governments, the focus has been firmly on trying to manage "physical" aspects of fisheries by measures such as limitation of effort, minimum allowable sizes for individual species, maximum allowable catches, and protected areas.

There have been both failures and cases of successful governmental management of fisheries focusing on physical aspects of fisheries. From the successes and failures so far, a number of lessons can be drawn (1,32,34–37).

- The problem of illegal catches exists, especially if stocks are close to the market. When the policing effort is not up to the ingenuity of illegal fishing, management efforts may well become a failure.
- With few exceptions ("dolphin safe" tuna fishing, the use of turtle excluders, and the Norwegian no-discard policy), management systems have been poor at limiting the negative impacts on stocks of by-catch and discards. Globally, discarding may be about 30% of landed tonnage.
- Many management strategies have opted for limitation of effort, for instance, by regulating the efficiency of fishing gear; engine size; fishing season; and/or limiting the number, size, and storage capacity of fishing boats. Only in a limited number of cases (e.g., the rock lobster fishery in West Australia) have such approaches been successful.
- A number of efforts have opted for allocating total allowable catches to political entities such as countries. In some cases, these efforts have been successes and in other cases, they have been failures. An important reason for failure, apart from illegal catches, has been that conservation goals were not separated from allocation, which resulted in losing conservation goals in allocation battles. Electoral considerations favoring perceived (short-term) interests of the fishing industry have also contributed to failure.
- More recently, there has been the tendency to base management on the allocation of long-term or even perpetual individual rights or individual transferable rights for their fishermen. In most cases, these rights have been based on past catch histories ("grandfather rights"). In some cases, such individual rights have been auctioned. There have been failures of such systems, such as the abalone fishery of British Columbia and the Southern school sharks fishery of Australia. But in other cases, this approach has worked relatively well. Success may be partly linked to the fact that individual rights that are allocated for a long time become more valuable if fishing practices are sustainable.
- The establishment of marine protected areas that are protected from fishing (which are aimed at conservation of fish stock but may also conserve or restore ecosystems) has so far not been practiced to an extent that allows a verdict on its effectiveness. The same holds for the allocation of fishing rights to cooperatives.

SUSTAINABLE MANAGEMENT OF ECOSYSTEMS

Natural ecosystems provide for a wide variety of services. Part of the services of natural ecosystems relate to water. Natural ecosystems are important in determining levels of greenhouse gases, and thereby climate, that in turn is a determinant of the global water cycle. Such ecosystems are also a major determinant of worldwide evapotranspiration. There are, furthermore, local quantitative and qualitative links between ecosystems and water. For instance, deep-rooted natural vegetation along watercourses catches minerals and returns these to topsoils. Thereby, it reduces the mineral content of surface waters, while increasing primary productivity on topsoils (38,39). Tropical rain forests are characterized by high levels of water recycling. When there is clear felling of such forests at low levels of externally added precipitation, the area may be converted into a savanna (40).

Marine, freshwater, and wetland ecosystems generate extensive services. It is estimated that the value of a number of ecosystem services in the entire biosphere is in the range of US$16–54 $\times 10^{12}$; the average (US $33 $\times 10^{12}$) is in excess of the gross world product (41). Of the average value of US $33 $\times 10^{12}$, somewhat over US $27 $\times 10^{12}$ comes from marine, freshwater, and wetland ecosystem services. There is even a case to attribute infinite monetary value to ecosystem services provided by living nature because human life would be impossible without them.

For sustainability, as defined here, ecosystem services should be maintained at their present level. To attain this, the area allocated to nature and the abiotic conditions under which nature functions should be such that ecosystem services do not change.

A debate has developed regarding the question, how much biodiversity can be reduced without reducing ecosystem services. Loss of a species should not lead to loss of function when there is functional redundancy. However, experimental evidence suggests that the statistical relation between species diversity and ecosystem functions important to humans may well be strong, though it is likely that actual contributions may show large differences between species (42–45). Even when a species seems functionally redundant, it has been found that the actual loss of apparent functional redundancy may come at great cost (46). Also a “redundant species” may still have an insurance function in case of ecosystem perturbation (47). So sustainable management is presumably strongly dependent on maintaining species diversity in ecosystems as that has developed.

A main problem in attaining criteria for sustainability is that many ecosystem services in practice do not have a price. There are economic incentives that may be conducive to the sustainable management of ecosystems. These include user fees for national parks, royalties from bioprospecting, conservation easements, and mitigation banking. So far, however, the application and effect of economic incentives are very limited (35). Legal systems for protecting nature are, with a few exceptions, rather focused on preventing the extinction of specific species than on ecosystem services. A major effort is needed to base nature conservation on the true value of ecosystem services.

SUSTAINABLE WATER MANAGEMENT ON MEDITERRANEAN ISLANDS: RESEARCH AND EDUCATION

Manfred A. Lange

Centre for Environmental Research
Münster, Germany

INTRODUCTION

The availability of water in adequate quality and sufficient quantity is indispensable for human beings and the functioning of the biosphere. Shortcomings in integrated water management practices aimed at linking natural, social, and economic needs in a given region, wasteful and inadequate use of water, and inadequate administrative practices have often resulted in depleted water resources. Pollution has exacerbated these problems.

