Removal of heavy metals by wetland hydrophytes presents the problem of plant biomass collection to prevent decomposition, thus recycling accumulated metals, because many of the wetland plant species typically undergo much faster decomposition compared to terrestrial species (7). Phytomining, the recovery of accumulated trace metals, might be side benefits of phytoremediation; however, concerns about plant matter getting into the food chain by direct consumption or by decomposition pathways (49) include considerable ecological and human health problems. Careful harvesting techniques must be used to prevent loss of metal-enriched plant biomass. Biomass recycling is a major concern because even wave action can remove fresh biomass prior to harvesting (7).

Removal of Nutrients

Removal of macronutrients, nitrogen and phosphorus, by stabilized constructed wetlands is a complex cyclic process believed to involve a number of "conceptual compartments," such as soils, sediments, and litter/peat (80% of the total nutrient load), water column (15–20%), and plants/other biota (5%) (20,53). The primary mechanisms of nutrient removal from wastewater in constructed wetlands are microbial processes such as nitrification and denitrification as well as physicochemical processes such as the fixation of phosphate by iron and aluminum in the soil filter (17). The hydraulic retention time, including the length of time the water is in contact with the plant roots, affects the extent to which the plant plays a significant role in the removal or breakdown of pollutants (17).

A survey of literature on the nutrient removal efficiencies of constructed wetlands indicates extreme variations (20). Phosphorus removal efficiency is strongly dependent on loading rate, 65–95% removal is achieved at loading rates less than 5 g/m^2/y. However, removal efficiency decreases to 30–40% or even less when phosphorus loadings are greater than 10–15 g/m^2/y (54). Nitrogen removal efficiencies reportedly decline at mass loading rates above 20 kg/ha/d (20). Total nitrogen removals up to 79% are reported at higher loading rates of up to 44 kg/ha/d from constructed wetland systems in the United States (55).

Nutrient removal by wetland systems is also a function of climate; tropical climatic conditions generally tend to increase nutrient removal efficiencies (20). The nitrogen and phosphorus removal efficiencies of a full-scale plant treating domestic wastewater in Bhubaneshwar, India, are over 70% and 43%, respectively (56). A pilot scale study in Central India also indicated higher removal efficiencies for both nitrogen and phosphorus in the range of 58 to 65% (57). A full-scale, gravel bed, horizontal flow system build in Kathmandu, Nepal, reports nitrogen removal in the range of 80–99% and phosphorus removal from as little as 5% to 69% (58).

SUMMARY AND FUTURE DIRECTIONS

Constructed wetlands can be designed to remove a wide range of pollutants from wastewater. Due to their low operating, maintenance, and energy costs, constructed wetlands could rapidly become the ideal method to achieve sustainable wastewater management goals. Several laboratory-scale mesocosmic studies have established the versatile nature of wetlands to remove pollutants, but only a few large-scale field studies have been conducted to gauge the remediation potential of constructed wetlands. The use of constructed wetlands to treat wastewater is a relatively new and emerging technology. The initial results are encouraging, but the full range of capabilities and limitations of this technology have not yet been uncovered.

Degradation of pollutants by wetlands involves complex interactions among wetland species, sediment/water geochemistry, and climate. Therefore, it is crucial to determine the effectiveness of remediation by implementing a detailed monitoring program that accounts for the interactions of numerous variables ranging from the composition of the plant species to the seasonality of hydrologic flow. Carefully planned monitoring programs are essential to determine the effectiveness of the wetland remediation strategy and are also instrumental in achieving regulatory acceptance.

Public concern during the past 20 years has strengthened regulations on wastewater discharges and resulted in substantial progress in treating point sources of water pollution, especially for large cities and major industries. Widespread implementation of the constructed wetlands treatment technology may accomplish the same for small communities, small industries, farmers, and developers, where low cost technologies are important. The available knowledge on constructed wetlands has grown extensively over the last decade, but much more research is needed to determine the capabilities of plants and microorganisms to remove pollutants from wastewater. As more wetland projects are undertaken and further field-based research is conducted, the treatment possibilities of constructed wetlands will be better understood.

UNRECOGNIZED POLLUTANTS

G. Fred Lee
Anne Jones-Lee
G. Fred Lee & Associates
El Macero, California

INTRODUCTION

The U.S. water pollution control program focuses on the control of a limited group of chemicals, the 126 current "priority pollutants." The chemicals included on the list of priority pollutants were originally selected in the mid-1970s through a litigation settlement. The list did not receive appropriate peer review for its representation of the chemical contaminants of most pressing importance to public health and environmental quality. That notwithstanding, the priority pollutants remain the focal point of water quality investigation and management. Limited attention is given to the evaluation and regulation of the many thousands of other potential pollutants that are in municipal and industrial liquid and solid wastes, even in light of the myriad of other chemicals currently in commercial and personal household use, and those that come into use annually.

Daughton (1) highlighted the growing concern about unrecognized, unregulated pollutants, indicating that over 22 million organic and inorganic substances exist, with nearly 6 million commercially available. The current water quality regulatory approach addresses fewer than 200 of these chemicals. He also noted,

> *"Since the 1970s, the impact of chemical pollution has focused almost exclusively on conventional "priority pollutants," especially on those collectively referred to as "persistent, bioaccumulative, toxic" (PBT) pollutants, "persistent organic pollutants" (POPs), or "bioaccumulative chemicals of concern" (BCCs).*
>
> *The "dirty dozen" is a ubiquitous, notorious subset of these, comprising highly halogenated organics (e.g., DDT, PCBs).*
>
> *The conventional priority pollutants, however, are only one piece of the larger risk puzzle.*
>
> *Regulated pollutants compose but a very small piece of the universe of chemical stressors to which organisms can be exposed on a continual basis.*

Similarly, Dr. K. Hooper of the Hazardous Materials Laboratory, California EPA Department of Toxic Substances Control, recently noted (2),

> *"Over the past 25 years, tens of thousands of new chemicals (7 chemicals per day) are introduced into commerce after evaluation by USEPA. Few (100–200) of the 85,000 chemicals presently in commerce are regulated. We have reasons to believe that a much larger number than 200 adversely affect human health and the environment."*

Periodically, unregulated chemicals that are in use are discovered to be widespread pollutants, posing a significant threat to public health and the environment. Examples of such findings and illustration of the need to address the broader issue of previously unrecognized pollutants are presented below.

EXAMPLES OF PREVIOUSLY UNRECOGNIZED POLLUTANTS

Pharmaceuticals and Personal Care Products (PPCPs)

Increasing attention is being given to pharmaceuticals and personal care products (PPCPs) as environmental pollutants. At the California Bay Delta Authority (CBDA) Contaminant Stressors Workshop, Dr. Christian Daughton, Chief, Environmental Chemistry Branch, US EPA National Exposure Research Laboratory, addressed this issue in his presentation entitled, "*Ubiquitous Pollution from Health and Cosmetic Care: Significance, Concern, Solutions, Stewardship—Pollution from Personal Actions*" (1).

Daughton (1) pointed out that a wide variety of chemicals that are introduced into domestic wastewaters are being found in the environment. Various chemicals (pharmaceuticals) used by individuals and to treat pets, outdated medications disposed of into sewage systems, and treated and untreated hospital wastes discharged to domestic sewage systems end up in receiving waters for domestic wastewater treatment plant effluents. Further, transfer of sewage solids ("biosolids") to land, industrial waste streams, landfill leachate, releases from aquaculture of medicated feeds, etc. also introduce these chemicals into the environment. Many of these chemicals are not new and have been present in wastewaters for some time. However, they are only now beginning to be recognized as potentially significant water pollutants and are largely unregulated as water pollutants.

According to Daughton (1),

> *"PPCPs* [Pharmaceuticals and Personal Care Products] *are a diverse group of chemicals comprising all human and veterinary drugs (available by prescription or over-the-counter; including the new genre of "biologics"), diagnostic agents (e.g., X-ray contrast media), "nutraceuticals" (bioactive food supplements such as huperzine A), and other consumer chemicals, such as fragrances (e.g., musks) and sun-screen agents (e.g., mehylbenzylidene camphor); also included are "excipients" (so-called "inert" ingredients used in PPCP manufacturing and formulation)."*

Although the full range of impacts of PPCPs is just beginning to be investigated, PPCPs are being found to have adverse impacts on aquatic ecosystems. For example, Daughton (1) discussed the relationship between PPCPs and endocrine disrupters, which are believed to be responsible for causing sex changes in fish. In addition, in a feature article in *Environmental Science and Technology*, Eggen et al. (3) reviewed a number of the issues pertinent to understanding the impacts of PPCPs and other chemicals that can cause endocrine disruption, DNA damage/mutagenesis, deficiencies in immune system, and neurological effects in fish and other aquatic life. (Additional information on PPCPs is available at www.epa.gov/nerlesd1/chemistry/pharma/ index.htm.)

Perchlorate

Perchlorate (ClO_4^-), used in highway safety flares and other applications, is another example of a chemical that is now being found in surface and groundwaters in sufficient concentrations to pose a threat to human health. Perchlorate is derived from several sources. Silva (4) of the Santa Clara Valley, CA Water District, noted the potential for highway safety flares to be a significant source of perchlorate contamination to water, even when the flares are 100% burned. According to him, one fully burned flare can leach up to almost 2,000 μg of perchlorate, and

> *"A single unburned 20-minute flare can potentially contaminate up to 2.2 acre-feet* [726,000 gallons] *of drinking water to just above the California Department of Health Services' current Action Level of 4 μg/L* [for perchlorate]" (4).

Silva also pointed out that more than 40 metric tons of flares were used/burned in 2002 alone in Santa Clara County. California's Office of Environmental Health Hazard Assessment recently conducted an evaluation of the hazards of perchlorate in drinking water. The 4 μg/L action level for perchlorate in drinking water was based on the detection limit; it has been revised to 6 μg/L based on the recent OEHHA evaluation.

Polybrominated Diphenyl Ethers (PBDE)

Another unrecognized, unregulated pollutant is the polybrominated diphenyl ethers (PBDEs) used as a flame retardant on furniture and other materials. Hooper (2) recently discussed finding PBDE in human breast milk and in San Francisco Bay seals, and the fact that archived human breast milk shows that this contamination has been occurring for over 20 years. According to McDonald (5) of the California Environmental Protection Agency, Office of Environmental Health Hazard Assessment,

> *"Approximately 75 million pounds of PBDEs are used each year in the U.S. as flame retardant additives for plastics in computers, televisions, appliances, building materials and vehicle parts; and foams for furniture. PBDEs migrate out of these products and into the environment, where they bioaccumulate. PBDEs are now ubiquitous in the environment and have been measured in indoor and outdoor air, house dust, food, streams and lakes, terrestrial and aquatic biota, and human tissues. Concentrations of PBDE measured in fish, marine mammals and people from the San Francisco Bay region are among the highest in the world, and these levels appear to be increasing with each passing year."*

PBDEs are similar to PCBs and are considered carcinogens. Some of the PBDEs are being banned in the United States and in other countries.

Pesticides

Another example of unidentified pollutants was given by Kuivila (6). She discussed the fact that approximately 150 pesticides used in California's Central Valley exist that are a threat to cause water quality problems in the Delta and its tributaries. The current pesticide water quality regulation program considers only about half a dozen of those.

CONCLUSIONS AND RECOMMENDATIONS

The presence of untold, unregulated pollutants in environmental systems, as illustrated above with the examples of PPCPs and others, is not unexpected based on the approach that is normally used to define constituents of concern in water pollution control programs. Based on the vast array of chemicals that are used in commerce, many of which are or could be introduced into aquatic systems from wastewater and stormwater runoff, it is likely that many other chemicals will be discovered in the future that are a threat to public health or aquatic ecosystems. A pressing need exists to significantly expand water quality monitoring programs to specifically search for new, previously unrecognized water pollutants. As demonstrated by the perchlorate and PBDE situations, monitoring programs that focus on priority pollutants stand to be significantly deficient in properly defining constituents of concern with respect to impairing the beneficial uses of waters.

POLLUTION OF SURFACE WATERS

Nitish Priyadarshi
Ranchi University
Jharkhand, Ranchi, India

INTRODUCTION

According to the American College Dictionary, pollution is defined as "to make foul or unclean; dirty." Water pollution occurs when a body of water is adversely affected by the addition of large amounts of materials to the water. When it is unfit for its intended use, water is considered polluted.

Comprising over 70% of the earth's surface, water is undoubtedly the most precious natural resource that exists on our planet. Without the seemingly invaluable compound of hydrogen and oxygen, life on the earth would be nonexistent. It is essential for everything on our planet to grow and prosper. Although we as humans recognize this fact, we disregard it by polluting our rivers, lakes, and oceans. We are slowly but surely harming our planet to the point where organisms are dying at a very alarming rate. In addition to innocent organisms dying off, our drinking water has become greatly affected, as is our ability to use water for recreation. To combat water pollution, we must understand the problem and become part of the solution.

Surface water pollutants are generally classified into these eight major categories:

1. sewage and waste
2. infectious agents
3. particulate soil and mineral matter
4. dissolved toxic pollutants.
5. mineral and chemical compounds
6. radioactive nuclides
7. thermal pollutants
8. organic chemical exotics

Surface water should be free from the following contaminants (1):

1. Compounds that impart color, turbidity, and odor such as greases, oils, toxic metals, phenols, and organics
2. Toxic radionuclides that acutely affect the physiology of humans, animals, and aquatic organisms
3. Substances that may precipitate to form objectionable deposits or float on the surface as oil, scum, or debris
4. Heavy materials that check the growth of aquatic flora and fauna
5. Thermal effluents should not increase the water temperature by 3 to 5 °F.
6. Substances that are likely to enhance the growth of undesirable aquatic life

Components of surface water are listed in Table 1.

Table 1. Typical Analysis of Some Surface Waters[a]

Component (ppm)	X[b]	Y[c]
Silica	9.5	1.2
Calcium	4.0	36.0
Magnesium	1.1	8.1
Iron (III)	0.07	0.02
Total hardness as $CaCO_3$	14.6	123
Sodium	2.6	6.5
Potassium	0.6	1.2
Sulphate	1.6	22
Chloride	2.0	13
Nitrate	0.41	0.1
Bicarbonate	18.3	119
Total dissolved solids	34	165

SOURCES OF SURFACE WATER POLLUTION

Surface water comes in direct contact with the atmosphere, streams, rivulets, and surface drains. So a continuous exchange of dissolved and atmospheric gases occurs and wastes are added through water conveyance.

There are many causes of surface water pollution but two general categories exist: direct and indirect contaminant sources. Direct sources include effluent outfalls from factories, refineries, waste treatment plants, decomposed plant animal matter, and radioactive materials and wastes. Indirect sources include effluent contaminants that enter the surface water supply from surface soils and from the atmosphere via rainwater. Soils contain the residue of human agricultural practices (fertilizers, pesticides, etc.) and improperly disposed of industrial wastes. Atmospheric contaminants are also derived from human practices (such as gaseous emissions from automobiles, factories, and even bakeries).

Impact of Livestock Production Practices on Surface Water Quality

Livestock practices that can impact surface water quality include both intensive and nonintensive operations. Intensive operations include feedlots (>500 head of cattle), dairies, and wintering sites; nonintensive operations include pasture, cow-calf operations, and watering sites for cattle. Waste management and disposal can also impact water quality. Livestock density is not the only factor affecting water quality; siting and management are also important considerations. Water quality parameters related to livestock production include nutrients (nitrogen and phosphorus), microorganisms (e.g., bacteria, faecal coliforms, *Cryptosporidium, Giardia*), and organic materials such as livestock wastes.

Impact of Pesticides on Surface Water Quality

Pesticides can move into surface water by both point and nonpoint source pollution. Point source pollution occurs when pollutants originate from a single event or fixed site. Point source events include chemical runoff during improper storage, mixing/loading, disposal or misapplication to waterbodies. Nonpoint source pollution is the movement of pesticides from areas across watersheds over time into the surface water. Runoff (water flow) and erosion (soil particles) are common forms of nonpoint source pollution of surface water from agriculture. Pesticides are most susceptible to runoff immediately after application when they are in the “mixing zone.” The mixing zone is the thin layer (1/10 to 1/3 inch) at the soil surface.

Impact of Fertilizers on Surface Water Quality

Fertilizers given to crops are not always fully consumed; part remains in the soil absorbed by soil colloids and influences the quality of surface water when it is dissolved. Chemical fertilizers consist mainly of relatively simple compounds of nitrogen, phosphorus, and potassium, which are nutritive elements for plants. Nitrogen when that enters surface water tends to cause eutrophication of lakes and other surface water reservoirs.

Impact of Mining

In many countries, water pollution related to the mining industry can be traced back to older times compared with that caused by other industries. The characteristics of waste water from mining industries vary greatly depending on the kind of mine (3).

Metal Mining Industry. Many kinds of wastewater are discharged. For example, mine water, ore dressing water, wastewater from smelters, in general, contain metal ions, sulfuric acid and suspended solids at high concentrations.

Coal Mining Industry. Wastewater from coal mines consists mainly of mine water, coal dressing water, trace and major elements and contains a large quantity of suspended solids.

Sulfur Mining. In general, wastewater from sulfur mines contains large quantities of sulfuric acid and iron and has a low pH.

Stone-Quarrying and Clay-Supply Industries. These industries supply limestone, building stones, porcelain clay, and so on. Wastewater from the sites of these industries generally contains large amounts of suspended solids. Mining activities generate large quantities of solid wastes in most cases from large heaps. Such wastes not only pollute surface water by exuding toxic substances and also by rapid generation of suspended solids in surface water when the heap is washed away by a heavy rainfall or a flood.

Food Processing Industry

A common characteristic of wastewater from all types of food processing industries is the high organic content. Materials contained in wastewater can be divided roughly into carbohydrate, protein, fat, and mixtures of them. In many instances, wastewater contains oil, nitrogen, and phosphorus. In starch production, sugar refining, and brewing, the BOD level of waste water is especially high.

Paper and Pulp Industries

These are typical water consuming industries, and the levels of COD and suspended solids in wastewater are extremely high. A large quantity of waste paper fiber is also discharged as suspended solids together with wastewater.

Iron and Steel Industry

Wastewater from the cooling and cleaning processes for coke furnace gas contains ammonia, cyanide, and phenols. There is also wastewater from the dust collecting process of each furnace that contains suspended solids (coke dust and ore) and that from the pickling process, which contains acid, iron, and oil.

Electroplating Industry

Toxic substances released through wastewater are various heavy metals (cadmium, zinc, copper, etc.), cyanide, hexavalent chromium, acids, and alkalies.

Additional Forms of Water Pollution

Additional forms of water pollution exist in the forms of petroleum, radioactive substances, and heat. Petroleum often pollutes surface waterbodies in the form of oil from oil spills. Besides supertankers, offshore drilling operations contribute a large share of pollution. One estimate is that one ton of oil is spilled for every million tons of oil transported. This equals about 0.0001%. Radioactive pollution can be human-made or natural. Radioactive substances are produced as waste from nuclear power plants and from the industrial, medical, and scientific use of radioactive materials, or they can come from naturally occurring radioactive isotopes in water like radon. Specific forms of waste are from uranium and thorium mining and refining.

The last form of water pollution is heat. Heat is a pollutant because increased temperatures result in the deaths of many aquatic organisms. These increases in temperature are caused by discharges of cooling water from factories and power plants.

POND AQUACULTURE—MODELING AND DECISION SUPPORT SYSTEMS

Maria A. Szumiec
Polish Academy of Sciences
Chybie, Poland

SOLAR RADIATION AND TEMPERATURE IN SHALLOW STAGNANT WATERS

Physical environment plays a controlling role in all processes and events that occur in waters. Knowledge of water's dynamic characteristics and model elaboration is basic. Shallow stagnant waters are characterized by the individuality resulting from their small capacity. This is displayed in their receptivity to external factors, such as weather variability, that differentiates them from lakes. In a temperate climate, quick and distinct changes in meteorological events are displayed in variations in the solar radiation that penetrates into shallow waters, thus, in variations in light and thermal conditions. These changes are then transferred directly and/or via chemical processes to different levels of the biological chain. In fishponds, the final link in the chain is the stenothermic organism which is affected by the ambient temperature in a complex way. Penetrating light plays the decisive role in fish survival, limiting the concentration of oxygen dissolved in the water. The thermal conditions inhibit development and growth of the warm water fish, such as carp, throughout the considerable part of the year.

An attempt to approach the time-vertical distribution of penetrating solar radiation and temperature is presented in descriptive form and in simple mathematical language. The majority of the material is obtained from constructed carp ponds situated in a temperate climate ($\phi = 49°52'\mathrm{N}, \lambda = 18°48'\mathrm{E}$). Both the differentiated pond morphometry and the various periods of their use allow following their effects on the physical environment. Their average surface area is equal to some thousand square meters, and the average depth varies from 120 cm in the warm season to 200 cm in winter. The simultaneous time-vertical distribution of temperature is presented in ponds whose surface areas are from some hundred to some thousand square meters and from 20–120 cm deep (Fig. 1). The gravitational water flow through the ponds requires inclination of their bottoms from the water inlet to its outlet. In deeper ponds, the difference in depth between shallow and deep places can exceed 1 m. Dikes one to two meters high above the water surface limit the wind stress, especially in smaller ponds.

Two periods limited by water temperature are distinguished; warm—from the beginning of April to the end of October, when the water temperature is above 4 °C, and cold—from November till March, when the temperature drops below 4 °C. Most of the examples presented deal with period from May till September, when the thermal conditions stimulate growth and development of the carp organism.

In the warm part of the year the water feeding ponds compensates only for evaporation and infiltration losses. During the winter, the scanty water flow through ponds covered with ice protects them from oxygen deficiency. The solar radiation flux density was monitored in the wavelength range 0.3–3.0 μm.

The Warm Season

Absorbed solar radiation is the main source of heat in shallow waters; the greatest heat losses take place in the evaporation process (1). In early spring, solar radiation

Figure 1. View from the air over the ponds of the Institute of Ichthyobiology and Aquaculture of the Polish Academy of Sciences at Gołysz.

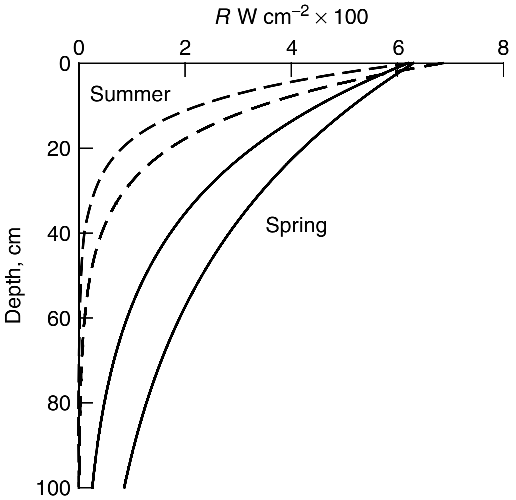

Figure 2. Density of the vertical solar radiation flux R under the free water surface in ponds during sunny and calm days; higher extinction presents ponds with a denser carp stock.

penetrates to the pond bottom. At night, cooling of the surface layers makes the whole water stratum circulate; a breeze enhances this process. Favorable light conditions during the day and nutrients released from the bottom during water circulation stimulate the development of flora and fauna and distinctly diminish the radiative flux penetrating to the bottom. Intensive absorption of the long waves and intensive scattering of the short waves of the radiative spectrum lead to high extinction in the surface layers and to an exponential decrease of R with the pond depth z (Fig. 2). On sunny days under the free water surface, $R(z)$ takes the form of

$$R(z) = R_0 e^{-\alpha z}$$

The coefficient α of vertical extinction is equal to 0.02 cm^{-1} in spring and increases in late summer; it also increases in ponds densely stocked with carp (Fig. 2) (2,3).

Values of α in ponds are approximately ten times higher than in most lakes, where they usually are computed per 1 m (4–6). A wind whose speed exceeds 3 m s^{-1} stimulates the circulation of the entire water stratum and also limits the penetration of vertical radiation to a certain degree. This distinct stratification of vertical radiation manifests in a distinct vertical decrease in temperature and oxygen content in ponds (Fig. 3).

In late summer in the deeper parts of ponds fertilized or densely stocked with carp, the oxygen concentration decreases below the saturation point (7). Macrophytes limit the radiation penetrating into ponds; however, the largest decrease occurs below dense floating plants. During sunny, calm days, the regular diel and seasonal solar radiative cycles follow the Sun's elevation in the whole water stratum (Fig. 4).

They can be approximately represented at all the depths by the geometric function

$$R(z,t)_d = \{A_R(z,t)\sin[\pi/T_R(z,t)]\}_d$$

Amplitude $A_{R,d}$ and period $T_{R,d}$ decrease approximately exponentially with depth. A decrease in $T_{R,d}$ shortens the day at the bottom (8). The seasonal cycle of $R(z,t)_s$ follows the Sun's elevation only in the surface water layer (Fig. 5). In the deeper parts, the average monthly radiative flux R decreases from May to September owing to decreasing water transparency.

An equation for the distribution $R(z,t)_s$ of seasonal–vertical solar radiation in ponds during sunny day is not a simple geometric function, though it can be satisfactorily computed using the first terms of the Fourier series

$$R(z,t)_s = \{\Sigma_n A(z)\sin[n\pi/T(z)t + \varphi(z)]\}_s$$

where $(A, T, \varphi)_s$ are the seasonal amplitude, period, and phase of $R(z,t)_s$ in the period from May–September.

The greater the surface area of ponds, the greater the role of wind in water circulation and in radiation extinction (9). Momentary cloudiness deforms the time–vertical

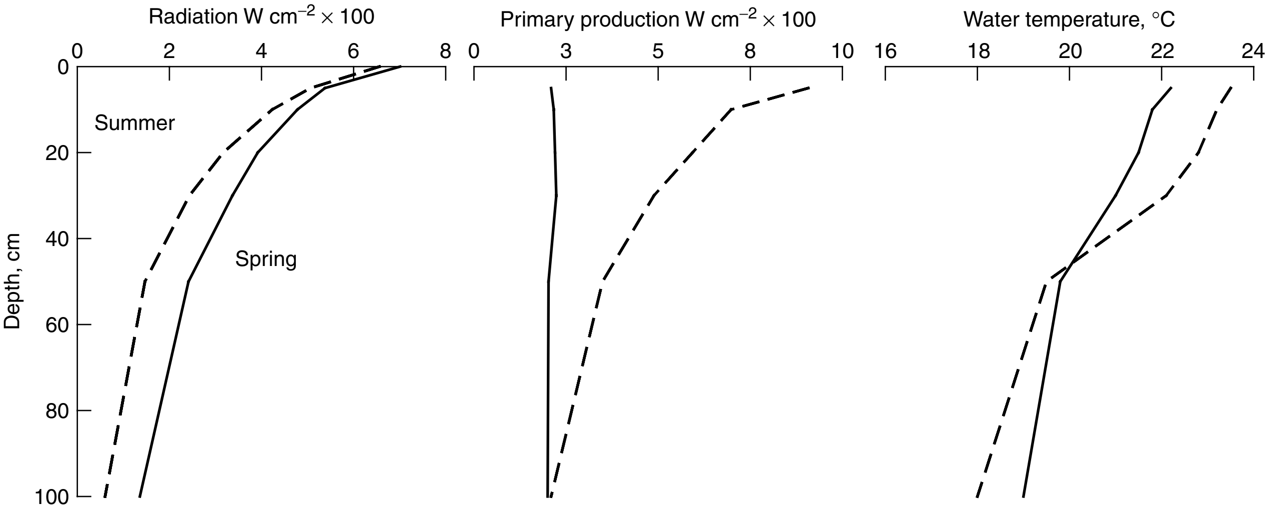

Figure 3. Example of the simultaneous vertical distribution of radiative flux, primary production, and water temperature in ponds on a sunny, calm summer day.

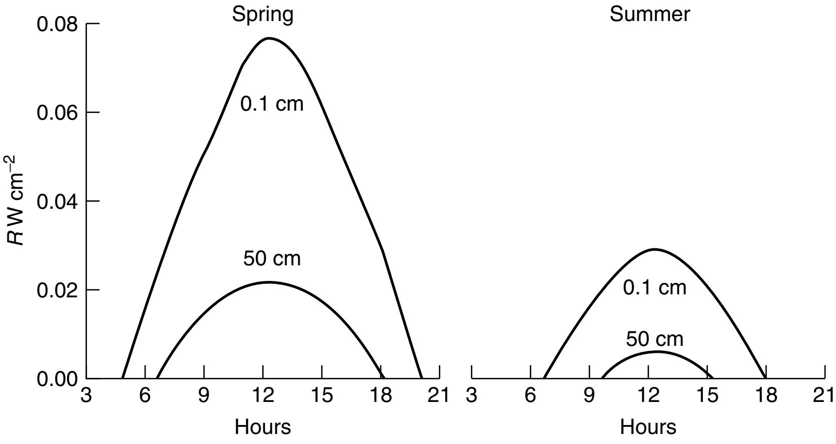

Figure 4. Diel cycles of radiative flux in ponds on sunny days.

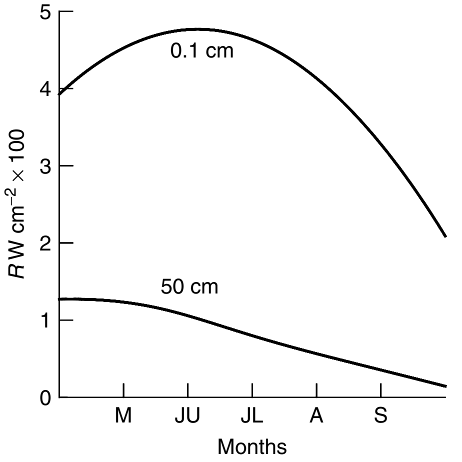

Figure 5. Seasonal cycles of radiative flux in ponds on sunny days.

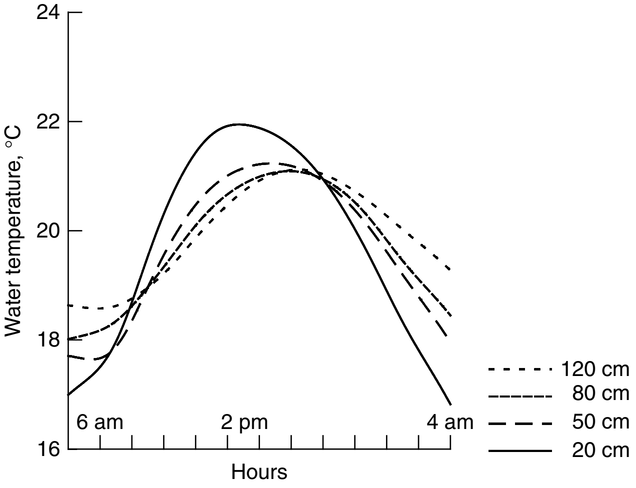

Figure 6. Simultaneous smoothed diel temperature cycles in ponds of different average depths on a sunny, calm summer day.

radiative flux and diminishes its density; cloudiness maintained for a whole day causes the daily radiative amplitude to approximate zero.

In shallow waters, the time–vertical distribution of the temperature ϑ is chiefly a resultant value of the absorbed radiation and heat losses in the evaporation process. During sunny, calm days, temperature cycles are semiregular geometric functions; that have with a slightly quicker increase in temperature during the morning hours and a distinctly slower decrease in the afternoon (Figs. 6 and 7). During the night, the temperature difference between surface and bottom water layers approaches zero. The diel amplitude and vertical gradient decrease exponentially as the average depth z of the pond increases (10,11).

In May, when sunny but cold northern air masses advect, the temperature in very shallow waters, for example, about 20 cm deep, can decrease to a few degrees in the early morning and increase to over 25 °C at noon. These great time variations may be lethal for some organisms, such as e.g., carp fry (12).

The Cold Part of the Year

In late autumn and in winter, the radiative flux reaches only a few percent of that recorded in summer and is additionally limited in ponds covered by ice. Only transparent ice allows radiation to penetrate to the bottom and to create favorable conditions for primary production. Under nontransparent ice, water flow through ponds is required to improve oxygen conditions. In non frozen ponds, the action of wind in stirring water ensures sufficient oxygen concentration for the fish.

The first autumnal deep cooling equalizes and lowers the temperature in the whole water stratum to 4 °C. A further temperature decrease is manifested in inverse stratification. Strong wind accompanied by cooling stirs the water, obstructs freezing, and lowers the temperatures in the whole stratum, sometimes even below 0.1 °C. In ponds covered by ice, the temperature in the lowest water layers is heated from the bottom and usually increases to 2–2.5 °C. Such vertical temperature distribution is normally maintained from the end of December to early March. The warm, windy weather in the second half of this month removes the ice cover and raises the water temperature to 4 °C, equalizing differences between the surface and the bottom (10).

In a temperate climate, the ice cover usually disappears one or more times from ponds (13), at first leading to momentary water heating and, under the consecutive

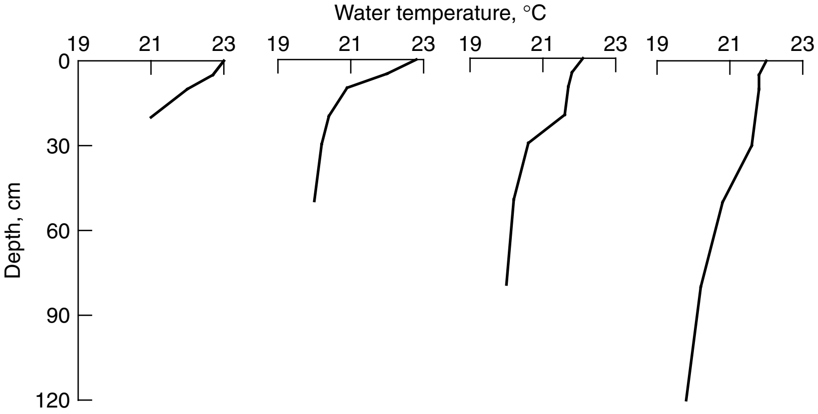

Figure 7. Simultaneous vertical temperature distribution in ponds of different average depths on a sunny, calm summer day.

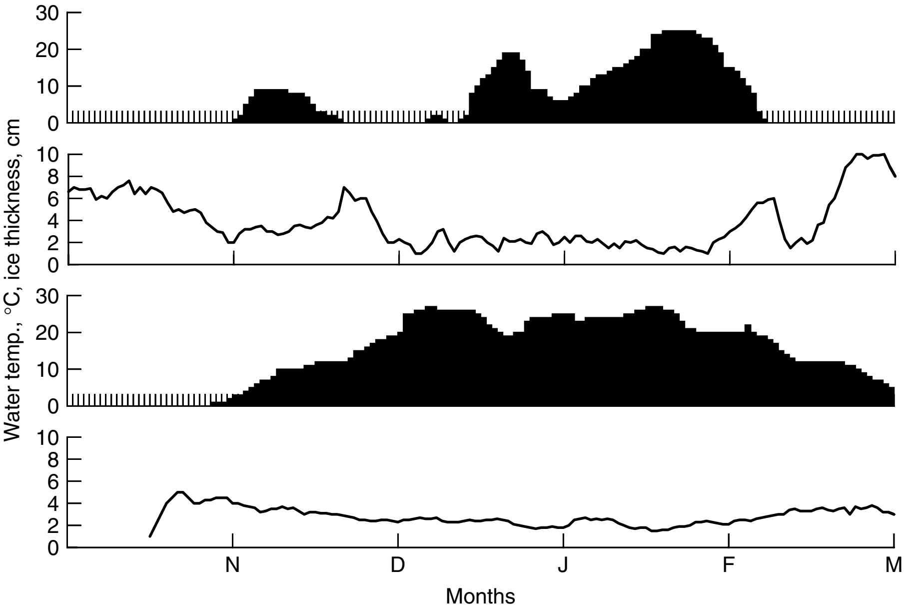

Figure 8. Examples of the average diel temperature patterns in the pond's bottom water layer during winter for momentary disappearances and permanent ice cover.

cooling, to a deep temperature decrease (Fig. 8). This creates unfavorable conditions for warm water organisms, for example, it increases the mortality of carp juveniles.

SUMMARY

The individuality of shallow stagnant waters, such as carp ponds, results from their small capacity and differentiates of their physical environment from lake environments. The density of the solar radiative flux that penetrates into water and the vertical temperature and oxygen stratification in ponds situated in a temperate climate are characterized by high extinction and vertical gradients, approximately ten times higher than in most lakes. Vertical extinction and attenuation increase from spring to late summer. Despite its high variability, average diel radiative courses can be represented by a simple geometric function, the seasonal distribution by the first several terms of the Fourier series. The diel cycle of water temperature in ponds corresponds to the annual cycle in lakes. The effect of increasing pond depths is displayed in the exponential decrease of the diel temperature amplitude and vertical gradient. During winter in ponds covered by ice, the temperature in the bottom water layer is maintained between 2 and 2.5 °C. Short warm weather periods lead to the momentary disappearance of ice and to a temperature increase, the consecutive cooling—to a considerable temperature decrease.

PUMPING STATIONS

Joseph D. Bankston
Louisiana State University
Baton Rouge, Louisiana

Surface water pumping stations are employed either to move water from an available surface location to where it is wanted or to remove it from a location where it is not wanted. Examples of the former include municipal or industrial water supply and irrigation, whereas municipal drainage pumps are examples of the latter.

Although differing in purpose, all have similarities of function and components. A pumping station must provide a water inlet for water to flow to the pump, a pump suitable for the water and delivery requirements, and a means of powering the pump. Although these requirements are interdependent to some degree, a reasonable approach is to consider them in order.

WATER INLET

Surface water frequently carries with it flotsam, jetsam, and aquatic species, both plant and animal, which must be prevented from entering the pump without severely restricting the flow of water. In addition, surface water levels often fluctuate. Settling basins, reservoirs, grids, screens, and multiple intakes or floating intakes have been used to address these problems.

Reservoirs and settling basins even out the water supply reducing fluctuation in the water level and because of reduced velocity of water flow, allow debris either to settle out or float to the surface. The reduced water flow also reduces the impact from objects in the water, which reduces the required strength of the intake structure.

It is preferable to obtain the water from a high-quality spot. For example, in many reservoirs, a preferred area is about 1 meter below the surface. As the level of the reservoirs change, this entails for a fixed structure, multiple ports located at different levels and valved so that the desired level may be chosen. Low entering velocities are desirable to avoid heavy loading of floating matter, sediment, and fish. Velocities of less than 0.5 ft/sec are preferable. Higher velocities result in heavier loading and greater maintenance requirements of the intakes. Current and foreseeable environmental conditions should be considered when siting the intakes. For example, winds that stir up sediments near shore may necessitate siting the intake away from the shoreline, as may pollution caused by shoreline development. Submerged intakes are possible if they do not interfere with navigation. Some small stations may employ floating intakes in which the intake is mounted on a floating structure such as a raft and connected to the pump with flexible pipe.

Pumps are guarded by physical barriers such as inlet grids or screens located upstream of the pump. These are usually arranged in series, beginning with those that have the largest openings and, by necessity, are the largest and strongest and proceeding to more restrictive barriers. These barriers must be cleaned periodically to prevent the accumulation of debris from severely restricting the water flow. Cleaning may be manual or automatic.

PUMPS

A pump (or pumps) is the second major component of a pumping plant. A pump must be capable of producing the required head while delivering the desired flow rate. It must also be able to handle the suction lift and the water quality or lack thereof. The latter is dependent on the water—its corrosiveness (salty water or chemical laden) and how much and what kind of trash or debris it may contain. An appropriate pump is constructed of materials that resist the corrosive characteristics of the water and of a design that is capable of handling the anticipated debris.

The head, suction lift, and flow rate are dependent on the piping system and the pump's characteristics. The piping system and pump interact to determine the operating point of the pump—flow rate and pressure. The pump cannot independently control these parameters. As the flow rate increases, the head (pressure) required to force the water through the pumping system also increases. A pump will typically have reduced capacity (flow) as the head it is pumping against increases. Thus, as the flow rate increases, the pressure a pump is capable of producing decreases while the pressure required to move the water increases. The operating point occurs at that flow rate under which the pressure produced by the pump is equal to the pressure required to move the water. The efficiency of a pump varies greatly with its operating point, with maximum efficiency occurring at a particular flow rate and falling off at higher or lower flow rates.

Manufacturers typically list an operating range in which the pumps performance is satisfactory; outside this range, the efficiency of the pump may be low and damage to the pump could occur. The required output of a pumping plant often varies over time. In order to avoid operating outside of the pumps designed range, a pumping station may employ multiple pumps or, when feasible, storage. Multiple pumps, although more costly initially, allow the flexibility of operating the pumps at an efficient operating point and also supply redundancy in case of pump failure.

Water is stored to equalize pumping rates over time. One example of storage is a system of drainage canals that themselves are drained by a pump (as in New Orleans, where much of the city lies below sea level and water must be pumped to provide drainage). The drainage canals provide storage volume as well as a means of flowing the water to the pumping station. Economies result from operating smaller pumps at their rated loads rather than large pumps at conditions less than optimum for the pump.

Two types of pumps are typically used in pumping stations—centrifugal and axial flow. Centrifugal pumps use centrifugal force to move water from one point to another and to develop pressure. Water enters at the center of an impeller, where it is spun and forced at a high velocity to the outer edge by the rotating impeller. The water is discharged into a casing where some of the velocity is converted into pressure. In an axial flow pump, both the water flow and the force exerted on the water by the pump is in a straight line along the axis of the pump. Axial flow pumps use a propeller or screw to apply force to the water. Axial flow pumps are particularly suited for high-volume low-head (pressure) applications. Their efficiency is high, especially when the head is in the range of 8 to 20 feet. An advantage of an axial flow pump is its ability to handle some debris. Centrifugal pumps, particularly high efficiency ones, often have close tolerances and may not handle trash as well. Centrifugal pumps are capable of operating efficiently at higher heads than axial flow pumps.

Suction lift is suction that a pump must apply to suck water into its inlet. It includes the height the pump is located above the water source, the friction loss in the pipe leading from the water source to the pump, and the energy imparted to the water as velocity. The amount of suction lift that a pump can produce is limited and varies with the individual pump. Excessive suction lift can cause inefficient operation, damage to the pump, or a failure to operate. For these reasons, it is preferable for the pump to be immersed in the water source or for the water to flow to the pump under gravity.

POWER

Pumps are powered by electric motors or internal combustion engines. Internal combustion engines include diesel, gasoline, natural gas, and liquefied petroleum gas (LPG) engines, with diesel being the most common. Each power source has advantages and disadvantages, many of which are site- and application-dependent. Deciding factors may include ability to do the job, reliability and availability of the power source and fuel supply, cost of equipment and installation, expected useful life, cost and ease of maintenance, convenience of operation, and the cost of energy to operate.

With the large variety of motors and engines available, a suitable example of either should be available and capable of powering the chosen pump. In general, internal combustion engines become more applicable as the power requirements and hours of use increase. Fuel efficiency of higher horsepower engines is usually better than for low horsepower engines (when each is properly matched to the load), and the higher fixed costs of engines as compared with motors can be spread over more operating hours as the hours of use increase. In addition, engines may be operated at varying speeds that provide more flexibility than most electric motors.

Advantages to electric motors exist if the cost of providing service and the cost of electricity, including energy, demand, and standby charges, are not prohibitive. The electric motor provides ease of operation, long life, requires minimal maintenance, and maintains its performance level year after year. In addition, initial costs are usually less than the cost of internal combustion engines, and the reliability is higher. They can, however, be shut down by the loss of electrical power. If the ability to operate during times when power is frequently lost (for example, during periods of flooding after a hurricane) is a necessity, or the pumping station is located in an area that suffers from frequent power outages, the internal combustion engine may be a better choice.

Natural gas engines and electric motors are dependent on the availability of natural gas service and electric service, respectively. If this service is not available, or the cost of obtaining it is too great, than diesel, gasoline, or LPG engines, which can be supplied with fuel from storage tanks, become the feasible power sources. Storage tanks allow considerable freedom in siting the power unit, but they also present additional concerns. The tanks should be designed to prevent pollution caused by leaks, spills, or evaporation, which includes guarding against leaks or spills and provides a means of containing the spill and of cleaning after a spill. For this reason, underground tanks are usually avoided. Above-ground tanks have their own sets of problems. They are more vulnerable to attack or vandalism and tend to have a greater degree of fuel evaporation than underground tanks. Not only does evaporation result in fuel loss, it may also lead to higher gum content of the fuel and poor engine performance and clogged filters, which, if severe enough, can prevent an engine from operating. Adulteration of the fuel can occur by the condensation of water inside the tank or, in the case of diesel fuel, by bacteria that feed on the fuel.

Energy costs are estimated under the conditions at which the pumping station operates. A thorough analysis requires the expected operating schedule including loading, time of occurrence, and duration of operation. Loading is particularly important in determining internal combustion engine fuel usage as the efficiency of delivered power is greatly impacted by the degree to which the engine is loaded. For example, Dr. Claude Boyd of Auburn

University obtained comparative efficiency data of an engine under different loading conditions. The engine, running at 1800 rpm, required 1.6 gal/hr of fuel to provide 4.9 horsepower. Increasing the load to 16.9 horsepower, a greater than three-fold increase, required 2.0 gal/hr, or only 25% greater fuel consumption. Similarly, the same engine running at 950 rpm required 0.7 gal/hr to supply 4.8 horsepower and 1.2 gal/hr to supply 16.7 horsepower. Under these different loading conditions, the number of horsepower hours produced by the same engine for each gallon of fuel consumed ranged from 3.1 to 13.9. Although not generally as sensitive to loading as internal combustion engines, electric motors also fall off in efficiency when underloaded, particularly at 50% or less of capacity. Energy costs for electricity is impacted by operating schedule as electric charges for commercial customers include demand and service charges in addition to energy costs. Demand and energy charges are charges for having electric power available, even if it is not used.

Maintenance costs can significantly affect the viability of a particular power option. Maintenance costs are considerably higher for internal combustion engines than for electric motors. Exact costs are difficult to pin down as they depend on duty cycle, cost of labor, degree of maintenance, and the individual engine or motor. A rough rule of thumb is to access internal combustion engines a 1 to 1.5 cent per horsepower-hour maintenance cost penalty in comparison with electric motors.

REGULATED RIVERS

Geoffrey Petts
University of Birmingham
Birmingham, United Kingdom

The regulation of river flows by dams and reservoirs has been fundamental to the advancement of civilization, and as dryland development continues, river regulation for water supply and power production continues to be central to economic growth. However, river ecosystems have evolved to become adapted to the natural pattern of flow variability from season to season and from year to year. Flow regulation has had dramatic impacts on both running-water and floodplain ecosystems, resulting in major changes in biodiversity and to fisheries.

River regulation involving the redistribution of water in space and time has been fundamental to the advancement of human society (see Water in History). Dams have been built to impound rivers and store runoff in large reservoirs for use in dry seasons, in drought years, for long-distance transfer to centers of high water demand—for irrigation agriculture or urban use—and for hydroelectric power production. It has been estimated that 800,000 dams of all sizes have been built on the world's rivers. The largest have dams over 150 m high and reservoirs with storage capacities greater than 25,000 million cubic meters or have a hydroelectric generation capacity of more than 1000 MW. Today, large dams contribute directly to about 15% of global food production and nearly 20% of the world's electricity supply (1). However, these dams, reservoirs, and diversions have had widespread ecological impacts. Worldwide, reservoirs have drowned about 1 million km^2 of land and in the United States 25,000 km of fast-flowing main rivers have been converted into stillwater lakes and on the Columbia-Snake system alone, 822 km of river habitats have been replaced by reservoirs. Here, the focus is on the regulated rivers downstream from dams.

By 1994, it was estimated that nearly 80% of the large river systems in Europe, the former Soviet Union, the United States, and Canada were at least moderately regulated by dams, reservoirs, and diversions (2). In the United States, the nation's major rivers, the Mississippi, Colorado, and Columbia, are completely regulated by a combination of large dams and weirs. Impoundments trap a river's sediment load and about 25% of the global flux of river sediments is trapped in reservoirs. Reservoirs can also alter the water quality of the river downstream of the dam, especially the annual pattern of temperature variations. However, the major impact of dams and reservoirs is to regulate the flow regime along the river below the dam and in many cases also to significantly reduce the total runoff (3).

In the 1990s, worldwide annual water withdrawals of 4430 km^3/yr represented between 35% and 50% of the average annual renewable resource, and irrigation agriculture consumed some 2500 km^3 of water. Obvious indicators of unsustainable water use include the failure of the Hwang He and Colorado Rivers to reach the sea in dry seasons and the shrinkage of the Aral Sea by 25,000 km^2. In the case of the Nile River, the influence of the Aswan Dam on the flow regime extends for 1000 km, changing the hydrographic conditions over the continental shelf of the southeast Mediterranean. Ecological indicators include the loss of productive floodplain wetlands, dramatic changes of channel size and shape, the degradation of river and floodplain fisheries, and the incursion of saltwater into coastal floodplain and delta areas.

Flow regulation includes the reduction of average annual runoff; reduced seasonal flow variability or reversal of the seasonal pattern to meet irrigation demands; altered timing of annual extremes, reduced flood magnitudes, and the imposition of unnatural, short-duration pulses associated with hydropower generation. Until the 1960s, most dams and reservoirs were designed and operated with little regard for the river and its flow-dependent ecosystems. In most cases, the only discharges from the dam were compensation flows—often a constant minimum flow—to meet the needs of industry along the river, especially for water mills, and other riparian uses, with higher flows during the rare periods of dam spill.

During low flow periods, many regulated rivers became dry until unregulated tributaries restored some flow. A survey in 1987 by the Institute of Hydrology of supply, regulating, and hydropower reservoirs in the United Kingdom showed mean compensation flows to the river below the dam of 15–17% of average daily flow, but for reservoirs operated only for water supply the compensation flow was zero. In dryland areas, often minimum *flows* were increased during the natural low-flow season to meet the needs of irrigation and other abstractors downstream, and along many rivers minimum water *levels* have been raised by weirs to meet navigation requirements.

All reservoirs regulate floods. The basic concept of flood regulation is empty space and reservoirs having a large flood-storage capacity in relation to the annual runoff can exert complete control upon the annual hydrograph of the river downstream. However, even when a reservoir is full to spillweir level, temporary storage of floodwaters within the lake plays an important role in reducing the maximum rate of outflow from the reservoir when the water area of a reservoir is 2% or upward of the catchment area. Along many regulated rivers, the mean annual flood has been reduced by more than 25% and there are examples where the 50-year flood has been reduced by over 20%.

Flood regulation and the maintenance or increase of minimum flows has led to major changes in the size and shape of river channels (4). Degradation has occurred immediately below some dams because of the trapping of the sediment load behind the dam, but the reduction of channel size in response to the reduced flood magnitudes has been dramatic—channel capacities being reduced by 50% or more in some cases. Rates of channel narrowing have been particularly rapid along some semiarid rivers where the maintenance of perennial flows encouraged the rapid establishment and growth of woody vegetation on exposed sediments. Elsewhere, rapid aggradation has occurred at confluences between regulated rivers and tributaries carrying high sediment loads forming deltas and bars that can extend for several kilometers below the confluence.

In the past, the most disturbing feature of regulated rivers was that the environmental changes resulting from regulation were not anticipated. A scientific journal, *Regulated Rivers*, was founded in 1988 to provide a focus for synthesizing studies of the environmental impacts of river regulation. In 2002 the journal changed its name and emphasis to *River Research and Applications*, reflecting major changes in both research on, and management of, regulated rivers. For 25 years attention had been moving to the determination of flows required to protect water-dependent ecosystems. By the start of this millennium there had developed a vanguard movement to restore regulated rivers and to reconnect rivers with their floodplains; to advance decision-making processes to balance consumptive water use with that needed to maintain a healthy river; and to allocating our limited water resources to meet the needs of both humans and riverine ecosystems (5). This issue is addressed in this volume under Environmental Flows.

RESERVOIRS-MULTIPURPOSE

Sharad K. Jain
National Institute of Hydrology
Roorkee, Uttranchal, India

NEED FOR RESERVOIRS

Reservoirs are developed for two main functions. The first is to store water to even out the fluctuations in river flow and match the availability to demand. Generally, the major part of annual stream flow is available during the few months of the rainy season, but the demand for water arises all year round. Therefore, it is necessary to store the excess water in the months of high flows and use it when the natural stream flow is inadequate to meet the demand. The water stored in a reservoir may also be diverted to faraway places where it is needed.

The second function is to raise the level of the water upstream of the dam to provide a hydraulic head. The creation of storage and head allows dams to generate electricity. The other important purpose of a reservoir is to control flooding in downstream areas.

The early Mesopotamians were the first dam builders. The Sumerians built networks of irrigation canals in the plains along the lower Tigris and Euphrates Rivers about 6500 years ago. Earth and rock-filled dams had been built around the Mediterranean, in the Middle East, China, and Central America by the late first millennium B.C. The remains of impressive dams and aqueducts in Spain are fine examples of the ingenuity of Roman engineers. South Asia has a long history of dam building. Long earthen embankments were built to store water for irrigation. The remains of the Indus Valley civilization which flourished 4000 to 5000 years ago show that these people had built well-planned networks of water supply and drainage works. The oldest reservoir in operation today is the Aftentang reservoir (capacity 100 million m^3), constructed west of Shanghai during 589 to 581 B.C. (1). The oldest continuously operating dam still in use is the Kofini flood control diversion dam and channel constructed in 1260

B.C. on the Lakissa River upstream of the town of Tiryns, Greece, which it continues to protect.

Worldwide, there were more than 36,000 large dams by 1986 (2); many more have been constructed since then. The Asian continent accounts for more than 64% of all dams, and China has built most of them. Engineers of the former USSR have built most of the large reservoirs; they are followed by engineers from Canada. More than 80% of the dams in the world are earth and rock-filled types.

A reservoir contains a number of structural features other than the main dam. Spillways are used to discharge water when the reservoir level threatens to become dangerously high. Dams built across broad plains may include long lengths of ancillary dams and dikes. A schematic diagram of a reservoir is given in Fig. 1.

A reservoir project requires huge amounts of money, manpower, land, and other resources and significantly affects the environment, population, and economy of the region. Once these projects are in place, it is not easy to undo their impacts. Therefore, they should be carefully planned to impart the maximum possible benefit to the national economy.

Multipurpose Reservoirs

The typical purposes of a reservoir are water supply for domestic and industrial uses, irrigation, navigation, generation of hydroelectric power, recreation, and flood control. Depending on the purposes served by the reservoir, it may be classified as either single purpose or multipurpose. A single purpose reservoir serves only one purpose. A multipurpose reservoir serves a combination of purposes. As a rule of thumb, the bigger a reservoir, the more purposes it can serve.

While planning a reservoir, all available data should be analyzed, and, if necessary, further information should be gathered so that the best decisions are made with respect to location, size and type of structure, and auxiliary facilities. After the best site is selected from amongst the potential sites, additional investigations are carried out to finalize the project details. These include engineering, geologic and hydrologic investigations, and economic analysis. The water yield at a site is commonly estimated using flow duration curves.

Storage Zones in a Reservoir

For ease of analysis and operation, the entire reservoir storage space is conceptually divided into a number of zones by drawing imaginary horizontal planes at various elevations. The lowest zone is the dead (or inactive) zone. The bulk of the storage capacity for conservation is provided in the conservation (or active) storage zone. The top level of the conservation zone is termed the full reservoir level (FRL) or normal pool level. If the storage space above the FRL is exclusively reserved for flood control, the maximum storage capacity is dead plus active storage. The maximum water level (MWL) is the highest elevation to which the water is allowed to rise in a reservoir.

Dead storage is provided in a reservoir for accumulating sediments or to provide the minimum head for the turbines of a hydropower dam.

Reservoir Storage–Yield Analysis

The procedures estimating the storage capacity needed to meet given demands or the possible yield from a given project constitute the storage–yield analysis. The reservoir storage–reliability–yield relationship relates inflow characteristics, reservoir capacity, release, and reliability. The inflow process, the reservoir storage, and the outflow process constitute the stream-flow regulation system. Its components are the reservoir storage capacity (S), yield (q), and a measure of reliability (R). The relationship among these variables can be symbolically designated by a function (3):

$$\phi = \phi(S, q, R) \tag{1}$$

where $S > 0, q > 0, 0 < R \leqslant 100\%$. This function is called the regulation regime function, or storage–yield function.

Critical period techniques are the earliest methods of storage–yield analysis. The critical period is the period in which an initially full reservoir, passing through various states (without spilling), empties. The *mass curve method* proposed by Rippl was the first rational method for computing the required storage capacity of a reservoir. This simple method is commonly used in the planning stage. Define a function $X(t)$ as

$$X(t) = \Sigma_t x(t)\,dt \tag{2}$$

where $x(t)$ represents inflows. The graph of $X(t)$ versus time is known as the mass curve. The reservoir capacity is obtained by finding the maximum difference between cumulative inflows and cumulative releases for the most critical period of recorded flow. This method, although

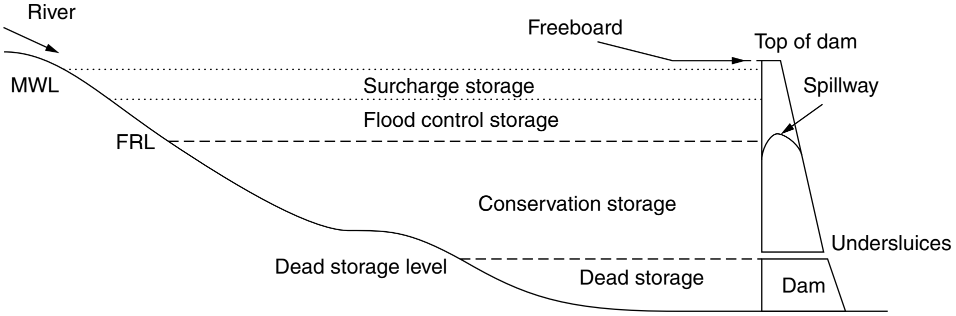

Figure 1. Schematic diagram of a reservoir.

simple and straightforward, has a few shortcomings. It is suitable when the draft is constant, and it is not possible to consider evaporation losses properly. The sequent peak algorithm overcomes some of the limitations of the mass curve method.

Systems analysis techniques such as optimization and simulation are frequently used for storage–yield analysis. Among the optimization techniques, linear programming and dynamic programming have been particularly suitable. Simulation is a widely used technique for solving a variety of problems in designing and operating a water resources system. The reason is that this approach can be realistically and conveniently used to examine and evaluate the performance of a set of alternative options. The simulation approach can be used as a stand-alone method or can be used to modify further and test the results of critical period or optimization methods. McMahon and Mein (4) describe storage–yield analysis techniques in detail.

Flood Control Storage Capacity

The requirement of storage for flood control conflicts with the requirements for conservation. Conservation requirements, such as water supply and hydropower generation, require the storage space to be full, whereas flood control requires empty storage space.

The demands for water supply and hydroelectric power are relatively deterministic, whereas the demand for flood control storage is highly stochastic. Furthermore, the usual time period for analysis of conservation is 1 month, whereas for flood control, it is of the order of a few hours. The storage requirement can be estimated by using the design flood hydrograph. An initial reservoir level at which this flood hydrograph impinges on the reservoir is assumed. The maximum level attained by the reservoir is computed by routing the hydrograph through the reservoir. The maximum height of a dam is obtained after adding the freeboard to this level.

RESERVOIR OPERATION

The efficient use of water resources requires judicious design and also proper operation. After a reservoir comes into being, the benefits that could be reaped depend largely on how well it is operated. Reservoir operation forms an important part of planning and managing a water resources system. Postconstruction, detailed guidelines are given to the operator which enable him to make appropriate management decisions. A reservoir operating policy specifies the amount of water to be released from storage at any time depending on the state of the reservoir, demands, and any information about the likely inflow to the reservoir. The operating problem for a single-purpose reservoir is to decide about the releases to be made, so that the benefits for that purpose are maximized. For a multipurpose reservoir, additionally, it is required to allocate the release optimally among various purposes. The complexity of the problem of reservoir operation depends on the extent to which the various intended purposes are compatible. If the purposes are compatible, comparatively less effort is needed for coordination.

Conflicts in a Multipurpose Reservoir

While operating a multipurpose reservoir, a number of conflicts can arise in satisfying various purposes. These are as follows:

Conflicts in Reservoir Space. These conflicts occur when a reservoir (of limited storage) is required to satisfy incompatible purposes, for example, water conservation and flood control. The satisfaction of conservation purposes requires the reservoir to be filled to the maximum extent, whereas the objective of flood control is best met when the reservoir has sufficient vacant space. The critical decision in regulation is whether to fill the reservoir or keep it vacant.

Conflicts among Purposes. Conflicts can also arise among conservation purposes when the pattern of water use is different and the requirement of storage space for one purpose is not in conformity with the other. The water required for uses such as irrigation, municipal, and industrial water is consumed and cannot be shared with any other use.

Conflicts within the Same Purpose. A deficit of water in a reservoir can be distributed over time in different ways. A typical decision is whether to cut the supply now so that there is a small deficit for a longer period or to postpone the cut for the future and risk a bigger shortage for a shorter time. The impact of these two decisions will be different.

Simple Approaches to Reservoir Operation

A reservoir is operated according to a set of rules to store and release water, depending on the purposes it is required to serve. The release decisions are made in accordance with the available water, current and forecasted inflows, demands, weather outlook, and time of the year. The drawdown–refill cycle of a reservoir is usually 12 months long, except when the reservoir capacity is large in relation to stream flows. In many regions of the world, the filling and drawdown periods are distinctly separated.

Standard Linear Operating Policy

The simplest of reservoir operating policies is the standard linear operating policy (SLOP), graphically represented in Fig. 2. According to this policy, if the amount of water available in a particular period, is less than the target demand (T), all available water is released. If the available water is more than the target demand but less than target demand plus available storage capacity, a release equal to the target demand is made, and the excess water is stored in the reservoir. If there is no space to store the excess water even after meeting the target demands, all the water in excess of the maximum storage capacity is released.

Note that SLOP is a one-time operating policy; future implications of the current decision are ignored. This type of time-isolated release of water is neither beneficial nor desirable. Though this policy is not used in day-to-day operation, it is frequently used in planning studies.

Rule Curves

A rule curve or level specifies the desired storage to be maintained in a reservoir during different times of

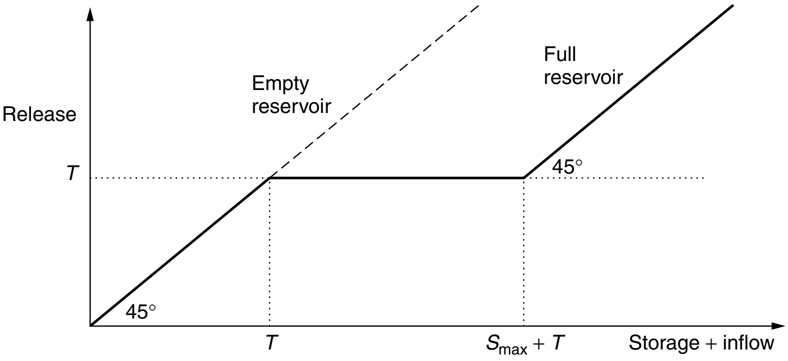

Figure 2. Graphical representation of standard linear operating policy.

the year while trying to meet various demands. The implicit assumption is that a reservoir can best satisfy its purposes if the storage levels specified by the rule curve are maintained at different times. Different rule curves may be developed for different purposes, such as water supply for domestic and industrial use, irrigation, hydropower generation, and flood control. The rule curve as such does not give the releases from the reservoir; these depend on actual inflows and demands.

The derivation of rule curves depends on the type and purposes of the reservoir. The data from the critical period are used for this purpose. Clearly, if the reservoir can meet the demands during the critical year, it will be able to serve its purpose for all other years. These days, many software packages are available for preparing rule curves.

While operating a reservoir following rule curves, if the reservoir level at any time is above the rule curve, releases are made to meet all conservation demands. If the reservoir water level is in the vicinity of the rule curve level, the release is restricted so that the reservoir level does not fall appreciably below the rule curve. If for some reason, the reservoir level drops below the rule curve, the release should be curtailed with the objective of returning to the rule curve at the earliest.

Rule curves implicitly reflect the established trade-off among various project objectives in the long run. These curves specify only the ideal levels to be maintained; the operators can use their experience and judgment to distribute the excess or deficit to maximize benefits. The operation of a reservoir may become quite rigid by strictly following the rule curves. To provide flexibility, different rule curves may be specified for different circumstances, viz., normal, dry, and wet. An operating schedule that gives some leverage to the operator to use his experience and hydrologic forecasts is termed a flexible schedule. Of course, this requires using detailed input data, good models, trained manpower, and careful planning. But at the same time, the benefits can be very large.

Concept of Storage Zoning

The entire reservoir storage space can be conceptually divided into a number of zones by drawing imaginary horizontal planes at various elevations. The sizes of these zones can vary with time as shown in Fig. 3.

Reservoir operators are expected to maintain the reservoir level within the specified zones. This conceptual division of a reservoir into a number of zones and the rules governing the maintenance of reservoir levels in a specified zone are based on the assumption that, at a specified time, an ideal storage zone exists for the reservoir and benefits can be maximized by keeping the storage in this zone. This concept is in some way akin to a rule curve and has the added advantage that it gives more flexibility to the decision-maker.

Operation of a Multireservoir System

The benefits from the joint operation of a system of reservoirs can be substantially larger than the sum of benefits from the operation of individual reservoirs. A system may consist of reservoirs in series, in parallel, or a combination. Various approaches for developing operating policies for a system of reservoirs have been discussed by Wurbs (5).

While managing multiple reservoirs, all reservoirs are maintained in the same zone at any time, to the

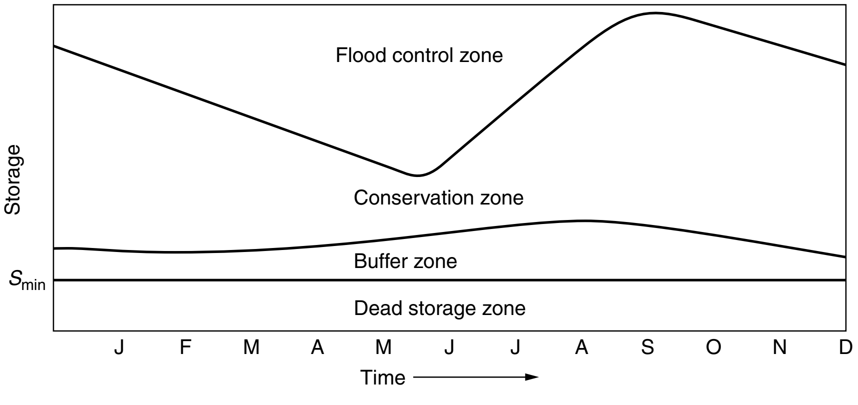

Figure 3. Variation of reservoir zones with time.

extent possible. This is necessary to have balance among reservoirs after an unexpected or extreme hydrologic event. There are three approaches for balancing reservoir contents. The first, known as the “equal function” policy, is to keep all reservoirs at their same zonal position. The second is based on a reservoir ranking or priority concept—the entire zone of the lowest ranking reservoir is used fully before drawing water from the next lowest ranking reservoir, and so on. The third concept is based on a “storage lag” policy. Withdrawals from the zones of some reservoirs are made before withdrawals are begun from the same zones of other reservoirs. After a certain volume has been released from the initial group of reservoirs, releases are made from all reservoirs, maintaining the percentage difference of the available zone volumes.

Conditional rules are also used to regulate multiple-reservoir systems. These policies define reservoir releases as a function of the existing storage volumes and the time of the year and also as a function of the expected natural inflows into the reservoirs for some prespecified future time period.

Reservoir Operation for Flood Control

A storage reservoir with gates is one of the most effective means of flood control. The moderation of a flood through storage is achieved by storing part of the flood volume in the rising phase of the hydrograph and releasing it gradually in the receding phase of the flood. The degree of moderation or flood attenuation depends on the empty storage space available in the reservoir when the flood impinges it. The flood control pool must be emptied as quickly as downstream flooding conditions allow; this will reduce the risk of highly damaging future releases, should major floods occur in quick succession.

In multipurpose reservoirs located in the regions where floods can be experienced at any time and flood control is one of the main purposes, space is permanently allocated for flood control at the top of the conservation pool. The amount of space depends upon the magnitude of likely floods. If the floods are experienced only in a particular season, space is allocated only during that season.

Reservoir regulation consists of storing the peak flows over and above the safe (nondamaging) carrying capacity of the channel at the damage point in the reservoir. The reservoir is emptied after the passage of the flood to make space for controlling subsequent floods. In Fig. 4, ABCDE represents the inflow hydrograph. The line ZZ represents the nondamaging carrying capacity of the river channel downstream of the reservoir. From point B to point D, the natural flow in the river exceeds its safe carrying capacity. If there were no reservoir, the flood water would have spilled over the channel banks and caused damage during the time B to D. The moderated release from the reservoir under ideal operation is given by the dotted curve AGDF. As soon as the inflow begins to increase, the release is gradually increased, till some point G where the release equals the safe carrying capacity. While the inflows from point B to D exceed the safe carrying capacity of the downstream channel, the release is maintained within a safe range by storing the volume in the segment BCD in the flood control zone of the reservoir. After point D, the inflows continue to fall rapidly but the release, while still in a safe zone, exceeds the inflow, so that the reservoir is quickly emptied.

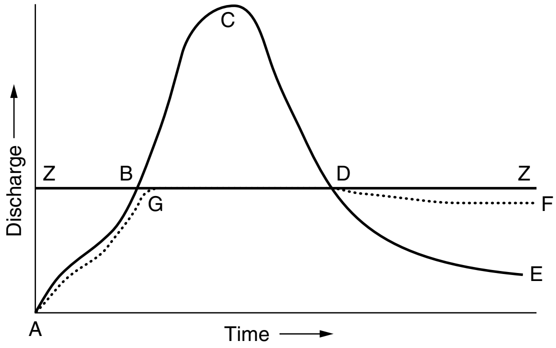

Figure 4. Ideal operation of a reservoir for flood control.

This is an ideal situation which is possible only if the perfect foreknowledge of the hydrograph is available. In actual operation, the release curve will deviate from the ideal shape. For example, if the operator makes smaller releases in the early part of the hydrograph, it is likely that the reservoir will completely fill before point D. In that eventuality, the operator will be forced to make releases at rates exceeding the safe carrying capacity of the downstream channel thereby causing flood damage. Conversely, if at the beginning of a flood, the operator starts making higher releases in the expectation of a major flood and such a flood does not occur, the reservoir may not fill to the desired level by the end of the filling season.

SYSTEMS ENGINEERING FOR RESERVOIR MANAGEMENT

Determination of the reservoir operating policy for efficient management of available water is a complex problem. Many attempts have been made to solve this problem using optimization and simulation models.

Optimization is the science of choosing the best solution from a number of possible alternatives. Optimization methods find a set of decision variables such that the objective function is optimized. Linear programming (LP) and dynamic programming (DP) techniques have been extensively used in water resources. Loucks et al. (6) illustrated applications of LP, nonlinear programming (NLP), and DP to water resources. Yeh (7) presented a state-of-the-art review and discussed in detail the various optimization models for multipurpose, multireservoir operating problems. Simonovic (8) provided a state-of-the-art review and applications of the systems approach to reservoir management and operation. Wurbs (9) reviewed the application of optimization, simulation, and network-flow models.

Simulation is the process of designing a model of a system and conducting experiments with it to understand the behavior of the system and to evaluate various strategies for operating it. The essence of simulation is to reproduce the behavior of the system. It allows controlled experimentation without disturbing the real system. However, simulation analysis does not yield an immediate optimal answer which can be arrived at iteratively. The simulation technique is possibly the most powerful tool for studying complex systems.

The simulation models associated with reservoir operation include the mass-balance computation of reservoir inflows, outflows, and changes in storage. They may also provide an economic evaluation of flood damage, hydropower benefits, irrigation benefits, and other similar characteristics. A large number of reservoir planning and operating studies have used simulation models because such models can provide a more realistic representation of reservoir systems and their operations. They also allow added flexibility to derive responses which cannot be readily defined in economic terms (recreational benefits, preservation of fish and wildlife). The results of simulation models are easier to explain to decision-makers and system operators because the ideas inherent in simulation modeling can be understood easily. Thus, these models are effective tools for a dialogue with operators and decision-makers.

A number of general-purpose computer software programs are available nowadays that can be used for analysis related to planning, design, and operation of multipurpose reservoirs. Some well-known simulation models are the HEC-5 model developed by the Hydrologic Engineering Center, (10), the Acres model (11); the Streamflow Synthesis and Reservoir Regulation (SSARR) Model (12), and the Interactive River System Simulation (IRIS) model (13). Jain and Goel (14) presented a generalized simulation model for conservation operation of a multipurpose reservoir system. Lund and Guzman (15) discussed derivation of operating rules for reservoir systems.

Real-Time Reservoir Operation

A multipurpose reservoir can be efficiently operated if the time interval between the occurrence of an event and the execution of the control adapted for that event is short. In real-time operation, release decisions for a finite future time horizon are made based on the condition of the reservoir at the instant when these decisions are made and the forecast about the likely inflows/demands over this time horizon. After a certain time interval, the new information about the system becomes available, the forecasts are updated, and the decisions are modified.

Real-time operation is especially suitable during floods where the catchment response changes rapidly and decisions have to be made quickly and adapted frequently. Successful application of the real-time operating procedure requires a good telemetry system through which data can be observed on-line. Real-time flood forecasting involves estimating discharge in a river at some period prior to its occurrence. It is very useful in real-time operation because the forecast leadtime proves useful in mitigating some of the adverse effects of flooding. Real-time hydrologic forecasting depends, to a large extent, on timely availability of good quality hydro-meteorological data at a forecasting station.

DAM REMOVAL AS RIVER RESTORATION

Chih Ted Yang
Colorado State University
Fort Collins, Colorado

River is a dynamic system. It makes spatial and temporal adjustments of its channel geometry, profile, and pattern to maintain a dynamic equilibrium condition compatible with changing independent variables or constraints applied to the river system. The dynamic adjustments of a river are accomplished through the processes of scour, sediment transport, and deposition. Human activities, especially the construction and operation of dams, have profoundly affected most rivers in the world. As a result of these activities, many rivers have lost their ability to maintain or recover their dynamic equilibrium and functions at a self-sustained level. The main purpose of river restoration is to reestablish the basic functions of transporting water and sediment to sustain the ecosystem of rivers and their corridors.

Dams are built and operated for flood control, irrigation, water supply, hydropower generation, navigation, recreation, and environmental purposes. Each dam was designed to last for a given useful lifetime with certain economic and other benefits in mind. A dam can also impose certain risk to downstream residents and properties. Most of the dams, especially small dams, were designed with an estimated useful life of 50 to 100 years. A dam may be removed because of one or more than one of the following factors:

- Economics
- Dam safety and security
- Legal and financial liability
- Ecosystem restoration
- Fish passage improvement
- Site restoration
- Recreation

Sediments are trapped in reservoirs after the completion of dams. The amount of sediments trapped in a reservoir depends on the trap efficiency of the reservoir, which is a function of sediment inflow, ratio between average annual inflow and reservoir volume, reservoir shape, and the dam's operational rules and facilities. A detailed sediment management plan must be developed before a dam's removal to prevent:

- Excessive downstream river channel aggradation, channel widening, bank erosion, increase of flood stage, plug water intake structure, turbidity, and descrupt aquatic habitats
- Adverse impact on water quality
- Excess sediment removal cost and difficulties of finding appropriate sediment storage site
- Head cutting of tributaries

Engineering considerations of dam removal include complete or partial removal; materials used in the dam construction; rate of dam removal and reservoir drawdown; and ability to draw reservoir pool and construction of bypass channel or low-level outlets. Table 1 summarizes some of the factors that need to be considered in dam removal.

Dam removal can be an engineering method for river restoration. Because of the dynamic nature of river adjustments in response to natural and manmade events, comprehensive studies of possible responses of a river must be carried out before a dam's removal. Lane (1) proposed the following qualitative equation to maintain a dynamic equilibrium among sediment load Q_s, sediment size d, water discharge Q, and river slope S.

$$Q_s d \propto QS \tag{1}$$

Table 1. Relationship Between Dam Decommissioning and Sediment Management Alternatives [modified from ASCE (4) by Randle and Greimann (5)]

Sediment Management Alternative	Dam Decommissioning Alternatives		
	Continued Operation	Partial Dam Removal	Full Dam Removal
No Action	• Reservoir sedimentation continues at existing rates, • Inflowing sediment loads are reduced through watershed conservation practices, or • Reservoir operations are modified to reduce sediment trap efficiency.	• Only applicable if most of the dam is left in place. • The reservoir sediment trap efficiency would be reduced. • Some sediment may be eroded from the reservoir.	• Not applicable.
River Erosion	• Sluice gates are installed or modified to flush sediment from the reservoir. • Reservoir drawdown to help flush sediment.	• Partial erosion of sediment from the reservoir into the downstream river channel. • Potential erosion of the remaining sediment by sluicing and reservoir drawdown.	• Erosion of sediment from the reservoir into the downstream river channel. Erosion rates depend on the rate of dam removal and reservoir inflow. The amount of erosion depends on the ratio of reservoir width to river width.
Mechanical Removal	• Sediment removed from shallow depths by dredging or by conventional excavation after reservoir drawdown.	• Sediment removed from shallow depths before reservoir drawdown. • Sediment removed from deeper depths during reservoir drawdown.	• Sediment removed from shallow depths before reservoir drawdown. • Sediment removed from deeper depths during reservoir drawdown.
Stabilization	• The sediments are already stable because of the presence of the dam and reservoir.	• Retain the lower portion of the dam to prevent the release of coarse sediments or retain most of the dam's length across the valley to help stabilize sediments along the reservoir margins. • Construction of a river channel through or around the reservoir sediments.	• Construction of a river channel through or around the existing reservoir sediments. • Relocate a portion of the sediments to areas within the reservoir area that will not be subject to high-velocity river flow.

where Q and Q_s = water and sediment discharge, respectively; d = sediment particle diameter, and S = channel slope.

Yang (2) introduced the following quantitative equation for the prediction of dynamic adjustment of a river based on his unit stream power equations (3,4)

$$C_t = I\left(\frac{VS}{\omega}\right)^J \tag{2}$$

or

$$\frac{Q_t}{Q} = I\left(\frac{QS}{WD\omega}\right)^J \tag{3}$$

where W = channel width, D = channel depth, ω = sediment fall velocity, C_t = total bed-material concentration, Q_t = total bed-material load, and I, J = coefficients.

Because sediment fall velocity is directly proportional to the square root of sediment diameter and J has an average value of 1.0 for rivers, (3) can be simplified to

$$\frac{Q_t d^{0.5}}{K} = \frac{Q^2 S}{WD} = \frac{Q^2 S}{A} \tag{4}$$

where A = channel cross-sectional area, d = median sediment partial diameter, and K = a site-specific parameter.

Equation (4) was used by Yang (7) for the prediction of river morphologic changes because of the construction and operation of a dam. Equation (4) can also be used for the prediction of dynamic adjustments of a river after the removal of a dam.

The rate and timing of a staged reservoir drawdown during the dam removal process should follow the following criteria, especially for the purpose of river restoration (6):

- The drawdown rate is slow enough so downstream flood wave does not cause damages.
- The release of coarse sediment is slow enough not to cause excessive downstream aggradation.
- The concentration of fine sediment is not too great or duration too long to cause an unacceptable impact on water quality and aquatic environment.

During the dam removal process, a comprehensive monitoring program should be carried out to determine

- Reservoir sediment erosion and redistribution
- Hill slope stability along reservoir and downstream river channel adjustment
- Water quality and suspended sediment concentration
- River bed aggradation and flood stage
- Aquifer characteristics
- River channel plan form and channel geometry adjustments
- Effect of large woody debris
- Effects on coastal process

Sediments in a reservoir can be removed by dry excavation, mechanical dredging, hydraulic dredging, sediment conveyance by river flow, and partial sediment removal and reservoir stabilization. Sediment removal by river flow is the least lost and most suitable method for river restoration purposes. This method also requires detailed studies of the hydrologic, hydraulic, sediment transport, scour, deposition, and river morphology. Because of the complexity of these studies, computer models are often used by experienced engineers to simulate and predict the dynamic adjustment of a river after the dam removal.

The U.S. Army Corps of Engineers' HEC-6 (8) and Bureau of Reclamation's GSTARS3 (9) and GSTAR-1D (10) are some of the commonly used computer models in public domain. Bureau of Reclamation's models and user's manuals can be downloaded by users by going to http://www.usbr.gov/pmts/sediment/ and following the links therein. In addition to computer models, physical models are also used for short-term simulation and prediction of erosion, sediment transport, and deposition during the dam removal process.

Dam removal and river restoration often require a multidisciplinary team approach with team members consist of engineers, environmentalists, river morphologists, fishery and aquatic experts, and representatives from local community. Useful references include, but are not limited to, books on *Stream Corridor Restoration: Principles, Process, and Practice* (11), *Erosion and Sedimentation Manual* (12), and *Sediment Transport: Theory and Practice* (7).

RIPARIAN SYSTEMS

Theodore A. Endreny
SUNY-ESF
Syracuse, New York

Riparian areas are those along the bank of a watercourse, which is a relatively narrow transition zone between a downslope aquatic waterbody and an upslope terrestrial watershed. Riparian areas are predominantly associated with a river or stream, but also define the bank of a lake, wetland, or other standing water. The riparian system refers to the atmospheric, vegetation, and soil components; their physical, chemical, and biological properties; and their interaction with each other and the upslope terrestrial and downslope aquatic hydrologic cycle. It is important to recognize that riparian areas may border both influent and effluent streams, known as those that lose or gain water to the groundwater.

DEFINITION

Riparian systems may be wetlands, but there are nonwetland riparian areas, and there is no jurisdictional definition of a riparian system as there is for wetlands, defined under Section 404 of the Clean Water Act (33 CFR 328.3(b)). For a discussion of the wetland function of riparian areas, see the entry for Wetlands. As for wetland areas, various federal agencies have attempted to define riparian systems to help in identify them. According to the U.S. Fish and Wildlife Service (FWS), either the presence of a set of obligate water-loving vegetative species (e.g., phreatophytes that have water-table roots) different from that of adjacent areas or more rigorously growing vegetative species similar to upslope areas distinguish the riparian area. The U.S. Department of Agriculture (USDA) considers that riparian areas are further distinguished from the surrounding lands by saturated soils resulting from a shallower depth to the water table, which implies a distinct hydrologic regime.

SYSTEM INPUTS, OUTPUTS, AND TRANSFORMATIONS

A riparian system, in hydroecological terms, can be viewed from its inputs, outputs, and transformations. Inputs arrive via the atmosphere, surface soil, and subsurface soil media, and outputs may travel within these same media after hydrologic and biochemical fluxes between and within the atmospheric, vegetative, and soil components. Atmospheric inputs include short-wave, or solar, and long-wave radiation, wet and dry precipitation, and wind-advected constituents. Surface inputs include upslope storm runoff water, overbank water from a flooded watercourse, eroded soil, as well as sorbed, entrained, and dissolved chemical species. Subsurface inputs include local and regional discharge from upgradient groundwater flow paths, bank storage from the watercourse, and dissolved and entrained chemical species.

Riparian systems are open systems that provide complex and useful chemical sinks, sources, and internal transformations of constituents important in aquatic chemistry and watercourse health. Energy flow into the riparian system, which provides riparian biota growth, reproduction, and maintenance, is derived principally from high-energy sunlight and the use of its short-wave radiation in autotrophic photosynthesis to form organic material from water and carbon dioxide. In the presence of an electron donor, such as oxygen, the organic material is harvested for its energy by heterotrophic organisms in respiration, the reverse process of photosynthesis. Because this energy is associated with the organic material, the food web energy flow has an associated mass cycle. In this cycle, the carbon and associated nutrients (e.g., phosphorous and nitrogen) pass through numerous organisms up the food web, and after excretion or organism death, the carbon and nutrients stop moving up the food web and are either transformed or decomposed back to their inorganic forms as part of mineralization. Microbes, such as bacteria and fungi, and rotifers (e.g., worms) are the key agents in transformation and decomposition.

Riparian input constituents include nutrient species (e.g., nitrogen and phosphorous), chemical pollutants from agrochemicals (e.g., herbicides and pesticides), metals from urban and industrial activities (e.g., lead, zinc, and copper), organic materials from watershed activities (e.g., waste from livestock or domestic pets and vegetative debris), suspended solids (e.g., sand, silt, and clays from eroded soils), pathogens from wildlife (e.g., *Giardia* and *Cryptosporidium*), and in residential areas, thermally heated water and human trash.

In time, the riparian system may accumulate these constituents from surface water that slows and deposits entrained constituents, from soil adsorbing (at the surface) and absorbing (internal to the structure) dissolved or entrained constituents, from vegetation taking the constituents into its root or stem system, or from water stores that fill in the surface or subsurface zone. Biochemical processes operating in the riparian system may transform material inputs that are retained, and another component of inputs that exceed storage may then discharge as outputs with subsequent wind advection, seasonal and storm based surface runoff, seasonal watertable fluctuations, and subsurface flow.

Riparian atmospheric and surface component transformations include mainly photolysis, saprophytic decay, animal digestion, and weathering. Microbial (e.g., fungi and bacteria) subsurface transformations are likely to fluctuate between those of aerobic and anaerobic conditions as the water table fluctuates. Fungi are solely aerobic, but bacteria can operate in both aerobic conditions and anaerobic and have a greater range of transformative options. Two governing principles for microbial transformations of chemicals require that they be energetically favorable and that enzymes are available as catalysts.

The biodegradation potential for a chemical is determined by the free energy change in its reaction with other environmentally available chemicals. This is determined from knowledge of the reduction–oxidation, or redox, potential of the riparian area, which has an ecological sequence from aerobic (O_2) to denitrification (NO_3^-), to manganese reduction (MnO_2), to iron [$Fe(OH)_3$] reduction, to sulfate reduction (SO_4^{2-}), to methanogenesis (CO_2). Given that many enzymes are extremely specific and that mutations occur in bacteria, some individuals in a given strain of bacteria may accomplish transformations not observed in other individuals.

VEGETATED RIPARIAN BUFFERS

Riparian zones supporting forest or grass cover are described structurally as vegetative filter strips (VFS) or functionally as riparian buffer zones (RBZs). Three defined zones for the riparian buffer have been identified by the USDA (1) for agricultural nonpoint source (NPS) runoff and water quality management. The most upslope area is zone 3 and as proposed, contains grasses that slow NPS runoff velocities and allow settling out of entrained constituents such as sediment and sorbed pollutants. The middle area, zone 2, dedicated to managing forestland that captures overland flow leaving zone 1, provides a root-based carbon substrate for microbes (fungi and bacteria) transforming nutrients in subsurface flow, as well as income for the landowner. The near-stream area, is zone 1, which is an undisturbed forest, provides function and habitat for the aquatic system. There are no fixed recommendations for the width of these zones, and many landowners are cautious about dedicating otherwise revenue generating land for forested buffers. In some states, recommended widths for the entire buffer have averaged between 10 and 30 m.

In zone 1, direct biotic and abiotic controls of the vegetative buffer on the aquatic system are many. The vegetative canopy provides cover from incoming solar radiation and blocks outgoing evening long-wave radiation for stable temperature control, as well as protection from predators. The vegetative zone also drops large wood debris into the watercourse for in-stream habitat; creates turbulent eddies (e.g., hydraulic circular flows) and conditions favorable for mobile species seeking to feed or rest by creating areas of refuge from strong downstream currents; and provides substrate for aquatic plants and sessile organisms. Further, the vegetative root wads and downed stems along the bank provide soil stability and erosion control, and the small woody and leaf debris enter the aquatic food web and feed shredders, nymphs; algae, and trout.

Zone 3 and 2 overland flow interception, slowing, settling, and filtering of runoff-entrained constituents requires that the runoff enter in a thin, dispersed sheet and that concentrated channels of flow be removed and flow respread. Methods for spreading the flow include constructed and natural methods (e.g., limbs from a tree). In addition to surface channels of short-circuited flow discharging directly to the watercourse and thereby avoiding riparian storage and transformation, flow can also preferentially short-circuit in the subsurface soil. Such short-circuiting might include preferential flow through macropores and agricultural tile drains that pass too quickly for effective microbial transformation, as well as deep groundwater flows that upwell into the stream at its base and bypass the microbial populations (see Fig. 1). Additional management interventions include removing accumulated sediment berms from the upslope edge of zone 3, as needed, and replacing vegetative materials that are not fixing or assimilating nutrients at target efficiency.

Vegetative riparian structure and function for the adjacent watercourse, it has been widely documented, provide critical resources for aquatic ecosystem health. Inside the United States, a great deal of this work was performed in the Coastal and Piedmont Regions in Maryland, Virginia, and North Carolina; studies in southern Finland and Sweden are also widely cited (2). Most studies have focused on nutrient transformations of nitrogen and phosphorous, and results indicate that nutrient retention varies as a function of nutrient load, riparian upslope steepness, and riparian buffer width, as well as vegetative types, health, subsurface flow paths, and microtopography (e.g., surface short-circuiting). Total nitrogen reduction estimates given for subsurface inputs are between 67 and 89% (3). Phosphorous reduction in U.S. riparian buffers ranges from 41 to 93% (4), and removal efficiency, it has been observed, decreases with time.

RIPARIAN BUFFER BEST MANAGEMENT PRACTICES

In U.S. Environmental Protection Agency (USEPA) research in the mid-Atlantic highland areas of Pennsylvania, Maryland, and Virginia, random sampling networks of benthic macroinvertebrate health, recorded as a biotic index (BI), trend strongly with riparian habitat health. For watersheds with land use stress, such as agricultural or residential occupancy, stream reaches that have low BI values (e.g., impaired) were also areas where riparian habitat was typically absent or degraded, whereas reaches that have high BI values had attendant healthy riparian habitat. Recommendations from these studies include using forested riparian areas as watershed restoration and best management practices (BMPs) to reduce upslope pollutant loads and improve aquatic health.

Hydrologic investigations in urban environments, such as the National Science Foundation (NSF) funded Long Term Ecological Research (LTER) research site in Baltimore, Maryland, have found differences between urban and rural riparian systems. Although the riparian

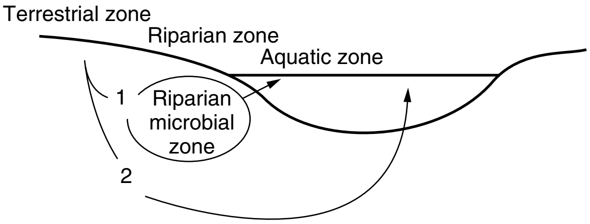

Figure 1. Flow paths from terrestrial to the aquatic zone showing (1) passage through the riparian microbial zone and (2) bypass beneath the riparian microbial zone where nutrient transformations occur.

system in both urban and rural cases is the transition between terrestrial and aquatic processes, the gradual blending of these zones found in rural areas is more abrupt in urban areas. In fact, in areas where streams have been channelized for flood control, leveed from their natural floodplain, and upslope ground water recharge has been reduced by impervious cover, urban riparian systems are drier than their counterpart rural systems. In such cases, vegetative species that are obligatory water loving will not survive in the urban riparian system that has greater depth to the water table and more pronounced mesic periods. Instead, the more common species found in urban riparian systems are obligatory highland, or dry tolerant, trees and shrubs.

For new storm water management under the Clean Water Act, known as the Municipal Separate Storm Sewer System (MS4), the USEPA has required permitting for most municipalities to document pollutant discharge reductions. These reductions may be obtained by BMPs and for retrofitting to existing urban structure, will require smaller footprint design and engineering than a traditional 10 to 30 m wide riparian system. One BMP design that borrows water treatment functional components from riparian buffers is referred to as a vegetated bioretention device, or rain garden. In a USEPA Factsheet, this device is suggested for redirecting runoff from parking lots, driveways, and urban streets, when collocated with storm drain inlets, vertically through the BMP and into the groundwater or a subsurface drainpipe. The mixture of vegetation, soils, and microbes will transform and reduce total Kjeldahl nitrogen (TKN, e.g., ammonia and organic nitrogen) by 68 to 80%; total phosphorous by 70 to 83%; lead, copper, and zinc metals by 93 to 98%; and total suspended solids, organics, and bacteria by 90% (5). Given that this system is intended for urban areas where water tables are, deeper plant species should be drought tolerant, and in colder regions, salt tolerant in areas where roads are deiced.

RIVERS

Pierre Y. Julien
Chih Ted Yang
Colorado State University
Fort Collins, Colorado

Rivers are natural streams typically larger than a creek. The distinction may be somewhat subjective, but creeks cannot be traveled by boat and rivers can. Rivers are the result of precipitation and runoff over land surfaces, followed by surface erosion and sediment transport. As water runs off to lower elevations, the erosion of the underlying earth and soil carves channels into the landscape. These natural channels convey the floodwaters from rainfall and snowmelt and also drain the aquifers during periods of low flow. Rivers are perennial when there is flowing water all year round. Rivers that dry out during part of the year are ephemeral streams, also called arroyos. Related nouns include riverbank or riverside to describe the banks of a river, as well as riverbed to designate the stream bottom. Other adjectives related to rivers include riverine, riparian, fluvial, and fluviatile.

The discharge, or rate of outflow, of a river depends on the channel width, flow depth, and flow velocity. The flow velocity depends on the flow depth, or hydraulic radius, the slope of the river, and the roughness of the riverbed. The volume of water that flows through a river is affected by the duration and intensity of rainfall precipitation or snowmelt in the drainage basin of the river. Over geologic times, it is possible for rivers to be deflected into a different drainage system. This phenomenon is called a capture and results in an increase in drainage area.

Traditionally river systems have been classified as young, mature, or old depending on their stage of development over geologic times. A young river typically flows in a steep valley and has a steep bed slope and numerous riverbed irregularities. Cliffs or escarpments and differences in the resistance of rocks create irregularities in a riverbed and can thus cause rapids and waterfalls. Young systems are characterized by discontinuous longitudinal profiles, lakes, and variable hydraulic geometry. At a mature stage, the river valley has a wide floor and flaring sides and more pronounced erosion by its tributaries. An old river system tends to have regular longitudinal profiles and a gradual decrease in riverbed slope in the downstream direction. Geologic discontinuities such as faults and active tectonics can cause sudden changes in bed elevation that effectively can rejuvenate old fluvial systems. The age classification of rivers is diminishing in popularity now that quantitative studies of river behavior are more common.

The topography of natural rivers depends on the balance between the quantity of sediment in the stream and its transport capacity. A river is alluvial when it can transport its own riverbed sediment and can form its own channel geometry. The weathering process of the land of a given watershed produces large masses of alluvium that can be carried by rivers over geologic periods. An alluvial river tends to eliminate irregularities and form a smooth

[a] After Reference 1.

gradient from its source to its base level. The lowest level to which a river flows is called the base level. Sea level is the ultimate base level, but a lake or reservoir may serve as a local and temporary base level.

Slight changes in sediment transport capacity or in sediment supply to a stream can result in a significant change in bed elevation and planform geometry. For instance, if a stream receives more sediment than it can transport the result is aggradation, or a raise in riverbed elevation through time. Conversely, when the sediment transport capacity exceeds the upstream supply, the water will erode the riverbed and riverbanks and degrades the riverbed.

Similar changes normally take place laterally in river bends. Typically, the velocity increases on the concave riverbank and the increased sediment transport capacity results in erosion and lateral migration of a meandering channel. Simultaneously, the decreased flow velocity near the convex bank of the river decreases transport capacity and results in sediment accumulation and aggradation through time to form point bars. As it approaches base level, downward cutting is replaced by lateral cutting, and the river widens its bed and valley and develops a sinuous course that forms exaggerated loops and bends called meanders. A river may open up a new channel across the arc of meander, called a neck cutoff, thereby cutting off a river segment and creating an oxbow lake as shown in Fig. 1.

River velocity is one of the primary factors that control the quantity and size of rock fragments and sediment carried by the river. When rivers reach oceans, lakes, or reservoirs, the decrease in flow velocity results in net deposition of the sediment load. Part of the load carried by the stream is deposited in the riverbed or on the floodplain beyond the channel. The flow of water during floods exceeds the conveyance of the stream channel, and

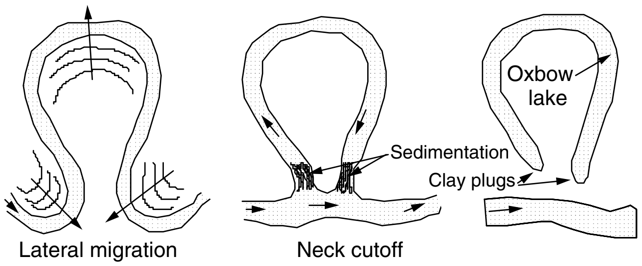

Figure 1. Oxbow lake formation process.

the water level increases to overtop the riverbank and flood adjacent floodplains. As the velocity reduces further on the floodplain, the deposition of sediment forms natural levees. Over long periods of time, landforms produced by deposition include floodplains, deltas, and alluvial fans.

Some typical characteristics including the watershed size, the water and sediment discharges of large rivers are presented in Table 1. The flow and drainage area of the Amazon far exceed that of any other river. On the other hand, the Yellow River (Huang Ho) and the Ganges have tremendous sediment concentrations for very large streams. Several textbooks describe the mechanics of river formation. Some of the recommended texts for future reading and reference in river morphology and river mechanics include Julien (1), Yalin and da Silva (2), Wohl (3), Yang (4) and the recent text of Bridge (5).

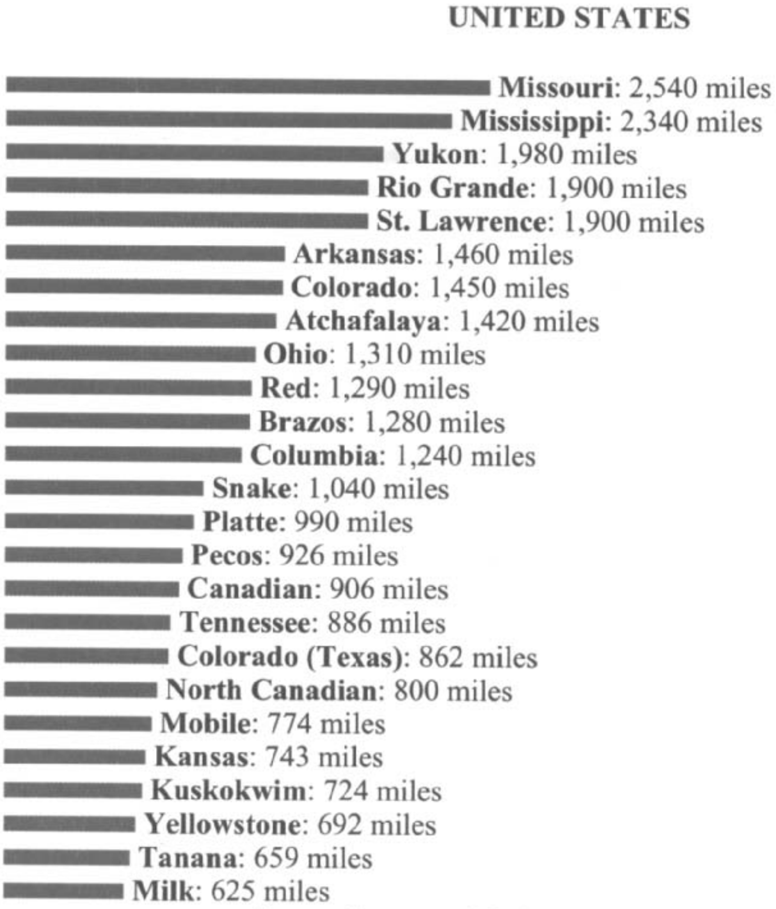
RIVER AND WATER FACTS

National Wild and Scenic Rivers
System - National Park Service

WATER FACTS

- River Lengths
- The National Wild and Scenic Rivers System has only 11, 303 river miles in it—just over one-quarter of one percent of our rivers are protected through this designation, and this protection is often contended.
- Currently, 600,000 miles of our rivers lie behind an estimated 60,000 to 80,000 dams.
- The United States has 3,500,000 miles of rivers. The 600,000 miles of rivers lying behind dams amounts to fully 17% of our river mileage.
- The Missouri River is about 2,540 miles long, making it the longest river in North America. The Nile is the longest river in the world at 4,132 miles as it travels northward from its remote headwaters in Burundi to the Mediterranean Sea.
- The 8 longest rivers in the U.S. are (in descending order) Missouri, Mississippi, Yukon, St. Lawrence (if you count the Great Lakes and its headwaters as one system), Rio Grande, Arkansas, Colorado, Ohio.
- The 8 largest rivers in the U.S., based on volume, are (in descending order) Mississippi, St. Lawrence, Ohio, Columbia, Yukon, Missouri, Tennessee, Mobile.
- Water covers nearly three-fourths of the earth's surface.
- Most of the earth's surface water is permanently frozen or salty.
- Over 90% of the world's supply of fresh water is located in Antarctica.
- The earth's total allotment of water has a volume of about 344 million cubic miles. Of this:
  - 315 million cubic miles (93%) is sea water!
  - 9 million cubic miles (2.5%) is in aquifers deep below the earth's surface.
  - 7 million cubic miles (2%) is frozen in polar ice caps.
  - 53,000 cubic miles of water pass through the planet's lakes and streams.
  - 4,000 cubic miles of water is atmospheric moisture.
  - 3,400 cubic miles of water are locked within the bodies of living things.
- If all the world's water were fit into a gallon jug, the fresh water available for us to use would equal only about one tablespoon.
- It doesn't take much salt to make water "salty." If one-thousandth (or more) of the weight of water is from salt, then the water is "saline."
- Saline water can be desalinated for use as drinking water by going through a process to remove the salt from the water. The process costs so much that it isn't done on a very large scale. The cost of desalting sea water in the U.S. ranges from $1 to $16 per 1000 gallons.
- The overall amount of water on our planet has remained the same for two billion years.
- The United States consumes water at twice the rate of other industrialized nations.
- 1.2 Billion—Number of people worldwide who do not have access to clean water. 6.8 Billion—Gallons of water Americans flush down their toilets every day.
- Each day almost 10,000 children under the age of 5 in Third World countries die as a result of illnesses contracted by use of impure water.
- Most of the world's people must walk at least 3 hours to fetch water.

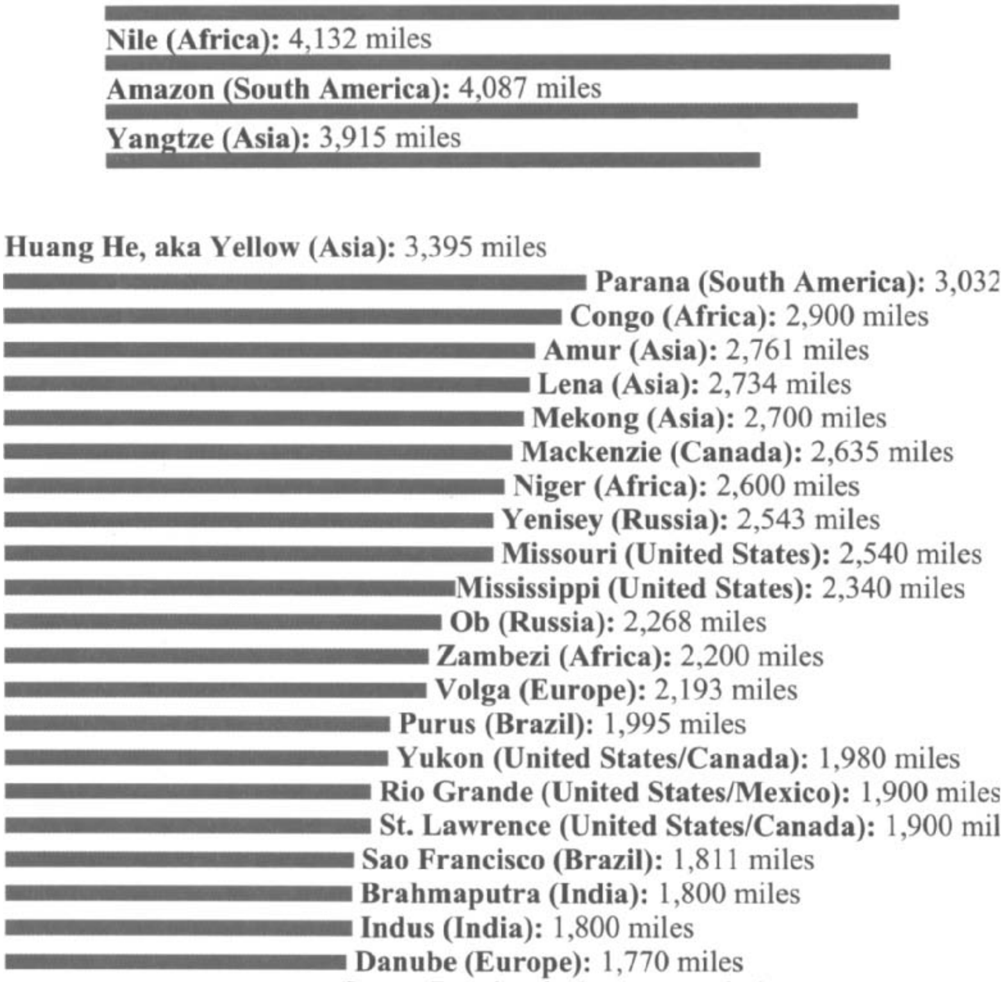
- By 2025, 52 countries—with two-thirds of the world's population—will likely have water shortages.
- The average single-family home uses 80 gallons of water *per person* each day in the winter and 120 gallons in the summer. Showering, bathing and using the toilet account for about two-thirds of the average family's water usage.
- The average person needs 2 quarts of water a day.
- During the 20th century, water use increased at double the rate of population growth; while the global population tripled, water use per capita increased by six times.
- Water use in the United States alone leaped from 330 million gallons per day in 1980 to 408 million gallons per day in 1990, despite a decade of improvements in water-saving technology.
- On a global average, most freshwater withdrawals—69%—are used for agriculture, while industry accounts for 23% and municipal use (drinking water, bathing and cleaning, and watering plants and grass) just 8%.
- Water used around the house for such things as drinking, cooking, bathing, toilet flushing, washing clothes and dishes, watering lawns and gardens, maintaining swimming pools, and washing cars accounts for only 1% of all the water used in the U.S. each year.
- Eighty percent of the fresh water we use in the U.S. is for irrigating crops and generating thermoelectric-power.
- More than 87% of the water consumed in Utah is used for agriculture and irrigation.
- Per capita water use in the western U.S. is much higher than in any other region, because of agricultural needs in this arid region. In 1985, daily per capita consumption in Idaho was 22,200 gallons versus 152 gallons in Rhode Island.
- A corn field of one acre gives off 4,000 gallons of water per day in evaporation.
- It takes about 6 gallons of water to grow a single serving of lettuce. More than 2,600 gallons is required to produce a single serving of steak.
- It takes almost 49 gallons of water to produce just one eight-ounce glass of milk. That includes water consumed by the cow and to grow the food she eats, plus water used to process the milk.
- About 6,800 gallons of water is required to grow a day's food for a family of four.
- The average American consumes 1,500 pounds of food each year; 1,000 gallons of water are required



(Source: Kammerer, J.C., Largest Rivers in the United States, U.S. Geological Survey Fact Sheet OFR 87-242 rev. 1990)

to grow and process each pound of that food.—1.5 million gallons of water is invested in the food eaten by just one person! This 200,000-cubic-feet-plus of water-per-person would be enough to cover a football field four feet deep.

- About 39,090 gallons of water is needed to make an automobile, tires included.
- Only 7% of the country's landscape is in a riparian zone—only 2% of which still supports riparian vegetation.
- The U.S. Fish and Wildlife Service estimate that 70% of the riparian habitat nationwide has been lost or altered.
- More than 247 million acres of United States' wetlands have been filled, dredged or channelized—an area greater than the size of California, Nevada and Oregon combined.
- Over 90% of the nearly 900,000 acres of riparian areas on Bureau of Land Management land are in degraded condition due to livestock grazing.
- Riparian areas in the West provide habitat for more species of birds than all other western vegetation combined—80% of neotropical migrant species (mostly songbirds) depend on riparian areas for nesting or migration.
- Fully 80% of all vertebrate wildlife in the Southwest depend on riparian areas for at least half of their life.
- Of the 1200 species listed as threatened or endangered, 50% depend on rivers and streams.
- One fifth of the world's freshwater fish—2,000 of 10,000 species identified—are endangered, vulnerable, or extinct. In North America, the continent most studied, 67% of all mussels, 51% of crayfish, 40% of amphibians, 37% of fish, and 75% of freshwater mollusks are rare, imperiled, or already gone.
- At least 123 freshwater species became extinct during the 20th century. These include 79 invertebrates, 40 fishes, and 4 amphibians. (There may well have been other species that were never identified.)
- Freshwater animals are disappearing five times faster than land animals.
- In the Pacific Northwest, over 100 stocks and subspecies of salmon and trout have gone extinct and another 200 are at risk due to a host of factors, dams and the loss of riparian habitat being prime factors.



(Source: Encyclopedia Britannica and others)

- A 1982 study showed that areas cleared of riparian vegetation in the Midwest had erosion rates of 15 to 60 tons per year.
- One mature tree in a riparian area can filter as much as 200 pounds of nitrates runoff per year.
- At least 9.6 million households and $390 billion in property lie in flood prone areas in the United States. The rate of urban growth in floodplains is approximately twice that of the rest of the country.
- If all the water in the Great Lakes was spread evenly across the continental U.S., the ground would be covered with almost 10 feet of water.
- One gallon of water weighs 8.34 pounds.

RIVER LENGTHS

It's not so easy to define how long a river is. If a number of tributaries merge to form a larger river, how would you define where the river actually begins? Here, we define river length as the distance to the outflow point from the original headwaters where the name defines the complete length. (Source: Statistical Abstract of the U.S., 1986).

WORLD

Estimates for the length of the world's rivers vary wildly depending on season of the year, who is doing the measuring, the capabilities of the cartographer and his equipment and sources. However, the biggest cause of disagreeing measurements is the inclusion or exclusion of tributaries. For example, many sources lump the Mississippi and Missouri Rivers into one river system, making it one of the longest in the world. The same is true of rivers such as the Ob-Irtysh system in Asia. Considered as a whole, it is one of the ten longest rivers in the world. Removing the Irytish drops the Ob down to 15th position—assuming the rivers ahead of it also weren't measured with massive tributaries included. Here, we have tried to separate the major tributaries. You can easily find other sources that disagree with these numbers; please do not send us further questions on this.

These numbers were taken from the Encyclopedia Britannica and tributaries were separated out with help from sources like Comptons Encyclopedia and others.

SEDIMENT LOAD MEASUREMENTS

Wayne D. Erskine
State Forests of New South Wales
Beecroft, New South Wales, Australia

"No matter how sophisticated, analysis and interpretation can never substitute for well collected data" (1). These words are particularly appropriate for stream sediment loads because most sediment moves during rare, large floods that collectively account for a very small portion of time when access and safety problems are acute (1).

MODES OF SEDIMENT TRANSPORT

Two modes of sediment transport by rivers, suspended load and bed load, are usually recognized on behavioral grounds. *Suspended load* refers to the relatively fine part of the total sediment load that is transported in continuous or intermittent suspension. For sediment to remain in suspension, flow turbulence and velocity must be sufficiently great to counter the tendency of suspended sediment to settle to the riverbed. The two main factors determining sediment settling velocity are grain size and density. *Bed or traction load* refers to the relatively coarse part of the total sediment load that is transported along or close to the riverbed by rolling, sliding, or saltation. The latter term refers to sand movement in a series of hops across a riverbed in a distinct, concentrated layer.

The two modes of sediment transport are not supplementary concepts because a certain grain size can be transported in suspension by a given discharge but as bed load by another smaller discharge. Einstein et al. (2) proposed two alternative modes on the basis of experimental work on the Enoree River in South Carolina, United States. *Wash load* is the finer part of the total sediment load that is not present in bed material in significant quantities and is supplied to and transported through the measurement reach. *Bed-material load* is the coarser part of the total sediment load that is composed of grains found in bed material in appreciable quantities and is transported at a rate dependent on stream discharge. For Einstein et al.'s (2) measurement reach on the Enoree River, 96% of the measured suspended sediment during a flood was finer than 0.351 mm, and not more than 7% of the bed material was finer than 0.351 mm. The rate of transport of sediment coarser than 0.351 mm was a function of discharge, whereas the transport rate for sediment finer than 0.351 mm was related to upstream sediment supply, irrespective of whether it was transported in suspension or by traction. This limiting grain size varies among rivers depending on watershed geology, relief, rainfall, vegetation, land use, channel form, and flood peak discharge and its variability.

Vertical, Lateral and Temporal Distribution of Suspended Sediment at a River Cross Section

If suspended sediment exhibits a uniform vertical and lateral distribution and changes little during short periods of time, then the suspended load can be measured at any point in a river cross section to obtain a mean concentration. Hyperconcentrations of suspended sediment ($400 - 1000$ kg/m^3) in the Yellow River, China, were uniformly distributed in the vertical (3). However, a large body of similar work on other rivers without hyperconcentrated suspended sediment has usually shown that the minimum concentration is found at the water surface and the maximum concentration is found near the riverbed (4,5). Furthermore, the coarsest fractions, which are usually sand, exhibit the greatest variation (5).

Nevertheless, Curtis et al. (4) reported that concentrations of particles as small as 1 or 2 μm (clay) in the Amazon River still showed slight but discernible differences between the riverbed and surface. They concluded that suspended sediment fluxes based only on surface samples are likely to contain significantly large errors.

A number of studies reviewed on the lateral variation of suspended sediment concentration at a cross section found that variations of 20% were common and that some were as large as 70% (5). This is caused by lateral variations in flow velocity and depth (and the consequent development of mobile bedforms) and by incomplete mixing of sediment-laden inflows from small tributaries into large rivers (Fig. 1). The latter effect needs to be evaluated carefully before selecting a field measurement site that should exhibit well-mixed conditions (Fig. 1).

Measured instantaneous fluctuations in depth-integrated (see below) suspended sediment concentration can vary by up to 24% (5,6). The problems of vertical, lateral, and temporal variations in suspended sediment concentration at a cross section are considerable and indicate that suspended sediment samples must be collected during a meaningful period of time from the full flow depth at multiple verticals on a river cross section.

Suspended Load. The suspended sediment load (Q_s in tonnes/day) is calculated from:

$$Q_s = 0.0864QC_s \tag{1}$$

where Q is the discharge (m^3/s) and C_s is the suspended sediment concentration (mg/L).

It is, therefore, necessary to know the discharge at the measurement site and also the mean suspended sediment concentration to calculate reliable suspended loads. For this reason, sediment load measurement sites should be located at well-mixed sections at river gauging stations.

Three requirements for an efficient suspended sediment sampler are

Figure 1. Upstream view of the Sacramento River at Knights Landing, California, showing a muddy plume originating from the tributary in the middle left of the photograph which follows the right bank for some distance before completely mixing with the less turbid mainstream flow (W.D. Erskine photograph).

1. the flow velocity at the sampler intake should be the same as stream flow velocity,
2. the sampler should cause minimum flow disturbance at the sampling point, and
3. the sampler intake should be oriented into the flow in both vertical and horizontal planes (7).

Six main types of suspended sediment samplers have been identified (7–10):

1. instantaneous samplers
2. point-integrating samplers
3. depth-integrating samplers
4. single stage samplers
5. pumping samplers
6. continuous monitoring techniques.

Instantaneous samplers collect a water–sediment mixture at a single time at a single point in a vertical in the stream. Clearly, they cannot account for any temporal, vertical, or lateral variations in concentration and hence are not recommended for use in sediment load programs. However, they are appropriate for other water quality or limnological programs. Point-integrating samplers collect a water–sediment mixture at a predetermined depth in a single vertical of a river cross section during a short time period and, therefore, are time-integrated samplers. A valve is used to open the nozzle, and a separate air exhaust expels the air displaced by the sample. A series of depth settings acceptable for point-integrating samplers was found (11). The U.S. Federal Inter-Agency Sedimentation Project (6,8,10) developed a series of such samplers (USP61, USP 63, USP 72); USP 61 is illustrated in Fig. 2.

Depth-integrating samplers continuously collect a water–sediment mixture at a rate proportional to the flow velocity from the water surface to near the bed as they are lowered and raised at a uniform rate at a series of verticals at a river cross section (6,9,10). The resultant suspended sediment concentration is a time- and velocity-weighted mean. Gregory and Walling (7) recommended that the vertical transit rate (the rate of lowering and raising) should not exceed 40% of the maximum flow velocity in the vertical. The intake nozzle diameter can also be changed to ensure that the sample bottle capacity is not exceeded for deep and/or fast streams. The U.S. Federal Inter-Agency Sedimentation Project (6,8,10) developed a series of such samplers (USD 43, USDH 48, USDH 59, USDH 75, USDH76, USDH 81, USD 49, USD 74, USD 77); USDH 48 and 59 are illustrated in Fig. 2. There is an unsampled zone about 0.1m high immediately above the bed for depth-integrated samplers because of the inclined sample bottle (Fig. 2) to ensure that bed material is not scooped into the nozzle when the sampler reaches the bed. Depth-integrated samplers have been the accepted standard for hand field measurements of suspended load for the last 50 years (6,7,9,10).

Depth-integrated suspended sediment sampling is conducted according to either the equal transit rate (or equal width increment) method or the equal discharge

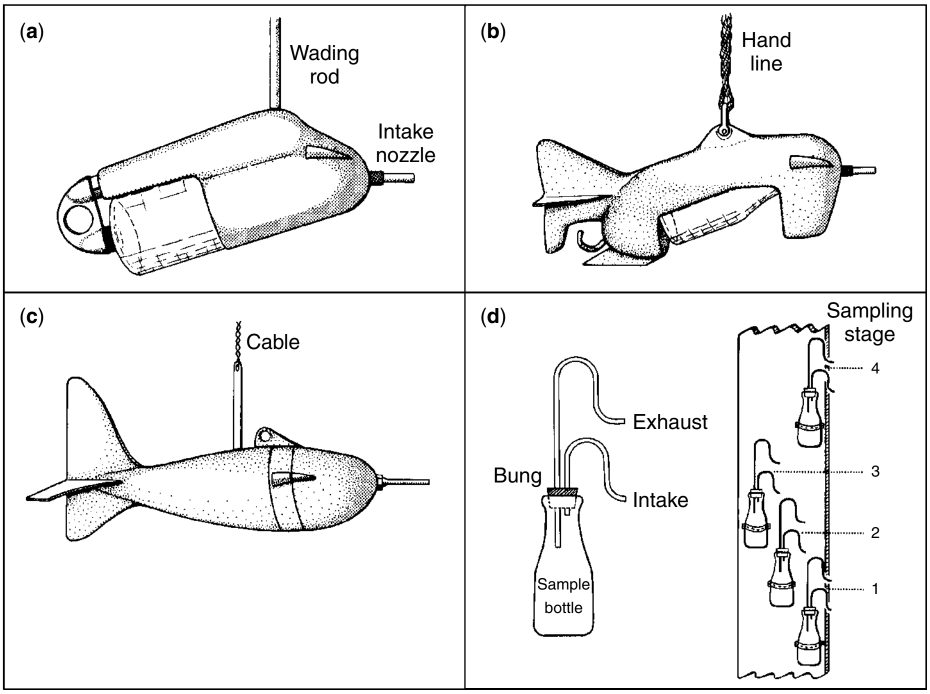


Figure 2. Suspended sediment samplers from Reference 7. (**a**) USDH 48 depth-integrating sampler; (**b**) USDH 59 depth-integrating sampler; (**c**) USP 61 point-integrating sampler which can also be used as a depth-integrating sampler if the valve is left open; and (**d**) single-stage (rising stage) samplers.

increment method (8,9). The equal transit rate method involves moving the sampler at a constant rate between the water surface and the bed at each of a series of verticals equally spaced across the channel. No prior knowledge of the velocity pattern is required at the sampling site to obtain a mean suspended sediment concentration for the whole section. Edwards and Glysson (8) developed guidelines for determining the number of verticals needed to achieve a given relative standard error based on the percentage of sand in the sample and an index of variability computed from the flow velocity and depth. The equal discharge increment method involves dividing the cross section into a series of segments of equal discharge and collecting depth-integrated samples at the centroid of each segment. Clearly, the latter method can be used only when complete velocity–area gauging has also been completed and calculated. This is not always the case.

Single-stage samplers are a type of automatic point-integrating device (10). They consist of a sample bottle equipped with intake and exhaust tubes which fills automatically when the stream first reaches the stage that submerges the sampler (Fig. 2). Such samplers usually do not collect a sample representative of the mean suspended sediment concentration at the cross section and can be contaminated by postinundation flows which can pass through the sampler.

Pump samplers remotely obtain detailed time series variations in suspended sediment concentrations at a fixed point in the stream and are required for accurate load determinations (9,10,12). Sampler intakes should be set either at a fixed position characterized by sufficient flow turbulence to ensure minimum variation in concentration throughout the cross section (13) or on a depth proportional intake boom (12). The latter consists of a hinged boom attached to the riverbed at a pivot and suspended by a float; the intake is set at an appropriate proportion of the flow depth (12). The boom should be at least twice as long as the maximum expected stage, and the intake should be set at an acceptable depth, 0.6 was adopted by Eads and Thomas (12). The boom rises and falls with the flood stage and can be depressed by transported large woody debris to avoid damage because it is oriented downstream. Nevertheless, a single pump sampler intake still equates to a point-integrating approach to sampling (12), and the representativeness of the sample intake point must always be determined.

Pump samplers can be programmed to collect water–sediment samples at specific turbidity thresholds (14) or by various stratified or variable probability plans that reduce the variance in the sediment load. Thomas and Lewis (15) evaluated flow-stratified, time-stratified, and selection-at-list time (SALT) sampling plans and found that

- time-stratified sampling generally gives the smallest variance in storm sediment loads;
- flow-stratified and SALT sampling have difficulties only with small storms because of lack of data; and
- flow-stratified sampling produces the lowest variance for longer, more complex hydrographs that have numerous peaks.

A number of simultaneous pump and depth-integrated samples should be obtained to determine if the pump sample intake position is appropriate to produce suspended sediment concentrations that are equivalent to, or can be converted to equivalence with, depth- and width-integrated samples (12,13). Pumped-sample suspended sediment concentrations obtained from a single, fixed-position intake in a zone of turbulent flow generally varied within 10% of depth-integrated samples without a consistent trend to over- or underestimate concentrations (13). Pump-sample suspended sediment concentrations collected by a constant depth proportion intake were closely related to depth- and width-integrated samples ($r^2 = 0.98$) but pumped concentrations were higher for concentrations above approximately 100 mg/L (12). These results highlight that pump samplers should be used for automatic suspended sediment sampling, providing that the resultant concentrations are equivalent to, or can be converted to equivalence with, depth- and width-integrated samples.

The most common continuous monitoring technique uses turbidity and measures the attenuation or scattering of an incident beam of radiation or light. Turbidity can be measured with an *in situ* probe at frequent time intervals, and the resultant values can often be converted to depth- and width-integrated suspended sediment concentrations (13,14,16–18). Reported r^2 values for relationships between depth-integrated suspended sediment concentration and turbidity can be as high as 0.90 to 0.99 (13,15). However, such relationships are usually site-specific and more reliable where suspended sediment is dominated by silt and clay (14,16).

Bed Load. A range of different portable and permanent bed load samplers has been developed for use in sand- and gravel-bed rivers, but their performance has often been poor (19). Portable samplers include baskets (7,19), trays (7,19), pressure-difference samplers (19–23), acoustic meters (19), and pumps (24). Permanent samplers are associated with major in-stream structures and include vortex tubes (25), pits (19), slot with a conveyor belt emptying into a continuous weighing hopper (26,27), and the Birkbeck bed load sampler (28). The latter consists of slots in the riverbed fitted with boxes resting on water-filled pressure pillows and combined with pressure transducers for stream height measurement (28). Most early samplers were unsatisfactory because of inaccurate measurements, variable and poor sampling efficiency (19), inconsistent sampler placement on the riverbed, and the oscillatory nature of bed load transport (19,29). The slot with a conveyor belt (26,27) is the most innovative and reliable technique devised to date but is also very expensive.

The Helley–Smith pressure-difference bed load sampler was designed and developed by the U.S. Geological Survey, Water Resources Division to be compatible with depth-integrated suspended sediment samplers (22) and is one of the most accurate (20,21,23). For sediments whose diameters are between 0.5 and 16 mm, the sampler has a near-perfect sampling efficiency that is higher for finer sediment and lower for coarser sediment (20,21). Sample bags can be filled to about 40% capacity with sediment larger than the mesh size without reducing hydraulic efficiency (20,21). Larger than standard sampling bags and increased bag mesh size improved sampling efficiencies in streams that have high sand and organic matter fluxes because of reduced bag plugging (23,30,31). Short sampling times also increase sampling efficiency in the same streams (31). Thin-walled samplers (1.5 mm) also measure larger sand fluxes than thick-walled (6.3 mm) samplers due to local hydraulic effects (32). To operate efficiently, the sampler must have a reasonable fit between the sampler base and the riverbed and will not sample satisfactorily when the bed is highly irregular (21). The inlet orifice diameter of the original Helley–Smith sampler (76.2 mm) closely approximates the unsampled zone between the intake nozzle and the bed for a depth-integrated suspended sediment sampler (22). Therefore, depth-integrated suspended load samplers collect intermittently suspended bed material and wash load whereas pressure-difference bed load samplers collect sediment moving by rolling and sliding, bedform migration, and saltation.

There is considerable temporal and spatial variability inherent in bed load transport rates (20,21,29,32,33) which makes field measurements difficult. Bed load fluxes measured at a fixed sampling point during constant discharge on a sand-bed stream that has dune bedforms range from near zero to approximately four times the mean rate, and about 60% are less than the mean (29,32,33). Field measurements indicate that highest transport rates occur in the center of the channel and diminish near the margins (32). The U.S. Geological Survey provisional method for bed load gaugings entails two complete traverses of a cross section and at least 20 equally spaced, point measurements for 30–60s at least 0.5m apart on each pass (21). Although instantaneous bed load fluxes are highly variable, it is usually possible to define a mean flux for a given discharge, provided thorough field measurements are made (21,32). Marked differences in bed load fluxes and their relationship to discharge occur between pools and riffles (21).

SEDIMENTATION

CHIH TED YANG
PIERRE Y. JULIEN
Colorado State University
Fort Collins, Colorado

Sedimentation is a science of interest to geologists, river morphologists, environmentalists, and engineers. Geologists are interested in the formation, mineral content, and age of sedimentary rocks. River morphologists are interested in the formation of rivers, their patterns, and profiles. Environmentalists are interested in the impacts of sediments on water quality, aquatic habitat, and ecosystems. Engineers are interested in the movement of sediment and its impact on the engineering design and operation of hydraulic structures. Due to these differences of interests and emphases, sedimentation studies can vary from qualitative to quantitative or a combination of both.

This article emphasizes the hydraulics of sediment transport. Due to the complexity of sediment transport, only basic assumptions and approaches used by engineers are summarized here. More detailed descriptions and analyses of sediment transport, scour, and deposition can be found in text books such as those by Julien (1), Yang (2), Simons and Sentürk (3), and Yalin (4).

Sediment transport can be classified as bed load, suspended load, and total load. Two basic approaches are used to study sediment transport, the probabilistic and deterministic approaches. Einstein (5) developed the most well-known probabilistic theory for sediment transport. Engineering applications of Einstein's transport functions are limited due to laborious computation procedures and extensive field data requirements. However, the modified Einstein method (6) has been used by engineers to estimate total bed-material load where direct bed load measurements are difficult to obtain.

The deterministic approach assumes that there is a one-to-one functional relationship between the dependent variable of sediment transport rate, or concentration, and independent variables. Commonly used independent variables are water discharge, average flow velocity, water surface or energy slope, shear stress, stream power, and unit stream power.

Figure 1 shows that unit stream power has the strongest one-to-one correlation with sediment discharge.

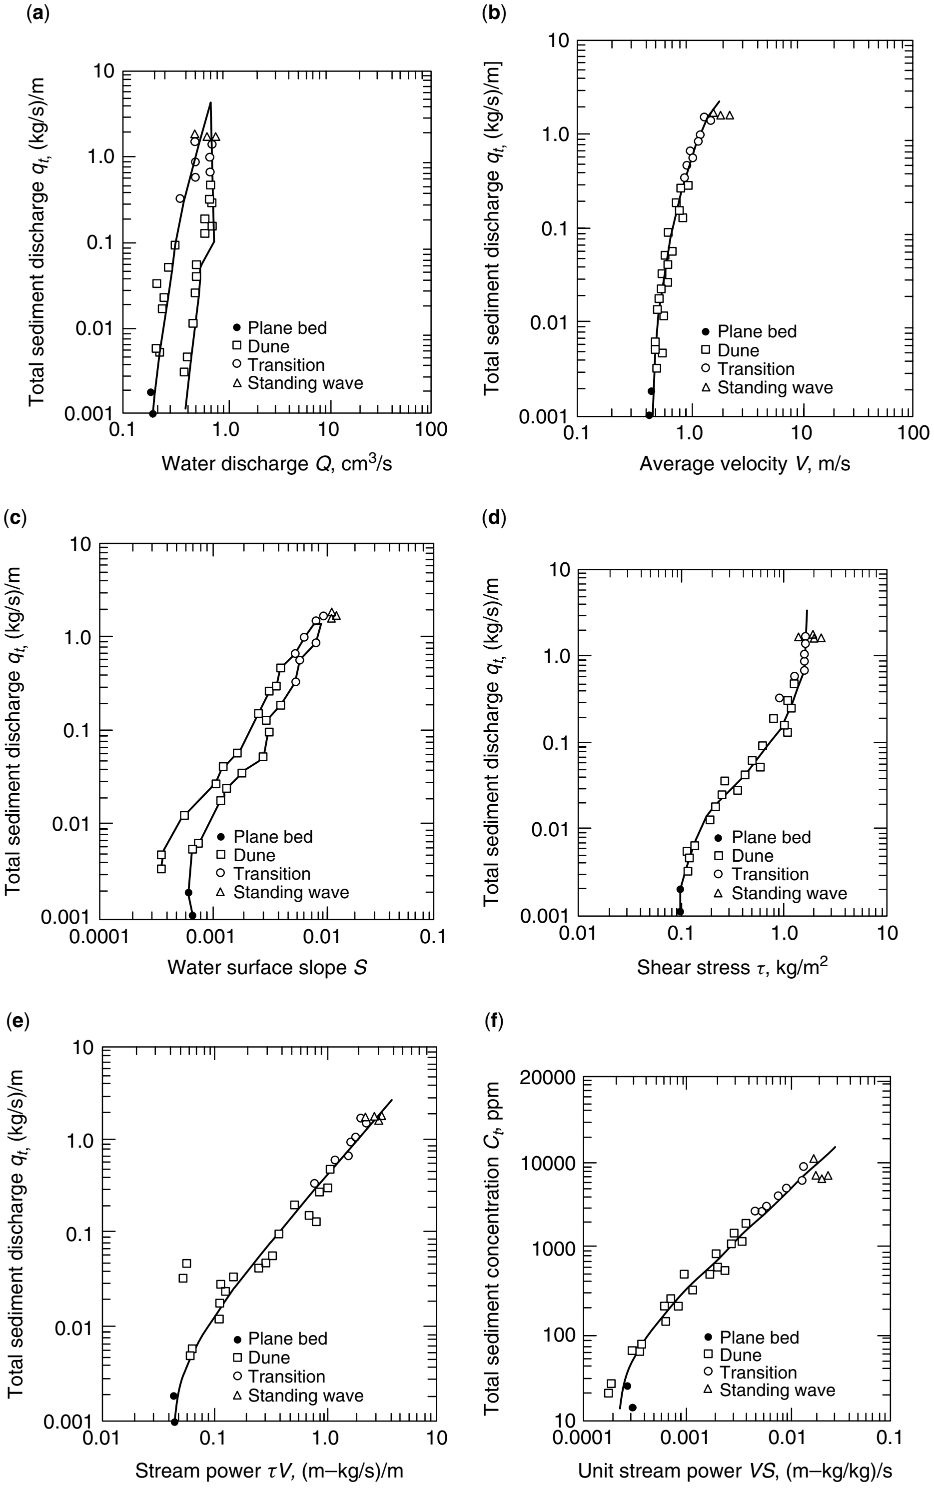

Figure 1. Relationships between total sediment discharge and (**a**) water discharge, (**b**) velocity, (**c**) slope, (**d**) shear stress, (**e**) stream power, and (**f**) unit stream power, for 0.93-mm sand in an 8-ft wide flume (7).

Yang's 1973 (8) dimensionless unit stream equation is

$$\log C_{\mathrm{ts}} = 5.435 - 0.286 \log \frac{\omega d}{\upsilon} - 0.457 \log \frac{U_*}{\omega} + \left(1.799 - 0.409 \log \frac{\omega d}{\upsilon} - 0.314 \log \frac{U_*}{\omega}\right) \log\left(\frac{VS}{\omega} - \frac{V_{\mathrm{cr}} S}{\omega}\right) \tag{1}$$

where C_{ts} = total sediment concentration in ppm by weight, VS = unit stream power, U_* = shear velocity, υ = kinematic viscosity of water, ω = fall velocity of sediment, d = median sediment particle diameter, V = average flow velocity, S = slope, and V_{cr} = critical flow velocity at incipient motion.

The independent variables in Eq. 1 can be measured directly in the field except the fall velocity of sediment.

The fall velocity can be obtained from figures based on experimental results recommended by the U.S. Inter-Agency Committee on Water Resources, Subcommittee on Sedimentation (9). The fall velocity can also be computed by Rubey's 1933 formula (10).

The sediment concentration or sediment load computed from different formulas can vary drastically from each other and from measurements. Figure 2 shows comparison among the computed total sediment discharges using different formulas and the measured results from the Niobrara River near Cody, Nebraska. Table 1 summarizes the ratings of some of the commonly used sediment transport formulas by the American Society of Civil Engineers Task Committee for users to consider.

Riverbed sediment particles are not uniform in size. Computations of sediment transport by size fraction are necessary to obtain realistic results for engineering purposes. Computer models are often used to simulate and predict the process of scour, transport, and deposition in rivers and reservoirs. The U.S. Army Corps of Engineers' HEC-6 (13) model and the Bureau of Reclamation's GSTARS 2.1 (14) and GSTARS3 (15) are some of the commonly used models in the public domain for solving river engineering and river morphology problems where the movement of sediment, scour, and deposition are subjects of concern. The Bureau of Reclamation's models and user's manuals can be obtained by going to http://www.usbr.gov/pmts/sediment/ and following the links therein.

Table 1. Summary of Rating of Selected Sediment Transport Formulas[a]

Formula Number	Reference	Type	Comments
1	Ackers and White	Total load	Rank = 3[b]
2	Engelund and Hansen	Total load	Rank = 4
3	Laursen	Total load	Rank = 2
4	MPME[c]	Total load	Rank = 6
5	Yang	Total load	Rank = 1, best overall predictions
6	Bagnold	Bed load	Rank = 5
7	Meyer-Peter and Müller	Bed load	Rank = 7
8	Yalin	Bed load	Rank = 8

SEDIMENTATION AND FLOTATION

SEDIMENTATION

Overview

Waters and wastewaters typically contain particulate matter ranging from a few microns to centimeters in diameter, although the actual size distribution is often highly variable. One of the most common methods for the removal of particulate matter from waters and wastewaters is simple gravity settling, often referred to as "sedimentation."

In water and wastewater treatment, four general classes of sedimentation can occur: Type 1, discrete settling; Type 2, flocculent settling; Type 3, hindered or "zone" settling; and Type 4, compression settling. In Type 1 settling, particles settle individually with no interparticle interactions. Consequently, no change in particle size occurs (i.e., floc formation). This system is often analyzed using *Stokes' Law*, based on a force balance on a single particle settling in a viscous medium under laminar flow conditions. The development and application of this method of analysis is demonstrated in a subsequent subsection.

In flocculent settling, small particles aggregate to form larger particles. As the particles increase in size, the particle settling velocity increases (for particles of equal density). In order to make this process occur, chemicals are added to induce particle coalescence/coagulation and to promote the formation of "floc." In water treatment, a coagulant such as [hydrated] aluminum sulfate ("alum"), ferric sulfate, ferric chloride, silica, clays, and polymers can all be used to promote the formation of larger particles. In order to determine the optimum coagulant dose for a particular water, bench-scale tests must be performed. Further, it should be noted that the effectiveness of individual coagulants can be highly pH-dependent. For example, the formation of $Al(OH)_3(\downarrow)$ through the addition of alum requires $5 \leq pH \leq 8$ and sufficient alkalinity for the reaction to initiate, as presented in Eq. 1. (Note that alum can also be hydrated with 18 H_2O.)

$$\mathrm{Al_2(SO_4)_3 \cdot 14H_2O} + \underbrace{\mathrm{3Ca(HCO_3)_2}}_{\mathrm{ALK}} \rightarrow \mathrm{2Al(OH)_3}(\downarrow) + \mathrm{3CaSO_4} + \mathrm{14H_2O} + \mathrm{6CO_2} \quad (1)$$

Hindered or "zone" settling occurs when interparticle interactions inhibit the discrete settling of adjacent particles. In this case, particles tend to remain in a fixed position with respect to one another. Consequently, the agglomerated particles settle as a zone and a distinct solid-liquid interface develops at the top of the settling mass. This process occurs without the addition of chemical coagulants. In Type 4 or "compression settling", a structure is formed in which settling occurs via gravity compression of the structure, because of the weight of particles. Compression settling typically occurs in samples with high solids concentration, such as the secondary clarifier in wastewater treatment or in sludge thickening facilities (1,2).

Analysis and Modeling

To develop an understanding of the physics involved in sedimentation, it is useful to examine the simplest case of discrete settling. Based on the general force balance presented in Fig. 1, the velocity of a solid spherical particle of a given diameter and density settling in a viscous medium can be determined according to Eq. 2a.

$$F_{\mathrm{gravity}} - F_{\mathrm{buoyant}} - F_{\mathrm{drag}} = m_{\mathrm{p}} a_{\mathrm{s}} \quad (2a)$$

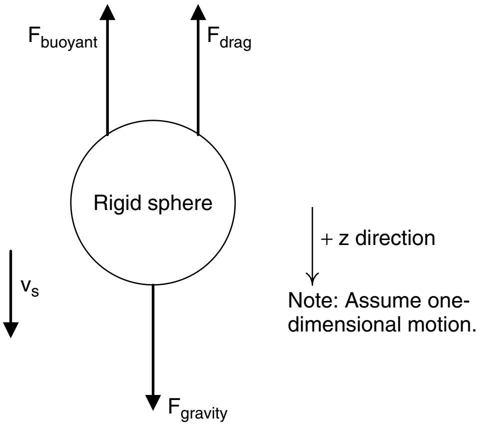

Figure 1. General force balance for a solid spherical particle settling in a viscous medium.

where $F_{\mathrm{gravity}} =$ gravitational force, $F_{\mathrm{buoyant}} =$ buoyant force, $F_{\mathrm{drag}} =$ drag force, $m_{\mathrm{p}} =$ particle mass, and $a_{\mathrm{s}} =$ acceleration of settling particle. If it is presumed that a terminal settling velocity has been reached (i.e., $a_{\mathrm{s}} = 0$), the force balance can be rewritten as:

$$F_{\mathrm{gravity}} - F_{\mathrm{buoyant}} - F_{\mathrm{drag}} = m_{\mathrm{p}} a_{\mathrm{s}} = m_{\mathrm{p}} \underbrace{\frac{dv_{\mathrm{s}}}{dt}}_{0} = 0 \qquad (2b)$$

The terms in the force balance can be written explicitly as presented in Eqs. 3a, 3b, and 3c.

$$F_{\mathrm{gravity}} = V_{\mathrm{p}} g \rho_{\mathrm{p}} \qquad (3a)$$

$$F_{\mathrm{bouyant}} = V_{\mathrm{p}} g \rho_{\mathrm{w}} \qquad (3b)$$

$$F_{\mathrm{drag}} = C_{\mathrm{D}} A_{\mathrm{p}} \rho_{\mathrm{w}} \frac{v_{\mathrm{s}}^2}{2} \qquad (3c)$$

where $V_{\mathrm{p}} =$ particle volume, $g =$ gravitational constant (9.8 m/s^2), $\rho_{\mathrm{p}} =$ density of particle (typical value = 1,400 kg/m^3), $\rho_{\mathrm{w}} =$ density of water (1,000 kg/m^3 under standard conditions), $C_{\mathrm{D}} =$ drag coefficient, $A_{\mathrm{p}} =$ cross-sectional area of the particle, and $v_{\mathrm{s}} =$ particle settling velocity.

Based on the general force balance presented in Fig. 1, and using Eqs. 2 and 3, the settling velocity for spherical particles of a given diameter and density can be determined as:

$$v_{\mathrm{s}} = \sqrt{\frac{4}{3} \frac{g(\rho_{\mathrm{p}} - \rho_{\mathrm{w}}) d_{\mathrm{p}}}{C_{\mathrm{D}} \rho_{\mathrm{w}}}}, \ \mathrm{Re} \geq 1 \qquad (4)$$

As only one-dimensional motion is considered, vector notation has been dropped and the sign convention presented in Fig. 1 is used throughout.

The drag coefficient for rigid spheres can be calculated according to Eq. 5, where C_{D} is a function of the hydraulic flow regime, established using the Reynolds number, Re, given in Eq. 6.

$$C_{\mathrm{D}} = \frac{24}{\mathrm{Re}} + \frac{3}{\sqrt{\mathrm{Re}}} + 0.34 \qquad (5)$$

$$\mathrm{Re} = \frac{v_{\mathrm{s}} d_{\mathrm{p}} \rho_{\mathrm{w}}}{\mu_{\mathrm{w}}} = \frac{v_{\mathrm{s}} d_{\mathrm{p}}}{\nu_{\mathrm{w}}} \qquad (6)$$

When spherical particles settle in a viscous medium under laminar flow conditions (Re < 1), the first term in Eq. 5 predominates (i.e., $C_{\mathrm{D}} \simeq 24/\mathrm{Re}$) and the expression for settling velocity becomes more simple:

$$v_{\mathrm{si}}(\text{Stokes'}) = \frac{g(\rho_{\mathrm{p}} - \rho_{\mathrm{w}}) {d_{\mathrm{pi}}}^2}{18 \mu_{\mathrm{w}}}, \ \mathrm{Re} < 1 \qquad (7)$$

This form of the settling velocity is known as "Stokes' Equation." As most waters and wastewaters contain particles of many different sizes, an additional subscript "i" is typically added to denote particles of the same size in an otherwise heterogeneous distribution. Consequently, a different settling velocity would have to be calculated for different size particles (1,2).

Application

In order to adequately analyze particle removal through sedimentation, it is necessary to establish a framework for analysis. In this case, consider the longitudinal cross section of a settling basin shown in Fig. 2. Assume a uniform distribution of particles at the entrance, along which particles can enter at any height. Further, any particle that settles into the sludge zone is permanently removed from the system. Now, define the "critical settling velocity" (v_{sc}) as the settling velocity of the smallest particle that will be 100% removed. To further ease the analysis of this system, the critical settling velocity vector will be broken into its horizontal (v_{h}) and vertical (v_{sc}) components. Note that in sedimentation, we are primarily concerned with motion in the vertical direction, so the vertical component of the settling velocity is often labeled "v_{sc}." The trajectory of particles with a velocity, v_{si}, equal to v_{sc} is also presented in Fig. 2. In this case, 100% of the particles are removed from the system, regardless of their entry position at the inlet.

Similarly, the trajectory of particles with a settling velocity greater than v_{sc} is presented in Fig. 3. [The trajectory of particles with a critical settling velocity (dashed lines) has been added to Fig. 3 for reference.] In this case, 100% of the particles are removed from the system, regardless of their entry position at the inlet.

The trajectory of particles with $v_{\mathrm{si}} < v_{\mathrm{sc}}$ is presented in Fig. 4. By examining the trajectories of these particles,

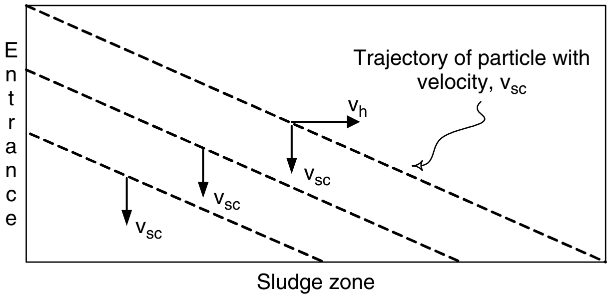

Figure 2. Trajectory of particles with a settling velocity equal to v_{sc}.

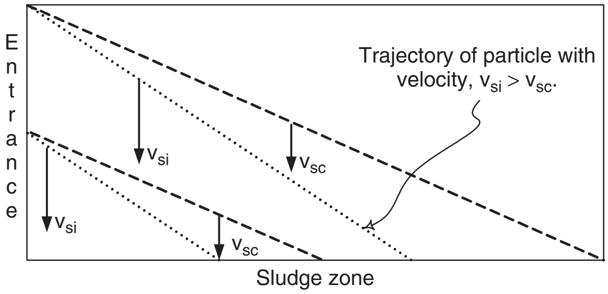

Figure 3. The trajectory of particles with a settling velocity greater than v_{sc}.

we can see that it is possible to have some particles "escape" through the outlet. Likewise, some particles may become trapped in the sludge zone, depending on their respective position at the inlet and the magnitude of v_{si} relative to v_{sc}. Consequently, when the settling velocity of an individual particle is less than the critical settling velocity, fractional particle removal will occur; the fraction of particles removed when $v_{si} < v_{sc}$ is given by Eq. 8 (1,2).

$$F_r = \frac{v_{si}}{v_{sc}} \tag{8}$$

Process Design and Implementation

In a typical water treatment process, sedimentation follows coagulation and flocculation, as presented schematically in Fig. 5. In activated sludge wastewater treatment, two sedimentation basins are used, as presented in Fig. 6. With regard to sedimentation basin design, it is common to determine the hydraulic detention time, θ_H, and hydraulic surface loading rate, S, presented in Eqs. 9 and 10, respectively. Typical design parameters for sedimentation tanks used in primary and secondary wastewater treatment are presented in Tables 1 and 2, respectively (1,3).

$$V_{basin} = \theta_H \cdot Q \tag{9}$$

$$S = \frac{Q}{A} \tag{10}$$

where V_{basin} = volume of sedimentation basin, θ_H = hydraulic detention time, Q = water/wastewater flow rate, and A = basin surface area.

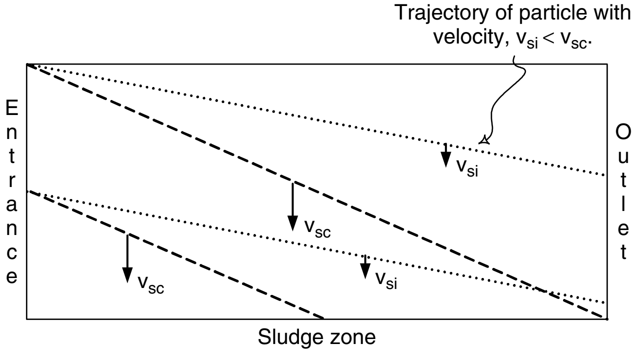

Figure 4. The trajectory of particles with a settling velocity less than v_{sc}.

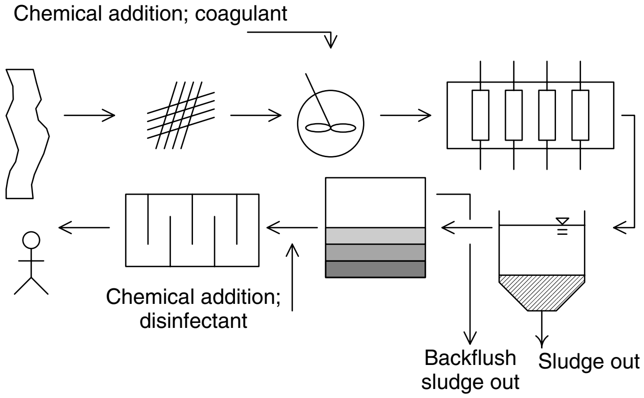

Figure 5. Schematic showing location of sedimentation in typical water treatment process.

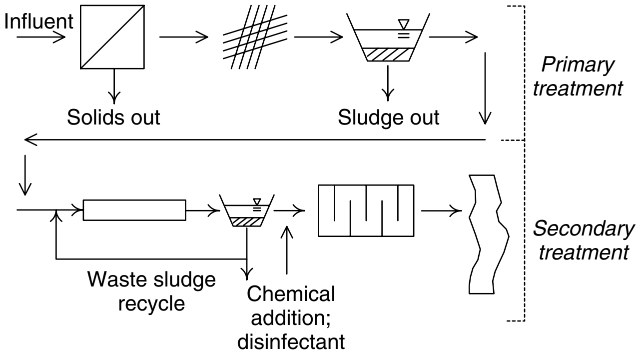

Figure 6. Schematic showing location of two sedimentation basins used in activated sludge wastewater treatment.

Table 1. Typical Design Parameters for Sedimentation Tanks Used in Primary Wastewater Treatment (1)

Primary Treatment Followed by Secondary Treatment	Range	Typical
Hydraulic detention time, hr	1.5–2.5	2.0
Average overflow rate (average flow), gal/ft^2·d	800–1,200	
Overflow rate (peak flow), gal/ft^2·d	2,000–3,000	2,500
Primary Treatment Followed by Waste Activated Sludge		
Hydraulic detention time, hr	1.5–2.5	2.0
Average overflow rate (average flow), gal/ft^2·d	600–800	
Overflow rate (peak flow), gal/ft^2·d	1,200–1,700	1,500

The data presented in Table 1 are for general reference purposes. In actual system design, factors such as water flow rate, basin depth, and desired solids removal must be considered (4).

FLOTATION

Flotation is a process for the separation of particulate matter from liquids in which bubbles are introduced into

Table 2. Typical Design Parameters for Sedimentation Tanks Used in Secondary Wastewater Treatment (3)

Secondary Treatment	Range
Average overflow rate (average flow), gal/ft$^2\cdot$ d	400–800
Overflow rate (peak flow), gal/ft$^2\cdot$ d	1,000–1,200
Average solids loading rate, lb/ft$^2\cdot$ d	0.8–1.2
Peak solids loading rate, lb/ft$^2\cdot$ d	2.0
Depth, ft	12–20

a wastewater and the solid particles rise with the bubbles. The particulate matter is then skimmed off the water surface and clarified water is removed from the bottom of the basin (1). A comparative schematic of sedimentation and flotation processes is presented in Fig. 7. Flotation is typically applied in cases where particles are difficult to remove via sedimentation; examples include synthetic fibers in the textile industry, wood fibers in the pulp and paper industry, and oily wastewaters (5). Flotation is also used in activated sludge thickening (1).

In general, air flotation and dissolved air flotation are the two types of flotation processes used most widely in industry. In air flotation, air is introduced via fine bubble diffusers. In this process, problems with diffuser clogging are common. Additionally, a large fraction of the operating cost is associated with the need to supply large amounts of power to force air bubbles through the diffusers.

Dissolved air flotation (DAF) is different from air flotation mainly in the conditions under which air enters the system. A schematic of a typical DAF process used to thicken activated sludge is presented in Fig. 8 (1). In dissolved air flotation, air is injected into wastewater under pressure. In typical wastewater applications, air is pressurized to 345–483 kPa (3.4–4.8 atm; 50–70 psi) (5), which results in an increase in the solubility of air in water. When the pressure is released to the atmosphere, the excess dissolved air comes out of the aqueous phase and rises. In order to enhance the particle removal efficiency of DAF processes, it is common to add chemicals that promote flocculation to the influent prior to pressurization. Reagents used for this purpose are similar to those used in coagulation/flocculation processes (e.g., alum, polymers, etc.) (1,5).

Vacuum flotation is a third technique in which wastewater is saturated with air under atmospheric pressure. A vacuum is applied to the wastewater in an enclosed tank, where the air is pulled from solution and particles rise to the top. The application of vacuum flotation is generally limited to small operations, because higher capital and operating costs associated with maintaining a closed reactor system.

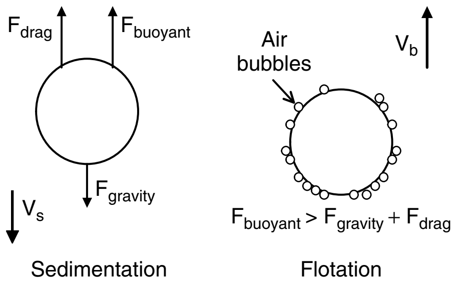

Figure 7. Comparative schematic of sedimentation and flotation.

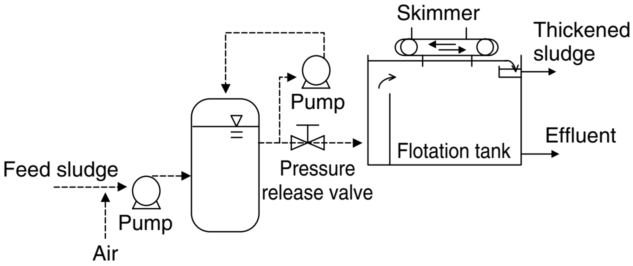

Figure 8. Schematic of a typical dissolved air flotation process used to thicken activated sludge. (Note: no recycle).

FLOTATION VERSUS SEDIMENTATION?

The selection of either sedimentation or flotation as a solid/liquid separation process depends on a large number of factors, including particle density, overflow rate, aesthetic requirements, sludge volume production rate, ease of operation, and availability of reliable design data. However, the guidelines presented in Table 3 can be used to compare and screen these processes for potential application.

Table 3. General Guidelines/Comparison for Selection of Sedimentation and Flotation Processes

Flotation	Sedimentation
Generally favored when particles with low density (low specific gravity) are to be removed.	Substantially less complicated to operate (e.g., fewer maintenance and operating problems, requires less skilled staff than flotation processes).
Can be used when space and/or capital are limited because higher overflow rates can be applied, which results in smaller tank requirements.	Requires less power for operation.
Odor problems can be minimized because of the lack of septic conditions.	Can easily be designed from the wealth of reliable performance data available.
A thicker sludge and, consequently, a lower sludge volume is produced.

RESERVOIR SEDIMENTATION

Sharad K. Jain
National Institute of Hydrology
Roorkee, Uttranchal, India

The detachment and transportation of soil is termed soil erosion. Every stream carries some sediment in suspension and moves larger particles along its bed. The deposition of sediment in channels or reservoirs creates a variety of problems, such as raising stream beds, meandering and overflow along the banks, and, of course, depletion of storage capacity in reservoirs.

The sediment content in river waters varies with flow conditions. It is small in lean flow months, but it attains a maximum value during floods. The total quantity of sediment transported annually to the sea by rivers of the world is about 2×10^{10} tons or about 13.5 km^3 in volume. Worldwide, reservoirs are annually losing about 1% of their storage capacity or about 65 km^3/year. The rate of loss of reservoir storage in the United States is about 0.22%/year which is equivalent to 2020 million m^3/year. Based on weighted average data from 144 reservoirs in India, the annual loss of gross storage was estimated at 0.44%.

Sediment source and reservoir locations are not uniformly distributed; the problem is really severe in some countries. China has more than 80,000 reservoirs that are annually losing, on average, 2.3% of their storage capacity due to sedimentation.

INTRODUCTION

Soil erosion is considerably high in arid climates. In India, about 5333 million tonnes (16.35 t/ha) of soil is detached annually due to agriculture and associated activities. Of this, about 29% is carried away to oceans by rivers. Nearly 10% of it is deposited in reservoirs resulting in loss of 1–2% of storage capacity (1). The sediment transport of selected rivers is given in Table 1.

Each sediment particle transported by flow is affected by two dynamic forces: a horizontal component acting in the direction of flow and a vertical component due to gravity; there is also the force of water turbulence. The specific gravity of soil materials is about 2.65, so particles of suspended sediment tend to settle to the channel bottom, but upward currents in the turbulent flow counteract gravitational settling. The sediment inflow and outflow in natural river reaches are mostly in balance. A reservoir changes the flow characteristics and its sediment transport capacity. Because the reservoir width is much bigger than the river width, the velocity of flow entering into it decreases tremendously and there is a dampening of turbulence. Consequently, the flow is unable to transport all the sediments, and the particles begin to deposit. First, the larger suspended particles and most of the bed load are deposited at the mouth of the reservoir. The smaller particles remain in suspension for a long time and some may leave the reservoir with water.

Table 1. Sediment Transported by Selected Rivers[a]

River	Drainage Area, km^2	Average Sediment Concentration, kg/m^3	Erosion Modulus, $ton/km^2/yr$
Nile	2,978,000	1.25	37
Missouri	1,370,000	3.54	159
Colorado	637,000	27.5	212
Indus	969,000	2.49	449
Irrawaddy	430,000	0.70	695

RESERVOIR SEDIMENTATION

The accumulation of sediments is one of the principal factors that threaten the longevity of reservoirs. Sometimes a project is not constructed just because the silting rate is so high that the reservoir will fill up before the investment is fully recovered.

The ultimate destiny of all reservoirs is to be filled by sediment. There are instances of reservoirs filling up within a few years of their operation. The Sanmexia dam was the first major dam on the middle reaches of the Yellow River. In the first 18 months after dam closure, 1.8 billion metric tons of sediment accumulated in the reservoir, representing a trap efficiency of 93% (3). The Xinghe Reservoir in Shaanxi Province took 2 years to construct but only 1 year to fill with sediment.

The right approach to solving a reservoir sedimentation problem has three segments: (1) collect and analyze field data, (2) set up appropriate models, and (3) develop an operational policy for the reservoir. Deposition and scouring may differ considerably when different operating policies are adopted.

The sediment deposits in a reservoir can be divided in three groups: topset beds, foreset beds, and bottomset beds (see Fig. 1). Topset beds are composed of large size sediment deposits but may also have fine particles. These extend up to the point where the backwater curve ends. The downstream limit of the topset bed corresponds to the downstream limit of bed material transport in the reservoir. These deposits cause a minor reduction in reservoir storage capacity. The foreset deposit is the face of the delta deposit advancing toward the dam. It is a transition zone that has steeper slopes and decreasing grain size. The bottomset beds consist of fine sediments that are deposited beyond the delta by turbidity currents or nonstratified flow. This pattern of deposits may change due to reservoir drawdown, slope failures, and extreme floods.

For proper reservoir management, knowledge about the sediment deposition pattern in various zones is

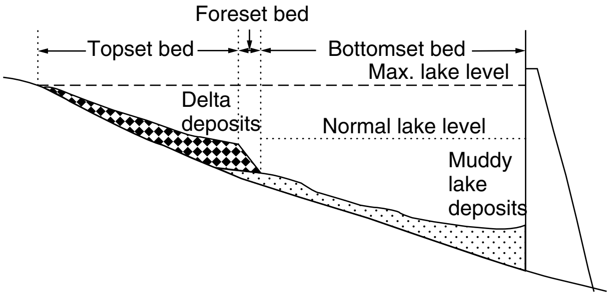

Figure 1. Sediment deposit zones in a reservoir.

essential. Timely remedial measures can be undertaken with correct knowledge of the sedimentation processes in a reservoir. A common procedure for tackling a sediment problem is to designate a portion of reservoir storage for sediment accumulation. But this approach does not solve the problem; it merely postpones the date when it becomes serious.

Factors Influencing Reservoir Sedimentation

Two dominant factors that influence the rate of silting in a reservoir are (1) capacity to inflow ratio (CIR) and (2) sediment content in the water flowing in. The other factors are the texture and size of the sediment, the trap efficiency of the reservoir, and the method of reservoir operation. The CIR is the ratio of reservoir storage capacity to mean annual inflow. A reservoir whose CIR is more than 50% is considered hydrologically large, may have significant carryover, and its trap efficiency will also be large. Note that the sediment inflow depends on the catchment area, too. All other things remaining the same, a dam of the same capacity in an upper catchment will have a higher rate of silting compared to a dam of the same design but constructed lower down in the valley.

The two principal factors mentioned above have a complete range of interplay. A reservoir that has a small CIR and small sediment inflow and one that has a large CIR and large sediment inflow may have more or less the same rate of sedimentation. A high rate of silting can also be expected from a high CIR and a high sediment content in the inflow. On the other hand, a high CIR and low sediment content in inflows will result in a low rate of silting.

Trap Efficiency

The trap efficiency of a reservoir is the ratio of sediment retained in the reservoir to the sediment inflow. It depends primarily on the sediment characteristics, the detention time of the inflow, the method of reservoir operation, and the age of the reservoir. A small reservoir on a large stream passes most of its inflow so quickly that the finer sediments are discharged downstream. A larger reservoir, on the other hand, may retain water for several years and the outflow from it may be completely devoid of suspended sediments. The trap efficiency of a reservoir decreases with age as the reservoir capacity is reduced by sediment accumulation. Thus complete filling of the reservoir may require a very long time.

The trap efficiency can be computed from the sediment inflow and outflow data. Brune (4) analyzed data from 44 reservoirs in the States; 40 were normal ponded reservoirs whose catchment areas vary from 0.098 sq. km to 478,110 sq. km and CI ratios range from 0.0016 to 2.05. The database also included two desilting basins and two semidry reservoirs. This analysis revealed that the laws of sediment deposition are the same for all types of reservoirs and the factors influencing the trap efficiency are independent of the size of the reservoir. Brune (4) presented a set of envelope curves between CIR and trap efficiency (see Fig. 2) that shows a semilogarithmic curvilinear relation between trap efficiency and CIR.

Sedimentation and Life of a Reservoir

The term *life of a reservoir* appears to be a misnomer because reservoirs do not have a single well-defined life which denotes two functional states: *ON* and *OFF*. Rather, they show a gradual degradation of performance. The 'life' of a reservoir for different purposes will be affected at different times. Murthy (5) defined the following terms connected to the life of a reservoir.

Useful Life. The period during which the capacity occupied by sediment does not prevent the reservoir from serving its intended primary purpose.

Economic Life. This is determined by the time after which the effect of various factors, such as physical deterioration by sedimentation and changing requirements for project services, cause the operating costs of the reservoir to exceed the additional benefits from its continuation.

Design Life. The period that is adopted for economic analysis. This is either the useful life or the shorter of the expected economic life or fixed span of life (say 50/100 years).

Full Life. The number of years required for full depletion of reservoir capacity by sedimentation.

LOSS OF STORAGE CAPACITY

Observations show that in reservoirs that have small sluicing capacity with respect to normal floods and have no upstream reservoirs, the siltation rate is comparatively high in the first 15–20 years and thereafter it falls off and may ultimately become negligible. From the data

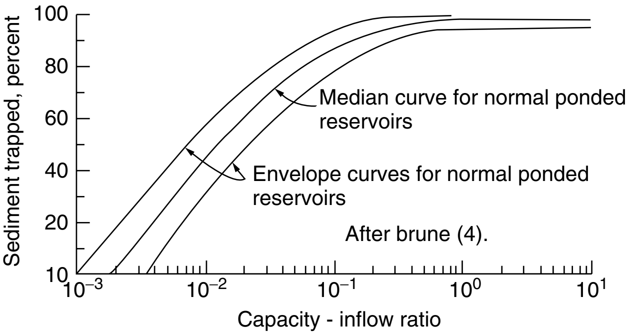

Figure 2. Brune's curves (4).

of reservoir capacity surveys, Shangle (6) found that the sedimentation rates in major reservoirs (storage > 100 million m^3) in India that have completed more than 50 years of their useful lives varied from 0.30 to 4.89 Ha-m/100 sq. km/year. The rate for those major reservoirs that have completed less than 50 years of their useful lives varied from 0.34 to 27.85 Ha-m/100 sq. km/year. Deyi and Fan (7) derived an empirical formula to determine the average annual loss rate of reservoir capacity.

The rate of siltation of a reservoir normally shows a falling trend with time. A plausible explanation is that the obstruction by the dam causes the dips and flanks of the storage basin to fill up with silt in early years. A stage comes when the river section adjusts itself to carry the normal discharge and disposal of the suspended load in the area of the reservoir is harmonized with the condition of the flow. Besides, the progressive development of deltas above the reservoir helps in trapping some of the silt load. Shrinkage and settlement of deposited silt also takes place with time due to superimposed loads of additional silt. This results in reduction in silt volume. However, a complete explanation of this behavior is not available.

Unit Weight of Sediments Deposited in a Reservoir

The unitweight of sediments is the dry weight (kg) per unit volume (cubic meter) of the material. It has been observed that the density of deposited sediment varies from 500–2000 kg/m^3. The important factors that influence the unit weight of deposited sediment are the manner of reservoir operation, the texture and size of sediment particles, and the consolidation rate. The reservoir operation is the most influential of these factors. If the water level of a reservoir is lowered from time to time, the deposited sediment is exposed to the Sun and air and gets dense. There may be considerable time for consolidation before floods. The degree of consolidation depends on the weight of overlying material, its exposure, sediment size, and time. The reservoir is always filled that has a low density of deposit. Power and irrigation reservoirs belong to the intermediate class. Generally, lower densities are observed in the vicinity of a dam under submerged conditions whereas higher densities are noticed in the upstream portions of reservoirs.

Lara and Pemberton of U.S.B.R. developed a method for estimating the initial unitweight of sediment deposits when the size analysis of the incoming sediment and the proposed reservoir operating schemes are known. Reservoir operations were classified in different types as follows:

Reservoir Type	Reservoir Operation	W_c	W_m	W_s
I	Sediment always submerged or nearly submerged	26	70	97
II	Normally moderate to considerable reservoir drawdown	35	71	97
III	Reservoir normally empty	40	73	97
IV	Riverbed sediments	60	73	97

The unitweight of the sediment deposits can be estimated from:

$$\gamma = 16.05(W_cP_c + W_mP_m + W_sP_s)$$

where γ is unitweight in kg/m^3; P_c, P_m, P_s are percentages of clay, silt, and sand, respectively, of the incoming sediment; and W_c, W_m, W_s are the coefficients of clay, silt, and sand, respectively, which may be obtained from the table above (15).

Distribution of Sediments in Reservoirs

Sediment distribution in a reservoir is important, and this requires careful consideration in planning and design stages. The pattern of sedimentation helps in predicting the extent to which services will be affected at various times and the remedial actions to be taken. The designer is interested to know the height of sediment accumulation to fix the sill elevation of the outlets, the penstock gate elevation, and to estimate the region where a delta would be formed and the consequent increase in backwater levels. Finally, the pattern is necessary to plan for recreational facilities. Four types of distribution patterns of deposits have been identified (3):

Delta Deposits. These deposits contain the coarsest fraction of the sediment load that is rapidly deposited in the zone of inflow.

Wedge-shaped Deposits. These are thickest at the dam and become thinner moving upstream.

Tapering Deposit. These occur when deposits become progressively thinner moving toward the dam.

Uniform Deposits. The thickness of these deposits is more or less uniform in the reservoir. Such deposits are not very common.

The consequences of reservoir sedimentation are gradual reduction in benefits. The extent of loss depends on the type and nature of the purposes being served and the rate of loss of storage capacity. The loss turns out to be really high when the replacement cost of the lost storage is considered.

A commonly used empirical method to estimate the new reservoir profile is discussed next.

Empirical Area Reduction Method

Based on the analysis of the sediment survey data of many reservoirs in the United States, it was found that the sediment distribution pattern depends on reservoir geometry, operation, and sediment characteristics. Depending upon the elevation–capacity characteristics, reservoirs are classified into four types: (a) gorge, (b) hill, (c) flood plain–foot hill, and (d) lake. Empirically derived sediment distribution curves are used to distribute the sediment throughout the reservoir section. The *Empirical Area Reduction* method, as revised by Lara (8), is the most popular for predicting a new reservoir bed profile. It is necessary first to estimate the amount of sediment deposited in the reservoir. The computational steps have been given in many books, such as Morris and Fan (3).

RESERVOIR SURVEYS

Sediments accumulated in an existing reservoir can be determined by periodically running sediment surveys. It is a direct measurement procedure for assessing the volume and pattern of deposits. Sediment data collected during the surveys are analyzed to determine the specific weights of the deposits, their grain size distribution, sediment accumulation rates, and reservoir efficiencies. Recent advances in technology have considerably reduced the effort to carry out reservoir surveys and analyze data.

The advantages of reservoir surveys are as follows:

1. The reservoir survey can be less costly than continuous sediment measurement at several locations in the catchment.
2. The accuracy of these surveys is usually very high, particularly if advanced equipment is used.
3. It is possible to estimate the total sediment (bed and suspended) load carried by a river.

There are some limitations of the reservoir sedimentation survey:

1. Such surveys do not provide any information about the variation of sediment yield with time and give only the total sediment accumulated since the last survey.
2. This method does not provide subcatchmentwise sediment yield.
3. This approach is not very effective where sedimentation is small as the errors of measurement may mask the true sedimentation rates.
4. To find the total sediment inflow, information about sediment outflow is also needed.

It is essential to have an accurate map of the reservoir on an appropriate scale before commencing a survey. Important reservoir features, such as the full reservoir level (FRL) along the periphery, the position of the dam, outlets, inflowing streams, etc., along with other details such as the position of nearby bridges, roads, and villages should be marked on the map. Horizontal and vertical control points are fixed at a suitable interval on the reservoir circumference. Next, cross-sections are planned at a suitable spacing, depending on the reservoir size.

The contour and range methods are two basic techniques for surveying reservoirs. The selection of a method depends on the quantity and distribution of sediment indicated by field inspections, the shape of the reservoir, the purpose of the survey, and the degree of accuracy desired. The volume of accumulated sediment is computed by subtracting the revised capacity from the original capacity at a given reservoir elevation (usually the FRL).

The frequency of surveying reservoirs depends on the sediment accumulation rate and the cost of a survey. Reservoirs that have high accumulation rates are surveyed more often than those with lower rates. Generally, the reservoirs are surveyed every 3 to 10 years. Special circumstances may necessitate a change in the established schedule. A reservoir might be surveyed after a major flood that has brought in a heavy sediment load. A survey may also be run following the closure of a major dam constructed upstream in the same catchment. An upstream dam reduces the free drainage area and hence reduces the sediment inflow.

Remote sensing techniques, enabling acquisition and analysis of synoptic data over a broad spectral range, are an alternative to the conventional way of data acquisition and processing. This technique is highly cost- and time-effective compared to conventional methods. The methodology for assessing reservoir sedimentation is described by Goel et al. (9).

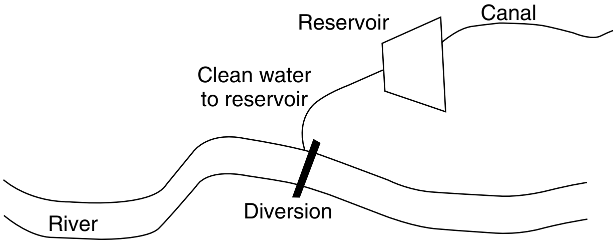

Figure 3. An offstream reservoir.

CONTROL OF SEDIMENT INFLOW INTO A RESERVOIR

The problem of reservoir sedimentation is complex but not unmanageable. It can be largely controlled by judicious design, construction, and management. The Yellow River in China is notorious for very high volumes of sediments in its water. The Sanmenxia Dam was the first dam built in the middle reach of the Yellow River in China. After the impounding commenced, about 1.8 billion metric tonnes of sediments accumulated during the first 18 months, representing a trap efficiency of 93%. The balance between sediment inflow and outflow was restored by providing high capacity bottom outlets, and reservoir operation was substantially changed.

There are various ways to manage the sedimentation problem, and the effectiveness of an approach depends on the site conditions. A single technique will not work everywhere. Broadly, the methods are

- Control the sediment inflow into the reservoir.
- Do not allow the entering sediment to settle in the reservoir.
- Remove the settled sediment from the reservoir.

Regarding the first approach, broadly, there are three ways to prevent sediment from entering a reservoir. These are (1) constructing reservoirs away from streams, (2) physical barriers in the way of sediment movement, and (3) better watershed management to check soil erosion.

Offstream Reservoirs

If the site conditions permit, a reservoir can be constructed away from the main stream (Fig. 3). This reservoir is filled with water of low sediment concentration that is diverted from the main river. The flows that contain high amounts of sediment load are excluded from diversion. An additional advantage of an offstream reservoir is that only a desired amount of flow is diverted to it, and therefore, its capacity can be limited.

Check Dams

A check dam is a small dam a few meters high that is constructed across a stream in the headwater region to control channel erosion. Most of the incoming sediment is deposited behind the check dam and relatively clear water comes out downstream. These dams can be highly effective in controlling reservoir sedimentation. The cost of a small check dam is not very high. These dams are more efficient for sediment trapping if they are spaced farther apart. These dams are not a long-term solution to the problem because they do not control the sediment erosion, and once the reservoir behind the check dam is filled with sediments, it no longer serves the purpose.

SEDIMENT ROUTING

This is an effective method for controlling reservoir sedimentation. It includes methods to manage the hydraulic behavior of the reservoir to allow the maximum sediments to pass through. The concepts of sediment routing were developed in China. The guiding principle is *discharge the muddy water, impound the clear water*. It is an environmental friendly approach because the characteristics of sediment transport are not significantly changed.

Reservoir Drawdown

Typically, the rising limb of the hydrograph carries larger amount of sediments than the falling limb. In this approach, the reservoir water level is bought down in the beginning of a flood to pass turbid flow without deposition.

Density Currents

A density current is the gravity flow of fluid under, over, or through another fluid of approximately equal density or density whose differs by a small amount from that of the primary current. Density currents are generated when sediment-laden water enters a relatively still waterbody. The density current venting approach (Fig. 4) provides a clear unhindered path to sediment-laden flows that are released through low-level outlets.

Sediment Bypass

This arrangement, shown in Fig. 5, prohibits sediment-laden flow from entering the reservoir. It consists of a diversion structure upstream of the dam by which the flows with heavy sediment concentration are diverted to a bypass channel or conduit which joins the main river downstream of the dam. As a result, relatively 'clean' flows enter the reservoir.

WATER FROM SATURATED RIVER SEDIMENT—SAND ABSTRACTION

Stephen W. Hussey
Dabane Trust
Burnside, Bulawayo, Zimbabwe

Water is available in the saturated sediment of sand-filled rivers. The removal of water from this sediment is known as sand abstraction. Despite the terminology, it is not the removal of sand but of water from a surface dry, seasonal river where the water is retained in the sediment, not abstraction of water from a flowing river.

Wherever there is erosion of land within the catchment area of a river, soil, sand, or gravel is carried into the river channel. The river becomes silted with sediment retained in depressions in the riverbed, behind rocks, and where the slope of the river is sufficiently low for sediment to be deposited rather than washed away.

In arid and semiarid areas, the sediment that accrues is often coarse grained, and, as the river basin drains, water is retained in the sediment in useable quantities. In spite of the intermittent flow of seasonal rivers, as the rivers drain and dry out, water is held in the sediment.

BACKGROUND INFORMATION

History and Traditional Use

There have been sand-filled rivers for centuries in arid and semiarid areas where intermittent rainfall and long dry periods exist (Fig. 1). These rivers have become increasingly filled with sediment since the land has become populated and built up. As surface water dropped into the sediment, people had to dig down to find their daily water requirements. This practice continues today in many arid areas.

Traditionally, people lived in river valleys, and as the seasonal rivers dried out, they excavated inverted cone-shaped holes to expose the water level in the sediment. As the loose, unstable sand continually filled the hole, people were forced to re-excavate their holes. A natural development was to insert an opened ended drum into the river sediment as a liner. This made a ‘sand well’ that was more stable and did not fill with sand after every use (Fig. 2). The water abstracted was then used for domestic, livestock, and small-scale gardening purposes.

Typical Uses

Domestic Use. A properly managed sand-abstraction system provides a suitable source of water for domestic use. A variety of schemes have been developed ranging from small-scale, individual families using basic hand pumps to reticulated systems for small towns.

Irrigation Schemes. These range from small family gardens to large-scale commercial schemes. Where gardens can be established on low river banks (above the flood line), sand-abstraction systems provide an excellent, low-cost option for conveying water to nutrition gardens. One small hand pump (for instance, a Rower) is sufficient to irrigate adequately more than 200 m^2 of garden—an average size brushwood-fenced garden (Fig. 3).

Figure 1. Typical sand river.

Figure 2. Traditional sand well.

Figure 3. A small-scale community garden where water is drawn by hand pumps from the sand river in the background.

Livestock Watering. Sand-abstraction systems provide a very suitable source of water for livestock, even in less than optimum conditions. A hand pump, either driven directly into the sand, discharging into a portable trough on the river sand, or a more complete system drawing water onto the river bank are both appropriate livestock watering systems.

Livelihood. Sand abstraction can provide water for small-scale, rural industry such as brickmaking, household construction and repair, and small livestock projects.

ADVANTAGES AND DISADVANTAGES

Advantages

1. Clean, naturally filtered water free of the contamination associated with open surface water such as dams.
2. The water has a natural taste free from mineral salt contamination often associated with groundwater.
3. Easy to access when compared with the labor involved in building a dam or digging a well.
4. On the traditional and small-scale level, the technology does not require pumps and expensive drilling equipment. It is a low-level technology that people can operate for themselves without outside intervention.
5. Lower cost per cubic meter yield of water compared with ground- or surface water developments.
6. Where extensive sediment deposits exist, large volumes of water can be held.
7. Reduced evaporation from water retained in the sediment as opposed to open surface water.
8. Low environmental impact from installation of sand-abstraction systems.
9. The technology can be used in various other medias such as tube wells and gravel beds.

Disadvantages

1. The system is as vulnerable as any other supply to inadequate recharge from poor rainfall and to seasonal water losses.
2. As there is no confined aquifer at the point of abstraction, if sites are not carefully selected, water can drain away from the site.
3. If not adequately secured, equipment can be washed away in flash floods.
4. The system is based on environmental degradation, it works only where there has been severe soil erosion.
5. At some sites, silt layers form and move through the river sand to clog installations.
6. In certain conditions, infiltration galleries and well points may be subject to bio-fouling.

EPHEMERAL RIVERS

In ephemeral river systems, people have, for generations, been drawing water from river pools and from the river sand. The system works best in large, slow-flowing rivers that cross extensive plains away from the watershed. Conditions for sand abstraction are ideal where rivers cut through igneous soils. Soils in these areas tend to contain large proportions of coarse-grained sands that are carried into and remain in the river systems and allow large volumes of water to be retained. The system is dependent to some degree on continuing soil erosion and is inappropriate in small fast-flowing rivers below the watershed that contain small amounts of unstable sand.

[b] WHO

The system is conditional on water freely percolating through sediment to the point of abstraction. Silt and clay create an impenetrable barrier to an abstraction system, and thus sand abstraction in such conditions is not an appropriate option. The ideal situation is a slow-flowing, wide river that has deep, coarse sediment. The ideal site is above a natural rock barrier or in a depression of the riverbed (typically, a former pool), which is continually recharged by water percolating from an expanse of sand above.

The system can be made to work on smaller rivers that contain coarse-grained sand by constructing a subsurface dam to retain sediment. This consists of a barrier to retain the water in the sediment. It is constructed across the river from the riverbed to the surface of the river sediment. A further possibility is a sand dam that is an impoundment, generally a weir, constructed to raise the level of river sediment. The impoundment is designed to silt up over several years; the entire length of the wall is raised by only some 0.3 to 0.5 meters a year. Coarse-grained sand is impounded and the finer silt is washed out of the weir each year. Water can be abstracted from these dams as through any other sand-abstraction system.

GEOGRAPHICAL CONTEXT

Suitable ephemeral rivers are extensive in much of southern Africa, parts of east Africa, the Sahel, the Middle East, the Indian subcontinent, the Southeast United States, parts of Mexico, and parts of Latin America and Australia. The technology of sand abstraction is particularly used in these arid and semiarid areas:

southern Africa—South Africa, Namibia, Swaziland, Botswana, Zimbabwe, and Zambia;
east Africa—Kenya, Ethiopia, Sudan, and Somalia.

WATER QUALITY

Unlike groundwater supplies, where water may be contaminated with mineral salts, water obtained from sand-abstraction sources is generally not tainted. Surface water supplies are very quickly contaminated by livestock that wade, urinate, and defecate in the water. Surface water should, therefore, not be considered fit for human consumption without treatment. Where extensive sands exist, the entire waterway acts as an enormous sand filter bed for a sand-abstraction system. Water drawn from a properly constructed scheme may thus be considered potable and require no treatment. However, unprotected sites can become clogged with deposits of clay or fouled with livestock droppings.

SUSTAINABILITY—VILLAGE-LEVEL OPERATION AND MAINTENANCE

1. Sand-abstraction systems draw water from river sands, and thus they are typically shallow water sources requiring only simple hand pumps, which communities that have few tools and little expertise can operate and maintain. In their simplest form, while still ensuring a protected water supply, buckets are quite adequate for drawing water.
2. Sand-abstraction sites can be identified by villagers, whereas groundwater sources generally require either a geophysical survey or dowsing. A greater sense of ownership and responsibility is thus promoted by sand-abstraction schemes.
3. Many groundwater sources are deep and beyond the capacity of village people to operate and maintain. Boreholes are expensive to drill and can seldom be undertaken by rural communities on their own. In many areas, the aquifers are small and are quickly overabstracted, resulting in blocked fissures and ultimately dry boreholes or wells. Boreholes and wells in sandstone localities are prone to collapse or become completely blocked by fine sediment that slowly percolates into the borehole and granite areas.
4. Small-scale units that can be managed by a Village Water Committee are a very practical option, especially in the Southern Hemisphere, considering the large number of possible sand-filled river sites.
5. In some rivers, there is a possibility that flooding will wash the well point (abstraction point) away. A further complication is that silt layers can move through the river sand and clog installations. Only practical experience can rule out these possibilities.

METHODS OF ABSTRACTING WATER FROM SAND

There are several systems of sand abstraction that have been developed over the years. Each depends on equipment that can be installed into the water-bearing river sand and at all times remain in free moving water. Schemes range in size from small-scale, hand-operated supplies right through to large-scale mechanized (diesel or electric-powered) irrigation schemes on large rivers (Figs. 4 and 5).

Well Screens

Well points or well screens, whose slots are generally 0.5, 1.0, or 1.5 mm wide, prevent entry of river sand into the

Figure 4. Small-scale, hand pump sand-abstraction scheme.

Figure 5. Submersible pumps drawing water for a commercial irrigation scheme from the sand of the Limpopo River in the background.

pump system. Slot size is selected in accordance with the coarseness of the river sand so that sand whose grain size is a diameter greater than the slot is prevented from entering. Smaller sand is initially drawn through the slots but coarser sand quickly collects around the immediate screen and then blocks the entry of finer sand; thus a natural graded filter is developed around the well point.

One or more well screens are connected to a suction pump on the river bank. Installations are done either when the river water is at its lowest level so that the well screen can be dug into the sand, or when the river sand is saturated with water to full depth. Well screens can then be pushed, or 'jetted,' into the lower levels of sand in an artificial 'quicksand' condition, caused by a water jet from a motorized centrifugal pump. This system of installation is relatively technically complex and depends on materials and equipment not readily available (Fig. 6).

Manifold and Well Points

This system depends on low velocity of water at the point of abstraction, sufficient to draw off water without drawing sand into the system. It is best installed toward the end of the dry season when the river water level is at its lowest. River sand is removed to the water-bearing level and a 'manifold' (a large diameter pipe) is laid on the water-bearing sand. Well points are installed at an angle into the sand and connected alternately at each side of the manifold. The manifold is connected to a suction pump on the riverbank. The number of well points, manifold size, and piping to the riverbank are calculated according to the velocity of water required in different parts of the system and on the quantity of water required. This is probably the most common system presently used, and, in general, all necessary materials are readily available.

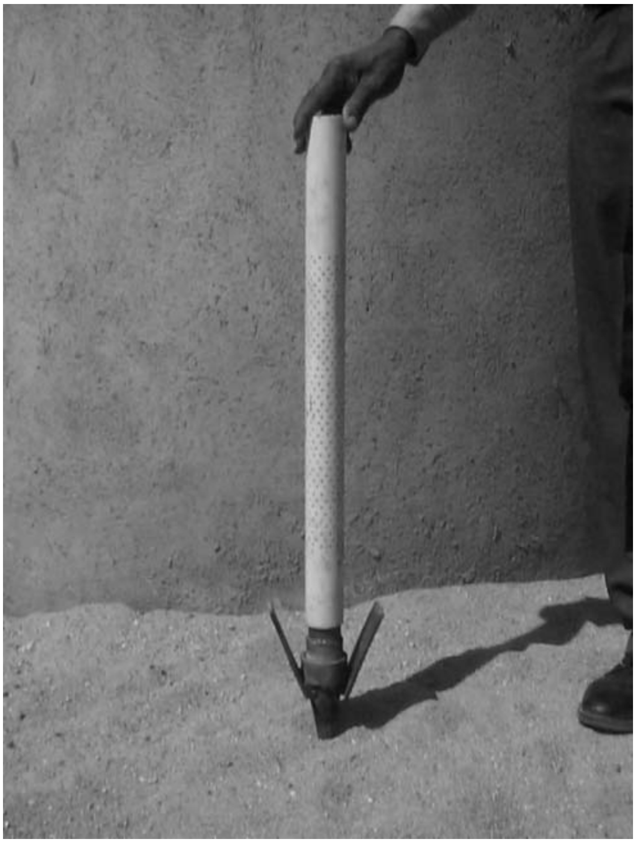

Figure 6. Well points suitable for small-scale sand-abstraction system.

Infiltration Galleries

Many original sand-abstraction installations were gravity supply systems and consisted of a number of interconnected well points. Sand had to be kept out of the pipes so that water could run in and flow to a sump or false well on the riverbank from where it could be pumped out. Modern synthetic materials have recently improved the potential of this system; before they were introduced, it was difficult to keep sand out. However, it is still difficult to ensure that the pipe system is sufficiently deep in the sand to keep it in water year-round. Further, it necessitates a lot of digging into the riverbank. It is relatively inexpensive and does not require complex equipment or expertise to operate or maintain. A windlass or basic hand pump can be used to draw water.

Caisson

Water is abstracted through the slotted base of a large (1.0 to 1.5 m diameter) flat cylindrical or slightly conical ‘caisson’ connected by pipes to a suction pump on the riverbank. The ‘caisson’ is dug into river sand as deeply as possible, and as the water level drops during the season, it is lowered to keep it in water continually. As in any of the systems, the installation is complete once a level has been reached that remains in water year-round. This system is more awkward due to the continual redigging and lowering, but once at its lowest point, can be used where silt tends to accumulate because of the large surface area for abstraction. However, slow recharge through the silt to the abstraction zone can significantly impede abstraction.

COST-EFFECTIVENESS

Small-Scale Schemes

Small sand-abstraction installations do not require any complex machinery such as tractors, graders, drilling rigs, or welders. People at the village level can undertake the installations themselves using primarily locally available equipment. Well points can be easily fabricated in PVC or steel and either jetted, driven, or dug into the saturated sediment. Water can then be abstracted with basic low-tech pumps that do not require expensive operation and maintenance.

Commercial Schemes

Some heavy machinery is needed for initial preparation of the river. However, overall, there is less material to be removed when installing sand-abstraction well points or infiltration galleries than in the constructing an earth embankment dam. Pumps that would typically be used to draw water from a dam or aquifer-based irrigation scheme may also be used in systems based on sand abstraction.

SEDIMENT TRANSPORT

Matjaz Mikos
University of Ljubljana
Ljubljana, Slovenia

SEDIMENT SOURCE AREAS

Sediment transport is a natural process of transporting solid particles called sediments from erosion sources to deposition or sedimentation areas. This process has been shaping landscapes throughout geological time. Sediments, sedimentary rocks, and the process by which they were formed are scientifically studied by sedimentology.

One important source of sediments is soil erosion. Geologic soil erosion occurs as surface removal of farm, forest, and other erodible soils in the form of sheet erosion, interrill and rill erosion, gully erosion or deflation, mainly caused by impacts of raindrops (splash erosion, rain erosion) and overland flow on bare soils or land without dense vegetative cover to protect soils. It may be checked on farm soils by such farm management practices as contour plowing, crop rotation, and mulching. Accelerated erosion is the speeding up of erosive processes, such as deforestation, overgrazing, and construction, either directly or indirectly, by the intervention of humans. Its most obvious effects can be seen in the alteration of a river’s regime by improper land use or by human intervention into the catchment area. Other important sediment sources are deposits of mass wasting phenomena, driven by gravity, such as rockfalls, rockslides, landslides, debris flows, and mudflows, exposed to fluvial processes of erosion, transportation, and sedimentation. The subjects of these processes are fluvial sediments—solid particles and particles of rock material that have been transported from their sources and deposited elsewhere by flowing water. A sediment particle is a solid particle, which settles after being suspended in a fluid, but the term usually includes all detritus produced by erosion processes and deposited by fluvial, lacustrine, marine, glacial, and aeolian agencies in the process of sedimentation. The term fluvial sediment is usually reserved for unconsolidated material found in a fluvial system.

PHYSICAL PROPERTIES

Sediment transport involves the two-phase flow of a water–sediment mixture. The most important physical properties of water as a nearly incompressible fluid are the mass density of the fluid (mass of fluid per unit volume), the specific weight of the fluid (fluid weight per unit volume of fluid), the dynamic viscosity (proportional factor between the shear stress causing fluid deformation and the deformation rate), and the kinematic viscosity (the dynamic viscosity of a fluid divided by the mass density of the same fluid). Both the density and the viscosity of water decrease as the temperature increases.

The most important physical properties of sediments as a solid phase can be divided into

— the properties of a single sediment particle: the mass density of solid particles (the mass per unit volume), the specific weight of solid particles (the solid weight per unit volume of solid), the submerged specific weight of a particle (the difference between the specific weights of solid particles and water), the specific gravity (the dimensionless ratio of the specific weight of a solid particle to the specific weight of a fluid at a standard reference temperature), the sediment size (e.g., sieve diameter, fall diameter, nominal diameter), the sediment shape (different shape factors and indexes, e.g., sphericity), and the sediment roundness (different indexes using the sharpness of the edges or corners of a particle to classify particles from angular to rounded);

— the bulk properties of sediments: the particle size frequency distribution (measured by wet or dry sieving equipment such as mechanical shakers or sedimentation tubes and represented as a histogram or a cumulative curve) and corresponding particle size parameters (mean, median, mode, sorting, skewness, kurtosis), the angle of repose (usually given as the slope angle of a cone of submerged loose material under incipient sliding conditions), the porosity (the volume of voids per total volume), the void ratio (the volume of voids per volume of solid), the unit weight (the weight of solid and water in voids per unit volume), and the dry unit weight (the weight of solid per unit volume).

The most important physical properties of a water-sediment mixture are the specific weight of the mixture (the total weight of solid and water in voids per unit volume), the specific mass of a mixture (the total mass of solid and water in voids per unit volume), the volumetric sediment concentration (the volume of solids divided by the total volume), the dynamic viscosity of a mixture (a function of the dynamic viscosity of water and the volumetric sediment concentration), and the kinematic viscosity of a mixture (the dynamic viscosity of a mixture divided by the mass density of the same mixture).

INCIPIENT MOTION

Due to the stochastic nature of sediment transport, it is difficult to define precisely the flow condition at which a sediment particle will begin to move. Fluid flow around sediment particles resting on the bottom of the flow exerts forces that tend to initiate motion. The resisting force of noncohesive sediment relates to submerged particle weight. Threshold conditions occur when the hydrodynamic overturning moment of forces acting on a single particle exceeds the resisting moment. Then the particle is in incipient motion, thus defining the threshold condition for sediment transport. The hydrodynamic forces acting on a noncohesive sediment particle are the submerged particle weight, the lift force, the drag force, and the resistance force. Most incipient motion criteria are derived from either the shear stress or the velocity approach. Because of the stochastic nature of sediment transport, probabilistic approaches have also been introduced.

The well-known Shields shear stress approach determines the threshold condition from the shear stress, the submerged specific weight of the particle, the particle diameter, the kinematic viscosity, and gravitational acceleration. These factors are grouped into two dimensionless quantities: the dimensionless shear stress called the Shields parameter (relating the shear stress and the submerged weight of a sediment particle), and the shear velocity Reynolds number (expressing the ratio of sediment size to the laminar sublayer thickness). The threshold of motion for granular material of uniform size depends on whether laminar or turbulent flow conditions prevail around the sediment particle; it is given in the form of a Shields diagram showing an experimentally determined relationship between both dimensionless quantities at the threshold condition. The value of the critical Shields parameter depends on whether the boundary is in a hydraulically smooth regime, a transition regime, or a completely rough regime. Typically, gravel-bed rivers fall within the completely rough regime, and sand-bed rivers fall within the transition and partially hydraulically smooth regime. Shear velocity appears in both the Shields parameter and the shear velocity Reynolds number, so it is possible to define the Shields diagram using the dimensionless particle diameter as an abscissa. For hydraulically rough turbulent flows, the critical shear stress becomes linearly proportional to sediment size.

A velocity approach equivalent to the Shields approach defines the relationship between critical flow velocities and the mean sediment size in the form of a diagram (e.g., Hjulstrom diagram) or defines the relationship between dimensionless critical average flow velocity (expressing the ratio between the average critical flow velocity at incipient motion and the sediment fall velocity in clear water) and the shear velocity Reynolds number (Yang criterion).

The probabilistic approach to incipient motion (proposed by Gessler), gives the mean condition that there is a 50% chance for a given sediment to move under specified flow conditions (turbulence fluctuations) and sediment conditions (particle position, orientation, and protrusion into the flow with respect to particles of different sizes and to bed forms).

MOVEMENT OF FLUVIAL SEDIMENTS

When flow conditions exceed the criteria for incipient motion, sediment particles on a streambed start to move. Once a sediment particle in a stream is in motion, the applied hydraulic load governs the mode of its motion. Generally, there are two modes of motion: near or on the streambed and in suspension.

Sediment that moves near or on the streambed is called bed load transport. Bed load can sometimes be divided into contact load, composed of particles rolling, sliding, or pushing, and saltating load, composed of particles bouncing, hopping, or jumping. The size of the particles that can be transported by saltation is usually correlated with the flow velocity and water density. The bed load, the amount of solid material carried on or near a streambed, usually amounts to less than 10% of the total sediment transported in large alluvial rivers. In mountain rivers and steep high-gradient streams, the major part of the total load may actually be bed load due to numerous mass-movement processes in the watershed and in-channel erosion of deposited fluvial sediments, such as in pools. Under fully developed sediment transport conditions, there is a steady exchange between bed load and suspended load.

Suspended load refers to sediment that stays in suspension for an appreciable length of time. In most natural streams, sediments are mainly transported as suspended load. Discharge-weighted total suspended solids concentrations range from practically 0 mg L^{-1} (clear water) during low flows in mountain environments to several kg L^{-1} during high flows in the form of hyperconcentrated flows, which typically occur in tropical regions and in loess or volcanic ashes.

Based on the modes of sediment transport, the total load is the sum of the bed load and the suspended load.

Based on the source of material transported, the total load can also be classified as the sum of the bed-material load and the wash load. The wash load consists of fine materials that are finer than those found in the streambed. The amount of wash load depends mainly on the supply from the watershed, not on the hydraulics of a stream. Consequently, it is difficult to predict the wash load based on the hydraulic characteristics of a stream.

An important part of a lowland stream's load may also be a dissolved load carried in solution. The proportion varies according to the climate, the chemical nature of the rocks, and the proportion of runoff contributing to the stream flow in relation to the amount of groundwater flow. The quantity of dissolved solids is given by the total concentration of dissolved material in water, measured by complete evaporation of a given quantity of water. The parameter is of use in any examination of the rate of chemical denudation and of the dissolved load of streams. Discharge-weighted total dissolved solids concentrations range from 5000 mg L^{-1} in arid saline environments to 5 mg L^{-1} in tropical rainforest regions.

TRANSPORT CAPACITY OF STREAMS

The ability of a stream to transport sediment, as measured by the maximum quantity (mass or volume) of sediment that can be carried past a specific point in the stream in a given unit of time is called transport capacity. The transport capacity increases as the water discharge becomes greater or the stream gradient becomes steeper, and decreases, as the particle size of the sediment becomes larger. Stream transport capacity is a function of bed width; for a given water discharge and gradient, the flow velocity near the streambed is lower in a wide, shallow stream than in a narrow, deep one.

The sediment discharge ratio in a stream is the ratio between the sediment discharge and the water discharge. When defining sediment discharge, the total solid transport in a stream through its cross section is taken regardless of the mode of sediment motion. The sediment-rating curve is then an empirical expression of the relationship between the stream water discharge and the stream sediment discharge at a given point. It is shown as an equation where the sediment discharge is defined as the water discharge multiplied by the mean sediment concentration and can then be written as a potential function of water discharge.

Flow competence is a term that is used in fluvial geomorphology and hydrology to indicate the ability of a stream to move particles of a particular size as bed load. It refers to the largest particle size that can be carried by a particular stream velocity. The largest particle that can be transported increases generally as a high (e.g., sixth) power of the stream velocity. The stream flow velocity at the bed is controlled by such factors as stream gradient and hydraulic radius. At equal water depth and gradient, near-bed flow velocity is higher in a wide shallow stream, where the hydraulic radius is practically the same as the average water depth, than in a narrow deep one, where, on the contrary, the hydraulic radius is much less than the average water depth. But a large, slowly moving stream may carry a large quantity of small particles in suspension, and although its (suspended) transport capacity is high, its flow competence is small. Conversely, a small but rapidly flowing stream can move relatively large particles (i.e., it has a high flow competence) although its transport (bed load and suspended load) capacity is small because of its limited water discharge.

Sediment yield is defined as the mean sediment load (total sediment discharge) carried by a stream per unit area of the catchment area; it gives some measure of the rate of erosion in a drainage basin in addition to the transport capacity of the stream itself. To establish the sediment budget of a catchment area, knowledge of sediment production in sediment source areas as well as sediment yield and sediment transport capacity of streams is important.

SEDIMENT TRANSPORT FUNCTIONS

Sediment transport is the mass transfer of solids by flowing water. Its mathematical representation in the form of a transport function needs the determination of sediment transport rates, given as the mass or weight of solids (sediment particles) transported through a cross section of a stream per unit time. Specific sediment transport rates are often given only per unit bed width to be then multiplied by the active streambed width.

Some of the classical formulas for estimating sediment transport rates were derived mainly for bed load, neglecting suspended load. In the way they approach the relation between water discharge and bed load discharge, these bed load formulas can be divided into groups that use shear stresses, energy slope, water discharge, bed forms, probability—turbulent flow fluctuations, stochastic modeling of single particle step lengths and rest periods, regression of laboratory data, and the equal mobility hypothesis as a basis for estimating bed load rates.

The starting point for suspended load equations is the vertical distribution of time-averaged velocities and sediment concentrations at given hydraulic conditions. It can be obtained from the exchange theory that states that under steady-state equilibrium conditions, the downward flux of sediment due to the fall velocity must be balanced by the net upward flux of sediment due to turbulent fluctuations. To obtain the suspended load in many such transport functions, one should know the suspended sediment concentration at some distance above the streambed.

Most total load equations are actually total bed-material load equations. In the comparison between computed and measured total bed-material load, wash load should be subtracted from the measurement before the comparison in most cases. There are two general approaches to determining total load. The first is to compute bed load and suspended load separately and then add them together to obtain total load. The second is to determine the total load function directly without dividing it into bed load and suspended load. A sediment particle may be transported as bed load at one time and as suspended load at another time or location. Except for coarse materials, which are mainly transported as bed load, total bed-material load equations should be used for determining sediment transport capacity in natural streams.

STREAM AGGRADATION AND DEGRADATION

Sediment transport is a process that interrelates erosion and sedimentation. When the rate of sediment supply from upstream is higher than a stream's sediment transport capacity, the streambed will start to aggrade at a rate defined by the difference between the rate of sediment supply and the sediment transport rate of the stream. The flow in the stream will be saturated with sediment, its transport capacity fully used. But if a stream's sediment transport capacity exceeds the rate of sediment supply from upstream, the balance of sediment load has to come from the channel itself. In this case, the channel starts to degrade.

The particle size distribution of the bed material on a streambed generally depends on the magnitude of the applied hydraulic loads in relation to the mobility of sediment particles of different sizes. In natural gravel-bed and sand-bed rivers, size nonuniformity of fluvial sediments is rather a general rule. The applied hydraulic load expressed as the applied shear stress can move none of the particles (zero sediment transport, no motion), finer and more exposed particles only (weak sediment transport, partial motion), or all particles (fully developed sediment transport, full motion). It is normally observed that without motion of finer particles, the streambed surface is composed of the original bed material. Due to motion of finer particles at a hydraulic load not sufficiently high to displace coarser particles and because of the nonuniformity of the bed-material size, finer material is transported at a faster rate than coarser material, and the remaining bed material on the bed surface becomes coarser. The bed load fractions are finer than those of the bed surface. This stage of the sediment transport is called the selective transport phase. The transition between the zero sediment transport stage and the weak sediment transport stage is smooth. This coarsening process (vertical sorting) on the streambed stops once a layer of coarse material completely covers the streambed and protects the finer materials beneath it from being transported. After this process is completed, the streambed is armored; the coarser layer is called an armor layer. Due to the variation in the flow condition of a natural stream (flood waves), usually more than one layer of armoring material is required to protect finer material beneath it from being eroded. When the applied hydraulic load is large enough to break the coarse armor layer, the finer particles are no longer shielded by stable coarser particles. All available particles of all sizes enter into motion and are found as bed load, as soon as the applied hydraulic load exceeds the threshold of motion of coarser particles. This concept is referred to as the equal-mobility concept for which all fractions of sediment enter into motion at the same value of applied shear stress. When the armor layer breaks, the transition between the weak sediment transport stage and the fully developed sediment transport stage is rather sharp.