Addressing issues of water quality and water supply, the European Union-Water Framework Directive (WFD) came into force on December 22, 2000 (1). Two basic goals are to be achieved by the parties within the following 10 to 15 years: (1) users will have to bear the full cost of the water supplied (1, Annex III, WFD), and (2) water will have to be provided based on "good ecological status" by adhering to practices that do not harm the environment. Moreover, the WFD strives toward implementing the "polluter pays principle."

Considering the long-term perspectives for sustainable water use in the European Union, the Mediterranean in general and its islands in particular deserve special attention for a number of reasons:

- Island water resources are largely influenced by the (non)existence, timing, and amount of precipitation. In some parts of the Mediterranean, the amount of (winter) precipitation has decreased (2), and the main precipitation period has shortened during the last few decades. This trend may continue as a result of regional climate change, thus exacerbating the problem (2,3).
- Overabstraction of aquifers, in many instances, has led to lowering of the water table and the deterioration of water quality, primarily through saltwater intrusion in coastal areas. In some cases, this has resulted in exploitation of lower lying aquifers, thereby further reducing the remaining reserves of the islands.
- The demand for water is expected to increase on Mediterranean islands because of, among others, an expected increase in the population and the number of tourists. Conflicts between competing users of water will inevitably intensify.
- Agriculture is the predominant consumer of water on most Mediterranean islands (Fig. 1). Agricultural activities threaten the availability (quantity) but

also the quality of water due to the use of fertilizers, pesticides, and the release of olive-oil-mill wastes. During the summer months, tourism also becomes a major water consumer, and competition between agriculture and tourism can lead to serious stakeholder conflicts.

- The rational distribution and use of water requires resolving conflicts among the different end users of water. Such conflicting interests have contributed to the unsustainable use of water in the past.
- Given the need for the protection and the sustainable use of island water resources, coupled with the need to satisfy the increasing water demand, the islands have to formulate strategic policies based on integrated water management and should pay proper attention to the objectives of the WFD.

The WFD may introduce an effective avenue to address these problems, but at the same time its implementation presents a challenge. The problems that govern the availability of water in the Mediterranean have specific manifestations on each of the islands, but the islands also share a number of general characteristics and patterns. Thus, learning how to implement the WFD best on selected Mediterranean islands through comparisons, mutual learning, and experience sharing offers the prospects of deriving a more generic set of recommendations.

The overriding characteristic that governs most of the problems mentioned lies in their complex and multifaceted nature, which requires a holistic approach involving the integration of natural and social sciences. Thus, in considering water availability and water use and deriving strategies for sustainable and equitable distribution of water, interdisciplinarity is a necessary condition.

Moreover, lasting solutions for sustainable water management in the Mediterranean will be found only through recommendations and/or regulations that are based on mutually agreed principles among the stakeholders. This requires a stakeholder-based, participatory process that builds on the results of scientific investigations, on the one hand, and on the consent of major stakeholders, on the other (5).

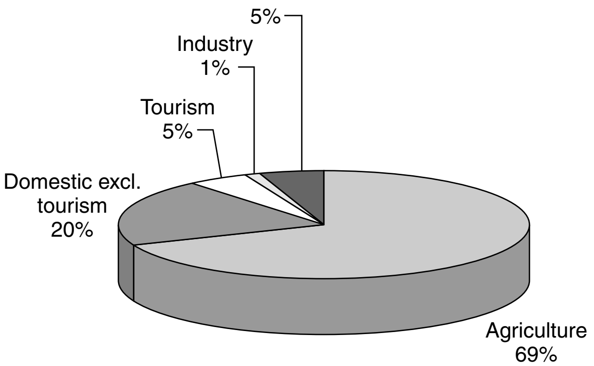

Figure 1. Distribution of water consumers on Cyprus in 2000 (after Reference 4). The predominance of agriculture as the major user is typical of most Mediterranean islands.

TOWARD SUSTAINABLE, STAKEHOLDER-BASED WATER MANAGEMENT PRACTICES: THE MEDIS PROJECT

To address the problems of water management on Mediterranean islands in accordance with the criteria just introduced and by observing the need to implement the WFD swiftly and effectively on these islands, an EU-funded research project, MEDIS (toward sustainable water use on Mediterranean islands: addressing conflicting demands and varying hydrological, social, and economic conditions), has been implemented. MEDIS is carried out by a consortium of 12 institutions from seven countries.

Goals and Objectives

The overall goal of MEDIS is to contribute to sustainable and equitable use of water on Mediterranean islands. This is to be achieved through a set of recommendations to implement sustainable, equitable water management regimes on each island that reflect the current and possible future (climatic) conditions on each island. These recommendations will comply with the WFD and will build on the conclusions reached in consultation with stakeholders from all five islands involved. More specifically, work in MEDIS

- concentrates on a synthesis of results from previous studies and integrating information from various disciplines;
- is carried out on a catchment scale on major islands of the Mediterranean stretching from the west to the east: Majorca, Corsica, Sicily, Crete, and Cyprus;
- seeks to develop an infrastructure for participatory stakeholder involvement that will enable establishing sustainable and equitable water management schemes;
- considers (possibly drastically) altered conditions that may arise due to changed climatic conditions through a set of what-if scenarios;
- concentrates on agriculture as the predominant consumer of water on Mediterranean islands; and
- undertakes comparative analyses between the islands to derive generic conclusions/recommendations and to use possible common solutions to water management problems in compliance with the WFD.