The armoring process can be combined with incipient motion criteria to compute the extent of stream degradation. When there is not enough coarse material to develop an armor layer, degradation can be computed using the stable slope approach. This method computes the volume of eroded material in a given stream reach due to limited sediment supply. The limiting slope or final stable slope of the stream can be computed using a sediment transport equation. When there is downstream bedrock or other type of fixed control in the stream, the limiting slope will start at that point and extend in the upstream direction.

DOWNSTREAM FINING IN STREAMS

Sediment transport is definitely selective in many ways and thus is interrelated to sorting processes. Generally, sorting is defined as a process by which materials are graded according to one of their particular attributes, such as shape, size, and density. In sedimentology, the natural sorting of sediments by particle size is a basis for classification into well sorted or poorly sorted deposits. Sediments that have been repeatedly reworked by marine waves or have traveled a long distance downstream in a fluvial system are usually well sorted into different-sized particles, because different particle sizes have different settling velocities. In general, sediments transported by glaciers and mass movement are poorly sorted. Fluvial sediments tend to be well sorted.

Sorting processes in a stream can be observed in three directions: laterally (e.g., differences between coarser sediments in the thalweg and finer sediments on a bar), vertically (e.g., differences between coarser armor layer and finer sublayers), and longitudinally (downstream decrease of mean sediment size due to decreasing flow competence).

The abrasion of fluvial sediments covers attrition processes during passive and active phases of sediment transport, such as breakage, chipping, wearing, and grinding. Consequently, fluvial sediments change their particle size distribution as sediment particles are size-dependently reduced in size and their roundness generally increases. Only breakage, more common in steep high-gradient streams or bedrock reaches, will increase the angularity of sediment particles.

Downstream fining is a process in natural streams that describes an approximately exponential decrease in mean sediment size under ideal conditions. It covers sorting processes and fluvial abrasion, as well as *in situ* processes such as chemical or frost weathering of temporarily stored but exposed fluvial sediments, for example, on a bar. Generally, sorting is the prevailing process responsible for fining; especially in specific situations as when a gravel-bed river suddenly turns into a sand-bed river. Abrasion generally prevails in steep high-gradient streams, where flow competence is high and sorting is thus less pronounced. The exponential decrease is often disrupted in sedimentary links, where fresh sediments from tributaries flow laterally into a stream. When sediment transport over longer reaches of a stream is to be modeled, sorting processes and fluvial abrasion of sediment particles should therefore be accounted for.

MODELING OF SEDIMENT TRANSPORT

On one hand, the problem can be studied practically in the field by observing and measuring most relevant process parameters or in a laboratory using physical (hydraulic) modeling. On the other hand, it can be studied theoretically using numerical modeling and also using appropriate field and laboratory data for model validation.

Sediment transport can be thus defined as a natural process manifesting in sediment-laden flows, and it is usually studied as part of applied mechanics (e.g., river mechanics) or river (loose boundary) hydraulics. The main problem to be solved is to establish functional relationships that relate hydrodynamics (water movement) to sediment movement or vice versa.

For sediment-laden flow, three types of movement can be differentiated:

- the mixture may be considered a Newtonian fluid (the volumetric concentration of solids is very small, e.g., less than 1%)—typically sediment transport in streams and rivers falls into this category;
- the mixture behaves as a quasi-Newtonian fluid (the volumetric concentration of solids remains small, e.g., less than 8–10%)—typically turbidity currents and concentrated suspension fall into this category;
- the mixture behaves as a non-Newtonian fluid (the volumetric concentration of solids becomes important, e.g., more than 8–10%)—typically hyperconcentrated flows (turbidity currents and suspensions) and debris flow fall into this category.

At low sediment concentration and low deformation rates, sediment-laden flow obeys Newton's law of deformation. The governing equations of motion are the continuity and the dynamic equations. These equations can be given in different coordinate systems, such as Cartesian, cylindrical, or spherical, in one, two, or three dimensions.

Modern mathematical models are two- or three-dimensional models, which can be divided into two groups: coupled and uncoupled models. Coupled models solve the governing equations for continuity (mass-balance) and dynamics (momentum-balance) of two-phase flow simultaneously; uncoupled models solve hydrodynamic equations separately from the sedimentologic equations. An important advantage of coupled models is that they can handle intensive unsteady-state processes, such as river changes during a dam break or flash flood waves. Sediment transport numerical models can predict morphological changes and help river engineers to take appropriate measures. Contemporary numerical models use computer power extensively to account for nonuniformity of fluvial sediments when developing fractional models rather than using different mean diameters of sediment.

STOCHASTIC SIMULATION OF HYDROSYSTEMS

Demetris Koutsoyiannis
National Technical University
Athens, Greece

INTRODUCTION

Simulation is defined as a technique for imitating the evolution of a real system by studying a model of the system. The model is an abstraction, a simplified and convenient mathematical representation of the actual system, typically coded and run as a computer program. If the model has a stochastic[1] element, then we have *stochastic simulation*. The term stochastic simulation sometimes is used synonymously with the *Monte-Carlo method*.

Stochastic simulation is regarded as mathematical experimentation and is appropriate for complex systems, whose study based on analytical methods is laborious or even impossible. For such systems, stochastic simulation provides an easy means to explore their behavior by answering specific 'what if' questions. Moreover, stochastic simulation can be viewed as a numerical method for solving mathematical problems in several fields such as statistical inference, optimization, integration, and even equation solving. Under certain conditions, stochastic simulation is more powerful than other more common numerical methods (e.g., numerical integration of high-dimensional differential equations).

[1] The term *stochastic* is etymologized from the Greek verb *στοχάζομαι* initially meaning to aim, point, or shoot (an arrow) at a target (*στόχος* is a target). Metaphorically, the verb meant to guess or to conjecture (the target). The modern Greek meaning is to imagine, to think, to meditate. It appears that the word *stochastic* is found in English since the seventeenth century, and the obsolete meaning pertains to conjecture. Its use as a scientific term is attributed to the Swiss mathematician Jakob Bernoulli (1654–1705), who in his famous masterpiece *Ars Conjectandi* realized that randomness and uncertainty are important aspects of our world and should be objects of scientific analysis. In its modern sense, *stochastic* can be regarded as synonymous with random or probabilistic, but it is mostly used for processes that indicate a mixture of structure and randomness; the term *stochastic process* was used in 1932 by A. N. Kolmogorov.

Due to their complexity, hydrosystems, including water resource systems, flood management systems, and hydropower systems, are frequently studied using stochastic simulation. A generalized solution procedure for hydrosystems problems, including systems identification, modeling and forecasting, hydrologic design, water resources management, and flood management, is discussed. Emphasis is given on the stochastic representation of hydrologic processes, which have a dominant role in hydrosystems. Peculiarities of hydrologic and other geophysical processes (seasonality, long-term persistence, intermittency, skewness, spatial variability) gave rise to substantial research that resulted in numerous stochastic tools appropriate for applications in hydrosystems. Four examples of such tools are discussed: (1) the multivariate periodic autoregressive model of order 1 [PAR(1)], which reproduces seasonality and skewness but not long-term persistence; (2) a generalized multivariate stationary model that reproduces all kinds of persistence and simultaneously skewness but not seasonality; (3) a combination of the previous two cases in a multivariate disaggregation framework that can respect almost all peculiarities except intermittency; and (4) the Bartlett-Lewis process that is appropriate for modeling rainfall and emphasizes its intermittent character on a fine time scale.

A BRIEF HISTORY

Synthetic stream-flow records were first used early in the twentieth century by Hazen (1) in studies of water supply reliability. Their construction, however, was not based on the theory of stochastic processes, then not developed, but on merging and rescaling observed records of several streams. This early work emphasizes the need for long synthetic records and the importance of simulation in water resources technology. The foundation of stochastic hydrology followed the significant developments in mathematics and physics in the 1940s, as well as the development of computers. Specifically, it followed the establishment of the Monte Carlo method, which was invented by Stanislaw Ulam in 1946. Notably, Ulam conceived the method while playing solitaire during convalescence from an illness, in an attempt to estimate the probabilities of success of the plays. As Ulam describes the story in some remarks later published by Eckhardt (2), "After spending a lot of time to estimate them by pure combinatorial calculations, I wondered whether a more practical method than 'abstract thinking' might not be to lay it out say one hundred times and simply observe and count the number of successful plays." Soon after, the method grew to solve neutron diffusion problems by himself and other great mathematicians and physicists in Los Alamos (John von Neumann, Nicholas Metropolis, and Enrico Fermi), and was first implemented on the ENIAC computer (2,3). The 'official' history of the method began in 1949 when a paper was published by Metropolis and Ulam (4).

In the field of water resources, the most significant initial steps were the works by Barnes (5) for generating uncorrelated annual flows at a site from normal distribution, Maass et al. (6) and Thomas and Fiering (7) for generating flows correlated in time, and Beard (8) and Matalas (9) for generating concurrent flows at several sites.

The classic book on time series analysis by Box and Jenkins (10) also originated from different, more fundamental scientific fields. However, it has subsequently become very popular in stochastic hydrology. Box and Jenkins developed a classification scheme for a large family of time series models. Their classification distinguishes among autoregressive models of order p [AR(p)]; moving average models of order q [MA(q)]; combinations of the two, called autoregressive-moving average [ARMA(p, q)] models; and autoregressive integrated moving average [ARIMA(p, d, q)] models. However, despite a large family, Box-Jenkins models do not fully cover the needs of hydrologic modeling, as they do not comply with some peculiarities of hydrologic and other geophysical processes. This gave rise to substantial research that resulted in numerous stochastic tools appropriate for application to water resources.

UTILITY OF STOCHASTIC SIMULATION IN HYDROSYSTEMS

Due to the significant uncertainties inherent in hydrosystems, among which the major uncertainty is hydrologic uncertainty (related to the unknown future of inflows to hydrosystems), an estimate of a system's reliability is important for its design and operation. The reliability of a system is defined as the probability that a system will perform the required function for a specified period of time under stated conditions (11, p. 434). Reliability is the complement of the probability of failure or risk, the probability that "loading" will exceed "capacity." In many instances, the risk can be estimated by analytical means, so stochastic simulation is not required. For example, in the design of dikes that confine a river's flow, the risk of overtopping dikes can be estimated in a typical probabilistic manner, provided that a long enough record of floods of the river exists (some decades). The estimating procedure includes selecting a probabilistic model (e.g., an extreme value distribution function), fitting the model based on the available record, and estimating the probability that a flood will exceed the discharge capacity of the designed river cross section (the estimate of the latter is a matter of hydraulics). Behind this procedure, there are two implicit assumptions that make the methodology appropriate for this problem:

1. The project under study (the dikes) does not modify the natural flow regime, so that if the project had been constructed many years before, the observed flow record would not be altered. Thus, the assumed probabilistic model, although fitted to past data, is still valid after construction of the project.
2. The quantity (flood discharge) whose exceedance was assumed to be the risk is the same quantity, for which we have observed data. Thus, the probabilistic model that was constructed for this quantity can yield the risk directly.

In many cases, however, these assumptions are not valid. Let us first examine the case where assumption 2 is untrue. For example, we may have available rainfall data, from which we can construct a probabilistic model for extreme rainfall intensity, and wish to estimate the probability of exceeding the flood discharge. In this case, we can use a simple one-to-one mapping (transformation) of rainfall to discharge values (e.g., to adopt the relation known as the rational formula), so that the risk of exceeding a certain discharge level equals the risk of exceeding the corresponding rainfall level. This methodology usually incorporates serious oversimplifications and ignorance of certain factors that affect the actual hydrologic process (e.g., retention and infiltration). A more realistic methodology is to use a more detailed model that transforms a rainfall series (not each isolated value) into a discharge series, also considering all processes involved in this transformation. In this case, we can use simulation to obtain a discharge series.

Assumption 1 can be untrue in many cases as well. For example, constructing a dam will alter the flood regime at the dam and downstream, as the spillway outflow does not equal the natural inflow (attenuation occurs due to temporal flood storage). The construction of a storm sewer will also modify the contributing areas and flow times in the area (in addition, it is impossible to have observed data for the sewer discharge in its design phase). Another typical example is a reservoir (see the entry RELIABILITY CONCEPTS IN RESERVOIR DESIGN), whose storage (a quantity that determines the risk, which is the probability of emptying the reservoir) did not exist before the construction of the reservoir. Obviously, in all these cases where assumption 1 is not valid, assumption 2 is also not valid. Thus, we will proceed as in the previous paragraph where simulation is the most appropriate procedure for obtaining a series of data values for the quantity of interest.

Even in an existing project (e.g., an existing reservoir), where the quantity of interest can be measured directly to obtain a historical record, simulation may be necessary again to assess the impacts of several possible changes in the future that were not experienced in the past. For example, a change in water use (e.g., an increase in water demand) and a change in land use or climate, which alters water availability, calls for simulation to estimate a series for the quantity of interest in the scenario examined.

The previous discussion explains why in most studies of hydrosystems (except cases where both assumptions listed previously are valid), it is necessary to simulate to transform some input time series of initial quantities into some output time series of the final quantities of interest. By grace of the power of computers, the simulation methodology has greatly replaced older methodologies that used simplified one-to-one transformations. But why should simulation be stochastic?

In stochastic simulation, the input time series are no longer the observed records but synthetic time series constructed by an appropriate stochastic model. An observed time series is unique and has a limited length equal to the period of observations. On the contrary, a stochastic model can produce as many time series as required and of any arbitrary length. The utility of a long time series becomes obvious in steady-state simulations (12, p. 1220), when estimating a low value of the probability of failure (risk). For example, in a problem where the accepted probability of failure is 1% per year, apparently several hundreds of simulated years are needed to detect a few failures. The utility of ensemble time series (as opposed to the unique observed record) becomes obvious in nonsteady-state problems (i.e., in terminating simulations) and in forecast problems in which the initial conditions (present and past values of the processes of interest) are known. In these cases, stochastic simulation offers the possibility of different sample paths of the quantity of interest, instead of having a single value at a time, so that we can estimate expected values and confidence zones.

COMPONENTS AND SOLUTION PROCEDURE OF STOCHASTIC SIMULATION

The components and the steps followed in the stochastic simulation of a hydrosystem are shown in Fig. 1. The entire procedure includes two main model components (marked 1 and 2 in Fig. 1) and two simpler procedures (marked 3 and 4 in Fig. 1). The first model component is the stochastic model of inputs, which produces a vector $\mathbf{X}(\boldsymbol{\mu}, \omega)$ of hydrological inputs (e.g., a time series of rainfall, evaporation, and river flow, depending on the problem studied) to the hydrosystem, where $\boldsymbol{\mu}$ is a vector that contains the parameters of hydrologic inputs (all estimated from the available records of observations) and ω denotes a sample path realization of the random variables (i.e., ω can be thought of as representing the randomness in the system, e.g., all random numbers in a simulation run). At a minimal configuration, the vector of parameters $\boldsymbol{\mu}$ includes mean values, standard deviations, autocorrelations (at least for lag one), and cross-correlations (for multiple-site models).

The second component is the transformation model which takes the inputs $\mathbf{X}(\boldsymbol{\mu}, \omega)$ and produces the outputs $\mathbf{Z}(\mathbf{X}(\boldsymbol{\mu}, \omega), \boldsymbol{\lambda})$ (e.g., river flow, if $\mathbf{X}$ is rainfall and evaporation, or reservoir release and storage, if $\mathbf{X}$ is river flow); here the vector $\boldsymbol{\lambda}$ contains parameters of the transformation model (e.g., parameters that determine the hydrologic cycle in a basin and/or parameters that determine the operation of a specific project such as a reservoir).

The third component is a procedure that takes the outputs $\mathbf{Z}(\mathbf{X}(\boldsymbol{\mu}, \omega), \boldsymbol{\lambda})$ and determines a sample performance measure $L((\mathbf{Z}(\mathbf{X}(\boldsymbol{\mu}, \omega), \boldsymbol{\lambda}))$ of the system that corresponds to the sample realization represented by ω. This performance measure depends on the problem examined; for instance, in a flood design problem, it can be the risk of exceeding a specified flood level; in a reservoir design problem, it can be either the risk of emptying a reservoir or the attained release for a stated reliability.

By repeating the execution of these three components using different simulation runs, represented by different ω, we can obtain an ensemble of simulations and a sample of performance measures, from which we can estimate the true (independent of ω) performance measure of the

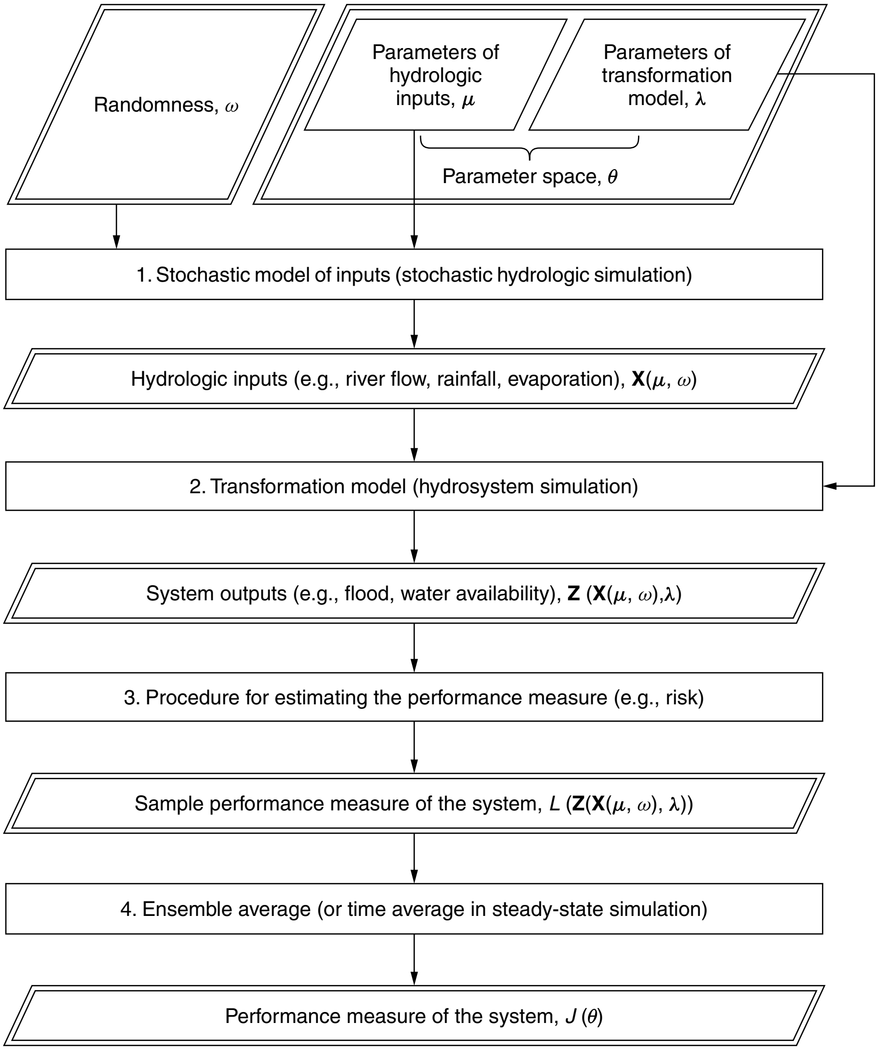

Figure 1. Schematic representation of the components and the solution procedure in hydrosystem simulation. Rectangles represent the components of the solution procedure, and parallelograms represent inputs and outputs of the different components.

system $J(\boldsymbol{\theta}) := E[L(\mathbf{Z}(\mathbf{X}(\boldsymbol{\mu}, \omega), \boldsymbol{\lambda}))]$, where $E[\ ]$ denotes the expected value and $\boldsymbol{\theta} := (\boldsymbol{\mu}, \boldsymbol{\lambda})$. However, if the system is stationary and ergodic (in other words, if we have a steady-state simulation), L will tend to J, as the simulation length tends to infinity. Therefore, a single instance of the sample performance measure, estimated from a simulation of large length, is an adequate estimate of the true performance measure. This is the case, for instance, in a reservoir simulation of constant water demand. Conversely, if the water demand is growing in time (a common situation in practice), the simulation is no longer steady-state, and numerous runs, typically of a short length, must be performed to estimate the true performance measure.

In the following part of the article, we will focus on the model component 1, the stochastic model of inputs.

TYPICAL BOX–JENKINS MODELS

Let X_i denote the process of interest (e.g., rainfall or streamflow at a site) where i denotes discrete time. To generate a time series of X_i, we start generating a sequence of independent identically distributed variables (iid, also known as white noise) V_i that have a specified distribution function (e.g., Gaussian). This is known as generation of random numbers; a concise introduction to this topic can be found in Papoulis (13) and a more detailed presentation can be found in Ripley (14). If it can be assumed that X_i is stationary (i.e., it has a probability distribution function that does not vary in time, which is typically the case if the time step is a year), the unstructured sequence of V_i can be converted to a structured sequence X_i by means of a recursive relationship, whose general form was studied by Box and Jenkins (10). From the large family of Box-Jenkins processes, those that have been widely used in stochastic hydrology are special cases of the equation,

$$X_i = aX_{i-1} + a'X_{i-2} + bV_i + b'V_{i-1} \tag{1}$$

where a, a', b, and b' are parameters that are estimated from the autocovariance properties of the process X_i. The special cases are

1. the iid or white noise or AR(0) process in which $a = a' = b' = 0; b \neq 0$;
2. the Markovian or AR(1) process in which $a' = b' = 0; a, b \neq 0$;

3. the AR(2) process in which $b' = 0; a, b, a' \neq 0$;
4. the ARMA(1, 1) process in which $a' = 0; a, b, b' \neq 0$.

The complete form of (1), known as the ARMA(2, 1) process, has been not used so frequently in hydrology. The special cases listed preserve autocovariance properties for lag 0 (case 1) to lag 2 (cases 2 and 3); beyond these lags, the model autocovariance is zero (case 1) or tends to zero exponentially (cases 2–4).

PECULIARITIES IN STOCHASTIC REPRESENTATION OF HYDROLOGIC PROCESSES

Simple stationary models, such as previously described, are often not the best choice in hydrologic modeling because of several peculiarities of hydrologic processes; the most important are discussed here.

Seasonality. When the timescale of interest is finer than annual, hydrologic processes cannot be regarded as stationary because of the effect of the season of the year on the properties of the process. A simple method often used to take into account seasonality is to standardize the process X_i using seasonal values of mean and standard deviation by setting $Y_i := (X_i - \mu_i)/\sigma_i$ and assuming that Y_i is a stationary process that can be modeled, for instance, by (1); here μ_i and σ_i denote the mean and standard deviation, respectively, of X_i, which, it is assumed, vary with i in a periodic manner. This standardization approach, however, is flawed; the stationarity assumption for Y_i implies that, apart from the mean and standard deviation, other statistical properties of X_i like autocorrelation and skewness do not vary in season, which is not true. A more precise way of modeling seasonality is to assume a cyclostationary (also known as periodic) process, that is expressed as in (1), but has parameters $a, b\ a', b', \ldots$, and statistics of the noise variables V_i that vary with i in a periodic manner.

Long-Term Persistence. Box–Jenkins models such as (1) are essentially of the short memory type; their autocorrelation structure decreases rapidly with lag time. However, the study of long historical time series of hydrologic and other geophysical processes has revealed that autocorrelations may be significant for large lags of 50 or 100 years. This property is related to the tendency of stream flows to stay above or below their mean for long periods, observed for the first time by Hurst (15), or, equivalently, to multiple timescale fluctuations of hydrologic processes (16). Therefore, models such as (1) are proven inadequate in stochastic hydrology, because it is important that the long-term persistence of hydrologic processes is reproduced (see the entry RELIABILITY CONCEPTS IN RESERVOIR DESIGN).

Intermittency. On fine timescales, some hydrologic processes such as rainfall and in some cases stream flow appear as intermittent processes; thus, rainfall alternates between two states, dry (zero rainfall) and wet (positive rainfall). This is manifested in the marginal probability distribution of rainfall depth by a discontinuity at zero. Box–Jenkins processes such as that in (1) need to be truncated to represent this discontinuity; this is not so easy, nor common. To model intermittency, alternative two-state processes, such as two-state Markov chains (17, p. 302) and point process models (18) have been proposed.

Skewness. Another peculiarity of hydrologic processes is the skewed distribution functions observed mostly on fine and intermediate timescales. This is not so common in other scientific fields whose processes are typically Gaussian. Therefore, attempts have been made to adapt standard models to enable treatment of skewness (19–22). Skewness is caused mainly by the fact that hydrologic variables are nonnegative and sometimes intermittent. Therefore, successful modeling of skewness indirectly contributes to avoiding negative values of simulated variables; however, it does not eliminate the problem, and some ad hoc techniques (such as truncating negative values) are often used in addition to modeling skewness.

Spatial Variation. Hydrologic processes evolve in both time and space. Typically, time series models consider only temporal evolution. The most precise mathematical representation of hydrologic processes can be achieved by extending the indexing set of the process from one dimension (representing time) to three dimensions (one for time and two for space). However, multidimensional modeling is not easy and has been implemented only in a few cases (for example in continuous time and space modeling of rainfall; 23). A midway solution, which is the most common in stochastic hydrology, is to use multivariate models, that describe the temporal evolution of the process simultaneously at a number of points. The same method can be used directly to model more than one cross-correlated hydrologic process (e.g., rainfall and runoff) at the same location simultaneously.

In the following sections, we give some characteristic examples of models that respect these peculiarities and together can deal with a large spectrum of problems in stochastic hydrologic simulation:

1. The multivariate periodic autoregressive model of order 1 [PAR(1)], which reproduces seasonality and skewness but not long-term persistence;
2. A generalized multivariate stationary model that reproduces all kinds of persistence and simultaneously skewness but not seasonality;
3. A combination of the previous two cases in a multivariate disaggregation framework that can respect almost all the previously listed peculiarities, except intermittency which such types of models may not easily handle;
4. The Bartlett–Lewis process that is appropriate for modeling rainfall and emphasizes its intermittent character on a fine timescale, but only on a single point basis.

The Multivariate PAR(1) Model

Let $\mathbf{X}_s := [X_s^1, X_s^2, \ldots, X_s^n]^T$ represent a hydrologic process on a subannual (e.g., monthly) timescale (δ) and at n locations (the subscript T denotes the transpose of a vector or matrix). The PAR(1) model is similar to the AR(1) model but has periodically varying parameters. In a multivariate setting, it is expressed by

$$\mathbf{X}_s = \mathbf{a}_s\mathbf{X}_{s-1} + \mathbf{b}_s\mathbf{V}_s \tag{2}$$

where $\mathbf{a}_s$ and $\mathbf{b}_s$ are $(n \times n)$ matrices of parameters and $\mathbf{V}_s$ is a vector of innovations (independent, random variables in both time and location) of size n. The time index s can take any integral value, but the parameters $\mathbf{a}_s$ and $\mathbf{b}_s$ are periodic functions of s whose period $k := 1$ year$/\delta$ (e.g., 12 if δ is one month). This model can reproduce the following set of statistics:

1. the mean values, i.e., the k vectors $\boldsymbol{\mu}_s := E[\mathbf{X}_s]$ each of size n;
2. the variances and lag-zero cross-covariances among different locations, i.e., the k matrices $\boldsymbol{\sigma}_{ss} := \mathrm{Cov}[\mathbf{X}_s, \mathbf{X}_s]$ $= E[(\mathbf{X}_s - \boldsymbol{\mu}_s)(\mathbf{X}_s - \boldsymbol{\mu}_s)^T]$ (where Cov[ ] denotes covariance), each of size $(n \times n)$;
3. the lag-1 autocovariances at each location, i.e., the k vectors $\boldsymbol{\gamma}_{s,1} := [\gamma_{s,1}^1, \ldots, \gamma_{s,1}^n]^T$, where $\gamma_{s,\tau}^l := \mathrm{Cov}[X_s^l, X_{s-\tau}^l] = E[(X_s^l - \mu_s^l)(X_{s-\tau}^l - \mu_{s-\tau}^l)]$, each of size n (notice the notational identity $\gamma_{s,0}^l \equiv \sigma_{ss}^{ll}$);
4. the third moments, the k vectors $\boldsymbol{\xi}_s = \mu_3[\mathbf{X}_s] = E[(X_s^l - \mu_s^l)^3, l = 1, \ldots, n]^T$ each of size n (where $\mu_3[\,]$ denotes the third central moment of a random variable or random vector).

The model parameters $\mathbf{a}_s$ and $\mathbf{b}_s$ are typically determined by the moment estimators that are

$$\mathbf{a}_s = \mathrm{diag}(\gamma_{s,1}^l/\gamma_{s-1,0}^l, l = 1, \ldots, n) \tag{3}$$

$$\mathbf{b}_s\mathbf{b}_s^T = \boldsymbol{\sigma}_{ss} - \mathbf{a}_s\boldsymbol{\sigma}_{s-1,s-1}\mathbf{a}_s \tag{4}$$

These equations are extensions of the seasonal model of those for the stationary Markov model given by Matalas and Wallis (19, p. 63). In an alternative estimate, a full (rather than a diagonal) matrix $\mathbf{a}_s$ can be derived, which enables preserving the lag-1 cross-covariances among different locations. However, the more parsimonious formulation in Eq. 3 is sufficient for most cases. The calculation of $\mathbf{b}_s$, given the product $\mathbf{b}_s\mathbf{b}_s^T$ from Eq. 4, is not a trivial issue. A generalized methodology to do this operation, also known as the extraction of the square root of a matrix, was proposed by Koutsoyiannis (21). Another group of model parameters are the moments of the auxiliary variables $\mathbf{V}_s$. The first moments (means) are obtained by

$$E[\mathbf{V}_s] = \mathbf{b}_s^{-1}(\boldsymbol{\mu}_s - \mathbf{a}_s\boldsymbol{\mu}_{s-1}) \tag{5}$$

By definition 1, the variances are $\mathrm{Var}[\mathbf{V}_s] = [1, \ldots, 1]^T$, and the third moments are obtained by

$$\mu_3[\mathbf{V}_s] = \left(\mathbf{b}_s^{(3)}\right)^{-1}(\xi_s - \mathbf{a}_s^{(3)}\xi_{s-1}) \tag{6}$$

where $\mathbf{a}_s^{(3)}$ and $\mathbf{b}_s^{(3)}$ denote the matrices whose elements are the cubes of $\mathbf{a}_s$ and $\mathbf{b}_s$, respectively.

A GENERALIZED MULTIVARIATE STATIONARY MODEL RESPECTING LONG-TERM PERSISTENCE

The most difficult and often the most important task in simulating hydrologic processes on an annual scale is to reproduce long-term persistence. The Box–Jenkins processes are inappropriate for this purpose. Other types of models such as fractional Gaussian noise (FGN) models and broken line models (whose comprehensive discussion can be found in Ref. 24) have several weak points such as parameter estimation problems, narrow type of autocorrelation functions that they can preserve, and their inability to reproduce skewness and simultaneously to perform in multivariate problems. In a recent paper (22), all these problems were remedied; the proposed generalized methodology can perform in multivariate problems for all categories of statistics listed in points 1–4 of the previous section and, in addition, for the autocovariances at all locations for any lag r.

The setting of the method is stationary, rather than cyclostationary, so all statistics and parameters are not functions of time, which is reflected in the notation used. For example, the autocovariance for lag τ is denoted as $\boldsymbol{\gamma}_\tau := [\gamma_\tau^1, \ldots, \gamma_\tau^n]^T$ where $\gamma_\tau^l := \mathrm{Cov}[X_i^l, X_{i-\tau}^l]$. Remember that long-term persistence implies nonignorable autocovariances for high lags (e.g., of the order $10^2 - 10^3$). Such autocovariances can be described by a power-type (as opposed to the exponential type of ARMA processes) function such as

$$\gamma_\tau^l = \gamma_0^l(1 + \kappa^l\beta^l\tau)^{-1/\beta^l} \tag{7}$$

where κ^l and β^l are constants. This generalized autocovariance structure (GAS) incorporates as special cases the exponential ARMA type structure (for $\beta = 0$) and the FGN structure (for a special combination of κ^l and β^l; see Ref. 22). The constants κ^l and β^l can be estimated by fitting Eq. 7 to the sample autocovariance estimates; note that Eq. 7 can be used for lags beyond a certain lag τ_0, thus allowing the possibility of specifying different values (i.e., the historical values of the sample autocovariance estimates) for smaller lags.

In each of the locations, the process X_i^l can be expressed in terms of some auxiliary variables V_i^l, uncorrelated in time i (i.e., $\mathrm{Cov}[V_i^l, V_m^k] = 0$ if $i \neq m$), but correlated in different locations l for the same time i by using

$$X_i^l = \sum_{r=-q}^{q} a_{|r|}^l V_{i+r}^l \tag{8}$$

This equation defines the so-called symmetrical moving average (SMA) scheme. Like the conventional (backward) moving average (MA) process, the SMA scheme transforms a sequence of temporally uncorrelated variables V_i^l into a process with autocorrelation by taking the weighted average of a number of V_i^l. In the SMA process, the weights a_r^l are symmetrical about a center (a_0^l) that corresponds to the variable V_i^l. The number of variables V_i^l that define X_i^l is $2q + 1$, where q is theoretically infinity but in practice can be restricted to a finite number, as the sequence of weights a_r^l tends to zero for increasing r. Koutsoyiannis (22) showed that the discrete Fourier transform $s_a^l(\omega)$ of the a_r^l sequence is related to the power spectrum $s_\gamma^l(\omega)$ of the process (i.e., the discrete Fourier transform of the sequence of γ_τ^l) by

$$s_a^l(\omega) = \sqrt{2 s_\gamma^l(\omega)} \tag{9}$$

This enables easy and fast (using the fast Fourier transform) computation of the sequence of a_r^l, even if the terms of the sequence are thousands. The computation includes transforming the sequence of γ_τ^l to $s_\gamma^l(\omega)$, calculating $s_a^l(\omega)$ from Eq. 9, and inversely transforming $s_a^l(\omega)$ to the sequence of a_r^l.

The auxiliary variables V_i^l, by definition, have unit variances, means $E[V_i^l]$, and third central moments $\mu_3[V_i^l]$ given by

$$\left(a_0 + 2\sum_{j=1}^{s} a_j\right) E[V_i^l] = \mu^l, \quad \left(a_0^3 + 2\sum_{j=1}^{q} a_j^3\right) \mu_3[V_i^l] = \xi^l \tag{10}$$

Their variance–covariance matrix $\mathbf{c} := \mathrm{Cov}[\mathbf{V}_i, \mathbf{V}_i]$ has elements c^{lk} that can be expressed in terms of σ^{lk} (the elements of the variance–covariance matrix $\boldsymbol{\sigma}$ of $\mathbf{X}_i$), and the sequences a_i^l and a_i^k by

$$c^{lk} = \sigma^{lk} / \sum_{r=-q}^{q} a_{|r|}^l a_{|r|}^k \tag{11}$$

Given the matrix $\mathbf{c}$, the vector of variables $\mathbf{V}_i = [V_i^1, V_i^2, \ldots, V_i^n]^T$ can be generated using the simple multivariate model,

$$\mathbf{V}_i = \mathbf{b}\mathbf{W}_i \tag{12}$$

where $\mathbf{W}_i = [W_i^1, W_i^2, \ldots, W_i^n]^T$ is a vector of innovations with unit variance, independent both in time i and in location $l = 1, \ldots, n$, and $\mathbf{b}$ is a matrix of size $n \times n$ such that

$$\mathbf{b}\,\mathbf{b}^T = \mathbf{c} \tag{13}$$

The other parameters needed to define model Eq. 12 completely are the vector of mean values $E[\mathbf{W}]$ and third moments $\mu_3[\mathbf{W}]$ of W_i^1. These can be calculated in terms of the corresponding vectors of V_i^1, already known from Eq. 10, by

$$E[\mathbf{W}] = \mathbf{b}^{-1} E[\mathbf{V}], \quad \mu_3[\mathbf{W}] = (\mathbf{b}^{(3)})^{-1} \mu_3[\mathbf{V}] \tag{14}$$

STOCHASTIC DISAGGREGATION TECHNIQUES

Seasonal models that can reproduce the long-term persistence of hydrologic processes do not exist at present. If the timescale of interest is finer than annual and, simultaneously, respecting of long-term persistence is important, a two-scale approach is followed. A stationary stochastic model like that described in the previous section is used to generate the annual time series. These are then disaggregated into a finer timescale so that the periodicity and short-term memory of the process of interest are respected. Traditionally, the latter task has been tackled by the so-called disaggregation models, which were initially proposed by Valencia and Schaake (25) and improved since then by the contribution of several researchers (for an outline of such contributions, see Refs. 26 and 27). These are purposely designed models to generate a process at the finer timescale given than at the coarser one. Specifically, they do not model the process of interest in the lower level timescale itself, but rather they are hybrid schemes simultaneously using both timescales. Sometimes (owing to nonlinear transformations of variables) these models cannot ensure consistency with the higher level process. Then, adjusting procedures are necessary to restore consistency (26,28).

A different approach was recently proposed by Koutsoyiannis (29), which is a generalized framework for coupling stochastic models on different timescales. This approach couples two independent stochastic models appropriate, respectively, for the coarser (annual) and finer (e.g., monthly) scales using a transformation that modifies the output of the latter to become consistent with the series produced by the former model. To demonstrate this approach, we will assume that the coarse scale model is the multivariate SMA model described in the previous section, which produces annual series $\mathbf{Z}_i$, and the finer scale model is the multivariate PAR(1) model described two sections before, which produces monthly series $\mathbf{X}_s$. Consistency of the two series requires that they obey

$$\sum_{s=(i-1)k+1}^{ik} \mathbf{X}_s = \mathbf{Z}_i, \tag{15}$$

where k is the number of fine-scale time steps within each coarse-scale time step ($k = 12$ in our example). The annual series $\mathbf{Z}_i$ is generated first. The finer scale model is run independently of the coarser scale one, without any reference to the known $\mathbf{Z}_i$, and produces monthly series $\tilde{\mathbf{X}}_s$. If we aggregate the latter on the annual scale (by means of Eq. 15), we will obtain some annual series $\tilde{\mathbf{Z}}_i$, which will apparently differ from $\mathbf{Z}_i$. In a subsequent step, we modify $\tilde{\mathbf{X}}_s$ thus producing $\mathbf{X}_s$ consistent with $\mathbf{Z}_i$ (in the sense that they obey Eq. 15) without affecting the stochastic structure that characterizes $\tilde{\mathbf{X}}_s$. For this modification, we use a linear transformation $\mathbf{X}_s = \mathbf{f}(\tilde{\mathbf{X}}_s, \tilde{\mathbf{Z}}_i, \tilde{\mathbf{Z}}_i)$ which has been termed the coupling transformation. This is given by (29)

$$\mathbf{X}_i^* = \tilde{\mathbf{X}}_i^* + \mathbf{h}(\mathbf{Z}_i^* - \tilde{\mathbf{Z}}_i^*) \tag{16}$$

where

$$\mathbf{X}_i^* := [\mathbf{X}_{(i-1)k+1,\ldots,}^T \mathbf{X}_{ik}^T]^T \tag{17}$$

$$\mathbf{Z}_i^* := [\mathbf{Z}_i^T, \mathbf{Z}_{i+1}^T, \mathbf{X}_{(i-1)k}^T]^T \tag{18}$$

$$\mathbf{h} = \mathrm{Cov}[\mathbf{X}_i^*, \mathbf{Z}_i^*]\{\mathrm{Cov}[\mathbf{Z}_i^* \mathbf{Z}_i^*]\}^{-1} \tag{19}$$

and $\tilde{\mathbf{X}}_i^*$ and $\tilde{\mathbf{Z}}_i^*$ are defined in terms of $\tilde{\mathbf{X}}_s$ and $\tilde{\mathbf{Z}}_i$ in a manner identical to that of the definition of $\mathbf{X}_i^*$ and $\mathbf{Z}_i^*$.

It is clarified that the vector $\mathbf{X}_i^*$ contains the monthly values of all 12 months of year i for all examined locations (e.g., for five locations, $\mathbf{X}_i^*$ contains $12 \times 5 = 60$ variables) and the vector $\mathbf{Z}_i^*$ contains (1) the annual values of the current year; (2) the annual values of the next year; and (3) the monthly values of the last month of the previous year (e.g., for five locations, $\mathbf{Z}_i^*$ contains $3 \times 5 = 15$ variables). Items (2) and (3) of $\mathbf{Z}_i^*$ are included to ensure that the transformation will preserve the covariance properties among the monthly values of each year and also the covariances for the previous and next years as well. Note that at the stage of the generation at year i, the monthly values of year $i-1$ are known (therefore, in $\mathbf{Z}_i^*$, we enter monthly values of the year $i-1$), but the monthly values of year $i+1$ are not known (therefore, in $\mathbf{Z}_i^*$, we enter annual values of the year $i+1$, which are known).

The quantity $\mathbf{h}(\mathbf{Z}_i^* - \tilde{\mathbf{Z}}_i^*)$ in Eq. 16 represents the correction applied to $\tilde{\mathbf{X}}$ to obtain $\mathbf{X}$. Whatever the value of this correction, the coupling transformation will ensure preservation of first- and second-order properties of variables (means and variance-covariance matrix) and linear relationships among them (in our case the additive property, Eq. 15). However, it is desirable to have this correction as small as possible so that the transformation does not seriously affect other properties of the simulated processes (e.g., the skewness). It is possible to make the correction small enough, if we keep repeating the generation process for the variables of each period (rather than performing a only single generation) until a measure of the correction becomes lower than an accepted limit. This measure can be defined as

$$\Delta = (1/m)||\mathbf{Z}_i^{\prime *} - \tilde{\mathbf{Z}}_i^{*}|| \qquad (20)$$

where $\mathbf{Z}_i^{\prime *}$ and $\tilde{\mathbf{Z}}_i^{\prime *}$ are respectively, $\mathbf{Z}_i^*$ and $\tilde{\mathbf{Z}}_i^*$ standardized by the standard deviation (i.e., $Z_i^{\prime *l} := Z_i^{*l}/\{\mathrm{Var}[Z_i^{*l}]\}^{1/2}$), m is the common size of $\mathbf{Z}_i^{\prime *}$, and $\tilde{\mathbf{Z}}_i^{\prime *}$, and $|| \cdot ||$ denotes the Euclidian norm.

POINT PROCESS MODELS

On even finer timescales such as daily or hourly, the intermittency of hydrologic processes dominates, and stochastic models like those described earlier can hardly describe it. Point process models have been the most widespread approach to representing intermittent hydrologic processes, particularly, rainfall. As a representative example, we summarize here the rainfall model based on the Bartlett–Lewis process; this was chosen due to its wide applicability and experience in calibrating and applying it to several climates. Accumulated evidence of its ability to reproduce important features of the rainfall field from the hourly to the daily scale and above can be found in the literature (30–32). This type of model has the important feature of representing rainfall in continuous time; the statistical properties on any discrete timescale are directly obtained from those in continuous time, and this enables model fitting combining statistics of different timescales.

The Bartlett–Lewis rectangular pulse model assumes that rainfall occurs in the form of storms of certain durations and each storm is a cluster of random cells; each storm has constant intensity during the time period it lasts. These are the general assumptions of the model (Fig. 2):

1. Storm origins t_i occur following a Poisson process at rate λ (this means that durations between consecutive storm origins, $t_i - t_{i-1}$, are independent identically distributed following an exponential distribution whose parameter is λ).
2. Origins t_{ij} of cells of each storm i arrive following a Poisson process at rate β.
3. Arrivals of each storm i terminate after a time v_i exponentially distributed with parameter γ.
4. Each cell has a duration w_{ij} exponentially distributed with parameter η.
5. Each cell has a uniform intensity X_{ij} with a specified distribution.

In the original version of the model, it is assumed that all model parameters are constant. In a modified version, parameter η is randomly varied from storm to storm using a gamma distribution of shape parameter α and scale parameter ν. Subsequently, parameters β and γ also vary so that the ratios $\kappa := \beta/\eta$ and $\phi := \gamma/\eta$ are constant.

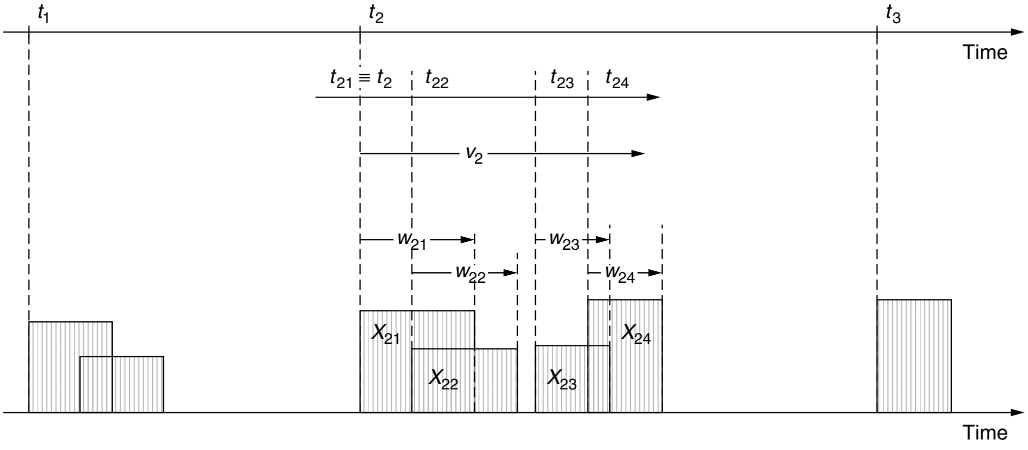

Figure 2. Explanatory sketch for the Bartlett–Lewis rectangular pulse model.

The distribution of the uniform intensity X_{ij} is typically assumed exponential with parameter $1/\mu_X$. Alternatively, it can be chosen as a two-parameter gamma with mean μ_X and standard deviation σ_X. Thus, in its most simplified version, the model uses five parameters, $\lambda, \beta, \gamma, \eta$, and $\mu_{X,}$ and in its most enriched version, seven parameters, $\lambda, \kappa, \phi, \alpha, \nu, \mu_X$, and σ_X.

The equations of the Bartlett–Lewis model, relating the statistical properties of the rainfall process in discrete time to the model parameters, may be found in the references mentioned before. These equations serve as the basis for model fitting.

CONCLUDING REMARKS

Stochastic simulation is a powerful method, easily applicable, and extremely flexible. Its main advantage is its ability to perform in complex systems describing them faithfully, without simplifying assumptions. However, it is an approximate procedure, and the accuracy of its results depends on the sample size. In addition, it is a slow procedure, as the estimation error decreases inversely proportional to the square root of the simulation length (i.e., for half the error, we need four times greater simulation length). Today, this is not a major problem as the progress in computer technology makes attainable even a vast simulation length in reasonable computer time.

In addition to the estimation error due to a finite simulation length, another significant source of uncertainty is always the limited historical records (based on hydrologic measurements), which are used to fit probabilistic or stochastic models. This source of uncertainty, which concerns the simulation method and also any method, including an analytical one, is forgotten sometimes, so the following points of caution should be stressed:

- The choice of a particular stochastic model and the estimation of its parameters are always based on available historical records, which are the only authentic source of information.
- Simulated (synthetic) hydrologic records do not replace historical records.
- The generation of a synthetic record (whose length is usually a multiple of that of the historical record) does not add any information nor does it extend the historical record length.

In conclusion, the following points should be added:

- In problems that can be solved analytically (as in the example of the design of dikes discussed earlier), stochastic simulation is not the preferable method.
- Stochastic simulation becomes a powerful numerical method when studying a complex system and analytical (or other numerical) methods are not applicable, are very difficult, or require oversimplifying assumptions for the system.

STORAGE AND DETENTION FACILITIES

XING FANG
Lamar University
Beaumont, Texas

The increase of population in the cities results in urbanization of undeveloped areas, which increases impervious areas, e.g., paved roads, parking facilities, residential houses, and commercial property development. The effects of urbanization include a pronounced impact on the characteristics of an area's hydrology; i.e., urbanization leads to an increase of peak flow rate and a reduction of the time to peak of runoff hydrographs. A common practice in storm water management is that the increase in peak flow rate caused by urbanization must be mitigated by reducing the peak flow rate to attain the predevelopment value by using storage and detention facilities. A storage and detention facility (pond or basin) is a low-lying area (natural or constructed), which is designed to hold a specific amount of runoff temporarily and used to attenuate peak flow rate. Once runoff has been collected in a detention facility, it is released to downstream conveyances (e.g., channels, bayous, or lakes) in a controlled manner such that downstream flooding and other adverse impacts are prevented or alleviated. Detention facilities can be surface and underground storage basins. Underground detention facilities are often used for small commercial development and consist of a series of connected large pipes or prefabricated custom chambers manufactured specifically for underground detention; e.g., a supermarket can install an underground detention pipe system under its parking lot to satisfy the zero runoff increase requirement specified by a regulatory agency. A surface detention pond is typically much larger in area and used for regional stormwater management, and it is a depressed or excavated area with earth embankments. Figure 1 shows a schematic of inflow hydrograph (after urban development) and outflow hydrograph from the outlet of a detention pond, and the peak flow of outflow hydrograph is equal to or smaller than the peak flow before development, which is much lower than the peak flow in the inflow hydrograph. From Fig. 1, one can see that the required volume of a detention pond is equal to the difference in area under inflow and outflow hydrographs.

Detention ponds can be classified as wet or dry ponds, depending on whether the principle outlet is constructed above the lowest point in the depression. The wet pond, also known as the retention pond, is designed to retain some of the inflow inside the pond. About 80% or more of detention facilities in the United States and Canada are dry ponds during no rain season, and they provide the maximum capacity for runoff detention during the next rainfall event. Sometimes pipes or channels may be necessary to divert inflow into detention facilities if the detention pond is outside of the main drainage pathway (off-line pond). An on-line pond is positioned along the drainage pathway, and all runoff naturally pass through it without any inflow diversion or collection system. Detention storage designs must consider the size of the pond, site selection, outflow structure (weir or orifice) design, construction of pond (cutting and filling), maintenance cost, and estimates of service life. Multiple ponds may be necessary to achieve the detention requirement under certain site conditions, particularly where the topography is flatter.

Design criteria for detention ponds vary widely. In the United States, detention regulations are typically adopted at the municipal or county level. Design of a detention pond like any other hydrologic design is always associated with one or more design storm events, e.g., typically specified as a certain return period. For example, a drainage district is to design a detention pond to hold all runoff for a 300-acre developed area during a 100-year, 24-hour rainfall event. The 100-year, 24-hour rainfall for the study area is 12 inches. If available land for the detention pond is 40 acres, what will be the depth for the pond? The depth will be 7.5 ft (300 acre × 12 inches/40 acre/12). This

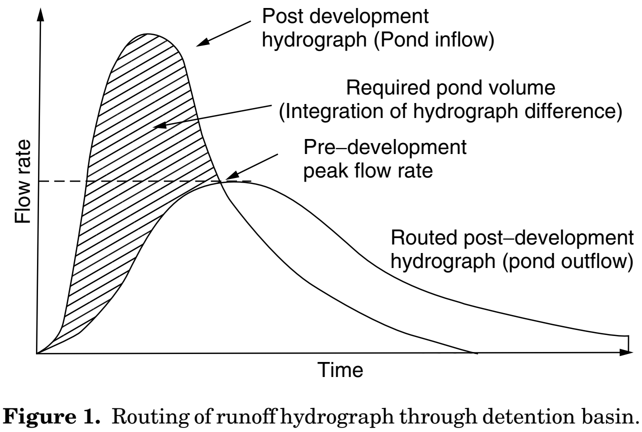

Figure 1. Routing of runoff hydrograph through detention basin.

detention pond design is simple because the pond holds all runoff during the rainfall event and the district plans to manually control outflow-gate to release the flow after the rainfall event. This design does not require any hydrologic routing analysis, but it requires a large amount of land requisition (40 acres).

The design of the storage volume (size) and outlet structure often requires knowledge of the predevelopment peak flow and an estimate of the inflow hydrograph under urbanized conditions. It needs to perform hydrologic routing analysis for the inflow hydrograph into the pond. Hydrograph routing (1) can predict the temporal and spatial variation of an inflow hydrograph as it traverses a river reach or reservoir (pond). Routing through a detention pond is meant to solve the continuity equation by using the storage–outflow relation. The storage-outflow relation is typically determined from two relationships: outflow (discharge) versus water surface elevation and storage (volume) versus water surface elevation. The first relationship is determined by the outflow structure design, and the second one is determined by the detention pond geometry (change horizontal area with respect to elevation) from contour or topographic maps.

Hydraulic analysis for detention pond design determines outflow through the outlet under different water surface elevations inside the pond, and outflow rate depends on type and geometry of the outlet. The most common outlet structures for detention ponds can be of orifice-type, weir-type (broad-crested, sharp-crested, spillways, and v-notch weir), or a combination of the two. The exit flow can be classified as submerged or free and depends on the effective head of water surface on the upstream side of the outlet structure. The outflow from each type of outlet structure is a function of several variables. For the flow through the orifice-type (e.g., a culvert), it is function of orifice area and the difference between the head water elevation and the centroid of the orifice. For the weir-type outlet (emergency spillway), it is function of effective crest length and the head over the weir crest. For the V-notch weir, it is a function of the notch angle and the head over the notch bottom. The riser pipe acts as weir at low heads and like an orifice at higher heads. The equations required to calculate the outflow from the detention pond for different outlet structures can be found in many textbooks and design handbooks (2,3).

A detention pond can be formed in a low-lying area by only constructing the earth embankment with the outflow structure and it could be fully constructed, i.e., digging a pond for certain depth (construction cost is high but sometimes that is the only choice). The side slopes of a constructed pond should be stabilized where needed to prevent the erosion. The side slopes should be 3H: 1V or flatter (4). Outlets should have trash racks, and course gravel packing should be provided if a perforated riser outlet prevents clogging of the riser caused by accumulation of sediment particles. Criteria for selecting the site for install of a pond should include the site's ability to support the environment as well as the cost effectiveness of locating a pond at that specific site. The pond should be located where the topography of the site allows for maximum storage at minimum construction cost (5). A site-specific constraint for pond construction includes underlying bedrock that would require expensive cutting operations to excavate. In designing the wet detention pond, the site must have adequate base-flow from the groundwater or from the drainage area to maintain the permanent pool. The storage capacity of the detention pond may be maintained properly by designing the outlet structure properly (appropriate opening size), so that the velocity of the water through the outlet as well as through the pond does not cause erosion of the bed material, interns which may cause clogging of the outlet opening.

The detention pond design process can be summarized as the following steps:

1. Select appropriate site and shape for detention pond design, and select material for detention structure construction.
2. Estimate inflow hydrograph and the peak inflow from watersheds to the detention pond.
3. Estimate the volume of water that can be stored in the detention pond and establish an elevation-storage relationship from the geometry of the pond.
4. Select the proper type of outlet structure and design the outlet opening.
5. Perform hydrologic routing analysis to determine the peak flow rate of the outflow hydrograph, to check weather it is smaller than the allowable one (peak rate before development) or it is safe, which does not cause flooding at downstream. If it does not satisfy the criteria, redesign the outlet or increase the height of the retaining structure to increase the storage.

Estimation of the size of a detention pond can also be accomplished by some simplified methods (1), e.g., natural storage loss method, modified Rational triangular hydrograph method, and NRCS TR-55 procedure, and by using computer software packages. Under normal operation of a detention pond, it is assumed that sufficient storage is available to regulate a flood without overtopping of the pond. Under special circumstances, the emergency operation scheme is implemented when the storage capacity is limited and inflows caused by heavy rainfall events (with a return period longer than the design return period) are expected to exceed the storage capacity (overtopping). Therefore, an emergency spillway should be provided to control overflow relief for large storms. The detention pond can also be designed to improve the water quality by removing some pollutants through sedimentation and other mechanisms as runoff is temporarily stored in the pond before the water is draining to another natural water body.

URBAN STORMWATER RUNOFF WATER QUALITY ISSUES

G. Fred Lee
Anne Jones-Lee
G. Fred Lee & Associates
El Macero, California

INTRODUCTION

Urban creeks and lakes can provide important habitats for aquatic life, as well as aesthetic assets to communities. A key component of this resource is the quality of water in these waterbodies. This chapter is devoted to a review of water quality problems in urban creeks and lakes caused by stormwater runoff-associated pollutants.

The primary function of many urban creeks is the conveyance of stormwater to prevent flooding. Often they have been channelized to assist in achieving rapid removal of stormwater from an urban area. This channelization, coupled with the development (paving) in the urban creek watershed, is at odds with providing high-quality aquatic life habitat. Urban creek flows can vary from a few cubic feet per second of groundwater-based flow to a thousand or more cubic feet per second during flood flow conditions associated with major runoff events. The high flows are detrimental to developing and maintaining desirable aquatic life habitat. Urban creeks also are frequently receptacles for waste materials, litter and debris, including shopping carts, yard waste, and so on. At the same time, urban creeks and lakes can provide important aesthetic amenities and, in some cases, recreational fisheries and nursery areas for aquatic life. The fisheries in urban creeks can range from a sustainable trout fishery to carp- or minnow-dominated waters. Some urban lakes provide good warmwater sport fisheries for bass, bluegill, and so on.

The Center for Watershed Protection report entitled, “Impacts of Impervious Cover on Aquatic Systems” (1), contains information on some aspects of the impact of urban stormwater runoff on water quality. This report is an expansion/update of earlier work by Schueler (2) on the impact of urbanization (paving) of an area on the waterbodies receiving the runoff from the area. Burton and Pitt (3) developed a *Stormwater Effects Handbook*, which provides background information on the water quality problems associated with stormwater runoff from urban and, to a lesser extent, rural areas. They discuss impacts on receiving water uses and sources of stormwater pollutants. Most of this over-900-page handbook is devoted to a discussion of approaches for assessing the characteristics of stormwater runoff and its impacts on receiving water quality. Another source of information on the impact of urban stormwater runoff-associated chemical constituents on water quality is the *Stormwater Runoff Water Quality Science/Engineering Newsletter* available from http://www.gfredlee.com.

REGULATING URBAN STORMWATER RUNOFF WATER QUALITY IMPACTS

The U.S. EPA (4) promulgated the national regulations that require cities with populations greater than 100,000 to develop stormwater runoff water pollution control programs to control pollution to the maximum extent practicable (MEP) using best management practices (BMPs). These requirements are also applicable to highway stormwater runoff. The EPA did not define MEP or the BMPs that are to be used. Urban stormwater runoff pollution is to be regulated by National Pollution Discharge Elimination System (NPDES) permits that ultimately require compliance with water quality standards. Although NPDES permits for domestic and industrial wastewater discharges are to prevent violations of water quality standards at the point of discharge or at the edge of a mixing zone if provided for, the NPDES permits issued to municipalities for controlling urban stormwater pollution, while requiring ultimately compliance with water quality standards, did not specify a date by which compliance with water quality standards is to be achieved. The current regulations require the use of a BMP ratcheting-down process to ultimately, but as of yet at an undefined date, control violations of water quality standards in the runoff. Justification for this difference in approach for regulating urban stormwater runoff, compared with urban wastewater discharges, develops from the significantly different characteristics of urban stormwater runoff.

ASCE (5) and CASQA (6) list a variety of “BMPs” that are advocated for the “treatment” of urban stormwater runoff to control water pollution, including ponds that allow settling of some chemical constituents, grassy areas that allow settling and removal of some chemicals, and infiltration basins that allow infiltration of the stormwater into groundwaters. These BMPs were largely based on hydraulic factors without evaluation of their effectiveness in treating stormwater runoff to achieve water quality standards. To the contrary, it has been found that ponds (detention basins), grassy swales, and so on cannot be considered adequate for treating urban stormwater runoff to achieve compliance with water quality standards.

The cost of retrofitting conventional BMPs to developed urban areas has been estimated to be on the order of $1 to $3 per person per day for the population served by the storm sewer collection system. These costs are primarily for the acquisition of land and effectively restrict implementation of these BMPs to new developments where their cost can be incorporated into the cost of the development. Although conventional BMPs are being installed especially in new developments, the most popular conventional BMPs will not be adequate to treat urban or highway stormwater runoff to achieve compliance with water quality standards. To achieve compliance with water quality standards for urban area and highway stormwater runoff, it will be necessary to construct, operate, and maintain treatment works of the type used in advanced wastewater treatment. The costs of such retrofitted treatment works in developed areas is projected to be on the order of $5 to $10 per person per day. These very high costs will require that a different approach be developed for regulating urban area stormwater runoff.

EVALUATION OF WATER QUALITY IMPACTS OF STORMWATER RUNOFF

Although there has been considerable work on the chemical characteristics of urban stormwater runoff, little work has been devoted to evaluating the water quality/beneficial use impacts of this runoff. Especially in light of the tremendous costs associated with providing for treatment/control of stormwater runoff, it is important to properly assess whether a chemical constituent derived from stormwater runoff that is present in an urban stream or lake is in a chemical form that is toxic or bioavailable, i.e., can cause pollution. Failure to make this evaluation can lead to expenditure of large amounts of public funds for the development and installation of so-called best managements practices that effect little or no improvement of the beneficial uses of an urban stream or lake or other waterbody receiving the stormwater runoff.

The quality of water in urban creeks, at times, is dominated by urban stormwater runoff-associated constituents. In the late 1970s/early 1980s, the U.S. EPA conducted a Nationwide Urban Runoff Program (NURP) in 28 communities across the United States. The NURP studies provided information on concentrations and loads of a variety of potential pollutants in urban stormwater runoff. Pitt and Field (7) summarized the results of the NURP studies, as did WEF/ASCE (8). Although the U.S. EPA NURP studies provided data on the concentrations and loads of a variety of potential pollutants in urban stormwater runoff, they failed to address true water quality issues, i.e., the impacts of the potential pollutants on the beneficial uses of the receiving waters for the runoff (9).

Heavy Metals

In the fall of 1998, the California Storm Water Quality Task Force conducted a review of constituents that are present in urban area and highway stormwater runoff in sufficient concentrations to cause violations of U.S. EPA water quality criteria and/or California Toxics Rule standards, which were developed by the U.S. EPA (10) for the state. Copper, lead, and zinc were found in almost all urban street and highway stormwater runoff in concentrations that would violate U.S. EPA worst-case-based water quality criteria and state standards based on those criteria. Sometimes cadmium and mercury were also present above those criteria/standards. These findings indicate that there is a potential for certain heavy metals in urban stormwater runoff to be toxic to aquatic life in urban creeks.

Lee and Taylor (11,12) presented the results of a study of heavy metal concentrations and aquatic life toxicity in ten different Upper Newport Bay (Orange County, California) watersheds during 1999–2000. Several watersheds had predominantly urban land use. Lee and Taylor found several heavy metals, including copper, zinc, and lead, in concentrations above water quality criteria/standards. Through toxicity identification evaluation (TIE) studies, Lee and Taylor (12) found, as have others, that heavy metals in urban residential area and highway stormwater runoff are in nontoxic forms. However, this is not necessarily the case for heavy metals in industrial stormwater runoff. Several examples exist in which heavy metals such as zinc from galvanized roofs or copper from copper roofs can be present in industrial stormwater runoff in sufficient concentrations and available forms to be toxic to aquatic life.

Aquatic Life Toxicity

Several constituents are normally present in urban-area stormwater runoff that could cause aquatic life toxicity. The constituents of greatest concern are the heavy metals, including copper, zinc, lead, and occasionally cadmium. Toxicity measurements of urban stormwater runoff from several areas (12–14) have shown that although runoff from urban residential and commercial areas may be toxic to *Ceriodaphnia* (a U.S. EPA standard freshwater zooplankton test organism), that toxicity has not been because of heavy metals. Toxicity identification evaluations have shown that the toxicity measured was caused by the organophosphorus (OP) pesticides diazinon and/or chlorpyrifos. Although the OP pesticides are of concern because of their toxicity to a few types of zooplankton, they are not toxic to fish or algae at the concentrations typically found in urban runoff.

Pesticide-Caused Toxicity

Lee et al. (13,14) reviewed the topic of OP-pesticide-caused toxicity. Diazinon and chlorpyrifos have been, or will soon be, phased out of urban use by the U.S. EPA because of their potential toxicity to children. Chlorpyrifos can no longer be sold for use as a pesticide in urban areas. The U.S. EPA and the registrants have agreed that it will no longer be legal to sell diazinon for urban use after December 2004. These OP pesticides are being replaced by others, especially the pyrethroid pesticides, in urban areas. However, the replacement pesticides have not been evaluated by the U.S. EPA Office of Pesticide Programs for their potential to cause aquatic life toxicity in stormwater runoff from their point of application. Several pesticides are more toxic to fish and zooplankton than the OP pesticides. Further, many of the pyrethroid pesticides tend to sorb strongly to soil particles and, therefore, will be transported in particulate form and accumulate in sediments. Weston (15) and Weston et al. (16) have reported finding that some sediment-sorbed pyrethroid-based pesticides are bioavailable to some benthic organisms. It is unclear whether this bioavailability leads to toxicity. It could, however, cause toxicity in urban streams and lakes and their sediments that is adverse to aquatic life-related beneficial uses of the waterbody.

Dissolved Oxygen

Stormwater runoff events can cause significant dissolved oxygen (DO) depletion in urban streams and other nearby waterbodies. DO measurements made by the DeltaKeeper (17) in waterbodies just before, during, and after a runoff event showed that the DO before the event was adequate for maintenance of aquatic life, i.e., above about 5 mg/L. However, shortly after the event began, the DO in some of the waterbodies dropped to less than 1 mg/L and stayed depressed for several days. A stormwater runoff event in November 2002, and another in August 2003, which were the first major runoff events of the summer/fall, led to large fish kills in half a dozen or so of those waterbodies.

Nutrients

Urban stormwater runoff contains elevated concentrations of various nutrients (nitrogen and phosphorus compounds) that can lead to excessive fertilization of urban creeks, lakes, and downstream waterbodies. Kluesener and Lee (18) and Rast and Lee (19) determined the nutrient loads associated with urban stormwater runoff. In addition to being derived from stormwater runoff, nutrients, especially nitrate, can also be present in groundwater flow to urban creeks and lakes, which can be an important source of nitrate.

Cowen and Lee (20) reported that part of the algal available P in urban stormwater runoff was derived from the leaching of tree leaves and flowers. Cowen and Lee (21) conducted studies of the algal available phosphorus in urban stormwater runoff in several urban areas. Lee et al. (22) summarized the results of those studies and those of others on algal available P in urban and agricultural runoff. In general, it has been found that the algal available P in stormwater runoff from urban and agricultural areas is equal to the sum of the soluble orthophosphate plus about 20% of the particulate phosphorus. Therefore, about 80% of the particulate phosphorus (which can be most of the phosphorus load in such runoff) does not support algal growth.

pH

There can be sufficient primary production in urban creeks and lakes to cause significant diel (over a 24-hr day) changes in pH and dissolved oxygen, which is especially true for those urban streams that have only limited areas where extensive canopy from trees along the bank shades the water. The U.S. EPA (23) Gold Book water quality criterion limits the pH of waters to 9. It is not unusual for the pH of waterbodies to exceed that value in the late afternoon, at the height of photosynthetic activity, and to be several units lower in early morning.

Ammonia

It is possible for the ammonia concentrations in urban creeks to be sufficiently high to violate ammonia water quality criteria based on potential toxicity to aquatic life in an urban stream or lake, which is especially likely if a significant storm sewer discharge contains storm sewer-accumulated sludge/sediments scoured during a runoff event, or scour of stream sediments, which would tend to have high ammonia concentrations. The impact of that ammonia would be exacerbated in those urban streams and lakes that are highly productive as they would tend to have an elevated pH in mid-afternoon because of photosynthetic activity.

Sanitary Quality

Especially during dry weather flow, urban stormwater runoff and, in some situations, drainage ways such as creeks in urban areas, often have greatly elevated concentrations of total coliforms, fecal coliforms, and *E. coli*. The U.S. EPA (24) announced that it was going to require that states adopt a revised contact-recreation criterion for fresh water based on the measurement of *E. coli*. *E. coli* has become the standard recommended organism for assessing the sanitary quality of a freshwater with respect to contact recreation. It is also a useful indicator of potential pathogens in domestic water supplies. Enterococci have become the standard fecal indicator organism for marine waters. The U.S. EPA (4) announced that it was implementing its 1986 criteria for those bacteria in states bordering Great Lakes and in ocean waters that had not adopted those criteria by April 2004. In 2005, the U.S. EPA will develop revised contact recreation-based water quality criteria for the inland waters of the United States.

In many communities, the design of the sanitary sewerage (collection) system is such that discharges of raw sewage to urban waterways can be associated with pump station power failure, blockage of the sewer, and other factors. Further, sanitary sewerage systems are sometimes poorly maintained, with the result that there can be discharges of raw sewage to nearby watercourses on an ongoing basis through leaks in the sewerage system. In addition, animals, including birds, can contribute significant amounts of fecal coliforms and *E. coli* to stormwater runoff, which, in turn, can cause urban creeks to have poor sanitary quality.

With increased emphasis on managing the water quality impacts of urban stormwater runoff in some parts of the country, such as Southern California (especially in the Santa Monica Bay watershed, because of the adverse impacts on sanitary quality of Santa Monica Bay beaches), efforts are being made to control *E. coli* and other pathogen indicators in stormwater runoff, as well as in separate storm sewers during dry weather flow. Ultimately, through comprehensive studies that are now being developed in the Los Angeles Basin and elsewhere, information will be gained on the specific sources of *E. coli* and the potential for their control. Information on the current understanding and control of the sanitary quality of urban stormwater runoff is available in the proceedings of the US EPA 2004 national Beaches conference: http://www.epa.gov/beaches/.

Total Organic Carbon (TOC)

Based on U.S. EPA regulations, domestic water supplies that have a total organic carbon (TOC) concentration above about 2 mg/L may be required to treat the water to remove the total organic carbon to that level, in order to reduce the potential for formation of trihalomethanes (THMs) and other disinfection byproducts during the disinfection of the water supply. This situation raises the question as to whether urban stormwater runoff could be a significant contributor of TOC to urban creeks and ultimately to downstream waterbodies that are used for domestic water supply purposes. Site-specific investigations need to be conducted to evaluate this situation for a particular waterbody.

Excessive Bioaccumulation of Hazardous Chemicals in Edible Aquatic Organisms

Fish and other edible aquatic organisms taken from some urban streams have been found to contain excessive concentrations of legacy pesticides such as DDT, dieldrin, and chlordane, derived from their former use in urban areas as well as from current runoff from urban areas that had been agricultural. In addition, fish and other aquatic life in urban streams can contain excessive concentrations of PCBs and dioxins/furans. As discussed by Lee and Jones-Lee (25), dioxins are known to be present in stormwater runoff from urban areas and highways and can, therefore, be present in urban streams and lakes, especially in the sediments. PCBs are sometimes found in urban stream fish because of spills of electrical transformer PCBs that have occurred in the urban stream watershed or illegal discharges of PCBs from industrial sources to the storm sewer system.

An example of this type of situation occurred in the Smith Canal in the city of Stockton, California. Some edible fish taken from that canal in 1998 contained concentrations of PCBs at levels that are considered hazardous for consumption because of the increased risk of cancer. Lee et al. (26) conducted a study on Smith Canal sediments to determine the total concentrations of PCBs in the sediments and their bioavailability using the U.S. EPA standard sediment bioavailability test procedure with *Lumbriculus variegatus*. It was found that although the sediments had high TOC, which would tend to make the PCBs less bioavailable, there still was significant uptake of the PCBs from the sediments by *Lumbriculus*, which indicates that those organisms would be a food-web source of the excessive PCBs that are found in higher trophic-level edible fish taken from parts of the Smith Canal.

Some measurements of mercury in urban stormwater runoff have shown that the concentrations are sufficient to potentially lead to excessive bioaccumulation of mercury in edible fish tissue. In urban streams or lakes where bioaccumulation of mercury is a potential concern, fish should be examined to determine if they have excessive bioaccumulation of mercury. Lee and Jones-Lee (25) and Lee (27) have provided guidance on approaches that should be followed to evaluate excessive mercury bioaccumulation by examination of edible fish tissue.

PAHs, Oil and Grease, and Unrecognized Hazardous/Deleterious Organic Chemicals

Numerous organic compounds are not pesticides or organochlorine bioaccumulatable chemicals but are of potential concern in urban stormwater runoff. These compounds include oil and grease, PAHs, and others included in the group of "total organic carbon." Within the oil and grease and TOC fractions in urban stormwater runoff can be thousands of unregulated organic chemicals that pose a threat of toxicity to aquatic life and/or bioaccumulate in edible aquatic life where they pose a threat to higher trophic-level organisms, including humans. Many chemicals have been in use and entering the environment for many years but have not been regulated. For example, Silva (28) of the Santa Clara Valley Water District, California has reported that sufficient perchlorate leaches from a flare used at a highway accident to contaminate 726,000 gallons of drinking water with perchlorate above the California Department of Health Services action level of 4 μg/L.

Daughton (29) indicated that although there are more than 22 million organic and inorganic substances, with nearly 6 million commercially available, fewer than 200 are addressed by the current water quality regulations. He noted special concern that in general pharmaceuticals and personal care products (PPCPs) are not regulated but can pose significant water quality concerns. Daughton stated, "Regulated pollutants compose but a very small piece of the universe of chemical stressors to which organisms can be exposed on a continual basis." Additional information on PPCPs is available at http://www.epa.gov/nerlesd1/chemistry/pharma/index.htm.

Suspended Sediment/Turbidity

If an urban creek watershed contains areas of new construction and/or if the urban creek watershed and the creek have soils that readily erode, there can be significant increases in suspended solids/turbidity in the creek during runoff events. The increased turbidity makes the water turbid (muddy), which can affect aquatic life habitat.

Trash

Urban creeks are notorious for accumulating materials that people discard, including grocery carts, tires, paper, Christmas trees and shrubbery, and lawn trimmings. Although some of these items can inhibit flow and thus lead to flooding, some of this material also provides habitat for aquatic organisms in the creek. The primary adverse impact of trash is on the aesthetic quality of the waterbody. Some creeks receive large amounts of trash, which is evidenced by the "creek days" that environmental/public groups conduct, when debris of various types is removed from the creek. With increased emphasis being placed on controlling trash in stormwater runoff in the Los Angeles area pursuant to a TMDL issued to control trash in urban stormwater runoff (30), there could be a reduction in the total amount of trash that is dumped into Los Angeles area urban creeks.

Aquatic Life Habitat

As part of its Water Quality Criteria and Standards Plan (24), the U.S. EPA specifically delineated urban stormwater runoff as a cause of deteriorated aquatic life habitat. The habitat degradation is a result of a variety of factors including channelization and increased urban stream flow caused by paved development in the watershed.

The CWP (1) report contains an extensive discussion of the impact of urbanization with the associated increase in impervious cover (e.g., paving) in urban stream watersheds, on the hydrological and morphological characteristics of urban streams. It reported that when the percentage of impervious cover in an urban stream's watershed exceeds about 10%, the stream's characteristics are typically impacted. When the impervious cover exceeds about 25%, severe impacts on the waterbody's characteristics tend to occur.

As part of the implementation of its Water Quality Criteria and Standards Plan, the U.S. EPA plans to pursue the use of bioassessment methodology to determine the degree of degradation caused by urban stormwater runoff that would need to be corrected to develop desirable aquatic life habitat in urban streams and other waterbodies that receive urban stormwater runoff (24). Thus far the U.S. EPA and state water pollution control agencies seem to have made little progress toward achieving this goal. Information on the U.S. EPA's current program in this area is presented at http://www.epa.gov/ebtpages/watewaterbioassessment.html.

OVERALL

It has become evident that a need exists for comprehensive water quality monitoring/evaluation programs to determine, for representative locations, the real, significant water quality-use-impairments that are occurring in urban lakes and streams (and, for that matter, downstream waters) receiving urban area and highway stormwater runoff. This monitoring/evaluation program should include defining the specific sources of the constituents that lead to the water quality/use impairments. Once the water quality problems have been defined and the sources of the responsible pollutants have been identified, then a reliable evaluation can be made of the management practices that can be implemented to control the pollution of urban streams and lakes by urban area stormwater runoff-associated constituents. In general, because of the high cost of treatment, it is likely that the management practices will focus on source control, as opposed to treatment of the stormwater runoff.

The U.S. EPA's announced "Strategy for Water Quality Standards and Criteria" (31) includes development of wet weather water quality standards. These standards would more appropriately consider how chemical constituents in stormwater runoff impact the beneficial uses of receiving waters. They would likely include a weight-of-evidence evaluation of the relationship between the concentrations of toxic/available forms of constituents in stormwater runoff and their impacts on aquatic-life-related resources in the waterbodies receiving the runoff. Lee and Jones-Lee (32) have reviewed this approach for managing urban area stormwater runoff water quality (33).

RIVERS AND STREAMS: ONE-WAY FLOW SYSTEM

CHRISTOPHE CUDENNEC
Ecole Nationale Supérieure
Agronomique
Rennes, France

Broadly speaking, rivers and streams are inscribed in the structural relief lines of the lowest local altitudes, the thalwegs. But they do not necessarily strictly follow these lines when they are considered on a very precise scale, because their exact drawing is constrained by local particularities such as the substratum, the vegetation, and anthropic artifacts. Inversely, there is not necessarily a river or a stream in a thalweg because the permanent flow and the landscape marking depend on many hydrologic and geomorphological factors.

Because of this particular position of rivers and streams, they have a major role in hillslope drainage, whatever the kinds of waterways through the hillslopes are. Then, any river or stream receives water from the sides and from upward, and makes it flow downward through a slope-oriented sense. Thus, a point of a stream or a river has a topological and functional relationship with all of its up and downward points. This relationship leads to defining the so-called 'one-way flow system' and makes structured objects emerge on a larger scale. Rivers and streams meet and are organized in a hierarchical branched network.

A drainage network is made up of particular points: upstream extremities called sources, junctions called confluences, and a unique downstream extremity called the outlet—and the identification of this outlet is directly related to the definition of a watershed. The channel joining two such points is a link (1–3). To characterize the position of any link within the system, one can identify its magnitude (4), which is the number of sources it drains. One can also attribute an order to it, according to one of the proposed ordering schemes (1,5). Particularly, according to Strahler's scheme, the notion of (network)-stream is defined as a set of successive links of the same order, from up to downstream (6).

From this identification of individual and collective characteristics of river and stream systems, many works have been performed to describe, explain, quantify, and simulate the organizational schemes and rules of the constituents and furthermore, to base the simulation of water flows on these schemes and rules.

Planar observation of individual channels led to observing different patterns and shapes, mostly based on sinuosity, braiding, and anabranching. The cross section of a given site in a channel can present very different shapes and sizes. Moreover, planar observation of drainage networks also points out different patterns. Such individual and network patterns result from complex interactions between the substratum, the vegetation, the anthropic constraints and influences, and the water fluxes. Moreover, these complex interactions are scale-dependent through a wide range of spatial, temporal, and frequency scales. Nevertheless, these patterns can be described by typologies and by quantifying some relevant geometric criteria (7,8). Among them are the sinuosity characteristics such as the meandering radius and the wavelength (9); the bankfull width, depth, and slope; and the drainage density (1,10).

Within the range of scale-dependencies, the relationship with the corresponding watershed is a major issue. First, even if the development of a drainage network follows up and down dynamics (1,6,11), the initiation of a channel has been related to planar geometric characteristics of the upward territory (1,6), called the source area. Furthermore this dependence can be linked to hydrologic processes and to slopes (12,13). Thus, the drainage density appears to depend partly on geometric and partly on hydrologic considerations (1,13,14), which generates great geographic and temporal variability (3,15).

Second, the local geometric and hydraulic characteristics of a channel are related to characteristics of the watershed at whose outlet it is located (8,16). The first such relation, found by Hack (17), is the expression of the length of the longest waterway as a power law of the area of the watershed. Then, other power law relationships have been identified and studied for a range of regimes and substratum between the discharge of a given frequency of occurrence and the area and between stream channel geometric parameters (depth, width, slope, and velocity) and the discharge.

The channel slope at any point is thus related to the upstream conditions. Along a waterway from a source to the outlet, the upstream characteristics vary, particularly the drainage area, and the channel slope presents a covariation. The longitudinal profile of a waterway demonstrates this covariation that generally presents a typical decreasing shape (18), whose characteristics and variability depend mostly on geology and climate and sometimes, on anthropic effects.

These interpretations of local characteristics within systemic trends are elements of an organization of the drainage network. Other watershed-scale elements tend to show that there is a kind of organization of the hydrogeomorphological one-way flow system. These elements come from the analysis of quantitative characteristics which are identified from geometric, topological, and hydrologic considerations.

"The pioneer work" in this domain is the identification of Horton laws of network planar composition, first proposed with Horton's ordering scheme (1) and then verified with Strahler's (6,19) by the "network definition" of a stream. These laws show that the number of streams of order i, the mean length of streams of order i, the mean total area contributing to streams of order i, and the mean slope of streams of order i broadly satisfy geometric series, according to characteristic ratios, respectively, the bifurcation, the length, the area, and the slope ratios. These laws were recognized as geometric-scaling relationships and were integrated in the fractal analysis of the river network organization (20,21), which was then applied to a wide range of parameters and functions (16,22). The width function, particularly, has both geomorphological and hydrologic significance and is deeply studied (7,16).

All these observations and quantifications of the one-way flow system of rivers and streams are characteristic of a given state of a system and can furthermore help follow the evolution of the system. The channels themselves and their relationships with upstream channels and hillslopes, and the network structure evolve according to natural trends and eventually to anthropic constraints. It appears then that the characteristic observations and quantifications tend to particular values or shapes which show a natural underlying tendency of energy optimality or of self-organized criticality (16,23).

Furthermore, on the basis of these observations and quantifications, many modelings can be proposed. First, organization models try to produce realistic networks, based on deterministic and/or statistical reasoning using topological, percolation, optimality, or self-organization rules (16). Second, hydraulic and hydrologic models can base the quantitative description of water fluxes on such actual and theoretical geomorphological considerations (7,16).

STREAMFLOW

XING FANG
Lamar University
Beaumont, Texas

A knowledge of hydrology is fundamental to decision-making processes where water is a component of the engineering system. Streamflow is an important component of the hydrologic cycle. The primary input in a hydrologic cycle is precipitation (rainfall or snowfall). Many forms of rainfall losses occur on Earth's surface, e.g., interception by surface vegetation, depression storage, and infiltration to soil. Rainfall excess is the net rainfall after subtracting rainfall losses from gross rainfall and turns into surface runoff. Surface runoff can eventually gather into natural streams or rivers, and flows in streams/rivers are referred to as streamflow. Streamflow typically quantifies as volumetric discharge in cubic meter or feet per second (cms or cfs). Streamflow is not directly recorded, even though streamflow is one of the most important parameters in hydrologic studies. Typically, the water level at a specific stream cross section is recorded and streamflow is deduced by means of a rating curve. The rating curve is developed by using a set of discharges and gauge heights measured over a period of months or years. Discharges used for rating curve development can be determined by numerical integration after flow velocities are measured at several locations along the cross section and where velocity changes. The principal sources of streamflow data for the United States are the U.S. Geological Survey, U.S. Natural Resources Conservation Service (NRCS), U.S. Forest Service, and U.S. Agricultural Research Service.

Streamflow, at a given location on a stream, is usually represented by a hydrograph. A streamflow hydrograph is a graphical representation of instantaneous discharge at a given location with respect to time. Two types of hydrographs are particularly important: the annual hydrograph and the storm hydrograph. The annual hydrograph is a plot of streamflow versus time over a year, and it shows long-term water balance of precipitation, evaporation, and streamflow in a watershed. From the annual hydrograph, a stream may be classified as a perennial river, ephemeral river, or snow-fed river. A perennial river typical under a humid climate has continuous flow conditions year round and even during no-rainfall periods. An ephemeral river in an arid climate has long periods when the river is dry (no flow condition). A snow-fed river has the bulk of the runoff yield occurring in the spring and early summer from snowmelt, and variation of discharge is smaller than that for other types of rivers. Annual hydrographs typically contain some spikes caused by rain storms. A storm hydrograph is a streamflow hydrograph during and after a storm.

An example storm hydrograph with typical timing parameters and rainfall hyetograph is shown in Fig. 1. A hydrograph is the response of a watershed under certain rainfall input, and it is affected by the watershed's physical, geological, vegetation, and climatic features. The integration of area under a hydrograph between any two points in time gives the total volume of runoff passing the stream cross section during the time interval. A typical hydrograph consists of rising limb, crest segment, receding limb, and base flow. The rising limb depends on duration and intensity of rainfall, antecedent moisture condition, and drainage characteristics of basin. The crest segment contains a peak that represents the highest concentration of runoff that usually occurs soon after the rainfall has ended. The receding limb represents the withdrawal of the

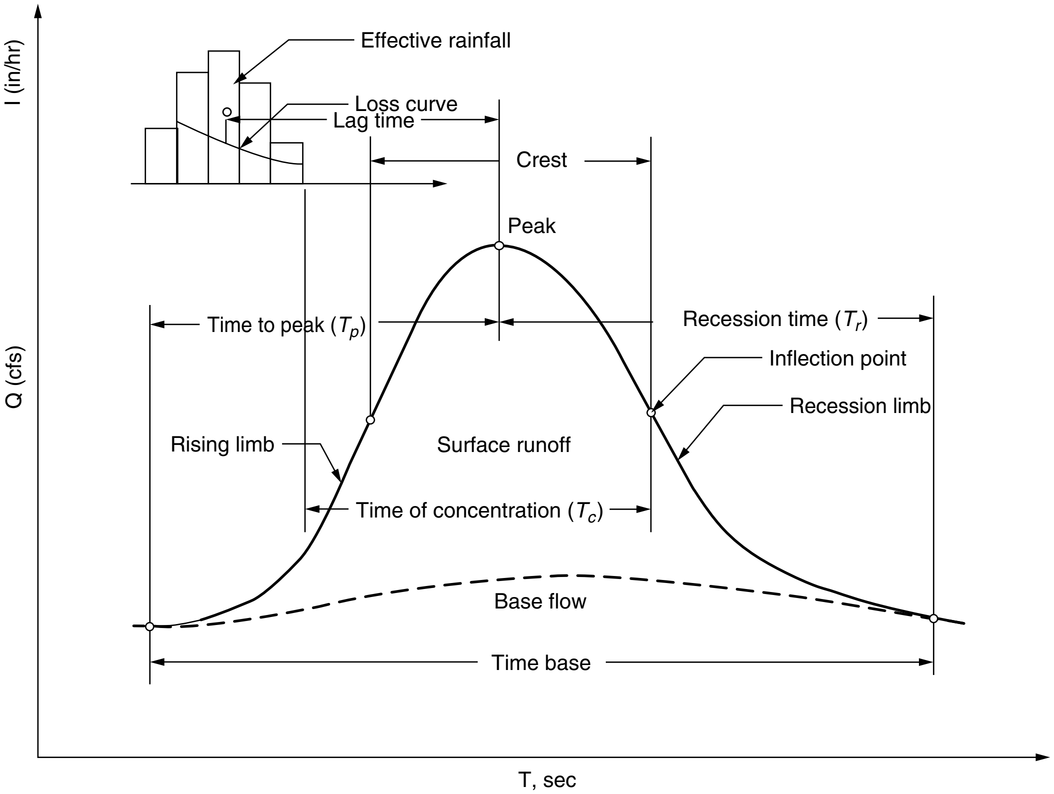

Figure 1. Schematic streamflow hydrograph including typical timing parameters and a rainfall hyetograph.

water from the storage after surface inflow to the channel has ceased. The base flow is that part of runoff that exists even before the occurrence of rainfall (e.g., in the perennial river during the no rainfall period). The total streamflow hydrograph has two components: direct runoff hydrograph (DRH) and base flow. The direct runoff hydrograph is the transformation of effective rainfall passing through a watershed. Base flow is the part of precipitation that percolates downward until it reaches ground water table and eventually discharges into the stream.

Study of a streamflow hydrograph is important for water management and environmental studies as it provides the peak flow rates and for which hydraulic structures can be designed. For the design problems, runoff volume alone is not adequate because the given volume of water may or may not present a flood hazard, but it depends on the time distribution of flood runoff. If the total volume is distributed over a long period of time, flood damages will be minimal, and if the volume is distributed for a short time, even though the volume is small, the damage may be hazardous. Several time parameters have been developed that reflect the timing of runoff, for example, lag time, time to peak, time of concentration, and recession time in Fig. 1. Although direct runoff begins with the commencement of effective rainfall (Fig. 1), the largest portion of runoff generally lags the rainfall because it takes time for runoff to travel from any location within the watershed to the outlet. The basin lag time could be defined as the time from the center of mass of the rainfall excess to the peak discharge rate on the hydrograph (Fig. 1). The time to peak is the time from the beginning to the peak discharge in a simple (single peak) direct runoff hydrograph (Fig. 1). Both the lag time and the time to peak of a hydrograph correlate to the time of concentration of a watershed. The time of concentration (T_c) is the time it takes a water parcel to travel from the hydraulically most distal part of watershed to the outlet or reference point downstream (1–5). In hydrograph analysis, the time of concentration is the time difference between the end of rainfall excess and the inflection point of a hydrograph where the recession curve begins as shown in Fig. 1.

Generally, for a hydrological design, a hydrologist is required to provide peak rates of discharge, a stage height of a hydraulic structure, or a complete discharge hydrograph for a design frequency. The peak discharge of streamflow can be obtained from long-term historical records or from regression equations developed from recorded streamflow. A compete hydrograph, which is needed for design of reservoirs and detention and retention ponds, can be estimated from various rainfall-runoff models or regional dimensional or dimensionless (unit) hydrographs (4). The unit hydrograph is the hydrograph that results from unit rainfall excess distributed uniformly over the drainage area at a constant rate for an effective duration (6). For example, NRCS has a dimensionless unit hydrograph (DUH) procedure for design applications. This DUH developed by Victor Mockus (3) was derived from a large number of natural unit hydrographs from watersheds varying widely in size and geographical locations. Time to peak (T_p) is equal to the watershed

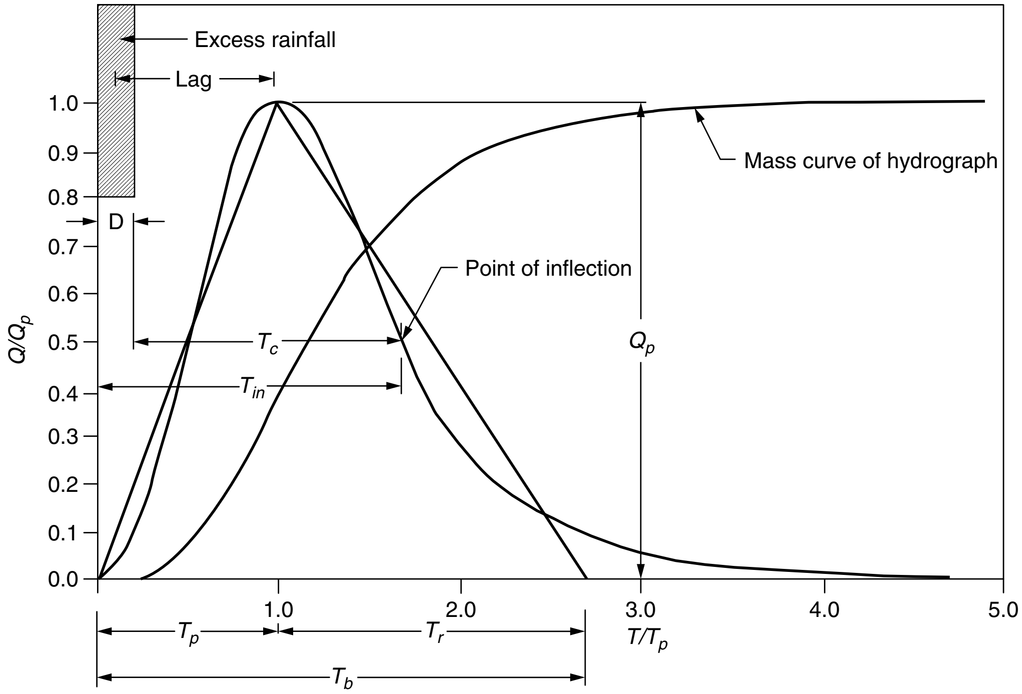

Figure 2. NRCS synthetic unit hydrographs including dimensionless hydrograph and triangular unit hydrograph.

lag time (T_L) plus half of the rainfall excess duration or the duration of unit hydrograph (D in Fig. 2).

$$T_p = T_L + D/2 \qquad (1)$$

This dimensionless unit hydrograph also can be represented by an equivalent triangular hydrograph (Fig. 2). These characteristics of the NRCS unit hydrograph represent values that have been adopted for an *average* watershed. For NRCS DUH, the peak discharge (Q_p) is given as

$$Q_p = KA/T_p \qquad (2)$$

where Q_p is in cfs (cubic feet per second), A (area) is in mile^2, and T_p is in hours. K is the peak rate factor (PRF) and is considered equal to 484, assuming a triangular hydrograph with a time base being 8/3 T_p (Fig. 2). K is related to the internal storage characteristic of a basin and can vary considerably depending on watershed characteristics and scale (size) of a basin. For example, K can range from a value of nearly 600 for steep mountainous conditions to a value nearly to 300 in the flat coastal plains (swampy country) of the state (3). For a very flat, high-water-table watershed, the NRCS peak rate factor of 484 or even 300 likely is too large. NRCS DUH also has an empirical relationship for average lag time that is assumed to be 0.6 T_c (the time of concentration).

$$T_L = 0.6\ T_c \qquad (3)$$

WATER QUALITY IN SUBURBAN WATERSHEDS

Charles W. Kirby
Paciulli, Simmons & Assoc.
Fairfax, Virginia

The story of water quality in suburban watersheds is primarily that of nonpoint source pollution (NPS). There may be instances where point sources contribute significantly to degraded water quality in suburban areas, such as privately owned or municipal sewage treatment plants, but the most salient characteristic of suburban basins is the conversion of land from a previous forested or agricultural land cover to highly impervious surfaces such as rooftops, roads, and sidewalks.

When rain or snow strikes the earth's surface, the water may infiltrate into the soil and become part of the groundwater, or it may flow over the surface and enter a stream system as runoff. Under natural conditions, a high proportion of precipitation soaks into the ground and does not directly enter the surface water network, although groundwater may reappear as surface water at the interface between streams and the water table. Forested watersheds can absorb huge amounts of precipitation without experiencing runoff; often one inch or more of precipitation may be absorbed into the soil (1–7). Alteration of the land surface within a watershed reduces infiltration and increases the proportion of precipitation directly entering the waterways as runoff. The increase in the percentage of impervious surface from urbanization in a stream basin is the primary threat to water quality in suburban areas. Zoppou (8) presents an up-to-date review of the numerical models currently used to simulate urban runoff.

Construction activities in land development pose a direct threat to stream quality by sedimentation from the newly cleared land surface. The removal of vegetation destabilizes the soil and allows rainfall to move large amounts of sediment rapidly into the waterways, burying the habitat for macroinvertebrates and juvenile fish and directly killing aquatic vegetation by interfering with photosynthesis (9,10) (Fig. 1). Many local governments require sediment control measures during construction to reduce damage to downstream waters, but many investigators have found that current erosion and sediment control methods are often ineffective (6,11–13).

Streams in suburban watersheds exhibit radically altered flow regimes compared to those in unaltered basins (14). The hydrographs of urbanized streams typically have higher peaks during storms and show more frequent flows above base level because precipitation that formerly soaked into the soil and joined the groundwater is now shunted into the stream network. Urban streams also have steeper rising and falling limbs of the hydrograph, as shown in Fig. 2. More frequent and rapid flooding is known as “flashiness.” These effects destabilize the streambed, which had reached a state of dynamic equilibrium in the predevelopment condition (9,15). The result is erosion of the bed and banks and accompanying increases in sedimentation and direct destruction of habitat for aquatic flora and fauna. Other physical alterations include increased temperature and increase in sediment load. The effects of velocity and other hydraulic parameters on stream fauna are presented cogently and entertainingly by Vogel (16).

Figure 1. Suburban streams typically have entrenched, widened channels with unstable banks.

Suburban development affects surface water chemistry as well, and suburban watersheds are second only to agricultural areas in degraded water quality from chemical contributions. Nutrients such as phosphorus and nitrogen are often increased by higher population density in a watershed. The use of lawn fertilizers may allow runoff of high concentrations of both elements during storms, and home users of these chemicals often apply amounts far in excess of the capacity of the turf to absorb and use them (3). Golf courses are often sources for these nutrients as well

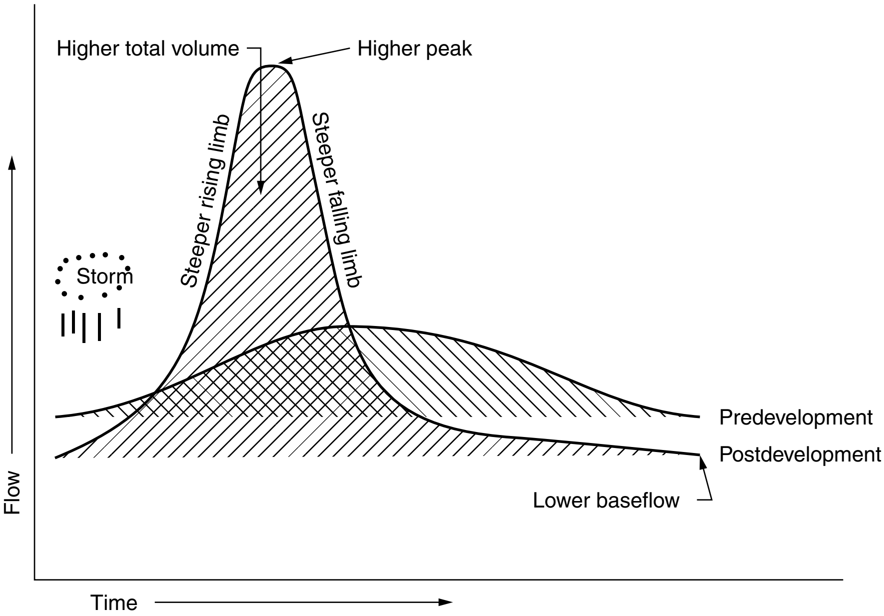

Figure 2. Increased impervious surface in suburban watersheds causes higher volume of runoff, higher peak flow, and lower base flow levels than in undeveloped watersheds.

as other pollutants in suburban areas. Nitrogen has no federally mandated maximum concentration, but such a limit has been set for phosphorus at 1 part per million by the Clean Water Act.

A number of metals are found in elevated concentrations in suburban surface waters. These include nickel, zinc, lead, mercury, cadmium, and copper. The sources of these pollutants range from dry deposition of lead and mercury to particles from automobile brakes and other systems in other cases. Metal concentrations rarely reach the acutely toxic levels found in surface waters drained from industrial sites, but suburban metals pollution nevertheless contributes to degradation of the macroinvertebrate fish, and periphyton populations. In lentic communities and higher order lotic habitats, adsorbed metals may remain permanently in bed sediments (17).

Current stormwater management practices codified in zoning ordinances and municipal facilities standards manuals concentrate almost exclusively on control of erosion and sedimentation (E&S). This emphasis can be traced to the early awareness of civil engineers and water resource managers of the loss of topsoil caused by poor agricultural and construction management practices in the first half of the twentieth century (18). The measures implemented in the period following World War II in most parts of the country are a significant improvement over the prior lack of attention to stream quality issues, but they have proven quite inadequate to preserve aquatic habitat, biotic diversity, and water quality. Engineering solutions to stormwater management problems go under the rubric of best management practices (BMPs). Erosion and sediment control policies for Fairfax County Virginia, an urban county near Washington, DC, are typical of jurisdictions that have recognized water and stream quality problems and the political will to address those problems through engineering standards. Fairfax County BMP requirements for E&S control during construction include

- Design and construction of detention ponds to limit postdevelopment runoff volume from the entire site to levels no higher than the predevelopment condition. The predevelopment and postdevelopment conditions must be demonstrated by hydrologic and hydraulic modeling, according to accepted standards.
- Design of outfall from any stormwater management structures must meet maximum velocity standards to prevent scouring and erosion of the natural stream channel receiving discharge from the constructed structures. The maximum permissible velocity must be hydraulically modeled prior to plan approval and must take into account the soil type in the receiving natural stream channel.
- Temporary E&S controls during construction such as temporary stormwater detention ponds and installation of silt fences intended to prevent sediment-laden runoff from denuded areas from entering off-site streams.
- Prohibitions or limitations on development within floodplains, wetlands, or within 100 feet of a tributary stream.

Environmental regulators in Fairfax County have sent letters to engineering firms and land development companies encouraging the use of innovative BMPs such as bioretention, dry swales, filtration structures, and extended detention ponds, which offer advantages in emulating the predevelopment surface water and groundwater hydrology, but does not require them. However, it is often perceived that innovative BMPS entail higher installation and maintenance costs and are rarely used in many localities. This condition may be expected to change as programs such as the Stage II National Pollutant Discharge Elimination System and the Total Maximum Daily Loads efforts advance to the implementation stage during the next several years. Both programs will place increasing responsibility on local regulatory agencies to decrease negative impacts on receiving waters from the full range of urban hydrology characteristics.

INTRODUCTION

Water is a basic necessity for human survival and sustenance of civilization. The ever-increasing population, steadily rising irrigation activities, rapidly expanding industries, growing urbanization, and rising standard of living exert tremendous pressure on the available water resources (1). The temporal and spatial distribution of the quantity and quality of these resources are highly uneven. Water is used for irrigation, industry, power generation, drinking, bathing, recreation, fisheries, wildlife propagation, pollution abatement, etc. Water in appropriate quantities of specified quality is required for each use (2). Therefore, the quantity as well as quality of river flow should be monitored in river management program.

Surface water pollution is a major environmental concern all over the world (3). The simplest definition of surface water pollution is “the loss of any of the actual or potential beneficial uses of water caused by any change in its composition due to human activity.” The beneficial uses of water are varied and if water is rendered unsuitable for any of the purposes as indicated earlier, then it is polluted to a greater or lesser degree, depending on the extent of the damage caused. Pollution eventually diminishes the aesthetic quality of lakes and rivers. Even more seriously, when contaminated water destroys aquatic life and reduces its reproductive abilities, then it eventually menaces human health.

Natural waters cannot be expected to be immediately suitable for the whole range of beneficial uses. For instance, nobody should expect to drink the water of any river without treatment. Depending on the local usage, weather, and other factors, the water, in its natural state, may be turbid or very highly colored and, hence, unattractive to the user. More importantly, river water is most unlikely to be microbiologically pure, that is, free of those minute organisms (bacteria and the like) that can cause disease in humans. In these cases, water pollution means that, because of some human activity, the water is no longer suitable for some potential use, such as drinking, even after treatment. To illustrate, if a river from which water is taken for treatment for drinking receives a discharge of chemical or possibly toxic waste, the water may be rendered completely unsuitable for eventual distribution. The local treatment works are usually designed to remove natural contaminants—coloring matter, particles causing turbidity, micro-organisms, etc—and therefore may be unable to cope with a heavy load of completely foreign matter, such as chemical waste.

SOURCES OF POLLUTION

The surface water pollution in rivers, lakes, reservoirs, coastal areas, and other surface water resources may occur mainly because of point-source pollution and nonpoint-source pollution. The term point-source pollution refers to pollutants discharged from one discrete location or point, such as an industry or municipal wastewater treatment plant, to surface water resources (Fig. 1). The effluent outfall from factories, refineries, waste treatment plants, etc. emits fluids of varying quality directly into surface waters.

The term nonpoint-source pollution refers to the discharge of pollutants that cannot be identified as coming from one discrete location or point. The pollution outflow from nonpoint source (NPS) pollution, or diffuse pollution, include contaminants that enter the water supply from soils/groundwater systems and from the atmosphere via rain water. Soils and groundwaters contain the residue of

Figure 1. Polluted river in United Kingdom.

human agricultural practices (fertilizers, pesticides, etc.) and improperly disposed of industrial wastes.

A majority of pollution instances are caused by sudden or continuing, accidental or deliberate, discharge of polluting material, which on first consideration might not seem harmful or offensive at all. Such pollution events are caused by the discharge of nontoxic organic matter waste from creameries, sewage (treated or untreated), manure slurry, food production waste, chemicals, and silage effluent to water bodies. When an uncontrolled discharge of organic material occurs, the constraining factor on the growth of the bacterial pollution is removed at a stroke. An immediate abundance of food exists and a corresponding plenitude of dissolved oxygen initially. Bacterial growth is promptly stimulated and the population increases rapidly, consuming the available oxygen as it does so.

The growth of bacteria, therefore, tends to reduce the amount of oxygen dissolved in the water. The extent of oxygen depletion that occurs depends on the rapidity with which the stream takes up oxygen from the atmosphere, i.e., its re-aeration capacity. This capacity is greatest in fast-flowing, turbulent streams and least in deep, slow-flowing rivers. In addition, the loss of oxygen may be counteracted by the photosynthesis of green plants, which produce oxygen during daylight. Where the degree of pollution is severe, these compensating factors may be insufficient to prevent the oxygen content of the water decreasing to very low levels, or, in the worst case, to anaerobic conditions, where a complete absence of free oxygen exists. In such conditions, foul-smelling compounds such as hydrogen sulphide may be formed.

Deoxygenation is the most important potential effect of organic waste discharge. However, toxic compounds, such as ammonia, may be present in such a waste, particularly where they have been stored for some time and have become septic, which can happen with farm waste, in which the presence of compounds, such as ammonia and hydrogen sulphide, probably contribute as much as the deoxygenating capacity of these wastes to the devastating effect on fish stocks in pollution incidents. When toxic pollution occurs, the effects are often direct and immediately apparent—fish are killed, the flora and fauna of the water receiving the pollution may be wiped out, different visible effects will be noticeable, and there may be noxious smells. The principal effects are those of direct poisoning by the offensive pollutants discharged.

EFFECTS OF POLLUTION ON DRINKING WATER

The surface water pollution occurring because of point and/or nonpoint sources of pollution creates a health hazard in many ways. Table 1 shows the effect of various water quality variables for drinking purposes.

TREATMENT OF POLLUTANTS

For many years, the main goal of treating municipal wastewater was simply to reduce its content of suspended solids, oxygen-demanding materials, dissolved inorganic compounds, and harmful bacteria. In recent years, however, more stress has been placed on improving means of disposal of the solid residues from the municipal treatment processes. The basic methods of treating municipal wastewater fall into three stages: primary treatment, including grit removal, screening, grinding, and sedimentation; secondary treatment, which entails oxidation of dissolved organic matter by means of using biologically active sludge, which is then filtered off; and tertiary treatment, in which advanced biological methods of nitrogen removal and chemical and physical methods such as granular filtration and activated carbon absorption are employed. The handling and disposal of solid residues can account for 25–50% of the capital and operational costs of a treatment plant. The characteristics of industrial wastewater can differ considerably both within and among industries. The impact of industrial discharges depends not only on their collective characteristics, such as biochemical oxygen demand and the amount of suspended solids, but also on their content of specific inorganic and organic substances. Three options are available in controlling industrial wastewater. Control can take place at the point of generation in the plant; wastewater can be pretreated for discharge to municipal treatment sources; or wastewater can be treated completely at the plant and either reused or discharged directly into receiving waters. Figure 2 illustrates the treatment procedure of polluted water.

Raw sewage includes waste from sinks, toilets, and industrial processes. Treatment of the sewage is required before it can be safely buried, used, or released back into local water systems. In a treatment plant, the waste is passed through a series of screens, chambers, and chemical processes to reduce its bulk and toxicity. The three general phases of treatment are primary, secondary, and tertiary. During primary treatment, a large percentage of the suspended solids and inorganic material is removed from the sewage. The focus of secondary treatment is reducing organic material by accelerating natural biological processes. Tertiary treatment is necessary when the water will be reused; 99% of solids are removed and various chemical processes are used to ensure the water is as free from impurity as possible.

INDIAN SCENARIO OF SURFACE WATER POLLUTION

Water Stress and Water Scarcity in India

In India, because of uneven distribution of rainfall, the available per capita water resources have been varying in different river basins. As a result, despite good annual rainfall, some river basins fall in the category of water-scarce and water-stressed regions, whereas many others suffer from absolute scarcity. The water availability in any region or country is reflected by “water stress index” (4). This index is based on the minimum per capita water required for basic household needs and to maintain good health. A region whose renewable fresh water availability is below 1700 cubic meters/capita/annum is a “water stress” region, whereas the one whose availability falls below 1000 cubic meters/capita/annum experiences “water scarcity.” The current national average per capita water

Table 1. Effects of Water Quality Parameters for Drinking Purposes

S. No.	Parameter	Prescribed Limits IS:10500, 1991 Desirable	Permissible Limit	Probable Effects
1.	Color (hazen unit)	5	25	Makes water aesthetically undesirable
2.	Odor	Essentially free from objectionable odor		Makes water aesthetically undesirable
3.	Taste	Agreeable		Makes water aesthetically undesirable
4.	Turbidity (NTU)	5	10	High turbidity indicates contamination/pollution
5.	PH	6.5	8.5	Indicative of acidic or alkaline waters, affects taste, corrosivity, and the water supply system
6.	Hardness as $CaCO_3$(mg/l)	300	600	Affects water supply system (scaling). Excessive soap consumption, calcification of arteries. There is no conclusive proof, but it may cause urinary concretins, diseases of kidney or bladder, and stomach disorders
7.	Iron (mg/l)	0.03	1.00	Gives bitter sweet astringent taste. Causes staining of laundry and porcelain. In traces, it is essential for nutrition
8.	Chloride (mg/l)	250	1000	May be injurious to some people suffering from diseases of heart or kidneys. Taste, indigestion, corrosion, and palatability are affected
9.	Residual Chlorine (mg/l) only when water is chlorinated	0.20	—	Excessive chlorination of drinking water may cause asthma, colitis, and exzema
10.	Total Dissolved Solid (mg/l) (TDS)	500	2000	Palatability decreases and may cause gastro-intestinal irritation in humans; may have laxative effect particularly on transits and corrosion; may damage water system
11.	Calcium (Ca) (mg/l)	75	200	Causes encrustation in water supply system. Although insufficiency causes a severe type of rickets, excess causes concretions in the body such as kidney or bladder stones and irritation in urinary passages. (Essential for nervous and muscular system, cardiac functions, and in coagulation of blood)
12.	Magnesium (Mg) mg/l	30	100	Its salts are cathartics and diuretic. High conc. may have laxative effect particularly on new users. Magnesium deficiency is associated with structural and functional changes. It is essential an activator of many enzyme systems
13.	Copper (Cu) mg/l	0.05	1.50	Astringent taste but essential and beneficial element in human metabolism. Deficiency results in nutritional anemia in infants. Large amount may result in liver damage, cause central nervous system irritation, and depression. In water supply, it enhances corrosion of aluminium in particular
14.	Sulphate (SO_4) mg/l	200	400	Causes gastro-intestinal irritation along with Mg or Na, can have a cathartic effect on users, concentration of more than 750 mg/l may have laxative effect along with Magnesium
15.	Nitrate (NO_3) mg/l	45	100	Cause infant methaemoglobinaemia (blue babies) at very high concentration, causes gastric cancer and adversely affects central nervous system and cardiovascular system
16.	Fluoride (F) mg/l	1.0	1.50	Reduces dental carries, very high concentration may cause crippling skeletal fluorosis

Table 1. (*Continued*)

S. No.	Parameter	Prescribed Limits IS:10500, 1991 Desirable	Prescribed Limits IS:10500, 1991 Permissible Limit	Probable Effects
17.	Cadmium (Cd) mg/l	0.01	—	Acute toxicity may be associated with renal, arterial hypertension, itai-itai disease (a bone disease). Cadmium salt causes cramps, nausea, vomiting, and diarrhea
18.	Lead (pb) mg/l	0.05	—	Toxic in both acute and chronic exposures. Burning in the mouth, severe inflammation of the gastrointestinal tract with vomiting and diarrhea; chronic toxicity produces nausea, several abdominal pain, paralysis, mental confusion, visual disturbances, anemia, etc.
19.	Zinc (Zn) mg/l	5	15	An essential and beneficial element in human metabolism. Taste threshold for Zn occurs at about 5 mg/l, imparts astringent taste to water
20.	Chromium (Cr + 6) mg/l	0.05	—	Hexavelant state of chromium produces lung tumors, can produce cutaneous and nasal mucous membrane ulcers and dermatitis
21.	Boron (B) mg/l	1.00	5.00	Affects central nervous system, its salt may cause nausea, cramps, convulsions, coma, etc.
22.	Alkalinity mg/l $CaCO_3$	200	600	Imparts distinctly unpleasant taste, may be deleterious to humans in presence of high pH, hardness, and total dissolved solids
23.	Pesticides mg/l	Absent	0.001	Imparts toxicity and accumulates in different organs of human body affecting immune and nervous systems, may be carcinogenic
24.	Phosphate (PO_4) mg/l	No guideline		High concentration may cause vomiting and diarrhea; stimulate secondary hyperthyroidism and bone loss
25.	Sodium (Na)	No guideline		Harmful to persons suffering from cardiac, renal, and circulatory diseases
26.	Potassium (K) mg/l	No guideline		An essential nutritional element, but in excess is cathartic
27.	Silica (SiO_2) mg/l	No guideline		—
28.	Nickel (Ni) mg/l	No guideline		Nontoxic element but may be carcinogenic in animals; can react with DNA resulting in DNA damage in animals
29.	Pathogens (a) total coliform (per 100 ml) (b) Fecal coliform (per 100 ml)	1	10	Causes water borne diseases like coliform, jaundice, typhoid, cholera, etc.; produces infections involving skin mucous membrane of eyes, ears, and throat

availability figure per annum is 2464 cubic meters, implying that India is not yet in the "water stress" range. However, this is only the national average figure. There are several parts of India that are water stressed (Fig. 3)—the regions in the Indus, Krishna, and Ganga subbasins. Regions under east-flowing rivers between Mahanadi and Pennar and west-flowing rivers of Kachchh and Kathiawar are experiencing water scarcity, whereas the regions under east-flowing rivers between Pennar and Kanyakumari are suffering with absolute water scarcity (situation where the per capita availability falls below 500 cubic meters/annum). The per capita water availability here falls as low as 411 cubic meters (5), as shown in Fig. 3. The annual rainfall received by India is unevenly distributed across its different parts and across different times of the year. As a result despite good annual rainfall, some river basins fall in the category of water-scarce and water-stressed regions, whereas many others suffer from absolute scarcity.

Surface Water Pollution in India

River Water Pollution. In addition to water scarcity and water stress, many rivers are being used indiscriminately for disposal of municipal, industrial, and agricultural wastes, thereby polluting the river water beyond the permissible limits; Fig. 4 shows major rivers.

As can be seen from Fig. 2, the river water is unfit even for irrigation purposes at some places. Thus, it has

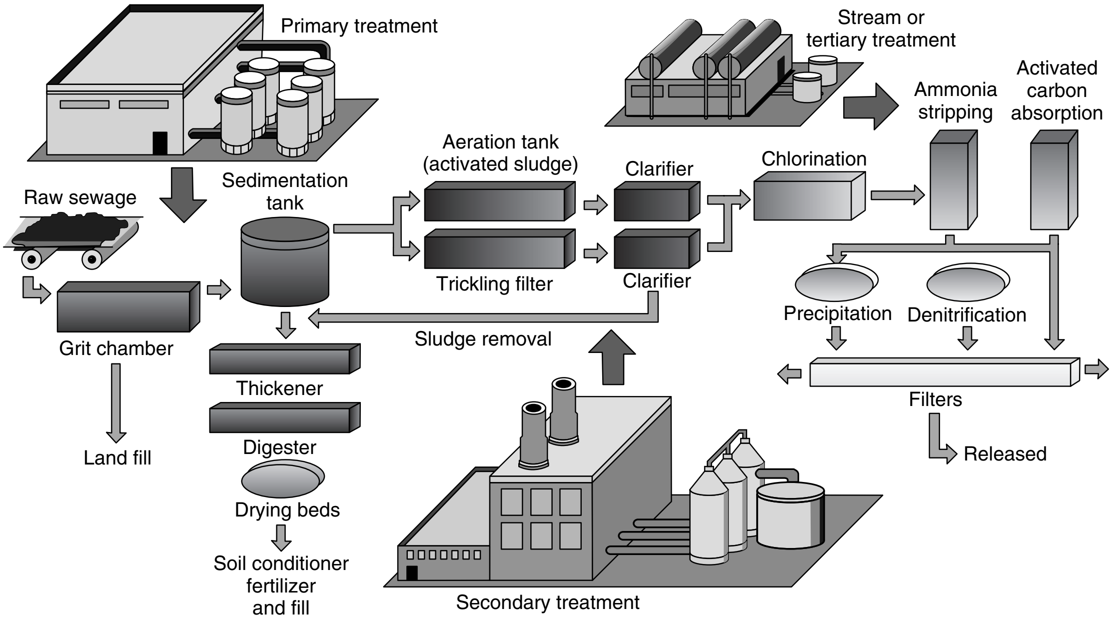

Figure 2. Wastewater treatment.

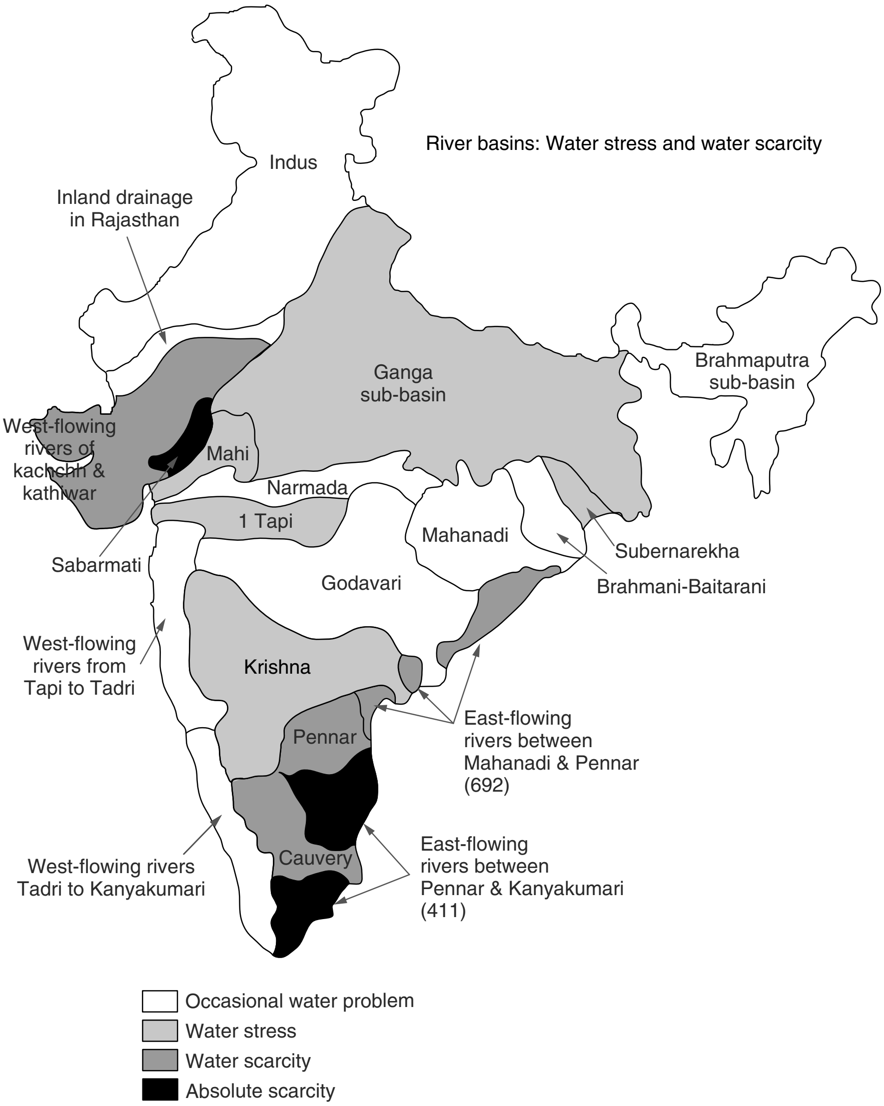

Figure 3. Water stress and water scarcity in India.

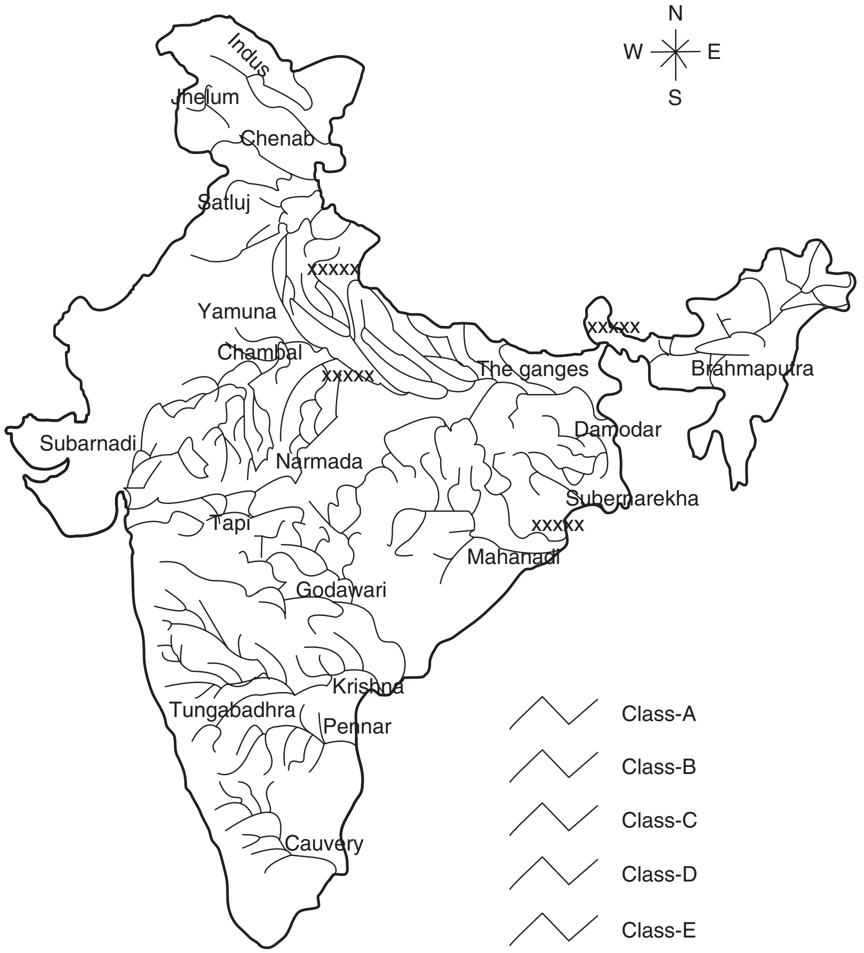

Figure 4. Generalized pattern of major rivers in India. Rivers will all be classified A to E.
Class A: Fit for drinking after proper disinfection with the addition of chlorine or bleaching powder.
Class B: Fit for bathing.
Class C: Fit for drinking only after proper treatment (screening to remove physical matters or particulate such as paper, plastic etc.
Class D: This is fit for fish and wildlife.
Class E: Suitable only for industrial cooling, irrigation, etc.

become absolutely essential to evaluate the environmental impacts of surface water resources to minimize the progressive deterioration in water quality. Water quality issues needing to be addressed with respect to rivers are discussed below.

Change in Physical Characteristics. Temperature, turbidity, and total suspended solids (TSS) in rivers can be greatly affected by human activities such as agriculture, deforestation, and the use of water for cooling. For example, the upward trend in soil erosion and the related increase in TSS in rivers can be seen in most of the mountainous regions in India (6).

Contamination by Fecal and Organic Matter. In India, fecal contamination is still the primary water quality issue in rivers, especially where human and animal wastes are not adequately collected and treated. Although this applies to both rural and urban areas, the situation is probably more critical in fast-growing cities.

The release of untreated domestic or industrial wastes high in organic matter into rivers results in a marked decline in oxygen concentration (sometimes resulting in anaerobic conditions) and an increase in ammonia and nitrogen concentrations downstream of the effluent input. The most obvious effect of the release of organic matter along the length of the river is the depletion of oxygen downstream of the discharge as shown by the so-called “oxygen-sag curve,” which plots dissolved oxygen concentration against distance. Industrial activities that discharge large organic loads include pulp and paper production and food processing. Fecal matter affects the use of water for drinking water source or bathing water, as well as ecological health of river.

Toxic Pollutants: Organics and Heavy Metals. Organic pollutants (mostly chemicals manufactured artificially by man) are also becoming an important water quality issue. Uncontrolled discharge of industrial wastewater often causes pollution because of toxic metals. Other sources of metal pollution are leachates from urban solid waste landfills and mining waste dumps.

Rivers such as the Yamuna, which pass through large towns and cities, are often badly affected with organic pollutants. Another example is that of Damodar River, which is polluted with heavy metals developing mostly from electroplating, tanning, and metal-based industries (6).

River Eutrophication. During the 1950s and 1960s, eutrophication (nutrient enrichment leading to increased plant arid algae growth) was observed mostly in lakes and reservoirs. Since the 1970s, the increasing levels of phosphates and nitrates entering rivers, particularly

Table 2. Grossly Polluted and Less Polluted Stretches of Some Major Rivers

in developed countries, were largely responsible for eutrophication occurring in running waters. In India, isolated reports have appeared for some river reaches, especially in plains around agriculture tracts of land.

In small rivers, eutrophication is said to promote macrophyte (large plants) development, whereas in large rivers, phytoplankton (algae) are usually more dominant than macrophyte. In such situations, the chlorophyll concentration of the water may reach extremely high values because of the fact that this pigment is present in all plants. Eutrophication can result in marked variations in dissolved oxygen arid pH throughout the day. The changes in water quality caused by eutrophication can be a major cause of stress to fish because of the release, at high pH, of highly toxic gaseous ammonia and depletion of oxygen after sunshine hours.

Salinization. Industrial and mining waste pollution results in increase in specifications. Evaporation, however, increases the concentration of all ions.

Table 2 shows the water quality of grossly polluted and less polluted major rivers of India. It is found that most of the rivers lie under the category C, which is suitable only for irrigation purposes.

Lake Water Pollution. Lakes serve as traps for pollutants carried by rivers and groundwater draining the watershed. The pollutant concentration in the lake usually builds up because of evaporation of water from the lake's surface unless a natural flushing with good quality water occurs.

Eutrophication. Simply speaking, eutrophication is the biological response to excess nutrient input to a lake. The production of biomass and its death and decay results in a number of effects, which individually and collectively result in impaired water use. The most important of these effects are decreased dissolved oxygen levels, release of odorous compounds (e.g., H_2S), and siltation.

Many important lakes in India [e.g., Hussein Sagar (Hyderabad), Nainital (Uttar Pradesh) and Dal (Jammu and Kashmir)] have reportedly progressed to advanced eutrophication levels (6).

Lake Acidification. One of the major issues related to lakes in particular, and to freshwaters in general, is the progressive acidification associated with deposition of rain and particulates (wet and dry deposition) enriched in mineral acids. The problem is characteristic of lakes in specific regions of the world that satisfy two major critical conditions: the lakes must have soft water (i.e., low hardness, conductivity, and dissolved salts) and be subjected to "acid rain."

To date, lake acidification has not been reported as a problem in India.

Bioaccumulation and Biomagnification. The processes of bioaccumulation and biomagnification are extremely important in the distribution of toxic substances (discharged in waste effluents) in fresh water ecosystems. The concentration of pollutants within the organism because of bioaccumulation and biomagnification depends on the duration of exposure of the organism to the contaminated environment and its trophic level in the food chain. Several fold increases in trace contaminant concentrations have been commonly observed in lakes and estuarine environments.

SURFACE RUNOFF AND SUBSURFACE DRAINAGE

Joseph Holden
University of Leeds
Leeds, United Kingdom

Runoff is the movement of water across or through the land surface. Sometimes, the word runoff is used simply to refer to river discharge. However, there are many different types of runoff, including overland flow (surface runoff) or throughflow (subsurface runoff, sometimes also called interflow). Figure 1 illustrates the main hillslope runoff pathways for water. Precipitation can either hit the surface of the hillslope directly or be intercepted by vegetation. This intercepted water can be stored on leaves and tree trunks which shelter the ground beneath, or it can trickle down to reach the surface via stem flow. There are then two possibilities for direct precipitation or stem flow, once it reaches the hillslope, either to infiltrate into the soil or to pond up and flow over the surface as overland flow. Water that enters the soil may percolate down or move laterally

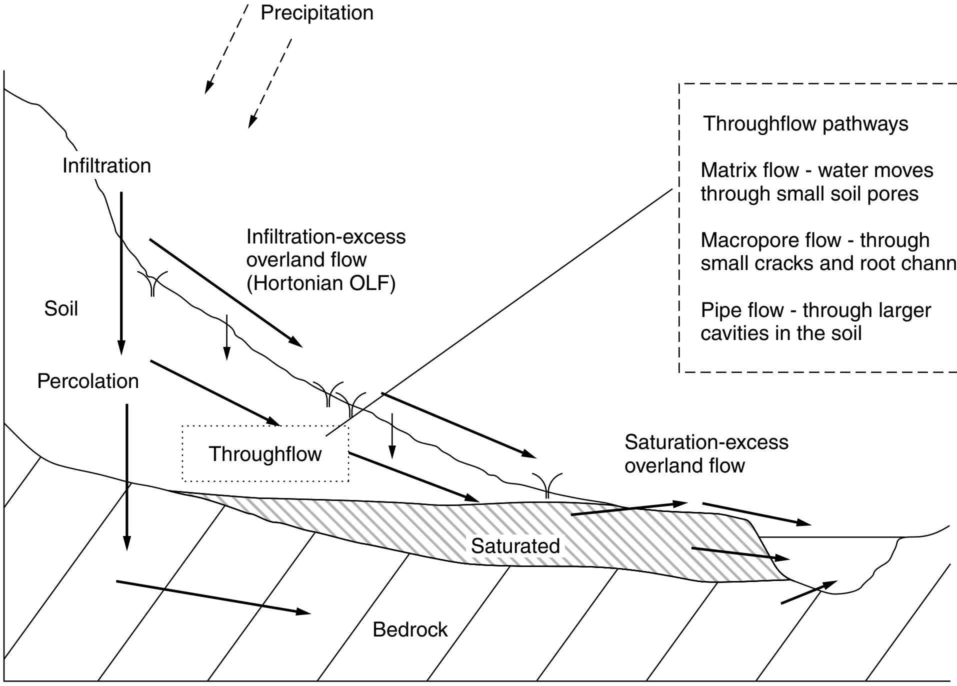

Figure 1. Main hillslope runoff pathways.

through the soil as throughflow, or it may return to the surface where the soil becomes saturated. The following sections provide details on each of the main interlinked overland flow and subsurface drainage mechanisms.

INFILTRATION-EXCESS OVERLAND FLOW

If the surface water supply is greater than the rate of infiltration into the soil, then surface storage will occur (even in urban catchments in small surface depressions). When the surface depressions are filled, they will start to overflow; this is called Hortonian overland flow (OLF) or infiltration-excess OLF. In Horton's theory, infiltration divides rainfall into two parts. One part goes via OLF to the stream channel; the other goes initially into the soil and then through groundwater flow to the stream or into groundwater storage or is lost by evapotranspiration. The dominance of Horton's (1) theory meant that research into subsurface flow mechanisms was neglected until the 1970s as it was assumed that infiltration-excess OLF was the major contributor to fast responding flow in rivers (2).

In many temperate areas of the world, infiltration-excess OLF is a rare occurrence except in urban locations. The infiltration capacity of many soils is too high to produce infiltration-excess overland flow. Infiltration-excess OLF is more likely in semiarid areas where soil surface crusts have developed and rainfall can be particularly intense. Often infiltration-excess OLF will occur only on spatially localized parts of a hillslope such as in tractor wheelings on arable land. This spatially localized infiltration-excess OLF is known as the partial contributing area concept (3). This suggests that only parts of the catchment or hillslope contribute infiltration-excess OLF, rather than the whole catchment, as Horton had originally suggested.

SATURATION-EXCESS OVERLAND FLOW

When water infiltrates into a soil, it fills up the available pore spaces. When all the pore spaces are full, the soil is saturated, and the water table is at the surface. Therefore, any extra water has difficulty entering the soil because it is saturated. Hence, OLF occurs. This type of OLF is known as saturation-excess overland flow. Saturation-excess OLF can occur at much lower rainfall intensities than required to generate infiltration-excess OLF. Saturation-excess OLF can occur even when it is not raining. This might happen, for example, at the foot of a hillslope. Water draining through the soil is known as throughflow. Throughflow from an upslope can fill up the soil pores at the bottom of the slope, and so the soil becomes saturated (Fig. 1). Any extra water is then forced out onto the surface to become OLF. This water, known as 'return flow,' is a component of saturation-excess OLF. Therefore saturation-excess OLF is more likely to occur at the bottom of a hillslope or on shallow soils where there is restricted pore space for water storage.

The area of a catchment or hillslope that produces saturation-excess OLF varies through time. During wet seasons, for example, more of a catchment or hillslope will be saturated and therefore can generate saturation-excess OLF than during dry seasons. During a rainfall, if the catchment starts off relatively dry, then not much of the area will generate saturation-excess OLF; but as rainfall continues, then, more of the catchment becomes saturated, especially in the valley bottoms, and therefore a larger area of the catchment will produce saturation-excess OLF. The fact that the area of a catchment in which saturation-excess OLF occurs tends to vary is known as the 'variable source area concept' (4). The variable source area model has become the dominant concept in catchment hydrology (2).

Saturation-excess OLF is a much more important process than infiltration-excess OLF across temperate zones. The main differences between the two OLF types are related to the water flow paths. For infiltration-excess OLF, all of the flow is fresh rainwater that has not been able to infiltrate into the soil. However, saturation-excess OLF is often a mixture of water that has been inside the soil (return flow) and fresh rainwater that reaches the hillslope surface.

THROUGHFLOW

If water infiltrates into soil, several things can happen; it can be taken up by plants and transpired (or be lost from the soil by evaporation); it can continue to percolate down into the bedrock; or it can travel laterally through the soil or rock—this is called throughflow.

Most water reaches rivers worldwide either by throughflow, through the soil layers or through bedrock. Throughflow can maintain low flows (baseflow) in rivers by slow subsurface drainage of water and can also contribute to peak flows (storm flow) by generating saturation-excess OLF and as an important process in its own right (5). There are different ways water can move through soil as throughflow, and this impacts the timing of water delivery to the river channel. Soils are not uniform deposits; they have cracks and fissures within them. Water can move through the very fine pores of soil as matrix flow, or it can move through larger pores called macropores (macropore flow), or even larger cavities called soil pipes (pipe flow). Water that moves through the soil matrix occurs in a laminar fashion whereas flow within macropores and pipes is turbulent.

Matrix Throughflow

It is possible to measure throughflow and overland flow on hillslopes by digging a trench across the slope and intercepting and collecting the flow from different soil layers. However, this is not always feasible, and disturbance of hillslope soils is not desirable. Flow through the matrix of a porous substance such as soil that occurs in a laminar fashion should behave according to Darcy's Law. This allows us to calculate the likely rate of water movement through a porous medium when it is saturated (saturated hydraulic conductivity). Thus, it is possible to estimate the amount of flow taking place as matrix throughflow. Often, the saturated hydraulic conductivity will vary with depth and soil type. Sandy soils typically have high hydraulic conductivity compared to clay soils that have low hydraulic conductivity. Therefore, water will drain through sandy soils more quickly than through clay soils. Lateral throughflow through the soil matrix will occur in any soil in which the hydraulic conductivity declines with depth. If both soil and bedrock remain permeable at depth, however, then percolation remains vertical and little lateral flow can occur; infiltrating water will only recharge groundwater storage (5).

Water also moves through soils on hillslopes that are unsaturated. Even after a long drought, most soils contain some water. This suggests that gravitational drainage and evapotranspiration are not the only forces at work in moving water within soils and that other forces involved must be very strong (2). It is possible to calculate how the interacting forces of gravity, matric potential (soil water tension), positive pore water pressure, and other forces that operate balance out. Once this soil water energy balance has been determined (by measuring pore water pressure and relative altitude, for example), it is possible to map spatially the directions of subsurface water movement. Water in different parts of the soil can move in different directions due to capillary, gravitational, and other forces. Often, it is possible to show that throughflow water preferentially flows into hillslope hollows, and thus these areas become more important contributors to subsurface flow and saturation-excess OLF.

Macropore and Pipe Throughflow

Macropores are pores larger than 0.1 mm in diameter, and soil pipes are those larger than 1 mm in diameter that transport water through the soil. Macropores and pipes can promote rapid, preferential transport of water and chemicals through the soil due to their size and also because they are connected and continuous across sufficient distances to bypass agriculturally and environmentally important soil layers (6). Water may drain more quickly through macropore and soil pipe networks than through the soil matrix. Darcy's Law does not provide a good estimate of subsurface drainage rates if a soil contains many hydrologically active soil pipes or macropores because it is valid only for nonturbulent flows. Macropores may not take up much space in the soil, and if they are open at the soil surface, they will often take up only a tiny proportion of the soil surface. Despite their small spatial role, macropores can still have a high impact on runoff and play a large role in throughflow drainage as water can preferentially flow through them. A study in Niger on a crusted sandy soil showed that 50% of infiltrated water moved through macropores (7). Some studies in upland peat catchments have indicated that 30% of throughflow moves through macropores (8) and 10% through soil pipes (9).

Groundwater Flow

Groundwater is water held below the water table in soil and rock. Therefore, groundwater flow has, to some extent, already been discussed before. However, further treatment of groundwater flow as a separate component is required because of its worldwide importance. In many catchments, water is supplied to the stream from groundwater in the bedrock. This is water that has percolated down through the overlying soil and entered the bedrock. Rock has small pores, fractures, and fissures. Therefore, it is possible to use Darcy's Law to investigate flow rates through bedrock where fissures are at a minimum. Where there are large fractures such as in cavernous limestone areas, then it may not be so useful. Groundwater may be a large store of water, but for it to be available to supply river flow, the holding material (rock or soil) needs to be not just porous but permeable. That is to say that a rock (or soil) may be porous but relatively impermeable either because the pores are not connected or because they are so small that water can only be forced through them with difficulty. Conversely a rock that has no voids except one or two large cracks will have low porosity and therefore a poor store of water, but because water can pass easily through the cracks, the permeability will be high (5).

RUNOFF PROCESS CONTROLS OF RIVER FLOW

Surface and subsurface flow processes are important controls on river flow and the response of a catchment to precipitation. The dominance of different types of runoff processes is controlled by local climate and catchment features such as geology, topography, soils, and vegetation. Land management can influence runoff processes by changing the infiltration capacity of the soil surface, altering the internal structure of a soil, or by changing the catchment water balance (e.g., through deforestation). Depending on the nature of the aquifer, baseflow discharge may be uniform throughout the year, or peak discharge may lag significantly behind precipitation inputs (2). Some catchments lack any significant groundwater storage and therefore have limited baseflow.

The occurrence of hillslope flow processes in the catchment and their relative dominance affect the speed at which water is delivered to a stream. Overland flow is typically much faster than subsurface drainage. This is why urbanization can lead to increased flood risk downstream. Surfaces created by urbanization reduce infiltration capacity and promote the formation of infiltration-excess OLF. Matrix flow is slower than macropore flow which, in turn, is a form of drainage slower than pipe flow. Many soil pipe flow waters can have velocities equal to that of overland flow.

Where infiltration-excess overland flow dominates the hillslope runoff response, then a river hydrograph is likely to have a short lag time and high peak flow. If throughflow in the small soil pores (matrix flow) dominates the runoff response on the hillslopes, then the hydrograph may have a much lower peak and longer lag times. However, throughflow contributes to saturation-excess OLF so throughflow can still lead to rapid and large flood peaks. In some soils, only a small amount of infiltration may be needed to cause the water table to rise to the surface. There may even be two river discharge peaks caused by one rainfall, where the first peak is saturation-excess overland flow and some precipitation directly in the channel and the second peak is much longer and larger caused by subsurface throughflow accumulating at the bottom of hillslopes and valley bottoms before entering the stream channel. Throughflow may also contribute directly to storm hydrographs by a mechanism called piston or displacement flow. This is where soil water at the bottom of a slope (old water) is rapidly pushed out of the soil by new fresh infiltrating water entering at the top of a slope. Determination of whether the water is old water being pushed out of a slope or new water can be done hydrochemically (by comparing the water to precipitation chemistry) or by using dyes. Where surface saturation occurs to any great extent such as on wide valley bottoms, saturation-excess OLF will dominate the flow response with higher peak discharges and lower lag times than are characteristic of throughflow storm contributions. Where soils are fairly impermeable through much of their profile, surface saturation may be extensive, and much more rainfall is translated into runoff. Where permeable soils overlie impermeable bedrock, however, throughflow can sometimes account for most storm discharge (5).

Runoff processes are by no means independent of one another, and water travelling across the surface at one point may later take the form of subsurface flow through the matrix and then flow through macropores before being returned to the soil matrix, for example. Hillslope runoff is dynamic, and the dominance of runoff production processes varies across both time and space.

TRACE ELEMENTS IN WATER, SEDIMENT, AND AQUATIC BIOTA—EFFECTS OF BIOLOGY AND HUMAN ACTIVITY

NITISH PRIYADARSHI
Ranchi University
Ranchi, Jharkhand, India

INTRODUCTION

Trace elements are defined here as those elements that generally occur in water at concentrations of less than 1 mg/L.

In recent years, the role of trace element studies in environmental chemistry is gaining attention. The deficiencies or excess distribution of these in water and foodstuffs may pose serious regional health hazards and cause diseases in human beings and animals. Proper evaluation of the environmental impact of trace elements on humans, animals, plants, and aquatic biota requires a multidisciplinary approach involving physicians and geoenvironmental scientists.

TRACE ELEMENTS IN WATER

Trace elements enter the aquatic environment in small soil particles that are redistributed during runoff as suspended particles in streams, lakes, and coastal marine locations. Trace elements in water are important; they are toxic to humans and aquatic life in excess, and they accumulate in food chains. Trace element activity in aquatic systems depends on the element species formed by natural hydrodynamic, chemical, and biological forces.

The concentrations of trace elements in water are often much lower than would be expected from either equilibrium solubility calculations or supply to water from various sources. The most common reason for the low concentrations is adsorption of elements onto a solid phase.

To understand the behavior of any trace elements in waters, it is essential to know the chemical forms of the element in the water. Anomalously high concentrations are often related to the presence of stable complexes in solution (1).

Adsorption of manganese and iron oxides, in particular, is probably the most important process in maintaining the concentrations of trace elements at levels far below those predicted by equilibrium solubility calculations. In general, elements in solution as cationic species are more likely to be adsorbed than anionic species. An important exception is the strong adsorption of phosphate anions by ferric oxyhydroxides (1).

TRACE ELEMENTS IN SEDIMENTS

The significance of studies of sediments in the context of water pollution was realized in the 1960s. Publications show that trace element studies in sediments began in the United States in 1963, the Netherlands in 1966, the Soviet Union in 1967, the Federal Republic of Germany and Sweden in 1968, Poland in 1969, Hungary in 1970, Australia in 1972, Israel and Japan in 1973, Switzerland in 1974, the United Kingdom in 1975, Yugoslavia in 1976, and so on.

The study of sediments is all the more important because, on one hand sediments are potential carriers of elements from a watershed to the receiving body of water, and, on the other, they play a significant role in the attenuation of toxic trace elements in polluted aquatic environments.

Sediments commonly form major sinks for trace element contaminants released during both past and present geological, industrial, and other human activities. Commonly, trace elements released from industrial activity are adsorbed onto other mineral surfaces (2).

Most trace elements in sediments (mercury, lead, cadmium, zinc, copper, nickel, cobalt, manganese, chromium, and silver) are chemically bound and require heat and low pH to convert them to soluble form. Various physical, chemical, and biological factors (such as the scouring action of water currents, dredging, changes in chemical parameters and in microbial activity) can bring about the redistribution and partial solution of trace elements from sediments.

Clay minerals that comprise a significant part of sediments together with freshly precipitated iron hydroxides, amorphous silicic acids, and organic substances can sorb cations from solution and release equivalent amounts of other cations into solution. However, the behavior of different clay minerals toward the various trace elements is not yet fully understood. It is reported that the exchange capacity increases in the order:

$$\text{Kalonite} < \text{chlorite} < \text{illite} < \text{montmorillonite}$$

The affinity of trace elements toward clay minerals has been established as follows (3):

$$\text{Pb} > \text{Ni} > \text{Cu} > \text{Zn}$$

Further, it has been established that Cr and Cu favor bonding to illite whereas V, Co, and Ni favor bonding to montmorillonite.

A general increase of trace element concentration from coarse to fine-grained fractions has generally been noted. Trace element content in particulate matter is 1000 to 100,000 times higher than the corresponding trace element content in the associated aquatic phase. The presence of a large proportion of heavy minerals results in characteristic enrichment of trace elements, particularly in fine sand-silt fractions. On the other hand, the high proportions of light minerals such as quartz and feldspar tend to have the opposite effect on the sedimentary trace element budget (4).

Dahlberg Model

The variations in the trace element content of stream sediments can be expressed as a function of potential controlling factors by the following model of Dahlberg (5):

$$T = f(LHGCVMe)$$

where T = resulting trace element concentration, f = function of potential controlling factors, L = influence of lithologic units, H = hydraulic effects, G = geologic features, C = cultural (man-made) influences, V = type of vegetative cover, M = the effect of mineralized zones, and e = error plus effects of additional factors not explicitly defined in the model.

In this model, factors other than C create natural pollution that can be recorded as the background value. However, it is not always not possible to distinguish between contamination of industrial or domestic origin and natural pollution.

The trace elements immobilized in bottom sediments do not necessarily remain in that condition but may be released as a result of changes in the aquatic milieu. These are the main causes of remobilization:

1. changes in redox conditions
2. elevated salt concentrations
3. lowering of pH
4. increased use of natural and synthetic complexing agents that can form soluble metal complexes
5. microbial activity

TRACE ELEMENTS IN AQUATIC BIOTA

The role of trace elements in aquatic biota has been treated in earlier literature reviews with emphasis on the toxicity of the individual elements. Only since mercury and cadmium poisoning in Japan has the accent been shifted toward investigations dealing with the influence of trace elements on the metabolism of aquatic biota and the ability of the latter to accumulate both essential and nonessential elements. Essential trace elements are used by aquatic biota in only trace amounts, and a slight increase in the concentration in water could lead to a significant element increase in aquatic biota. Experiments on the impact of trace elements on aquatic biota have been carried out for many years (6–9).

Phytoplankton

The relative short life of phytoplankton (a few days to a few months) makes it very susceptible to changes in abiotic parameters. The element concentrations, therefore, can vary considerably within a short period of time. Knauer and Martin (10) established that the respective element concentrations for cadmium, copper, manganese, zinc, and lead underwent comparable changes in phytoplankton in Monterey Bay, California. The cadmium concentrations in the water distinctly decreased whereas at the same time, the cadmium content in phytoplankton increased. A similar observation was made for manganese.

Macroalgae

Macroalgae can also be used as indicators of elemental pollution. Their elemental content is directly related to the elemental concentrations in water. A detailed analysis of bladder wrack (*Fucus vesiculosus*) populations in coastal waters around Great Britain revealed significantly higher contamination in the eastern Irish Sea and North Sea by zinc, iron, manganese, copper, nickel, lead, silver, and cadmium than in other coastal waters surrounding Great Britain. The maximum values in the entire investigation area were 962 ppm zinc, 1517 ppm iron, 190 ppm manganese, 28.4 ppm copper, 18.0 ppm nickel, 9.0 ppm lead, 0.79 ppm silver, and 20.8 ppm cadmium (dry weight).

In the compiled data of macroalgae investigations, cadmium values are generally between 1 and 2 ppm. Copper concentrations vary widely. Minimum content is near 6 ppm. The lower concentrations of lead are between 2 and 3 ppm. Chromium appears in an average concentration of 2–3 ppm. The minimum concentrations of manganese lie between 6 and 10 ppm. Nickel has a concentration range similar to that of lead. A maximum of 72 ppb has been reported.

Mosses

It has generally been observed that mosses have a particular storage capacity for lead. Lead content of 277.4 ppm was found in *Fontinalis antipyretica* in the Elsenz River (Federal Republic of Germany). Samples taken from the heavily polluted Ruhr River had cadmium concentrations between 0.17 and 13.2 ppm, and the record amount of 13.2 ppm occurred in *Lagarosiphon major* from Lago Maggiore in Italy.

Higher plants

The roots of higher aquatic plants enable them to incorporate additional elements from sediment (interstitial water). Trace element enrichment differs from species to species. High arsenic enrichment was identified in different families of higher aquatic plants from the Waikito River, New Zealand. Maximum amounts up to 0.5 g arsenic per kg of dry mass were recorded. Different amounts of Cd, Zn, Pb, and Cu in the roots, stems, and leaves of different species were also identified. The highest concentrations were found in the leaves.

Zooplankton

High mercury concentration has been reported in zooplankton from different parts of the world. The maximum concentration recorded was 25.21 ppm Hg. The mercury concentrations in plankton samples gradually diminished with distance from the source. Zooplankton samples taken off the eastern coast of United States between Cape Hatteras and Cap Cod had an average mercury content of 0.5 ppm. From South African coastal waters, a maximum of 132 ppm of zinc was recorded. Cobalt varied from 0.004–0.26 ppm.

Trace Elements in Fish

The study of fish muscle tissue is one means for investigating the amount of elements entering humans by food chain enrichment and has therefore been investigated more than other organs. The absolute increase in trace elements in muscle tissue of contaminated fish is often much lower than that in other organs (11). A generally higher species-specific variation in element content cannot, therefore, always be determined by analyzing muscle tissue. Furthermore, it appears that the musculature becomes enriched by trace elements only when contamination is extremely high. In the musculature of the roach (*Rutilus rutilus*) from a section of the Neckar River, a 25-fold relative increase between minimum and maximum cadmium contamination was registered. In the liver, there was a 156-fold increase and in the kidney, a 196-fold increase (12). When contamination is severe, primarily the gills show elevated cadmium concentrations. The scales of Atlantic salmon (*Salmon salar*) and brown trout (*Salmon trutta*) were analyzed by Abdullah et al. (13) to determine element contamination. In part of the sample, a distinct correlation was established between concentrations in the scales and in the environment.

Of all the elements, mercury is known to be the most toxic. Several cases have been reported of mercury contamination in fish and shellfish. One of the most striking investigations is that of Miller et al. (14), who detected similar mercury concentrations in museum specimens of tuna and swordfish species and freshly caught fish. In the field study, it was found that, on average, 88.9% of the total mercury in fish musculature was methylmercury, irrespective of the weight, length, and species of the fish. The assumption can be made that most of the mercury in the ecosystem is available to fish as organic mercury compounds.

Trace Elements in Aquatic Biota in Sediments

The distribution of elements in the aquatic milieu shows that the highest element concentrations are generally found in bottom sediment. The amount of elements concentrated there present, however, a particular danger to organisms, especially to those that live in the sediment and enter the food chain. Kushner (15) found bacteria in the Ottawa River of which 50% and more were resistant to 1 ppm Hg^{2+} and some were even resistant to 10 ppm Hg^{2+}. These bacteria could transform Hg^{2+} into a volatile mercury compound. The accumulation of radioactive cadmium from sediments and sea water by polychaetes was observed by Ueda et al. (16). Worms in contact with sediments accumulated six times more cadmium than worms not in contact with sediments.

Zn, Cu, Pb, and Cd elemental values in goldfish were much higher than those in catfish. This discrepancy can probably be explained by the different feeding habits of the species; the goldfish burrow when searching for food, whereas the catfish is a predatory fish.

EFFECTS OF GEOLOGY

This is the source of baseline or background levels. It is to be expected that in areas characterized by element-bearing formations, these elements will also occur at elevated levels in the water and bottom sediments of the particular area. Trace elements may be derived from the weathering of rocks. Average concentrations of some trace elements in rocks are shown in Table 1.

Whether a particular trace element goes into solution during weathering depends on the mineral in which the element occurs and on the intensity of chemical weathering. Many trace elements do not substitute readily in feldspars or common ferromagnesian minerals. They may be present in chemically resistant accessory minerals such as zircon, apatite, or monazite, or as sulfides, which weather rapidly in oxygenated water. The resistant minerals generally remain unaltered unless weathering is very intense (gibbsite formation), and so alteration of them never causes high trace element concentrations in water. Where many elements occur in high concentrations and hence in many economic deposits, the elements occur as sulfides (e.g., copper, zinc, molybdenum, silver, mercury, lead), and these sulfides often contain selenium, arsenic, and cadmium. Sulfides weather rapidly, so such ore deposits can give rise to local high concentrations of dissolved trace elements.

EFFECTS OF HUMAN ACTIVITY

Human activities introduce trace elements into the hydrosphere in many ways. Burning of fossil fuels and smelting of ores put elements into the hydrosphere, where they are washed out by rain into surface water.

Table 1. Concentration of Selected Elements in Rocks (ppm)[a]

	Granite	Basalt	Shale	Sandstone	Limestone
Aluminum	Major	Major	Major	Major	4200
Arsenic	2	2	13	1	1
Beryllium	3	1	3	–	–
Boron	10	5	100	35	20
Cadmium	0.13	0.2	0.3	–	0.03
Chromium	10	170	90	35	11
Cobalt	4	48	19	0.3	0.1
Fluorine	800	400	740	270	330
Iodine	0.5	0.5	2	1	1
Lead	17	6	20	7	9
Lithium	30	17	66	15	5
Manganese	450	1500	850	50	1100
Mercury	0.03	0.001	0.4	0.03	0.04
Molybdenum	1	1.5	2.6	0.2	0.4
Nickel	10	130	68	2	20
Rare earths	0.5–70	1–80	1–80	0.05–15	0.05–8
Scandium	10	30	13	1	1
Selenium	0.05	0.05	0.6	0.05	0.9
Thallium	1.5	0.2	1.4	0.8	–
Thorium	14	2.7	12	5.5	2
Titanium	Major	Major	Major	Major	400
Uranium	3	1	4	2	2
Vanadium	50	250	130	20	20

[a] Reference 17.

A wide range of trace elements in fossil fuels are either emitted into the environment as particles during combustion or accumulate in ash which may itself be transported and contaminate water. Some of the elements arising as pollutants from fossil fuel combustion are Pb, Cd, Zn, As, Sb, Se, Ba, Cu, Mn, and V.

Municipal sewage and industrial effluent introduce trace elements directly. Mining activities can result in release of elements because previously impermeable rocks are broken up and exposed to water and because sulfide-containing rocks are exposed to oxygen, resulting in rapid alteration and dissolution. In the mining industry, there are two major contaminant waste streams: (1) elements discharged in solution via mine drainage and (2) particulate grains of ore-forming or related minerals released after ore processing (18). Underground disposal of toxic wastes, including radioactive wastes, has the potential to release a variety of substances to groundwater and hence to surface waters.

Agriculture constitutes one of the very important nonpoint sources of trace elements. The main sources are

1. impurities in fertilizers: Cd, Cr, Mo, Pb, U, V, Zn, (e.g., Cd and U in phosphatic fertilizers)
2. pesticides: Cu, As, Hg, Pb, Mn, Zn
3. wood preservatives: As, Cu
4. wastes from intensive pig and poultry production: Cu, As
5. composts and manures: Cd, Cu, Ni, Pb, Zn, As

The human input of trace elements in many rivers and lakes is many times greater than the natural input.

INNOVATIVE PENS HATCH THOUSANDS OF TROUT

Richard Dowling
Pittsburgh District
U.S. Army Corps of Engineers

For a fellow who doesn't fish, Pittsburgh District's Mike Fowles has sure helped to put a lot of trout into the creels of Pennsylvania anglers.

US Army Corps
of Engineers
Natural Resource
Management

A fish and wildlife specialist for the U.S. Army Corps of Engineers for the last 26 years, Fowles has worked out a landmark agreement with a local chapter of Trout Unlimited to establish a cooperative fish hatchery in the tailrace of the district's Youghiogheny Lake. The effort has put an estimated 20,000 trout ranging from 12 to 16 inches into various area waters, and earned Pittsburgh District recognition across the state as a friend of fish.

The Chestnut Ridge Chapter of Trout Unlimited (TU) this spring signed a five-year extension to its memorandum of understanding (MOU) to run the hatchery. Other signers along with the Corps were the Pennsylvania Fish and Boat Commission and D/R Hydro, operators of an electric power generating plant at the dam. The initial three-year MOU was due to expire in June, and has been hailed as a success beyond anyone's expectations.

The key to this success, according to Fowles, is the use of "cage culture" nursery pens actually submerged in the flowing water of the Youghiogheny River, rather than the more common hatchery practice of long concrete tanks with artificial flows and aeration.

The fish arrive in early summer as three-inch fingerlings, and are fed a high-quality protein meal by TU members, who are also responsible for trash pick-up and maintenance of the submerged pens. Corps and D/R Hydro monitor water quality in the tailrace to insure that the young trout have the best possible living conditions. The result a year later is that thousands of the former fingerlings are more than a foot long, and ready to be stocked. "This is a really good growth rate," said Fowles.

Some of the fish go right into the Youghiogheny River (one of Western Pennsylvania's premiere trout streams) while others are trucked to other nearby waters. The in-river hatchery offers much better growth and survival rates for the trout, which include rainbows, brown trout, brook trout, and an exotic strain of rainbows known as "palomino" trout.

Sections of the river downstream from the hatchery are designated "trophy trout" sections by the State Fish and Boat Commission, and draw anglers from throughout the eastern U.S.

The state provides the trout fingerlings each spring. For its part, the hydroelectric company provides free power from its nearby generators to support the hatchery.

"This is truly a win-win situation for all the partners," said Fowles on the day of that the partners extended the MOU. "This is an outstanding example of how Pittsburgh District is developing new partnerships to accomplish our natural resource management and environmental stewardship objectives."

Tom Shetterly, president of the Chestnut Ridge Chapter of TU, said about a half dozen of his group's members rotate the daily feeding duty for the young trout through the year. "When it's time to stock, we get 12 to 15 guys there," he said. The annual feeding bill runs about $2,000.

He said that the Corps of Engineers "is just a great partner with us; you guys have just bent over backwards to make this program better than anybody could have ever expected." He also praised the efforts of other Pittsburgh District personnel, including Mike Koryak, district limnologist (one who studies fresh waters), and Pat Docherty, area operations manager.

Working with the Corps and the state, TU has also received permission to place gravel for enhanced natural spawning beds in the river and the stilling basin below the Yough Dam.

"We're seeing some of the first fish we stocked come back to the same area to spawn," Shetterly said. Raising the fish in submerged cages apparently has imprinted them with the characteristics of their immediate surroundings, something that Shetterly says has never been accomplished elsewhere. "This thing is huge," he marveled. "It's going to be world-famous."

Another bonus of the in-river cage culture is the way the trout benefit from natural food, adding up to 12 ounces in weight gain for each pound of artificial fish food added to the cages. Waste from the trout and any food that goes through the bottom of the cages also combine to increase the alkalinity of the water, thus improving the environment, according to Shetterly.

The trout hatchery is one of many programs supporting fishing in Pittsburgh District. For example, working with the Yough Walleye Association, the district is supporting efforts to put crushed limestone into Tub Run, a tributary of Youghiogheny Lake, to neutralize the highly-acidic waters, a legacy of abandoned coal mining.

Youghiogheny Lake is one of 16 multi-purpose flood control reservoirs built and operated by Pittsburgh District in Western Pennsylvania, New York, Ohio, West Virginia, and northern Maryland. Pittsburgh District also works with various state fish and wildlife agencies to conduct annual fish census sampling at its navigation locks on the Ohio River.

All in all, Fowles has worked hard to help improve fish habitat and fishing as a sport, but don't ask him to tell you his own fishing stories. "I don't fish," he said simply. "And I don't hunt either, though of course I recognize both as legitimate outdoor activities."

He is passionate about bird watching, a hobby he and his wife picked up in 1973 while an undergraduate at Ohio University. His logbook shows he has sighted thousands of bird species all over the world.

Thousands of brook, rainbow and brown trout are raised each year in these submerged pens in the tailwaters if the Youhiogheny River. (Photo courtesy of Pittsburgh District)

"My list is rapidly approaching the 5,000 mark, a goal I set for myself when I first started birding." Comparing the two sports, he says of birders, "Oh, we get our prey. We just don't kill 'em."

WATERSHED

Karen D. Brettschneider
Houston-Galveston Area
Council
Houston, Texas

DEFINITION

Everyone lives in a watershed. A watershed is the hydrologic or geographic boundary of a river system. Watersheds can be delineated for any waterbody, whether it is the creek flowing through your neighborhood or the Mississippi River (Fig. 1).

Watersheds are defined by first selecting a point along a stream or river. The stream and its tributaries, if any, are then traced backward from there, and the topography of the terrain is analyzed. The watershed boundary is defined by the high point, or ridge, between streams flowing to separate major waterbodies or "stems." All waters falling within the watershed boundary, in theory, eventually flow to the original point designated to define the watershed.

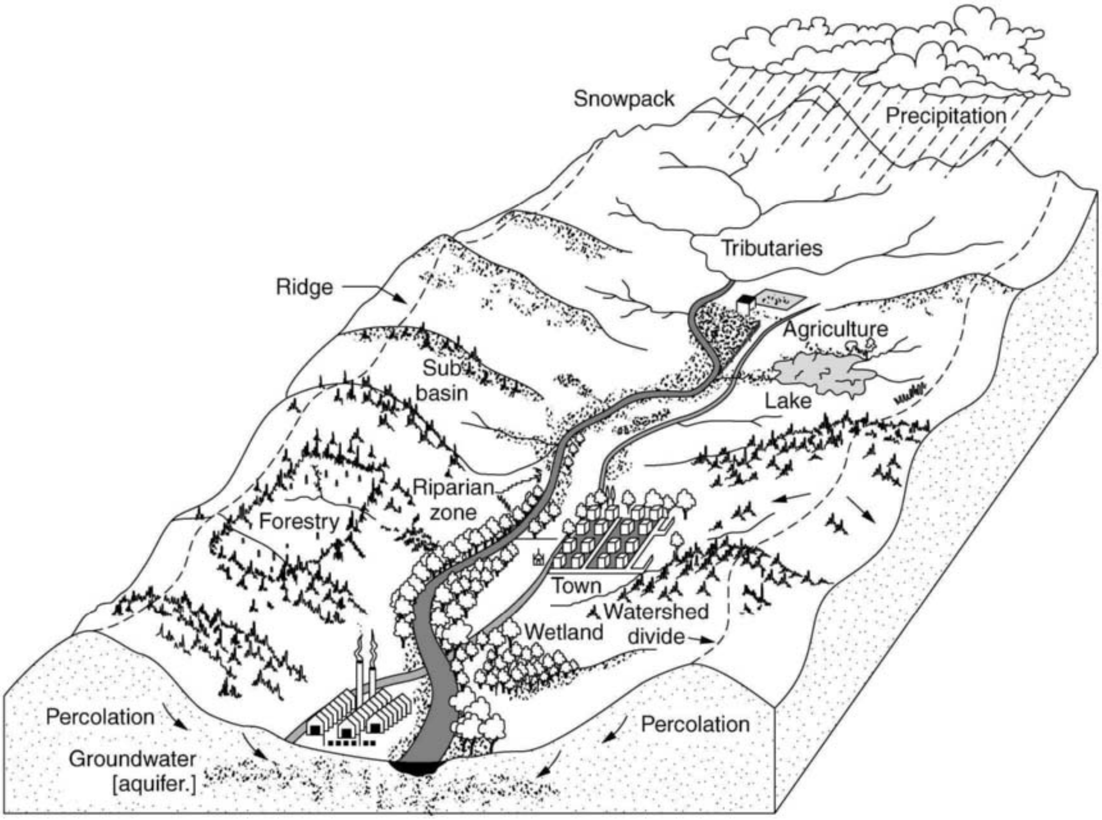
WATER QUALITY

All factors and activities within a watershed directly or indirectly affect the water quality of river systems. Although local climate, geology, soil type, and vegetation play an important role in determining of the water quality conditions within a watershed, one of the most important factors affecting water quality is land use. Runoff from different land use types, such as agricultural, industrial, urban, or even barren or deforested land may contribute a number of pollutants to a waterbody. Some of these pollutants include excessively applied fertilizers or pesticides, animal waste, toxic chemicals, sewage from broken sewer lines or septic tanks, oil, and sediment.

Best management practices on all types of land use help reduce the amount of pollution entering waterways. Preserving, restoring, or creating wetlands, which "filter out" many pollutants is another way to help ensure clean water and a clean environment within a watershed.

FLOOD POTENTIAL

Flooding is also influenced by factors such as the percentage of impervious cover within the watershed boundary. In addition, concrete drainage control ditches and canals have been built over the years to help control flooding. When a channel is lined with concrete, natural aquatic habitats are disturbed or destroyed, and pollutants



Produced by lane council of governments

Figure 1. Sample drawing of a watershed (Used with permission of the Lane Council of Governments, Eugene, Oregon).

can more easily enter a waterway due to the lack of vegetation to control and filter runoff.

Recently, engineers have used more “environmentally friendly” types of flood control. Some these include constructed wetlands and detention ponds. In these cases, habitat is not destroyed, but created, and pollutants are kept from entering waterways.

Although a person or entity may not be located near a waterbody, the results of various actions eventually flow downhill or through stormwater infrastructure to creeks and streams.

COMBUSTIBLE WATERSHEDS

V. Kulik
CYPUM PTY LTD
Canberra City, Australia

Existing hydrological networks can be used for conflagration prediction. Runoff data allows predicting high fire danger earlier, highlights the most dangerous watersheds, and makes forecasting more foolproof. In some cases, a hydroforecast improves the likelihood of preventing a major disaster. This technique has certain differences from standard meteorological methods: (1) It predicts conflagrations not for an administrative or geographical region, but for a watershed—so, a conflagration can be forecast for the area around water supply reservoirs. (2) It allows forecasting the fire danger earlier and estimates of the amount of time available for active response. (3) It excludes most false alarms. (4) It is more accurate, simply because it uses hydrographic data, which are more representative than meteorological data. (5) It is more foolproof and less dependent on errors in observations. (6) It depends less on the stochastic nature of summer rains and other meteorological elements. (7) It is simpler than any other method.

THE SIMPLEST TECHNIQUE

1969

Watershed = 671 sq.km, 30 km SSW from Canberra City (capital of Australia), adjacent to the water supply watersheds of Cotter River (mainly eucalyptus forest overlying granitic soils).

1970

45° = baseflow recession during cool periods (semilog scale for cumecs).

1971

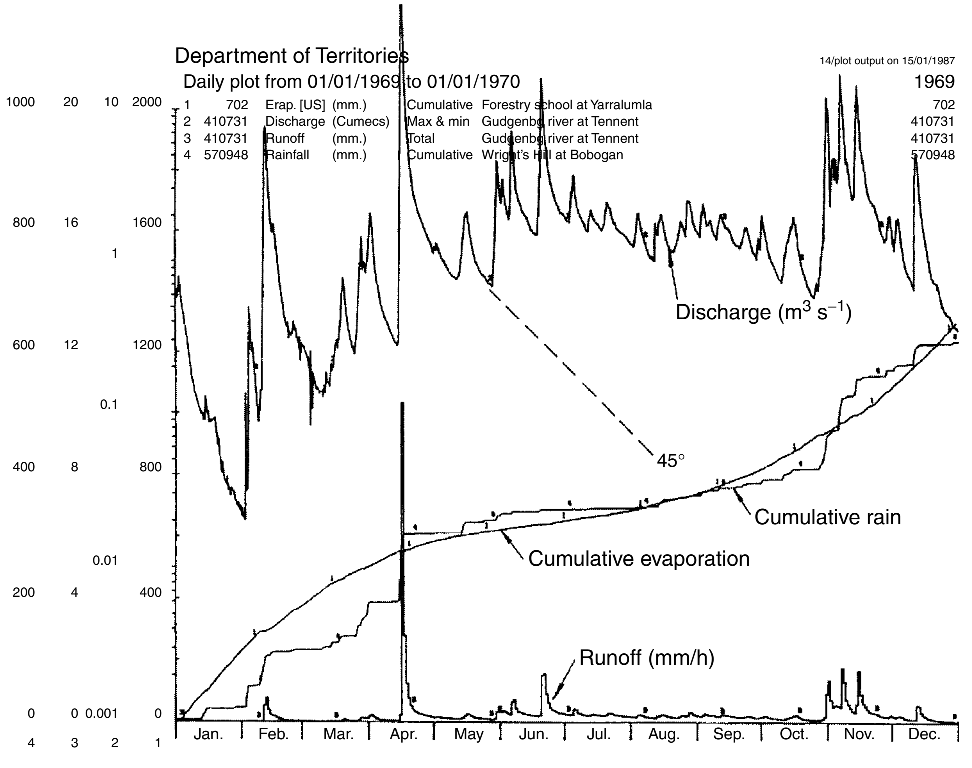
Vertical scales have to be the same for all years.

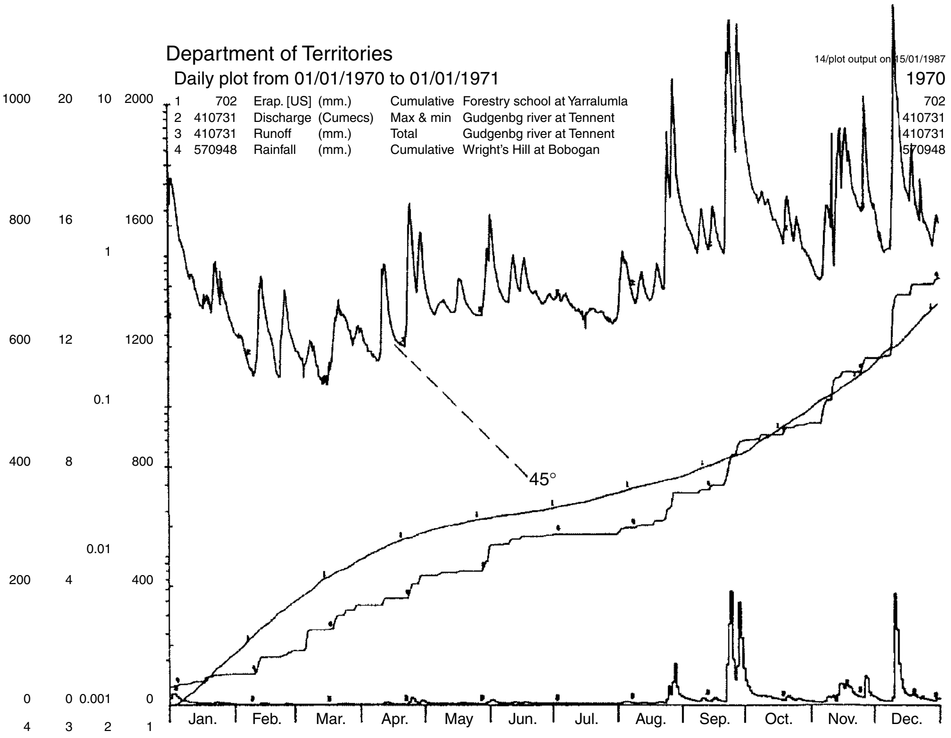
1972

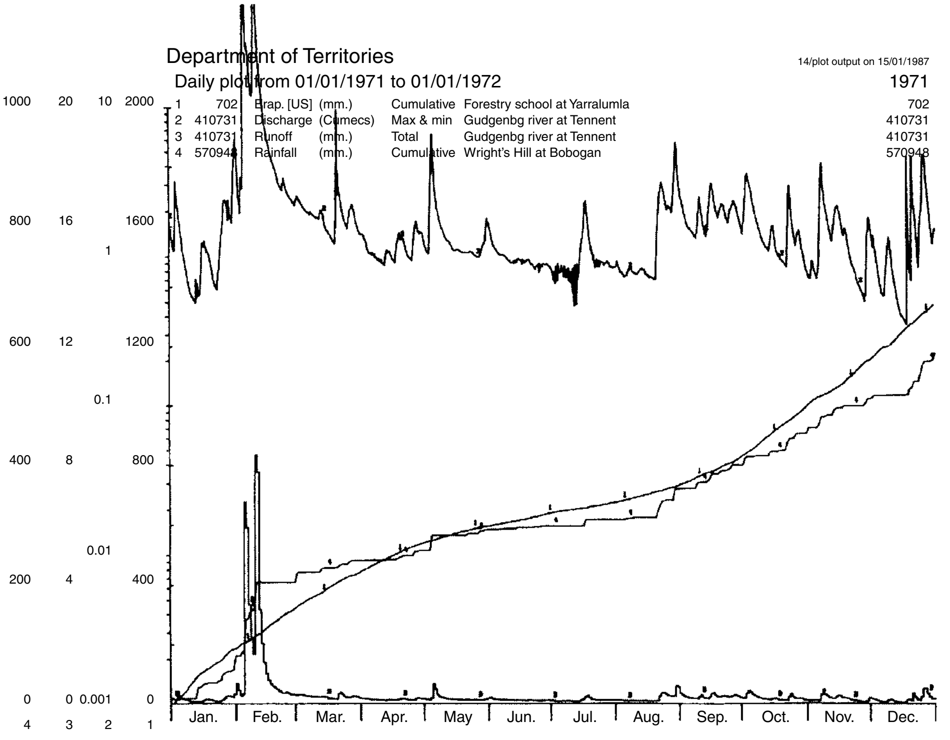
Every summer there are many small fires. A fire > 1 sq. km starts, when the discharge < 0.1 cumecs and the recession > 45°.

1973

For this and 4 previous years: cumulative evaporation = two cumulative rainfalls.



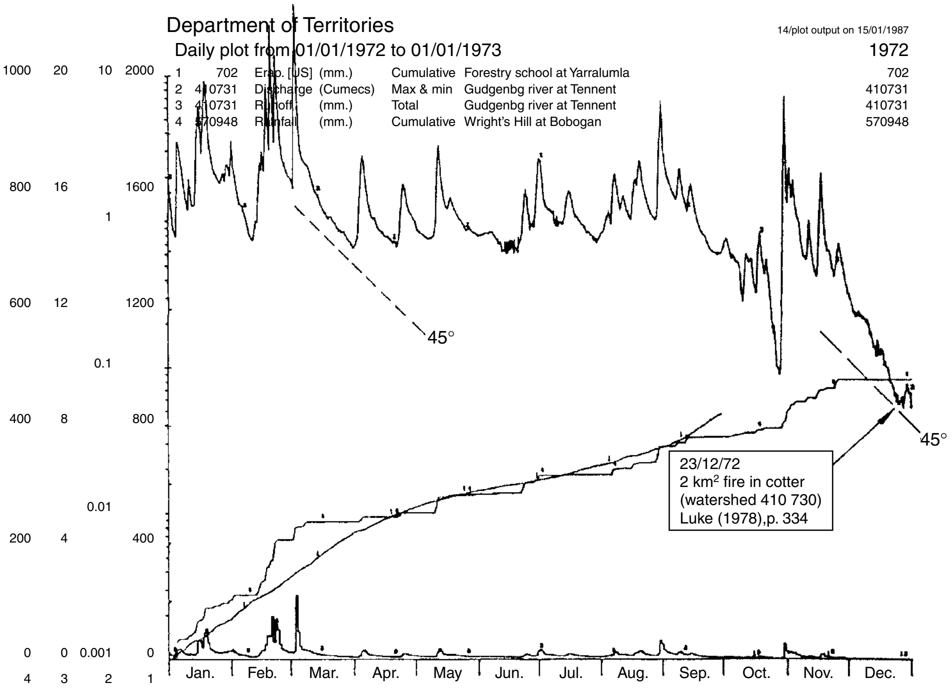


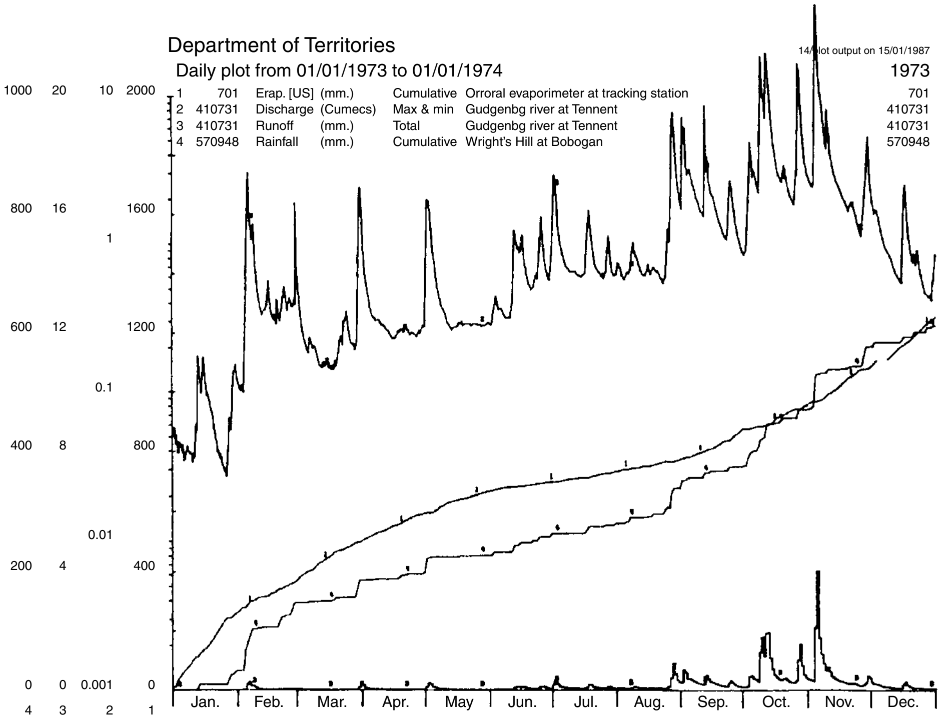


1974

Floods: Cumulative evaporation < two cumulative rainfalls. Meteo database problem: "negative rain" for October 1974. Dryness of fuel affects the intensity of a fire. Several special indexes are used to forecast it. There are no approved international standards for calculating these indexes, and even in one country, several different drought and fire danger indexes may be used (1–2).

The idea behind any antecedent moisture content index is to "sum" the rainfall and evaporation across a certain time interval. Hence, a mistake in a daily rain record could be fatal, not only for this daily index, but also for subsequent days.





1975

Small fires only. Defect of meteo data: evaporation. Turner (2, p. 12) stated that "a single day of careless weather observations could strongly affect fire weather indices."

1976

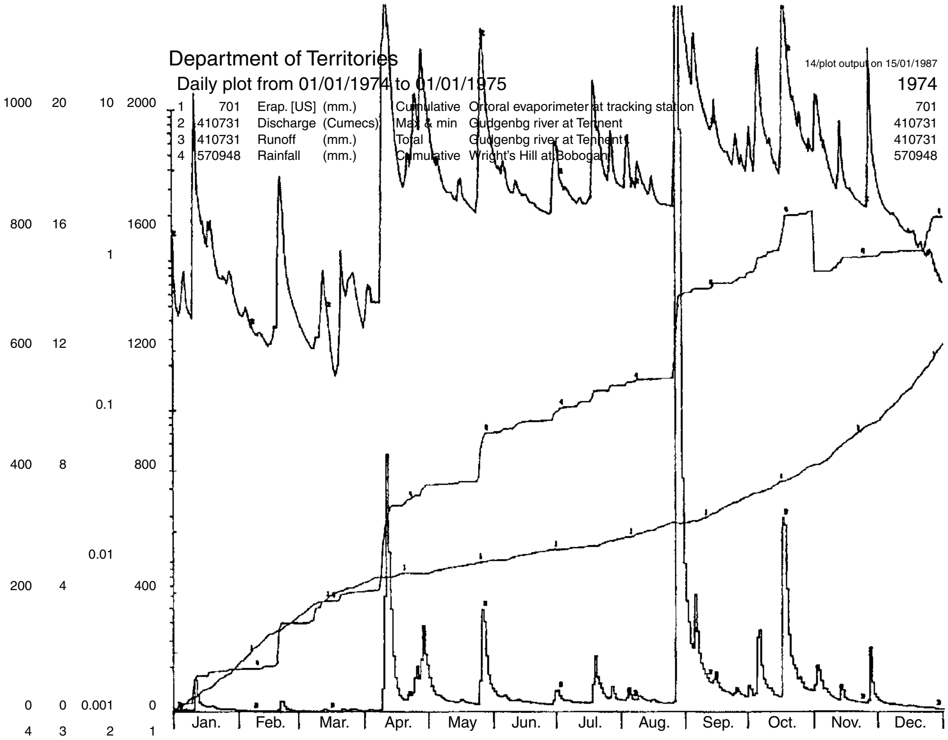
Similar problem with meteo data (as in 1972, December 1973, 1975).

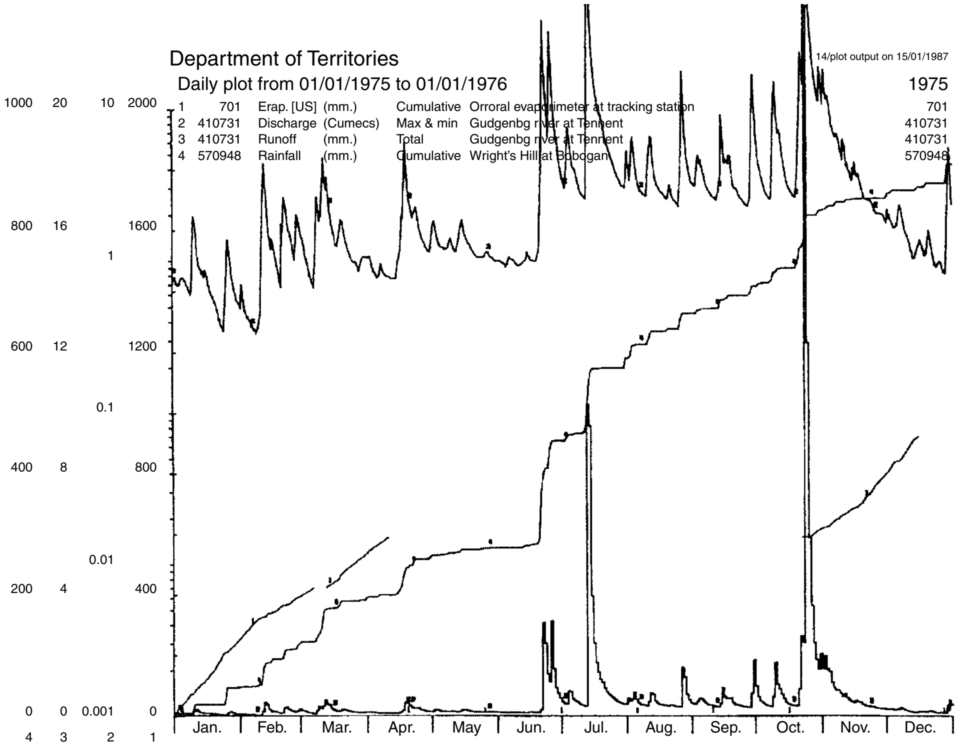
1977

Low flow does not indicate a fire, if the recession = 45° (compare with 1972).

1978

February: discharge = 0.1 cumecs, but the recession is concave. Small fires only.



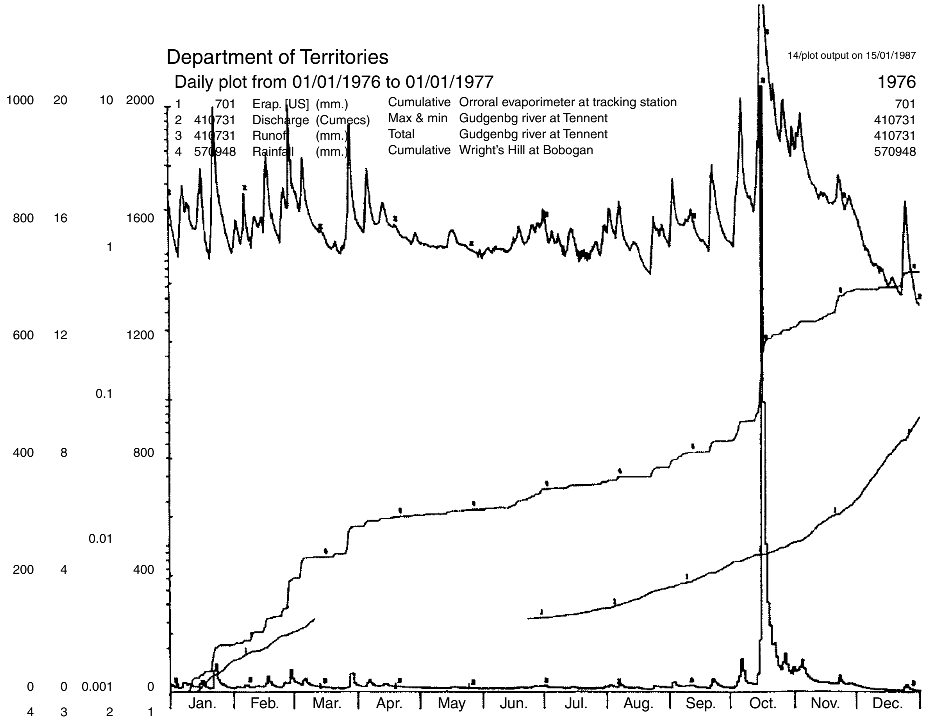


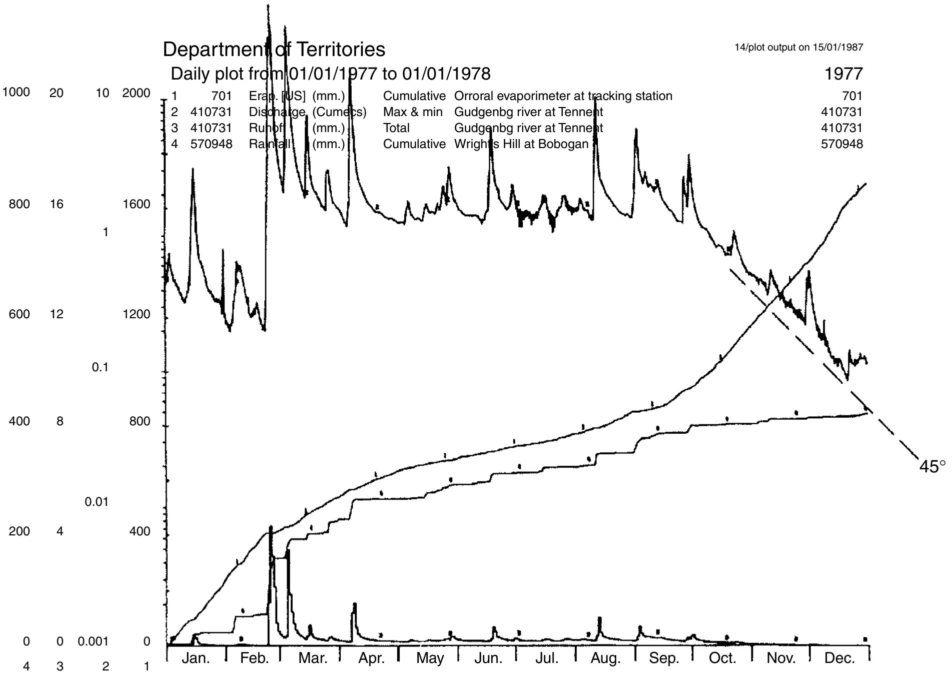
1979

Small fires only. Cumulative evaporation > two cumulative rainfalls, meteo fire danger is "extreme." It does not mean, however, that the meteo indices and other techniques of bushfire forecasting are to be abolished and forgotten. The hydrologic technique only supplements them.

1980

Cumulative evaporation > two cumulative rainfalls, but the recession is concave. Small fires only. Bushfires can start almost any time. Even during autumn rains, lightning could start a bushfire. A wet forest will not burn as well as a dry one, but it may burn. However,





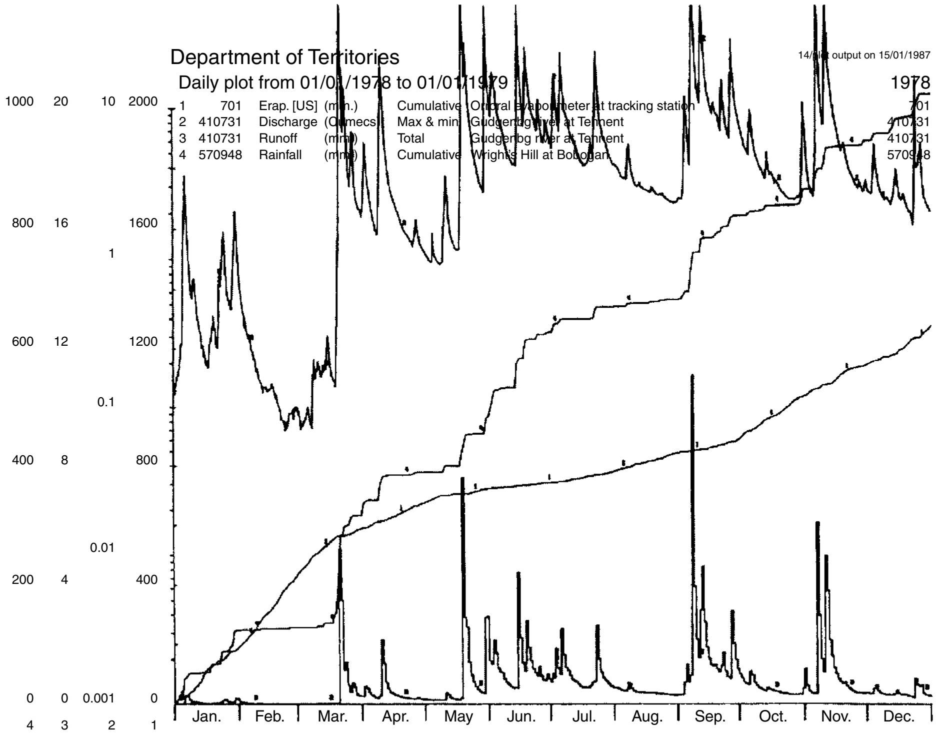
the intensity of such bushfires is usually very low, and it is generally thought that such bushfires are not a major hazard. They decrease the amount of the accumulated fuel and hence to some extent, prevent the more dangerous, intense conflagrations.

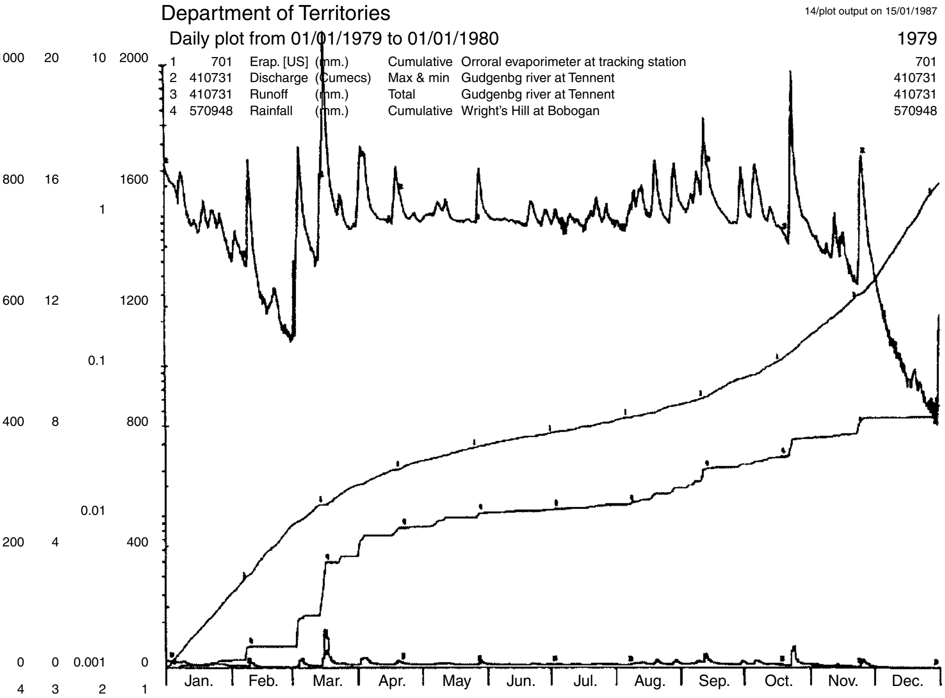
1981

Cumulative evaporation > two cumulative rainfalls, but the recession is concave. Small fires only. Small fires are used for prescribed burnings and are considered generally a useful tool when controlled effectively and sufficiently, little damage results in the long-term components of the environment. These artificial bushfires are called Fuel Reduction Burnings (3–5). The 1981 hydrograph shows that it was a good year for prescribed burnings.

1982

There are two groups of predictors: (a) Early predictors: (a1) low flow; (a2) change of the curvature of the recession curve from concave to convex (semilog paper); (a3)

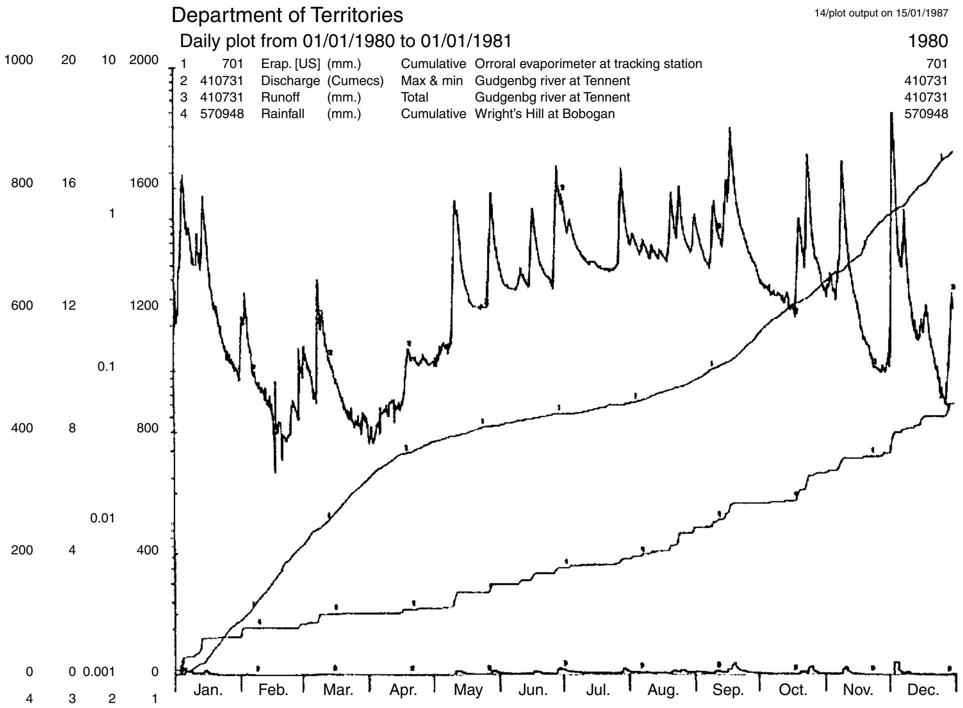


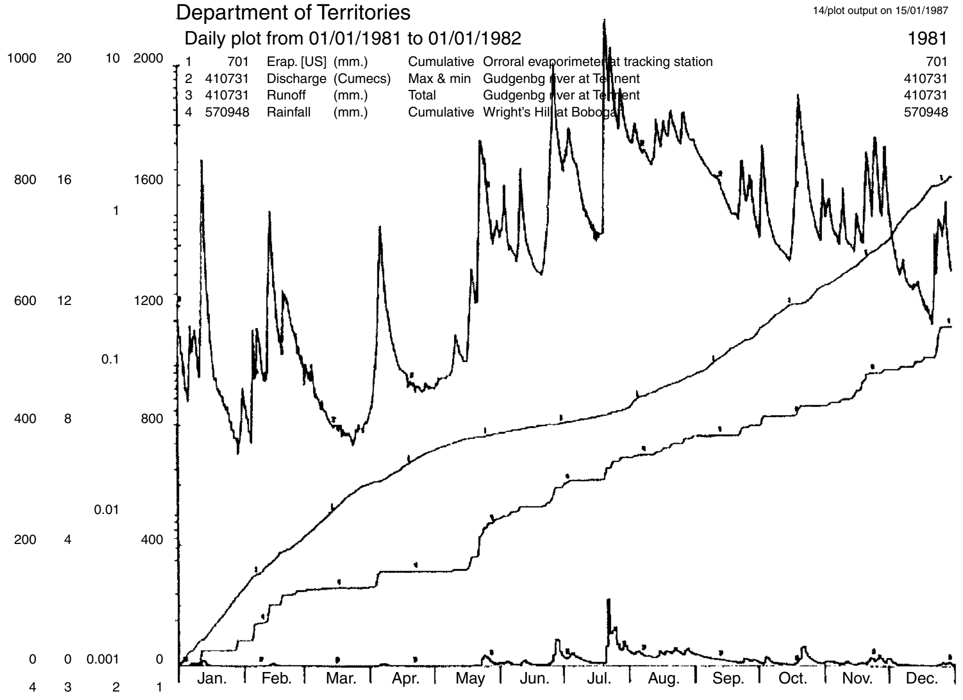


accelerated recession. These early predictors can be used to estimate how many days there are before the critical fire danger starts (by extrapolating the recession curve). (b) Later predictors: (b1) stabilization of the runoff to a "zero flow" value; (b2) Steep rate of recession after intermediate minor rains; (b3) Convex recession after intermediate rains. (b4) Abrupt stabilization of runoff to "zero flow" several days after a minor rain. The manifestation of these late predictors means that the probability of a conflagration has increased dramatically.

1983. Combustion January 9, 1983

In January 1983, a wild fire burnt out approximately 58 km^2, representing 30% of the Corin Dam catchment on the Cotter River and 300 km^2 of the adjacent Gudgenby River catchment. It was a conflagration of





very high intensity. The conflagration completely burned the Boboyan pine tree plantation (300 ha), despite all attempts to save it (by concentrating firefighting resources on protecting the plantation). Later on, attempts to control the conflagration were only partly successful, as the conflagration continued to spread for about 3 weeks. (Note recession after intermediate rains). The approximate cost of conflagration suppression operations was $477,000 (6).

SUMMARY

A major forest conflagration is a very rare phenomenon; to collect a sufficient amount of information for development of the forecasting technique, it is necessary simply to analyze more cases. We ask everybody who has at hand data on watersheds, affected by a conflagration, to try this simple technique, to develop it, and to communicate their results.

TIME OF CONCENTRATION AND TRAVEL TIME IN WATERSHEDS

Bahram Saghafian
Soil Conservation and
Watershed Management
Research Institute
Tehran, Iran

INTRODUCTION

Time of concentration, denoted by T_c throughout this article, is one of the oldest and most fundamental concepts in hydrologic science and engineering. Time of concentration and travel time (T_t) are two measures of watershed runoff response time. Travel time represents a broader hydrologic term, and time of concentration may be considered a special case of travel time. Several hydrologic analysis and design procedures require direct knowledge of T_c or T_t. In the rational method, T_c must be known to determine the duration of design storm and thus, the flood peak. The Muskingum stream routing method requires wave travel time through stream reaches as a measure of the storage time constant. The application of time–area or Clark rainfall–runoff transformation is optimum when the spatial distribution of travel time is known.

DEFINITIONS

Time of concentration is usually defined as one of the following categories:

1. The time that it takes for water to travel from the most distant part of a watershed to the outlet. Some literature appropriately emphasizes that the distance has a hydraulic base and not necessarily a geometric base.
2. The wave travel time from the most hydraulically remote point to the outlet of a watershed.
3. The time elapsed for which all parts of a watershed contribute to direct runoff at the outlet.
4. In hydrograph analysis, T_c is defined as the time between the end of excess rainfall and the inflection point on the falling limb of the hydrograph. It is assumed that the inflection point indicates the end of direct runoff. The centroid of the rainfall hyetograph is sometimes defined as the beginning of T_c.

Definitions 2, 3, and 4 represent a similar interpretation of watershed time response, but definition 1 is based on water velocity which is different from wave celerity. As we will see in the next section, some methods explicitly rely on definition 1 for estimating T_c. Definitions 2 and 3 are similar but depend on the duration of rainfall excess (T_r). If, in theory, excess rainfall intensity is constant and T_r is sufficiently long or at least equal to the time to equilibrium (T_e) at which the watershed reaches a steady state, then $T_c = T_e$. On the other hand, when $T_r < T_e$, definitions 2 and 3 are still valid, but the time in neither is equal to T_e. The case of $T_r < T_e$ represents a dominant case in the hydrology of watersheds, so time of concentration becomes event-dependent, not just intensity-dependent, and this is not convenient in practice. Even almost all hydraulic T_c equations avoid dealing with the issue of variable rainfall duration.

Travel time follows definition 2 and may be determined from any point in the watershed to another point of interest downstream. Thus, time of concentration is specifically a travel time whose starting and ending points are the hydraulically farthest and the outlet of the watershed, respectively. By restricting travel time to channel systems, Linsley et al. (1) describes T_t as the time between a crest at one station and the crest at a downstream station. Again, some definitions of travel time refer to definition 1, in which the water travel time is considered rather than wave travel time. T_t is also a subject in underground flow, but in this article only surface water is discussed.

THEORETICAL CONSIDERATIONS

Uncertainty in computing T_c and T_t representing watershed time responses is due mainly to simplifications of complex rainfall–runoff processes. Watershed time response depends strongly on watershed static characteristics, such as shape, area, slope, length, roughness (neglecting long-term changes), and drainage pattern. On the other hand, time response is a function of nonstationary factors such as spatial and temporal rainfall variations. Therefore, watershed time response is generally event-dependent and not a stationary character of a watershed.