Methodology

The major stages of the research strategy applied in MEDIS, which are carried out during a 4-year period, are depicted in Fig. 2. The initial phase of the project comprises a thorough assessment of the major characteristics that determine the availability and the demand of water on each island. This includes (current and future) climatic conditions; (geo) physical, pedological, and hydrologic characteristics as well as the vegetative cover on each island; major sources and consumers of water; agricultural practices in irrigation and agrochemical use; conditions governing water management and administration; basic demographic and social conditions; and major economic indicators, particularly related to water-dependent economic sectors. This assessment leads to a typology of water management regimes for each island, based on a number

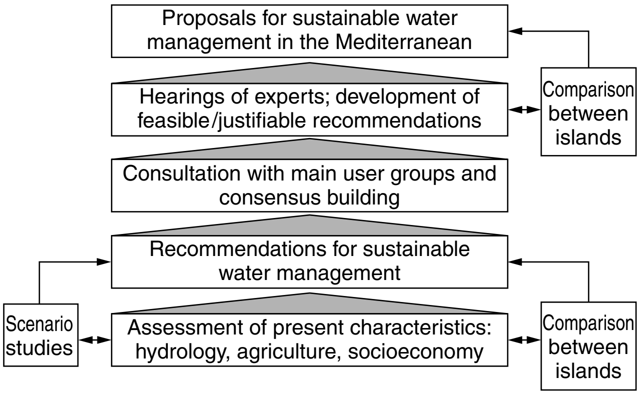

Figure 2. Schematic of major stages of the MEDIS research strategy (for details, see text).

of well-defined parameters, that share similar quantitative or qualitative ranges for each of the types specified. The final result of this project stage is a first set of recommendations for improved water management practices geared to each of the management types identified.

An integral part of the work during this stage of the project is involving stakeholders and gaining their help in specifying some of the previously mentioned parameters. They are either part of the supply network for water and/or consumers of water, so their experience and expertise are indispensable for the initial assessment. Therefore, an important activity during the first project stage is identifying relevant stakeholders and involving them in Intra-Island Workshops. In addition, Inter-Island Workshops among the islands under consideration are conducted.

Current physical/climatic conditions and possible future variations (i.e., scenario studies) are also considered. For climate, the results of the Intergovernmental Panel on Climate Change (IPCC) scenarios (6) are used in a downscaled format (or through a dedicated regional climate model). When considering prospective situations on each of the islands, future scenarios of other major determinants of water supply and demand are taken into account accordingly.

The spatial scales of the investigations depend on the specific questions asked. MEDIS is being carried out on a local (hundreds of m to km) and/or catchment scale, and inferences for all islands are drawn by appropriate upscaling. The Mediterranean scale is being addressed by comparing islands. As for temporal scales, MEDIS focuses on two time slices of 20 years centered at 2020 and 2050, corresponding to the IPCC assessments.

The second stage in the project comprises intensive consultation with the stakeholders on each island. Typical stakeholders include regional or national water administrative bodies, representatives of institutions or enterprises representing major water users, agricultural or industrial enterprises that develop and/or maintain water management schemes, nongovernmental organizations concerned with water issues, farmers and farming cooperatives, tourist enterprises and operators, and communities/residents in need of water.

The major goal comprises a consensus among the different stakeholder groups concerning their major objectives for an improved water management regime. At the same time, the stakeholders should bear in mind the recommendations from the first stage of MEDIS and specify possible alterations and amendments to these recommendations. Ultimately, a new set of recommendations will be obtained that represents both the factual basis and the mutually agreed upon principles for an improved water management regime on each island.

During the third stage of the project the second set of recommendations will be subject to scrutiny by legal and institutional experts. The objective here is to ensure that the recommendations comply with regional and national laws and regulations, and agree with the goals and principles of the WFD. This may result in a third set of recommendations that reflect the factual basis, the stakeholder consensus, and the legal and institutional requirements on national and European scales.

In the final stage of the project, island-specific conclusions will be discussed in the broader context of the Mediterranean Basin through Inter-Island Workshops and attempts to synthesize conclusions. The common solutions and possible deviations in the conclusions among the islands will be discussed and resolution attempted. Ultimately, this results in desired recommendations for improved, sustainable and equitable water management in compliance with the WFD and national rules and regulations. It is expected that these recommendations will significantly enhance the implementation of the WFD in the Mediterranean Basin.

First Results

Essential information was compiled in a series of Island Reports. In summary, the islands

- comprise areas between 3600 km^2 (Majorca) and 28,000 km^2 (Sicily),
- have permanent populations between 0.26 million (Corsica) and 5.6 million (Sicily),
- receive mean annual precipitation between 500 (Cyprus) and 1000 mm (Corsica, Sicily),