Following definition 2, we first assume:

1. Excess rainfall intensity remains constant through time.
2. Rainfall duration is sufficiently long to reach a state of equilibrium.

The most comprehensive analytical derivation of travel time in watersheds with spatially variable characteristics is presented by Saghafian and Julien (2). The general relation for the travel time from location X_1 to location X_2 downstream is as follows:

$$T_t = \int_{X_1}^{X_2} \frac{dx}{c} \qquad (1)$$

where x is the distance measured along the hydraulically longest flow path from X_1 to X_2 and c is the wave celerity.

Skipping details of substitutions and using the Manning resistance equation, one can finally obtain

$$T_t = \int_{X_1}^{X_2} (1-\gamma)\left(\frac{a_1}{Q_e}\right)^{\gamma}\left(\frac{n}{a_2^{2/3}S_0^{1/2}}\right)^{1-\gamma} dx \qquad (2)$$

where Q_e is the equilibrium discharge, a_1, a_2, and γ are flow cross-sectional parameters, S_0 is the bed slope corresponding to the *kinematic travel time*, and n is the Manning roughness coefficient.

The equilibrium discharge Q_e passing through a given cross section at location x is equal to the excess rainfall rate spatially integrated over the drainage area of that cross section. This is mathematically expressed by

$$Q_e(x) = \int_0^{A(x)} i dA \qquad (3)$$

where $A(x)$ is the drainage area or flow accumulation at distance x and i is the excess rainfall intensity at any point draining to x. The substitution of Q_e in Equation 2 requires knowledge of the spatial variability of excess rainfall and of the drainage area along the hydraulically longest flow path.

Total travel time (T_t) can be separated into the travel time for overland flow, T_{to}, and for channel flow, T_{tc}, such that $T_t = T_{to} + T_{tc}$. Travel time may be computed for all locations in the watershed using Eq. 2. Note that Eqs. 2 and 3 hold for spatially variable excess rainfall. For $X_1 = 0$ at the most hydraulically distant point and $X_2 = L$ at the outlet of the watershed of interest, $T_t = T_c$. Note that the hydraulically longest path may be unknown at first, so one must determine T_t by trial and error.

Certain relations must be obtained for flow cross-sectional area $A_x(h,x)$, hydraulic radius $R(h,x)$, bed slope $S_0(x)$, and equilibrium discharge $Q_e(x)$, or alternatively i and $A(x)$, so that the travel time integral for channel flow can be calculated. Both A_x and R may be expressed as functions of flow depth h, either precisely through geometric relationships or approximately through regression curves. In a general form, $A_x = a_1 h^{b_1}$, and $R = a_2 h^{b_2}$, where a_1, a_2, b_1, and b_2 are constants for a given cross section. Also in Eq. 2, $\gamma = 2b_2/(2b_2 + 3b_1)$ when using Manning's equation. For overland flow and flow in wide channels, a_2, b_1, and b_2 equal one and $\gamma = 0.4$. Details for solving Eq. 2 in a discretized raster model are discussed in Saghafian and Julien (2).

If the excess rainfall intensity i is uniformly distributed in space, then $Q_e = iA$, and the term $1/i$ can be taken out of the integral. Then, the travel time is proportional to $i^{-\gamma}$:

$$T_t = Ci^{-\gamma} \qquad (4)$$

where C is a watershed hydrogeomorphologic index conglomerating spatially distributed characteristics such as surface roughness, slope, flow length, flow accumulation, drainage pattern, and channel geometry. For the special case of watersheds with wide channels, γ equals 0.4.

Consider a simple case of an overland plane of length L and slope S_0. Equation 2 reduces to the following equation for travel time from the upstream of the plane ($X_1 = 0$) to its lower edge ($X_2 = L$):

$$T_t = \frac{n^{0.6}L^{0.6}}{i^{0.4}S_0^{0.3}} \qquad (5)$$

The travel time obtained from Eq. 5 is essentially the time of concentration of the overland plane. For travel time in channels, Eq. 2 can be applied similarly with knowledge of the required parameters.

In practice, however, the application of these derivations is time-consuming and requires data that may not be readily available. In the following section, we describe the most commonly used T_c methods. Comparison of the such methods with the theoretical derivation can help to evaluate practice results versus theory.

METHODS AND FORMULAS

Numerous references have discussed different methods and formulas to compute T_c. However, some hydrology literature is not clear in the definition of appropriate terms in formulas, applicability, limitations, condition of original data used in developing the formulas, and even the units. In some methods, variables such as length, slope, and roughness are used with slightly different meanings. It is not possible to review all methods here, hence the discussion is limited to a few more widely practiced methods described in well-known hydrology references.

There are two general approaches for estimating T_c: hydraulic-based and empirical. The hydraulic laws of free surface flow are applied in the former approach in which the travel times for sequential reaches are added up. In the latter approach, however, empirical formulas are derived from field data, and the watershed is treated mostly as a lumped unit. One example of hydraulic-based methods is the method outlined in the previous section. This section proceeds with description of other hydraulic methods.

Hydraulic Methods

The kinematic wave model is the preferred method for the overland flow portion:

$$T_c = 0.94 n^{0.6} L^{0.6} i^{-0.4} S^{-0.3} \qquad (6)$$

where T_c is in minutes, n is the Manning roughness coefficient, L is the flow length (in feet), i is the rainfall intensity (in inches per hour), and S is the slope (ft/ft). The coefficient of Eq. 6 becomes 0.88 in SI units with T_c in seconds, L in meters, and i in meters per second. In theory, as in Eq. 5, the coefficient must be one. The resulting difference may be partly attributed to flow convergence. Typical values of overland Manning's n are given by Engman (3), Ponce (4), and McCuen (5). It is recommended that L not exceed 300 feet. Iteration is required in applying Equation 6 for the rational method because both T_c and i are unknown but related through intensity-duration frequency (IDF) curves.

The Soil Conservation Service (6) proposed the average-velocity method for T_c, which can also be applied more broadly to compute T_t, as follows:

$$T_c = \sum_{j=1}^{N} \frac{L_j}{60V_j} \tag{7}$$

where T_c is in minutes, L_j is the length of the jth flow segment (in feet), V_j is the velocity through the jth segment (in feet per second), and N is the number of segments. This equation and a similar one proposed by Chow et al. (7), clearly follow definition 1 that is based on flow velocity rather than wave velocity. The hydraulically longest flow path can be divided into N segments according to different flow types: sheet, concentrated, or channel. The segments should be approximately uniform in slope, roughness, and cross section (for channels). Charts of overland flow velocity are provided as a function of slope and cover by the SCS (6). The charts are part of a method known as the "upland method." A curve that represents concentrated flow velocity in small upland gullies is also provided (6). The flow velocities generally vary from 0.2 ft/s for mildly sloped forest lands to 15 ft/s for steep paved areas.

Equation 7 may be used to estimate the travel time through a channel. Manning's formula corresponding to a 2-year or bankful discharge may be used to compute the average velocity. For greater design return periods and/or higher than bankful discharges, however, average flow velocity must be computed considering the floodplain condition. In using Eq. 7, note that wave celerity may be 1.4 to 2.0 times the water velocity (1). So there are relatively large errors in computing channel travel time based on average water velocity. Therefore, using the wave celerity in computing travel time is recommended. Theoretically, the kinematic wave celerity is equal to βV in wide channels, where $\beta = 1.67$ for Manning's equation and $\beta = 1.5$ for Chezy's formula (4). If the Muskingum storage time constant (K) is already determined for a reach, this value can be used as a reasonable measure of wave travel time through that reach.

Linsley et al. (1) suggested station hydrograph analysis to obtain travel time in a stream. If the local inflow between the stations is negligible, travel time can be determined from the lag time between the hydrograph peaks measured at the two stations. Travel time is not a constant characteristic for a reach, so a range of stage-discharges is necessary to study the change in travel time as a function of stage. Travel time is expected to decrease as stage increases to bankful, and then it increases at stages higher than bankful.

Empirical Methods

Most empirical methods developed to estimate time of concentration assume the watershed as a simple lumped unit. Kirpich (8) presented one of the most commonly used formulas for estimating T_c based on data from some small watersheds in the United States. For Tennessee watersheds ranging in size from 1 to 112 acres, slopes from 3% to 10%, and well-defined channels, the following formula was proposed by Kirpich (8):

$$T_c = 0.0078L^{0.77}S^{-0.385} \tag{8}$$

where T_c is in minutes, L is the length from the farthest point along the channels to the outlet (in feet), and S is the slope along L or approximately the average watershed slope (in feet per feet). T_c is multiplied by 0.4 for concrete and asphalt overland surfaces, and by 0.2 for concrete channels. With units of L in km and S in m/m, the coefficient in Eq. 8 becomes 3.97.

The Bransby–Williams formula (9), which is used for watersheds up to 50 sq. miles in size, is written as

$$T_c = LA^{0.4}D^{-1}S^{-0.2} \tag{9}$$

where T_c is in hours, L is the longest distance from the watershed boundary to the outlet (in miles), A is the watershed area (in sq. miles), D (in miles) is the diameter of a circle with area A, and S is the average elevation drop along L (in feet per 100 feet). With units of T_c in minutes, L in km, A in km^2, and S in m/m, and by converting D to A:

$$T_c = 14.6LA^{-0.1}S^{-0.2} \tag{10}$$

Equation 10 is one of the most widely used formulas.

A variant of the Kirpich formula was developed by the USBR (10) for small mountainous watersheds in California:

$$T_c = 60(11.9L^3/H)^{0.385} \tag{11}$$

where T_c is in minutes, L is the length of the longest stream (in miles), and H is the elevation difference between the watershed divide and the outlet (in feet).

Johnston and Cross (11) presented a relationship for T_c derived from the data of several watersheds ranging in size from 25 to 1624 sq. miles:

$$T_c = 4.7r^{-2}(L/S)^{0.5} \tag{12}$$

where T_c is in hours, r is the stream branching factor, L is the length of the main stream (in miles), and S is the average stream slope (in feet per mile). One may alternatively omit r and use 5.0 as the coefficient of the equation.

The SCS lag equation, developed from data on agricultural watersheds, can be modified by assuming that T_c is equal to 1.67 times the watershed lag:

$$T_c = \frac{1.67L^{0.8}[(1000/\mathrm{CN}) - 9]^{0.7}}{1900S^{0.5}} \tag{13}$$

where T_c is in minutes, L is the length of the longest flow path (in feet), CN is the SCS curve number, and S is the average watershed slope (in %). This equation has been found acceptable for urban watersheds smaller than 2000 acres in size with completely paved areas.

GENERAL RECOMMENDATIONS

Selection of the equation for estimating T_c and T_t is subjective. Some general recommendations, however, can be proposed. First try to make up your mind about the proper definition of time of concentration and travel time. Definition 2 is based on wave travel time and is preferred, but water velocity in definition 1 can be also transformed into wave celerity. Use definition 4 when hyetograph-hydrograph data are available, although rainfall spatial variability in large watersheds and nonreproducibility of response time are two major issues that are not addressed in this definition. Another important consideration is the preference to estimate T_c and T_t as functions of design rainfall intensity in an iterative procedure.

Next is the choice between hydraulic and empirical methods. Choose a hydraulic method when proper data can be collected to apply it and the estimate of T_c is considered a critical step in the project. If repetitive use of the selected method for various watersheds and for many outlet points inside the watershed of interest is required, the development of a GIS-based computer model based on Eq. 2 may be justified. Curves of T_c can be constructed for any watershed by running the model for various rainfall intensities. This leads to calibration of γ and C in Eq. 4.

The next option in hydraulic-based methods may be the combination of the kinematic wave model (Eq. 6) for overland flow, the upland method for concentrated flow, and Manning's equation for channel flow. Travel time through channel reaches must be adjusted based on wave celerity, as discussed in "Hydraulic methods."

In using empirical methods, one must be aware of the conditions and assumptions on which the development of these methods was originally based. It is important to compare the characteristics of the watershed considered with the range of watershed area, land use/cover, slope, and rainfall intensity of the original data set used in developing that empirical method. Simplicity and practicality of empirical methods comes at the expense of lost generality and accuracy.

College of Environmental
Science and Forestry
Syracuse, New York

INTRODUCTION

Consideration of a drainage basin as the basic unit of supply and management goes beyond merely calling attention to the need for watershed management based on what we typically visualize of the natural environment. This article seeks to establish a broad base for anyone who wishes to base policy decisions on sound science, in this case, on some readily identified and easily comprehended fundamentals about natural and disturbed hydrologic environments. This article organizes, defines, and explains the importance of seven basic functions of watersheds, augmented by some essential topics aimed at a more thorough understanding of the functions.

It is essential to consider a watershed as a basic unit of landscape for managing the water resource. The reasoning underlying this practical concept is actually rooted in the fundamental role of water on this planet more than on the obvious practical management needs. The watershed is, first, a *system* whose primary focus is on interactions between the topography and runoff-producing events. Topography defines a watershed's limits and is a useful framework within which to examine, describe, and manipulate its *functions*, or how the watershed works. Runoff-producing events, rain, snow, or ice storms, and snowmelt induce stream flow that provides sites for chemical reactions and habitat for wildlife as well as pathways for energy, nutrients, and waste products between the land and the oceans. Second, the watershed is a dynamic *hydrologic unit*, whose behavior interacts with biological systems to construct a range of *aquatic ecosystems* that have unique properties reflecting the *quantity, regimen,* and *quality* of the water resource. These watershed functions blend on larger geographical and temporal scales with physical, chemical, and energy components of the universe, thereby affording the opportunity for humans to establish working landscapes that are environmentally sensitive, sensible, and sustainable.

Terminology: Three Important Terms

A watershed (also *catchment* or *drainage basin*) is the natural unit of land on which water collects, is stored, and

---

[1] The material in this article is summarized from *Watershed Hydrology*, Second Edition, 1996, CRC Press/Lewis Publishers, Boca Raton, FL, and, in part, from an animated and narrated nutshell autotutorial short course on compact disk accompanied by a manual under the title *Concepts of Watershed Hydrology*, published by the author in 2002 (www.waterbudget.com).

is redistributed to the atmosphere, streams, and larger water bodies. The simplest definition is "an area of land on which precipitation collects and runs off through a common outlet." The "outlet" is the lowest place on the watershed; it is selected as the best location for monitoring stream flow, its quality, and temporal distribution. The term also applies to the high ground between two drainage basins, which is also known as a *topographic divide*.

Hydrology is *the study of the movement and storage of water in the natural and disturbed environment*. The term also refers to the *condition of the hydrologic environment at some specified time or place*, as in "the hydrology of Eagle River just prior to the June flood...."

Antecedent moisture conditions refers to *a description of meteorologic, vegetative cover and/or land use circumstances, soil characteristics, and the amount of water in storage on a watershed that collectively affect runoff behavior at the start of a hydrologic event of interest*.

Units

Both English and Metric System units are used throughout aquatic disciplines. Most of the well-established stream flow and water quality records made during the twentieth century in the United States and Great Britain were in units of inches, feet, and acres. Other regions of the developed world used the cgs (or metric) system of millimeters, meters, and hectares. Hydrologists need to be familiar with both sets of units and should be able to convert readily from one to the other. Each has benefits. For example, conversion from water quality units of *concentration* in milligrams per liter (mg/L) to *load* in kilograms per hectare is easier in the metric system. The large volume of water represented by the *acre-foot* (43,560 square feet covered by water one foot deep) can be readily derived from the basic unit of stream flow in the English system, one cubic foot per second (cfs, or second-foot), which is a reasonable minimum measurable flow in the field. Thus, a constant flow of 1 cfs for 1 day is very close to 2 *acre-feet/day*, or about a third of a million gallons.

WATERSHED FUNCTIONS

The seven watershed functions are arranged in three groups: three *hydrologic* functions, two *ecological* functions, and two *response* functions. Large watersheds are made up of many small watersheds, so the discussion here focuses on *small* watersheds, where stream flow is dominated by storm flow or discharge from runoff-causing events.[2] How runoff events from small watersheds combine to produce discharges on large watersheds is the subject of extensive research and complex models and research techniques. Runoff from large watersheds is dominated by baseflow (discharge from a groundwater reservoir). The behavior of these two types of flow is very different, but once the water is in the stream, visual separation is often difficult. In contrast, however, the chemical characteristics of storm flow and baseflow are also quite different: they have different storage histories that are reflected chemically. That provides a developing field of research into using water chemistry to understand, model, and therefore predict hydrologic behavior.

Hydrologic Functions

The names of the hydrologic functions derive simply from what they do. The British term for the drainage basin is *catchment;* the U. S. term is *watershed*. Both are self-descriptive. Between them, the water is *stored*.

Collection. The collection function is clearly the first step in a process-oriented description of the hydrologic cycle on land.[3] An essential first consideration in this function is where, how, for how long, and in what form the runoff-causing event impacts the watershed. For example, the same rainstorm at different locations on a watershed will result in different distributions of stream flow (Fig. 1). Thus, a small-area but intense[4] summer thunderstorm near the outlet of a watershed will produce a short-duration, high-peak runoff flow in contrast to the same storm occurring at the upper end of the watershed where the length of stream provides time for the runoff to spread out in time and space, thereby producing a lower peak but longer duration of flow. The hydrograph for the storm near the outlet is said to be "flashy," a common characteristic of small watersheds as well as impervious parking lots and urban watersheds.

It is clear that the location of the runoff-producing event is of considerable importance in determining hydrologic behavior. Size and type of storm, therefore, also become important. Thus, in a region where summer thunderstorms are prevalent, short-duration, flashy stream flow may be expected, especially if the watershed under consideration is at a high elevation where slopes are steeper, soils are thinner, and intense storms can readily cover the entire small watershed. These are *weather* events. In contrast, snowmelt is a *climatic* event that embraces a longer time and greater areal extent than thunderstorms. In between, cyclonic storms and hurricanes may be the dominating determinant of runoff behavior on intermediate size and midelevation watersheds. Climate and weather are characteristic of different areas, so hydrologic behavior is similarly geographically determined.

Summarizing, the collection function reflects how and where the water that falls on a watershed influences the storage and discharge functions. Further, the different types of runoff-causing events interact with and define

---

[2] A small watershed has been defined as (1) from 200 acres to 1 square mile in size for applying the Rational Formula to determine peak flows (1); (2) one in which runoff behavior is dominated by *overland flow* as opposed to *channel flow* (2), and, for legislative/programmatic purposes; and (3) one that is up to 250,000 acres (PL 566, 1954). It is suggested here that the small watershed be defined *functionally* as one on which the water resource issue of concern be under the primary influence of *storm flow* as opposed to *baseflow*.

[3] There is, of course, a hydrologic cycle on waterbodies, too. It consists largely of the same functions as those on terrestrial (land) environments, but in the oceans, without the discharge, attenuation, or flushing functions.

[4] Expressed in inches or millimeters per hour.

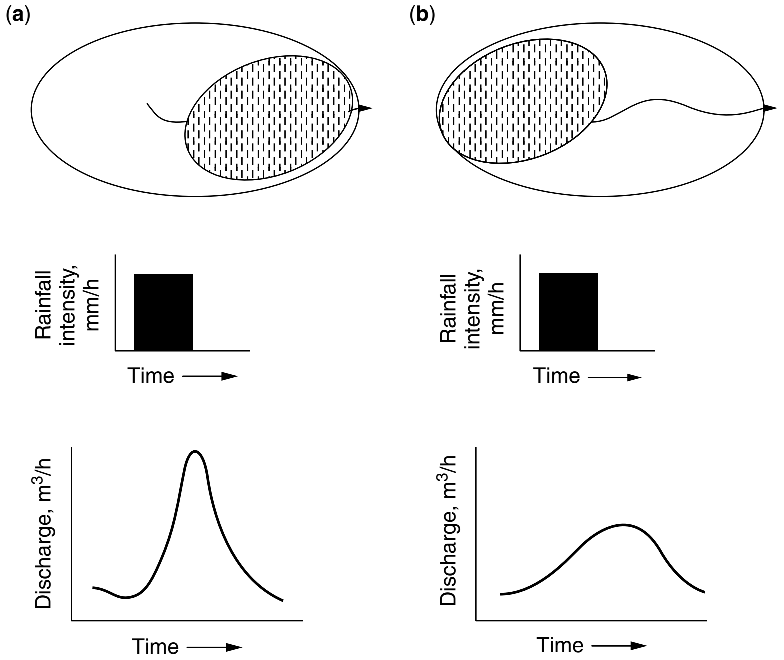

Figure 1. Storm hydrographs from the same rainstorm (hatched area) at different locations on the same watershed. (**a**) Storm is near the outlet. (**b**) Storm is near the headwaters. The volume of water running off might be the same (the area under the hydrographs), but the time pattern of runoff is different.

typical *hydrographic regions* in which homogeneous areas exhibit similar hydrologic behavior.

Storage. The storage function is the focus of a small watershed (Fig. 2). There are six types of storage in and on a watershed: *channel, depression, retention, detention, groundwater*, and *vegetation* storage.

When water arrives at the land surface, three things can happen to it. First, water may fall directly into channels, including small lakes and ponds, as well as streams and rivers. From these, of course, it is simply a continuing process for this water to flow out of the watershed by joining other waters in the stream and be reclassified as channel runoff.

Second, water may be held on the surface as *depression* storage in a thin film or as puddles. Wetted surfaces of all types—on blades of grass or leaves, rooftops, parking lots, even in some cases wetlands—may be considered depression storage. Snowpack is also a form of depression storage. The water thus detained on the surface may enter the soil if the pores in the soil are not already full and are large enough to allow water in; often, water in depression storage evaporates from the surface under the influence of wind, a warm surface, or sunlight following the storm. Runoff from depression storage is minimal.

Third, water may infiltrate (move into) the soil. How much and how fast this occurs depends on the openings or pores in the soil, whether there are small soil grains that can be washed into and clog the pores, how much of the soil pore space is already filled with water, and how much and how fast the water already in the soil can drain downward (*percolation*). Some larger scale factors that affect the infiltration rate[5] include surface roughness, slope of the land, and extent of soil particle size variety, often dependent on the geologic history of the area and its erosion (known collectively as *geomorphology*). If the rate at which the precipitation falls—*rainfall intensity*—is greater than the capacity of the soil to absorb it—*infiltration capacity*—then excess water runs off the top of the soil as *surface runoff*.

Once in the soil, water may be held tightly (close to soil surfaces) and for long periods in the capillary (or *micropores*) against the force of gravity, or it may be held temporarily (not as close to soil particle surfaces) in the larger, noncapillary or *macropores*. The water *retained* for a long time is called *retention storage,* whereas the water temporarily *detained* is *detention storage.*[6] Upon infiltrating the soil, water will move first into retention storage if it is not filled (where the water is pulled in and held at higher tensions) and into detention storage only if the retention storage is already filled, or recharged.

Water in retention storage is held tightly against the force of gravity, so water cannot flow out of retention storage. In contrast, water can flow out of detention storage and is referred to as subsurface runoff.[7] Subsurface flow may go either to a nearby stream or to a *groundwater* reservoir, the body of water beneath the *water table*. A groundwater reservoir is the saturated zone from which water tends to flow off rather slowly as *baseflow* in contrast to the greater degree of flashiness exhibited by *storm flow*. The latter is made up of channel, surface, and subsurface runoff, sometimes referred to as "wet weather flow."

Topography (and geological history) plays a significant role in the development of soil storage reservoirs. Elevation, slope, aspect (of slopes), orientation (of the

---

[5] The rate at which water moves across the air–soil interface, in inches or millimeters per hour.

[6] The difference may be readily committed to memory by recalling the term used to describe the punishment for improper behavior in school when a student would be sent to a temporary hour-long study hall (*detention*), not commitment to life in prison (*retention*).

[7] The terms "runoff" and "flow" are often used interchangeably.

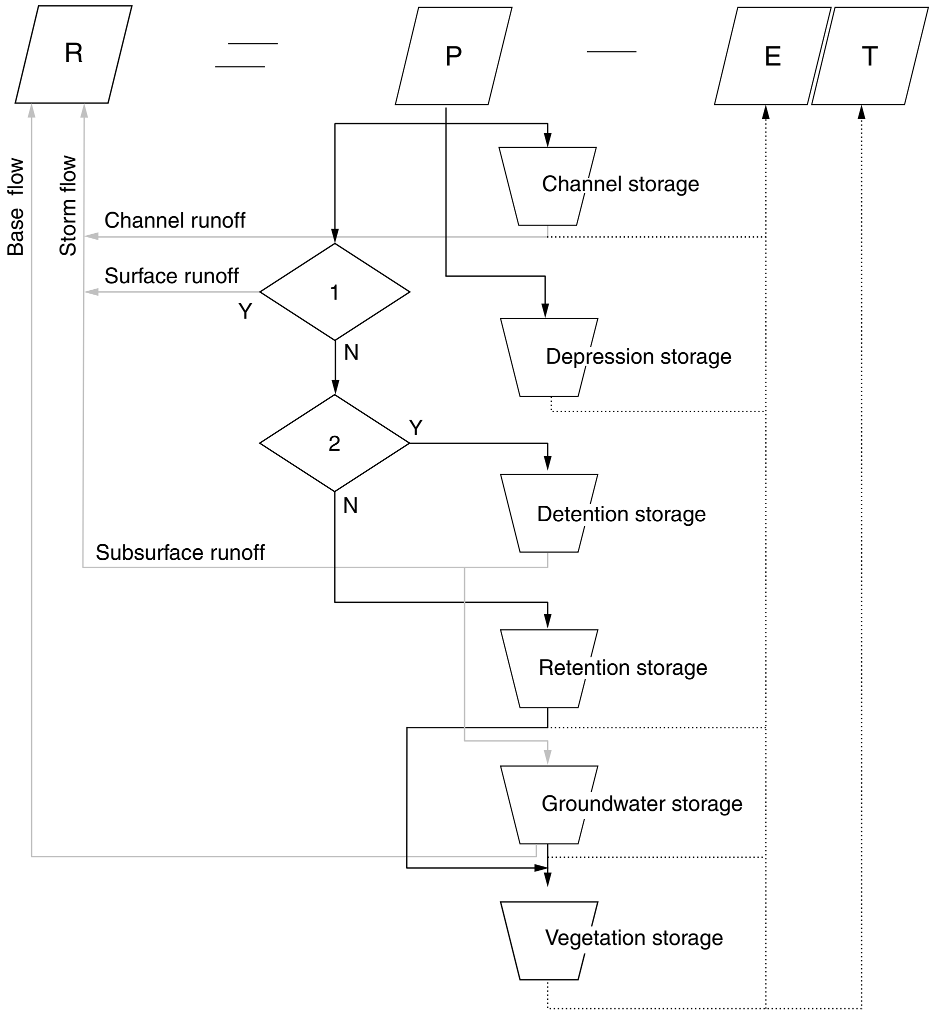

Figure 2. The hydrologic cycle depicted by focusing on the six types of watershed storage and the basic water balance equation (R = Runoff; P = Precipitation; E = Evaporation; and T = Transpiration) at the top. Choice box #1 asks "Does precipitation intensity exceed infiltration capacity?" and choice box #2 asks "Is retention storage full?" Some features, storm flow and baseflow, are kept separate to emphasize that they behave differently; water can leave retention storage only through evapotranspiration (E_t) processes; and water in detention storage, which flows out in response to gravity within about 24 hours, generally is not around long enough to supply E_t at all. See text for full description.

stream), and the distribution of those features throughout the watershed affect the antecedent moisture conditions as well as the storage characteristics of soil reservoirs. For example, south-facing slopes in the Northern Hemisphere are drier than their northern counterparts because they receive more incident energy that is used to evaporate moisture. Soils on south-facing slopes are less well developed and thinner, have lower water holding capacities, and a greater percentage of the soil pores in detention storage where less water is available for vegetation, therefore fewer and/or different species. In short, south-facing slopes tend to be drier than north-facing slopes in the Northern Hemisphere and, of course, the opposite south of the equator.

Finally, water may be stored in *vegetation*. Water enters vegetation when vapor condenses on plant tissues, when it is intercepted as rain or snow, or when absorbed directly through leaves and bark. More water enters through the roots, however, and, because it ascends in response to atmospheric evaporative tension working through tiny openings in leaves called stomates or stomata,[8] it is often combined with the water that evaporates from depression (surface) storage on the vegetative parts as *evapotranspiration* (E_t). E_t refers to all of the evaporative processes and may be modeled as an object of research that focuses on the amount of energy available for evaporation (3). Evapotranspiration is strong enough to pull water away from high-tension films close to soil particles (retention storage). In contrast, water in detention storage is held loosely in the macropores and flows out usually within 24 hours; during that time there usually are waning storm clouds, high humidity, and often cooler temperatures all of which diminish the energy (and water) available for evapotranspiration. The bottom line is that water held in detention storage is not generally available to plants or E_t.

From this examination of the storage function, it is clear that storage type and distribution in the soil profile and topographically over the watershed modify the broad hydrographic patterns imprinted by the climate and weather factors that characterize the collection function. The infiltration capacity concept and the distribution of retention and detention storage are two of the most important concepts in watershed hydrology. And, in practice, the relationship between infiltration capacity and precipitation intensity combines to define the limits to surface runoff and attendant flooding that occurs at the

---

[8] The process is known as *transpiration*.

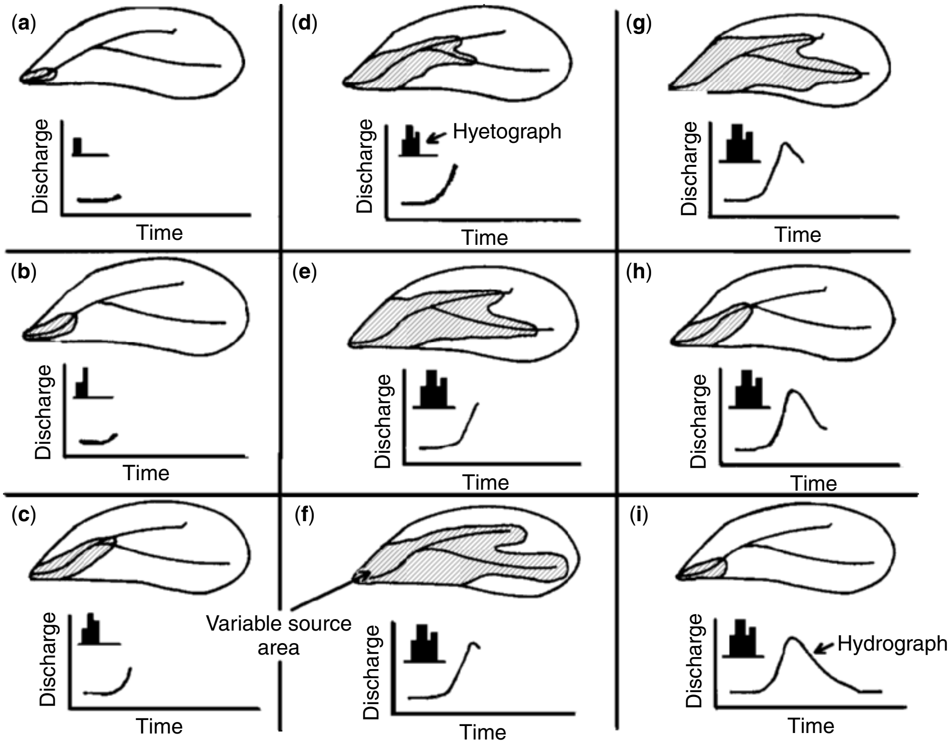

Figure 3. The variable source area. During a storm that uniformly, instantaneously, and completely covers a watershed, the zone contributing to runoff changes.

air–soil interface where humans have the greatest impact on the hydrologic cycle.

Summarizing, the storage function focuses on how water is retained and detained on a watershed and what its characteristics are as it moves between storage reservoirs. Storm flow dominates small watershed runoff behavior. The fact that water can readily absorb elements and compounds gives rise to the chemical function (below) and makes it possible to use water chemistry to monitor and model water storage.

Discharge. As we have just seen, there are two categories of runoff: *baseflow* and *storm flow*, which include channel runoff, surface runoff,[9] and subsurface runoff. Storm runoff is ramified in the *storm hydrograph*, a plot of runoff over time that translates unique watershed characteristics into a typical discharge (often, a flood). Changing land use or vegetative cover can profoundly affect the storm hydrograph on small watersheds and, if done over a wide enough area, even on large ones. The baseflow hydrograph also exhibits patterns that are unique to the watershed from which it flows. However, baseflow integrates the runoff over longer times and broader landscapes, so it is less sensitive to land use and vegetative cover changes. Both types of flow display typical patterns for hydrographic regions, allowing extrapolation of hydrologic information from one watershed to another within the same region. Thus, regional flood behavior curves may be estimated for ungauged streams. The storm hydrograph is influenced primarily by *weather*; the baseflow hydrograph is influenced primarily by *climate*.

An important concept of discharge is that the portion of the watershed that contributes to storm runoff changes during the runoff-causing event, even if uniform rainfall that instantaneously and completely covers the watershed is assumed. The variable source area model identified by Hewlett and Hibbert (4) promotes understanding how and when water gets to the stream (Fig. 3). It also provides a sound scientific basis for protecting and restoring the near-stream *riparian zone* areas, also referred to as *buffer zones* or simply as *buffers*. Water flowing off or through the soil, or in saturated stream bottom zones, appears rather quickly as storm flow, so it follows that water from these zones is likely to be a major source of nonpoint sources of pollution.[10] *Isotope hydrology,* which monitors specified elements or ions in the environment, is one method of tracking water in time and space as it moves through natural and disturbed environments enabling identification of how “old” and “new” water contributes to stream flow. Other isotopic elements and dyes may also be used.

Summarizing, the discharge function integrates antecedent moisture conditions and characteristics of the collection and storage functions. Storm and base flow portions of runoff need to be analyzed separately because they arrive at the stream from different watershed storage reservoirs, are influenced by different characteristics, and consequently behave differently. Both the *storm* and *baseflow* hydrographs are unique to a particular watershed. Hydrographs may be used to analyze, describe, and

---

[9] Under undisturbed and most natural conditions, surface runoff (also referred to as *overland flow*) does not occur. Exceptions are evident on steep slopes that have shallow soils and intense precipitation.

[10] Pollutants that are diffused across the surface of the land and have no apparent end-of-the-pipe outlet as do point sources.

predict stream behavior on ungauged watersheds. A great deal may be learned about the watershed by careful analyzes of the storm and baseflow hydrographs and their relationships to other hydrologic parameters (e.g., precipitation, infiltration, and soil storage) of the drainage basin.

Ecological Functions

Ecological functions refer to *chemical reactions* and *habitat*. Except for nuclear reactions, virtually all chemical reactions on the earth, in our solar system, and throughout the universe, take place in the presence of water, which therefore plays an essential role in environmental chemistry and life itself. The aquatic chemistry of our body cells, organs, and blood, in soil water, streams, wetlands, ponds, and lakes, and in the oceans define life. Life is considered as existing only in the presence of water and, consequently, the ongoing search for extraterrestrial life focuses on a search for water.

Chemical Reactions. As drops of water form in the atmosphere following cooling and condensation, carbon dioxide readily dissolves in them. This shifts the *reaction*[11] (or pH) of natural rainfall from a neutral value of 7.0 to about 5.7 (slightly acid), which makes precipitation rather corrosive: it dissolves many of the elements and/or compounds found in rocks and soils that derive from them. Carbon dioxide, dihydrogen oxide (water), and several forms of carbonate all disassociate (to hydrogen and hydroxyl ions) in aquatic environments and result in various concentrations of hydrogen ions; hence the use of pH to monitor one of the major water quality parameters. Others include *conductivity*, an index to dissolved salts based on how much electricity the water conducts; *temperature*, a measure of the energy content of the water; *turbidity*, a measure of the amount of suspended solids in the water; *dissolved gases* (oxygen, carbon dioxide, methane, ozone, etc.); *dissolved nutrients* (nitrogen, phosphorous, potassium, and sulfur); *heavy metals* (iron, lead, mercury, etc.); *color*, an indication of dissolved substances such as tannin; and *contaminants*, including toxins and disease-causing bacteria and/or viruses, and spores.

Some of the chemical exchanges that are evident in the presence of water may, in turn, be used to assist in evaluating the hydrology of a waterbody: where it came from, with what it has come in contact, and so on. For example, silica dissolves readily when water moves through sandy soil. If that water flows into a wetland, abundant plant life will remove silica from the water column to produce cells, which differ from animal cells in that they have silica-based cell walls. And, because the great growth of plants in wetlands ensures a plentiful supply of decayed plant and animal remains, water flowing out of a wetland will tend to be low in oxygen and high in carbon dioxide (as well as low in silica and pH).

Water is considered a universal solvent (although it won't dissolve the noble metals gold, silver, platinum, etc.) and naturally conveys waste materials from our body cells, organs, individuals, communities, and nations. It even assists in carrying nutrients *upstream* in the bodies of migratory salmon and related species that feed in the oceans and die when they have completed their reproductive journey to the headwaters of the stream of their birth, ironically, succeeding because of the unique stream chemistry that they can trace to the stream in which they were spawned. It is also believed that it plays an essential role in the carbon cycle (5).

The hydrologic cycle also interacts with the energy balance of the earth in two ways. First, water vapor is one of the chief greenhouse gases along with carbon dioxide, methane, ozone, and other two-atom molecule gases. Second, water vapor in the form of cloud cover plays a direct role in the energy balance of the planet by reflecting solar radiation to space, thereby affecting the temperature of the atmosphere and the earth's surface. We need to explore ways in which our land and water management strategies and policies might adversely or beneficially impact the role of water in these critical interactions.

Summarizing, the *chemical reaction* function brings a whole new and exciting dimension to the field of watershed hydrology and land management, not only water chemistry, but environmental and astrophysical chemistry. These are some very significant and fundamental characteristics of the earth and the universe.

Habitat. The habitat function embraces the observation that wildlife (terrestrial, aquatic, and avian) evolved under a variety of conditions and require that they be maintained to survive. Ecosystem support for all species needs to be preserved and/or restored to ensure continued biodiversity in our environment, especially aquatic environments. Human beings themselves may have evolved at the beginnings of civilization at the seashore, in the presence of water and all that it has to offer as sustenance, food, protection, and a myriad of services (6).

This function is not dealt with in depth in this paper, but it is important to point out that a great deal of time and money have been invested in restoring (and preserving) wetlands, and recently increased activity in watershed restoration as well. These preservation and restoration efforts are often lackadaisically directed toward restoring habitat rather than hydrologic functions. But, when habitat—particularly aquatic habitat—is restored, the chances are very good that hydrologic functions have been restored as well.

Summarizing, the habitat function might be viewed as a surrogate for evaluation of restoration of watershed functions that are harder to visualize, measure, or model. The importance of viable ecosystems and associated biodiversity, however, is a value of aquatic habitats that transcends even semiserious personal desires.

Response Functions

The response functions are so called because they represent practical functions that play important roles

---

[11] A measure of the relative acidity and alkalinity of a compound in terms of the hydrogen ion concentration. The range is from 1 to 14 (the numbers are logarithms to condense an otherwise very broad scale), where 7.0 is neutral.

in our aquatic environments. The responses really involve how the storm hydrograph reacts with other considerations: in the *attenuation function*, the peak discharge, Q_p, is seen to diminish as the area of a watershed increases. In the *flushing function*, the concentration of dissolved and/or suspended substances appears to relate to the stages of the storm hydrograph in a predictable manner.

Attenuation. It is the nature of storms to have the most (depth) and most intense (depth per unit time, e.g., inches per hour) precipitation at or near the center, and precipitation diminishes until both become zero. This observation flies in the face of the earlier assumptions of uniform, instantaneous, and complete storm coverage: in fact, the larger the watershed, the longer it takes for water falling at any point to reach the outlet, in addition to the fact that there will be a place where the rainfall is most intense and greatest in depth. Given, too, that slopes and stream gradients generally diminish downstream, it follows that the length of time between the start (or centroid) of the runoff-causing event and the time of occurrence of the consequent peak flow Q_p (in this case, Q_p is reported in units of cubic measure per unit time *per unit area,* e.g., cubic feet per second per square mile, csm, or cubic meters per second per square kilometer) also diminishes (Fig. 4).

Summarizing the attenuation function, it is easy to remember that the three "*L*s" go together: thus the storm peak in runoff per unit area is *L*ower and *L*ater on *L*arger watersheds.

Flushing. Flushing is a natural characteristic of all aquatic ecosystems except the ocean. As relatively pure water arrives at the land surface (or channels), it dilutes whatever substances are already in the stream (Fig. 5). Then, as water flows off the near-stream zones within the variable source area, it carries with it soil particles and dissolved materials and starts a cleansing or flushing action in the stream/watershed system. As the velocity and volume of stream flow increases, more and more particles deposited earlier in the streambed may also be picked up and transported downstream. A plot (*pollutograph*) of the concentration (e.g., mg/L) of dissolved and suspended materials increases until peak flow occurs and then quickly diminishes. Put another way, the plot of the concentration over time, the pollutograph, peaks during the rising limb of the storm hydrograph (or during the rising stage of the annual hydrograph's spring peak, for example), then rapidly decreases until the prerunoff-causing event stream flow level is reached.

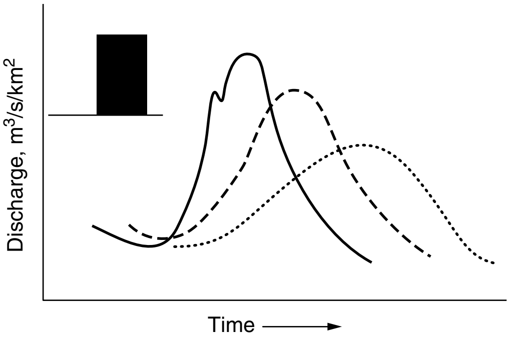

Figure 4. The initial upstream storm hydrograph diminishes and spreads out as the peak moves downstream. Note: the vertical axis is in volume *per unit area,* and the initial channel interception prepeak on the rising limb disappears.

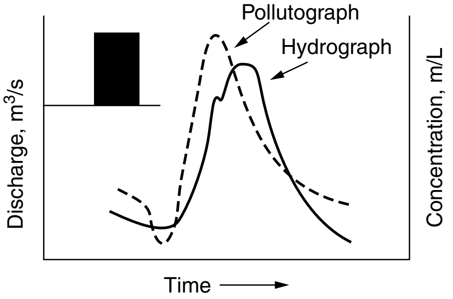

Figure 5. Flushing of some suspended solid (read on right-hand axis) superimposed on storm hydrograph (read on left-hand axis).

Some of the potential pollutographs are well known. For example, a great deal of field data and physical modeling have produced reliable suspended-sediment pollutographs. However, there is a paucity of data and studies on pollutographs for dissolved gases, pH, temperature, and dissolved solids. Intuitively, pollutographs generally follow this pattern. But there are not enough studies on this topic to back up that assertion.

Summarizing the flushing function, nearly pure water from runoff-causing events dilutes water in the stream and initiates dilution and then a flushing action, within and near the stream, that peaks during the rising limb and returns to the preevent level commensurate with stream flow.

SUMMARY

Essential to life as we know it and expect that it evolved on other planets, water pervades our local, regional, national, and worldly environments. We have the greatest access to it locally, but our attention to careful science-based management of water on all scales is demanded to ensure our sustainability. Understanding water in the natural and disturbed environments starts with honoring basic hydrology on a watershed basis.

WATERSHED MANAGEMENT FOR ENVIRONMENTAL QUALITY AND FOOD SECURITY

G. S. Shrivastava
University of the West Indies
St. Augustine, Trinidad,
West Indies

Watershed management is a broad term. It comprises the planning, implementation, and operation of programs and practices for the optimal utilization and preservation of natural resources such as water, forest, and wildlife. The term is rooted in forestry, and the adverse impacts of deforestation relating to soil erosion, sedimentation, and on water yield are well known (1), and they need not be elaborated here. Suffice it to say that the frequency and severity of floods and droughts, mudslides, and water quality are closely linked to the state of watershed management. In this article, however, watershed management is considered with specific reference to environmental quality and food security.

Environmental quality is an illusive term that embraces physical, psychological, and emotional factors, and biodiversity is an important aspect of the same. Furthermore, an increasing awareness of the critical interdependence of ecology and hydrology has led to the emergence of a new study field of ecohydrology (2). It is a frontier full of challenging and unexplored questions, embracing problems, which are crucially related to biodiversity and ecosystem functioning; e.g., how do hydrologic systems control (or how they are controlled by) ecological systems?

In a given landscape, its flora and fauna dynamically interact with the hydrologic cycle over varying spatial and temporal scales, and the ecological structure and function of ecosystems are intimately tied to the hydrological regime of floods and droughts. Accordingly, ecological diversity is a function of varying flow. Moreover, it is essential to not only identify these interactions, but also to ascertain the limits to perturbation before the ecosystems begin to break down. In this context, estimation of instream flows plays a vital role for the preservation of environmental quality (3). Furthermore, two other aspects are important as well. First, within an overall watershed management strategy, ecotourism development should be mild to moderate lest it endangers the very environment that the tourists want to experience. Second, it should be recognized that the places where biodiversity is greatest are often the same places where conservation measures are most difficult to enforce because of poverty, difficulty in controlling poaching, and habitat destruction.

Food security can be simply defined as the ability of a nation to feed itself by means of its agricultural resources, and such ability is largely dependent on irrigation and drainage infrastructure. Inadequacy of such infrastructure leads to poor crop yields and loss of fertile land because of salinization. However, central to irrigation is the availability of water resources, and it is the watersheds that generate this vital resource. Unfortunately, in some parts of the world, such as in the Middle East and the Caribbean (4,5), watershed management does not get the attention it deserves, because, virtual water, embedded in grain imports, creates an illusory sense of food security, which in turn slows the pace of socioeconomic reform needed to improve watershed management.

In conclusion, although watershed management policies are shaped in the political arena, it is hydrology that can steer decisions in the right direction. Therefore, political and economic pressures should not prevail over hydrologic evidence and reasoning. Ultimately, there is either science and sustainability or crisis and conflict in the sphere of watershed management.

WATER HYACINTH—THE WORLD'S MOST PROBLEMATIC WEED

Adrian E. Williams
APEM Ltd.
Manchester, United Kingdom

INTRODUCTION

Water hyacinth (*Eichhornia crassipes*), a perennial, herbaceous monocotyledon member of the pickerelweed family (Pontederiaceae), is native to tropical America. It is usually found as a floating plant with mature specimens having long feathery roots that can be over 2 m in length (Fig. 1). However, in shallow waters, individuals can root themselves into sediment, and individual plants can even be found fully rooted on banksides. Water hyacinth is found in a number of differing morphological growth forms, and the morphology and architecture of leaves, petioles, and clonal groups can be highly plastic (1–3). However, two forms dominate (4,5). One, typically found in open

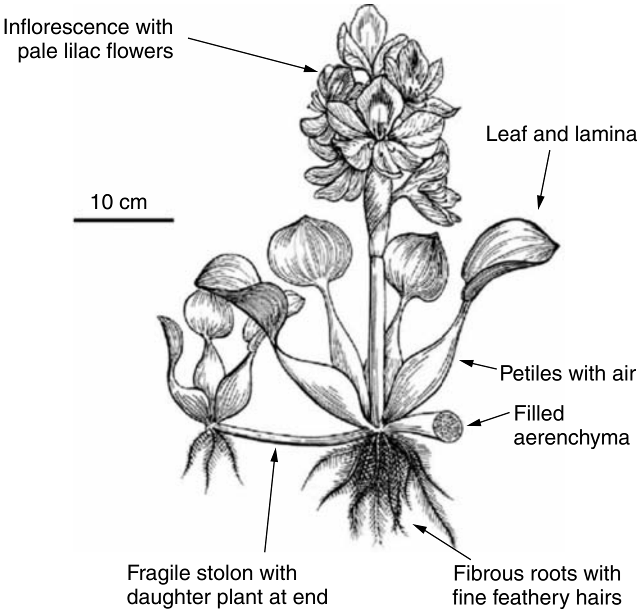

Figure 1. Water hyacinth (*Eichhornia crassipes*).

water or at the edges of plant mats, is characterized by short bulbous and very buoyant petioles containing air-filled aerenchyma, whereas another form occurs in crowded areas, such as in the middle of plant mats, with slender, tall, nonbulbous petioles. The short bulbous form can develop into the tall nonbulbous form if crowding occurs and sufficient nutrients are available (1). Petioles can therefore grow to over a meter in length, although 50 cm is usually more typical. Center and Spencer (2) found that in mature plants, between 6 and 8 leaves or lamina are present on each plant and that an equilibrium establishes between new leaves appearing and old leaves senescing.

Plants can double their biomass in 6 days (6) and although water hyacinth produces seeds, which form part of the waterbodies seed bank, plants generally reproduce through clonal propagation with daughter plants being produced at the ends of fragile runners or stolons. These stolons are easily broken by wind, current, or animal and boat movements, thus allowing the detached clones to disperse and colonize new areas.

In the center of each mature rosette of leaves rises a broad stem, on top of which is an inflorescence that usually bears between 6 and 14 lily-like pale lilac or violet flowers. Each flower consists of 6 petals, the upper one marked with blue and yellow, 6 stamens, and a 3 segmented ovary. The fruit that develops comprises of a simple capsule containing in the region of 400 to 500 seeds. After flowering, the inflorescence bends down into the water and seeds sink to the bottom of the waterbody where they can remain dormant for 20+ years (7) before germinating if the correct conditions prevail. For instance, a waterbody may become temporarily dry, resulting in all the parent plants dying; however, following the replenishment of water to the system, the seeds can germinate, thus providing a new stock of plants.

The fine feathery hairs that surround the main fibrous roots have a purple tinge and capture small particles as well as removing nutrients from the water column. Ideal growth conditions include a high nutrient concentration, especially of nitrogen and phosphorus, with water hyacinth thriving especially well where anthropogenic influences have artificially raised these levels. In addition, tropical temperatures, plenty of sunlight, and a high relative humidity all benefit the growth and expansion of water hyacinth.

With different morphological forms and an ability to adapt the growth form to the prevailing conditions, water hyacinth is able to colonize new areas very quickly. Although mats often develop out from the shoreline of lakes, rivers, and reservoirs, detached floating mats can also exist that are many kilometres in diameter and several meters thick. However, in its native habitat, the plant is kept in check through both natural pests and, more importantly, annual floods. During these periods, rivers may rise by over 10 meters, resulting in a torrent of water that sweeps the plants out to sea where they perish because of the effects of salinity. A few individuals remain, however, snagged on the banks and protected in quieter backwaters, which act as the new source of the following years stock. Overall, therefore, water hyacinth only becomes a significant problem when it finds its way into areas outside of its natural range.

THE PROBLEM

Water hyacinth was seen as a botanical speciality and, because of its beautiful and delicate inflorescence, used to decorate ornamental ponds (6,8). Therefore, from its native range, it was spread around the world during the nineteenth century. It was recorded in Egypt in the 1870s, the United States in the 1880s, Australia and southern Asia by the 1890s, China and the Pacific by the early 1900s, South Africa in 1910, East Africa by the 1930s, and West Africa by the 1970s. It is now established throughout tropical and warm temperate regions of the world (5,9). Moreover, as demonstrated in the Democratic Republic of Congo, where two plants were seen to produce 1200 daughter plants over four months (10), water hyacinth has massive growth potential. In terms of biomass, a m^2 of the weed can increase by up to 500 g each day so within a year, a hectare of plant can increase by over 1800 tons fresh weight, which, of course, does not include the subsequent growth of the new material. This exceptional growth rate is often partly attributable to the presence of large quantities of available nitrogen and phosphorus, and unfortunately, because anthropogenic eutrophication has affected the great majority of waterbodies throughout the world, the growth of water hyacinth and the problems associated with it have been greatly exacerbated. As such, and further aided by its ability to colonize new habitats and a lack of natural controls outside of its native range, water hyacinth is now commonly described as the world's most problematic aquatic weed (Fig. 2).

Invasive species such as water hyacinth have been referred to as a form of biological pollution because they can upset equilibria between native species that have

Figure 2. Lake Victoria in 1995. A mat of water hyacinth stretches out into the lake resulting in enormous ecological, sociological, and economic impacts.

formed slowly over millennia. When an invasive plant such as water hyacinth enters a new habitat it will out-compete and thus displace native vegetation, thereby becoming established. Some of the ways such displacements affect the native biota include a reduction in biodiversity, a decrease in habitat and food, and an overall change to ecological processes (11).

In the case of water hyacinth, native plants along the fringes of rivers and lakes are eliminated through successional shifts and, generally, a loss of biodiversity occurs (12). Furthermore, as native flora and fauna have coevolved over long periods of time, replacement of native vegetative systems with ones dominated by water hyacinth typically alters these relationships with accompanying reductions in available habitat and food. For instance, under the dense mats that can form, a reduced light and oxygen climate can lead to a decrease in plankton primary production, resulting ultimately in the death of native fish.

Ecosystem processes may change as a result of the spread of water hyacinth. Native ecosystems have developed under and adapted to particular abiotic factors and processes, such as rates of nutrient cycling, rainfall patterns, and fire regimes. The presence of alien species can alter these processes, which has a knock on effect to the ecosystem as a whole (13). For instance, where water hyacinth has been introduced, it can disrupt the natural hydrologic cycle by transpiring greater quantities of water, up to three times more, than native vegetation in the same habitat (11). Water tables and some surface water habitats are thus reduced and native species impacted.

Water hyacinth, with its characteristic thick fringes and floating mats, also has more direct impacts on anthropogenic activities. The weed can impede navigation, even in motorized boats, and transportation costs may increase because of the necessity of taking alternative indirect routes or as a result of motoring through the mats, which, if physically possible, increases fuel consumption (14,15). The weed has affected fishermen by fouling their nets and traps, reducing catches, and preventing access to landing sites. In West Africa, the inland waters of Ghana, Burkina Faso, and Togo have been particularly hard hit. Here, not only has the weed slowed down the boats of fishermen, it has also made landing difficult to the point that more of their catch goes off (14). Fish are often an important source of protein to lakeside communities, and without it, health suffers. Moreover, the mats are breeding grounds for carriers of human and animal disease such as malaria, schistosomiasis, encephalitis, and river blindness (11,16). Irrigation schemes have been put under pressure and, indeed, irrigation channels blocked. In many cases, the weed has reduced the supply of clean potable water and caused difficulties in water extraction. Unsurprisingly, its presence has increased disputes between local communities and overall has been responsible for the translocation of some communities away from affected areas when local watering points and lake access have become unavailable. Furthermore, in Lake Victoria, apart from the reduction in national revenue from the reduced export of fish produce, tourism has declined and intermittent closure of the hydroelectric plant in Jinga, because of weed buildup, has caused disruption within Uganda's capital, Kampala (6,16,17).

Unsurprisingly, therefore, the World Bank, together with the United Nations, the International Monetary Fund, and a plethora of other international and national organizations, has pumped hundreds of billions of dollars into tackling the problem of water hyacinth around the world.

METHODS OF CONTROL

Once established, water hyacinth is extremely difficult, if not impossible, to eliminate, and attempts to do so often adversely impact remnant native vegetation (18). More achievable, however, is the control of the weed, but the elimination or even control of waterweeds is a costly process both in fiscal and temporal terms. Three basic methods exist to remove water hyacinth: physical, chemical, and biological controls.

Physical control involves employing manual labor and mechanical harvesters to remove the weed. The use of physical barriers, such as floating booms, to corral water hyacinth and prevent its spread as well as aiding ease of physical removal can also be implemented (14). Often, manual removal at landing stages can be undertaken extensively by locals if they are provided with equipment such as rakes and wheelbarrows. Aquatic vegetation cutters or "Swamp devils" have been used widely throughout the world, and booms are often used in conjunction to reduce weed expansion (19). These techniques have often worked in that weed can be contained and removed. However, often as a result of the sheer scale of the problem, benefits are typically short lived as a cleared site can be inundated with new weed in a matter of days, either through growth of any remaining weed or immigration of plants from outside of the site. Furthermore, booms can become overburdened from the weight of the weed (20) and machinery can breakdown. Unfortunately, with a lack of expertise, tools, and spare parts, the expensive harvesters have, on occasion, been left to rust on the shore. However, physical control has been used successfully throughout the world to manage water hyacinth (21), and in Nigeria, such methods are considered relatively effective (22). Nonetheless, physical control has to be intensive and regular and is thus ultimately expensive. The cost of clearing a hectare of weed is estimated to be between US $2400–30,000 (23,24). Therefore, for a waterbody of more than a few tens of hectares, physical control is not a feasible long-term control option.

Chemical control is, worldwide, one of the most commonly used methods of macrophyte repression. Chemicals can be applied from the air, water, or land, and some degree of accuracy as to where the herbicide lands can be achieved. Chemicals such as diquat, glyphsophate, amitrole, and the amine and acid formulations of 2,4-D are the most effective and commonly used chemicals against water hyacinth. Application needs to be undertaken by trained individuals using correct dosages and applied at appropriate stages of growth. When they are applied incorrectly, problems can be encountered, not least of which is killing nontargeted plant species such as aquatic macrophytes or agricultural crops (18). Herbicides themselves typically only cost in the region of US $ 50 ha^{-1} of treated area; however, application costs whether by plane, boat, or hand are in addition to this (25). Therefore, herbicide use is only viable over small areas; on the larger scale application, it can become prohibitively expensive. However, whatever the operational costs, if weeds grow faster than chemicals can be applied, then the control of water hyacinth is clearly not accomplished (11). Moreover, if the dead or dying weed is not removed, the rotting biomass can lead to localized deoxygenation, which can, in turn, lead to other detrimental impacts on the waterbody (19,26). Furthermore, although plants may appear to have been controlled, the problem may not have been solved if, as in the case of water hyacinth, seeds remain buried in the sediment and propagate some years later or, as is more typical, plants remaining in the marginal vegetation recolonize the waterbody. Repeated applications are therefore required (5).

The main problem associated with herbicide use, and indeed the reason they are not used as widely as they might be, is the potential effect, real or perceived, of chemicals on humans either directly through ingestion or indirectly through reduced income. Many affected rivers and lakes are major sources of drinking water, and therefore the problem of ingestion is clear. Also, the sites most affected by water hyacinth, and therefore most in need of herbicide application, are typically adjacent to lakeshore communities and farmlands, which increases the risk of destroying nontargeted plants and crops. Furthermore, fear concerning the impact on native biota, not just the loss of nontargeted plants, but also the potential for bioaccumulation of contaminant dioxins through the food chain, is also an area of concern for governments considering their own populations health and the sale of fish to international exporters (27). Lake Victoria, for instance, supports an extremely valuable export fishery that earns critical foreign exchange for the riparian countries. The European Union, which is a major importer of fish from the lake, made it very clear that widespread application of chemicals could threaten the marketability of the fish. Finally, if biological control is used (see below), the application of herbicides may have impacts on the biological agents. Although experiments have found that diquat, glyphsophate, and 2,4-D do not increase mortality rates of *Neochetina eichhorniae* (Fig. 3), they did move away from treated plants to untreated ones (28). In addition, researchers found that *N. bruchi* mortality was increased by several of the commonly used herbicides (29).

On the whole, chemical control, if undertaken correctly, can be very effective in the short term, but as with physical control, the use of herbicides is too expensive for repeated use on large expanses of water.

Biological control involves the use of host-specific agents that are naturally occurring enemies of invasive weeds in their native bioregion. The United States Department of Agriculture initiated biological control in Argentina in 1961, and since then, weevils, moths, and fungi have been tested for host specificity (30). Host-specific agents have now been successfully used to control water hyacinth in a variety of localities around the globe (5,11,31). Indeed, by 1998 a total of 7 agents had been released in 33 countries (32). Biological control of water hyacinth has therefore become very popular, and two weevils in particular, *N. eichhorniae* and *N. bruchi*, have been used extensively and successfully in North America, Asia, Australia, and Africa.

In the long term, once the weed is under control, a natural flux between agent and weed should exist, thus

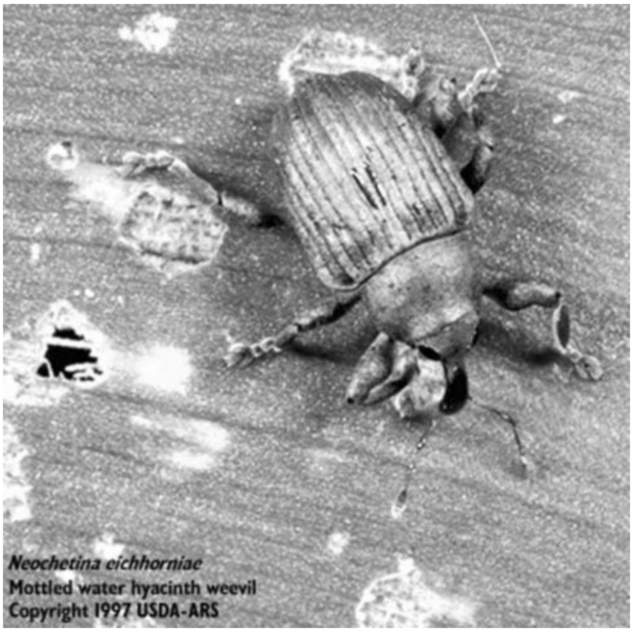

Figure 3. Biological control using the mottled water hyacinth beetle—Neochetina eichhorniae.

keeping in balance the density of weed and numbers of weevils present (33), although, as with all dynamic systems, fluctuations in both populations will occur (34). Biological control can provide an environmentally sensitive, cost-effective, and permanent solution to the problem of water hyacinth. However, the two drawbacks, assuming that host specificity is guaranteed, is that biological control usually takes between 3 to 5 years for the weevil populations to reach a level from which control can be achieved (5,25) and, moreover, it does not always work (35–37).

Overall, of most use in the control of water hyacinth is an integrated method of control. Integrated control employs all three of the above control methods in an overall management strategy. Each of the three is tailored to suit a specific problem, and the extent to which each is used varies with location. In general, however, mechanical and chemical controls are used initially to bring short-term benefits, whereas the biological approach, taking longer to implement and develop, follows after the first two control strategies (11,25). In this regard, maintaining weevil-rearing centers is an essential feature of active management to ensure that weevil populations remain at an adequate level for control.

One other type of control exists that is of key importance but yet is not mentioned as often as the above control methods—the control of nutrient inputs. The levels of available nitrogen and phosphorus have often been cited as the most important factors in limiting water hyacinth growth (38–43). Indeed, a Commonwealth Science Council survey of exotic floating weeds throughout Africa (34) recommended "that action be taken at a national and sub-regional level to reduce nutrient input (particularly from urban and industrial waste) into water bodies, and to develop land-use schemes for long-term utilisation and sustainable development of watersheds." However, in 1993, at a symposium on water hyacinth control, only three papers from 13 country and regional reports mentioned the importance of managing nutrient inputs through improved watershed management. In 1998, during a global working group on biological and integrated control of water hyacinth, in a session dedicated to integrated management, only two out of the 13 papers presented identified the importance of nutrients in controlling water hyacinth. A similar scenario was seen in 2000, at the second meeting of the global working group.

It is understandable and necessary that from within affected countries scientists and practitioners of weed control turn to mechanical, chemical, and biological means of short-term control and management. Moreover, in the short term, all biological possibilities should be vigorously explored, as appropriate insects are available and have been used elsewhere often to good effect. Yet the only real long-term solution to the water hyacinth problem is not biological control but rather the control of anthropogenic eutrophication through sustainable management of watersheds and resources. The reliance of developing nations on biological control as a long-term solution rather than sustainable management and development of their treasured resources is of major concern.

WATER QUALITY IN PONDS

Nitish Priyadarshi
Ranchi University
Ranchi, Jharkhand, India

INTRODUCTION

A pond is a body of water usually smaller than a lake, encircled by vegetation, and generally shallow enough for sunlight to reach the bottom. Rotted plants can grow in any spot within the pond. Widespread plant growth, such as pickerelweed, spatterdock, and cattails, is quite common in and around ponds and aids in creating a habitat for various forms of animal life, including insects (e.g., damselflies and dragonflies), bullfrogs, greenfrogs, red winged blackbirds, marsh wrens, and bats.

Temporary ponds, that is, ponds that are dry for part of the year, are especially interesting and support a unique community. Organisms in such ponds must be able to survive in a dormant stage during dry periods or be able to move in and out of ponds, as can amphibians and adult aquatic insects. The temporary pond is a favorable place for those organisms adapted to it because interspecific competition and predation are reduced (1).

The chemical composition of any pond water ultimately depends on those elements and compounds in solution, in suspension, and those accumulating along the pond bottom, most of which come secondarily to the ponds from runoff. Other substances are produced by chemical reactions between the different elements and/or compounds by vegetation growing in or around the ponds.

POND WATER QUALITY

Salts

Water in closed pond basins is unlike the waters of other ponds in two respects: (1) it continually experiences a change in chemical composition because (2) it continually increases its concentration of various salts, mainly due to a high evaporation rate (2). However, the increase in salts in a closed basin is not infinite. Certainly, as water flows into a dry pond basin, perhaps from the first rains of late summer or early fall, it carries the salts from rocks surrounding the lake basin and dissolves the surface salts of the playa, providing they have not been removed by deflation. As precipitation declines, generally after the early spring rains, evaporation becomes greater than inflow which then starts the inevitable process of concentration of the salts in solution. Salts concentrated in the waters of closed basins depend mainly on the rock type(s) of the surrounding basins and/or the chemical characters of any influents and, to a minor degree, on several inorganic ions in rainwater.

Pollutants

This catchall category of pollutants means anything added to the pond that is not wanted in the pond. Pollutants can consist of items that may or may not be harmful to human beings as well as fish, and they may or may not be visible. They may float on the surface, sink to the bottom, or dissolve in the water. They may come from outside the pond or from within the pond itself, for example, oil leaking from a submerged pump. Some pollutants are easy to identify and control and/or remove, such as leaves, pollen, and dead rats; some just add to the filter load if not removed but cause few other problems if not in excessive amounts, for example, bird droppings. Most harmful pollutants that dissolve in water are hard to identify or quantify. Surface water runoff that can enter the pond is often a major source of pollutants. That is why all ponds should be designed with a raised edge or at least some type of channel around them so that the surface water does not enter.

Dissolved Oxygen

Whenever air is in contact with water, whether through natural or artificial means, a transfer of oxygen from the air to the water takes place until the water becomes saturated. Plants under light convert carbon dioxide to oxygen in water. Fish, plants at night, and aerobic bacterial action consume the oxygen.

As the air components dissolve in the water, a point is reached where no more can be added. This point is called saturation. The saturation points are different for each of the gases and depend on several factors, but temperature is the most important. As the temperature increases, the water simply cannot hold as much of each type of gas. For oxygen, the approximate saturation level is 11.5 mg/L at 50 °F, 9 mg/L at 70 °F, and 7.5 mg/L at 90 °F. Impurities added to the water (i.e., salt) decrease these saturation levels.

Water whose oxygen concentration is less than 3 mg/L will not generally support fish. When the concentration falls to about 3–4 mg/L, fish start gasping for air at the surface. Levels from 3–5 mg/L can normally be tolerated for short periods. Above 5 mg/L, almost all aquatic organisms can survive indefinitely, provided other environmental parameters are within allowable limits.

Surface oxygen from 11–15 mg/L creates a highly eutrophic condition. Depletion of dissolved oxygen in pond water can encourage the microbial reduction of nitrate to nitrite and sulfate to sulfide, giving rise to odor problems. It can also cause an increase in the concentration of iron (II) in solution (3).

Color

The color of pond water depends on the depth, the color of the surrounding area and sky, the scattered light rays coming from the water, and in most cases, absorption of scattered light rays by dissolved or suspended materials.

Pond water is typically blue for pure, clear water, and various shades of blue–green to a definite green, then into the yellows and browns; the various colors are produced by the innumerable contaminants (Table 1). In general, black pond water results from high organic content, and blue pond water results from an absence of contaminating materials. The color of most pond water exists because of light scattering by vibrating water molecules blue predominates because molecular scattering is greater for shorter wavelengths.

Ammonia

Ammonia (NH_3), in parts per million (ppm), is the first measurement to determine the “health” of a biological converter. Ammonia should not be detectable in a pond that has a “healthy” bioconverter. The ideal and normal measurement of ammonia is zero. When ammonia is dissolved in water, it is partially ionized depending upon the pH and temperature. Ionized ammonia is called ammonium and is not toxic to fish. As the pH drops and the temperature decreases, ionization and ammonium increase, which decreases the toxicity. The presence of ammonia in ponds at higher than geogenic levels is an important indicator of fecal pollution (5).

Table 1. Variation in Water Color[a]

Color	Contaminants
Clear blue (pure water)	No contaminants of suspended materials; color due to molecular scattering
Bluish green	Suspension of blue-green algae, phytoplankton
Green	Colloidal $CaCO_3$ (hard water)
Yellowish green	Suspended sulfur
Greenish yellow	High plankton content, excluding humic debris
Yellow	Diatoms
Yellow brown	Diatoms-fluorescent compounds, humic acids, carboxylic acids, organic matter
Gray	*Spirostomum*
Black	Organic debris, oxidation of ferrous iron, *Stentor*
Red to orange to purple	Suspended clays, ferrous hydroxide, *Oscillataria rubescens, Euglena sanquinea, Haematococcus pluviolis, Dunaliella salina, Bacterium halobium*, purple sulfur bacteria, zooplankton.

[a] Reference 4.

Ammonia tends to block oxygen transfer from fish gills to the blood and can cause both immediate and long-term gill damage. The mucous-producing membranes can be destroyed, reducing both the external slime coat and damaging the internal intestinal surfaces. Fish suffering from ammonia poisoning usually appear sluggish, often at the surface as if gasping for air.

Ammonia is a gas primarily released from fish gills as a metabolic waste from protein breakdown and from some lesser secondary sources such as bacterial action on solid wastes and urea.

When ammonia is detected (assuming a pH of about 7.5),

1. Increase aeration to maximum. Add supplemental air if possible.
2. Stop feeding the fish if detected in an established pond.
3. For an ammonia level of 0.1 ppm, conduct a 10% water change out. For a level of 1.0 ppm, conduct a 25% change out.
4. Consider transferring fish if the ammonia level reaches 2.5 ppm.
5. Retest in 12 to 24 hours.

Nitrite

Nitrite is produced by the autotrophic *Nitrosomonas* bacteria that combine oxygen and ammonia in the bioconverter and to a lesser degree on the walls of the pond.

Nitrite has been termed the invisible killer. The pond water may look great, but nitrite cannot be seen. It can be deadly, particularly to the smaller fish, in concentrations as low as 0.25 ppm. Nitrite damages the nervous system, liver, spleen, and kidneys of fish.

Whenever 0.25 ppm of nitrite or more is detected in a pond,

1. Increase aeration to maximum. For a nitrite level of 1 ppm or greater, add supplemental air, if possible.
2. Discontinue use of any UV sterilizers and ozone generators.
3. For a nitrite level less than 1 ppm, conduct a 10% water change out, and add 1 pound of salt per hundred gallons of changed water.
4. For nitrite levels of 4.0 or greater, consider transferring fish.

Nitrate

Nitrate is produced by the autotrophic *Nitrobacter* that combine oxygen and nitrite in the bioconverter and to a lesser degree on the walls of the pond. The nitrate concentration in surface water is normally low but can reach high levels as a result of agricultural runoff, refuse dump runoff, or animal wastes. Concentrations from zero to 200 ppm are acceptable. Ammonia and nitrite are toxic to fish, but nitrate is essentially harmless.

The nitrate concentration is controlled naturally through routine water change outs and to a lesser degree through plant/algae consumption.

Temperature

The temperature of the water in a pond is seldom constant; variations depend on depth, season, and geography. Pond water is heated by absorption of solar radiation. Events generally happen faster at higher temperature and in smaller ponds. Over normal temperature ranges, biological activity doubles for each 10 °C rise in temperature. The toxicity of ammonia increases as the temperature rises, and the amount of dissolved oxygen that the water can hold decreases.

Direct sunlight during the day can cause the temperature to rise higher, and heat loss on clear nights can cause the temperature to drop lower than that of shaded ponds. A clear night sky can absorb a large amount of heat from a small pond and actually drive the pond temperature below air temperature.

Plant Nutrients and Cultural Eutrophication

Pond water clarity (transparency) is affected by sediments, chemicals, and the abundance of plankton organisms; it is a useful measure of water quality and water pollution. Ponds that have clear water and low biological productivity are said to be oligotrophic. By contrast, eutrophic waters are rich in organisms and organic materials. Eutrophication, an increase in nutrient levels and biological productivity, often accompanies successional changes in ponds. Surrounding runoffs bring in sediments and nutrients that stimulate plant growth. Over time, ponds often fill in, becoming marshes or even terrestrial biomes. The rate of eutrophication depends on water chemistry and depth, volume of inflow, mineral content of the surrounding watershed, and the biota of the pond itself (6).

Human activities can greatly accelerate eutrophication, an effect called cultural eutrophication. Cultural eutrophication is caused mainly by increased nutrient input into a waterbody. Eutrophication produces "blooms" of algae or thick growth of aquatic plants stimulated by elevated phosphorus or nitrogen levels (Fig. 1). Bacterial populations then increase, fed by larger amounts of organic matter. The water often becomes cloudy or turbid and has unpleasant tastes and odors. Cultural eutrophication can accelerate the "aging" of a waterbody enormously over natural rates. Ponds that normally might exist for hundreds of years can be filled in a matter of decades.

pH

The pH of water is a measure of the acid–base equilibrium and, in most natural waters, is controlled by the carbon dioxide–bicarbonate–carbonate equilibrium. An increased carbon dioxide concentration in pond water will therefore lower pH, whereas a decrease causes it to rise. Temperature also affects the equilibria and the pH. In pure water, a decrease in pH of about 0.45 occurs as the temperature is raised by 25 °C.

A pH measurement helps to determine if water is suitable for fish. The pH should normally be between 7.0 and 8.5; it is probably acceptable if it is anywhere between 6.0 and 9.0. Although most fish could tolerate a pH as low as 5.0, bioconverter bacteria are subject to damage. Long-term conditions above pH 9.0 can cause kidney damage to some fish.

A sudden change of a half or more pH unit in an established pond is an indication that something happened, and the cause should be determined. An increasing pH trend in a pond is normally caused by lime leaching out of concrete and to a lesser degree by concentration due to evaporation and decomposing organic matter. Decreasing pH is due primarily to bacterial action that releases acidic compounds. Established ponds normally maintain their equilibrium pH if sludge and decaying organic material are routinely removed. Scheduled water change outs (10% per week for small pond, less for larger ponds) are also helpful. At pH extremes approaching 4 or 11, remove any remaining fish.

Figure 1. Eutrophic pond. Nutrients from agriculture and domestic sources have stimulated the growth of aquatic plants. This reduces water quality, alters species composition, and lowers the pond's aesthetic values.

Saprotrophic Organisms

Aquatic bacteria, flagellates, and fungi are distributed throughout a pond, but they are especially abundant in the mud–water interface along the bottom where bodies of plants and animals accumulate. A few of the bacteria and fungi are pathogenetic, attack living organisms, and cause disease, but the great majority begins attack only after an organism dies. When temperature conditions are favorable, decomposition occurs rapidly in a body of water; dead organisms do not retain their identification for very long but are soon broken up into pieces, consumed by the combined action of detritus-feeding animals and microorganisms, and their nutrients are released for reuse (1).

WATER TURBINE

Xing Fang
Lamar University
Beaumont, Texas

Water turbine, also called a hydraulic turbine, is a rotary machine that converts the power of flowing water into usable electronic or mechanical power. The word *turbine* is derived from the Latin word for "whirling" or a "vortex". Water turbines were developed in the nineteenth century during the Industrial Revolution, using scientific principals and methods, for industrial power. Now they are mostly used for hydropower generation, which typically requires a construction of a dam to form a reservoir. They are one of the cleanest producers of power, replacing the burning of fossil fuels and eliminating nuclear waste. They use a renewable energy source and are designed to operate for decades. They produce significant amounts of the world's electrical supply. On the other hand, there are some negative consequences; by their nature, water

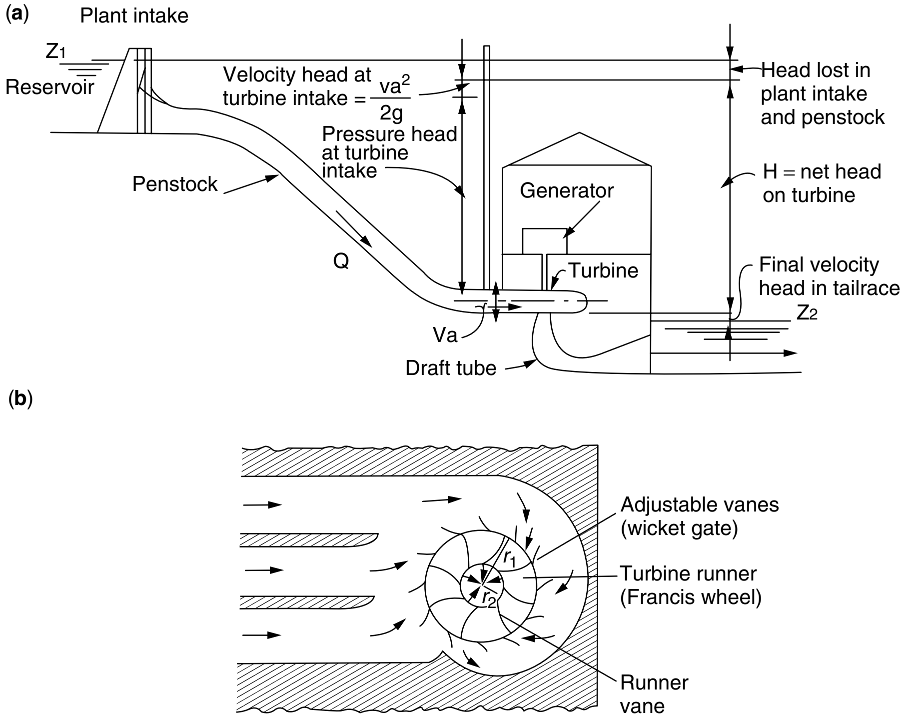

Figure 1. Hydropower arrangement for reaction turbine. (**a**) Hydropower arrangement from upstream reservoir to downstream river. (**b**) Plane view of reaction turbine installation.

turbines interrupt the natural ecology of rivers, stopping migrations of fishing.

A water turbine is usually connected to an elevated reservoir (Fig. 1) through large pipe (penstock), which transfers potential energy of water into kinetic energy. Total hydraulic head (H) available for a turbine is equal to the elevation difference of water surfaces between upstream reservoir (Z_1) and downstream river (Z_2) minus any friction and local energy losses (HL) though penstock, inlet, and turbine system. The electric power generated by a water turbine is

$$P = \frac{\gamma Q H \eta}{1000} = \frac{\gamma Q (Z_1 - Z_2 - HL)\eta}{1000} \text{ (SI units)}$$
$$P = \frac{\gamma Q H \eta}{550} \text{ (English units)} \tag{1}$$

where η is the turbine efficiency and P is the electric power in kilowatts for SI units and in horsepower for English units. Large industrial water turbines typically operate at efficiencies greater than 90%, which is much higher than overall efficiency of thermal power generation (on the order of 30%). From Equation 1, it indicates that decrease of energy losses in penstock and inlets results in an increase of power generation by a turbine. Power generation depends on elevation differences of water surface in upstream reservoir and downstream river, which fluctuate over season and over year. Water turbines can run continuously to provide electricity generation but typically vary power output over a season. Water turbine system can be relatively easy to turn on and turn off in comparison a with a thermal or nuclear power system; therefore, some of water turbines only provide electricity during high-power demand periods (e.g., during the day). When the power network has extra power during night, e.g., developed by thermal and nuclear power plants, extra power can pump water from a downstream reservoir to an upstream reservoir and can be used for future power generation. A pump turbine is used for the above purpose and is a hydraulic machine that operates as a pump in one mode of operation and as a turbine in a different mode. A turbine and generator can supply power under varying load demands at a constant rotational speed by adjusting control wicket gates (Fig. 1), but overall efficiency and performance of turbine will vary somewhat with the gate opening.

Water turbines are divided into two groups: impulse turbines and reaction turbines, according to their hydraulics action. Impulse turbines are the modern forms of water wheels that have been used for thousands of years for industrial power. The impulse turbine is typically used for high-head hydropower installation (e.g., $H > 1500$ ft) but for relative small discharge. In the impulse turbine, jets of water issuing from one or several nozzles impinge on vanes (buckets) of the turbine wheel (also called runner), which reverses the flow of water, and the resulting change in momentum (impulse) causes the turbine to spin. A nozzle in reducing flow area is to create a high speed of water jet (V_j). The fluid momentum equation can determine what forces can be developed on buckets because of a water jet. When the speed of turbine runner is half of the speed of water jet, the optimum power is developed by an impulse turbine:

$$P = \gamma Q \left(\frac{V_j^2}{2g}\right) \tag{2}$$

Reaction turbines are typically used for low-head (1–100 ft) and medium-head (90–1500 ft) hydropower plants with moderate-to-high discharges. For reaction turbines, only part of the available head (H) is converted into kinetic energy, and a substantial part remains as a pressure head that varies throughout the turbine water passage. Reaction turbines include radial-flow Francis turbines for medium-head and axial-flow Kaplan turbines with or without adjustable runner blades for low-head hydropower plants. In 1849, James B. Francis conducted sophisticated tests, developed engineering methods for water turbine design, and improved the efficiency of reaction turbine to over 90%. The Francis turbine, named for him, was the first modern water turbine. It is still the most widely used water turbine in the world today. The Kaplan turbine, a propeller type machine, was invented around 1913 by Victor Kaplan. It was an evolution of the Francis turbine, but it revolutionized the ability to develop low-head hydropower plants. S-type and bulb turbines are other axial flow reaction turbines used for tidal rivers or estuaries that have only several feet of water surface elevation differences. They can generate electric power for tidal flow in two different flow directions.

As the swirling mass of water spins into a tighter rotation of a reaction turbine, it tries to speed up to conserve energy. This property acts on the runner; in addition to the water's falling weight, water pressure decreases to zero as it passes through turbine blades and gives up its energy to make the turbine runner to rotate continuously. Francis turbines have fixed runner blades and use a series of adjustable wicket gates (Fig. 1) to control flow into turbine runner to achieve high efficiency under various flow rate and available head conditions. Flow for the Francis turbine enters the runner in a radial direction, whereas flow of the Kaplan turbine enters the runner in a direction parallel to the turbine's rotational axis. A Kaplan turbine can have adjustable blades for its runner to improve turbine efficiency.

The specific speed (n_s or N_s) of a turbine characterizes the turbine's shape and performance in a way that is not related to its size, which allows a new turbine design to be scaled from an existing design of known performance. The specific speed is the main criteria to select the correct turbine type for matching a specific hydropower development.

$$n_s = \frac{nQ^{1/2}}{g^{3/4}H^{3/4}} \quad \text{or} \quad N_s = \frac{NP^{1/2}}{H^{5/4}} \tag{3}$$

The specific speed n_s is a dimensionless parameter; n is the rotational speed of turbine runner in rps (revolution per second), Q is the discharge passing through turbine in ft^3/s or m^3/s, H is the available head in ft or m, and g is the acceleration of gravity as 32.2 ft/s^2 or 9.81 m/s^2. The specific speed N_s requires N in rpm (revolution per minute), P in horsepower, and H in feet. The specific speed of a turbine is given by the manufacturer (along with other ratings) and will always refer to the point of maximum efficiency. These allow accurate calculations to be made of the turbine's performance for a range of heads and flows. Given a flow and a head for a specific hydropower development site, and the rpm requirement of the generator, one can calculate the specific speed. The result is the main criterion for turbine selection; e.g., impulse turbines have N_s less than 20; Francis turbines have N_s about from15 to 85; and Kaplan turbines have N_s about from 65 to 195 (1).

What should be the diameter of a turbine runner (D)? It is dependent on the turbine's speed ratio ϕ:

$$D = \frac{60 \times \phi\sqrt{2gH}}{\pi N} \quad \text{or} \quad \phi = \frac{u}{\sqrt{2gH}} = \frac{\pi DN/60}{\sqrt{2gH}}$$

where u is the linear rotational speed of a turbine runner and N is the rotational speed in rpm. For a 60-cycle frequency, N is equal to 7200 divided by the number of poles (n) in the generator, which must be an even number. In Europe and South America, where the frequency is 50 cycles/second, the speed N is given as 6000/n. The ranges of speed ratios for maximum efficiency for the different types of turbines are 0.43–0.47 for impulse turbine, 0.5–1.0 for Francis turbine, and 1.5–3.0 for Kaplan propeller turbine.

Turbines and pumps are susceptible to cavitation. Cavitation can damage the turbine runner and affect turbine performance. The region of a turbine where cavitations are most likely to occur is on the downstream side of the turbine impeller blades. The cavitation index (σ) can evaluate the possibility of turbine cavitation:

$$\sigma = \frac{(P_{atm} - P_v)/\gamma - (Z_t - Z_2)}{H}$$

where P_{atm} and P_v are the local absolute atmospheric pressure and vapor pressure of water and Z_t and Z_2 (Fig. 1) are elevations of the downstream side of the turbine runner and tailwater. Lower values of σ indicate a greater tendency for cavitation. The critical sigma (σ_c) for different types of turbines are obtained experimentally and typically provided by turbine manufacturers. When σ is greater than σ_c, there is no cavitation; otherwise cavitation is highly possible.

WETLANDS: USES, FUNCTIONS, AND VALUES

Matthew P. McCartney
International Water
Management Institute
Pretoria, South Africa

Throughout history, wetlands have played an important role in human development. They have brought benefits, but also caused difficulties for people. Their perceived value to society has varied from place to place and has changed over time.

In many arid and semiarid regions of the world, societies have flourished because of the water and other resources provided by wetlands. Many of the great civilizations of history have benefited from wetlands. For example, the Maya, Inca, and Aztec civilizations in Latin America; the Khmer civilization of Angkor in the lower basin of the Mekong; and the civilizations of the Nile, Niger, and Mesopotamia were all dependent on wetland resources. In contrast, in wetter parts of the world, wetlands were for many centuries widely thought of as unproductive wastelands often associated with disease, difficulty of access, and danger. In East Anglia in the United Kingdom, poor drainage within an area of approximately 3,870 km^2 of fens meant serious delays in sowing crops and loss of harvests because of flash floods. Furthermore, illnesses and epidemics were believed to originate in the bad air ("miasmas") of swamps and bogs. A common perception was that wetlands were "awful reservoirs of stagnated water, which poisons the circumambient air for many miles around about and sickens and frequently destroys many of the inhabitants" (1).

In Europe, land drainage schemes were initiated as early as the thirteenth century to dry out wetlands and improve their agricultural productivity. Major drainage schemes in Britain in the seventeenth century converted thousands of square kilometers of fens and marsh into, what is today, some of the most productive farmland in the country (2). Similar schemes were implemented across Europe and elsewhere in the world. During the twentieth century, technological advances coupled with greater intensity of agriculture, as well as urban and industrial development, increased the pace of change. Alteration in the water balance and the quality of water entering wetlands can result in desiccation and degradation of wetland habitat. Although very difficult to quantify, it is estimated that globally more than half of all wetlands have been destroyed as a consequence of human activities (3).

In recent years, it has been realized that wetlands are valuable ecosystems. It is now understood that they maintain environmental quality, sustain livelihoods, support immense biodiversity, and have important recreational and aesthetic qualities.

Wetlands continue to play an important role in sustaining the livelihoods of many millions of people, particularly in Africa and Asia. For example, the valley bottom wetlands in Africa are of major importance in agricultural systems. Saturated during the wet season, they remain wet into the dry season effectively extending the growing season. As a result, these wetlands act as a key resource for cultivators and pastoralists by providing a source of arable land or grazing throughout the dry season and during droughts. Similarly, in Bangladesh, many thousands of cattle that graze on floodplains during the dry season are watered from perennially flooded areas known locally as *beels*.

Insight into their value has led to a radical change in attitude toward wetlands and has been the primary reason for a range of national and international conservation policies. Throughout Europe, the United States, and many other countries, considerable efforts are now being made to protect and even recreate wetlands (4).

WETLAND FUNCTIONS

Wetlands are among the most productive ecosystems in the world, characterized by high primary productivity and a multiplicity of habitats that enables them to support a large diversity of life. The wide range of natural phenomena that occur within wetlands makes them valuable in socioeconomic as well as ecological terms.

Wetland values arise from the ecological functions they perform. Ecological functions are the result of the physical, chemical, and biological processes that occur through the interaction of the biotic (i.e., flora and fauna) and abiotic (i.e., soil and water) components that comprise an ecosystem. The exact nature of the functions is unique to any particular wetland and depends on site-specific factors, including climate, geology, topography, and the wetland's location within a catchment. However, it is now recognized that biodiversity per se, plays an important role in maintaining wetland processes (e.g., condensation and evapotranspiration) across a range of temporal and spatial scales (5).

Not all wetland functions are useful to people. Some are harmful. For example, provision of habitat for mosquitoes and other insects that transmit illnesses is a function of many wetlands that throughout history has resulted in incalculable human suffering. However, many wetland functions do enhance human well-being, and it is now widely accepted that, overall, the advantages of wetlands outweigh their disadvantages.

The *physical* benefits human populations derive from wetlands comprise "goods" and "services." Goods are the natural resources that occur within a wetland and can be exploited by people. Examples include plants and wildlife used for food, trees and reeds used for construction materials, and vegetation used for medicine. Services are the nonresource benefits that people gain from the interaction of wetland processes. Examples include hydrologic, water quality, and geomorphological functions, such as flood reduction, nutrient transformation, and sediment retention. A summary of some of the physical benefits that human societies gain from wetland functions is presented in Table 1.

The high productivity of wetland ecosystems is reflected in the high human populations that they can support. In Africa and Asia, hundreds of millions of people depend on wetlands for water, rice, fish, shrimp, and other food production. In many tropical wetlands, fisheries production is extremely high. The lower Mekong Basin supports an inland fishery whose annual yield is approximately 500,000 tons, and in Indonesia, half the commercial fish catch comprises species dependent on estuarine wetland systems (6). The freshwater and estuarine wetlands of the Nile, Congo, Rifiji, Tana, Niger, and Zambezi river catchments in Africa each sustain the livelihoods of many hundreds of thousands of people by providing fisheries; dry season grazing for cattle; water for domestic use; and agriculture and plants for traditional medicines, mat production, and firewood. Similarly the great riverine and floodplain systems of South and Central America support large numbers of subsistence and commercial fisheries. It is estimated that 75% of the commercial fish catch of the Amazon River depends on food chains originating in seasonally flooded forest wetlands (6).

Table 1. Examples of Wetland Functions that Benefit Human Populations

Wetland Function	Use by Society	Examples
• Storage of precipitation and runoff	• Water supply	• In Florida, U.S., approximately 5 million people, including many in the city of Miami are supplied with water from the wetlands of the Florida Everglades. • 10,000 people living in the vicinity of Laguna El Jocotal, a shallow floodplain lake in El Salvador, depend on the lake for their dry season water supply.
	• Flood protection	• A flood prevention value of about US$13,500 per hectare per year has been attributed to wetlands in the Charles River catchment in Massachusetts, U.S.
	• Agriculture	• In West Africa, the shallow groundwater and elevated soil moisture of about 5 million hectares of inland valley wetlands are used extensively in crop cultivation.
• Groundwater discharge	• Water supply	• 8% of the discharge of the Mzima springs in Tsavo National Park, Kenya, is diverted to supply the coastal city of Mombasa.
• Groundwater recharge	• Water supply	• The Hadejia–Nguru wetlands in Nigeria contribute to the recharge of an aquifer used for water supply by approximately 1 million people who live in the region. • Gravels underlying riverine forest wetlands adjacent to the Danube supply a large proportion of the water to the 1.6 million people of Vienna, Austria.
• Sediment retention	• Shoreline protection	• The mangroves of the Indus delta protect the coastline from wind and currents and shelter Port Qasim, Pakistan's second largest port.
• Nutrient transformation	• Wastewater treatment	• 12,000 hectares of wetland to the east of Calcutta, India, are used to treat approximately 68 million liters of sewage each day. In 10 days, it is transformed into "sweet water" suitable for irrigation.
	• Protection of water resources	• A riparian wetland system on the River Lambourn, UK, removed up to 85% of the nutrients in agricultural runoff before it reached the river.
• Biomass production (e.g., wood, grass, fish)	• Food	• Local people use the fruits, seeds, tubers, roots, and leaves of around 200 plants from the wetlands surrounding Lake Chilwa in Malawi. • The wetlands of the Kafue floodplain in Zambia support fisheries averaging 6,500 tons per year.
	• Building and construction materials	• In Matang Forest Reserve, Malaysia, 40,000 hectares of mangroves annually yield timber worth US$9 million.
• Maintenance of biodiversity	• Medicine	• The St. Regis Mohawk tribe in the United States uses some 85 wetland plants for medicine, including *Acorus calamus* used for chills, fevers, and coughs and *Lobelia cardinalis* used as a blood purifier. • In Peninsular Malaysia, the sale of medicinal plants originating in wetlands can earn households up to US$ 80 per month.
• Chemical cycling	• Gas regulation	• Wetlands are important in the biogeochemical cycling of carbon dioxide, methane, and hydrogen sulfide. • Globally, wetland peat deposits occupy just 3% of the world's land area but store 16–24% of the planet's soil carbon pool.

Some wetlands play an important role in maintaining or improving water quality. The large number of chemical and biological processes that take place within wetlands (including nitrification, denitrification, ammonification, and volatilization) may convert heavy metals to insoluble forms and remove nutrients from the water. In Uganda, the Nakivubo papyrus swamp receives semitreated effluent from the sewage works of the capital city, Kampala. During the passage of the effluent through the wetland, the papyrus vegetation absorbs nutrients and the concentration of pollutants is reduced before the water enters Lake Victoria, the principal water source for the city (7). In Malaysia, the North Selangor peat swamp protects the quality of water used for water supply and irrigation by promoting sedimentation, nutrient uptake, toxic metal removal, and pH buffering (8).

People also gain *nonphysical* benefits from wetland functions. These are associated with spiritual enrichment, cognitive development, and aesthetic experience. For example, the culture of the Lozi people in western Zambia has developed as a consequence of the hydrologic dynamics of the Barotse floodplain. Each year, cultural ceremonies are conducted when the people move out of the floodplain during periods of high water and back again when water levels fall. Such ceremonies are important in enhancing the social cohesiveness of communities. Elsewhere, wetlands such as the Florida Everglades in the United States, the Okavango Delta in Botswana and the Caroni Swamp in Trinidad are major tourist attractions, not only enriching the lives of visitors, but also generating income for others.

Wetlands support a rich diversity of flora and fauna. Some animals live permanently in wetlands (e.g., the manatee, swamp tortoise, and lechwe antelope); others use them as refuges and migrate to them when conditions of drought or food scarcity exist elsewhere or at particular stages of their life cycle. Wetlands are especially important for migratory birds. Of the 300 species of birds that migrate between Europe and Africa each year, a large number depend on wetland habitats to support them enroute. The Patanal wetland in South America provides habitat for some 865 species of birds, and the Okavango Delta and Kafue Flats in Africa each support 400 species. It is estimated that the Inner Delta of the Niger Delta hosts up to 1.5 million birds each year (9). The beauty and naturalness of what are perceived to be pristine and increasingly rare ecosystems, and the variety of wildlife that they support, are important and of value to increasing numbers of people worldwide.

Hence, wetlands bring a wide variety of both tangible and intangible benefits to a huge number of people. The way in which they do so is complex, multifunctional, and very often not obvious. Many groups of people benefit from wetlands, and very often the benefits are experienced far beyond the boundaries of the wetland itself. Many wetland contributions to human welfare accrue without people being aware of them. As a consequence, wetland functions have in the past often gone unrecognized in development and resource planning and management.

WETLAND VALUES

The values attributed to wetlands depend largely on social perceptions of the uses and the benefits to be gained from them. The view that wetlands are wastelands arose in countries where agricultural productivity is not usually limited by water scarcity, at a time when rapidly rising populations required increased food production and there was very little understanding of the benefits provided by wetlands.

Today, in the developed countries of the world, the situation is very different. The ecosystems that people most depend on are those in which the functions, composition, and structure are far removed from natural systems. High levels of social and economic security have been obtained through application of complex technologies and considerable alteration of natural ecosystems, including wetlands.

These societies are now sufficiently prosperous that they can contemplate a large number of options in the way that they manage ecosystems, and paradoxically, many of them are now placing very high value on the aesthetic quality and biodiversity functions of their remaining wetlands.

In contrast, many millions of people in much of the developing world remain directly dependent on ecosystems that are in a much more natural state. For many individuals, wetland functions provide the most important contributions to their livelihoods and welfare by providing food supplies, medicines, income, employment, and cultural integrity. Such communities often have limited alternative livelihood options, and this makes them particularly vulnerable to changes in the condition of the natural environment on which they depend.

As a consequence of these different perspectives, wetland values were, until recently, very different. In the developed world, the primary focus was on conservation of wetland “wilderness” for recreation and to maintain wildlife habitat, especially for waterfowl. In much of the developing world, the emphasis was on the utility of wetlands, in particular their role in food production and livelihood support. However, there is now a widespread convergence of views brought about by the realization of two factors. First, that although the natural resources they provide may not be as important in the developed world, wetlands, nevertheless, support or protect a wide range of economic activities: for example, through their role in flood reduction and water purification; second, that social and economic factors are the main reasons for wetland loss; poverty and environmental degradation are inextricably intertwined. Consequently, sustainable development is a prerequisite for successful conservation.

This convergence of views is reflected in the widely promulgated “wise use” policy of the Convention on Wetlands of International Importance especially as Waterfowl Habitat—commonly referred to as the Ramsar Convention. This states that “the wise use of wetlands is their sustainable utilisation for the benefit of humankind in a way compatible with the maintenance of the natural properties of the ecosystem” (10). Explicit in the guidelines of the Ramsar Convention is the need to identify the values that local people, who use wetlands directly, can bring to all aspects of wetland wise use.

The site-specific nature and diversity of wetland functions makes quantification of wetland values extremely difficult. However, the wise use of wetlands requires a way of comparing the various benefits and consequences of development options on wetland functions. Traditionally, valuation techniques were strictly financial. However, it is impossible to assess all the issues relevant to wetlands using money as the sole determinant in the assessment process. Consequently, in recent years, economists have developed a number of environmental valuation techniques that enable assessment of nonmonetary impacts (11). Such methods, for example, multicriteria analysis, enable assessment of nonmonetary values and are being increasingly used to evaluate alternatives in wetland management.

Management of environmental resources, including wetlands, will be a key human endeavor in the twenty-first century. The biotic impoverishment and disruption of wetland functions caused by past decisions and continuing mismanagement severely constrain the options for future management. If the benefits wetlands bring are to be used more wisely in the future, there is need for much greater insight into the dynamics of wetland functions and the links between wetlands and human society. Only through such understanding will the true value of wetlands be determined.

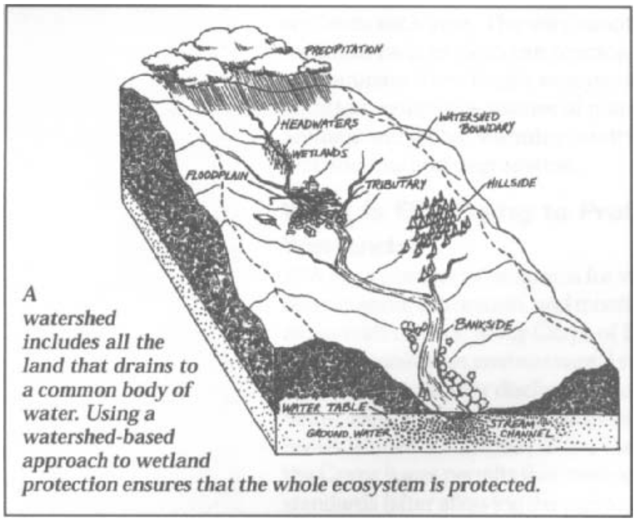
WETLANDS OVERVIEW

U.S. Environmental Protection
Agency—Office of Water, Office
of Wetlands, Oceans
and Watersheds

WHAT IS A WETLAND?

Although wetlands are often wet, a wetland might not be wet year-round. In fact, some of the most important wetlands are only seasonally wet. Wetlands are the link between the land and the water. They are transition zones where the flow of water, the cycling of nutrients, and the energy of the sun meet to produce a unique ecosystem characterized by hydrology, soils, and vegetation—making these areas very important features of a watershed. Using a watershed-based approach to wetland protection ensures that the whole system, including land, air, and water resources, is protected.



A watershed includes all the land that drains to a common body of water. Using a watershed-based approach to wetland protection ensures that the whole ecosystem is protected.

Wetlands found in the United States fall into four general categories—marshes, swamps, bogs, and fens. Marshes are wetlands dominated by soft-stemmed vegetation, while swamps have mostly woody plants. Bogs are freshwater wetlands, often formed in old glacial lakes, characterized by spongy peat deposits, evergreen trees and shrubs, and a floor covered by a thick carpet of sphagnum moss. Fens are freshwater peat-forming wetlands covered mostly by grasses, sedges, reeds, and wildflowers.

GOOD NEWS

Often called "nurseries of life," wetlands provide habitat for thousands of species of both aquatic and terrestrial plants and animals. These nurseries support the critical

---

Two-thirds of the 10 million to 12 million waterfowl of the continental United States reproduce in the prairie pothole wetlands of the Midwest, and in the winter millions of ducks like these can be found in the wetlands of the south-central United States

developmental stages for many plants and animals. Although wetlands are best known for being home to water lilies, turtles, frogs, snakes, alligators, and crocodiles, they also provide important habitat for waterfowl, fish, and mammals. Migrating birds use wetlands to rest and feed during their cross-continental journeys and as nesting sites when they are at home. As a result, wetland loss has a serious impact on these species. Habitat degradation since the 1970s has been a leading cause of species extinction.

> Living systems cleanse water and make it fit, among other things, for human consumption.
>
> *Elliot A. Norse*,
> in R.J. Hoage, ed.,
> Animal Extinctions, *1985*

> The nation behaves well if it treats the natural resources as assets which it must turn over to the next generation increased, and not impaired, in value.
>
> Theodore Roosevelt, 1907

Wetlands do more than provide habitat for plants and animals in the watershed. When rivers overflow, wetlands help to absorb and slow floodwaters. This ability to control floods can significantly prevent property damage and loss and can even save lives. Wetlands also absorb excess nutrients, sediment, and other pollutants before they reach rivers, lakes, and other waterbodies. They are great spots for fishing, canoeing, hiking, and bird-watching, and they make wonderful outdoor classrooms for people of all ages.

BAD NEWS

Despite all the benefits provided by wetlands, the United States loses about 60,000 acres of wetlands each year. The very runoff that wetlands help to clean can overload and contaminate these fragile ecosystems. In addition, nonnative species of plants and animals and global warming contribute to wetland loss and degradation.

WHAT IS EPA DOING TO PROTECT WETLANDS?

EPA has a number of programs for wetland conservation, restoration, and monitoring. EPA, along with the U.S. Army Corps of Engineers (Corps), establishes environmental standards for reviewing permits for discharges that affect wetlands, such as residential development, roads, and levees. Under Section 404 of the Clean Water Act, the Corps issues permits that meet environmental standards (after allowing the public to comment).

WORKING TOGETHER TO PROTECT AND RESTORE WETLANDS

In addition to providing regulatory protection for wetlands, EPA works in partnership with states, tribes, and local governments, the private sector, and citizen organizations to monitor, protect, and restore these valuable habitats. EPA is helping states and tribes incorporate wetland monitoring, protection, and restoration into their watershed plans. EPA is also working to develop national guidance on wetland restoration, as well as constructed wetlands used to treat storm water and sewage. Nationally, EPA's Five-Star Restoration Program provides grants and promotes information exchange through community-based education and restoration projects.

Wetland habitat along this Idaho riparian corridor provides food and shelter for many different wildlife species

EPA works with a variety of other federal agencies to protect and restore wetlands, including the U.S. Fish and Wildlife Service, the U.S. Department of Agriculture, and the National Marine Fisheries Service. EPA is working with these agencies and others to achieve a net increase of 100,000 acres of wetlands each year by 2005. EPA also partners with private interests and public organizations like the Association of State Wetland Managers, the National Association of Counties, the Izaak Walton League, local watershed associations, schools, and universities to advance conservation and restoration programs.

If bottomland hardwood swamps are protected, Bald Cypress trees like these can grow for more than 2000 years.

HOW CAN I HELP?

You can do many things to help protect wetlands in your area. First, identify your watershed and find the wetlands in your neighborhood. Learn more about them and share what you learn with someone you know! Encourage neighbors, developers, and state and local governments to protect the functions and values of wetlands in your watershed.

To prevent wetland loss or degradation, follow these simple guidelines:

- Invest in wetlands by buying duck stamps. Proceeds from these $15 migratory bird hunting stamps support wetland acquisition and restoration. The stamps are available on-line at the U.S. Fish and Wildlife Service's web site (www.fws.gov) or at your local post office.
- Rather than draining or filling wetlands, find more compatible uses that would not damage the wetlands, such as waterfowl and wildlife habitat.
- When developing your landscaping plan, keep wetlands in mind. Plant native grasses or forested buffer strips along wetlands on your property to protect water quality.

- "Get into" your wetland by participating in a volunteer monitoring program.
- Plan to avoid wetlands when developing or improving a site. Get technical assistance from your state environmental agency before you alter a wetland.
- Maintain wetlands and adjacent buffer strips as open space.
- Support your local watershed association.
- Plan a wetland program or invite a wetland expert to speak at your school, club, youth group, or professional organization.
- Build a wetland in your backyard. Learn how by visiting the U.S. Department of Agriculture's web site at www.nrcs.usda.gov/feature/backyard.

Wetlands can be found in every county and climatic zone in the United States.

CLASSIFICATION OF WETLANDS AND DEEPWATER HABITATS OF THE UNITED STATES

Lewis M. Cowardin
Virginia Carter
Francis C. Golet
Edward T. Laroe
U.S. Department of the Interior

USE OF THE CLASSIFICATION SYSTEM

This System was designed for use over an extremely wide geographic area and for use by individuals and organizations with varied interests and objectives. The classification employs 5 System names, 8 Subsystem names, 11 Class names, 28 Subclass names, and an unspecified number of Dominance Types. It is, of necessity, a complex System when viewed in its entirety, but use of the System for a specific purpose at a local site should be simple and straightforward. Artificial keys to the Systems and Classes (Appendix E) are furnished to aid the user of the classification, but reference to detailed definitions in the text is also required. The purpose of this section is to illustrate how the System should be used and some of the potential pitfalls that could lead to its misuse.

Before attempting to apply the System, the user should consider four important points:

(1) Information about the area to be classified must be available before the System can be applied. This information may be in the form of historical data, aerial photographs, brief on-site inspection, or detailed and intensive studies. The System is designed for use at varying degrees of detail. There are few areas for which sufficient information is available to allow the most detailed application of the System. If the level of detail provided by the data is not sufficient for the needs of the user, additional data gathering is mandatory.

(2) Below the level of Class, the System is open-ended and incomplete. We give only examples of the vast number of Dominance Types that occur. The user may identify additional Dominance Types and determine where these fit into the classification hierarchy. It is also probable that as the System is used the need for additional Subclasses will become apparent.

(3) One of the main purposes of the new classification is to ensure uniformity throughout the United States. It is important that the user pay particular attention to the definitions in the classification. Any attempt at modification of these definitions will lead to lack of uniformity in application.

(4) One of the principal uses of the classification system will be the inventory and mapping of wetlands and deepwater habitats. A classification used in the mapping is scale-specific, both for the minimum size of units mapped and for the degree of detail attainable. It is necessary for the user to develop a specific set of mapping conventions for each application and to demonstrate their relationship to the generalized classification described here. For example, there are a number of possible mapping conventions for a small wetland basin 50 m (164 feet) in diameter with concentric rings of vegetation about the deepest zone. At a scale of 1:500 each zone may be classified and mapped; at 1:20,000 it might be necessary to map the entire basin as one zone and ignore the peripheral bands; and at 1:100,000 the entire wetland basin may be smaller than the smallest mappable unit, and such a small-scale map is seldom adequate for a detailed inventory and must be supplemented by information gathered by sampling. In other areas, it may be necessary to develop mapping conventions for taxa that cannot be easily recognized; for instance, Aquatic Beds in turbid waters may have to be mapped simply as Unconsolidated Bottom.

HIERARCHICAL LEVELS AND MODIFIERS

We have designed the various levels of the system for specific purposes, and the relative importance of each will vary among users. The Systems and Subsystems are most important in applications involving large regions or the entire country. They serve to organize the Classes into meaningful assemblages of information for data storage and retrieval.

The Classes and Subclasses are the most important part of the system for many users and are basic to wetland mapping. Most Classes should be easily recognizable by users in a wide variety of disciplines. However, the Class designations apply to average conditions over a period of years, and since many wetlands are dynamic and subject to rapid changes in appearance, the proper classification of a wetland will frequently require data that span a period of years and several seasons in each of those years.

The Dominance Type is most important to users interested in detailed regional studies. It may be necessary to identify Dominance Types in order to determine which modifying terms are appropriate, because plants and animals present in an area tend to reflect environmental conditions over a period of time. Water regime can be determined from long-term hydrologic studies where these are available. The more common procedure will be to estimate this characteristic from the Dominance Types. Several studies have related water regimes to the presence and distribution of plants or animals (e.g., Stephenson and Stephenson 1972; Stewart and Kantrud 1972; Chapman 1974).

Similarly, we do not intend that salinity measurements be made for all wetlands except where these data are required; often plant species or associations can be used to indicate broad salinity classes. Lists of halophytes have been prepared for both coastal and inland areas (e.g., Duncan 1974; MacDonald and Barbour 1974; Ungar 1974), and a number of floristic and ecological studies have described plants that are indicators of salinity (e.g., Penfound and Hathaway 1938; Moyle 1945; Kurz and Wagner 1957; Dillon 1966; Anderson et al. 1968; Chabreck 1972; Stewart and Kantrud 1972; Ungar 1974).

In areas where the Dominance Types to be expected under different water regimes and types of water chemistry conditions have not been identified, detailed regional studies will be required before the classification can be applied in detail. In areas where detailed soil maps are available, it is also possible to infer water regime and water chemistry from soil series (U.S. Soil Conservation Service, Soil Survey Staff 1975).

Some of the Modifiers are an integral part of this system and their use is essential; others are used only for detailed applications or for special cases. Modifiers are never used with Systems and Subsystems; however, at least one Water Regime Modifier, one Water Chemistry Modifier, and one Soil Modifier must be used at all lower levels in the hierarchy. Use of the Modifiers listed under mixosaline and mixohaline (Table 1) is optional but these finer categories should be used whenever supporting data are available. The user is urged not to rely on single observations of water regime or water chemistry. Such measurements give misleading results in all but the most stable wetlands. If a more detailed Soil Modifier, such as soil order or suborder (U.S. Soil Conservation Service, Soil Survey Staff 1975) can be obtained, it should be used in place of the Modifiers, mineral and organic. Special Modifiers are used where appropriate.

RELATIONSHIP TO OTHER WETLAND CLASSIFICATIONS

There are numerous wetland classifications in use in the United States. Here we relate this system to three published classifications that have gained widespread acceptance. It is not possible to equate these systems directly for several reasons: (1) the criteria selected for establishing categories differ; (2) some of the classifications are not applied consistently in different parts of the country; and (3) the elements classified are not the same in various classifications.

The most widely used classification system in the United States is that of Martin et al. (1953) which was republished in U.S. Fish and Wildlife Service *Circular 39* (Shaw and Fredine 1956). The wetland types are based on criteria such as water depth and permanence, water chemistry, life form of vegetation, and dominant plant species. In Table 4 we compare some of the major components of our system with the type descriptions listed in *Circular 39*.

In response to the need for more detailed wetland classification in the glaciated Northeast, Golet and Larson (1974) refined the freshwater wetland types of *Circular 39* by writing more detailed descriptions and subdividing classes on the basis of finer differences in plant life forms. Golet and Larson's classes are roughly equivalent to Types 1–8 of *Circular 39*, except that they restrict Type 1 to river floodplains. The Golet and Larson system does not recognize the coastal (tidal) fresh wetlands of *Circular 39* (Types 12–14) as a separate category, but classifies these areas in the same manner as nontidal wetlands. In addition to devising 24 subclasses, they also created 5 size categories, 6 site types giving a wetland's hydrologic and topographic location; 8 cover types (modified from Stewart and Kantrud 1971) expressing the distribution and relative proportions of cover and water; 3 vegetative interspersion types; and 6 surrounding habitat types. Since this system is based on the classes of Martin et al. (1953), Table 4 may also be used to compare the Golet and Larson system with the one described here. Although our system does not include size categories and site types, this information will be available from the results of the new inventory of wetlands and deepwater habitats of the United States.

Stewart and Kantrud (1971) devised a new classification system to better serve the needs of researchers and wetland managers in the glaciated prairies. Their system recognizes seven classes of wetlands which are distinguished by the vegetational zone occupying the central or deepest part and covering 5% or more of the wetland basin. The classes thus reflect the wetland's water regime; for example, temporary ponds (Class II) are those where the wet-meadow zone occupies the deepest part of the wetland. Six possible subclasses were created, based on differences in plant species composition that are correlated with variations in average salinity of surface water. The third component of classification in their system is the cover type, which represents differences in the spatial relation of emergent cover to open water or exposed bottom soil. The zones of Stewart and Kantrud's system are readily related to our water regime modifiers (Table 1), and the subclasses are roughly equivalent to our Water Chemistry Modifiers (Fig. 8).

Wetlands represent only one type of land and the classification of this part separate from the rest is done for practical rather than for ecological reasons (Cowardin 1978). Recently there has been a flurry of interest in a holistic approach to land classification (in Land Classification Series, *Journal of Forestry*, vol. 46, no. 10). A number of classifications have been developed (e.g., Radford 1978) or are under development (e.g., Driscoll et al. 1978). Parts

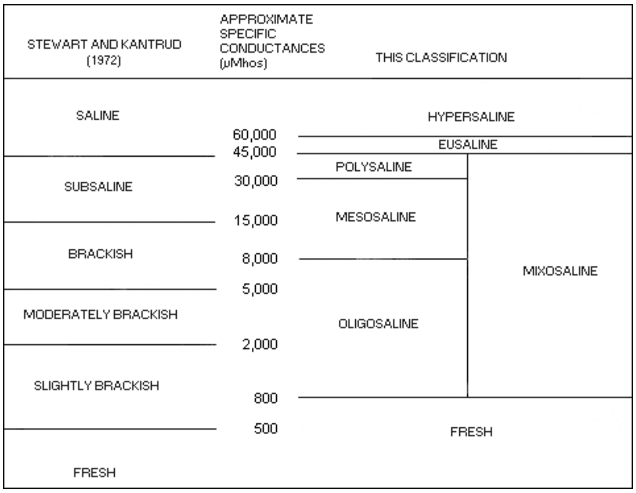

Figure 1. Comparison of the water chemistry subclasses of Stewart and Kantrud (1972) with Water Chemistry Modifiers used in the present classification system.

Table 1. Comparison of the Zones of Stewart and Kantrud's (1971) Classification with the Water Regime Modifiers used in the Present Classification System

Zone	Water Regime Modifier
Wetland-low-prairie	Non-wetland by our definition
Wet meadow	Temporarily flooded
Shallow marsh	Seasonally flooded
Deep marsh	Semipermanently flooded Intermittently exposed
Intermittent-alkali	Intermittently flooded (with eusaline or hypersaline water)
Permanent-open-water	Permanently flooded (with mixohaline water)
Fen (alkaline bog)	Saturated

of this wetland classification can be incorporated into broader hierarchical land classifications.

A classification system is most easily learned through use. To illustrate the application of this system, we have classified a representative group of wetlands and deepwater habitats of the United States (Plates 1–86).

URBAN RUNOFF

Miklas Scholz
The University of Edinburgh
Edinburgh, United Kingdom

INTRODUCTION

Urban runoff comprises the stormwater runoff from urban areas such as roads and roofs. Road and car park runoff is often more contaminated with heavy metals and organic matter than roof runoff. Runoff is usually collected in gully pots that require regular cleaning. Stormwater pipes transfer urban runoff either directly to watercourses or to sustainable urban drainage systems (also called best management practice in the United States) such as ponds or wetlands. However, urban runoff is frequently treated only by silt traps that need to be cleaned regularly. This chapter highlights the main areas in urban runoff research and contain general background information supported by case studies.

ROAD RUNOFF DRAINAGE

Background to Road Runoff

Conventional stormwater systems are designed to dispose of rainfall runoff as quickly as possible. This results in 'end of pipe' solutions that often involve large interceptor and relief sewers, huge storage tanks at downstream locations, and centralized wastewater treatment (1–3).

In contrast, sustainable urban drainage systems such as combined attenuation pond and infiltration basin systems (4) can be applied as cost-effective local 'source control' drainage solutions, for example, for collecting road runoff. It is often possible to divert all road runoff for infiltration or storage and subsequent recycling. Runoff from roads is a major contributor to the quantity of surface water requiring disposal, so this is a particularly beneficial approach when suitable ground conditions prevail (1). Furthermore, infiltration of road runoff can reduce the concentration of diffuse pollutants such as oil, leaves, metals, and feces, thereby improving the water quality of surface water runoff (3,4).

Case Study: Design and Operation of Urban Stormwater Ponds Treating Road Runoff

Combined wetlands and infiltration basins are cost-effective 'end of pipe' drainage solutions that can be used for local source control. The aims of this case study were to assess the constraints of the design and operation of these systems, the influence of wetland plants on infiltration rates, and the water treatment potential. Road runoff was first stored and treated in a constructed wetland before it overflowed into parallel infiltration basins; one was planted and the other was unplanted (Fig. 1). British Building Research Establishment and Construction Industry Research and Information Association and German Association for Water, Wastewater and Waste design guidelines were unacceptable because they did not take vertical soil property variations fully into account. Wetland plants in one infiltration basin had no significant influence on drainage properties. The water quality of both infiltration basins was not acceptable for recycling directly after the system setup (5).

ROOF RUNOFF DRAINAGE

Background to Roof Runoff

Combined wet and dry ponds as cost-effective 'end of pipe' drainage solutions can be used for local source control, for example, diversion or collection of roof runoff. It is often possible to divert all roof runoff for infiltration or storage and subsequent recycling. Runoff from roofs is a major contributor to the quantity of surface water requiring

Figure 1. Experimental ponds treating road runoff in Scotland.

Figure 2. Experimental infiltration pond for roof runoff in England.

disposal, so this is a particularly beneficial approach when suitable ground conditions prevail (1). Furthermore, roof runoff is usually cleaner than road runoff. However, diffuse pollution from the atmosphere and degrading building materials can have a significant impact on the water quality of any surface water runoff (3).

Case Study: Design and Operation of Stormwater Ponds for Roof Runoff Treatment

The purpose of this case study was to optimize design, operation and maintenance guidelines and to assess the water treatment potential of a stormwater pond system after 15 months of operation. The system was based on a combined silt trap, attenuation pond (wet pond) and dry pond construction used for drainage of roof water runoff from a single domestic property (Fig. 2). British Building Research Establishment and Construction Industry Research and Information Association, and German Association for Water, Wastewater and Waste design guidelines were tested. These design guidelines failed because they do not consider local hydrologic and soil conditions. The infiltration function for the dry pond is logarithmic and depends on the season. Furthermore, algae control techniques were successfully applied, and water treatment of rainwater runoff from roofs was largely unnecessary. However, seasonal and diurnal variations in biochemical oxygen demand, dissolved oxygen and pH were recorded (4).

URBAN RUNOFF AND GULLY POT EFFLUENT TREATMENT

Background to Gully Pot Effluent

Gully pots can be viewed as simple physical, chemical and biological reactors. They are particularly effective in retaining suspended solids and settleable solids (6). Currently, gully pot effluent is extracted once or twice per annum from road drains and transported (often over long distances) for treatment at sewage works (1). A more sustainable solution would be to treat gully pot effluent locally in potentially sustainable constructed wetlands, reducing transport and treatment costs. Furthermore, gully pot effluent treated by constructed wetlands can be recycled for cleansing gully pots and washing wastewater tankers. Heavy metals within urban runoff originate from fuel additives, car body corrosion, and tire and brake wear. Common metal pollutants from road vehicles include lead, zinc, copper, chromium, nickel and cadmium. Typical concentration ranges for most heavy metals are between 0.05 and 2 mg/L (7).

Case Study: Design and Operation of Constructed Wetlands Applied to Gully Pot Effluent Contaminated with Heavy Metals

The aim was to assess the treatment efficiencies for gully pot effluent of experimental vertical-flow constructed wetland filters containing *Phragmites australis* (Cav.) Trin. ex Steud. (common reed) and filter media of different adsorption capacities. Six out of 12 filters received inflow water spiked with heavy metals. For one year, hydrated copper nitrate and hydrated nickel nitrate were added to sieved gully pot effluent to simulate contaminated primary treated stormwater runoff. The inflow concentrations for dissolved copper, nickel and nitrate were approximately 1.0, 1.0 and 3.7 mg/L, respectively. For those six filters receiving metals, an obvious breakthrough of dissolved nickel was recorded after road gritting and salting during winter. Sodium chloride was responsible for leaching of dissolved nickel (Fig. 3). Reductions of copper, nickel, biochemical oxygen demand, and suspended solids were frequently insufficient compared to international secondary wastewater treatment standards. An analysis of variance indicated that all filters were similar in their treatment performance (8).

URBAN RUNOFF DISCHARGING INTO URBAN WATERCOURSES

Background to Urban Runoff Discharge to Waters

Stormwater runoff is usually transferred within a combined sewer (rainwater and sewage) or separate stormwater pipeline. Depending on the degree of pollution,

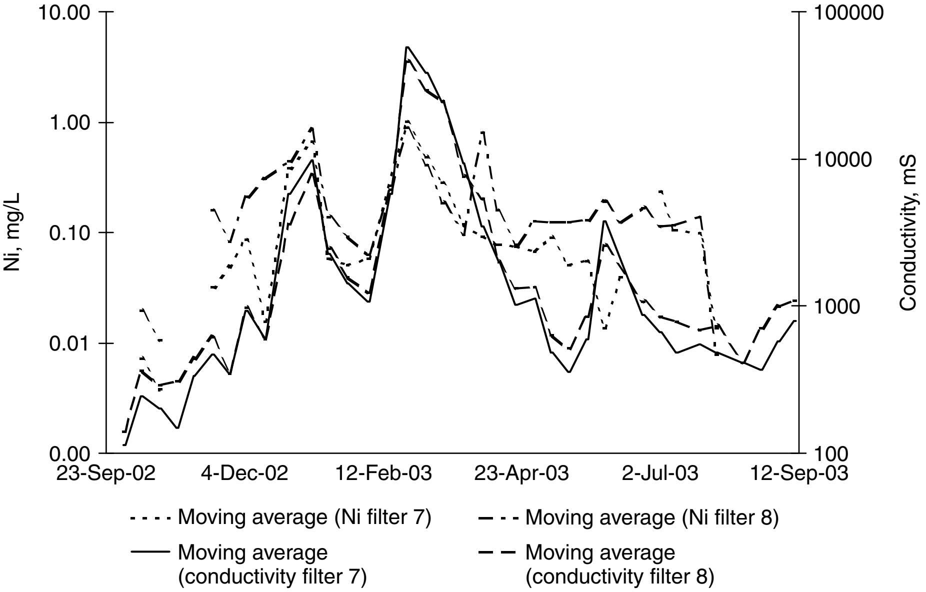

Figure 3. Relationship between the breakthrough of nickel (Ni) and conductivity within the outflows of two experimental constructed wetlands.

it may require further conventional treatment at the wastewater treatment plant. Alternatively, stormwater runoff may be treated by more sustainable technologies, including stormwater ponds, or simply by disposing it via ground infiltration or drainage into a local watercourse (1).

Common preliminary treatment steps for stormwater that is to be discharged into a local watercourse are extended storage within the stormwater pipeline and transfer through a silt trap (also referred to as a sediment trap). The silt trap is often the only active preliminary treatment of surface water runoff despite the fact that stormwater is frequently contaminated with heavy metals and hydrocarbons (9). Heavy metals within road runoff are from fuel additives, car body corrosion, and tire and brake wear (1).

The dimensioning of silt traps is based predominantly on the settlement properties of the particles and the maximum flow-through velocity. As a general rule, the outflow should be located on the same axis as the inflow, so that continuous flow ensures particle settlement over the full length of the silt trap (10). The structure should be small and simple to keep capital costs low.

Various international and British guidelines exist for designing outflow structures. In practice, designs vary considerably. However, silt traps are usually longer than wider by a factor of up to five. Silt trap depths vary considerably but are usually about 40 cm. However, often the lack of maintenance of outflow structures such as silt traps leads to problems years after the structure has been commissioned. Accumulated sediment has to be removed from silt traps to retain their original design performance and to avoid resuspension of accumulated pollutants during storms, causing pollution in receiving waterbodies (11). Watercourses in urban (built-up) areas that receive surface water runoff may be subject to pollution, particularly, if silt traps, for example, are insufficiently maintained (e.g., low frequency of sediment removal). Furthermore, the additional water load may contribute to local flooding (11).

Case Study: Urban Runoff Quality Associated with a Full Silt Trap Discharging into an Urban Watercourse

The aim was to assess the influence of a full silt trap at the end of a stormwater drainage pipe on the water quality of stormwater discharged into a semi-natural urban watercourse. For approximately eleven weeks, the water qualities of the preliminarily treated stormwater and of the receiving watercourse (Braid Burn) were studied. The mean outflow concentrations of suspended solids were 2.0 and 34.1 mg/L during dry and wet weather conditions, respectively. Suspended solids concentrations of up to 141.6 mg/L were recorded during storms. Suspended solids values for treated stormwater were often too high compared to international secondary wastewater treatment standards of approximately 30 mg/L. Pollutants, including heavy metals (e.g., zinc, copper, and nickel) accumulated in the silt trap (Fig. 4). However, high outflow velocities during heavy rainfalls did not result in clearly defined sediment layers due to sediment resuspension. Metals did not accumulate in the receiving watercourse (12).

URBAN WATER STUDIES

Karen D. Brettschneider
Houston-Galveston Area Council
Houston, Texas

INTRODUCTION

The urban landscape contains many elements that can alter the water quality of a waterbody. Before development occurs, grass and other natural vegetation hold sediment in place. Streams flowing through undeveloped terrain have no major sources of contaminants, such as bacteria (except for wildlife), that affect contact recreation. There are also no major sources of toxins that could negatively impact humans and wildlife. Development (residential, commercial, industrial, and agricultural, for example) brings issues that have the potential to compromise the character of streams through point source pollution or nonpoint source pollution (Fig. 1). The best way to prevent or deal with these issues is to have cooperation among a broad group of stakeholders in each watershed, the area of land (and tributaries) that drains to a particular waterbody. These individuals must work together to develop sound watershed management to protect or to restore the health of the ecosystem of that watershed.

WHAT HAPPENS TO THE QUALITY OF WATER WHEN DEVELOPMENT BEGINS?

One of the first concerns for water quality during development involves construction sites. When the natural vegetation is removed and bare soil is exposed, rainwater easily collects sediment, along with any pollutant attached to that sediment, and drains eventually to a stream. Additional sediment added to the water column may pose impacts to humans, such as complications with sources of public water supply, as well as to aquatic organisms. Sediment reduces sunlight for aquatic photosynthesis, clogs fish gills, disturbs bottom-dwelling organisms, and overall reduces the aesthetic value of the stream.

DURING AND AFTER DEVELOPMENT—POINT SOURCE AND NONPOINT SOURCE POLLUTION

Development includes the establishment of industrial plants, wastewater treatment plants, and other entities that discharge treated water to an outfall that connects to a stream. State and/or federal laws and standards regulate the effluent (point source) of these plants, but there still lies the potential for overflows, illegal discharges, and accidental spills.

Although there have been major strides in controlling pollutants from point sources, nonpoint source pollution (NPS) remains one of the most complex and elusive problems to deal with in watershed management. NPS pollution stems from those constituents that flow overground from diffuse sources directly into area waterways or indirectly through stormwater infrastructure to outfalls that connect to rivers and streams. One important factor to remember is that water that flows from homes to wastewater treatment facilities and then to a specified waterbody is clean as it leaves the plant. Stormwater receives no treatment. Left uncontrolled, these pollutants often have a significant impact on the quality of the water.

Some potential NPS pollutants carried in rainwater runoff include the following:

- excessive fertilizer applied to lawns or agricultural fields
- excessive pesticides and herbicides applied to lawns or agricultural fields
- grass clippings left on streets or blown down storm drains
- motor oil or other vehicle fluids from leaking automobiles or from illegal dumping
- trash
- animal waste
- sewage from broken sewer lines
- sewage from failing septic systems

Some of the consequences of these components entering a waterway include the following:

- excessive nutrient levels that may lead to eutrophic conditions
- depressed dissolved oxygen levels that can be harmful to aquatic species
- harmful elements exposed to wildlife
- increased bacteria counts
- impaired aesthetics
- impaired recreational value

APPROACHING THE ISSUES—WATERSHED MANAGEMENT

When analyzing water quality for an urban area, a watershed approach is the most effective means of defining problem areas and addressing concerns. Studying the various aspects within the watershed and how they interact is a scientifically sound approach to preventing and to solving water quality problems. Some of the various layers of information easily available to use in conjunction with water quality data include topographic information, detailed drainage information, soil types and characteristics, groundwater/aquifer information, vegetation types, climate information, and geology. Land cover or land use data can be obtained from aerial photography or other digital imagery.

Figure 1. An urban stream with many potential sources of pollution.

After gathering this type of information, participants in the watershed management plan may locate individual potential pollution sources, such as treatment plant or stormwater outfall locations. They may also locate potential areas of concern, such as areas of concentrated industrial activity, areas with large numbers of septic tanks, or areas with concentrated animal feeding operations. The latter activities are commonly found in rural areas, but these operations in the watershed influence the character of the waterbody as well.

Gathering of individuals, or stakeholders, from agriculture, industry, local business, government, local neighborhoods, the environmental profession, as well as other interested parties is the next step in addressing issues on a watershed scale. Each of these individuals can lend support in various aspects of the activities within the watershed.

Monitoring

Due to the size of urban areas, there are typically a number of entities that measure water quality for specific purposes. Gathering this information and coordinating among different groups, including city offices, county offices, river authorities, and other environmental groups can lead to a wealth of information about water quality throughout a watershed. Many agencies may be willing to modify their programs to help collect data in certain areas that are not monitored by any other entity. This action is commonly referred to as coordinated monitoring.

Common parameters used to assess the overall health of a waterbody include the following:

Field Measurements

- dissolved oxygen
- pH
- water temperature
- specific conductance

- salinity in marine waters
- Secchi depth
- flow
- days since last significant rainfall
- observational information, including water appearance and weather (and as applicable, biological activity; pertinent observations related to water quality or stream uses, e.g., boating, swimming, fishing, irrigation pumps, etc.; watershed or in-stream activities, e.g., bridge construction; unusual odors; specific sample information; and missing parameters)

Conventional Chemical Parameters

- ammonia –N
- nitrate + nitrite –N
- total phosphorus
- orthophosphorus
- chlorophyll *a*
- pheophytin
- total dissolved solids
- total suspended solids
- sulfate
- chloride
- total hardness

Bacteria

- fecal coliform
- *E. Coli* or *Enterococcus*

Flow Measurement

- direct measurement or USGS gage data
- flow estimate

Additional parameters for total maximum daily load (TMDL) purposes, load calculations, modeling, trend analysis, etc. or other specific purposes not related to the 305(b) screening:

- alkalinity
- total Kjeldahl nitrogen
- total organic carbon
- BOD5
- COD
- Toxics (metals or organics in water) for aquatic life/habitat monitoring

Routine monitoring should not include ambient toxicity, toxics in sediment or fish tissue, 24-hour dissolved oxygen measurements, and monitoring to determine the extent of impairment.

In addition to collecting data on water chemistry, biological and habitat data can assist in more comprehensively understanding the health of a watershed.

DEFINING ISSUES

Approaching concerns at a watershed level is appropriate in most situations; however, there may be issues confined to only one part of the watershed. Based on available data, researchers may be able to pinpoint a problem to a certain area. For example, the main stem of a channel may be contaminated with bacteria from a certain point downstream of a confluence with a tributary. Detailed study of that tributary's subwatershed may lead to sources of the bacteria that may help resolve the overall issue. So, while taking a watershed approach to water quality, it sometimes may be beneficial to go a step further to the subwatershed level, especially when trying to mitigate a particular pollutant. Eliminating or simply reducing input from small tributaries is the first step in cleaning up the entire watershed.

PREVENTING THE PROBLEMS—BEST MANAGEMENT PRACTICES AND PUBLIC EDUCATION

An important component of addressing water quality problems associated with NPS is through a preventive approach with using best management practices (BMP) at construction sites and other facilities to prevent contaminated runoff. Another strong preventive is public education. Once people know they can have a positive impact on the waterbodies in their community and watershed, then communities are one step closer to establishing healthy ecosystems in urban areas.

CONCLUSION

Urban areas often contain an immense network of flowing waterbodies containing quality aquatic habitat and recreational opportunities such as boating, canoeing, fishing, and swimming. At the same time, the many waterbodies that run through highly urbanized or impacted landscapes face challenges that require the cooperation of various entities to produce sound watershed management. The maintenance of a network of stakeholders and monitoring entities that works toward this goal is essential. Preventive steps such as BMPs, public education, and outreach opportunities are also very important in creating and maintaining quality places in which to live.

SUBGLACIAL LAKE VOSTOK

Brent C. Christopher
John C. Priscu
Montana State University
Bozeman, Montana

When Captain Robert F. Scott first observed the McMurdo Dry Valleys in December 1903, he wrote, "We have seen no living thing, not even a moss or a lichen... it is certainly a valley of the dead." Eight years later, Scott's team reached the South Pole and his entry referencing conditions on the polar plateau read "Great God! This is an awful place." Scott was unaware that life surrounded him in the dry valleys, and he could not have realized that microbial life could exist miles beneath his feet in an environment sealed from the atmosphere by Antarctica's expansive continental ice sheet. The realization that there was life on the Antarctic continent, other than that associated with the marine system, did not come to light until the seminal investigations initiated by the International Geophysical Year in the late 1950s and early 1960s. Biological studies during this period were exploratory in nature, describing life forms and their habitat in terrestrial and surface lake environments. These important pioneering studies reshaped our understanding of the potential for life in the coldest, driest, and windiest place on Earth. However, it was not until about 5 years ago that microbiological evidence suggested that the Antarctic interior could serve as an environment for life, which resulted from investigations conducted on a deep ice core from Vostok Station. These studies suggested that the cryosphere of Antarctica could support some of the most unusual and extreme microbial ecosystems on the planet. This information, coupled with the recent discovery of an extensive network of subglacial lakes beneath the East Antarctic Ice Sheet (EAIS), has changed our view of life in Antarctica. Although it is well documented and widely known that life exists in the permanently cold margins and marine environments of Antarctica, the cryosphere has traditionally been viewed as being devoid of life.

Subglacial Lake Vostok is by far the largest of the more than 140 subglacial lakes that have been identified thus far (Fig. 1), with a surface area of more than 14,000 km^2 and a depth in excess of 800 m, which makes it one of the largest lakes on Earth. The base of the central EAIS is relatively warm as a result of the combined effect of geothermal heating and the insulation caused by the overlying ~4 km of ice, despite surface air temperatures commonly below −60 °C. Lake Vostok has only recently become a focus of research, even though its presence was first noted in the early 1960s when Soviet Antarctic Expedition (SAE) pilots observed an extremely flat area near Vostok Station that could represent ice floating over water. These airborne

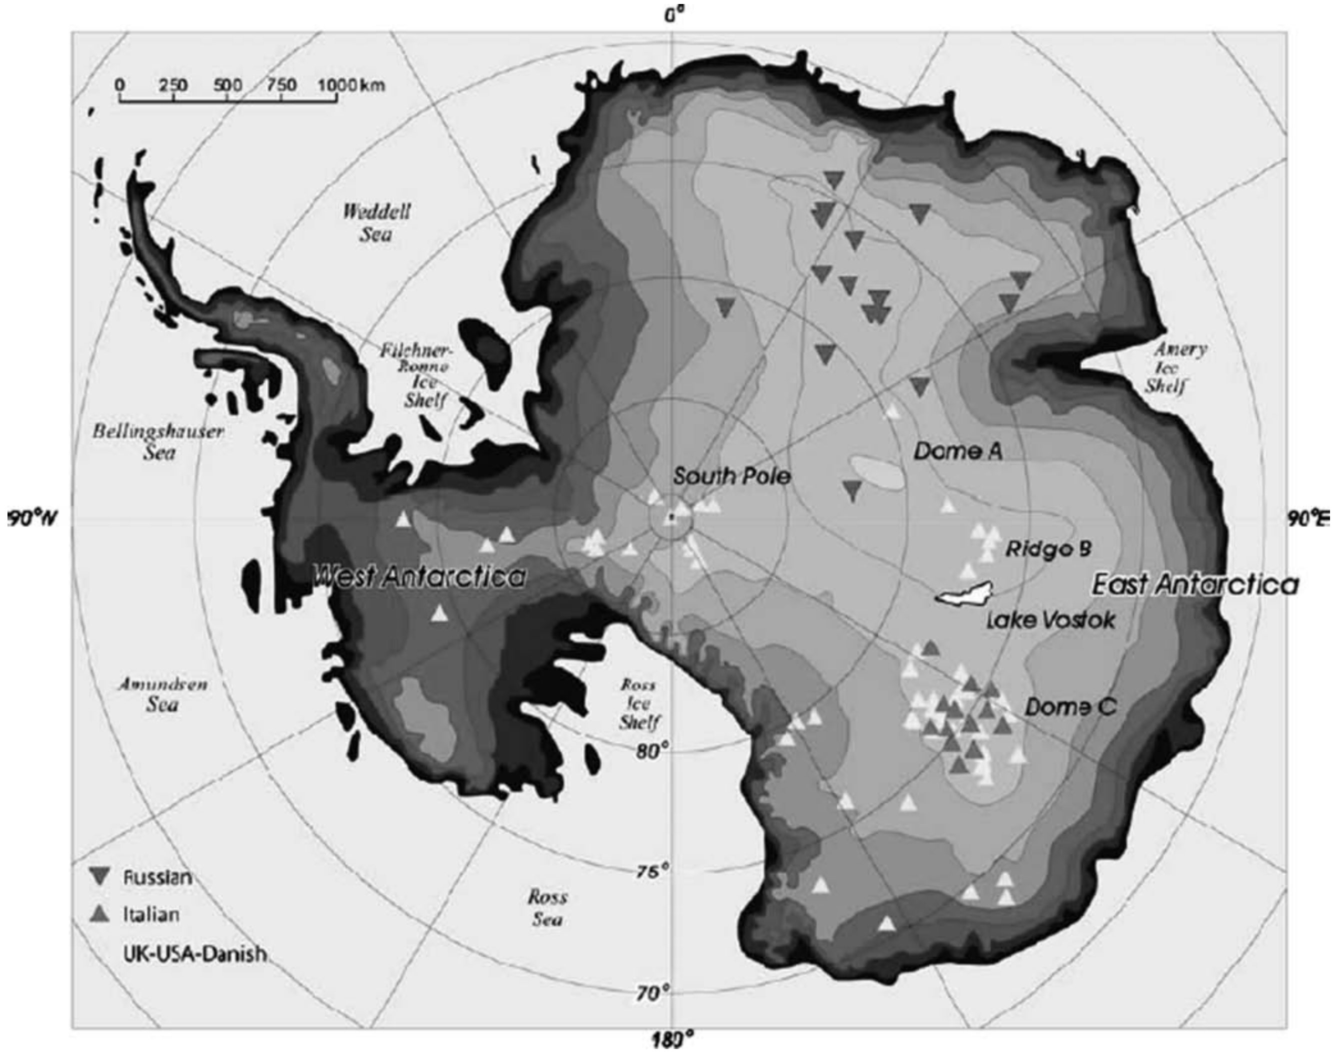

Figure 1. Locations of Antarctic subglacial lakes. Lakes discovered by Italian (blue triangles), Russian (red down white triangles), and U.K.–U.S.–Danish (yellow triangles) teams are included (Lake Vostok is shown in outline). The ice-sheet surface is contoured at 500-m intervals. Reproduced from Priscu et al., '*Subglacial Antarctic Lake Environments: International Planning for Exploration and Research*.' EOS, in press.

observations were soon confirmed by seismic data, radar profiles, and satellite images made near Vostok Station. The discovery of Lake Vostok and several additional subglacial lakes in central Antarctica during the early 1970s went relatively unnoticed by the biological scientific community until the late 1990s. However, curiosity about the nature of this environment and the potential existence of microbial life in subglacial lakes has recently intensified.

The site selection for Vostok Station by the SAE was truly fortuitous for subglacial lake research. Several deep ice cores have been extracted from the ice sheet at Vostok Station since drilling began in the mid-1960s (the first 500-m-deep borehole was made in 1965). The most recent and deepest (3623 m below the surface) ice core (borehole 5G) stopped ~120 m above the lake-ice interface, because of concerns of contaminating the lake. The upper 3310 m of the ice core has provided a detailed paleoclimate record spanning the past 420,000 years. Ice at depths between 3310 and 3538 m is deformed by contact with bedrock and does not contain useful paleoclimate data. The basal portion of the ice core from 3539 to 3623 m has a chemistry and crystallography distinctly different from the "normal"

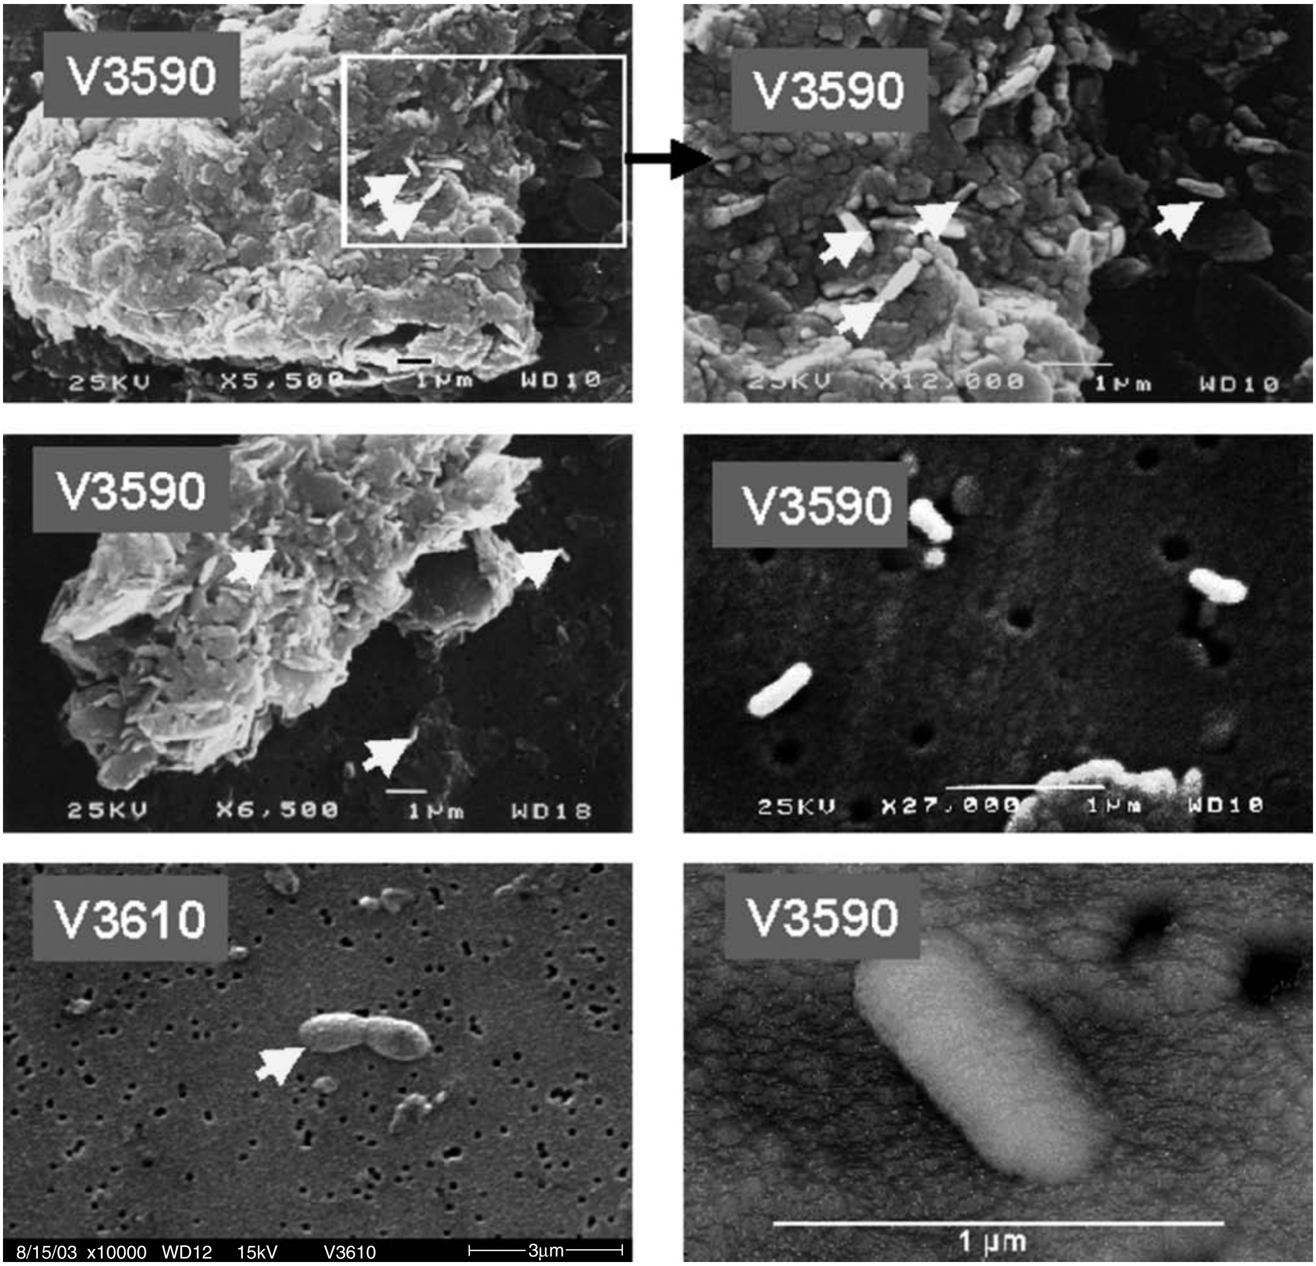

Figure 2. Scanning electron micrographs of microbes in Lake Vostok accretion ice. Samples are designated by their depth of recovery from below the surface in meters, and yellow arrows indicate prokaryotic cells. Melt water was filtered onto 0.2-µm polycarbonate filters sputter coated with 10-nm Au-Pd and imaged with a cryogenic scanning electron microscope. Adapted from Priscu et al., *Science* **286**: 2141–2144 (1999).

glacial ice above it. This basal ice has extremely low conductivity, large (up to 1 m) ice crystals, and numerous sediment inclusions. The mineral composition of ice-bound sediments below 3539 m is dominated by micas and is clearly different than typical crustal composition and particles within the overlying glacial ice. The isotopic composition of this basal ice in concert with other data indicates that it formed by the refreezing (accretion) of Lake Vostok lake water to the underside of the ice sheet. Thus, there is ~210 m of Lake Vostok water frozen on the underside of the glacial ice beneath Vostok Station. Recent airborne radar surveys have shown that the accretion ice is dynamic and actually flows out of the lake on the downstream side.

The freshwater in Lake Vostok originates from the overlying ice sheet, which melts near the shoreline of the lake and at the ice–water interface in the north. Accretion to the base of the ice sheet occurs in the central and southern regions, removing water from the lake. As the accreted ice is essentially gas-free, the lake water is thought to have a relatively high dissolved gas content supplied from air bubbles released from the overlying glacial ice. Estimates on the gas content of Lake Vostok suggest that it could have an oxygen concentration 50 times higher than that in the open ocean. Although it seems inevitable that viable microorganisms from the overlying glacial ice and in sediment scoured from bedrock adjacent to the lake are regularly seeded into the lake, the question remains whether these or preexisting microorganisms have established a flourishing community within Lake Vostok. Evidence for the existence of geothermal activity is supported by the recent interpretation by French scientists of He^3/He^4 data from accretion ice. These data imply that there may be extensive faulting beneath Lake Vostok, which results in geothermal plumes entering the bottom of the lake in the southern part of Lake Vostok. If this emerging picture is correct, Lake Vostok could harbor an ecosystem fueled by geochemical energy much like that observed in deep-sea vent systems.

Because of concerns of contaminating these pristine subglacial environments and the current lack of an adequate sampling strategy to meet these needs, no direct samples have yet been obtained from subglacial lakes. Therefore, the accreted ice retrieved from Vostok Station has offered the only opportunity for microbial ecologists and geochemists to investigate material derived from a subglacial lake. Microbiological and molecular-based studies of accreted ice by four independent laboratories have indicated that these cores contain bacteria (Fig. 2). Metabolic and culturing experiments demonstrate that a portion of the assemblage becomes metabolically active upon melting and exposure to nutrients which suggests Lake Vostok contains a viable microbial community. Molecular profiling of microbes within the accreted ice (by both culturing and direct 16S rDNA amplification) shows close agreement with present-day surface microbiota, consisting of phylotypes within the bacterial divisions *Proteobacteria* (alpha, beta, gamma, and delta), Low G + C Gram Positives, *Actinobacteria*, and the *Cytophaga–Flavobacterium–Bacteroides* line of descent. If microbes within the accreted ice are representative of the lake microbiota, this would imply that bacteria within Lake Vostok do not represent an evolutionarily distinct subglacial biota. The time scale of isolation within Lake Vostok (~20–25 million years) is not long in terms of prokaryotic evolution compared with their 3.7×10^9 year history on Earth. An alternative scenario is that glacial melt water entering the lake forms a lens overlying the Lake Vostok water column. If so, the microbes entrapped within accretion ice would likely have spent little time within the actual lake water (few, if any cell divisions occurring) before being frozen within the accretion ice. The microbes within the main body of the lake below such a freshwater lens may have originated primarily from basal sediments, rocks, and/or the preexisting environment before Lake Vostok became ice-covered. If so, their period of isolation may be adequate for significant evolutionary divergence, particularly given the potential selection pressures that may exist within this unusual subglacial environment.

Epifluorescence (of DNA-stained cells) and scanning electron microscopy have measured bacterial cell densities of 2.8×10^3 and 3.6×10^4 cells mL^{-1}, respectively, in Vostok accretion ice (3590 m below the surface). Additionally, the concentration of dissolved organic carbon (DOC) in this core was measured at 0.51 mg L^{-1}. Based on these values and partitioning coefficients for the water to ice phase change, it is estimated that the water in Lake Vostok had bacterial cell concentrations of 10^5 to 10^6 mL^{-1} and a DOC concentration of 1.2 mg L^{-1}. Using data on the volume of the Antarctic ice sheet and subglacial lakes in concert with published bacterial volume to carbon conversion factors, the cell number and carbon content within the Antarctic ice sheet and subglacial lakes can be estimated, assuming that concentrations of bacterial cells and DOC in other subglacial lakes are similar to those estimated for Lake Vostok. Based on these calculations, subglacial lakes contain about 12% of the total cell number and cell carbon with respect to the pools associated with the Antarctic continent (e.g., subglacial lakes + ice sheet). The number of cells and prokaryotic cell carbon content for subglacial lakes plus the ice sheet (1.00×10^{26} cells; 2.77×10^{-3} Pg) approaches that reported for Earth's freshwater lakes and rivers (1.3×10^{26}; 2.99×10^{-3} Pg), which suggests these environments contain nontrivial amounts of cells and carbon. These estimates of the number of prokaryotes and organic carbon associated with Antarctic subglacial lakes and glacial ice are clearly tentative and should be refined once additional data become available; however, they do imply that Antarctica contains an organic carbon reservoir that should be considered when addressing issues concerning global total carbon storage reservoirs and dynamics.

The seminal reports of life in subglacial Antarctic lakes have spawned many new ideas about how life evolved on our planet and others, how life adapts to extremely cold conditions, and how ecosystems function beneath 4 km of ice, and it has changed our view of the extent of Earth's biosphere. One new idea theorizes that microbes might thrive throughout most of the Antarctic ice sheet within intercrystalline veins. The veins, formed at junctions where three ice crystals meet, may offer a unique habitat for microbes in "solid" ice that has not yet been considered. These veins contain a relatively solute-rich solution that both lowers the freezing point and provides nutrition for microbial growth. This idea is supported by new data on the isotopic composition of gases within cores of Vostok glacial ice, which suggests biological modification. If it is eventually shown that such a microbial habitat does indeed exist in solid ice, then much of the Antarctic ice sheet may harbor active microbes, a notion previously unheard of. Important new information based on airborne radar surveys has shown that at least 140 more subglacial lakes exist beneath the EAIS. Most of these lakes exist near Dome C. These lakes, although not nearly as large as Vostok, are still substantial with at least one exceeding 500 km^2 in surface area. The density of lakes near Dome C, together with maps of bottom topography, implies that a hydrologically interconnected lake district may exist in this region of Antarctica. These lakes provide many new environments that presumably contain life in what was once thought to be an inhospitable environment.

Future research of microbial ecosystems in subglacial lakes depends on a plan in which water samples are collected and returned to the surface. The overriding and limiting issues of this entire strategy are environmental concerns and the control of contamination in both forward and return excursions into the lakes. As such, it is of prime importance that environmental stewardship precedes all scientific endeavors, and that such an undertaking not be attempted until adequate sampling techniques are established. To this end, the Scientific Committee on Antarctic Research (SCAR) has established an international body of specialists to outline a detailed plan for eventual lake entry and sample return. This plan calls for the establishment of a network of instruments that gather limnological data continuously, collection of water samples for return to the surface, and recovery of deep sediment cores that can reconstruct paleoclimate and geological records for Antarctica. The next 10 years should prove to be an interesting time of discovery for Antarctic science, one that follows the Antarctic tradition of melding interdisciplinary and international science. We can expect subglacial lakes to be at the forefront of such discovery because they remain one of the last unexplored frontiers on our planet.

WATER—THE CANADIAN TRANSPORTER

Environment Canada

Water plays an important role in the transformation of the Canadian landscape by moving large amounts of soil, in the form of *sediment*. Sediment is eroded from the landscape, transported by river systems, and eventually deposited in a lake or the sea. For example, the Fraser River carries an average of 20 million tonnes of sediment a year into the marine environment.

The sediment cycle starts with the process of *erosion*, whereby particles or fragments are weathered from rock

---

This article is produced by Environment Canada and is reproduced with permission.

material. Action by water, wind, glaciers, and plant and animal activities all contribute to the erosion of the earth's surface. Fluvial sediment is the term used to describe the case where water is the key agent for erosion. Natural, or geologic, erosion takes place slowly, over centuries or millennia. Erosion that occurs as a result of human activity may take place much faster. It is important to understand the role of each when studying sediment transport.

Any material that can be dislodged is ready to be transported. The *transportation* process is initiated on the land surface when raindrops result in sheet erosion. Rills, gullies, streams, and rivers then act as conduits for sediment movement. The greater the discharge, or rate of flow, the higher the capacity there is for sediment transport.

The final process in the cycle is *deposition*. When there is not enough energy to transport the sediment, it comes to rest. Sinks, or depositional areas, can be visible as newly deposited material on a flood plain, bars and islands in a channel, and deltas. Considerable deposition occurs that may not be apparent, as on lake and river beds. A knowledge of sediment dynamics is an integral part of understanding the aquatic ecosystem.

Canada's waterways move many millions of tonnes of sediment annually in this never-ending cycle of erosion, transportation, and deposition. Sediment is measured and classified according to its dynamic characteristics:

- suspended load (suspended in the water)
- bed load (rolling or bouncing along the bottom)
- bed material (stationary on the bed)

WHY IS SEDIMENT IMPORTANT?

Sediment carried in water has a variety of effects: what are they and why are they important?

Toxic Chemicals

Sediment plays a major role in the transport and fate of pollutants and so is clearly a concern in water quality management. Toxic chemicals can become attached, or adsorbed, to sediment particles and then transported to and deposited in other areas. These pollutants may later be released into the environment. By studying the quantity, quality, and characteristics of sediment in the stream, scientists and engineers can determine the sources and evaluate the impact of the pollutants on the aquatic environment. Once the sources and impact are known, action can be taken to reduce the pollutants. The association of toxic chemicals with sediment is an issue of national importance.

Navigation

Deposition of sediment in rivers or lakes can decrease water depth, making navigation difficult or impossible. To ensure access, some of the sediment may be dredged from the stream or harbour, but this may release toxic chemicals into the environment. To determine how much dredging needs to be done and how often, water levels must be monitored, and the rates of sediment transport and deposition estimated. Sedimentation of navigation channels is a concern in the Fraser River (British Columbia), the Mackenzie River (Northwest Territories), and the Great Lakes-St. Lawrence system (Ontario and Quebec).

Fisheries/Aquatic Habitat

Streamborne sediment directly affects fish populations in several ways:

- Suspended sediment decreases the penetration of light into the water. This affects fish feeding and schooling practices, and can lead to reduced survival.
- Suspended sediment in high concentrations irritates the gills of fish, and can cause death.
- Sediment can destroy the protective mucous covering the eyes and scales of fish, making them more susceptible to infection and disease.
- Sediment particles absorb warmth from the sun and thus increase water temperature. This can stress some species of fish.
- Suspended sediment in high concentrations can dislodge plants, invertebrates, and insects in the stream bed. This affects the food source of fish, and can result in smaller and fewer fish.
- Settling sediments can bury and suffocate fish eggs.
- Sediment particles can carry toxic agricultural and industrial compounds. If these are released in the habitat they can cause abnormalities or death in the fish.

Forestry

Some forestry practices have negative impacts on the environment. Extensive tree cutting in an area may not only destroy habitat but increase natural water runoff and accelerate soil erosion. These can lead to increased flow and sediment loads in nearby streams. They can also release chemical substances occurring naturally in forest soils, and allow them to contaminate rivers or lakes. Both the chemicals and the additional sediment can harm fish and other organisms. Sediment problems resulting from forestry practices are prevalent in British Columbia, Ontario, Quebec, New Brunswick, and Newfoundland.

Water Supply

Sediment can affect the delivery of water. When water is taken from streams and lakes for domestic, industrial, and agricultural uses, the presence of sediment in the water can wear out the pumps and turbines. As this increases maintenance costs, it is important to determine the amount of sediment in the stream so that the appropriate equipment can be chosen when designing a water supply plant.

Energy Production

The amount of sediment transported affects both the size and the life expectancy of reservoirs created for power generation. A dam traps sediment that would normally be carried downstream, and that sediment decreases the size of the reservoir and thus its use for power generation. Therefore, it is necessary to know the amount of sediment to ensure the effective design of reservoirs for the long term.

Agriculture

Some farming practices increase soil erosion and add toxic chemicals to the environment. Thus, productive soil is lost to farms, sediment and pollutants are added to streams, and maintenance costs of irrigation systems are increased. Sediment data and information are necessary in the evaluation of cropping practices and their environmental effects. Sediment-related problems associated with agriculture occur across the country.

Case Study: Aquatic Habitat and Construction In St. John's, Newfoundland

A considerable amount of sediment is lost from building sites during construction. Depending on its location, this sediment finds its way to sewer or stream systems, increasing the costs of water treatment or impacting on aquatic habitat. In 1982, construction was started on a building to house the Institute for Marine Dynamics in St. John's, Newfoundland. The site, near the Rennie's River, required massive excavation. To minimize the impact of the sediment on the aquatic environment, a de-sedimentation facility was built. A settling pond was used, and alum was added to help settle the sediment, alum having no significant impact on the ecosystem. Without the de-sedimentation facility, toxic chemicals and sediment could have contaminated the fish, buried fish eggs, dislodged aquatic plants, and generally overwhelmed the aquatic habitat. Over three years, 1250 tonnes of sediment were kept from entering the river waters. The cost of the de-sedimentation was less that one tenth of one percent of the building costs, and a highly productive trout habitat was protected from contamination.

HOW IS SEDIMENT SAMPLED?

Sediment quantity and quality are sampled in a variety of ways:

- Specially designed *suspended-sediment* samplers are used to collect water/sediment samples that are analyzed for sediment quantity and sometimes quality.
- *Bed-load* samples are usually taken by lowering a specially made sampler to the stream bed. Resting there, the sampler traps the material moving along the bottom.
- *Bed-material* samples may be taken simply by hand from exposed bars or stream banks, or by samplers from the stream bed. Some samplers scoop sediment by simply digging into the bed, while other kinds extract a core from the bed.

Once collected, suspended-sediment samples are analyzed for concentration and particle size. This is usually done in a laboratory. The *concentration* is the ratio of sediment (dry weight) to the total water-sediment mixture, expressed as milligrams per litre (mg/L). The *particle size* is simply the size of the sediment particles. Depending on their size, they are classified as sand, silt, or clay.

To find out how much material is transported by a river, one can combine the concentration with the stream discharge, or flow. This gives the sediment load, which indicates the total amount of sediment transported over a certain time period, whether an hour, a day, month, or year. In such a way, it has been estimated that at Montreal the St. Lawrence River transports 2.3 million tonnes of sediment in suspension each year, or the equivalent of 230,000 truck-loads of soil.

Water, and more specifically the hydrologic cycle, plays a major role in driving the sediment life cycle. The amount of water and its distribution over time influence how and when sediment is sampled.

In Canada, sampling is usually for suspended-sediment data. Most of this sampling is done during high-flow conditions (spring, summer, and fall rainstorms), when most of the sediment is transported through the river system. However, a few samples may be taken at other times throughout the year, to better define the sediment regime. Bed-load sampling is typically undertaken in the spring, when high discharge mobilizes the stream bed. Bed-material may be sampled during the summer, when low-flow conditions may expose parts of the stream bed, making sampling easier.

Once the samples have been analyzed, the data on concentrations, particle sizes, or loads can be applied to engineering and environmental questions.

Average Annual Suspended Sediment Load (tonnes) for Selected Rivers in Canada

Glaciers retreated 10,000 years ago, leaving large amounts of easily erodible material across much of western Canada. In mountainous areas (e.g., the Fraser, Peace, and upper Mackenzie rivers), steepness and abundant water supply enable large amounts of sediment to be carried away. In contrast, the flat and dry conditions of the Prairies result in much lower sediment loads. In eastern Canada, where much of the land is bedrock, there is a limited sediment supply and therefore smaller loads.

SEDIMENT DATA AND INFORMATION

The measurement of sediments in streams in Canada dates back to 1948, in Saskatchewan. The federal government has conducted a national sediment program since 1961 in cooperation with the provinces, territories, and other interested agencies, such as hydroelectric companies. Data-collection techniques are standardized across the country to maintain data quality and comparability. Provincial governments also collect sediment data either as part of a regular sampling program or for specific

studies. Consulting engineers and planners, as well as university researchers, also carry out sampling for site-specific projects.

These data have been used extensively to address reservoir sedimentation, environmental impact assessment, sediment-associated contaminant transport, and other concerns.

Sediment data and information are available from a variety of sources. A large amount of data is contained in a national computer data base operated by Environment Canada. The data base contains historical and current data for about 750 stations throughout the country, about 300 of which are currently monitored.

The types of data that are stored in the national computer data base are as follows:

- suspended-sediment concentrations
- suspended-sediment loads
- suspended-sediment particle size
- bed load
- bed-load particle size
- bed-material particle size
- sediment quality

The data are published annually on CD-Rom and are available from Water Survey of Canada, Meteorological Service of Canada, Environment Canada, Ottawa, Ontario K1A 0H3, Tel.: (613) 992-7121, Fax: (613) 992-4288.

FLOOD PREVENTION

Slobodan P. Simonovic
The University of Western Ontario
London, Ontario, Canada

INTRODUCTION

Although people cannot do much about floods, they can influence the nature and extent of flood losses. The latter can be achieved through flood management policies and programs. The first section of this contribution describes some of the causes of flooding in order to provide insight into why some flood protection and response polices might succeed in one area but fail in another. Since natural flood mechanisms exist and socioeconomic conditions vary throughout the world, a mix of responses is necessary to effectively deal with the flood problem. The second section of this contribution describes the nature of some specific flood protection activities. In this manner, the need for effective flood management is demonstrated.

CAUSES OF FLOODING

Hydrometeorological Mechanisms

Flooding is caused primarily by hydrometeorological mechanisms, acting either individually or in combination (1,2). The regional variability in the intensity of these mechanisms reflects the diversity of climate across the region. The relative importance of the hydrometeorological flood mechanisms varies considerably throughout the year because of their close link to climate. In particular, severe flooding may result when several of these mechanisms occur coincidentally, as can happen in the spring.

Snowmelt Runoff Floods. The melting of a snowpack that has accumulated during the winter months is a common flood type. This occurs in watersheds of all sizes, often in combination with storm-rainfall runoff and/or ice jams. The amount of snowmelt runoff is controlled directly by the thickness, ripeness, and extent of the snowpack and by the rate of melting. The greater the amount of snow on the ground during a melt period, the more water is potentially available for snowmelt runoff. Ultimately, however, the rate of snowmelt is controlled primarily by radiant energy (3). Relatively cool weather causes slow melting of the snowpack and the gradual release of meltwater, while warm weather speeds melting and releases meltwater more rapidly, thereby increasing the possibility of flooding. Severe flooding from snowmelt can happen when there is a rapid shift from cold to warm temperatures in the spring following a winter of high snow accumulation. It can also be triggered during the winter months by a sudden and rapid thaw. Since the climatic factors influencing both the accumulation of snow and the rate of melt are regional, snowmelt flooding commonly occurs over large areas and affects numerous watersheds.

Storm-Rainfall Floods. Heavy or torrential rainfall associated with convective storms and midlatitude and tropical cyclones (including hurricanes) can cause flooding, even after a period of drought. This type of flood can develop rapidly, particularly when the ground is saturated and the rate of rainfall far exceeds the capacity of the ground to absorb the water, or when a significant portion of the ground surface is covered with impermeable materials, such as concrete or pavement in urban areas. The magnitude of storm-rainfall flooding depends on the intensity and duration of the rainfall, the areal extent of the storm, prestorm ground moisture conditions, and drainage basin characteristics (e.g., topography, overburden thickness, vegetative cover, drainage density). Storm-rainfall floods can significantly affect watersheds of up to 100,000 km^2 in size throughout the world. Rivers with larger watersheds generally are unaffected because the zone of intense rainfall within a storm system commonly is concentrated within a smaller portion of the drainage basin. However, prolonged, heavy rainfall over a large area from a succession of storms may produce storm-rainfall flooding along a river draining a very large watershed.

Rain-on-Snow Floods. Rain-on-snow floods are a combination of snowmelt runoff and storm-rainfall floods. They occur when rainfall runoff is augmented by snowmelt, which increases the amount of water flowing into a stream system. The rate of snowmelt during a rainstorm is affected directly by air and rainfall temperatures, amounts of rainfall, and wind speeds. However, the amount of surface runoff released from a snowpack is controlled by snowpack ripeness, since an unripe snowpack will store more rainwater than a ripe snowpack. When heavy or sustained rainfall occurring in combination with other meteorological conditions leads to ripening and significant melting of a moderately deep snowpack, rain-on-snow can generate substantial runoff causing very severe flooding (3).

Ice Jam Floods. Ice jam floods result from the temporary obstruction of river flow by the buildup of ice fragments within the channel and can occur during both the freeze-up and breakup periods. However, ice jams during breakup are more likely to cause flooding. Once formed, an ice jam causes the river to rise immediately upstream and may overtop its banks, depending on the height of the obstruction relative to the sides of the channel. The failure of an ice jam can release a surge of water and ice downstream that causes a sudden rise in water levels and flow velocities downstream. Ice jams that form during the breakup period commonly coincide with the freshet flow arising from snowmelt runoff and can accentuate the level of flooding. Flooding from ice jams tends to be localized since it is dependent directly on the formation of an ice jam, and the tendency for an ice jam to form at any given location along a river is variable. Ice jam formation along a river is promoted by the presence of local sections of intact ice cover during breakup and/or local channel characteristics (e.g., channel shoaling, variation in channel width, channel splitting by islands or bars, and sharp bends). However, ice jams can also form behind bridges and other artificial structures that constrict a channel. The severity of ice jamming varies from year-to-year and depends on factors such as the harshness of the winter, the amount of ice decay and melting prior to breakup, and the amount of rise in river level immediately prior to and at the time of breakup. Ice jams are commonly associated with larger, north-flowing rivers.

Natural Dams

Floods can also be caused by the formation and failure of natural dams, although these events are far more localized and less frequent (at the national scale) than hydrometeorological flooding. Floods from natural dams occur due to the blockage of drainage by landslides, glaciers, and moraines. Flooding occurs upstream of the natural dam as a result of ponding, but also downstream if there is a failure of the dam (or in some instances the development of a tunnel under a glacier) that allows the rapid drainage of the impounded water. These "outburst floods" produce peak discharges that are proportional to the volume of the impoundment, rather than the area of the contributing watershed, and the resulting flood can be larger by an order of magnitude or more than the maximum expected hydrological flood for the stream. Such large floods consequently may cause enormous erosion and channel change along the flood paths for many kilometers downstream of a dam and represent a much greater potential risk than the flooding behind the dam. With some specific glacier dams, outburst floods have happened nearly annually over periods of up to several decades because the dam has reformed repeatedly after successive drainages of the impoundment.

FLOOD MANAGEMENT

Preventing flood damages is one important element of flood management. There are a large number of strategies and methods available today to address flood hazards and disasters. Floods are natural environmental events (2). They present a hazard and may cause a disaster only after humans construct an environment on flood-prone lands (1,4–6). Building structures within floodplains is a development strategy chosen frequently by many societies all over the world. As a result, floods and floodplains need to be "managed" (7). Today, the common framework for dealing with floods comprises four general types of activities: (1) modifying flooding, (2) modifying susceptibility to flooding, (3) modifying the impacts of flooding, and (4) preserving the natural and beneficial functions of floodplains. Modifying flooding refers to structural flood control measures that are designed and constructed to keep the flood hazard away from people and buildings. Modifying susceptibility to flooding refers to activities designed to keep people and buildings away from the flood hazard. These are generally called nonstructural mitigation measures and include a broad set of tools (8,9). Modification of impacts of flooding on people includes floodplain management activities. These activities do not reduce the amount of damage that floods might cause, but they help "spread" the costs associated with those damages. The fourth set of management activities seeks to preserve the natural and beneficial functions of floodplains from an ecological perspective.

Flood Management Process

The flood management process can be divided into three major stages: planning, flood emergency management, and postflood recovery (10). During the *planning* stage, different alternative measures (structural and nonstructural) are analyzed and compared for possible implementation in order to reduce flood damages in the region. The analysis of alternative measures involves project formulation for each measure, understanding advantages and disadvantages of alternative project arrangements, evaluation of positive and negative project impacts, and finally relative comparison of alternative measures. Flood *emergency management* includes regular appraisal of the current flood situation and daily operation of flood control works. A very important aspect of the appraisal process is identification of potential events that could affect the current flood situation (such as dike breaches, wind setup, and heavy rainfall). At this stage decisions are made on urgent major capital works and flood upgrading measures for existing structures. From the appraisal of the current situation information is initiated regarding evacuation and repopulation of different areas. *Postflood recovery* involves numerous hard decisions regarding return to the "normal life." Issues of main concern during this stage of the flood management process include evaluation of damages, rehabilitation of damaged properties, and provision of flood assistance to flood victims. At this stage also, all environmental impacts are evaluated and mitigation strategies selected.

Structural Flood Management Measure

Flood management has the objective to evaluate utilization of possible methods for reducing flood damages to existing buildings and other facilities and reducing flood risk to permit additional growth. Structural measures can be further divided into local protection measures and upstream flood protection measures (usually storage reservoirs). Structural measures emphasize construction of levees or walls to prevent inundation from floods below some specific design flood flow. Additional works may include drainage and pumping facilities for areas that are sealed off from precipitation runoff to the river by the levees; diversion structures to divert flow during the peak from the protected region; channel modifications to increase the hydraulic capacity or stability of the river; and one or more reservoirs upstream from the protected area to capture the volume of a designed flood and release it at nondamaging rates.

Nonstructural Flood Management Measures

Nonstructural measures include zoning (to limit the types of land uses permitted to those that may not be severely damaged by floods), protection of individual properties (e.g., waterproofing of the lower floors of existing buildings), a flood warning system (to evacuate residents and to move valuables), and flood insurance (to recognize the risks of floods and to provide compensation when damages are not avoidable at acceptable cost) (11,12).

Responding to Floods and Sharing the Risks

As no flood risk management program can provide absolute protection, it is also appropriate to examine the institutional arrangements for responding to and recovering from floods. In most countries there are important federal flood management agencies. They usually coordinate and encourage emergency preparedness activities within the federal government, and between federal and lower level governments. In the context of flood response, as for all disaster response, they place initial responsibility upon individuals. Based on the extent of the flood and on an individual's capacity to respond, responsibility can move from municipal, to regional, and finally to federal levels. Each level of government must request the support of the next one. Emergency preparedness and response is clearly a shared activity among individuals, the private sector, and all levels of government.

EFFECTS OF DDT IN SURFACE WATER ON BIRD ABUNDANCE AND REPRODUCTION—A HISTORY

J. Gordon Edwards
San Jose, California

Early in the DDT controversy so many allegations were made that it was difficult to respond to them all in the available time. Hundreds of scientists patiently refuted those allegations, however, and their contributions are summarized in many books and articles. The news media were notified that they had been misinformed by some environmentalists, and a few carried stories that agreed more with the facts. They also became aware that most scientists disputed the allegations that DDT caused cancer, mutations, hepatitis, poliomyelitis or other human illnesses. It was made clear that DDT residues did NOT "build up" in animal food chains, because they were metabolized or excreted by fish, birds and mammals.

BIRD POPULATIONS THREATENED?

Some persons attempted to link bird declines with the heavy usage of DDT between 1946 and 1960 and to imply that birds later increased after DDT was banned. When those claims were investigated with objectively, it became evident that most declines had occurred either before DDT was present, OR after levels of DDT had waned. The Environmental Defense Fund commented on the abundance of birds during the DDT years, with "increasing numbers of pheasants, quail, doves, turkeys and other game species." To the list of increasing bird populations, the Audubon Society added eagles, gulls, ravens, herons, egrets, swallows, robins, grackles, red-winged blackbirds, cowbirds, and starlings. The annual Audubon Christmas Bird Counts between 1941 (pre-DDT) and 1960 (after DDT use had waned) showed that at least 26 different kinds of birds became more numerous during those decades of greatest DDT usage. They documented an overall increase from 1,379 birds seen per observer in 1941 to 5,742 birds seen per observer in 1960. Statistical analyses of the Audubon data confirmed the perceived increases.

At Hawk Mountain, Pennsylvania, counts of migrating raptors were made daily by teams of ornithologists for more than 40 years. The results were published annually by the Hawk Mountain Sanctuary Association and revealed great increases (not decreases) of most kinds of hawks during the DDT years. Total numbers of hawks counted there increased from 9,291 in 1946 to 13,616 in 1956 and 20,196 by 1967. Sparrow hawks seen were as follows: 1946–98; 1956–192; 1965–408; and 1967–666.

The activists could not explain the population explosions of white-tailed kites in heavily-sprayed California, or of robins, starlings, cowbirds and red-winged blackbirds throughout North America. They tried, saying that not all birds were affected by DDT, but only predators. Because it was evident that predators were also multiplying rapidly, they decided that not all predators were affected, but only those that preyed on fish. But the fish-eating murres, ospreys, and gulls were rapidly increasing, too. The murres on Funk Island (along the North Atlantic Coast) increased during the DDT decades, from 15,000 pairs in 1945 to a million and a half pairs by 1971, and gannets there went from 200 pairs in 1942 to 3,000 pairs in 1970 (1).

Herring gull numbers in Massachusetts exploded during the DDT decades, from 2,000 pairs (1941) to 35,000 pairs (by 1971). Although they were on the "protected" list, Massachusetts gave the Audubon bird-lovers permission to poison 30,000 of them on Tern Island. The local Audubon president, William Drury, said "It's kind of like weeding a garden" (2).

Many other kinds of birds multiplied so well in the presence of DDT and DDE that they became destructive pests. In North Carolina, 6 million blackbirds ruined the town of Scotland Neck in 1970, polluting streams, depositing 9 inches of droppings on the ground, and fouling the forests where they roosted at night. Near Fort Campbell, Kentucky, 77 million blackbirds were roosting, and the resulting threat of human disease (histoplasmosis) was of great concern (3). When marshes were sprayed in the Midwest to control mosquitoes, a common result was reported: "Today in a small area of northern Ohio, 10 million redwings mill about in the cornfields after the nesting season." They destroyed the crops, while farmers begged for avicidal relief. In Virginia, the Department of Agriculture stated, "We can no longer tolerate the damage caused by redwings... 15 million tons of grain are destroyed annually—enough to feed 90 million people" (4).

Rachel Carson started environmental activists down the path to extremism when she wrote *Silent Spring* in 1962 (5). Later, the groups were joined by extremists opposed to technology and dedicated to reducing human populations in Third World Countries in every way possible, including insect-transmitted diseases.

In the front of her book, Rachel Carson wrote that it was "Dedicated to Dr. Albert Schweitzer, who said 'Man has lost the capacity to foresee and to forestall. He will end by destroying the earth.'" Miss Carson certainly knew he was referring to atomic warfare when she quoted that, but she implied that he meant there were hazards from pesticides such as DDT. Because I had found so many other errors in her book, I got a copy of Schweitzer's autobiography to see if he really mentioned DDT. He did, writing on page 253: "How much labor and waste of time these wicked insects do cause us... but a ray of hope, in the use of DDT, is now held out to us" (6).

She also wrote (5, p. 118): "Like the robin, another American bird [the bald eagle] seems to be on the verge of extinction." Yet the robin was never endangered at all! Roger Tory Peterson, America's leading ornithologist, also writing in 1962 (7), stated that the robin was "the most abundant bird in North America". There is no doubt as to who was correct! The eagles had declined before DDT, but they increased during the DDT years. In addition, the Audubon Society's Christmas Bird Counts revealed that twelve times more robins were counted, per person, in the 1960 count than were seen during the 1941 count (before DDT). In addition, there were 21 times more cowbirds, 38 times more blackbirds, 131 times more grackles, and so forth. No matter how deceitful her prose, the influence of Carson's *Silent Spring* was great, and it continues to shape environmentalist propaganda as well as U.S. policy.

I taught medical entomology for years and was concerned about malaria, yellow fever, typhus, encephalitis, river blindness, leishmaniasis, and other tropical diseases that were transmitted by blood-sucking insects and could be controlled only by insecticides. The National Academy of Sciences wrote in its 1970 book, *The Life Sciences*, that "In little more than two decades DDT has prevented 500 million deaths due to malaria and other diseases, that would otherwise have been inevitable" (8). I found no references to those diseases in *Silent Spring*, however she wrote (5, p. 187): "Only yesterday mankind lived in fear of scourges of smallpox, cholera and plague. Now our major concern is no longer with the disease organisms that once were omnipresent; sanitation, better living conditions and new drugs have given us control over infectious disease. Today we are concerned with a different kind of hazard that lurks in our environment." She then launched into many pages of unsupported attacks on insecticides, with never a mention of those millions of human lives that had already been saved by DDT!

Charles Wurster was the chief Environmental Defense Fund biologist. He got some tanks of sea water, put some marine algae in them, and poured large amounts of DDT into the tanks, to see if it would harm the algae. He described how ethanol was added to each flask of DDT, "in order to yield the desired concentrations [500 parts per billion]." The solubility of DDT in water is only 1.2 parts per billion, so we wondered about the validity of his research, exposing the algae to hundreds of times more DDT in solution than would be possible without the alcohol. In previous tests with the same kinds of algae, Ravenna Ukeles and others had found that 600 ppb of DDT in the water did not affect the algae.

Wurster published his non-scientific results in *Science* magazine (9). In 1969 Dr. Paul Ehrlich expanded on Wurster's hoax and wrote what he called a "scenario" based upon it. He titled his article "*Ecocatastrophe*," and published it in *Ramparts* magazine (10). His article began with:

> "The end of the ocean came late in the summer of 1979, and it came even more rapidly than biologists had expected. There had been signs for more than a decade, commencing with the discovery in 1968 that DDT slows down photosynthesis in marine plant life. It was announced in a short paper in *Science*, but to ecologists it smacked of doomsday. They knew that DDT and similar chlorinated hydrocarbons had polluted the entire surface of the earth, including the sea."

Thousands of school children were required to read Ehrlich's scenario. It was a surprise to see that same exact article published by Ehrlich in England a year later, in a journal titled "*The Year's Best Science Fiction*."

BIRD DATA

Although at first many anti-DDT activists said that DDT was killing off adult birds, they soon had to admit it was not. They were not "dropping from the sky dead," as alleged by some environmentalists (5, p. 124), (11), nor were they "falling out of the trees by the thousands," as other extremists wrote (12).

Wurster (13) referred to "increasing numbers of pheasants, quail, turkeys, and other game species," and Audubon naturalists added at least 26 other species that increased in numbers during the decades of greatest DDT use (14,15).

The propagandists changed their story, and said DDT was killing nestling birds. That was shown by tests to be untrue, when all of the food given to experimental nestlings contained DDT, but no adverse effects resulted (16). They next said perhaps DDT makes the eggs thin-shelled or kills the developing embryos. Legitimate tests proved that they were wrong again.

In their effort to make people believe that DDT in normal bird diets caused thinning of eggshells, the environmental industry fostered tendentious feeding experiments during which their birds were exposed to treatments that every poultryman knew would cause severe eggshell thinning. This included removing calcium from the food, starving the birds, depriving them of water, and cutting the light from 16 hours a day to 8 hours a day.

Obviously, heavy DDT usage was not eradicating birds of any kind but what was causing the great *increase* of birds in areas that had been sprayed with DDT? Causes included the reduction in numbers of blood-sucking insect parasites, which provided birds protection from avian malaria, rickettsial-pox, bronchitis, Newcastle disease and encephalitis. Also, more bird-feed seeds and fruits were available for birds after phytophagous insects had been killed by insecticide sprays. Perhaps even more important was the medicinal effect of DDT. When ingested, DDT triggered the induction of hepatic enzymes that detoxified potent carcinogens such as aflatoxins produced by *Aspergillus* fungi, which abound in the natural foods eaten by birds. Aflatoxins are carcinogenic at levels of 0.03 to 0.08 ppm in the diets of birds, fish and mammals. Many humans in third world countries also die because of aflatoxins in their food.

The anti-DDT extremists relied on just three or four studies in their attempt to convince the Environmental Protection Agency hearing examiner that DDT causes serious thinning of the shells of birds. The studies included Bitman et al. (17), and Porter and Wiemeyer (18). Of course they could not explain the thin shells that occurred before DDT was used, nor could they explain the lack of adverse effects on eggs of captive birds that were experimentally dosed with DDT.

Research by Bitman was designed in such away that thin eggshells would have resulted regardless of whether DDT was added to the diet. His Japanese quail were fed a diet containing only 0.56% calcium “to provide calcium stress during egg-laying.” The DDT concentration added to the diet was 4,000 times the concentration in normal human diets in the United States. They blamed the DDT, instead of the calcium deficiency, for the production of thinner shells.

Compare that with the 1970 tests by FWS researchers Tucker and Haegele (19). They fed different amounts of calcium to each of three different cages of quails, *without* DDT: 3% calcium to the “controls”, 1.73% calcium to another group, and 1% calcium to the third group. None got any DDT or DDE. The shells formed by the 1% calcium birds were 9.3% thinner than the controls. Remember, Bitman and his colleagues at the FWS laboratory fed their quail food with only 0.56% calcium! That would be expected to result in much thinner eggshells than did Tucker’s 1% calcium group, even if Bitman had not added any DDT or DDE to the food.

During Congressional testimony, I criticized Bitman’s calcium-deficient quail diets. He evidently understood my criticisms and subsequently performed additional research with his quail. This time he fed the quail 2.7% calcium in the diet, instead of 0.56%. The result was that both the DDT-fed and the DDE-fed birds produced heavier eggshells, and there was no difference in shell thickness between the DDT-fed birds and the ‘controls.’ He sought to publish those results in *Science* magazine, but this time they were rejected. He had to publish them, instead, in *Poultry Science* (20).

Why did *Science* refuse Bitman’s second article? The editor of *Science* had informed Dr. Thomas Jukes earlier that *Science* would never publish any article about DDT that was not antagonistic to that insecticide, and through the years he enforced that attitude. Anti-DDT writers simply kept expanding their anti-DDT propaganda in *Science* magazine. It was written by the same coterie, and for references in *Science*, they simply kept citing each other. No other studies were accepted by America’s leading science journal. Without that sheltered bias, the case against DDT would have quickly folded and millions more human lives would have been saved.

BENEFICIAL RESULTS OF DDT

There was no scientific basis for the allegations that DDT caused bird populations to experience declines. On the contrary, it is obvious that proper use of DDT actually increased the populations of fish, birds and mammals, because of the following actions: (*1*) DDT applications increased the yield of plant products in fields, woods, marshes, fencerows, and roadside ditches; (*2*) they increased protective vegetative cover for birds and mammals and provided better nesting and denning sites; (*3*) they killed mosquitoes, flies, fleas, lice, and mites in sprayed areas, not only reducing stress and annoyance, but also preventing bird diseases transmitted by those arthropods (avian malaria, bronchitis, rickettsia-pox, Newcastle disease, and so forth); and (*4*) DDT stimulated the liver to produce more hepatic microsomal enzymes that broke down toxic substances in the body, including “aflatoxins” that occur commonly in natural foods such as moldy grain, nuts, cotton seed. Those aflatoxins, resulting from *Aspergillus* fungi, are among the most potent carcinogens known in foods. DDT-induced hepatic enzymes prevent the development of tumors in birds and mammals, according to research by McLean and McLean (21), Edward Laws (22), and Salinskas and Okey (23).

The anti-DDT propaganda was refuted by scientific research and also by the multiplying hoards of birds counted during the Christmas Bird Counts and the Hawk Mountain Sanctuary migration counts.

The anti-DDTers were apparently not impressed, even when birds became so abundant that they destroyed fields of corn or broke down the tree branches upon which they roosted. They didn’t seem to realize that DDT had failed to harm the destructive birds. They apparently felt that DDT caused good birds to decline and bad birds to have population explosions!

PERSISTENCE OF DDT RESIDUES

During the seven months of EPA hearings on DDT, Dr. George Woodwell testified regarding an article written by him and Charles Wurster (24). The hearing transcript contained a statement that: “DDT residues in an extensive salt marsh on the south shore of Long Island average more than 13 pounds per acre” (This was discussed on p. 7232 of the hearing transcript, on January 13, 1972), as follows:

The USDA attorney asked Woodwell:

Q “Isn’t it a fact that after you initially studied this marsh you continued your samplings, and found as a result that you were getting an average of one pound per acre of DDT?"

A "No, I wouldn't agree with that."

Q "Didn't you also find out later that one of the areas where you took your samples was an area that was convenient for the mosquito Commission's spray truck, too?"

A "I can't say that I discovered that, either. I don't believe there's any evidence to that effect."

Q "Dr. Wurster, perhaps?" [We had told the attorneys the details of Wurster's Seattle testimony, and Wurster was in the audience, this day.]

A "I don't believe he knows that, either. I don't believe there's any evidence to that effect."

Q "Dr. Wurster, your coauthor, made the following statement at the Washington state hearings, and I'm quoting him verbatim: He testified: 'We have since sampled that marsh more extensively, and we found that the average in the marsh was closer to one pound per acre. The discrepancy was because our initial sampling was in a convenient place, and this turned out to be a convenient place for the mosquito Commission's spray truck, too.' Did you learn that after the fact, Doctor?"

A "That is a true statement in my experience. I did not know that Dr. Wurster had said that, but that is a true statement."

Q "Doctor, have you ever published a retraction of this 13 pounds per acre, or a further article which discloses the results of your further sampling which brings the average down to around one pound per acre?"

A "I never felt that this was necessary."

(Woodwell also admitted they had only taken six samples of the soil in that extensive marsh!)

BREAKDOWN AND DISAPPEARANCE OF DDT

Earlier, George Woodwell et al. wrote (25), that "6 billion pounds of DDT had been used, but only 12 million pounds could be accounted for in all of the earth's biota", and that was "less than a thirtieth of one year's production of DDT in the 1960's." He wrote that "most of the DDT has either been degraded to innocuousness or sequestered in places where it is not freely available." That contrasted so sharply with his testimony during the EPA hearings that a reporter asked him why he had completely omitted it from his testimony. Woodwell replied that the EPA lawyers told him not to mention the article, "lest my testimony be disallowed" (26).

A Department of Interior study at Gulf Breeze, Florida was reported in *Chemical Assays* (27). Huge glass containers were filled with sea water, a large amount of DDT was added, and the closed containers were suspended in the Gulf. Nearly every day, a sample was taken out for analysis. After 38 days, 92% of the DDT (and its metabolites, DDD and DDE), had disappeared.

In Washington state estuaries, the Bureau of Commercial Fisheries monitored pesticide residues in shellfish at 19 stations during 3 years of heavy DDT use (1966–1969). Ninety-three percent of the samples contained less than 10 parts per billion of DDT (and the highest level found was only 0.1 part per million). Only 3% of the samples contained chlorinated hydrocarbon insecticides. Shellfish are known to "concentrate" chlorinated hydrocarbons in their systems at levels 40,000 to 70,000 times as great as that in the surrounding water, so it is evident that the coastal waters were very free of DDT residues.

DDT is broken down rather rapidly by heat, cold, moisture, sunlight, alkalinity, salinity, soil micro-organisms, and a great many other things. Studies abound regarding DDT disappearance from soil, sand, leaf litter, plant tissues, animal tissues, and water.

Croker and Wilson applied DDT to a tidal marsh (28). In less than 24 hours, only traces remained, and even those traces disappeared in five days.

Finally, the environmental extremists had to resort simply to endlessly repeating all of the old allegations and hoping that most people had not heard about the refutations. The failure of the news media to report the truth helped them get away with that ruse, and pseudo-environmental magazines continued to frighten readers with the same old unsubstantiated myths.

BROWN PELICANS

In 1918, T. Gilbert Pearson and Robert Allen investigated habitats of brown pelicans along the 1,500-mile coastline of the Gulf of Mexico from Key West to the mouth of the Rio Grande. Belatedly reporting his results in *National Geographic* magazine in March 1934, (29), Pearson estimated a total of 65,000 pelicans during that survey. Robert Allen repeated that Gulf survey in 1934, after becoming president of the National Audubon Society. He discovered there had been an 82% decrease in pelican numbers in the 16 years since their earlier survey. He saw only 900 pelicans in Texas and practically none in Louisiana (30). In 1937, the results were published *in Adventures in Bird Protection* (31). According to *Conservation In The United States* (32, p. 414), 17 colonies existed along the Texas coast in 1918, but only one colony of 500 pelicans remained in 1939, and it declined to 200 by 1941.

I reported on these and dozens of other findings during my testimony in Congressman W.R. Poage's hearings for the House Agriculture Committee, on March 18 1971. Finley and Keith (of the U. S. Fish & Wildlife Service), however, were issuing bulletins stating that "A catastrophic decline has occurred on the Gulf Coasts of Texas and Louisiana where a population of over 50,000 brown pelicans has all but disappeared since 1961." The cause, they insisted, was DDT!

In 1961, van Tets saw the last active nesting colony in Louisiana, on North Island, containing only 200 pairs (33). Those, plus the 900 reported in Texas, fell far short of the alleged 50,000 conjured up by Finley, so I called him to ask for details. He answered on March 29, 1971, saying "In response to your inquiry, I have investigated the source of the reported 50,000 brown pelicans on the Texas and Louisiana coasts. The only comprehensive estimate was made by T.G. Pearson: 65,000 birds, in his 1934 book." Was it possible that Finley didn't know that the total in 1918 was for the entire 1,500-mile Gulf Coast and was in *National Geographic*, instead of a book? Was it also possible that he was unaware of Robert Allen's 1934 survey? He cited only five references, dated 1879 to 1955, and concluded "Although the reports are sketchy, Jim Keith and I both feel that the estimate of 50,000 is not unreasonably high." Five months later, however, (August 2, 1971), he wrote to Congressman Poage, stating: "The year 1961 was merely a hasty approximation of an unknown time. After reviewing the evidence, I think now that I should have said the 50,000 pelicans disappeared **by** 1961 [instead of **since** 1961]." (emphasis added). The truth was that the total number did not exceed 300 pelicans along the entire Texas coast in 1942 (before DDT), according to Audubon researchers. If the pelicans had somehow multiplied from less than 500 in 1959 to 50,000 before 1961, as Finley and Keith claimed, they would have had to do it in a habitat that was rich in DDT!

The significance of Finley's belated retraction of the untruthful "50,000 pelican disappearance" was great. It removed the possibility that DDT could have caused a pelican disappearance that never occurred! In fact, the declines obviously occurred long before any DDT was present, and resulted from human persecution, oil spills, gas blowouts, bombing, machine gun practice by the military, and hurricanes.

In 1968, Schreiber and DeLong surveyed California's Anacapa Island pelican colony for the Smithsonian Institution and wrote: "While fluctuations in numbers do occur, there has been no apparent decline in recent years along the California coast" (34). (There were no adverse effects from DDT).

In 1968, Jehl and Keith saw dozens of sick pelicans along the shore of the Gulf of California (35). Soon thereafter, coastal southern California experienced a severe epidemic of Newcastle Disease. A major symptom of that disease is the production of misshapen, soft-shelled eggs.

On January 28, 1969, the Santa Barbara Oil Spill occurred near the southern California coast. Oil surrounded Anacapa Island, and two biologists (Jehl and Risebrough) went out in March to see how much damage the oil was causing to sea lions. They also entered a brown pelican colony and it was reported in *Cry California* (36) that there were many soft or broken eggshells in and near the nests there. Jehl recalled that "As soon as the [poor] condition of the eggs was appreciated, Risebrough was able to postulate that chlorinated hydrocarbon pesticides [DDT] were probably responsible" (37, p. 18).

In California, the pelicans had experienced no difficulties during the 20 years of heavy DDT usage but suddenly suffered a reproductive failure just after the great oil spill surrounded their Anacapa Island colony, according to Jehl and Kennedy. Scientists should have been impressed by that, but the oil spill was not discussed in any reports about the pelican nesting failure.

The oil film, through which the pelicans were diving for fish, contained 21 ppm of mercury (38), and the anchovies upon which the pelicans fed contained 17 ppm of mercury. Mercury is known to have in serious adverse effects on birds, their eggs, and their young.

Environmentalists concealed the fact that California Fish & Game biologists had found that those anchovies contained high levels of lead, which is known to cause severe shell-thinning. They collected hundreds of pelican eggs from that colony during the next two summers, and their shells were measured with screw micrometers. In April 1972, I obtained all of those measurements and found that they clearly revealed inverse correlations between DDT residues and shell thicknesses. Some of the thinnest shells were those of eggs with low DDT levels, and the higher DDT concentrations were often in the thicker-shelled eggs (39). That was also reported by Switzer at the 1972 EPA hearings on transcript pages 1812–1836. I had discussed all of this during my testimony before Congressman Poage, and it was published as a document by the *Committee on Agriculture*, March 18, 1971 (40). Robert Finley, who was in charge of Fish & Wildlife Service pelican studies throughout the United States, responded to my testimony before Congressman Poage's Committee by writing Poage (August 2, 1971) that "there is not a shred of evidence that spilled oil is capable of causing thin-shelled eggs or otherwise affecting bird reproduction." On the contrary, Hartung (41) said that spilled oil reduces hatchability by 68%. Anonymous reports in *Conservation News* (NWF) (42) discussed "Embryo mortality from oil on feathers of adult birds." Dieter wrote that "oil on eggs kills 76 to 98% of embryos inside, and birds that have ingested oil produce 70% to 100% fewer eggs than normal" and "Liver and spleen atrophy may result from oil exposure." (43). King (44) said, "oil is a cause of pelican mortality for six weeks after a spill." Szaro (45) reported that "oil causes kidney nephrosis, pancreatic degeneration and lipid pneumonia." Birds may lose their ability to compensate for osmotic water loss when oil inhibits water uptake by the intestine, which in turn fails to trigger the necessary desalination of water by the nasal glands. He concluded that "It is possible that dehydration may cause the death of many oil-contaminated birds."

In 1923, Dawson described, in *Birds of California* (46), how "merely the brief presence of a human on Anacapa caused adult pelicans to spring from their nests, breaking their eggs with their feet as they did so, and the exposed eggs and nestlings were quickly eaten by marauding gulls." All such warnings were ignored by the Fish & Wildlife specialists! The FWS biologist in charge (Jehl) even admitted that **they had shotgunned pelicans sitting on their nests of eggs** (47), so they could compare the DDT residues in the birds with those in their eggs. They also admitted that they had **collected 72% of all intact eggs in the Anacapa pelican colonies for analysis!** Those analyses revealed an inverse statistical correlation between DDT residues and shell thickness! When the government biologists again invaded the Anacapa colony in 1969, the results must certainly have been anticipated, yet they sought to blame the nesting difficulties entirely on "traces of DDT in the fish" eaten by the birds.

My student and collaborator, Richard Main, was employed by the National Park Service for 2 years. He trapped many large Norway rats beside pelican nests in the Anacapa colony (in "safe traps"). The National Park Service wanted to poison the rats, to protect the young pelicans, but that was prohibited by the California Fish & Game Department because, they said, they feared that native rodents there might also be killed. Several feral cats also roamed about in the colony because a man named Frenchy left them there when he moved from Frenchy's Cove a few years earlier.

Franklin Gress, a graduate student at the University of California, studied the Anacapa pelicans in 1970. The desertion of the colony occurred following his flights to the island by helicopter and his hours sitting in nests in the colonies. His extensive notes were released in 1970 by the Resources Agency of the California Department of Fish & Game. His first visit was March 29, when he counted 127 nests, but he wrote that "The number of nesting birds dwindled, as nests were deserted, until by April 1st the colony was virtually abandoned." He returned on April 20th, and soon wrote that "the nesting attempts seemed to be irresolute." Two days later "the colony was suddenly deserted." A similar result followed his third visit, on June 1st, when he noted that "It was evident that the process of abandonment had begun." By June 20, "the colony was nearly abandoned, and there was no other nesting on the island." On June 29, he returned and reported that "only one nest contained a nestling... this was the only pelican to hatch in either colony on Anacapa Island in 1970." (It should be noted that the Park Rangers who patrolled the island by boat laughed and said they saw numerous young pelicans standing on nests during the intervals between Gress' disruptive visits.)

In 1971, at the request of the National Park Service and Secretary of the Interior William Pecora, Richard Main and I drew up protective regulations for the Anacapa pelican colonies, keeping the destructive government biologists out of the colony during the following breeding season, from March 15 to July 31. The oil was mostly gone, and there had not been time enough for DDT levels to decrease in the water or in the fish, yet the pelican productivity was great! The pelicans quickly recovered their breeding potential (48,49).

The Federal Fish & Wildlife Service and the California Fish & Game Department continued to issue pelican reports that never mentioned the oil spill, the rats, the disruptions by humans and helicopters, the egg predation by biologists, the lead in the pelican bones, or the epidemic of Newcastle Disease in coastal Southern California. They always attributed the alleged declines, however, to DDT!

Those allegations played a very important part in the EPA hearings that led to the banning of DDT in December 1972. We, and many National Park personnel, were convinced that they wanted to totally destroy the colony which would help the EPA to ban DDT. (Malaria would then continue to destroy millions of humans in the Third World and halt the population explosions there.) As it turned out, they succeeded in the broader goal, but failed to actually destroy the pelican colonies.

The Fish and Wildlife Service never publicly corrected its erroneous "since 1961" propaganda, so the news media continued to say that DDT nearly caused the marvelous pelicans to become extinct during the 1960s. Perhaps many people still think that the pelicans were saved from extinction "because attorney William Ruckelshaus banned DDT in 1972!"

That was enough to shake our confidence in the Fish & Wildlife Service, the Environmental Protection Agency, their pelican propaganda, and their integrity!

THE ENDANGERED OSPREY

Long before DDT was used in this country, Hickey (50) attributed a 70% decline of eastern ospreys to "pole trapping" around fish hatcheries. In 1971, Chesapeake Bay ospreys had no problem with DDT or DDE, but "lipids of osprey eggs had PCB levels from 545 to 2270 parts per million" (51). In 1972 Hickey avoided mentioning that ospreys were abundant throughout the west, despite massive applications of DDT there (52). Studies in Wisconsin and Michigan revealed an increase in nesting osprey productivity, from 11 young in 1965 to 74 young in 1970, before the DDT ban. Because data from other regions were sparse or unavailable, many incorrectly assumed that the population crashes were uniform throughout North America, but actually Ornithologist Charles Henny said, "there may be more of the birds in the West than ever before. Their future appears good" (53). Henny estimated that there were 5,000 or more breeding pairs in North America, plus non-breeding adults and juveniles. He wrote that "The population declines of the 1960s, largely attributed to DDT, were not as widespread as originally thought."

After DDT was developed, Hickey ignored the pole trapping and shooting of ospreys and blamed only DDT for all bird declines. I was a member of the Hawk Mountain Sanctuary Association and was impressed by its published data on ospreys. At Hawk Mountain, Pennsylvania, the survey of migrating ospreys during the DDT years revealed the following results: 191 ospreys in 1946, 254 in 1951, 352 in 1961, 457 in 1967, 529 in 1969, and 630 in 1972 (54). It was difficult to believe the charges that DDT threatened osprey extinction, when more were migrating every year after the introduction of DDT, setting new all-time records in several of those years.

There were many reports of high levels of mercury in the fish upon which ospreys depended for food. (Mercury causes drastic thinning of shells of eggs.) It was alleged, however, that DDT and DDE had contaminated the fish world-wide, and that, as a result, fish-eating birds could not reproduce successfully! Chesapeake Bay ospreys had no trouble with DDT or DDE, but their eggs contained high PCB levels (51). That was shown to cause drastic thinning of eggshells, as well as many other adverse effects, yet environmentalists continued to place the blame solely on DDT, despite the fact that feeding birds high levels of DDT alone did not cause birds to produce such thin eggshells.

After DDT was banned, the Hawk Mountain Sanctuary Association *Newsletter* reported in April 1976 that "For reasons we do not understand at all, the number of osprey going south is returning to something like normal, just 318 in 1974 and 279 in 1975." (Notice how many fewer there were in the years after DDT disappeared!)

BALD EAGLES

These birds have suffered much at the hand of humans, but not because of DDT. In 1917, Alaska enacted legislation providing a bounty of 50¢ per eagle and increased the bounty, later. From that time until 1952, the state paid bounties on 128,000 dead eagles (more than $100,000). An article in a 1921 issue of *Ecology* magazine (55) was titled "Threatened Extinction of the Bald Eagle."

In the 1930s, there were no records of bald eagles in most of New England, not more than 10 in Pennsylvania, and perhaps 15 or 20 along Chesapeake Bay. *Bird Lore* magazine (56) stated, "this will give some idea of the rarity of the eagle in eastern United States." That was 14 years before DDT was present, and the eagles surely could not have disappeared in anticipation of DDT!

In 1937, Bent wrote that "the bald eagle probably nested at one time over much of New England, but there are no recent authentic records of them nesting in the three southern states there." (57).

Each year, thousands of bird watchers participate in the annual Christmas Bird Count for the National Audubon Society. In 1941 (before any DDT was used), they saw 197 bald eagles (14), but in 1960 (after 15 years of heavy DDT use), the count was 891 bald eagles seen (15). If those results had been the reverse, I might have also thought that DDT was killing them!

The Hawk Mountain Sanctuary censuses, tabulated almost daily throughout the years, showed that the number of bald eagles migrating over Pennsylvania more than doubled during the first 6 years of heavy DDT use (1946–1952). (Their summaries also revealed great increases in most other kinds of raptors during the "DDT years.")

In 1943, in *Science News Letter* (58), it was stated "When the timber was cleared it was inevitable that the eagles had to go. The cities grew and fouled the rivers with sewage and industrial waste. The once-teeming fish population vanished. With their main source of food thus taken away, it was only natural that the eagles might vanish also." Notice that was written years before DDT appeared in North America!

In America's Eagle Heritage (59), the study of bald eagles in the Everglades is discussed. "In 1959 there were 24 active nests, which produced 18 young; in 1964 there were 51 nests, which produced 41 eaglets." Notice the sizeable increase! The chief Everglades biologist reported that "The population is stable and is reproducing at a rate more than adequate to maintain its numbers (and) I know of no evidence that the region ever supported a larger number of nesting eagles."

At the Patuxent Wildlife Research Center in Maryland (U.S. Department of Interior), autopsies were performed on all bald eagles found dead in eastern U.S. between 1960 and 1965. Coon et al. (60) stated that none of those deaths was blamed on DDT. Forty-six had been shot or trapped, and 7 died of injuries from flying into buildings or towers. Between 1965 and 1980, they performed autopsies on 652 more bald eagles from across the nation. The major cause of death was always shooting and trapping, but there were also many deaths from electrocution or impact with solid structures. The scientists concluded that "the role of pesticides has been greatly exaggerated." In 1972, the carcasses contained twice as much PCB as DDT, DDD, and DDE combined, and the brains had four times as much PCB" (61).

In 1983, New York State contained only three active eagle nests. Later, 150 bald eagles were imported from Alaska. Peter Nye (62) wrote, "My colleagues and I identified 80 locations in New York believed to have been bald eagle nesting sites between 1880 and 1960. By 1940 only a handful of pairs could be identified; yet [he said] the oft-mentioned culprit, DDT, wasn't put into use until the last few nesting eagles were already struggling for their survival" Nye and his colleagues imported eaglets from Alaska beginning in 1976, including 49 in the first 3 years. Now a healthy population is there.

Postupalski (63) found no significant correlation between DDT or DDE residues and shell thickness in a large series of Bald Eagle eggs. However, Stickel reported that bald eagles produced eggs whose shells were 14% to 21% thinner after lead, mercury, or a small dose of parathion was added to their food (64).

Krantz et al. (65) analyzed bald eagle eggs from three states and found that eggshells from Florida were thinnest (0.50 mm), followed by those from Maine (0.53) and Wisconsin (0.55). Analyses of their DDT residues revealed an inverse correlation: the eggs from Maine contained 21.76 ppm, twice as much as those from Florida and five times as much as those from Wisconsin. Obviously, DDT and DDE were not correlated with that shell thinning.

In Wisconsin and Michigan, an increase in nesting bald eagle productivity was noted, from 51 young produced in 1964 to 107 in 1970. In 1966, Fish & Wildlife biologists fed large amounts of DDT to captive bald eagles for 112 days, then concluded that "DDT residues encountered by eagles in the environment would not adversely affect eagles or their eggs" (64). Other wildlife authorities attributed bald eagle reductions to "widespread loss of suitable habitat," but said "illegal shooting continues to be the leading cause of direct mortality in both adult and immature bald eagles."

To summarize, the bald eagle in the lower 48 states was on the verge of extinction in the 1920s and 1930s, long before DDT was discovered. They were shot on sight for fun, bounty, or feathers, trapped accidentally, killed by impact with buildings and towers, or electrocuted by power lines. Many more may have died because of the high levels of PCBs in their lipids and brains. Thousands have now been reared in captivity and released into the wild. The increased numbers of bald eagles are admired and protected.

The most surprising thing is that the environmental industry and the news media continued erroneously to attribute the increase in eagle numbers from 1946 to 1970 to just one thing... the 1972 ban on DDT!

EGGSHELL THINNING

Shell-less eggs or eggs with thin or distorted shells are the result of any of a great number of factors. Older birds produce thin-shelled eggs, as do some young birds, and perfectly normal eggshells become 5% to 10% thinner as the developing embryo withdraws calcium for bone formation. Even the same bird produces varying eggshell thicknesses as time passes. Higher temperatures and dehydration cause thinner shells to be formed, as does higher relative humidity. A reduction in illumination causes drastic changes in shell formation, and the duration of the light has physiological effects as well as regulating the amount of food the birds have time to eat. Stress from excitement, fear, and noise is very destructive to egg-laying success. Simple restraint interferes with the transport of calcium throughout the bird's body, preventing it from reaching the shell gland and forming good eggshells. Lower than normal temperatures reduce the carbonic anhydrase activity, which causes thinner shells.

A great many environmental substances inhibit a bird's ability to produce normal eggshells (oil, lead, mercury, PCBs, 2,4-D, cadmium, lithium, chromium, selenium, and sulfur compounds in the diet). Sulfa drugs, especially sulfanilamide, may result in the complete absence of a shell around the yolk.

Tucker (66) reported that after water was withheld from quail for 36 hours, they produced eggshells 29.6% thinner when drinking was resumed. He also found that parathion ingestion caused 4.8% thinner shells, Sevin caused 8.7% thinning, mercury caused 8.6% thinning, and lead caused 14.5% thinner shells, but *p,p′*-DDT and DDE caused NO shell thinning and *o,p′*-DDT caused shells 0.5% thicker to be formed.

Many bird diseases, such as avian bronchitis, avian malaria, rickettsia pox, or Newcastle disease, may cause great thinning of eggshells. Such information has been well covered in the literature, including a great book, *The Avian Egg*, by the Romanoffs (67). The environmental extremists, who sought to blame DDT, never mentioned that book or Romanoff's *The Avian Embryo* (68).

A deficiency of phosphorus or Vitamin D also results in thin eggshells, but the most notorious cause of thinning is the lack of sufficient calcium. When the diet contains less than 1% calcium, the bird's leg bones may soften to such an extent that even walking is difficult. Wasn't it curious that the FWS researchers at Patuxent deliberately fed their DDT-dosed birds only food that was deficient in calcium, and then attributed the shell thinning to the massive amounts of DDT and DDE they added to the diets?

Dozens of researchers (and thousands of farmers) found that DDT did *not* cause shell-thinning. Jefferies fed his finches 50 to 300 micrograms per day of DDT, which "caused calcium metabolism to tend toward the production of *heavier* shells." (emphasis added) After 2 years they still formed shells that were 7% thicker (69). Frank Cherms fed quail 200 mg/kg of DDT for months, with no effect on shell thickness through four generations. DeWitt (70) fed his pheasants diets containing 50 ppm DDT throughout the year, and reported that the birds produced 23% more hatchable eggs than the controls (and 2 weeks later 100% of the DDT chicks were alive, but 6% of the "controls" had died).

It was demonstrated repeatedly in caged experiments that DDT, DDD, and DDE did not cause shell-thinning, even at levels hundreds of times greater than wild birds would ever accumulate. During many years of carefully controlled feeding experiments, Scott et al. (71) found "no tremors, no mortality, no thinning of egg shells and no interference with reproduction caused by levels of DDT which were as high as those reported to be present in most of the wild birds where 'catastrophic' decreases in shell quality and reproduction have been claimed." Scott et al. also found that, "DDT did not have any deleterious effect upon the sex hormones involved in egg production and indeed may have had a beneficial effect upon egg shell quality."

Early egg collectors routinely saved only thick-shelled eggs. Comparisons between the shell thickness of museum eggs and those collected more recently are misleading and have led to much of the eggshell propaganda during the DDT years. Hickey and Anderson (72) measured the shells of 1729 museum eggs, and reported differences in shell weights of the eggs of five bird species, but said "changes did not occur in the five other species we studied, or in dozens of others, not studied." Four of the five species they reported in their big table had eggs that were *heavier* after DDT use began than those produced during pre-DDT years. Golden eagle eggshells during the "DDT years" were 5% thicker than those produced before any DDT was used. Red-tailed hawk eggs just before DDT was present had much thinner shells than did the pre-1937 eggs, but during the years of heavy DDT use, the birds produced shells that were 6% thicker.

Claus and Bolander in *Ecological Sanity* (73) wrote,

> "We have nowhere seen reports of changes in the shell thickness of any species which exceed 50 to 60 microns (0.05 to 0.06 mm) and in some cases differences of 5 to 7 microns have been reported as 'significant decreases' (0.005 to 0.007 mm differences). Since only the 2nd and in some cases the 3rd decimal point differ, one wonders how significant those differences really were!"

Morris et al. (74) reported that "the most critical area of light intensity change is in the range between 8 and 16 hours and decreasing photoperiods depress rate of lay." It was interesting that Peakall (75) deliberately used those precise hours in his efforts to incriminate DDT. Peakall kept his ring-doves in a cage on a 16-hour light and 8-hour dark schedule. When ready for the experiment, he put the female of each pair into isolation and abruptly reduced the light to only 8 hours per day. At the same time, he began feeding the doves 10 ppm of DDT in all of their food! Poultry would have stopped laying entirely under those conditions, but the doves continued to produce good eggs. Apparently determined to stop their productivity, Peakall then began to inject intraperitoneally large amounts (150 mg/kg) of DDE (not DDT!) into each bird! (They still continued to lay eggs.)

Hauser (76) warned that "Providing adequate light is just as important as vaccination, parasite control, and feeding programs. When lightbulbs in the hen-house are dirty and the hen receives less light than needed, the stress may be severe enough to cause a premature molt." (The effect of Peakall's 50% reduction in illumination would obviously be severe!)

Details of such "experiments" were exposed and discussed in detail by many qualified biologists, however, the media, the pseudoenvironmentalists, and the financially-rewarded anti-DDT "researchers" failed to publicize frauds. Consequently, the general public remained misinformed about the causes of eggshell thinning, and anti-DDT extremists continued to accumulate money and power as a result.

Measuring Eggshell Thickness

The great book by Claus and Bolander (73) includes nearly 300 pages dealing with DDT frauds. They revealed many examples of the untruthfulness of anti-DDT propagandists. A section titled "The Turning of the Screw" (73, pp. 400–405) exposes the reasons that screw micrometers failed to measure bird eggshells accurately. The differences between thicknesses of shells were measured "to the nearest 0.01 mm" (10 microns) and were, in some cases, reported as "significant" thinning if the difference was 5 to 7 microns! Claus and Bolander reminded readers that a human red blood cell is about 8 microns across and a human hair may be 50 to 80 microns in diameter. Also, an eggshell that has a soft texture and an easily-compressible inner membrane might not be measured very accurately with a screw micrometer by a person seeking to prove that DDT caused eggshell thinning.

POLYCHLORINATED BIPHENYLS

There are known to be about 200 different PCBs in the environment. They came into usage in the 1930s as plasticizers on wires and cables and for protective coatings on metals, plastics, and wood. They are also paint extenders and heat exchange fluids in transformers. Every fluorescent light ballast contained liquid PCB, so gas chromatograph analyses for DDT performed in rooms with those lights distorted all results. The plastic tubing in the apparatus, and other plastics that had been in contact with the samples also resulted in false analyses of DDT. Samples to be analyzed were frequently stored in plastic or cellophane containers, which also produced PCBs. In 1985, Wolff and Peel (77) confirmed that the famous allegations of high DDT levels in Antarctic samples "were overblown by more than 100-fold" because the plastic bags in which they were stored contained so much PCB (78). In 1969, Peterle (79) attempted to measure DDT in Antarctic snow and melt-water. Only one of his five filters indicated any DDT presence, but based on that single filter, he wrote that "there should be five million pounds of DDT in Antarctic snow." (No other analyses confirmed his guess.)

PCBs occurred in most fish and wildlife samples at higher concentrations than did DDT residues. In 1970, Risebrough et al. pointed out that "PCBs are more important enzyme inducers than DDE, causing delayed breeding" (80). When ingested by birds, they were known to cause infertility, eggshell thinning, non-hatchability, and severe physiological damage. Curley et al. (81) stated that "PCBs throw off hormonal levels in birds, affecting calcium reserves, which in turn result in thinner eggshells."

In 1971, Risebrough and Spitzer stated that Chesapeake Bay ospreys had no trouble with DDT or DDE, but that their eggs contained PCB levels from 545 to 2,270 parts per million (82). Boyle (83) reported that Herring gulls from the Great Lakes contained an average of 2,224 ppm of PCB" and "signs of eggshell thinning were found in nine of thirteen species in the region."

Scott et al. (84) observed that "Many reports relating reproductive declines of wild birds to DDT and DDE were based on analytical procedures that did not distinguish between DDT and PCBs." Because PCBs caused such severe effects on fish, birds, and wildlife, it was noteworthy that so great a proportion of the difficulties were later admitted to have really been PCBs, instead of DDT. Feeding birds high levels of DDT alone did not cause birds to produce those thin eggshells.

By 1971, 5,000 tons of PCBs were being produced annually in the United States. After 20 years of faulty analyses of DDT, it was finally admitted that we had been misinformed and that many individuals who *knew* the truth had deliberately concealed it to foster banning DDT!

Lichtenstein et al. (85) prepared a table revealing GLC analyses of 11 Aroclor™ plasticizers and listing various chlorinated hydrocarbon insecticides whose peaks were identical to some peaks of PCBs. Those insecticides included DDT, DDD, Lindane, heptachlor, heptachlor epoxide, aldrin, and dieldrin.

Aquatic habitats have often been seriously threatened by PCBs. Harvey (86) and (87) stated that there was "twice as much PCB as DDT in Atlantic sea water," and Giam et al. (88) found similar levels in plankton from the Gulf of Mexico and the Caribbean. Hom et al. (89) reported that there were large amounts of PCB in the Santa Barbara Basin of southern California (near Anacapa Island), where a high "apparent DDE" concentration was reported in sediment that was deposited 12 years before any DDT or DDE existed. They explained that away by saying "we attribute the higher DDE concentration in the 1930 sediment to spurious contamination during collection, storage or analysis."

In 1965, Anderson et al. analyzed five samples of egg-pools, which they then claimed contained high levels of DDT. Years later, after DDT had been banned, they reanalyzed those five samples and belatedly reported that three of the five samples actually contained no DDT at all, and the other two had only a fourth as much as touted in their earlier article (90). Scott et al. (84, p. 364) reminded us that those authors had led the campaign to ban DDT because of its supposedly "proven effects on eggshells," but they later sought to implicate PCBs as having been the *real* hazard.

Sherman (91) called attention to these developments and observed that "This negated the putative data that were the basis for previous alleged sensational charges against DDT. For thirty years DDT was a scapegoat for artifacts and mimics of that pesticide."

If the errors that were so frequently repeated by anti-DDT activists were actually unintentional, they should have corrected them. That practice of not correcting misstatements also seemed to appeal to journalists, politicians, and environmentalists. As a result, DDT was eventually placed on trial by William Ruckelshaus, the head of the Environmental Protection Agency.

In April 1972, after 7 months presiding over those EPA hearings, Judge Edmund Sweeney concluded that "DDT is not a carcinogenic hazard to man... DDT is not a mutagenic or teratogenic hazard to man... The uses of DDT under the regulations involved here do not have a deleterious effect on freshwater fish, estuarine organisms, wild birds or other wildlife. The evidence in this proceeding supports the conclusion that there is a present need for the essential uses of DDT" (92).

Incredibly, EPA Administrator Ruckelshaus (an attorney, with no knowledge of the scientific facts) never attended a single day of the seven months of hearings, and (according to his special assistant, Marshall Miller, did not even read the transcript of those vital hearings) (93). However, he overruled the judge (and ignored the hundreds of truthful scientists who had traveled to testify during the hearings). He was a strong supporter of the Environmental Defense Fund, and deliberately ignored the scientists' 9,000 pages of testimony and personally banned DDT. Several of the serious errors and untruths in Ruckelshaus' "Opinion and Decision" concerning DDT were exposed and were published in the *Congressional Record* by Senator Barry Goldwater in 1972 (94). The information concerning his decision was never adequately reported by the news media or by the pseudoenvironmentalists. Ruckelshaus mistakenly applied the wrong name to DDT, erroneously stated that DDE was also an insecticide, and proposed that applications of DDT be replaced by parathion (which had already killed or injured hundreds of people).

John Quarles' June 3, 1982 affidavit to the U.S. District Court for Northern Alabama is of interest because it discussed the irresponsible Ruckelshaus ban of DDT. Quarles had served as General Council for Mr. Ruckelshaus in 1971 and 1972. He testified, "After seven months of hearings, the EPA Hearing Examiner made findings generally supportive of the position that DDT did not cause undue harm and that an adequate basis did not exist for cancelling the uses of DDT." Quarles added that "There were no findings that DDT had caused harm or would cause harm under a specific set of circumstances or at any particular time or place." This was of course not reported by the news media and was buried by every environmental group.

On April 26, 1979, in a letter to Allan Grant (the president of the American Farm Bureau Federation), Mr. Ruckelshaus wrote, "Decisions by the government involving the use of toxic substances are political, with a small 'p'. Science has a role to play, but the ultimate judgement remains political, (and) the power to make this judgement has been delegated to the Administrator of the EPA." By the time Ruckelshaus wrote that letter, he had become senior vice president of the (non-environmental) Weyerhauser Lumber Company! Later he took charge of the Browning-Ferris garbage disposal company and sought to dump trash and garbage into a pleasant little stream in Apanolia Canyon, near Half Moon Bay, California. That would have destroyed irreplaceable riparian habitats and an ecological complex of great diversity." Fortunately, local outrage against Ruckelshaus's scheme halted his destructive actions, *that* time!

MISIDENTIFICATIONS OF DDT

Glotfelty and Caro (95) commented that "misidentifications of chlorinated hydrocarbon insecticides resulted from interference by pigment-related natural products found in photosynthetic tissues."

Sims, plant pathologist and biochemist at University of California, discovered that certain red algae produce halogen compounds that had been misidentified as DDT metabolites. He said, "the natural halogens were unknown previously but are now known to be common in natural marine habitats. Compounds containing bromine or iodine rather than chlorine may also have registered as DDT on the gas chromatograph" (96).

Frazier et al. analyzed 34 soil samples that had been sealed in glass jars since they were collected in 1911 (97). The gas chromatograph indicated that five kinds of chlorinated hydrocarbon insecticides were in that soil, even though none of them had been in existence until 30 years after those samples were sealed. They concluded that "the apparent insecticides were actually misidentifications caused by the presence of co-extracted naturally-occurring soil components."

Coon confirmed that material he and his colleagues at the WARF Institute earlier believed to contain DDT residues actually had none at all (98). He also reported on a gibbon that was collected in Burma in 1935 and sealed in a tight container for 30 years before being analyzed. The analysis indicated DDE in the kidneys, testes, liver and fat tissues, even though DDE did not exist anywhere on earth until 6 years after the gibbon was preserved.

Bowman et al. (99) analyzed soil that was sealed in 1940 (years before DDT) and reported "a naturally-occurring extraneous substance appearing in pre-DDT soil that gave the same chromatographic retention times on GLC as DDT (62 ppm) and DDE (35 ppb)."

Hickey sent a robin that had been collected and stored in formalin in 1938 to the WARF Institute for analysis (99). Although it was collected 7 years before DDT was present, the analysis indicated that the robin contained DDT and DDD! Dozens of other robins were similarly analyzed in Michigan and Wisconsin before it became evident that mercury in the earthworms eaten by those birds actually caused the symptoms that had been attributed to DDT poisoning, including tremors, ataxia, and death. Massive amounts of DDT fed to caged robins failed to make them ill. Even nestling robins were not sickened after they were fed only food containing DDT.

DDT SAVING FORESTS

Despite the absence of any confirmation that wild birds suffered illnesses or mortality caused by DDT, activists succeeded in halting the use of DDT on American elm trees, following which thousands of the stately trees died in five midwestern states because of the Dutch Elm Disease that was transmitted by uncontrolled Bark Beetles. Later, millions of eastern oak trees were killed by gypsy moth larvae, which had previously been quickly controlled by a single spray of DDT. Their caterpillars defoliated more than 9 million acres of forest annually before DDT was available, but 1 pound of DDT per acre eradicated the gypsy moths from New England and all adjacent states. The National Audubon Society wrote "No damage was done to bird life, including nestlings." USDA biologists wrote (100), "without this insecticide, there is little hope of preventing the spread throughout their potential range." Environmentalists fought desperately to halt the use of DDT in the infested forests! Forest destruction accelerated after DDT was banned.

In 1974, a campaign was launched to spray DDT on forests in three northwestern states to halt a great Douglas-fir tussock moth outbreak. Permission to spray DDT was granted by the EPA, after 3 years of ridiculous obstinancy. The DDT spraying was then quickly completed, the pests were eradicated, and thousands of acres of Douglas-fir forests were saved. Analyses of vegetation, soil, birds, mammals, and stream inhabitants revealed no harmful effects caused by DDT. Ignoring all science, however, two local newspapers editorialized regarding the persistence of DDT. The *Vancouver Sun* and the *Lewiston Tribune* both wrote in editorials (101) that "DDT has a half-life of several thousand years." (It had only been in existence for 30 years!) I sent each editor copies of literature citing truthful scientific data, but neither of them responded.

BIOLOGICAL MAGNIFICATION UP FOOD CHAINS

A great effort was made by environmental extremists to convince us that there was "biological magnification of DDT up food chains." The theory was as follows: "Small crustaceans ingest DDT, and when hundreds of them are eaten by a fish, that fish might contain a higher DDT concentration than any one crustacean. If many of those fish are eaten by a duck, it might then harbor a higher concentration of DDT than any one fish. After hawks eat the ducks, they could theoretically contain tremendous amounts of DDT! The major difficulty with this theory is that it simply doesn't work that way, where DDT is involved, because DDT is eliminated in faeces, metabolized in blood and cells, and excreted in the urine.

A typical propagandist diagram shows 0.04 ppm DDT in the zooplankton or tiny crustaceans, compared with 25 ppm in the brain of a hawk at the top of the food chain (an increase of 600 times). However, propagandists said that "DDT levels increased 10 million times." They untruthfully sought to start the food-chain with 3 parts per trillion (ppt) of DDT in the water (*before* it entered any food chain!) They then concluded that "DDT is magnified a million or more times as it passes up the food chains."

DDT adheres to particles in the lake bed, so the mud or sand contains a much higher DDT concentration than the water itself. As Hickey pointed out (102), "biological magnification only begins *after* the DDT gets into some living creature." Transfers before that time are *not* "biological", and are not any part of any food chain!

Another source of misinformation is also obvious. If *wet*-weight samples of crustaceans are compared with *dry*-weight samples of fish muscle, the dry tissues will appear to have higher concentrations of DDT because the samples are not diluted by water. Duck muscles do not contain higher concentrations of DDT than do fish muscles, if the samples are prepared and analyzed similarly (103, p. 2160).

Freed (104) proved that about 85% of the DDT in a fish enters through the gills, and very little through the diet. Davis found that "trout pass all of the blood in their body through the gills every 64 seconds, causing rapid transfer of chemicals from the water into the body tissues (105). After the fish is eaten by a duck, most of the DDT passes through the duck's digestive tract and is eliminated.

Comparison of DDT concentrations at each step up a food chain are difficult, and the approximate levels of DDT at each step in the food chain are difficult to determine!

Animals usually store *lower* levels of DDT than were in their food. Anchovies in Monterey Bay contained no more DDT residues than the algae they fed upon (750 to 1,000 parts per billion). Sea lions were found to contain much lower concentrations of DDT than the fish upon which they fed.

Jefferies and Davis (69) reported that earthworms kept in soil saturated with dieldrin contained a lower concentration of dieldrin than the soil, and thrushes that were fed *only* on those earthworms never accumulated any higher concentration of dieldrin than the individual earthworms had contained.

POSTSCRIPT

On June 10, 1971, Philip Butler's report for the National Academy of Sciences claimed (106), "As much as 25% of the DDT produced to date may have been transferred to the sea." Two other panels of the NAS, headed by Kanwisher (107) and by Harvey (108), later refuted such reports. The *Washington Post* (109), however, expanded upon that untruthful claim, saying "Nearly 25% of all DDT manufactured to date is now in the world's oceans, where it is killing baby fish." Jacques Cousteau must have been confused by it all, for in his testimony before the Senate Commerce Committee on October 18, 1971, he stated, "For example, we now know that 25% of all DDT compounds so far produced are already in the sea, and finally they all will end up in the sea." That false statement was repeated in *U.S. News & World Report*, (110).

So, a false estimate of how much DDT *may* have gotten into the sea (made by the man whose own EPA laboratory at Gulf Breeze, Florida, had shown that DDT and its metabolites break down very rapidly in sea water), was escalated to a solid statement by the *Washington Post* (and alleged to "kill baby fish"). It was then blown completely out of context by Cousteau and the anti-DDT press, warning that **ALL of the DDT and its metabolites ever produced will "finally . . . end up in the sea."** The same sort of misstatements and deliberately false allegations are still being directed against many other chemicals that are of great potential benefit to mankind and the environment.

With scientists who behave like so many of those in this report, how can industry, education, conservation, and public health programs survive in America?

INSTREAM FLOW METHODS

G.V. Loganathan
Virginia Polytechnic Institute
and State University
Blacksburg, Virginia

Water use is typically classified into offstream use (withdrawals) and instream use. Offstream demands include industrial, commercial, agricultural, and domestic uses. Instream demands include hydropower, recreation, navigation, fish and wildlife habitat management, and assimilation of waste. Unlike offstream demands, which should be satisfied separately, instream demands in general are satisfied simultaneously. That is, the same quantity of water is utilized in instream demands. Therefore, the largest of these instream flow demands must be satisfied. This demand may be in terms of discharge, depth of flow, and velocity. Jowett (1) classifies the methods as *historic flow regime*, *hydraulic*, and *habitat* but points out that the hydraulic methods are not usually used to assess seasonal flow requirements. A key determinant in managing instream flows is the presence of an upstream reservoir. Low flow augmentation is possible with the availability of stored water and efficient management of the reservoir is an important aspect. When a reservoir is not available, the low flows in the stream form the basis for minimum instream flow assessment. The competing offstream demands, public preference, local economy, aesthetics, regulations, water rights, and water quality form the constraints.

When there is an abundance of water, the competing needs can be met easily. When there is only a limited supply, problems emerge. Because river flows are random, it is likely that low flows will occur and proper planning should address the issue. The determination of minimum instream flow may be based on an exceedance criterion such as 90% to guarantee a relatively uninterrupted supply; it may also be based on the nature of the demand such as maintaining a minimum depth or velocity. Hydropower depends on both available flow and hydraulic head. For runoff without storage, the amount of energy that can be guaranteed over 90% (to 97%) of the time is called the firm energy. The required flow is determined as the flow that will be equaled or exceeded 90% of the time. The plot of discharge against percent time equaled or exceeded is called the *flow-duration curve*. If a reservoir is available, a set of *rule curves* is typically followed in making the releases to optimize the available storage subject to the inflow behavior (2). Navigation and recreational boating require maintenance of flow depth based on the barge and boat size. The required flow is to be determined based on the depth requirement.

The procedure given here is in general followed to determine flows that are equaled or exceeded by a certain percentage. A list of moving average values for a fixed averaging duration such as 7 d is generated. Using these moving average values, flows corresponding to various return periods such as 10 yr (90% exceedance) are determined by *frequency analysis* (3,4). The resulting flow is called 7-d 10-yr flow or 7Q10. Virginia Department of Health recommends 1-d 30-yr flow as the characteristic low flow for drought-related studies. For fish habitat, the Tennant or Montana method recommends 30% of annual mean flow as the flow providing required channel flow conditions.

Dissolved oxygen, temperature, water quality, substrate, stream toe width, velocity, flow, and depth are considered key elements in preserving fish habitat. The instream flow incremental methodology (IFIM) utilizes detailed physical habitat simulation (PHABSIM) models. In PHABSIM, for each physical variable of depth, velocity, and substrate a habitat preference curve is defined for a specified species at a specified life stage. For a flow value, the pattern of distribution of depth, velocity, cover, and substrate is analyzed over a stream reach with the aid of a hydraulic model. Using the physical variables, the values from the habitat preference curves are combined into an index called weighted usable area (WUA). For a range of flow values, the WUA values can be obtained. Based on the weighted usable area values, a suitable set of flows can be determined for different levels of species protection and enhancement (4,5). Hardy (6) provides a comprehensive discussion of habitat modeling.

FLOODPLAIN

Mark R. Tompkins
University of California
Berkeley, California

The term *floodplain* has a range of physically and ecologically based definitions, in addition to a regulatory (i.e., flood control) definition. From the physical perspective, floodplains are a component of the dimensions and geometry of river channels, which as a whole reflect the runoff and sediment load they carry (1). Floodplains have been defined as the relatively flat level floor formed of sediment deposits, which extends from the edge of the channel to the valley walls (2). Nanson and Croke (3) define floodplains more precisely as “the largely horizontally-bedded alluvial landform adjacent to a channel, separated from the channel by banks, and built of sediment transported by the present flow-regime.” They identify lateral point bar accretion, overbank vertical accretion, and braid-channel accretion as the dominant floodplain forming processes in their genetic floodplain classification based on stream power and sediment texture. Figure 1 is a conceptual diagram of a natural river basin that identifies the valley floor, floodplain, river corridor, and channel areas of a basin. Floodplains and riparian areas immediately adjacent to active channels have been documented as very important in sediment retention during high flows (4). Floodplains also act to dissipate bed shear stress and attenuate flood peaks contained in the primary channel. In addition, flood peaks travel downstream faster when a river corridor becomes confined laterally from its floodplain. Floodplains provide important aquatic and terrestrial habitat in addition to significant hydrologic, water quality, and aesthetic benefits (5).

The biological and ecological importance of floodplains has been well documented. Many species of aquatic organisms require floodplains to complete stages of their life history (6,7), including reproduction, rearing, and hibernation. Floodplains also provide important refugia for aquatic organisms during episodes of high flow or vulnerability to predators (8). Aquatic invertebrates and fish seek refuge from high bed shear stresses and

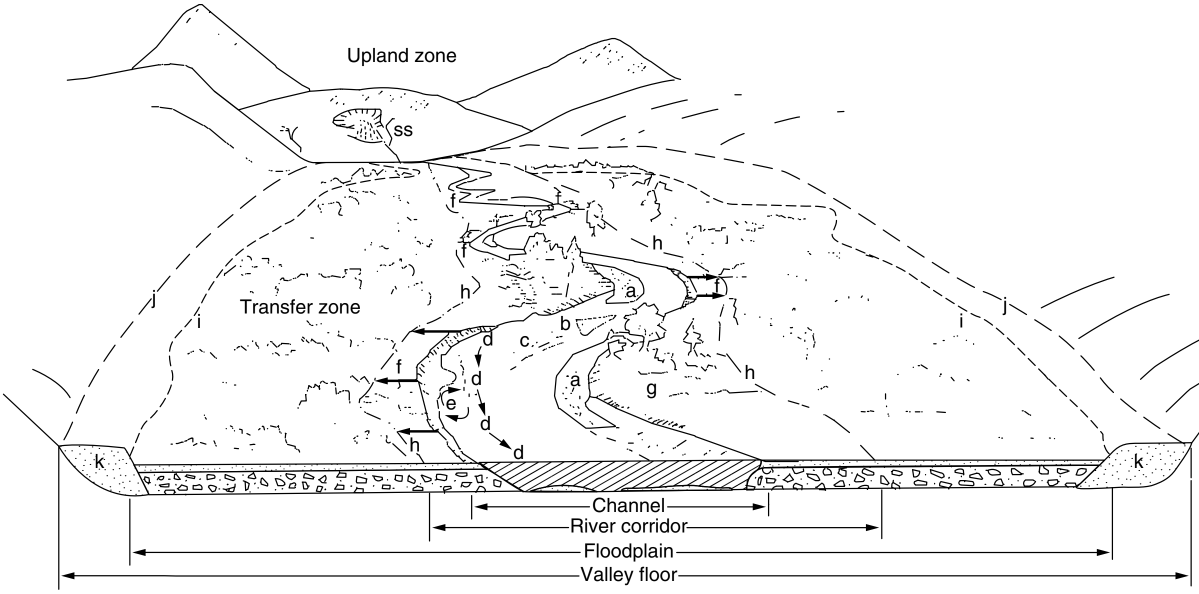

Figure 1. Generalized valley floor, floodplain, river corridor, and channel orientation (after Ref. 5). Letters refer to channel corridor characteristics: (a) point bar, (b) midchannel bar, (c) riffle, (d) pool, (e) secondary current, (f) bank erosion, (g) riparian vegetation, (h) corridor boundary, (i) floodplain boundary, (j) valley floor boundary, (k) terrace, (ss) sediment supply and storage zone.

flow velocities during floods in the hydraulically rough, slow-moving areas beyond the margins of the active channel and on the floodplain. The importance of these floodplain functions has been shown in population growth simulation models that predict increases in biomass of fish and aquatic invertebrates with increases in floodplain width (9). Floodplains have been recognized as critical elements of healthy river ecosystems (10). Without a connected and functioning floodplain, a river corridor ecosystem is incomplete. In their work on the flood pulse concept, Junk et al. (11) describe an aquatic–terrestrial transition zone that moves across the floodplain as flood waters rise. This moving transitional zone is essential to the successful recruitment, establishment, and growth of many species of vegetation, fish, and other organisms in river corridor ecosystems. Historically, floods were often viewed as destructive disturbances to floodplain ecosystems. More recently, however, the prevention of floods has been viewed as the more destructive disturbance to floodplain ecosystems.

The regulatory definition of floodplains originated because valley floors and floodplains have historically been attractive sites for human settlement (12). For thousands of years, humans have built civilizations along river corridors. In fact, the very “cradle of civilization” was built near the confluence of the Tigris and Euphrates Rivers in what is now southern Iraq. Most human development along river corridors has been established on floodplains. Floodplains are naturally flat, close to water, and have fertile soils, making them ideal for agriculture, building sites, and industry location (13). Therefore, a regulatory floodplain is a surface next to a channel that is inundated once during a given return period (14). Regulatory floodplains may or may not be related to physical floodplains. In most cases, some form of flood protection is provided on regulatory floodplains. The administration of regulatory floodplains differs from country to country. In the United States, Congress established the National Flood Insurance Program (NFIP) with the passage of the National Flood Insurance Act of 1968 to identify regulatory floodplains and administer flood protection. The Federal Emergency Management Agency (FEMA) currently administers the NFIP. In return for federally subsidized insurance, communities with access to the NFIP must adopt and enforce a floodplain management ordinance to reduce future flood risks to new construction in Special Flood Hazard Areas (SFHAs). A SFHA is an area within the 100-year floodplain (note this is not a physical reality, but rather a regulatory designation that is discussed in more detail below). Development may take place within a SFHA, provided that development complies with local floodplain management ordinances, which must meet the minimum federal requirements. Communities that participate in the NFIP must implement floodplain management measures in the development of their floodplain lands. FEMA expects these measures to constitute an overall community program of corrective and preventive measures for reducing future flood damage. In general, floodplain management measures address zoning, subdivision, or building requirements for structures in the floodplain and special-purpose floodplain ordinances.

The 100-year flood (and floodplain) was selected by an expert panel as the standard for protection within the NFIP. The 100-year flood (or the 1% annual-chance flood) was chosen on the basis that it provides a higher level of protection (FEMA does not specify what “higher” refers to) while not imposing overly stringent requirements or the burden of excessive costs on property owners. Flood Insurance Studies (FIS), which apply detailed hydrologic and hydraulic analyses, have been performed for many of the watersheds in the United States that are currently included in the NFIP. The results of these analyses include flood insurance rate maps (FIRMs) that identify areas of flood risk and, perhaps most importantly, the boundaries of the regulatory 100-year floodway. The regulatory floodway is defined as the channel of a stream plus any adjacent floodplain areas that must be kept free of encroachment so that the entire base flood (100-year flood) discharge can be conveyed with no greater than a 1.0-foot increase in the base flood elevation.

The references listed in the Bibliography provide a thorough treatment of floodplains for those wishing to develop a deeper understanding of this broad and diverse topic.

FISH PASSAGE FACILITIES

Mark R. Tompkins
University of California
Berkeley, California

A *fish passage facility* provides fish with a watered route around or through a barrier to migration in a fluvial system. Fish passage facilities have been designed for both natural and artificial barriers. Some passage facilities allow fish to propel themselves past the barrier, while others physically transport fish past the barrier. Fish passage facilities must provide passage during periods dictated by migratory requirements without injuring or unduly stressing fish. Fish passage facilities have been designed and constructed in North American, Europe, Russia, Latin American, Africa, Australia, New Zealand, China, and Japan. Depending on the region and type of application, fish passage facilities are also referred to as fishways, fish ladders, fish passes, fish bypasses, fish locks, and fish elevators.

Many fish species (e.g., Chinook salmon, American shad, striped bass) must travel upstream and downstream in river systems to complete their life cycles. The development of infrastructure (e.g., dams, water diversions, culverts at road crossings) on rivers has blocked fish passage on rivers around the world. In many cases, viable populations of some fish species have been threatened by these passage barriers. To mitigate this threat, fisheries professionals have designed and constructed fish passage facilities. Many fish passage facilities have been constructed as retrofits to existing barriers that were designed and built before fish passage was required, or before the technology was fully developed. More recently, some infrastructure on rivers has been designed in a "fish friendly" manner that integrates requirements for safe and effective fish migration in the original design (e.g., "fish-safe" turbines, pumps, spillways). As multispecies fish conservation and restoration increases in importance, fish passage facilities will be required to provide a range of hydraulic conditions (i.e., depths and velocities) throughout the year to provide passage for a range of fish species and life stages.

A variety of fish passage facility designs have been developed (see Table 1) to address a wide range of barriers to fish migration. However, asOdeh and Haro (1) note, all fish passage facilities include five common features: (1) the immediate reach of river or waterway served by the fish passage facility; (2) the entrance to the fish passage facility; (3) the fish passage facility itself; (4) the exit of the fish passage facility; and (5) the reach of river where fish exit the passage facility. An effective fish passage facility must allow fish to navigate each of these components of the facility safely and in a manner that meets the temporal requirements of their migratory movements.

Table 1. Fish Passage Facility Designs

Fish Passage Facility Type	Primary Passage Direction	Mode of Fish Movement	Energy Dissipation
Pool and weir	Upstream	Active	Turbulence in pools
Weir and orifice	Upstream	Active	Turbulence in pools
Denil	Upstream	Active	Partial reversal of flow direction
Vertical slot	Upstream	Active	Partial reversal of flow direction
Fish lock	Upstream	Passive	N/A
Fish lift	Upstream	Passive	N/A
Screen and bypass	Downstream	Active	N/A
"Nature-like"	Upstream/ downstream	Active	Turbulence from "natural bed elements"
Road crossing culverts	Upstream/ downstream	Active	Turbulence from roughness elements added to culvert

Fish passage facilities can facilitate both upstream and downstream passage around barriers in fluvial systems. However, most facilities are designed primarily for passage in one direction or the other. Table 1 lists the most common types of fish passage facilities and summarizes for each the primary passage direction (upstream or downstream), mode of fish movement (active or passive), and mechanism of energy dissipation (e.g., turbulence). Fish passage facilities must be designed to align hydraulics and physical characteristics of the facility with the swimming capacity and behavior of the species of concern. Designers must carefully consider flow velocities, depths, turbulence, dissolved oxygen levels, temperature, noise, light, and even odor in the design of a fish passage facility.

Upstream fish passage facilities must attract migrating fish to a specified location in the river downstream of the barrier with an appropriate flow, and then move the fish actively (i.e., by encouraging them to swim) or passively (i.e., by trapping and transporting them) around the barrier. Upstream fish passage facilities for adult anadromous salmonids (e.g., salmon and trout) and clupeids (e.g., shad and alewives) have a long history in North America and Europe. Upstream fish passage facilities have also been designed for juvenile catadromous fish (e.g., American eel). The most common upstream fish passage facilities are described briefly below.

Pool and Weir. The pool and weir facility consists of a series of pools separated by weirs (Fig. 1) that allow fish to ascend by jumping or swimming from the downstream end at the river to the upstream end at the top of the barrier. Flow energy is dissipated as turbulence in pools.

Weir and Orifice. The weir and orifice facility is similar to the pool and weir except that each dividing wall between

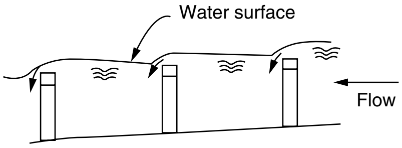

Figure 1. Pool and weir.

pools has a submerged orifice (Fig. 2). Some facilities of this type allow passage from pool to pool through an orifice or over a weir. Again, flow energy is dissipated as turbulence in pools.

Denil. The denil facility consists of a steep flume with vanes along the sides and bottom (Fig. 3). Fish ascend from the downstream end of the barrier to the upstream end by swimming through the center of the flume. The vanes in the denil partially reverse flow direction to dissipate the energy.

Vertical Slot. The vertical slot facility is similar to the pool and orifice type except that the orifice extends for the full height of the baffle between pools (Fig. 4), allowing migrating fish to pass upstream from pool to pool at any depth in the water column. Similar to the denil, the vertical slot dissipates energy by partially reversing the direction of the flow in the facility.

Fish Lock. A fish lock operates in a similar manner as a navigation lock (Fig. 5). Fish enter a chamber at the downstream end of the barrier that is flooded to raise the water surface elevation in the chamber. Fish are then passed upstream through chambers until the water surface elevation difference between the chamber and the upstream end of the barrier is small enough for the fish to pass.

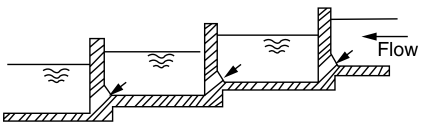

Figure 2. Weir and orifice.

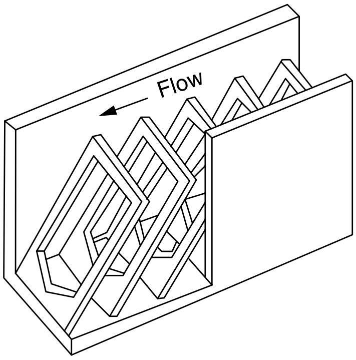

Figure 3. Denil.

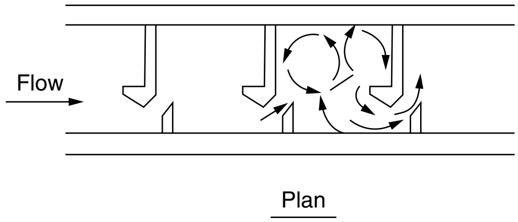

Figure 4. Vertical slot.

Fish Lift. A fish lift can include any mechanical means of transporting fish around a barrier such as tank trucks, large buckets, or other flooded containers (Fig. 6). Migrating fish must be lured into the flooded container and then provided with suitable conditions to maintain their health for the duration of the lift.

Downstream fish passage has received significantly less attention than upstream passage, and therefore the facilities designed to provide downstream passage are less developed. To date, no country has found a satisfactory solution to downstream migration problems, especially at large passage barriers (2). Downstream fish passage facilities have been developed primarily for juvenile anadromous fish. Most downstream fish passage facilities consist of some kind of screen and a bypass. The screen diverts fish away from potential harm associated with the passage barrier (e.g., turbines or agricultural diversions) and the bypass returns fish to the river downstream of the passage barrier. Bypasses must be designed to accommodate the behavior and swimming abilities of the fish species of interest. The most common screens are described briefly below.

Physical Screens. Physical screens (Fig. 7) typically divert downstream migrating fish away from potential harm using screens made of a wide variety of materials (e.g., perforated plates, metal bars, wedgewire, plastic or metal mesh). Screens are normally placed diagonally to flow and must meet maximum approach velocity (i.e., the velocity of flow passing through the screen) and mesh size criteria suitable to prevent impingement of the species of interest. This category of barriers includes drum screens, inclined plane screens, self-cleaning screens, and screens installed perpendicular to flow.

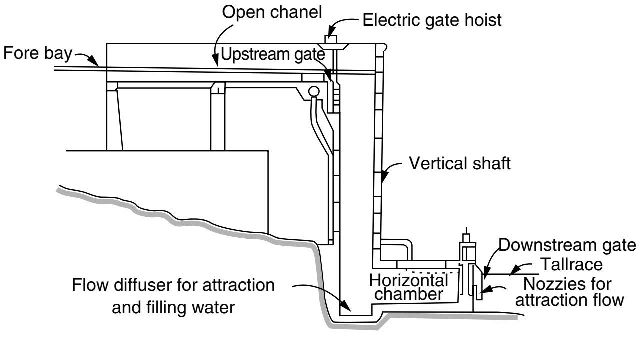

Figure 5. Fish lock.

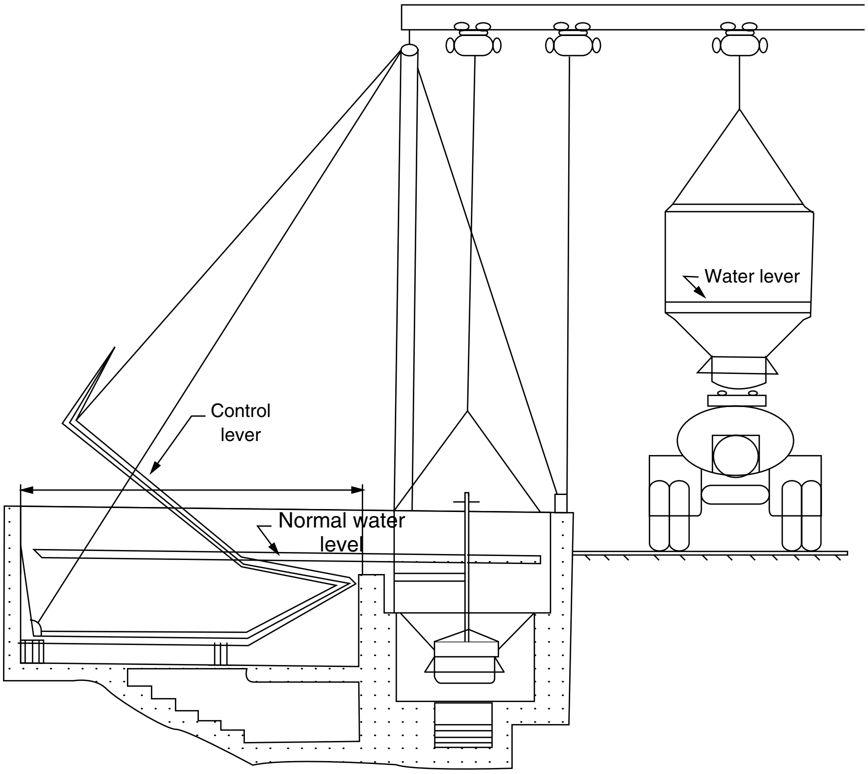

Figure 6. Fish lift.

Behavioral Screens. Behavioral screen facilities for downstream passage have been designed to take advantage of behavioral responses of the fish species of interest to attract or repel fish from a specified location. These approaches have relied on visual (e.g., air bubbles or light arrays), auditory (e.g., audio signal arrays), electrical (e.g., electric currents), and hydrodynamic (e.g., altered velocities and flow patterns) signals to elicit the desired response from the fish species of concern.

Some fish passage facilities provide both upstream and downstream passage to a variety of fish species. These facilities are typically designed for barriers with relatively small water surface elevation differences. Two of these types of facilities are described briefly below.

"Nature Like". Nature-like fish passage facilities incorporate features of natural channels to dissipate energy and provide suitable passage conditions for the fish species of interest (Fig. 8). Specific designs of this type include rock-ramp fishways, ramp fishways with boulders and pools, and boulder block fishways. Each of these approaches achieves upstream and downstream passage in a manner that is more aesthetically compatible with the natural stream environment.

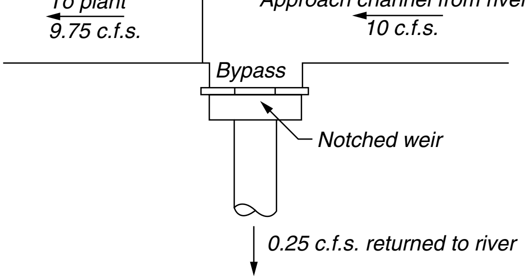

Figure 7. Physical screen.

Road Crossing Culverts. When designed to provide passage for fish under a range of flow conditions, culverts at road crossings can be considered fish passage facilities. Inappropriately designed culverts are often barriers to fish passage. New culvert designs and culvert retrofit designs for fish passage must consider the upstream and downstream migration behavior and the swimming ability of the fish species and life stages of interest. Culverts with baffles, slotted weirs, spoilers, and more natural roughness elements such as cemented boulders have been installed to provide adequate passage conditions.

A significant amount of research and development has occurred in the field of fish passage facilities. References 1–7 provide a good starting point for further investigation of this topic.

FISHING WATERS

Mark R. Tompkins
University of California
Berkeley, California

The term *fishing waters* refers to all bodies of water where fish are legally captured by humans. Fishing waters can be defined and regulated internationally, nationally, and locally. The four primary categories of fishing that occur in fishing waters are commercial, recreational, subsistence, and indigenous. More than one category of fishing can occur in a given fishing water, and extractive fishing does not have to occur in all fishing waters.

International fishing waters include vast areas of open ocean outside of the zones managed under national fishing regulations. Fishing in international waters is governed by conventions enacted by the United Nations. The most recent conventions dealing with international fishing waters are the Convention on Fishing and Conservation of Living Resources of the High Seas, and the Convention on the Law of the Sea. Nearly all of the fishing in international waters is commercial in nature.

National fishing waters include oceanic zones nearer to coasts and managed by individual nations. Each country manages fishing in these fishing waters differently. In the United States, national fishing waters are governed by The Magnuson–Stevens Fishery Conservation and Management Act. This Act was signed into law in 1976 and covers all fishing activities that occur in federal waters within the United States' 200 nautical mile limit, referred to as the Exclusive Economic Zone (EEZ). The Act also sets forth a system for the management and monitoring of the fish stocks in waters within the United States' EEZ. This system includes eight regional Fishery Management Councils to provide a forum for state, industry, and public participation in the management of American ocean fisheries. The National Marine Fisheries Service (NMFS) is the agency responsible for administering the fishery management requirements of the Act. The Fishery Management Councils develop fishery management plans for each zone that are administered by the NMFS and enforced by the U.S. Coast Guard. Most of the fishing in national waters is commercial in nature.

Local fishing waters can include near shore ocean areas, lakes, reservoirs, rivers, and streams. Again, each country manages local fishing waters differently. In the United States, the U.S. Fish and Wildlife Service together with state Departments of Fish and Game are primarily responsible for the management of fishing in local waters. These agencies are also involved in stocking programs that are used to maintain, enhance, and create fishing waters. In addition, these agencies assist in the management of subsistence and indigenous fisheries. State-issued licenses are typically required to fish in local fishing waters, and most of the fishing in these waters is recreational in nature.

As introduced above, the primary requirement for a body of water to be defined as a fishing water is for some type of fishing to occur in that body of water. Commercial fishing is the most extensive practice that defines a body of water as a fishing water. Commercial fishing occurs in every coastal region in the United States and many different techniques and types of equipment are employed in this endeavor. Any fishing that results in the sale of the captured fish is considered commercial fishing. Recreational fishing is probably the second most extensive practice that defines a body of water as a fishing water. Fishing is considered recreational when fish are captured for pleasure rather than profit. Recreational fishing includes both “catch-and-keep” fishing and “catch-and-release” fishing. Subsistence and indigenous fishing are significantly less extensive practices that define bodies of water as fishing waters. Subsistence fishing provides food or other products for the people who catch the fish, and indigenous fishing is provided for and managed by treaties between the federal government and native peoples (in the United States).

The topic of fishing waters is large and diverse. References 1–4 provide a useful introduction to the topic.

LAND SURFACE MODELING

XU LIANG
University of California
Berkeley, California

INTRODUCTION

Land surface modeling consists of developing and applying computational models that integrate complicated hydrologic and physical processes that occur at the land surface, between the land surface and the atmosphere, and within the soil column. A land surface model or macroscale hydrologic model, as these types of models are called, has two important characteristics: (a) it considers processes related to both the energy and water budgets and their interactions, and (b) it operates over relatively large spatial domains with short temporal scales. Depending on their complexity, these models generally include representations for some or all of the following major physical processes:

- Snow and snowmelt
- Frozen soil
- Infiltration
- Surface runoff
- Subsurface runoff (e.g., flows from unsaturated and/or saturated zones)
- Evaporation and transpiration
- Vegetation dynamics
- Processes related to the energy budget (e.g., radiation, sensible heat flux, ground heat flux, etc.)

The above processes are interconnected and constrained by the available water and energy. Evapotranspiration links the energy and water aspects of a land surface model together. Soil moisture and surface temperature relate various different physical, hydrological, and biogeochemical processes to one another.

MOTIVATION

One of the main purposes of developing a land surface model is to couple it with (i.e., connect it to) atmospheric or climate models to study the influence of the atmosphere on the land surface, and vice versa, the feedbacks or impacts of the land surface (e.g., the processes listed above) on the atmosphere. Adequate representations of such two-way feedbacks (called land-atmosphere interactions) can improve the accuracy of numerical weather forecasts and climate predictions that play a dominant role in hydrologic forecasting. A land surface model (or a macroscale hydrologic model) is also a physically based tool to assess water resources and hydrologic impacts caused by climatic changes over large river basins or continents. Hydrologic applications at such large spatial scales are impossible without the development of the concept and approach of land surface modeling.

BACKGROUND

We often hear the terms “land surface model” and “hydrologic model.” Do they refer to the same thing? Strictly speaking, traditional hydrologic models do not belong to the category of land surface models, which is because hydrologic models do not describe energy budget-related processes, such as radiation and sensible and ground heat fluxes, although some may include limited energy related calculations such as that related to snow and snowmelt processes. In addition, land surface models have more detailed representations of vegetation-related processes than traditional hydrologic models. Furthermore, traditional hydrologic models mainly focus on the movement of water and its distribution at the land surface and within the vadose zone over small spatial domains with relatively large temporal scales. As atmospheric models deal with physical processes happening over much larger spatial domains at much shorter time steps or temporal scales (e.g., weather phenomena can occur on time scales of minutes), land surface models must also have the capability to deal with hydrologic and physical processes at short temporal scales over large spatial domains for representation of heat and water exchange between the land surface and the atmosphere.

Although land surface models and traditional hydrologic models are developed for different applications, they share some common features as evident by the evolution of these models. The work by Manabe (1) was the first to include land surface impacts in a climate model. Although his land surface model (called the "Bucket" model) includes overly simplified hydrologic processes, a simple energy balance equation, and no vegetation, Manabe's pioneer work ignited many innovative and significant development in the later generation of land surface models.

The evolution of land surface models since Manabe's Bucket model can be characterized by three major phases/stages. The first phase was led by the work of Deardorff (2) (e.g., the force-restore scheme), Dickinson et al. (3,4) (e.g., the BATS model), and Sellers et al. (5,6) (e.g., the SiB model) in which much better vegetation representations and more complex energy budget calculation are considered to realistically represent the energy exchange between the land surface and the atmosphere. To date, a large number of novel models were developed with their roots linked to these three schemes [e.g., (7–15)].

The second phase was led by the work of Liang et al. (16,17) (e.g., the VIC model), Famiglietti and Wood (18), and Schaake et al. (19) in which the effects of subgrid spatial variability on water and energy budgets (e.g., surface runoff, evapotranspiration, etc.) because of heterogeneity of soil properties, topography, vegetation, and precipitation are considered using statistical-dynamical approaches. Also, this phase is marked by improved parameterizations of hydrologic processes (e.g., infiltration, subsurface runoff, etc.) that were overly simplified in the past to provide realistic representations of water and energy exchanges between the land surface and the atmosphere. The oversimplifications of hydrologic processes [e.g., (1)] have been found to lead to significant errors in water and energy budget-related calculations (e.g., soil moisture, runoff, and evaporation) [e.g., (20)]. Crossley et al. (21) and Gedney and Cox (22) also noted that inadequate representations of major hydrologic processes can limit our ability of projecting future climate change. With the advancement over the last decade, major hydrologic processes over the land surface and within the vadose zone are now more adequately represented [e.g., (23–26)] in many land surface models.

Motivated by the need of a more comprehensive representation of the carbon cycle to address climate change issues, the third phase was led by the work of Bonan (27), Sellers et al. (6), Cox et al. (28), and Dai et al. (29) in which vegetation dynamics are included to account for carbon uptake by plants and feedbacks between climate and vegetation. Pitman (30) provides a comprehensive discussion of these models designed for coupling to climate models.

As the land surface impacts hydrologic, energy, and carbon cycles through the interactions among hydrological, physical, and biogeochemical processes, it is essential that these processes be considered or treated in an ***integrated*** way through a unified representation of the atmosphereland system. Land surface models have evolved substantially toward this goal. With the new generation of land surface models, it is now possible to address complex issues and quantify the impacts of surface water hydrology and vegetation on the physical processes that govern atmospheric circulation, and vice versa. For example, Xue (31) showed that degradation of the land surface can have a significant impact on the Sahelian regional climate by increasing surface air temperature and reducing precipitation, runoff, and soil moisture during the summer season. Xue et al. (32) also demonstrated the important role of the land surface for simulating more realistic monthly mean precipitation and flood areas over the United States. Entekhabi et al. (33) further showed the significant impact of soil moisture on numerical forecasting of extreme events (i.e., extreme events of drought and flood). Their study also established the role of land memory as an important source of climate predictability for the United States. Pitman et al. (34) showed the important impact of land cover change on rainfall trends in Australia that are consistent with observations.

LAND SURFACE (MACROSCALE HYDROLOGIC) MODELING FRAMEWORK

In a land surface model, processes associated with the water budget that were identified in the Introduction are connected by the Richards equation. The Richards equation can be written in one-dimensional, two-dimensional, or three-dimensional form. The one-dimensional (1-D) form is more typically used in land surface models. The change of soil moisture content throughout the soil column (i.e., from the soil surface to bedrock) with time can be described by the 1-D Richards equation as

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial z}\left(D(\theta)\frac{\partial \theta}{\partial z}\right) - \frac{\partial K(\theta)}{\partial z} - \sin k(z, t) \qquad (1)$$

where θ is the volumetric soil moisture content [L^3/L^3], $D(\theta)$ is the hydraulic diffusivity [L^2/T], $K(\theta)$ is the hydraulic conductivity [L/T], $\text{sink}(z, t)$ is a sink term (e.g., to represent transpiration, E_t, from the root zone), and z represents the vertical direction and is assumed positive downward in Eq. (1). If $q(z, t)$ represents the flux [L/T] across a horizontal plane at depth z and time t, then the boundary condition at the land surface can be expressed as

$$q(z, t)|_{z=0} = P - R - E_o \qquad (2)$$

where P is the precipitation rate, throughfall rate, or snowmelt rate [L/T]; R is the total surface runoff rate (i.e., overland flow) [L/T]; and E_o is the evaporation from bare soil [L/T]. If no flux across the lower boundary exists (i.e., the interface between soil column and bedrock at depth

$z = D$), but the drainage Q_b [L/T], then the lower boundary condition can be expressed as

$$q(z,t)|_{z=D} = Q_b \tag{3}$$

Processes associated with the energy budget as identified in the Introduction are connected to the water budget processes through evapotranspiration. Applying the energy balance equation at the land surface, we have

$$R_n = LE + SH + G \tag{4}$$

where R_n is the net radiation [EL^{-2}T^{-1}], LE is the evapotranspiration [EL^{-2}T^{-1}], SH is the sensible heat flux [EL^{-2}T^{-1}], and G is the ground heat flux [EL^{-2}T^{-1}], all of which can be expressed as a function of the surface temperature, T_s. The net radiation includes net shortwave radiation and net longwave radiation, which are expressed as

$$R_n = (1-\alpha)S_{\text{down}} + L_{\text{down}} - \varepsilon\sigma T_s^4 \tag{5}$$

where α is the surface albedo, S_{down} and L_{down} are the downward shortwave and longwave radiation [EL^{-2}T^{-1}], respectively, ε is the surface emissivity, and σ is the Stefan–Boltzmann constant ($\sigma = 5.67\times10^{-8}$ W K^{-4}m^{-2}). Furthermore, if E represents evapotranspiration [L/T], then E and LE are related as follows:

$$LE = L_e\rho_w E \tag{6}$$

where L_e is the latent heat of vaporization [EM^{-1}] and ρ_w is the density of water [M/L^3]. Hence, the evapotranspiration links the water and energy budgets.

Theoretically speaking, one can obtain the soil moisture θ at different soil depth and the surface temperature T_s at any time t based on Equations (1)– (6), provided the initial soil moisture condition is known, because the processes governing P, R, Q_b, E, SH, and G may be related to either θ or T_s, or both, among other things. Practically, however, it is not feasible to solve for θ and T_s analytically based on Equations (1)– (6) and the initial soil moisture condition unless extreme simplifications are made/introduced.

As a result of the complexity and nonlinearity of the physical processes, the soil moisture θ and surface temperature T_s are usually solved ***numerically*** in a land surface model. The degree of complexity with which the processes are represented physically and/or numerically determines the degree of complexity of a land surface model. For instance, a land surface model can consider either or both infiltration excess runoff and saturation excess runoff in the surface runoff (R) generation mechanisms [e.g., (24)]. Different approaches can also be used to describe evapotranspiration (e.g., Penman–Monteith, supply-demand, mass transfer, α-formulation, etc.), with different degrees of complexity and accuracy.

To numerically solve Equations (1)– (6) (or their variations), land surface models are applied to a study domain (i.e., a study region) that is divided by grids in the horizontal plane (e.g., at the land surface), called model grids, and the vertical soil column is divided into a number of discrete layers. Therefore, each modeling unit has specified lengths in the x- and y-horizontal directions associated to the model grid, and a depth in the vertical or along the soil column. The size of a model grid (i.e., its lengths in the x- and y-directions) determines the spatial resolution at which the land surface model is applied. Finer (coarser) spatial resolutions refer to smaller (larger) sizes of the horizontal modeling grids. The vertical resolution is normally defined by the depth of each vertical layer in the soil column. Higher vertical resolution implies smaller soil depth for each soil layer. Within a horizontal modeling grid, multiple land cover types are allowed. A study area may contain several modeling grids depending on its size. The vertical soil layers include both the saturated and unsaturated zones, separated by the groundwater table.

Most of the current generation land surface models lump the unsaturated and saturated zones together and treat the entire soil column as an unsaturated zone. As an exception, Liang et al. (35) presented a new approach to dynamically represent the movement of the groundwater table within the soil column in a land surface model to consider the impacts of surface water and groundwater interactions on energy and water exchanges. Their results showed the important impacts of such interactions on the partitioning of water budget components, and suggested more attention on issues in this area. Although the idea of investigating the impacts of surface and groundwater interactions on the land-atmosphere system has not yet received much attention, the dynamical representation [e.g., (35)] of groundwater table in land surface models may provide new insights about the water cycle as a whole. For example, is groundwater discharge a significant source of fresh water recycling to the estuaries and the oceans? Can groundwater recharge and discharge processes provide feedback mechanisms that affect climate?

Typical land surface models may, for example, have one vegetation layer, and three vertical soil layers in the soil column (i.e., from the land surface to the bedrock). The three soil layers are normally divided into a top thin soil layer (e.g., 5–10 cm deep), an upper soil layer (e.g., 20–200 cm deep), and a lower soil layer (e.g., from 50 cm to a few meters). The top thin layer is used to capture the quick bare soil evaporation following small summer rainfall events and to facilitate applications using remote sensing information on near-surface soil moisture. The upper soil layer is used to represent the dynamic response of the soil to rainfall events, and the lower layer is used to characterize the seasonal soil moisture behavior.

As a result of the characteristics and intended applications, land surface models typically have large grid sizes (e.g., from a few km^2 to hundreds of km^2 or larger). Therefore, it is very important to consider subgrid spatial variability (i.e., variations at spatial scales finer than the modeling grid) in soil properties, vegetation properties, topography, precipitation, etc., as these variables relate nonlinearly to the physical and hydrologic processes, such as the infiltration, runoff generation, evapotranspiration, etc., that are represented and solved only at the scale of the model grid. This problem is very challenging, and it is not fully addressed yet, although significant progress has been made in recent years.

After discretizing the study domain into modeling grids and vertical soil layers, Equations (1)–(6), together with the initial soil moisture conditions and the representations (or parameterizations) of each relevant physical and hydrologic process (e.g., surface runoff, subsurface runoff, evapotranspiration, etc.), T_s and θ are numerically solved at each model grid and for each soil layer to obtain R, Q_b, E, SH, and G, for example, at each time step t within a study period.

INPUTS AND OUTPUTS

Model Inputs

A typical land surface model requires four types of input information: (a) meteorological data, (b) vegetation data, (c) soil property data, and (d) model parameters.

Meteorological data may include precipitation, air temperature, humidity, surface pressure, wind speed, and downward shortwave and longwave radiation, or a subset of them, when the land surface model is executed offline, i.e., when the land surface model is not coupled with an atmospheric model. In the offline mode, some relationships (both empirical and semitheoretical) can be used to calculate humidity, surface pressure, and radiation, so that only the time series of precipitation, air temperature, and wind speed are needed. If the land surface model is coupled with an atmospheric model, the meteorological information listed above is provided by the atmospheric model instead.

Vegetation data generally include vegetation type, vegetation fractional coverage, leaf area index (LAI) or normalized difference vegetation index (NDVI), root distribution in the soil column (usually difficult to obtain), minimum stomatal resistance, displacement height, and roughness length, and their seasonal dependence. Depending on the complexity of the parameterizations, some models may require more information, such as green leaf fraction, stem and dead-matter area index, and light sensitivity factor, whereas others require less.

Soil property data usually include soil type, soil porosity, wilting point, field capacity, saturated hydraulic conductivity, soil water potential at saturation, soil heat capacity, and soil thermal conductivity. Similar to vegetation data, some models may require more information (e.g., the Clapp–Hornberger B parameter, soil temperature at the model lower boundary, etc.) than others, depending on the level of model complexity.

Most land surface models have some model parameters that cannot be precisely estimated because of observational limits or the absence of direct relationships with available observations. These model parameters are usually estimated based on model calibration (see the discussion on calibration in this encyclopedia) using observed time series, such as streamflow, evapotranspiration, etc. Methods for estimating model parameters through calibration can be found in the literature [e.g., (36–39)].

Model Outputs

A typical land surface model provides the following time series as output:

- snow water equivalent, depth of snowpack, temperature of snowpack;
- surface runoff, subsurface runoff, soil moisture for each soil layer;
- latent, sensible, and ground heat fluxes, and net radiation;
- surface temperature, and soil temperature of each soil layer.

Land surface models that consider surface and groundwater interactions can also provide additional information, such as time series of groundwater table depth, recharge, and discharge. Land surface models that are coupled with a river network routing scheme can also yield time series of streamflow as outputs.

REMARKS

In the past decade, the scientific community has made significant progress in the development of land surface models over three major phases/stages. Land surface models will continue to evolve to include more complete and important processes, such as surface and groundwater interactions, sediment transport, and biogeochemical processes (e.g., for studying carbon and nitrogen exchange), and to improve the representations (or parameterizations) of subgrid spatial variability associated with hydrologic and other physical processes of the integrated atmosphere-vegetation-land-soil system. It is anticipated that with further advancement of land surface models, processes such as floods, droughts, desertification, and the biogeochemical cycles (e.g., carbon, nitrogen, etc.) can be quantitatively and more realistically investigated, and through new discovery, improved understanding of the fundamental laws that control these phenomena may be revealed. Moreover, it is anticipated that new interdisciplinary fields will emerge that integrate atmospheric science, hydrology, public health, ecology, biology, etc. to investigate and predict potential epidemic outbreaks of environmental and/or waterborne diseases that result from integrated effects of natural extremes (e.g., flood and drought), human activity, land cover, land use change, etc.

ANIMAL FARMING OPERATIONS: GROUNDWATER QUALITY ISSUES

Thomas Harter
University of California
Davis, California

Animal farming operations (AFOs) include feedlots, dairies, cattle farms, hog farms, chicken farms, and other facilities that raise or maintain a significant number of animals either seasonally or year-round. With respect to groundwater quality, the fate, reuse, and disposal of animal manure produced at AFOs is of critical concern.

Groundwater benefits a wide variety of uses including production as drinking water for domestic/municipal use, production as irrigation water for agricultural/municipal uses, ecosystem support, and providing base flow in rivers and streams that is vital to the ecological health of these surface waters. AFO related groundwater quality issues result from potentially detrimental impacts during the collection, transport, storage, and land application of animal manure and animal wastes.

Potential groundwater pollutants originating from AFOs are (1) salts and nutrients, (2) bacteria that indicate the presence of pathogens, and (3) organic or inorganic chemicals specifically associated with the management of AFOs. Table 1 lists water quality standards and goals for some of these pollutants, given various groundwater uses. As in other nonanimal farms, any crop production areas that are part of the AFO are also subject to application of pesticides and commercial fertilizers, which may affect groundwater quality.

Animal manure is physically characterized by its weight, volume, moisture content, and solids content. Key chemical properties of manure include nitrogen, phosphorus, and potassium content, 5-day biological oxygen demand (BOD_5), and chemical oxygen demand (COD). Nitrogen content is differentiated by organic nitrogen, ammonium-nitrogen, and nitrate-nitrogen content. Typical values of the chemical composition of animal manure can be found in USDA-NRCS (1) or in the American Society of Agricultural Engineers (ASAE) Standards (X384.2: Manure Production and Characteristics) (2). The specific composition of freshly excreted animal manure varies over a wide range depending on the animal species, the age/production stage of the animal, the diet of the animal, and the effects of weather, season, and animal care. The specific operation of the manure collection, transport, and storage facilities also greatly affect animal manure and waste water composition due to mixing (including mixing with nonmanure wastewaters collected within the AFO facility), separation of solids and liquids, waste digestion, aging, and any incidental or constructed waste treatment processes.

Animal manure is subject to leaching into the subsurface anywhere within the AFO and its land application area, except in concrete-lined or otherwise isolated areas of the operation. This includes unlined feedlots, open corrals, manure solids storage areas, manure and wastewater storage lagoons, and the fields that receive manure from land application in either liquid or solid form or as a sludge amendment.

The leaching of chemicals and pathogens into groundwater is greatly affected by the timing and amount of recharge, which may originate from precipitation, irrigation, application of manure slurry, or from ponding of wastewater (e.g., in storage lagoons). Soil texture, soil permeability, organic matter content, cation exchange capacity, and soil temperature further influence the fate of some of the salts, nutrients, chemicals, and pathogens released from manure excretion and manure land applications.

NITROGEN

Animal manure contains predominantly organic nitrogen, N_{org}, and ammonium nitrogen, NH_4-N. Organic nitrogen is the dominant form of nitrogen in manure solids (particularly if they are separated from the liquid and dried). The liquid portion of animal manure is rich in both organic and ammonia nitrogen.

Organic nitrogen, if applied to land, is highly sorptive and has very limited mobility: significant amounts of organic nitrogen are usually found only in the top 5–30 cm, depending on land management practices. Over time, organic nitrogen will be converted to ammonium ion (NH_4^+), a process referred to as mineralization. The mineralization rate at which organic nitrogen converts to ammonium depends on the manure composition, moisture conditions, and temperature. After application onto soils or incorporation into soils, higher temperature under sufficiently moist conditions leads to rapidly increasing mineralization rates.

Ammonium is subject to two major environmental pathways: volatilization as ammonia gas (NH_3) and microbially facilitated oxidation to nitrate nitrogen, NO_3-N. Ammonia volatilization may account for a significant amount of the nitrogen loss from an AFO and is a major environmental pathway of the total nitrogen excreted in AFOs. High temperature and exposure of large surface areas of manure to wind or air movement (e.g., during the land application process) facilitate volatilization. Once incorporated into the soil, ammonium volatilization is limited due to strong sorption of the positively charged ammonium ion to soil particles. Ammonium mobility in soils is higher than that of organic nitrogen but still sufficiently limited to prevent significant ammonium movement to depths of more than 1–2 m. In sandy soils with limited cation exchange capacity, ammonium mobility can be enhanced if soil/groundwater redox conditions are anoxic.

Under aerated, oxic conditions, microbial oxidation of ammonium in soils is responsible for the conversion of ammonium to nitrate (NO_3^-). This process is referred to as "nitrification." The time frame needed for complete nitrification of soil ammonium varies from hours or days under warm, moist conditions to months under near freezing conditions.

Table 1. Selected Water Quality Standards and Guidelines for Various Uses

Contaminant	Drinking Water	Livestock Water Supply[c]	Industrial Uses[c]
Nitrate (as N)	10 mg/L[a]	100 mg/L	Petroleum: 2 mg/L
Selenium	0.045 mg/L[a]		
Total coliform bacteria	No more than one coliform-positive sample/month (or no more than 5% coliform-positive for systems that analyze more than 40 samples/month)[a]	<200 to <1,000,000	
Fecal coliform bacteria	0[a]	<1 to <10	
Iron	0.3 mg/L[b]	—	
Manganese	0.05 mg/L[b]	—	
Chloride	250 mg/L[b]	—	
Sulfate	250 mg/L[b]	<250 mg/L to <2,000 mg/L	
Total dissolved solids	500 mg/L[b]	<500 mg/L to <3,000 mg/L	Textile: 150 mg/L Cooling water: 1000 mg/L Paper: 1000 mg/L Chemical: 2500 mg/L

Nitrate, a negatively charged ion, has no sorptive capacity and is highly mobile. It can be readily leached from shallow soils and contaminates groundwater. Under anoxic conditions, however, nitrate is reduced to harmless nitrogen gas ("denitrification"). Denitrification is significant in heavy soils and in fine-grained unsaturated sediments and rocks that are subject to anoxic conditions. Reducing conditions in groundwater also lead to significant denitrification.

Of concern to groundwater is the concentration of nitrate in the recharge to groundwater. The potential nitrate concentration is difficult to estimate because the amount of volatilization and denitrification that occurs after land application of manure is typically not known with a high degree of accuracy. Where denitrification and volatilization in the soil and unsaturated zone above the water table are not significant processes, the potential concentration of nitrate in recharge water can be obtained from estimated annual nitrogen leaching losses and from estimated amounts of annual recharge:

$$\mathrm{NO_3(mg/L)} = \frac{\text{annual N leaching loss (kg/ha)}}{\text{annual recharge (mm)}} \times 100 \times 4.42$$

For example, leaching losses of 50 kg/ha nitrate-nitrogen per year in a location with 250 mm annual recharge potentially leads to a nitrate concentration of 89 mg/L in recharge water. The limit in drinking water set by the U.S. Environmental Protection Agency is 45 mg/L.

PHOSPHORUS

Phosphorus is not a concern with respect to the use of groundwater as drinking or irrigation water. It is only a significant concern, where groundwater discharges into streams or lakes. Total phosphorus levels above 0.05–0.1 mg/L potentially lead to significant eutrophication of these surface waterbodies.

Manure contains significant amounts of phosphorus. However, phosphorus is strongly sorbed to soil particles and subject to plant uptake, when manure is applied to crops. On sandy soils with limited cation exchange capacity and on cracked clay soils, repeated applications of manure may result in some phosphorus leaching to shallow groundwater. If shallow groundwater is collected in tile drains, drain ditches, or if it discharges into nearby streams, elevated phosphorus concentration may become a significant concern.

SALINITY

Solid and liquid manure are rich in total salinity (determined by the amount of total dissolved solids), which is readily leachable through soil and into groundwater. Crops grown on fields that are fertilized with manure may consume a limited amount of that salinity. Salinity leaching out of the root zone into groundwater is not subject to any degradation or sorption.

PATHOGENS

Pathogens are ubiquitous in animal waste, but soils provide a significant buffer against groundwater pollution. In the subsurface, pathogens become entrained in dead-end pores, are collected via filtration onto grain surfaces, or chemically interact with the grain surfaces of the soil/aquifer material. Over time, pathogens die off ("inactivation"). However, where soils and shallow groundwater sediments have large pores (sandy soils, sandy and gravelly aquifer sediments, highly fractured rocks, and finely textured soils with macropores), pathogens travel significant distances in relatively short periods of time. Frequent detections of total coliform concentrations in shallow groundwater underneath AFOs are the result of limited pathogen filtration capacity in the soil or unsaturated zone that overlies the groundwater. Shallow wells, often small domestic supply wells, in the immediate vicinity of the AFO are most likely to be affected.

PHARMACEUTICALS (ANTIBIOTICS AND HORMONES)

Only recently, analytical methods have been established that are sensitive enough to detect these pharmaceutical compounds in water resources. They occur in significant concentrations in the inflow to and discharge from wastewater treatment plants, in surface water, and they are also present in animal manure. Research on the fate of these organic compounds in the subsurface is still in its infancy.

Pullman, Washington

INTRODUCTION

Aquaculture is the fastest growing sector of agriculture in many parts of the world because of the healthy nature of seafood, the increasing demands on protein worldwide, and the reduction of ocean catch. According to FAO statistics (1), aquaculture's contribution to global supplies of fish, crustaceans, and molluscs continues to grow, increasing from 3.9% of total production by weight in 1970 to 27.3% in 2000. Worldwide, the aquaculture sector has increased at a rate that exceeds that of any other agriculture sector, with an average compounded rate of 9.2% per year since 1970 compared with only 1.4% for capture fisheries and 2.8% for terrestrial farmed meat production systems. In 2000, the reported total aquaculture production was 45.7 million tons by weight and $56.5 billion by value with 10.1 million tons and $5.6 billion of the value coming from aquatic plants. More than half of the total world aquaculture production in 2000 was finfish, although growth in the other major species groups continues to be rapid with no apparent slowdown in production to date.

In the United States, the National Aquaculture Act of 1980 established a national policy "to encourage the development of aquaculture," which was then followed by the development of the *Aquaculture Research and Development Strategic Plan* by the Joint Subcommittee on Aquaculture. To develop a globally competitive U.S. aquaculture industry, the plan calls for (1) improving the efficiency of U.S. aquaculture production, (2) improving aquaculture production systems, and (3) improving the sustainability and environmental compatibility of aquaculture production.

The major limitations to the development of aquaculture in many regions are availability of water resources and environmental impact. Water is critical to aquatic animals, for it both serves as the medium that supplies the required oxygen and creates the physical environment that allows for movement of the animals. As world population has grown and industries have increased their production to meet the demands of the growing population, water has become a scarce resource that has had many conflicting demands placed upon it. Consequently, the major strategy for increasing aquaculture production with this limited water resource is production intensification. As fish biomass density increases, however, the amount of oxygen dissolved naturally in water becomes limited, thus necessitating supplemental aeration and oxygenation. In addition, the increased use of artificial feed as a means to developing a high density culture system leads to water pollution that stems from the facts that aquatic animals cannot completely utilize the feed and that the animals will excrete other metabolic products such as ammonia that are toxic to the aquatic animals at elevated levels. Internally, the waste produced deteriorates the water quality and makes the water unsuitable for fish to live in, while externally, discharge of the polluted water, if not properly managed, may lead to adverse effects on the environment.

Water uses and environmental impacts of different aquaculture operations can vary significantly because of the extremely diverse natures of the aquaculture systems and their associated technologies. In contrast to terrestrial farming systems, where the bulk of global production is based on a limited number of animal and plant species, more than 210 different farmed aquatic animal and plant species were reported in 2000 (1). This great diversity reflects the large number of aquatic species that are readily adaptable to the wide range of production systems and conditions present in the different countries and regions of the world. Here, we limit our scope to major freshwater systems for finfish production, namely, ponds, raceways, recirculating systems, and cage culture, as these system are predominant in production aquaculture.

POND SYSTEMS

Description

Ponds account for the majority of aquaculture production worldwide (2). In the simplest terms, a pond is an earthen or concrete impoundment that holds water. Water is generally not passed through the system and therefore water is normally only required to fill the pond and replace that which is lost to evaporation and seepage (2). Pond culture is practiced worldwide with it being the predominant system employed in Asia (3), where it totals over 287,400 tons of fish processed. Pond production of channel catfish is the largest single aquaculture enterprise in the United States (4).

Regardless of the species cultured, ponds can be classified by construction method, by location, and by use (2). Typical construction classifications are levee ponds, watershed ponds, hybrid ponds, marsh ponds, beach ponds, and intertidal ponds. Levee ponds are constructed by removing the soil from the area that will become the pond bottom and require a source of pumped water to fill and maintain the pond (5). Watershed ponds are built in hilly areas through the damming of a watercourse and obtain their water from the surrounding watershed. Hybrid ponds usually consist of two or three levees across a shallow drainage basin, which provides the majority of water for the pond, but they also require a source of pumped water to meet their needs (5). Marsh ponds in coastal areas are constructed with levees above ground level. Water salinity ranges from fresh to saline and filling and draining are usually done by pumping, although some marsh ponds have weirs to allow tidal waters to move in and out (2). Beach ponds are more prominent in Asia and are constructed on the shore in sandy locations where seepage is often a problem. Concrete or plastic may be used to avoid seepage problems and water ranging in salinity from brackish to saline is usually pumped with some ponds having weirs to allow for tidal flushing (2). Intertidal ponds are located just off shore in a location where a cove or bay may be blocked off with either a levee or net. Levees are often constructed out of coral rubble or rocks. The levee is designed so as to confine the cultured species while allowing for water exchange through tidal fluctuation (2). Examples of use classifications are broodstock pond, fingerling pond, and food-fish production pond. Each of the use classifications may be employed with any of the aforementioned construction classifications.

Pond Effluent and Its Constituents

Water is discharged from ponds for several reasons. First, unintentional discharge may occur due to rain if inadequate storage capacity is provided. Second, ponds may be drained either completely or partially during harvesting activities. Lastly, water may be discharged during flushing of the pond in an attempt to improve water quality or as a disease treatment (5). Effluent volume is a factor of pond use as pond drainings vary with use. In the U.S. channel catfish industry, broodstock ponds are drained every 1–5 years while fingerling ponds are drained annually and food-fish production ponds vary between 1 and 20 years (5).

Constituents of aquaculture ponds that may affect the receiving water body include solids, organic matter, nutrients, pH, dissolved oxygen, and toxic chemicals (5). Suspended solids (mainly phytoplankton cells) may be deposited in the receiving water and possibly lead to changes in benthic invertebrate and fish populations due to alterations in the biological oxygen demand (BOD). However, the BOD in aquaculture effluents is usually relatively low and is expressed over a longer time period than most wastewaters (6).

Properly managed pond cultures operate within the limits imposed by natural processes within the pond and make it possible to operate them with minimal impact on the environment (5). The fate of nutrients within a pond is of extreme importance to fish culture. In fact, simple mass balances show that with the above noted limited water exchange in ponds, concentrations of waste products would build to levels that could kill fish.

Waste products such as nitrogen and phosphorus generated by fish can be estimated by calculating the quantity of nutrients added to the pond through feed and so on, then subtracting the amount recovered when the fish are harvested. Unfortunately, organic matter is more difficult to calculate. Carbon may be retained by the fish, respired as carbon dioxide, or lost in waste products. In 1988, empirical values for organic matter generation in fecal solids were determined by Henderson and Bromage (7) to be between 0.3 and 0.7 kg/kg of feed. Two to four times more organic matter is produced within a pond due to phytoplankton growth from inorganic nutrients in fish waste than would be calculated solely as fish waste (8).

Luckily, natural biological, chemical, and physical processes known in limnology and waste water engineering take place within the pond, which remove much of the waste products from the water (5). In fact, after several years of production, catfish ponds average 6 mg/L total nitrogen, 0.5 mg/L total phosphorus, and 75 mg/L organic matter, which is 25%, 10%, and 10%, respectively of the expected values calculated by a mass balance over just a single year (5). Nutrient and organic levels never reach the levels predicted by simple mass balance calculations due to the following processes: nitrogen is lost from the water as a gas through denitrification and ammonia volatilization and as particulate organic matter settles to the bottom and decomposes; phosphorus is lost to pond soils as precipitates of calcium phosphate and particulate organic phosphorus; and additionally, microbial processes are continuously oxidizing organic matter within the pond (5).

Levels of dissolved oxygen, pH, or toxic chemicals within aquaculture pond water have been shown to have little effect on the receiving water body (5). In a stream study, dissolved oxygen concentrations were found to be higher downstream from catfish ponds compared to upstream levels (9). Pond water pH fluctuations beyond equilibrium levels of 6.5–8.5 are due to biological activity of phytoplankton, which usually does not coincide with discharge (10). Equilibrium pH will be quickly reestablished due to dilution, reactions with the receiving waters buffer system, and/or reaeration that will equalize dissolved carbon dioxide concentrations and moderate the pH (5). Pesticides and therapeutants used in pond culture must be EPA-approved chemicals and are used infrequently due to the expense of treating large volumes of water. Additionally, long residence times and intense microbial activity within the pond allow chemicals to be dissipated prior to discharge (5).

Pond Operation and Management

It is expected that regulatory programs in several nations will be implemented based on best management practices (BMPs) (11). Effluent management within the context of pond aquaculture poses a difficult challenge for monitoring and treatment due to infrequent discharges and high volumes of a dilute nature. Recommendations on BMPs that are being made to the pond-raised catfish industry (5) include reducing water exchange rates, providing storage within the ponds, using high-quality feeds and efficient feeding practices, managing assimilative capacity within the pond, providing adequate aeration and circulation, positioning mechanical aerators to minimize erosion, allowing solids to settle before discharging water, reusing water that is drained from ponds, and using effluents to irrigate terrestrial crops. In terms of pond construction and renovation practices, recommended practices include optimizing the ratio of watershed to pond area, protecting against erosion, and providing sedimentation basins.

RACEWAY SYSTEM

Description

Flow-through (FT) aquaculture systems can be defined as those production systems where water enters and leaves the system without being recycled for further use. These systems are characterized based on the type of culture unit employed and the pattern of water flow through the system. Culture units that have been used include ponds, tanks, and/or flumes called raceways. The water flow, in turn, is classified as either a single pass system or a serial reuse system in which water flows, respectively, through a single culture unit or several culture units before being discharged.

Flow-through systems are typically energetically passive systems, where water flows from the farm inlet to the outlet via gravity and aeration/reaeration occurs as a result of hydraulic water cascades before and after the culture units. Much information is available concerning FT production system design, construction, and use (12–16). Currently, the most prominent flow-through system is a serial reuse raceway system constructed of concrete.

Flow-through production systems offer several production advantages resulting from the design. Typical raceway culture units possess length and width ratios of 7:1 with depths generally less than 1 m. These dimensions facilitate grading and harvesting operations as well as the easy observation of fish (17). The continuous flow of clean water transports waste metabolites out of the culture units and provides dissolved oxygen needed for life support. In most U.S. raceway operations, there is typically a quiescent zone at the end of the raceway for solids capture. The quiescent zone facilitates the settling of fecal particles as no fish is present to create disturbance. The solids accumulated in the quiescent zone are removed periodically and stored in an offline settling basin.

Aquaculture production using FT raceway systems is common worldwide for many species of fish. In the United States, FT systems are the second most commonly used aquaculture production system (18). Warm, cool, and cold water species such as catfish *Ictalurus* sp., yellow perch *Perca flavescens*, and rainbow trout *Oncorhynchus mykiss*, respectively, are cultured in FT systems. However, coldwater fish production from government hatcheries and the commercial production of salmonids, particularly rainbow trout, are by far the most common uses of flow-through aquaculture systems.

Water Use

Because no water recycling occurs in FT systems, substantial quantities of water are utilized—more than any other type of aquaculture production system. In particular, the culture of coldwater fish, which are naturally more susceptible to poor water quality conditions and require higher dissolved oxygen concentrations than warm and cool water species, requires substantial water resources. However, for all practical purposes, FT system water use is nonconsumptive and does not reduce water availability for other uses.

Depending on farm location and the available water resources, there is a wide range of FT total farm flow rates, which are beneficial in understanding system water use. For example, in the United States, rainbow trout farm total flow rates can range from less than 1699 L/min to 5097×10^2 L/min for the largest farm. On a per unit production basis, typical FT systems are able to produce 6 kg/yr of fish per 1 L/min water flow (19). Based on these values, total water use for FT aquaculture trout production in the United States can be estimated. In the United States approximately 32 million kg of trout were produced in 2000 (20). This corresponds to a nonconsumptive cumulative water flow rate of 5.3×10^6 L/min, which is 15.5% of the consumptive water flow rate required to supply New York City's 9 million people (34.1×10^6 L/min). Clearly, the magnitude of the FT flow rate per production is directly related to the quantity of effluent and has important implications on subsequent FT system environmental impacts and effluent treatments.

Environmental Impact

Environmental regulations controlling FT effluent discharge have been established in many regions (21–23). Potential flow-through effluent pollutants can be grouped into three categories: (1) pathogenic bacteria or parasites, (2) therapeutic chemicals and drugs, and (3) metabolic products and food wastes (17). Regulations primarily target metabolic and food wastes, although recent regulations have begun to address the pathogenic and therapeutant components even though evidence of the environmental impact of the first two is limited (17).

Extensive work has been done to characterize FT effluents and the associated environmental impacts due to metabolic and food wastes. Flow-through effluents contain solid and dissolved organic and nutrient pollutants. Organic pollutants are derived from feces and uneaten feed and are described by biological and chemical oxygen demands, while the nutrient pollutants, nitrogen and phosphorus, are excreted from fish gills and urine. Flow-through effluent characterizations for locations across the world have been summarized in several reviews (17,24). These studies showed that effects from FT effluent discharge are site specific and range from insignificant to heavily impacted, although heavily impacted water bodies are few in the United States (25). The general insignificant impact of FT effluents on receiving waters has been linked to the low pollutant concentrations resulting from high system flow rates. A European study compared FT effluents to domestic wastewater and showed that total suspended solids (TSS), total phosphorus (TP), total nitrogen (TN), and biological oxygen demand (BOD) concentrations were far less, 3% or less, than the same components in medium strength domestic wastewater (26).

Effluent Treatment

The treatment of FT effluents is difficult due to the dilute concentrations, high flow rates, and the high costs of traditional treatment technologies (26). Currently, strategies to treat FT effluent discharge include implementing best management practices for solid waste control (23); optimizing dietary P requirements to reduce excess P excretions (27); and/or utilizing mechanical screen filters, submerged biofilters, or other effluent treatment processes (22,24). These strategies have effectively lowered pollutant discharges from many FT systems. However, the scale-up of the effluent treatment options for applications in large facilities is still problematic with applications of many of the best available technologies to FT effluents for solids and nutrient control being limited by treatment efficiencies and/or inhibitory treatment costs resulting from treatment process operations and/or sizing considerations (28).

NET PEN SYSTEM

Description

Net pens are commonly located in coastal waters although they may also be found in open ocean or freshwater ponds and lakes. Coastal net pens are usually a net bag suspended below a floating rigid top frame. Typical net pens of this type are 10–20 m per side at the surface and 10 or more meters deep. Open ocean net pens are designed with a more rigid structure and can be as large as thousands of cubic meters in volume. Freshwater net pens are generally relatively small rigid structures covered by netting or wire mesh.

Until recently, freshwater net pens were the most common form of aquaculture being utilized throughout the world. However, this culturing technique is no longer the dominant form for freshwater aquaculture, although freshwater net pen culturing is becoming increasingly popular in China. Today, its most dominant application is coastal aquaculture with a trend toward moving further offshore. Marine net pen aquaculture has become progressively more intensive due to new technologies, expansion of suitable sites, improved feeds, increased understanding of the cultured species biology, and increased water quality within farming systems. In some countries, marine net pen culture is the dominant culture method. Atlantic salmon are currently being cultured in net pens and cages in Canada, Chili, Ireland, Japan, Scotland, Norway, and the United States. Other species currently being cultured in net pens throughout the world include sea bream and sea bass in the Mediterranean Sea, yellowtail and red sea bream in Japan, and tuna and cobia culture is growing.

Objections to net pen culture include degradation of the environment, disease transmission, antibiotic use, and interaction of escapees with wild populations. Law suits have been filed for odors, excessive noise, and even visual pollution. Environmental impacts from intensive aquaculture include hypernutrification (eutrophication), benthic enrichment, increased biological oxygen demand, and changes in the bacterial flora. Serious impacts from net pen culture occurred in Japan in the 1990s, resulting in changes in culture practices, and Taiwan is planning for sustainable marine aquaculture as it moves toward cage culture.

Water Quality

Water quality may be affected by net pen culture due to waste metabolites released by the fish and dissolution of nutrients from the feed and feces. Impacts are affected by bottom topography, geography, and hydrographic conditions and tend to be more severe if the location chosen has poor water exchange. Net pen culture has been practiced worldwide in both marine and freshwater with little impact to substantial impact on water quality.

Benthic Environment

The best-studied aspect of marine net pen culture is the deposition of organic matter below the cages or pens. The culturing of animals in pens or cages results in some loss of feed and the production of feces. Uneaten feed and feces may accumulate under or near (usually no more than 30 m from the edge) the net pens or cages. Tidal flow, depth of site, composition, temperature, and salinity of the seawater are among the factors that influence the distribution of solids under each site. Accumulation of uneaten feed and feces can lead to anoxic sediments concurrent with changes in the microbial community and possibly leading to the release of methane, carbon dioxide, and hydrogen sulfide. As mentioned previously, there may or may not be links between water quality and the benthic environment. Therefore, those with more interest in this aspect are directed to Mahnken, who cited a number of studies covering nutrient dynamics and deposition with regard to the benthic community structure.

Methods of Reducing Impacts

As in other forms of aquaculture, methods to reduce the impact of aquaculture have been studied and proposed. Utilization of specifically formulated feeds and improving feeding efficiency have been recommended to reduce the amount of waste produced in both the water and benthic environment. Another approach, which has been successful in Switzerland, is to diaper the cages or net pens. The most common approach to dealing with waste accumulation is the proper placement of farms. This is leading to more farms being sited in open water with better flushing rates and ability to naturally assimilate nutrients.

RECIRCULATING SYSTEM

Description

Recirculating systems are aquaculture systems in which the majority of water is treated or conditioned continuously for repeated use. One of the major advantages of recirculating systems is that a high density of fish biomass can be kept at optimum temperatures. The recirculating system is a relatively new technology that has been developed in the last two decades. There are various designs for recirculating aquaculture systems. An effective recirculating system will usually include a culture tank, an aeration or oxygenation system, a biofilter, and a suspended solids removal unit. The biofilter provides a medium for aerobic bacteria to break down organic fish waste and to convert excreted toxic ammonia into nitrate. Some systems will include additional treatment units such as disinfection.

Water Use

In a recirculating system, the water is processed continuously to guarantee optimum growing conditions. Water is pumped into the tanks through mechanical and biological filtration systems and disinfection systems and then returned into the tanks. Two terms that are often used in relation to recirculating systems are recirculation rate and water exchange rate. Recirculation rate (turnover time) is the amount of water per unit of time pumped out of the tank, through the biofilter, and back into the tank. This can easily be determined by dividing the volume of water in the tank by the capacity of the pump (in gallons per minute). An increase in recirculation rate will increase the number of turnovers per day in the culture tank and thereby provide reduced ammonia levels. Most production recirculation systems are designed to provide at least one complete turnover per hour (24 cycles/day). Exchange rate refers to the amount of water replaced per day. Most recirculating systems recommend 5–10% water exchange rate per day depending on the sensitivity of the species to water quality, stocking density, and feeding rates. The major consumption of water in recirculating systems is associated with the removal of solids such as backwashing the particulate filter or biofilters, while another major consumption derives from the need to replace evaporative loss.

Water Treatment

An excellent culture environment for fish is crucial. In the recirculating systems, the major unit operations to consider for the maintenance of a good environment are ammonia removal/conversion and solids removal.

In respect to solids removal, waste solids, including uneaten feed and by-products of fish metabolism, have to be removed as quickly as possible. Left in the system, the solids could generate additional oxygen demand and produce carbon dioxide and ammonia nitrogen when undergoing bacterial decomposition. Solids removal is generally accomplished by the use of settlement, screen filters, or granular media filter such as bead filters or sand filters.

The most critical nonsolids water quality parameter is ammonia nitrogen. Ammonia is a principal excretory product of fish metabolism and in its un-ionized form is highly toxic to fish. Fish will excrete about 30 g of ammonia for each kilogram of food consumed (at 35% protein content in the feed). The most common technique used for ammonia removal is biofiltration that works on the principle of biological nitrification in which ammonia is oxidized successively to nitrite and finally to nitrate. Nitrate is much less toxic to fish, especially in freshwater. Another process called denitrification is an anaerobic process where nitrate is converted to nitrogen gas. Although not normally employed in commercial aquaculture facilities today, the denitrification process is becoming increasingly important as stocking densities increase and water exchange rates are reduced; resulting in excessive levels of nitrate in the culture system (29). Necessary conditions for nitrification are availability of dissolved oxygen, proper pH, and adequate alkalinity in the water. The rate of the biofiltration process is dependent on temperature, pH, salinity, surface area of the biofilter, and flow rate.

The types of biofilters commonly used in recirculating aquaculture systems include submerged biofilters, trickling biofilters, rotating biological contactors (RBCs), floating bead biofilters, and fluidized-bed biofilters. A common feature to all these biofilters is that they rely on a “fixed film” process in which nitrification bacteria develop on the surface of the support material of the filter and form an active bacterial biomass layer called biofilm. As fish culture water flows through the surface of the film, nutrients such as ammonia and oxygen will diffuse into the biofilm to be utilized by the nitrifying bacteria. The biofilm’s importance also derives from the fact that, as a result of the bacterial attachment to a media, they are free from the risk of being washed out from the system when significant water exchange rate occurs.

Environmental Impact

Recirculation technology, predominantly used in land-based operations, enables farmers to achieve high efficiencies, providing them with greater control over the rearing environment. With the advent of recirculation technology for aquaculture, the incoming source water is reused to varying degrees and undergoes various treatment processes to ensure its purity. The farmer thereby gains considerable control over the rearing environment, being able to manipulate temperature, dissolved oxygen, photoperiod, and water clarity. With more control over water parameters, the stocking densities can be increased, thereby allowing for greater economies of scale. Also, greater control is gained in the separation of uneaten feed and fecal material from the water, thereby preventing these nutrients from entering the downstream environment. Consequently, a recirculating system can significantly reduce effluent volume. However, a recirculating system cannot eliminate the production of fish waste. Thus, as with other animal production systems, a waste management plan is necessary for operation.

BIOFUEL ALTERNATIVES TO FOSSIL FUELS

Lucas Reijnders
Universiteit van Amsterdam
Amsterdam, The Netherlands

INTRODUCTION

Our species has been exclusively dependent on biomass for fuel during most of its existence. The use of coal and mineral oil emerged due to the scarcity of biofuels (1). By now, the world energy market, which supplies a yearly energy consumption of about 400×10^{18} joule (J), is dominated by fossil fuels. Still, about 14% of yearly world fuel consumption is based on biofuels (2,3). Most of this consumption is similar to the use before the Industrial Revolution and is located in the countryside of developing countries. It is often associated with poor indoor and outdoor air quality. Negative impacts on soils, on the availability of groundwater, and on water for generating hydroelectricity have also been linked to biofuels in developing countries (4–6).

Against this background, it may be somewhat surprising to see increased advocacy for biofuels. This concerns mainly "modern biomass": biofuels applied while using advanced conversion technology to generate electricity and heat and for automotive power (7).

There are several main drivers behind the increased advocacy for biofuels. First, there are efforts to become less dependent on mineral oil, driven by concerns about energy scarcity, political instability in the Middle East, and oil price shocks. A second driver is environmental concern. Some applications of biofuels result in lower emissions of such pollutants as hydrocarbons, carbon monoxide (CO), sulfur oxides, and nitrogen oxides. It has also been argued that in combusting biofuels, one simply puts back into the atmosphere carbon dioxide (CO_2) that has been recently fixed by photosynthesis, thus ensuring climate neutrality, in contrast to the combustion of fossil fuels which puts CO_2 in the atmosphere that was fixed many millions of years ago. The need to find an outlet for agricultural surpluses has also been conducive to biofuel advocacy.

Advocacy and also actual combustion of "modern biomass" are increasing. A major application is the use of ethanol and to a lesser extent fatty acid methylester as fuel in motorcars. Ethanol is used mainly in Brazil, North America, and the European Union (EU). In Brazil, sugarcane is the major feedstock for ethanol production, and in the EU and North America, the main feedstock for ethanol is starch from grains. The use of biomass for modern electricity and heat production is mainly on the increase in the European Union. Expansion of biomass-based waste incineration, cocombustion of biomass in coal-fired power plants, and energetic use of residual biomass by industry contribute significantly to this trend.

Here the implications of modern biomass use that are relevant for water are discussed. Some of these implications are direct. By clear felling forests for the supply of biomass, there can be a major direct impact on surface water, such as changes in peak flows and runoff. Other implications are indirect. The extent to which modern biomass influences atmospheric levels of greenhouse gases such as CO_2 and CH_4 (methane) is a determinant of climate change and this in turn influences the biogeochemical water cycle. Current climate change leads among other things to sea level rise (that in turn may lead to increasing intrusion of saltwater) and an increase in land surface precipitation of 0.5–1%/decade in mid- and high latitudes of the Northern Hemisphere, whereas there is a decrease of such precipitation in subtropical land areas of 0.3%/decade (8). Due to climate change, there may be changes in water erosion, seasonal river flows, and groundwater tables; impacts on biological activity; and the presence of species in water. Increasing temperatures also increase human freshwater use (9).

In this article, we deal with the following questions:

- — Is the use of biofuels "climate neutral"?
- — What is the impact of biofuels on (fresh) water use?
- — What is the impact of biofuels on substance flows that may impact water?

ARE BIOFUELS "CLIMATE NEUTRAL"?

To answer the question whether biofuels are "climate neutral," a life cycle perspective on biofuel combustion is necessary. Such a perspective includes all stages of the biofuel life cycle. For instance, if trees from forests are used as biofuel, the cycle starts with the seed and ends with the postharvesting fate of the forest. The main matters to consider in establishing the impact of the biofuel life cycle on climate are the input of fossil fuels during the life cycle and the impact of the biofuel life cycle on biogenic carbon stocks. Both influence atmospheric concentrations of greenhouse gases such as CO_2 and CH_4. One should also consider the fate of compounds containing nitrogen (N) in the biofuel life cycle. Such compounds may be partly converted into the potent greenhouse gas N_2O (dinitrogen oxide). This aspect tends to be less important than the impact on atmospheric gases containing carbon, but may still be significant in agricultural production of biofuels.

Because the use of fossil fuels is so dominant in worldwide energy consumption, it is not surprising that usually there is an input of fossil fuels in the biofuel life cycle. Quantitatively, such inputs vary widely depending on the kind of biofuel and its actual production. For instance, in forest-derived biofuels, the input of fossil fuels is usually 5–10% of the energy value represented by the biofuel (output). This gives an "output to input energy ratio" of 10–20, meaning that the biofuel can supply 10–20 times the equivalent of the input of fossil fuels in the biofuel life cycle. In animal meal that is cocombusted with coal in a number of European power plants, the output to input energy ratio is about 0.24 (10). Table 1 gives output to input energy ratios for several biofuels.

This table shows, among other things, that for ethanol from U.S. corn, there is no agreement on the energy ratio. The underlying disagreements result in part from different estimates of the actual fossil fuel inputs in the biofuel life cycle. When corn is used to produce the biofuel ethanol, there are also coproducts, such as cattle feed. In this case, the allocation of fossil fuel input to the different outputs (products) arises. One possibility is to allocate all fossil inputs to the biofuel. Another possibility is to divide the fossil fuel inputs by the products involved. Such an allocation may be done in different ways, for instance, based on a monetary or on an energy basis, and these different ways lead to different outcomes. For ethanol produced from corn in the United States, the U.S. Department of Agriculture (12) has argued that the biofuel energy output to fossil fuel energy input ratio is currently 1.3, whereas Pimentel (13) calculates an output to input energy ratio of 0.58–0.74, depending on the allocation to ethanol and its coproducts.

However, notwithstanding this disagreement, one may conclude that when ethanol is produced from U.S. corn starch, the input of fossil fuels is at least a large share of the energy output from the biofuel. A similar conclusion can, for instance, be drawn regarding oil-methylesters

Table 1. Ratios of Current Energy Output to Fossil Fuel Input for the Life Cycles of a Number of Biofuels[a]

Type of Biofuel and Application	Ratio of Energy Output to Fossil Fuel Input
Forest derived (short transport distances), for electricity production	10–20
Ethanol from Brazilian sugarcane (bagasse as production fuel), transportation fuel	~7
Ethanol enzymatically produced from woody crops, transportation fuel	~4
Chicken manure (energetic allocation) produced in the European Union, for electricity production	~1
Ethanol from U.S. corn, transportation fuel	0.58–1.3
Animal meal produced in the European Union for electricity production	0.24

[a] References 3, 10–13.

produced from oil crops such as rapeseed, sunflower, or soybean (14). More in general, one can conclude that burning biofuels is not only a matter of giving back to the atmosphere carbon that was recently fixed. Usually, there is the added emission of fossil fuel derived carbon compounds, such as CO_2. Especially when high-input agricultural production is involved and when further processing is fueled by fossil fuels, this emission tends to be important.

A second important matter to be considered is the effect of the biofuel life cycle on biogenic carbon stocks: biomass and soil organic carbon (C). The last stock is of great quantitative importance. It is currently about three times the atmospheric stock and about four times the stock of C in biomass. Since the beginning of the Industrial Revolution, the combustion of fossil fuels has added an estimated 270×10^{15} g C to the atmosphere, whereas biogenic sources (deforestation, biomass burning, and loss of soil organic carbon) added $\sim 136 \times 10^{15}$ g C. Depletion of the stock of soil organic C since the start of the Industrial Revolution is an estimated 78×10^{15} g C (15).

The biofuel life cycle can substantially reduce and add to biogenic carbon stocks. If biofuel is produced from deforestation and conversion into agricultural land, large emissions of carbon containing gases from soil to the atmosphere can occur. On the other hand, when biofuel is produced from reforestation or conservation tillage and the use of compost and manure, there can be net sequestration of carbon in the soil (15). In Table 2, this is exemplified by the life cycle emission of 68×10^2 g CO_2/kWh, when the production of forest derived fuel is accompanied by deforestation. The net sequestration of 19×10^2 g CO_2/kWh is from reforestation of agricultural land.

If we survey the relation between biofuel use and the emission of greenhouse gases that affect climate, it will be clear that the relation is more complicated than "giving back" recently fixed carbon dioxide to the atmosphere. As Tables 1 and 2 show, net life cycle additions of greenhouse gases to the atmosphere can be larger than that from combusting an equivalent amount of fossil fuel.

Table 2. Life Cycle CO_2 Emission Factors for Several Current Types of Power Generation in 10^2 g CO_2/kWh[a]

Type of Fuel	Life Cycle Emission Factor in 10^2 g CO_2/kWh
Hard coal	+10
Natural gas	+ 4
Forest derived biofuel	−19–+68

THE IMPACT OF BIOFUELS ON (FRESH) WATER USE AND WATER AVAILABILITY

The replacement of forests by plantations or annual biofuel crop production may lead to a decrease in available water due to increased drainage and increases in peak flows and storm flows. Soil degradation from clear felling of forests may lead to insufficient replenishment of groundwater reserves and increased peak and storm flows (16,17).

Water is also an important resource in biofuel production. Fast growing woody crops such as poplar and eucalyptus use relatively much water. For instance, Tuskan (18) has calculated that in the United States hybrid poplar requires roughly 1 meter/hectare yearly of (ground) water during midrotation. In southern China, it has been found that under comparable conditions, water tables under eucalyptus plantations were 50 cm lower than under mixed forests (19). Water use for biofuel crops may be expected to increase when temperatures rise (20).

Although there are some waterlogged areas where large uptakes of water by energy crops can be considered a benefit, it will be more common that water can be a limiting factor in biofuel production. Currently, in nearly 80 countries that have 40% of the world population, water demands already exceed additions to stock (21), and such countries are unlikely to embark on major energy crop production programs. In countries that currently have surplus water, if compared with demand, limitations may also emerge. For instance, in Ethiopia where eucalyptus is grown for biofuel production, competition between food crops and eucalyptus for scarce water resources has led to restrictions on the latter (4). Berndes (22) has pointed out that large-scale biofuel production countries such as Poland and South Africa may face absolute water scarcity, resulting in lowering of water tables.

Judicious choice of biofuel crop may limit water use. C_4 biofuel crops generally use water more efficiently than C_3 crops (22). Water efficiency may also be improved by some types of agroforestry, reducing runoff, direct evaporation of water, and drainage (17,23).

BIOFUEL SUBSTANCE FLOWS THAT MAY IMPACT WATER

The biofuel life cycle mobilizes large amounts of substances. When biofuels are produced by agriculture (e.g., ethanol made from starch or sugar), higher inputs of sediments, nutrients, and pesticides in water accompany increased agricultural land use. Such increases may also be large because land requirements may be large. If, for instance, the United States were to decide to cover current U.S. gasoline consumption by corn-based ethanol fuels, more land would be needed than current total U.S. cropland (11).

When biofuels are derived from tree plantations, erosion may be much increased. Studies of plantation forestry on slopes has shown that, especially in the planting and timber harvesting phase, erosion can be extensive, giving rise to silting of lakes and reservoirs and channel instability downstream (24). The sequestration of minerals may be reduced by clear felling, leading to increased levels in surface water (25).

Another matter for concern in tree plantations is the use of plant nutrients to stimulate biomass production. High productivity is strongly linked to large inputs of plant nutrients containing K (potassium), N, and P (phosphorus), and to poor efficiencies in output (nutrients in biofuel) to input ratios (16,26). This may lead to major nutrient losses to water.

The actual impact of biomass production, of course, strongly depends on the measures taken to limit such impacts. Woodlands generating yearly, on average, 3 metric tons of woody biomass per hectare will lose much less nutrients and soil than high productivity plantations (27). In the agricultural production of biofuels, conservation tillage, applying crop residues, terracing, and other provisions to trap sediment, reduce fertilizer application, and minimize hydrologic changes may limit impact.

The combined life cycle emissions of acidifying substances such as NO_x and SO_2 are for biofuels of the same order of magnitude as the corresponding emissions from fossil fuel life cycles (28–30). The generation of persistent organic pollutants such as chlorinated dioxins and benzofurans and polycyclic aromatic hydrocarbons is not less than that from fossil fuels (31,32). The mobilization of heavy metals and other hazardous elements may be substantial. In Denmark, for instance, the application of fly ash originating in the combustion of wood and straw to soil is banned because of its cadmium content (33). Klee and Graedel (34) have compiled a survey of elements in coal and the average concentration in dry plant material. Significant differences emerge from this survey. For a number of hazardous substances, including Hg, As, Pb, Cr, and Ni, concentrations in biomass are lower. On the other hand, there are also elements that may have an environmental impact that have higher concentrations in biomass, such as P, K, Co, and Cd.

The load of hazardous elements generated by biomass combustion may be much increased when such elements are added to biomass during its stay in the economy. Examples are the treatments of wood with chromated copper and arsenic salts or metaborates for conservation. When wastes of such treated woods are burned as biomass especially the level of hazardous elements in ash is elevated. Sewage sludge that is combusted as biomass is another case in point.

Again actual impacts will depend on the measures taken. For instance, state-of-the-art use of desulfurization and de-NO_x technology will strongly limit acidification risk for poorly buffered surface waters. And indefinite containment of hazardous elements in ashes will better protect ground- and surface water than application of ashes to soils or the use of settling ponds for ashes.

SOIL CONSERVATION

R.J. Rickson
M. McHugh
R.P.C. Morgan
Cranfield University
Silsoe, United Kingdom

INTRODUCTION

Soil is a precious natural resource, which performs many vital functions. As a growing medium, soil provides nutrients, air, and water to sustain life on earth, supporting global agricultural and manufacturing industries with renewable raw materials, enabling sustainable economic growth and prosperity. As a habitat, soil is an essential gene reservoir, maintaining a healthy biodiversity that enables micro- and macroorganisms to adapt successfully to environmental changes. Soil influences our natural and cultural landscapes by providing the foundation and raw materials for infrastructure, thus affecting the aesthetics of the world around us. Soils have enormous storage capacity, absorbing surface water, which helps to reduce flooding risk, and providing water supplies for agricultural, domestic, and industrial demands. Soil filters the water passing through it, and chemical transformations help neutralize potentially harmful substances. Soils also store nutrients, trace elements, and organic carbon. Soils are essential in the sequestration of carbon and in the absorption, storage, and reflection of solar energy—important processes that influence global climate and climate change.

Soil formation rates are very low, roughly equivalent to $0.1\ \mathrm{mm} \cdot \mathrm{y}^{-1}$ in temperate regions (1). With such limited rates of renewal, soil should be treated as a nonrenewable resource, which must be protected and conserved so that the functions of the soil, as listed above, can be maintained for future generations.

THE NEED FOR SOIL CONSERVATION

Soil conservation aims to prevent degradation of the soil resource. Such degradation occurs when one or more of the functions described above are impaired, either through *in situ* changes in soil properties, such as loss of soil organic carbon or depletion of nutrients, or through physical loss of the soil through erosion. As the latter process is irreversible, emphasis on erosion control is given here. Erosion is initiated when the kinetic energy from running water or wind is sufficient to detach and transport soil particles and aggregates from the soil mass. The eroded soil is transported and some or all of it may be deposited downslope. Often, however, the finer particles, mainly clays and organic matter, are transported into adjacent watercourses, where the nutrients associated with them can cause pollution, and deposition of the soil particles (sedimentation) can restrict water flow.

Soil conservation aims at conserving the soil properties associated with fertility (Table 1) by preventing *in situ* degradation and preventing physical loss of soil by controlling erosion. Ideally, soil conservation should also improve the levels of these fertility indicators to ensure continuing soil health and functionality and to minimize the detrimental impact of any future soil degradation process.

SOIL CONSERVATION APPROACHES

Soil conservation techniques can be classified into three approaches:

1. *Mechanical Methods*—the use of engineering structures to conserve fertility and control soil erosion.

Table 1. Main Components of Soil Fertility

Physical components	Soil depth Bulk density Soil water/water holding capacity Aggregation/soil structure Porosity/soil air
Biological components	Microorganisms Macroinvertebrates Soil respiration Organic matter/carbon
Chemical components	Extractable nutrients Essential elements Cation exchange capacity pH Electrical conductivity C/N ratio

2. *Agronomic Methods*—the use of vegetation or simulated vegetation to conserve fertility and control soil erosion.
3. *Soil Management Methods*—the manipulation of soil conditions to conserve fertility and control soil erosion.

These methods are interrelated and multipurpose in that they aim to conserve both soil fertility and control soil erosion simultaneously. In many situations, a single approach is insufficient on its own and several approaches need to be combined in an integrated soil conservation system.

Mechanical Methods of Soil Conservation

Introduction. Mechanical methods of soil conservation are applied to control soil erosion by water. Some techniques date back to ancient times such as terraces, which were adopted by Phoenician, Roman, Chinese, and Incan civilizations but are seldom used in modern times, due to high capital and labor costs incurred in construction and maintenance.

Types of Mechanical Soil Conservation Measures. Terraces are constructed on hill slopes where soil conservation is needed because of erosion risk. Terraces control soil erosion by reducing slope length and local slope steepness, thus reducing overland flow energy to erode and maintaining inherent soil fertility.

There are many different types of soil conservation terrace, often developed for local environmental conditions (e.g., the "fanya juu" terrace of eastern Africa). Generic types of terrace include the channel and bench terrace. Channel terraces are suited to slopes no steeper than 7° (12%) (2,3) (Fig. 1). They consist of a cut channel and a filled ridge (constructed from the cut material), excavated across the slope.

The distance between consecutive terraces downslope can be determined by equations based on site conditions (4,5). However, a general rule of thumb is to use a vertical interval between terraces of 1 m. This results in varying distances between terrace channels as the slope gradient changes, with shorter terrace intervals on steeper slopes. This may cause practical problems for mechanized farming.

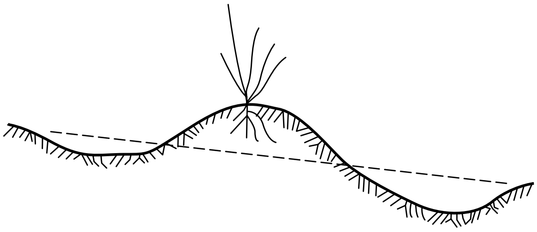

Figure 1. Cross section of a channel terrace (http//www.fao.org/documents).

The terrace channel reduces slope length, and overland flow generated between terrace channels discharges into the channel. The size (width × depth) and gradient of the channel across slope (usually at 1: 250 = 0.4% slope) determine its capacity in conveying overland flow to a safe outlet (see lined waterways below). The gentle gradient of the channel ensures that erosion within the channel itself does not occur.

Bench terraces are steplike structures, constructed across slope, which prevent soil erosion by dissecting the slope into smaller, shorter components, each with a level or near-level bench (Fig. 2). The dimensions of the benches depend on slope steepness, the desirable width of cultivable land (i.e., bench width), and the acceptable height of the steep wall of the terrace, or "riser" (4,5). The construction of the level bench requires the oversteepening of the terrace riser. To prevent the collapse of the riser, it must be supported with stones, rocks, masonry, timber, or simply a dense network of vegetation roots.

By concentrating and redirecting overland flow, terraces will change the natural hydrology, which may incur increased risk of erosion. To avoid this, flow in the terrace channels is directed to lined waterways, which are designed to carry increased volume and velocity of overland flow without causing erosion. These waterways, ideally located in natural depressions to minimize earth moving, are lined with dense, short vegetation, stones, or geotextiles. These linings permit high velocity flows without causing erosion. The width and depth of the waterway are determined by the volume of overland flow and the waterway slope and lining.

In conclusion, mechanical measures of soil conservation control the physical loss of soil by erosion. As the soil is kept *in situ*, soil fertility is also maintained.

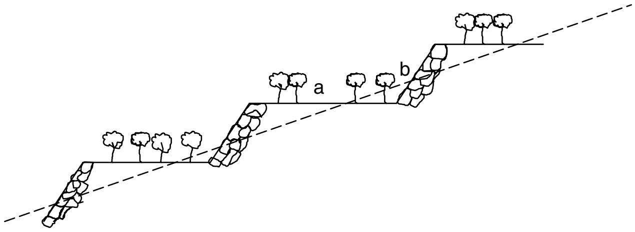

Figure 2. Cross section of bench terraces: a—level bench; b—riser.

Agronomic Methods of Soil Conservation

Introduction. Vegetation is highly effective at controlling soil erosion (6). Agronomic methods of soil conservation involve the use of vegetation to control soil erosion and to maintain or enhance soil fertility.

Water Erosion Control. The canopy, stem, and root components of plants interact with soil erosion processes. A plant canopy intercepts rainfall, changing raindrop sizes and reducing fall velocities, so that rainfall kinetic energy available for erosion is reduced. Plant stems distort overland flow paths and impart roughness to the flow, reducing flow velocity and thus kinetic energy to erode. Plant roots encourage infiltration, reducing overland flow generation, and also increase soil shear resistance against the shearing forces of overland flow. These beneficial effects of vegetation have been quantified by many workers (7–10). A fully mature, low growing, dense vegetation cover is able to control soil loss by two or three orders of magnitude compared to bare soil.

Agronomic methods of soil conservation apply these principles in the field. Maximum cover on the soil surface will protect the soil from erosive raindrops and overland flow, absorbing their energy and thus reducing the ability to erode. High stem and root densities reduce overland flow volumes, velocities, and energy to erode. These effects are achieved through cover cropping, high density planting, crop rotations, mulching, and erosion control mats. All of these control soil erosion and enhance soil fertility by contributing nutrients, organic matter, and carbon to the soil, thus encouraging microbial biomass and activity and improving soil structure and aggregate stability. A fertile, noneroding soil will be able to support a dense vegetative sward with high percentage cover, stem, and root densities, which in turn are effective at controlling erosion and enhancing soil fertility.

Vegetation is used to reduce slope length and steepness when grown in strips parallel to the contour. The strips may be of different crops (strip cropping) or as a single field strip across the slope. The strips restrict the generation of overland flow and encourage deposition of eroded sediment, so that local slope gradients might be reduced. The deposited sediments are also rich in nutrients, which are retained within the field, thus maintaining fertility and avoiding diffuse pollution off-site.

Agroforestry systems combine erosion control and maintenance of soil fertility (11). One common practice is to grow perennial trees/shrubs alongside annual crops. The trees form across-slope barriers to overland flow (also known as “alley cropping”), thus reducing erosion. While the annual crops may deplete soil nutrients in the topsoil, these can be replaced by release of nutrients assimilated in the leaves that fall from the trees. These nutrients come from reserves deeper in the soil by the tree roots, so competition for nutrients between the two components is minimal.

Wind Erosion Control. By exerting a drag on air flow, vegetation can reduce the velocity of wind below that required to initiate erosion and can enhance the deposition of soil already in the air. The most common use of vegetation is in the form of shelterbelts spaced at regular intervals at right angles to the direction of the erosive winds. Traditionally, trees have been used to form shelterbelts but they need to be supplemented by shrubs (bushes) and grasses to provide cover close to the ground surface, as 70–75% of the soil eroded by wind is carried within the lower 1 m of the atmosphere. Modern shelterbelts are based on species of willow and alder, both of which can be coppiced to encourage growth close to the ground. The most important characteristic of a shelterbelt is its density or porosity. The belt needs to be porous so that some air passes through the belt but at a low velocity. Clearly, if the belt is too sparse, the velocity of the wind is not reduced. A porosity of 40–50% is generally considered optimum. Belts are usually designed to maintain wind speeds below 75% of the speeds recorded over open ground. To achieve this, they need to be spaced at intervals of between 12 and 17 times the belt height.

The principles of shelterbelts can also be used to design in-field shelter systems in which crops are alternated on a strip system, aligned at right angles to the prevailing wind. Thus, strips of barley, spaced at 5–10 m intervals, can be alternated with strips of carrots, onions, or sugar beet to control erosion.

Since shelterbelts require a certain amount of time to become effective, they are not appropriate where immediate control of wind erosion is required. In these situations, windbreaks can be made from brushwood or plastic netting. Brushwood fences are commonly constructed on coastal dunes to reduce wind velocities and stabilize the mobile sand, which can then be seeded or planted with shrubs and trees to provide long-term stability and reclamation.

Soil Management Methods of Soil Conservation

Farming operations carried out up and down the slope will increase the risk of overland flow generation and loss of soil and nutrients. Changing to contour cultivations will reduce these risks significantly, but this is not always practical, especially on complex or steep slopes, where the arrangement of fields on the contour makes harvesting difficult and incurs high energy consumption. Contour ridging creates raised ridges across slope, which will reduce slope length an effective catchment area for overland flow generation, and intercept any overland flow that is generated. The across-slope ridges can be joined together at regular intervals by “ties” running up/downslope, thus creating small basins that trap any overland flow and eroded soil, conserving both soil and water within the ”tied ridges.”

The factors affecting the susceptibility of soil to erosion can be affected by soil management methods, which can both degrade or conserve soil. For example, intensive arable production can lead to severe soil degradation, as soil is broken down by numerous tillage practices into a loose, fine tilth seedbed. The resulting small soil aggregates are highly susceptible to erosion. Studdard (12) and Pochard (13) showed that under conventional arable production, there is little time between cultivations for aggregates to reform into larger, more stable, less erodible units. Soil structural stability is further reduced by loss of carbon by oxidation as tillage exposes deeper soil layers to the air. Soil faunal biomass, including fungal mycelia and earthworms, is important in maintaining cohesive bonds within and between aggregates, but it can be destroyed during soil disturbance.

Reducing the number and/or intensity of cultivations preserves soil structural stability and aggregation. Less disturbed aggregates are able to resist erosive forces, as cohesive bonds within the aggregates are maintained. Fewer, less invasive cultivations mean more of the vegetative biomass remains on or within the soil. This biomass is able to absorb the energy of erosive agents, so erosion is controlled. For example, a rough, trashy soil surface imparts friction to overland or air flow, causing turbulence and eddying, resulting in a reduced flow velocity and kinetic energy to erode.

The relative reduction in soil disturbance and retention of vegetative material on and within the soil are the principles behind the use of "conservation tillage." This term incorporates a continuum of soil management methods such as minimum till, zero till, mulch tillage, direct drilling, noninversion tillage, subsurface mulch tillage, and plough/plant cultivation (14). Conservation tillage aims at maintaining soil fertility and controlling erosion. It can also reduce input costs to agriculture, as fewer, less invasive cultivations expend less energy and fuel, resulting in dramatic adoption rates in the 1970s in the United States during the oil crisis. It should be noted that the success of conservation tillage is related to soil type and timeliness of operations. For example, there is evidence that reducing the number of cultivations can increase bulk density on structureless soils, leading to overland flow generation and flooding risk, which can only be alleviated by deep subsoiling periodically. Supporters of conservation tillage claim that these are short-term effects, which are offset in the medium to long term by the improvement of aggregation and inherent soil structure resulting from increased levels of biotic activity and organic matter levels.

Manipulation of the soil surface condition by tillage is used to control wind erosion. On light soils such as sands and silts, the soil is ploughed and then pressed with a heavy roller. Drilling is then carried out at 90° to the plough/press operation. The resultant tilth is rough and cloddy, to impart maximum friction to air flow, thus reducing wind speed and ability to detach and transport soil.

Soil conditioners are applied to soils susceptible to degradation, especially erosion. These products can perform the dual role of enhancing soil fertility and controlling erosion. Products with high organic matter (such as seaweed extract and tree bark) improve inherent soil fertility in terms of nutrients and organic matter, thus improving aggregation, structure, porosity, infiltration capacity, and water holding capacity.

Hydrophilic soil conditioners including bark, limestone, palm oil effluent, and seaweed extract increase aggregation and infiltration capacity, so overland flow is less likely to occur. The increase in organic matter from these products helps control erosion by increasing cohesive bonds and the stability of aggregates. Hydrophobic soil conditioners including latex, emulsions, and molasses form an impermeable film on the soil surface, which repels water and increases the soil's resistance to erosion. While these latter products control soil erosion, they have no effect on inherent soil fertility.

Table 2. Objectives of Soil Conservation Measures in Relation to Economic and Social Factors

1. The need for soil conservation should be recognized by all stakeholders—farmers, local communities, landowners, advisory services, government departments, NGOs, and politicians.
2. Soil conservation measures must be compatible with present and future management plans: they should not be imposed by external bodies such as researchers, scientists, advisory and extension services, or politicians.
3. Methods of construction will be based on available and appropriate technology and level of education. Technology transfer will be "bottom-up" not "top-down."
4. The easiest and minimal maintenance of soil conservation scheme will be adopted.
5. Present infrastructure should not be radically changed by soil conservation measures.
6. Mechanical measures should be laid out economically.
7. Crop selection will be based on economic as well as soil conserving properties.
8. Available grants and subsidies will be used. This has been demonstrated in the United States for many years. Farmers are eligible for USDA farm subsidies, but only if they demonstrate soil conservation practices have been implemented. A similar scheme will operate in England and Wales under the DEFRA Single Payment Scheme. To be compliant with the scheme, farmers have to draw up a simple risk-based soil management plan that protects against soil erosion and maintains soil organic matter and soil structure.
9. Conservation measures will ensure long-term productivity. Farmers are considered "land stewards," taking responsibility for conserving the soil resource for future generations. This concept is exemplified by the "Landcare" movement in Australia and New Zealand.

IMPLEMENTATION AND ADOPTION OF SOIL CONSERVATION MEASURES

While much is known of soil conservation techniques, they will fail unless the right social, economic, and political conditions prevail (15). Table 2 highlights the main considerations for the adoption and long-term success of soil conservation measures.

CONCLUSIONS

Soil is a sustainable resource, if treated carefully and with respect. Failing to protect and conserve soil can lead to rapid soil degradation, which in turn can be an irreversible process. Soil conservation can be defined as the maintenance of soil fertility and the control of soil erosion. These two objectives can be realized by appropriate management of the soil resource, using diverse soil conservation approaches. Application of these techniques will ensure that the diverse forms and functions of soil will be conserved for future generations.

LANDSCAPE WATER-CONSERVATION TECHNIQUES

Douglas H. Fender
International Turf Producers
Foundation
Meadows, Illinois

When given information and technology, people will make the effort to conserve. Plant selection will have less impact on water use than either irrigation or soil preparation. Water budgets give consumers more options and personal choice, while providing an effective way to conserve water.

Outdoor water-conservation measures typically focus on reducing or eliminating landscape water use. But implementing new scientific findings and advanced technology and general education can go a long way toward achieving the same end, just as these methods have proved successful in conserving water indoors. People will act to conserve water and improve the environment when properly informed of and motivated by the best scientific knowledge and technology.

AN INDIVIDUAL'S RIGHT TO CHOICE

Numerous water-use studies have documented that, depending on an area's climate, residential outdoor water use can account for between 22 to 67% of total annual water use. Clearly, this represents a vast opportunity for conservation. But to maintain an individual's right to personal choice and to maximize the positive environmental benefits of landscaping, a variety of factors need to be addressed that take location into account. When dealing with living plants, a one-size-fits-all solution will not be effective. But proven advanced scientific landscape water-conservation principles and practices do exist, and these can be modified and refined according to area-specific needs (Fig. 1).

THE NEED FOR CLEAR AND CAREFUL DEFINITIONS

First, however, potential targets for widespread outdoor water conservation should be clearly and carefully defined. Too often, a narrow definition focuses exclusively on landscape water use. Narrow definitions often overlook potentially high water-use elements such as swimming pools or other water features, whose evaporative losses are as great as or greater than those from landscape application.

Other nonlandscape outdoor water uses include washing cars, driveways, sidewalks and siding—and even some types of children's water toys. In addition to conserving in these areas, many techniques can be applied landscape water conservation as well.

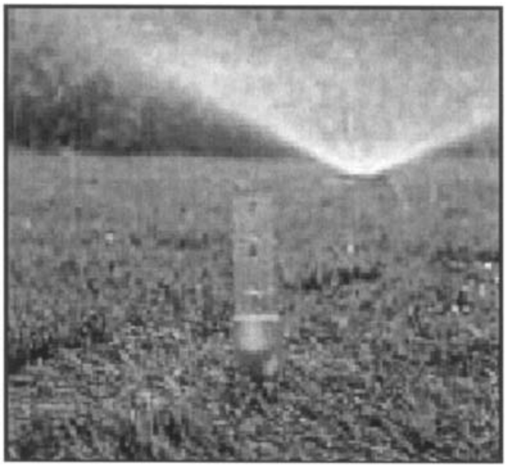

Figure 1. Rather than attempting to regulate or ban a specific water use, the water budget technique leaves the determination in the hands of the rate-paying water user.

THE WATER BUDGET PROGRAM

One of the most effective techniques is based on the practice of advising people how much water they can use, rather than telling them how they must use it. Termed a "water budget" or "water allocation" method, water providers establish a series of escalating allocation/pricing tiers so that every unit of water (i.e., 1000 gallons) in excess of a base quantity costs more than the previous unit.

Because outdoor water use can be measured and priced higher, people adjust their end uses according to their personal desires and financial concerns. This approach eliminates the need for contentious public hearings on landscape ordinances and the development of debatable plant lists, as well as the potential for draconian enforcement practices and so-called "water police."

Water budgets, for both indoor and outdoor water use, encourage individual freedom of choice and allow artistic expression by homeowners and landscape designers. Rather than attempting to regulate or ban a specific water use, this technique leaves the determination in the hands of the rate-paying water user. As we've seen, when gasoline prices rise, individuals can quickly adjust their use patterns. The same holds true for water.

Once purveyors decide how to allocate and price water, they then have the very important role of assisting in the development and distribution of scientifically based educational materials on water conservation. Again, successful indoor conservation practices can be easily converted to outdoor water conservation, particularly as it relates to landscape water use.

The Two-Track Strategy

Moving from general to more specific landscape water-conservation recommendations, a two-track strategy that emphasizes different approaches for existing landscapes and newly planned and installed landscapes may be most effective, as follows.

Existing Landscape Areas

Predrought/Premaximum Heat-Day Practices

1. **Increase water infiltration** with dethatching or hollow-core aerification of all lawn areas, as well as under the drip line of trees. Till garden areas to break up surface crusting, adding mulch where appropriate.
2. **Trim or prune** trees, shrubs, and bushes to remove low-hanging, broken or diseased parts and allow greater sunlight penetration throughout and beneath the plant. Generally speaking, plant water use is proportional to total leaf surface; thus, properly pruned plants should require less water.
3. **Fertilize all plants** (when soil temperatures reach at least 50 °F or 10 °C) with a balanced plant food that contains nitrogen (N), phosphorus (P), and potassium (K) according to the results of soil testing or as experience has shown is appropriate.
4. **Sharpen pruning shears and mower blades**. Dull blades encourage plant water losses and the introduction of disease.
5. **Establish or confirm soil type(s)** to match water-infiltration rates with future water-application rates and to determine if soil pH adjustments are recommended.
6. **Perform irrigation-system maintenance**, regardless of type (hose-end, drip, in-ground, etc.) to ensure maximum uniformity of coverage and overall operation. Repair or replace broken or damaged nozzles or heads. Flush drip system emitters to ensure proper flow. Ensure that rainfall shutoffs and other devices are working properly.
   a. Acquire and/or install hose-end water timers for all hose bibs.
   b. Adjust in-ground system controllers according to plant's seasonal needs.
7. **Upgrade in-ground irrigation systems** by adding soil-moisture meters, rain shutoff devices, or evapotranspiration (ET)-based controllers.
8. **Relocate drip emitters**, particularly around trees, to the outer edge of their drip lines. This will result in higher water use, but it will also encourage a better root system that will anchor the tree in high winds and provide the water and nutrients that are needed by large trees, shrubs, and other plants (Fig. 2).

Figure 2. Locate drip emitters to provide water and nutrients needed by large trees, shrubs, and other plants.

Figure 3. Water in the early morning.

9. **Confirm water-application rates** for hose-end or automatic systems to know the actual running times required to distribute a specified amount of water within a given amount of time.
10. **Water in early morning** (Fig. 3) when wind and heat are lowest, to maximize the availability of the water to the selected plants.
11. **Irrigate all plants infrequently and deeply**, according to local ET or soil-moisture requirements, to establish a deep, healthy root system. A core-extracting soil probe or even a simple screwdriver can help determine when to water if the more sophisticated ET rates are not available (Fig. 4). Professional turf managers gradually lengthen the interval between irrigations to create gradual water stress for deeper rooting.
12. **Cycle irrigation applications** (on-off-on-off) to allow penetration and avoid runoff. Depending on soil types, the running times may be from 5 to 15 minutes and off times from 1 to 3 hours. Repeat this cycle until necessary amounts of water are applied and maximum penetration is achieved.
13. **Begin regular mowing** when grass blades are one-third higher than desired postmowing length, and keep clippings on the lawn.
14. **Raise the mowing height** as the summer progresses to the highest acceptable level to encourage deep rooting. (Note: This has been a traditional recommendation, but further study is required to refine this approach and maximize effective water use and/or conservation.)

Drought or Maximum Heat-Day Practices—to Maximize Landscape Appearance

1. **Withhold fertilizers**, particularly nitrogen, on turfgrass; however, small amounts of potassium will aid in developing more efficient roots.
2. **Reduce mowing frequency** to minimize shock to turf areas.
3. **Reduce traffic on turf areas**, this will minimize wear and possible soil compaction.
4. **Adjust automatic timers** of in-ground irrigation systems according to plant's seasonally changing water needs.

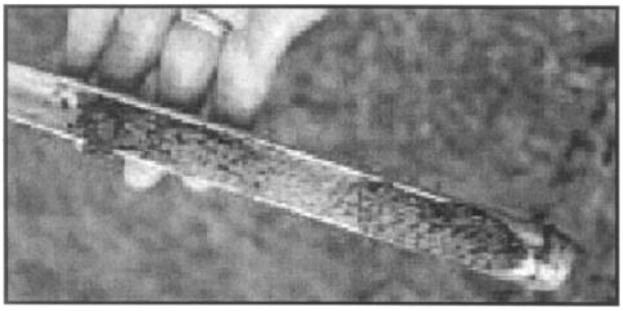

Figure 4. An example of a core-extracting soil probe.

Drought or Maximum Heat-Day Practices—If Dormant Turf Appearance is Acceptable

1. **Eliminate all traffic on turf areas**, including mowing, which will probably not be necessary because of the extremely slow growth rate.
2. **Adjust automatic timers to manual** or use hose-end sprinklers to apply approximately one-quarter inch of water a week. The dormant lawn will have a tan, golden, or light brown appearance; however, light/infrequent watering will be sufficient to maintain life in the crowns of the grass plant during this period.
3. **Minimize water applications** for all plant materials to the essential amounts needed to maintain plant vitality.

Postdrought or Maximum Heat-Day Practices Irrigate All Plants to Reestablish Soil-Moisture Levels, beginning with staged increases in watering and progressing toward deep and infrequent watering. By gradually lengthening the running times but adding greater spacing between watering applications, the initially shallower roots will extend to reach deeper soil moisture. Previously dormant turf will recover rather quickly, and other plants will regain their vigor.

Newly Planned or Installed Landscape Areas. Though fewer in number than existing landscape areas, newly planned and installed landscape areas can generally achieve greater water savings if all of the best design, plant selection, installation, and management practices now available are closely observed and fully implemented.

The basic principles of xeriscape landscaping provide an excellent starting point, providing they are fully understood and properly applied. However, note that it is incorrect to assume that a xeriscape is supposed to be a totally grassless landscape or one that uses only rocks, cactus, or driftwood.

Dr. Doug Welsh, former director of the National Xeriscape Council, wrote in *Xeriscape Gardening: Water Conservation for the American Landscape:* "In xeriscape landscaping we try to plan the amount of turf so that the investment in water will be repaid in use and beauty. In many instances grass *is* the best choice. For play areas, playing fields and areas for small pets, grass is often the only ground cover that will stand up to the wear. Turf also provides unity and simplicity when used as a design component."

Rather than duplicate information contained in several xeriscape manuals, this publication will focus on a limited number of very critical elements that can maximize landscape water conservation.

Efficient irrigation is without question an important water-conservation activity. People waste water; plants don't. Overwatering not only wastes water, but it also weakens or kills plants more than underwatering. Another wasteful practice seen all too often is misapplication of water, resulting in rotted fences and house siding, flooded

Figure 5. A wasteful practice seen all too often is misapplication of water, resulting in flooded sidewalks or driveways and rivers of water wastefully flowing down gutters.

sidewalks or driveways and rivers of water wastefully flowing down gutters (Fig. 5).

Though less so today, many new in-ground landscape-irrigation systems have been sold in the recent past on the basis of simplicity, for example, "set it and forget it." Homeowners, intimidated by the sophisticated appearance of the system's control box, would not modify the settings for seasonal plant water-use changes. Even worse, to be cost-competitive, many systems did not include readily available and relatively inexpensive soil-moisture meters, rain shutoff devices, or multistation programs. These deficiencies have resulted in overwatered landscapes, where water runs down the streets and systems continue to operate during torrential downpours.

Because of its high visibility, turf watering can be seen as the antithesis of water conservation and is often an out-and-out target for elimination. In some locales, "cash-for-grass" programs are used to pay homeowners handsomely to remove grass from their landscapes. One highly respected West Coast water official noted at a conservation convention: "It isn't the grass that causes a problem, it's the poorly designed and poorly operated irrigation system. I can't control the irrigation systems, but I can reduce the amount of grass in a landscape, and that will control the water-use problem created by bad irrigation." The fault was not the grass, but the fact that it was being improperly watered.

Soil analysis and improvements are another very important aspect of water conservation. The soil on most new residential and commercial landscape sites has literally been turned upside-down during the construction process, and the topsoil is placed beneath a layer of clay. Then it is compacted as hard as cement by equipment, piles of building materials, and construction-worker foot traffic. The soil's texture, chemistry, and natural flora and fauna are destroyed.

More water could be conserved and healthy landscape plants more easily grown by improving the soil before planting than by any other process or technique. The initial cost of adding topsoil and soil test-guided amendments to improve the soil may seem high, but the return on that investment will be even higher. Failing to improve the soil prior to planting, when it is most practical and efficient, will result in roots not being able to penetrate as deeply as possible and runoff occurring almost instantaneously. If the soil pH is not correct, plants will not be healthy, nutrients will not be used, and chemical leaching can take place.

Appropriate plant selection can be a source of frustration or misunderstanding and not produce the hoped-for water savings, particularly when it is combined with "practical turf areas." Lists of low water-use landscape plants can cause confusion because they are based on the incorrect assumption that those plants capable of surviving in arid regions are low water users, when the plants typically are only drought-resistant (Fig. 6).

The majority of turfgrass species and cultivars have been scientifically assessed for their evapotranspiration (water-use) rates and can be selected according to the needs of a specific climate. On the other hand, very few tree and shrub species and cultivars have undergone comparable quantitative water-use assessments. One stunning exception comes from research at the University of Nevada, where Dr. Dale Devitt found that "one oak tree will require the same amount of irrigation as 1800 square feet of low-nitrogen fertilized turfgrass!"

It is also important to understand that though "low water-use" plant lists were developed with the best intentions and purposes in mind, practically all of these lists have been based on anecdotal evidence or consensus judgments, not scientific measurement under controlled procedures. Quite simply, a given group decides that based on their experiences and suppositions, a certain

Figure 6. The minilysimeter gauges water use under actual turf conditions. This photo at Washington State University's research site in Puyallup, shows minilysimeters being weighed. The pots are weighed for daily water evaporation, rewetted, and returned to their "holes" in the turf. These scientific measurements under controlled procedures help researchers better understand low-water use.

plant should or should not be placed on a "low water-use" list. As has been seen time after time, it typically is not the plant that wastes water, but the person who is in charge of its care.

When establishing new lawns, turfgrass sod has been shown to require less water than seeding; the evaporative losses from bare soil are greater for seeded areas than they are for turf-covered soil beneath sod (Fig. 7).

Water "harvesting" and reuse is another water-conserving practice gaining greater use. It can be employed to conserve public water supplies and recharge groundwater supplies.

Historically, planners and designers have focused their efforts on moving rainwater and snowmelt away from a property as quickly as possible, giving little thought to the possible advantages of using that water for landscape purposes. Consider the fact that during a 1-inch rainfall, a 35-foot-by-60-foot roof (approximately 2000 square feet) will collect nearly 1250 gallons of water. Rushing this water to gutters and then sewers makes little sense when it could conceivably go into a system that could capture or distribute it across a landscaped area.

Another increasingly feasible source of additional landscape water is recycled or gray water. Some communities are installing dual water-delivery systems where one carries potable water for drinking, cooking, cleaning, and other general household uses and a second system delivers less thoroughly treated (but very safe) water for use on landscapes. On a small scale, some locales encourage collecting a home's gray water (from clothes washers, etc., but not toilets) for use on landscapes.

After being applied to a landscape area, harvested, recycled, or gray water is either transpired by plants and evaporates into the atmosphere or finds its way into groundwater supplies after it has been cleansed by the plant's root structure.

Figure 7. When establishing new lawns, turfgrass sod has been shown to require less water than seeding.

As science and technology continue to advance, new and better information, tools, and systems will become available to help people establish and maintain water-conserving and environmentally beneficial landscapes. An ongoing challenge will be keeping pace with these developments, sharing that information, and continually improving best management practices.

Just as we improve our health by using water to brush our teeth and to wash our bodies and clothes, applying water judiciously to a properly designed and installed landscape can improve our health and the general environment.

Efforts to eliminate landscape water use not only take away freedom of personal choice; they also bring many environmental, economic, and emotional drawbacks that could be more costly in the long run.

CROP WATER REQUIREMENTS

Mladen Todorovic
Mediterranean Agronomic
Institute of Bari
Valenzano, Bari, Italy

Crop water requirements (CWR) refer to the amount of water required to compensate for evapotranspiration losses from a cropped field during a specified period of time. Crop water requirements are expressed usually in mm/day, mm/month, or mm/season, and they are used for management purposes in estimating irrigation water requirements, irrigation scheduling, and water delivery scheduling.

The concept of crop water requirements is intimately connected with crop evapotranspiration because both refer to the same amount of water. Nevertheless, there is some difference between them. Crop evapotranspiration represents the water losses that occur (i.e., a hydrological term), but crop water requirement indicates the amount of water that should be supplied to account for these losses (i.e., an irrigation management term). In fact, this amount of water corresponds to the effective irrigation water supply necessary to reach the maximum yield. Therefore, the estimation of crop evapotranspiration precedes the estimation of crop water requirements where the latter usually represents the values of crop evapotranspiration aggregated over some period of time. For management purposes, crop evapotranspiration should be transformed into crop water requirements to be used for estimating irrigation water requirements and later, management of the irrigation water supply. Then, crop water requirements are satisfied by the amount of irrigation water effectively supplied to the root zone and the effective precipitation.

The concept of crop water requirements has become important due to the development of large engineering works when it was necessary to estimate the water volumes to be supplied to newly irrigated areas. In general, it is possible to distinguish between crop water requirements for long-term planning, where an average climate or a climate with a certain probability of occurrence can be used for a CWR estimate, and crop water requirements for real-time management, where climatic data of the ongoing season are applied.

The procedures for estimating crop water requirements correspond to those of crop evapotranspiration because both terms refer to the same amount of water. More details of measuring and estimating crop water requirements are given under the article on CROP EVAPOTRANSPIRATION of this Encyclopedia.

Example of an estimate of seasonal crop water requirements for tomato growing in the Mediterranean region based on a planting date of April 15th and where the average monthly reference evapotranspiration values are as follows: $\mathrm{ET}_{o_{\mathrm{April}}} = 3.5$ mm/day; $\mathrm{ET}_{o_{\mathrm{May}}} = 4.4$ mm/day; $\mathrm{ET}_{o_{\mathrm{June}}} = 5.1$ mm/day; $\mathrm{ET}_{o_{\mathrm{July}}} = 5.8$ mm/day; $\mathrm{ET}_{o_{\mathrm{August}}} = 5.6$ mm/day, and $\mathrm{ET}_{o_{\mathrm{September}}} = 4.2$ mm/day.

Calculation Procedure. Some data necessary for calculation are taken from the article on CROP EVAPOTRANSPIRATION of this Encyclopedia: the lengths of the growing stages are taken from Table 3 and K_c values from Table 4 of that article. The growing cycle of tomato can be presented graphically as in Fig. 1: K_c is fixed at 0.5 from April 15th to May 15th, then it increases linearly until June 24th when it reaches the value 1.15; K_c is fixed at 1.15 from June 24th to August 7th; then it decreases linearly to 0.8 on September 6th, the last day of growing cycle. Hence, the average monthly values of K_c are determined as follows: $K_{c_{\mathrm{April}}} = 0.5$; $K_{c_{\mathrm{May}}} = 0.57$; $K_{c_{\mathrm{June}}} = 0.94$; $K_{c_{\mathrm{July}}} = 1.15$; $K_{c_{\mathrm{August}}} = 1.04$; $K_{c_{\mathrm{September}}} = 0.835$.

Then, the crop water requirements are calculated for each month as

$$\begin{aligned}
\mathrm{CWR}_{\mathrm{April}} &= K_{c_{\mathrm{April}}} * \mathrm{ET}_{o_{\mathrm{April}}} * 15\\
&= 0.5 * 3.5 * 15 = 26.2 \text{ mm/month}\\
\mathrm{CWR}_{\mathrm{May}} &= K_{c_{\mathrm{May}}} * \mathrm{ET}_{o_{\mathrm{May}}} * 31\\
&= 0.57 * 4.4 * 31 = 77.8 \text{ mm/month}
\end{aligned}$$

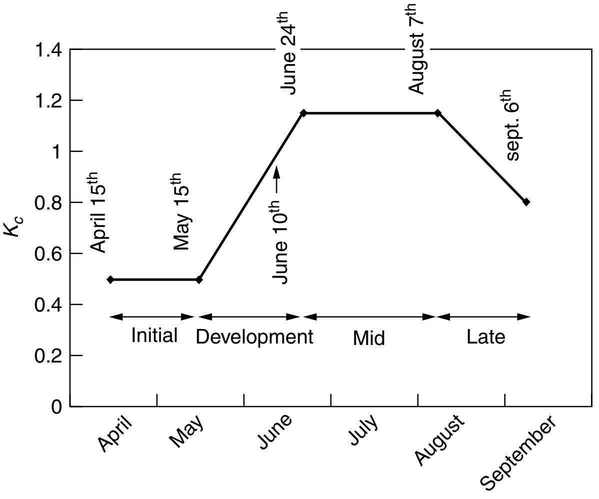

Figure 1. The variation of K_c for a tomato crop during the growing season.

$$\begin{aligned}
\mathrm{CWR}_{\mathrm{June}} &= K_{c_{\mathrm{June}}} * \mathrm{ET}_{o_{\mathrm{June}}} * 30\\
&= 0.94 * 5.1 * 30 = 143.8 \text{ mm/month}\\
\mathrm{CWR}_{\mathrm{July}} &= K_{c_{\mathrm{July}}} * \mathrm{ET}_{o_{\mathrm{July}}} * 31\\
&= 1.15 * 5.8 * 31 = 206.8 \text{ mm/month}\\
\mathrm{CWR}_{\mathrm{August}} &= K_{c_{\mathrm{August}}} * \mathrm{ET}_{o_{\mathrm{August}}} * 31\\
&= 1.04 * 5.6 * 31 = 180.5 \text{ mm/month}\\
\mathrm{CWR}_{\mathrm{September}} &= K_{c_{\mathrm{September}}} * \mathrm{ET}_{o_{\mathrm{September}}} * 6\\
&= 0.835 * 4.2 * 6 = 21.0 \text{ mm/month}
\end{aligned}$$

The seasonal crop water requirements represent the sum of the monthly values, 656.1 mm/season.

Crop water requirements can also be estimated daily, provided that daily values of reference evapotranspiration are available. There, K_c values can be interpolated similarly, as in the previous example, or they can be estimated using more complicated approaches (e.g., the dual K_c approach).

Crop water requirements of one crop variety vary from one location to another due to variations in climatic parameters and, therefore, to different reference evapotranspiration, different planting dates and lengths of growing season, different K_c values, etc.

AGRICULTURAL WATER USE EFFICIENCY (WUE) AND PRODUCTIVITY (WP)

PASQUALE STEDUTO
Mediterranean Agronomic
Institute
Valenzano, Italy

Among the different sectors of society, agriculture represents the major water consumer. Rain-fed and irrigated agriculture uses water at various degrees of *efficiency*, resulting in different levels of *productivity*.

The general term *efficiency (e)* indicates the ratio of *output* to *input* of variables (Eq. 1) associated with *transformation* (e.g., of energy) or *transport* (e.g., of mass and energy) *processes*:

$$e = \frac{\text{output}}{\text{input}} \tag{1}$$

The *efficiency* term (e) has two peculiarities: (1) the units are nondimensional and (2) the values are always between the theoretical limits of 0 and 1. In water use, the efficiency (e_w) has water amounts (e.g., volumes, quantities, or depth) in both *input* and *output* variables.

The general term *productivity* (p) still indicates a ratio of output to *input* of variables, as in Equation 1, but these *output* and *input* variables are not associated with *transport processes* and might be associated, but not necessarily, with a *transformation process*. The consequent peculiarities of the *productivity* term (p) do not match those of the *efficiency* term (e), that is, the units are dimensional, and the theoretical limits of 0 and 1 are lost. In water use, the productivity term (p_w) has water amounts (e.g., volumes, quantities, or depth) only in the *input*. The *output*, instead, generally takes the form of quantities produced: physical (e.g., dry matter or final yield of crops, or meat or dairy products from animal husbandry, etc.), economic (e.g., gross income, net revenue, etc.), or any other form.

The efficiency term e_w has to do more with the way water is used by the system, whereas p_w has to do more with the outcome from the system per unit of water it consumes. Nevertheless, it turns out that a change in e_w is reflected in a change in p_w, implying that there is a link between e_w and p_w, though the reverse is not the case. Moreover, though p_w cannot be strictly defined by Equation 1, it still resembles a sort of efficiency of the system to produce a given *output* for a given *input*. The undefined degree of commonality and distinction between e_w and p_w has led to some confusion in investigating agricultural water use.

A GENERAL FRAMEWORK FOR AGRICULTURAL WATER USE EFFICIENCY AND WATER PRODUCTIVITY

Figure 1 illustrates a suitable framework for identifying the *efficiency* (e_w) and the *productivity* (p_w) components within the domain of agricultural water use. The framework distinguishes irrigated from rain-fed agriculture and splits the overall path that water "travels" to produce a given yield into single segments of particular relevance and specific boundary conditions.

In irrigated agriculture, the source of water can be a reservoir (e.g., a dam) from which water will be conveyed and delivered to the farm. Applying Equation 1 to the whole path from the reservoir to a cropped field at farm level, will express the *efficiency* (e_w) in water transport where the *input* is the outflow from the reservoir (*Res_w_out*) and the *output* is the water effectively stored in the soil root zone (*Root_zone_w*). The whole path can

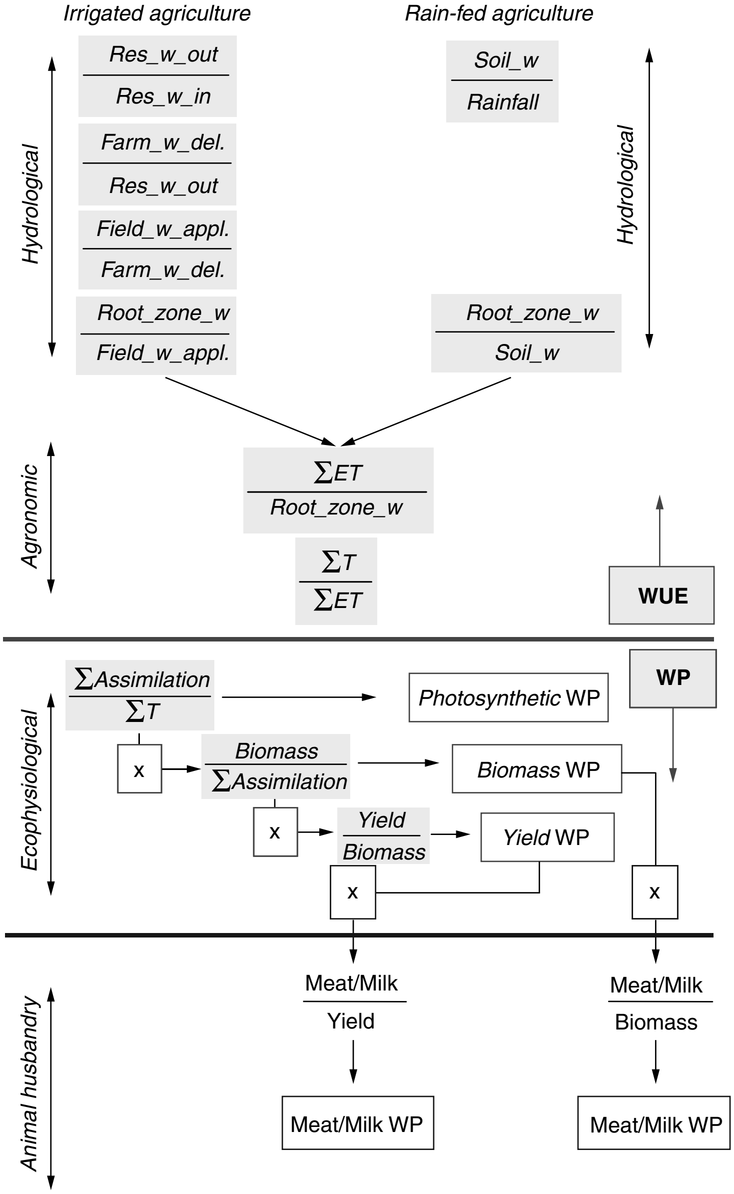

Figure 1. Suggested framework for analyzing components of *water use efficiency* and *water productivity* in agricultural crop production and animal husbandry. The overall path "traveled" by water is split into different segments where appropriate analysis can be performed. See text for explanation.

be split into different segments (e.g., from the dam to the collective irrigation system; from the collective system to the hydrant of a single farm, from the hydrant to the cropped field where an irrigation system is present, and from the outlets of the irrigation system into the root zone of the crop being irrigated) to investigate the single component efficiencies and the overall efficiency obtained from the product of the single-segment efficiencies.

In rain-fed agriculture, rainfall represents the source of water, and the ratio of the water stored in the soil (*Soil_w*) to the water from the rain (*Rainfall*) represents the rain storage *efficiency*. Out of all the water stored in the soil (*Soil_w*), only a portion may be available in the soil explored by crop roots (*Root_zone_w*), and this represents the available water *efficiency*. All efficiencies mentioned so far can be qualified as *hydrological*.

After the final allocation of water in the *root zone* (whether irrigated or rain-fed), water follows a common pathway for the crop production process: it enters the plants and evapotranspires into the atmosphere. We can identify two additional efficiencies that may be qualified as *agronomic*: one is expressed by the ratio of the amount of water used by evapotranspiration (ΣET) to the water stored in the soil root zone (*Root_zon_w*); the other is expressed by the ratio of the amount of effectively transpired (ΣT) and the total amount of evapotranspired water (ΣET). This last segment of the water path is essential because nontranspired water is not considered productive to the crop. Thus, a distinction has to be made between soil evaporation (E), which is a loss, and crop transpiration (T).

At this point, the water has finished its trip from the source, all the way through the system, passing through the soil, entering the plant, and ending up into the atmosphere, beginning as a liquid phase and ending up as a vapor phase. So far, all the expressions of *efficiency* for the different segments (either those pertaining to the *hydrological* pathway or those pertaining to the *agronomic* pathway) properly match the definition of Equation 1. because they are nondimensional and have theoretical limits between 0 and 1.

Examining the remaining segments of the framework reported in Fig. 1, we next enter the *physiological* (or better, *ecophysiological*) domain of the agricultural system where the term *efficiency* loses its rigorous meaning and it is more appropriate to talk in terms of *water productivity* (p_w). Three major expressions for p_w can be identified: (1) *photosynthetic water productivity* (*photosynthetic* p_w); (2) *biomass water productivity* (*biomass* p_w); and (3) *yield water productivity* (*yield* p_w).

Photosynthetic p_w is defined as the ratio of leaf net assimilation to leaf transpiration (*A*/*T*) and varies among species according to their photosynthetic pathways. These species can be grouped into three major types: the C_3, C_4, and CAM plants. All three types ultimately rely on the Calvin photosynthetic carbon reduction cycle for their CO_2 assimilation, but some additional features characterize those groups that make the *photosynthetic* p_w of CAM plants higher than that of C_4 plants, which in turn is higher than that of C_3 plants, in comparable environmental conditions. Values of *photosynthetic* p_w may also vary according to the nutritional status of the leaves and their age. Variable environmental conditions (e.g., radiation regime, dryness of the atmosphere, etc.) may also affect the values of *photosynthetic* p_w. Under equal ambient conditions, all species belonging to the same group type have similar *photosynthetic* p_w values.

Biomass p_w is defined as the ratio of cumulative aboveground biomass (biomass) of a crop canopy to cumulative transpiration (ΣT) by the crop. The relationship between cumulative aboveground biomass and ΣT is generally quite strict. The slope of the relationship may vary from year to year and from location to location, depending on the different environmental conditions and the biomass composition of the various species. When ΣT is normalized for a reference evaporative demand of a given climatic environment and the nutritional conditions are similar, many crop species follow the same slope and group into the same types as indicated for the *photosynthetic pathways* p_w (C_3, C_4, and CAM) and the main production compounds (e.g., carbohydrates, proteins, or lipids).

Yield p_w is defined as the product of *biomass* p_w times the harvest index (HI, i.e., the ratio of the marketable yield to aboveground biomass). *Yield* p_w values are variable among species and cultivars, depending on the values of HI, which in turn depend on the partitioning of assimilates in the various plant organs (e.g., leaves, stem, grains). Of course, HI can also vary greatly as a consequence of the environmental conditions where the plant is growing (e.g., water stress, nutritional deficit, etc.).

The water productivity concept can be extended to animal production systems when the crop's biomass and/or yield are used as feed. Then, the product of biomass or yield water productivity is multiplied by the factor of conversion of the feed into animal production (dairy product or meat). The ratio approach can be extended throughout the system up to the final step of interest (Fig. 1).

Furthermore, when the amount of product (the nominator of the productivity ratio) is expressed as gross income (e.g., multiplying it by the price) or as net income (e.g., deducting production costs), the ratio can represent the *economic water productivity* (*economic* p_w), better indicated as *water return* (r_w) having the unit of "currency" (dollars, euro, etc.) per unit amount of water (volume, quantity, or depth).

LARGE AREA SURFACE ENERGY BALANCE ESTIMATION USING SATELLITE IMAGERY

Peyman Daneshkar Arasteh
Soil Conservation and
Watershed Management
Research Institute (SCWMRI)
Tehran, Iran

INTRODUCTION

Many activities such as irrigation and agricultural scheduling, water resources planning, weather forecasting, atmospheric circulation modeling, energy resources management and development, and even health related issues involve studying the surface energy balance (EB) of the earth. Photosynthesis and other metabolic processes in green plants, evaporation from free water and soil surfaces, wind effects, atmospheric and oceanic circulation, and many other phenomena are mainly functions of solar radiation. In other words, they are functions of surface EB, in which solar radiation is the most important driving force.

Due to nonuniform properties of the earth's surface (albedo, heat capacity, soil cover, etc.) and also due to temporal variation of the earth's surface properties, the earth's surface phenomena must be monitored on spatial and temporal scales. Due to spatial variations, ground-based monitoring of the earth surface can cover only small areas because of economic restrictions.

Generally, installing a dense monitoring network is not feasible or it is technically impossible. For example, first-order climatology stations may be 100 km apart. But variations in soil texture, soil cover, topography and microclimate may occur on a much smaller spatial scale. On the other hand, interpolation/extrapolation of point observations may be insufficient due to weak ground coverage. And, the need for distributed models increases.

Satellite imagery provides a large view of the earth's surface. Such a spatially continuous, but time discrete, data acquisition system provides a suitable framework for distributed modeling, provided that the phenomenon to be modeled has spectral behavior.

All features on or near the earth's surface, including soil surface, water bodies, vegetation cover, and near surface atmosphere, exhibit spectral characteristics. Therefore, remote sensing can monitor the earth's surface directly or indirectly. During the past two decades, several satellites were launched with a large variety of sensor capabilities. Many articles in the literature report using remote sensing to study the energy partitioning of the earth's surface. In this respect, Bastiaanssen (1) developed a model for energy partitioning using a remote sensing algorithm named SEBAL (surface energy balance algorithm for land). Bastiaanssen et al. (2) used SEBAL to model evapotranspiration on a catchment scale in Spain, Niger, China, and Egypt. Bastiaanssen (3) also tested the model in Turkey. Silberstein et al. (4) correlated the surface effective temperature with the satellite-derived surface temperature to form the energy balance on a catchment scale.

Remote sensing is being applied in a large number of investigations, such as Xin and Shih (5), Laymon et al. (6), and Biftu and Gan (7) to model surface evaporation and canopy evapotranspiration. Bastiaanssen et al. (8) introduced the possibilities of applications in agriculture, and Arasteh (9) developed a model to estimate evaporation from the Hamoon Wetlands called HRSE (Hamoons remotely sensed evaporation) within an area of 4000 km^2 on the Iran–Afghanistan border using NOAA-AVHRR images.

The advantages of using remote sensing in hydrologic studies have been stated by Prince (10) and Dubayah et al. (11) as follows:

1. large aerial coverage
2. higher spatial resolution than ground-point observations
3. availability of long-term records from area without ground observations
4. possibility of change detection

In this article, the EB is studied using remotely sensed data and some common methods are introduced. Then, the EB components of the Hamoon Wetlands are described as a case study.

ENERGY BALANCE

All climatic and hydrologic phenomena in the atmosphere and on the earth's surface are affected by the EB of the surface. The EB is one of the main subjects in climatology, hydrology, civil and traffic engineering, biology, and health. EB is the balance between the inward and outgoing energy components of the surface.

Understanding the behavior of the terrestrial hydrosphere, biosphere, and climatic systems and their possible changes requires knowledge of the nature of the EB (11). The EB of a surface is the radiative transfer of energy through the top of the earth's surface and the molecular energy transfer into the soil matrix or free waterbody (12). Fig. 1 shows the components of the EB.

As shown in Fig. 1, the EB has several components. The net radiation flux of the surface, R_n, is the algebraic sum of the following components:

$$R_n + A - S - G - \lambda E - \Delta Q = 0, \qquad (1)$$

where A, S, G, λE, and ΔQ are advective and convective sensible heat, soil heat, latent heat fluxes and change in heat storage, respectively. All of the fluxes have the dimension of MT^{-3} with units such as MJ/m^2-day. In Eq. 1, all sources of energy (R_n and A) are positive values, and sink terms (S, G, λE, and ΔQ) are negative.

There is also a radiation balance at the surface, in which the net radiation is calculated from the algebraic sum of the inward and outward radiations (Eq. 2).

$$R_n = R_s \downarrow - R_s \uparrow + R_l \downarrow - R_l \uparrow, \qquad (2)$$

where R_s and R_l are short- and long-wave radiation, respectively; ↓ and ↑, represent inward and outward radiation to and from the surface.

Using Stephan's law, Eq. 2 changes to (6,13):

$$R_n = (1-\alpha)R_s + C\sigma(\varepsilon_{sky}{T_a}^4 - \varepsilon_{surface}{T_S}^4) \qquad (3)$$

where α is surface albedo; ε_{sky} and $\varepsilon_{surface}$ are the emissivities of the atmosphere and the surface, respectively; C is the cloudiness factor; σ is the Stephan–Boltzman constant (4.903×10^{-9} MJ/K^4-m^2-day); and T_s and T_a, are surface and near surface atmosphere temperatures (K).

Other components of EB, S and λE, may be determined by aerodynamic resistance relations (6,13,14) and G can be modeled on the basis of heat conduction theory (12):

$$S = \frac{\rho C_p}{r_a}(T_s - T_a) \qquad (4)$$

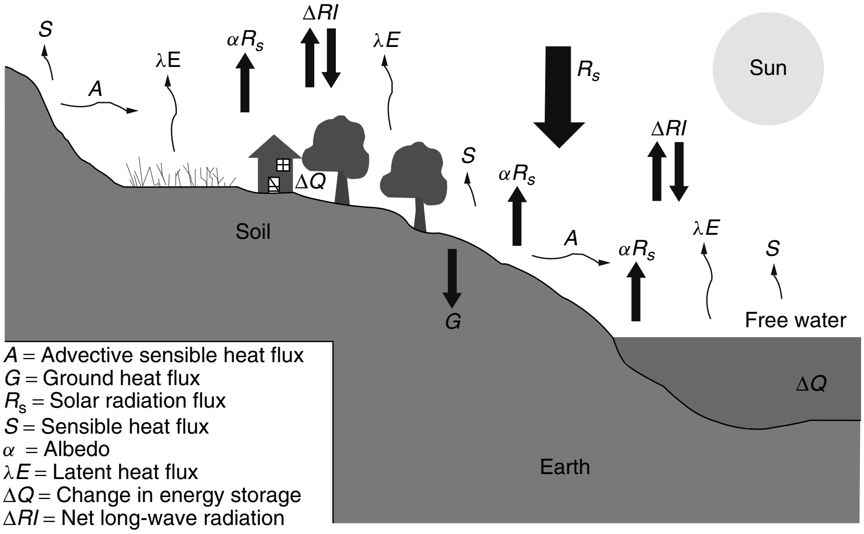

Figure 1. Schematic components of the EB.

$$\lambda E = \frac{\rho C_\mathrm{p}}{\gamma} \frac{e_\mathrm{S}(T_\mathrm{s}) - e_\mathrm{a}}{r_\mathrm{a} + r_\mathrm{s}} \tag{5}$$

$$G = dC_\mathrm{s} \frac{dT}{dt} \tag{6}$$

where ρ is air density (kg/m^3); C_p is the specific heat of air (MJ/kg-K); C_s is the soil matrix or waterbody heat capacity (MJ/m^3-K); γ is the psychometric constant; $\mathrm{r_a}$ and $\mathrm{r_s}$ are aerodynamic and surface resistances, respectively (s/m); e_s and e_a are saturated vapor pressure at T_s and actual air vapor pressure, respectively (kPa); d is the depth of soil or water (m); and dT/dt is the change in temperature per unit time.

Equations 3–6 have some variables that can be determined by remote sensing and others must be obtained from ground observations. The received solar radiation, R_s, is introduced in several texts on the basis of the earth–Sun geometric relationships (15). Determination of surface temperature and near surface air temperature, dew point, precipitable water in atmosphere column, vapor pressure deficit, and albedo are reviewed by Cracknell, (16), Prince et al. (10), Dubayah et al. (11), Menenti (17), Granger (18), and Schmugge et al. (19).

REMOTELY SENSED EB

Satellite remote sensing is a collection of sciences, technologies, and methods of inferring the earth's surface parameters by measuring the electromagnetic radiation of the surface (18). Visible (VIS), near infrared (NIR) and thermal infrared (TIR) channels are used for EB processing (16,17,19).

Some primary surface parameters such as surface albedo, surface temperature, air temperature, surface roughness, land cover, and land use may be provided by remote sensing. In the following, satellite data acquisitions are introduced.

Surface Albedo

Reflected directional radiance in VIS and NIR channels (0.4 to 2.5 μm) are being used to determine surface albedo (16–18). To determine surface albedo, Gutman (20) and Csiszar and Gutman (21) introduced the following methodology:

1. Normalizing VIS and NIR channels reflectances with respect to solar zenith angle (SZA):

$$\begin{aligned}(\rho_1)_\mathrm{TOA} &= R_1 \cos(\mathrm{SZA}) \\ (\rho_2)_\mathrm{TOA} &= R_2 \cos(\mathrm{SZA})\end{aligned} \tag{7}$$

   where R is reflectance; ρ is normalized reflectance; SZA is solar zenith angle (radians); 1 and 2 indexes represent VIS and NIR channels, respectively; and TOA is top of atmosphere.

2. Converting VIS and NIR narrowband reflectance to a broadband reflectance by a linear relation to determine top of atmosphere (TOA) reflectance:

$$(\rho)_\mathrm{TOA} = a + b(\rho_1)_\mathrm{TOA} + c(\rho_2)_\mathrm{TOA} \tag{8}$$

   where a, b, c are regression coefficients.

3. Correcting TOA reflectance for anisotropy to determine TOA albedo:

$$(\alpha)_\mathrm{TOA} = (\rho)_\mathrm{TOA}(\mathrm{ARF})^{-1} \tag{9}$$

   where ARF is the anisotropic reflectance factor.

4. Modifying TOA albedo for atmospheric effects to determine surface albedo:

$$\alpha = f[(\alpha)_\mathrm{TOA}, \mathrm{SZA,AWV,AA}] \tag{10}$$

   where α is albedo (%), AWV is atmospheric water vapor, and AA are atmospheric aerosols. Song and Gao (22) gave calibrated nonlinear relations between coefficients b and c and NDVI (normalized difference vegetation index) or SAVI.

$$\mathrm{NDVI} = \frac{\mathrm{NIR} - R}{\mathrm{NIR} + R} \tag{11}$$

$$\mathrm{SAVI} = 1.5\left(\frac{\mathrm{NIR} - R}{\mathrm{NIR} + R + 0.5}\right) \tag{12}$$

where R is the red channel of the spectrum.

Instead of the linear relation of Equation 8 Granger (18) emphasized that the AVHRR-NIR channel could be used individually to determine the out of atmosphere reflectance and the corresponding albedo.

Surface Temperature

Surface temperature is the result of the thermodynamic equilibrium between the energy condition in the near surface atmosphere, soil surface, and subsurface soil. It is also a function of surface emissivity (19). The first step in inferring surface temperature by remote sensing is to determine the brightness temperature, T_B, of TIR channels. The T_B at satellite temperature is the temperature of a blackbody and can be determined by solving Planck's spectral distribution function for blackbody temperature (16):

$$R(T_\mathrm{B}) = \frac{\displaystyle\int_{\nu_1}^{\nu_2} E(\nu, T_\mathrm{B})\Phi(\nu)d\nu}{\displaystyle\int_{\nu_1}^{\nu_2} \Phi(\nu)d\nu} \tag{13}$$

where R is radiance (MJ/m^2-Sr-cm); T_B is brightness temperature (K); E is Planck's radiation energy of a blackbody (MJ/m^2-Sr-cm); Φ is spectral response function; and ν is wave number equal to the inverse of wavelength (cm^{-1}).

Spectral radiance, R, is determined from the sensor calibration equation on the basis of the image digital number. Equation 13 must be solved numerically for energy E. Then the brightness temperature, T_B, is determined by solving Planck's law (16):

$$T_\mathrm{B} = \frac{C_2\nu}{\ln\left(1 + \dfrac{C_1\nu^3}{E}\right)} \tag{14}$$

in which $C_1 = 1.1910659 \times 10^{-5}$ MJ/s-m^2-Sr-cm^{-4} and $C_2 = 1.438833$ [cm-K].

To determine surface temperature, there are several methods classified in three major categories:

1. Ground observation based calibration
2. Atmospheric effects back-modeling
3. Atmospheric effects omission (two-look method and multichannel method or split window)

Cracknell (18) has described these methods in detail. The split window method for determining surface temperature is the most common (10,18,23,24).

Air Temperature

Ground observation calibration methods can be used to determine air temperature. Air temperature can also, be derived from the thermal vegetation index (10,11) where the surface temperature of a closed canopy is assumed equal to its adjacent air temperature.

Sky and Surface Emissivities

Surface and near surface atmosphere emissions are related to surface indexes such as NDVI, SAVI, etc. (6,25):

$$\varepsilon_\mathrm{surface} = a_1 \cdot \mathrm{NDVI} + a_2 \tag{15}$$

$$\varepsilon_\mathrm{surface} = b_1 \cdot \ln(\mathrm{NDVI}) + b_2 \tag{16}$$

where a_1, a_2, b_1, and b_2, are regression coefficients.

Net Radiation, Sensible and Latent Heat Flux Densities

According to Eq. 3, from the earth–Sun geometry and satellite data acquisition, using previously mentioned methods, one can determine R_n. Using satellite derived T_s and T_a and ground based data, other energy components of the surface of Eqs. 4–6 can be determined. In this respect, surface and aerodynamic resistances and surface roughness length are related to LAI (leaf area index) and consequently to remote sensing by indexes such as NDVI or SAVI (3,25):

$$Z_{0\mathrm{m}} = \exp(a' \cdot \mathrm{NDVI} + b') \tag{17}$$

$$\mathrm{LAI} = a'' \cdot \ln(b'' + \mathrm{NDVI}) \tag{18}$$

$$\mathrm{LAI} = a''' \cdot \exp(b''' \cdot \mathrm{NDVI}) \tag{19}$$

$$\begin{aligned} r_\mathrm{s} &= f(\mathrm{LAI}) \\ r_\mathrm{a} &= f(Z_{0\mathrm{h}}) \end{aligned} \tag{20}$$

where $Z_{0\mathrm{m}}$ and $Z_{0\mathrm{h}}$ are the surface roughness length due to turbulence and heat, respectively; r_a and r_s, are aerodynamic and surface resistances; and a', a'', a''', b', b'', and b''' are regression coefficients.

Case Study

To show an example of a remotely sensed EB application, the study by Arasteh (9) on Hamoon Wetlands is summarized as follows:

The Hamoon Wetlands located between Iran and Afghanistan form a complex hydraulic-hydrologic system of three neighboring wetlands with an average water area of 4000 km^2 in wet years. The wetlands are transboundary and affect all human activities in the region (Fig. 2).

Determining an estimate of evaporation from the free water surface of the Hamoon Wetlands was the main objective of the study by Arasteh (9). For this, it was required to study remotely sensed EB. Arasteh (9) used energy partitioning to fulfill this objective. Using his algorithm with the NOAA-AVHRR-14 image of May 10, 1998, the net radiation, sensible heat, and latent heat of the Hamoon surface are shown in Fig. 3.

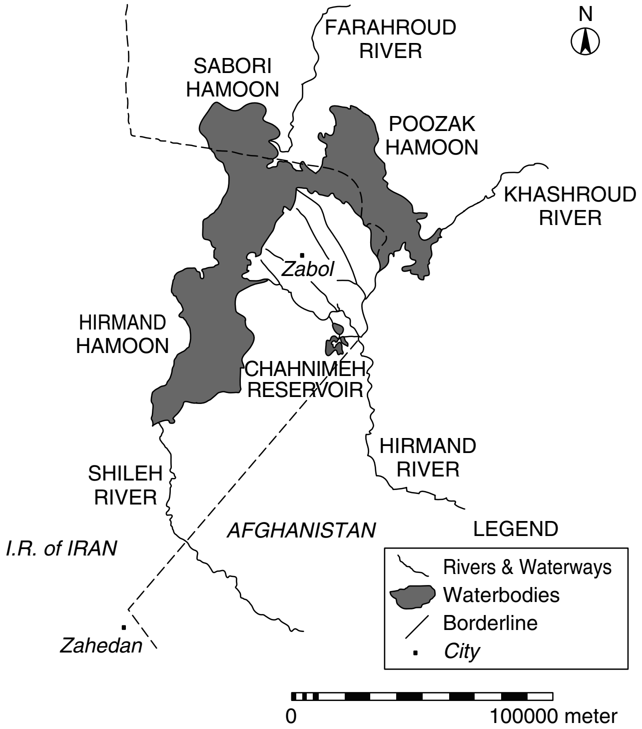

Figure 2. Hamoon Wetlands region between Iran and Afghanistan.

DATA ACCURACY

To use each method, it is necessary to consider its accuracy. Therefore, it is very important to consider the question of the accuracy of remotely sensed EB.

Considering Eqs. 1 and 3–6, there are various variables with their own sources of error. Cracknell (16) reported a variation of 0.5 to 1.4 K in the sea surface temperature for only a 2% change in surface emissivity. Menenti (17) reviewed the literature and reported errors of less than 3% in latent heat and obtained an average error of 15% for this component. Dubayah et al. (11) stated that it is not possible to estimate downwelling long-wave radiation with accuracy less than 20 W/m^2 using AVHRR data.

Finally, it can be concluded that the accuracy of a remotely sensed EB is related mainly to the spatial resolution of images, the spectral resolution (number of channels and bandwidth for each channel), the accuracy of ground-based observations, and the range of applicability of calibrated equations.

SOURCES OF SATELLITE EB

Carleton (26) summarized some sources of satellite based EB (Table 1). He emphasized METEOSAT, GMS, and ERBS satellite systems as the most important sources of global coverage of EB. The ERBS is a professional system. The Earth Radiation Budget Experiment (ERBE) included ERBS and NOAA 9–10 platforms.

Table 1. Some Satellite Systems Related to EB Generation[a]

Variable	Spectral Region	Sensor	Satellite	Type of Satellite
Surface albedo	VIS	SR	NOAA	Polar orbiter
	NIR	AVHRR	NOAA	Polar orbiter

INTRODUCTION

Soil erosion is the removal of soil or other slope-forming materials by erosive agents, namely, water and wind. Accelerated soil loss, in excess of the rate of natural soil erosion, is perpetuated when surface vegetation is compromised or removed. It is therefore more likely to occur wherever land is used by humans for agricultural production, infrastructural construction, mineral abstraction, or recreation, and where measures for soil protection are not in place.

Soil erosion involves a two-phase process of soil detachment and transport, both of which require an energy input. Much of the energy of erosion derives from water or wind flow over the soil surface or is provided by gravity. Although reducing the energy of erosive forces is the most effective way of controlling soil erosion, one consequence of reducing energy may be the deposition of any material already eroded. As eroded sediment is often enriched with nutrients, organic matter, and contaminants preferentially adsorbed onto the sediment surface, sediment deposition may allow contaminant release into the environment. It is necessary, therefore, to reduce erosive energy at the source areas of sediment rather than after the sediment has been detached and transported.

SOIL EROSION

Water Erosion

Rainsplash (detachment and removal of soil particles and aggregates at the soil surface by raindrop impact) is an important soil-detaching agent. The energy available for erosion is related to raindrop size and velocity. Raindrops have greater kinetic energy than the same volume of runoff and are thus potentially more erosive, although most raindrop energy is expended in soil detachment, leaving little energy available for sediment transport. Rainsplash plays a further role in slope erosion through the detachment, dispersion, and redeposition of fine soil particles on the soil surface. Soil pores are blocked by the redeposited particles, resulting in a surface seal, a reduction in infiltration, and an increase in erosive runoff.

Rainsplash constitutes only a negligible proportion of total soil loss except where runoff is not generated, where it can be the dominant process of sediment removal (1). Where runoff does occur, particle suspension is greatly enhanced by raindrop impact (2) and rainsplash operates as a “feeder” mechanism to rill and runoff erosion. Runoff may also present a buffer between falling raindrops and the soil surface, so that detachment by rainsplash can be limited by runoff. This depends on water depth and raindrop size (3).

Runoff in unchanneled form has a relatively low kinetic energy and, while able to transport soil particles thrown into the flow by raindrop impact, is not able to detach new material. Hortonian runoff (when rainfall intensity exceeds the infiltration capacity of the soil) depends critically on rainfall intensity and amount and soil infiltration capacity. Saturation runoff (when rainfall amount exceeds soil storage capacity) depends on rainfall intensity, subsoil permeability, and the porosity and permeability of the topsoil.

Runoff channeled into rills or gullies has higher kinetic energy and is a much more powerful agent, able to detach and transport soil particles of all sizes, including gravels and small stones. Its considerable erosive power can account for up to 78% of the total material transported within an erosion event.

Wind Erosion

The main factor affecting wind erosion is the velocity of moving air. Because of the roughness imparted by vegetation, soil, and other obstacles, wind speeds are lowest nearest the ground surface. Above this, wind speed increases exponentially with height. The movement of soil particles can be related to critical shear velocity, which is the velocity of wind required to dislodge soil particles from the ground surface and is dependent on soil particle size and soil cohesiveness. Very high shear velocities are required to initiate soil particle movement by wind, and this energy may be translated to adjacent soil particles at the same time, thus causing a chain reaction of motion. Sediment-laden air also acts to detach and mobilize other soil particles by bombarding or impacting on the soil surface. Once in motion, soil particles are transported by wind in suspension (in the air), as surface creep (rolling along the ground surface), and as saltation (particle movement in jumps) (4).

Rates of Soil Erosion

Rates of soil erosion are normally expressed in terms of the mass or volume of soil removed from a unit area of land per unit of time (t or $m^3{\cdot}ha^{-1}{\cdot}y^{-1}$). Typical annual rates of erosion on hillslopes under forest or natural grassland are 0.01–0.5 $t{\cdot}ha^{-1}$ in areas of moderate slope steepness and 0.1–5 $t{\cdot}ha^{-1}$ on steeper slopes. These rates are generally considered low and representative of erosion as a natural geomorphological process. On agricultural land, annual rates are much higher, ranging from 0.1 to 200 $t{\cdot}ha^{-1}$, reflecting the poorer protection afforded by various crops. Arable land is particularly vulnerable to erosion seasonally when the soil is bare between ploughing and crop emergence and also from emergence until the crop canopy closes. Grazing land is vulnerable if overgrazing removes the vegetation cover. Even higher rates of erosion have been recorded on construction sites, often reaching 1000 or even 5000 $t{\cdot}ha^{-1}{\cdot}yr^{-1}$.

Since erosion is a natural process, it is implicit that it cannot be prevented. Erosion can, however, be controlled at an acceptable rate, which should be no faster than the rate at which new soil forms. As little is known about rates of soil formation, except that they are extremely slow, a value of 1 $t{\cdot}ha^{-1}$ (equivalent to 0.1 $mm{\cdot}y^{-1}$) is sometimes accepted as an average annual rate for temperate areas. A more pragmatic approach is to consider the environmental damage that can occur if no control measures are in place (Table 1). Decisions can then be made about the level of damage tolerable relative to the costs of preventing that damage.

Impacts of Soil Erosion

Soil is a valuable resource *in situ* but when eroded by wind and water it can cause significant impacts both on and off site. The on-site implications of soil erosion include declines in cultivable soil depth, available soil moisture, soil organic matter, nutrient content, soil fertility, and soil structure as well as large-scale losses in productive area through gullying or mass movement (4). These on-site effects are particularly important on agricultural land:

Table 1. Rates of Erosion at a Field Scale and Associated Levels of Damage from Individual Storm Events

Erosion Rate, $t{\cdot}ha^{-1}$	Class	Indicators
<1	Natural	No surface evidence of erosion; land well-protected by vegetation cover (90–100% ground cover); very low sediment concentrations in runoff water, which appears clear.
1–2	Very slight	No surface evidence of erosion; land protected by vegetation cover (70–90% ground cover); low sediment concentrations in runoff water, which is clear to slightly cloudy.
2–5	Slight	Some crusting of the soil surface; localized wash, small channels (rills) every 50–100 m spacing; 30–70% ground cover; slight risk of pollution if runoff discharges directly into water courses.
5–10	Moderate	Evidence of surface wash; rills spaced every 20–50 m; exposed tree roots mark level of former soil surface; slight to moderate surface crusting; 30–70% ground cover; risk of pollution if runoff discharges directly into water courses.
10–50	High	Continuous network of rill channels every 5–10 m or deeper channels (gullies) every 50–100 m; surface crusting of soils over large area; <30% ground cover; danger of pollution and sedimentation downstream.
50–100	Severe	Land scarred by continuous network of rills every 2–5 m or gullies every 20 m; sediment splays of coarse material; bare soil; siltation of water bodies; damage to roads by erosion and sedimentation; risk of muddy floods.
100–500	Very severe	Land heavily scarred by continuous network of channels with gullies every 5–10 m; soil heavily crusted; bare soil; severe siltation, pollution, flooding, and eutrophication problems downstream.
>500	Catastrophic	Extensive network of rills and gullies; large gullies (>100 m^2) every 20 m; most of original soil surface removed; severe damage from erosion, pollution, flooding, and sedimentation downstream.

annual agricultural damage costs due to erosion have been estimated at £264 million in the United Kingdom alone (5). The net effect of these impacts is a loss in productivity, which both restricts what can be grown and results in increased expenditure on fertilizers and irrigation to maintain yields. Later this threatens food production and may ultimately lead to land abandonment, with a concurrent decline in the value of land as it changes from productive farmland to wasteland (4). A further consequence of this is the unsustainable exploitation of land resources elsewhere.

The deposition of eroded sediment reduces the capacity of rivers and drainage ditches, enhances flooding, blocks irrigation canals, and shortens the design life of reservoirs (4). Deposited sediment also represents a risk to infrastructure. Chemicals, including fertilizers and pesticides, and nutrients such as nitrogen (N) and phosphorus (P) deposited with eroding soil may have detrimental effects on water quality for supply, recreation, and fisheries. Further impacts on aquatic ecosystems include increases in turbidity reducing light penetration and O_2 availability, thereby reducing plant growth and key biological activities such as photosynthesis; submergence and physical damage to floodplain and in-stream plants; and clogging of fish spawning gravels.

CONTROLLING SOIL EROSION

Measures to control erosion rely on reduction of the energy of erosive forces. Reducing the rate at which soil is detached and transported involves increasing interception and infiltration of rainfall and runoff; reducing runoff volume, velocity, and energy; decreasing the area over which runoff occurs; increasing soil resistance; and increasing soil aggregate stability. The practical measures available to achieve these conditions include mechanical, agronomic, and soil management methods of erosion control.

Mechanical Methods of Erosion Control

Mechanical methods of soil conservation are useful in the control of soil erosion by water. They include terraces, constructed on hill slopes to control soil erosion by reducing slope length and slope steepness, thus limiting the energy of runoff to detach and transport soil material (6). There are many different types of terrace but generic types include the channel and bench terrace. Channel terraces are suited to slopes no steeper than 7° (12%) (6) and consist of a cut channel and filled ridge (constructed from the cut material) constructed across the slope. The distance between consecutive terraces downslope is influenced by site conditions, with greater distances between terraces on gentler slopes and shorter terrace intervals on steeper slopes.

Bench terraces are steplike structures constructed across a slope to prevent erosion by dissecting the hill slope into smaller, shorter slope components, each with a level or near-level bench. The dimensions of the benches depend on slope steepness, the desirable width of cultivable land, and the acceptable height of the steep wall (riser) of the terrace, which is often related to soil depth. As construction of the level bench requires oversteepening of the terrace riser, this near-vertical wall must be supported with stones, masonry, or timber to prevent collapse.

In channel terrace systems, runoff is discharged into a channel constructed at a gentle gradient across slope to ensure that erosion within the channel itself does not occur. The channels are usually kept free of vegetation, so that any accumulated sediment can be excavated each year. From there, flow is directed to lined waterways, which are designed to cope with increased volume and velocity of runoff without causing erosion. These waterways, ideally located in natural depressions to minimize the need for earth moving, are lined with vegetation, stones, or geotextiles with high shear resistance to minimize the risk of erosion.

Agronomic Methods of Erosion Control

Water Erosion Control. Agronomic methods involve the use of vegetation to control soil erosion and are highly effective (7). A plant canopy intercepts rainfall, changing raindrop size distribution and reducing fall velocities, so that kinetic energy available for erosion via raindrop impact is reduced. Plant stems distort and impart roughness to runoff paths, reducing flow velocity and thus kinetic energy to detach and transport soil material. Plant roots encourage infiltration through the soil profile and thus reduce the risk of runoff generation. Lateral plant roots also increase the resistance of soil against the shearing forces of runoff.

Agronomic methods of erosion control include ensuring maximum cover on the soil surface, especially during high rainfall periods, to protect the soil from erosive raindrops and maintaining high stem and root densities to reduce runoff volumes, velocities, and energy. These can be achieved through cover cropping, high density planting, crop rotations, mulching, and erosion control geotextiles. A geotextile is any permeable textile material that is an integral part of a constructed project, structure, or system. It may be made of synthetic or natural fibers. Geotextiles have many applications in land and water management, but those used for erosion control are usually in the form of two- or three-dimensional mats, webs, nets, grids, or sheets.

Natural fiber geotextiles are biodegradable and designed to be laid over the surface of the soil to provide protection against erosion until a vegetative cover is established: in this way, geotextiles act as simulated vegetation. Artificial fiber geotextiles are designed to give permanent protection to the soil surface and are usually buried to reinforce the soil both before and after vegetation establishment. Surface-laid, natural fiber geotextiles are more effective at controlling soil erosion by raindrop impact because they provide good surface cover, high water absorption, and a rough surface on which water can pond. They also reduce erosion by runoff because they impart roughness to the soil surface and therefore reduce runoff velocity. Buried geotextiles reduce erosion to a lesser extent as they cannot control rainsplash erosion and actually increase erosion if they are backfilled with loosely consolidated, and therefore highly erodible, material. Over time, natural fiber geotextiles biodegrade and become less effective as vegetation establishes on the slope while artificial fiber mats continue to perform.

These measures also control soil erosion by contributing nutrients, organic matter, and carbon to the soil, thus encouraging microbial activity and improving soil structure and aggregate stability, which in turn further reduces the potential for soil erosion. Vegetation can also be used to reduce slope length and steepness (and thus erosion risk) when grown in strips parallel to the contour. The strips may be of different crops (strip cropping) or as a single field strip across the slope. The strips restrict the potential for runoff generation and encourage deposition of eroded sediment within the strips so that local slope gradients may be reduced. Common in areas where field boundaries (e.g., hedges) have been removed to increase field size and allow agricultural intensification, field grass strips can be established along former field boundaries, reinstating shorter slope lengths and reducing erosion risk. As farm machinery can traverse the field strips, this simple but effective soil erosion control measure may be adopted willingly by farmers.

Agroforestry systems, in which perennial trees or shrubs grow alongside annual crops, also help to control soil erosion. The trees or shrubs form across-slope barriers to runoff, thus reducing slope lengths and soil losses on the slope.

Wind Erosion Control. Vegetation is also widely used to control wind erosion. By exerting a drag on air flow, vegetation can reduce the velocity of the wind below that required to initiate erosion and can enhance the deposition of soil already being carried in the air. The most common use of vegetation is in the form of shelter belts spaced at regular intervals at right angles to the direction of the erosive winds. Traditionally, trees have been used to form shelterbelts but they need to be supplemented by shrubs (bushes) and grasses to provide cover close to the ground surface since some 70–75% of the soil eroded by wind is carried within the lower 1 m of the atmosphere. The most important characteristic of a shelterbelt is its density or porosity. If too dense, the belt acts like a solid wall and air flowing over the top will create erosive eddies in the lee. The belt therefore needs to be porous so that some air passes through the belt but at a low velocity. Conversely, if the belt is too sparse, the velocity of the wind is not reduced. A porosity of 40–50% is generally considered optimum. Belts are usually designed to maintain wind speeds below 75% of the speeds recorded in open ground. To achieve this, they need to be spaced at intervals of between 12 and 17 times the belt height.

While many shelterbelts comprise single rows of trees, some consist of three rows made up of alternating nurse trees, durable trees, and bushes. The advantage of these mixed belts is they can withstand the loss of an individual species due to disease or pest since other species within the belt can fill any gaps. They also provide a habitat for wildlife.

In arable farming, shelterbelts are considered boundary features and are placed around field edges. However, the principles of shelterbelts can also be used to design in-field shelter systems in which crops are alternated on a strip system, aligned at right angles to the wind. Thus, strips of barley, spaced at 5–10 m intervals, can be alternated with strips of carrots, onions, or sugar beet to control erosion. The barley is sown in late autumn to allow sufficient time for it to emerge before the main crop is drilled in the spring. The barley strips reduce wind velocity until the cover of the main crop is sufficient to protect the soil, at which point the barley is killed off with a selective herbicide so that it does not compete with the crop.

Since shelterbelts require a certain amount of time to grow and become effective, they are not appropriate where immediate control of wind erosion is required. In these situations, windbreaks made from brushwood or plastic netting can be used. The design principles remain the same, aiming for 40–50% porosity and spacings of 12–17 times the windbreak height. Brushwood fences are commonly constructed on coastal dunes to reduce wind velocities and stabilize the mobile sand, which can then be seeded or planted with shrubs and trees to provide long-term stability.

Soil Management Methods of Soil Conservation

The inherent susceptibility of a soil to erosion depends on the soil type and this is difficult to adjust. However, soil management can affect other factors that can increase or decrease soil erosion. For example, intensive arable production can lead to severe soil degradation as soil is broken down by numerous, invasive tillage practices into a loose, fine tilth seedbed. The resulting small soil aggregates are highly susceptible to dispersion, detachment, and transport by rainfall, runoff, and wind. Soil structural stability is further reduced by loss of carbon through oxidation as tillage exposes deeper soil layers to the air, and by loss of soil faunal biomass destroyed during soil disturbance.

The way in which soil is managed in arable production systems therefore has important impacts on soil erosion control. Farming operations carried out up and down the slope will increase the risk of runoff generation while contour cultivations will reduce these risks significantly. Contour ridging enhances this principle by creating raised ridges across slope to reduce local slope length, reduce effective catchment area for runoff generation, and intercept any runoff that is generated. A development of contour ridging is the use of "tied" ridges, where the ridges are joined at regular intervals by "ties" running up and down slope, so creating small basins that trap runoff and eroded soil.

Reducing the number and intensity of cultivations may preserve soil structural stability and aggregation. Less disturbed aggregates are able to resist the dispersive forces of rainfall, runoff, and wind as cohesive bonds within the aggregates are maintained. Soil microorganisms and macroinvertebrates, which also help bind soil particles together and increase aggregate stability, are also less disturbed. Fewer, less invasive cultivations mean more of the vegetative biomass remains on or within the soil (in the form of standing stubble, cut stems, and roots) and is available to absorb the rainfall and runoff energy otherwise available for soil detachment and transport.

The relative reduction in soil disturbance and retention of vegetative material on and within the soil are the principles behind the use of conservation tillage for the control of soil erosion. This umbrella term incorporates a continuum of soil management methods such as minimum tillage, zero tillage, mulch tillage, direct drilling, noninversion tillage, subsurface mulch tillage, and plough/plant cultivation. Conservation tillage aims at maintaining soil fertility and controlling erosion but has an added aim of reducing input costs to agriculture, as fewer, less invasive cultivations expend less energy and fuel costs.

Manipulation of the soil surface condition by tillage is used to control local wind speeds at the ground surface in an attempt to control soil loss by wind erosion. On light, friable soils such as sands and silts, primary cultivations (ploughing and pressing) are performed in one direction, followed by drilling at 90° to this. The resultant tilth is rough and cloddy and imparts maximum friction to air flow, thus reducing wind speed and the ability to detach soil. Tillage techniques can also be used to minimize water erosion, for example, the Aqueel minimizes erosion by maintaining water within surface depressions on the soil surface (8).

Soil conditioners applied to soils susceptible to erosion can perform the dual role of enhancing soil fertility and controlling erosion. Products with high organic matter (such as seaweed extract and tree bark) add nutrients and organic matter to inherent soil fertility, so improving aggregation, structure, porosity, infiltration capacity, and water holding capacity. Soil conditioners reduce soil erosion by either increasing runoff infiltration or increasing resistance to soil detachment. Hydrophilic soil conditioners include bark, limestone, palm oil effluent, and seaweed extract, which increase aggregation and infiltration capacity, so runoff is less likely to occur. The increase in organic matter from these products also helps control erosion by increasing cohesive bonds in the soil, thus improving the stability of aggregates against soil erosion processes. Hydrophobic soil conditioners, including latex, emulsions, and molasses, form a water-repellent film on the soil surface and increase soil resistance to detachment and transport by rainsplash and runoff.

CONCLUSION

The accelerated loss of soil through water and wind erosion processes is a globally important phenomenon with significant and wide-ranging implications for land and water quality. Controlling the impacts of soil erosion is therefore imperative. A range of control measures are presented, illustrating that soil erosion control can be effectively addressed from a mechanical, agronomic, or soil conservation perspective, depending on the environment, skills, time, and resources available.

WATER TABLE CONTRIBUTION TO CROP EVAPOTRANSPIRATION

Chandra Madramootoo
Macdonald Campus of McGill University
Ste-Anne de Bellevue, Quebec, Canada

Evapotranspiration (ET) is the transfer of water vapor from the soil root zone to the atmosphere via the process of photosynthesis. Water vapor can also move directly from the ground surface to the atmosphere. The rate of ET depends on several climatic, soil water, and crop factors, including rainfall, relative humidity, wind speed, air temperature, solar radiation, cloud cover, soil moisture, and stage of crop growth. The plant transpires at the potential rate if soil water is not limiting, which depends on the soil water content.

Water is held in the soil root zone in three distinct phases (see Fig. 1): hygroscopic water, capillary water, and gravitational water. Because of the high tension of the hydroscopic water, it is not available to plants. Both capillary water and gravitational water are available for crop uptake in the ET process.

As the soil water near the soil surface evaporates, the water content near the surface is reduced and the moisture tension increases. Consequently, the tension gradient exceeds the gravitational gradient, and moisture will move upward from the water table toward the soil surface. If root zone soil moisture is between field capacity and saturation, the crop will transpire at the potential rate. In this case, gravitational water contributes to the ET. However, once the soil moisture drops below field capacity, ET is met from the capillary water. In shallow water table soils, the water table contributes to part of the ET, which is known as capillary rise or upward flux. Depending on the position of the water table, the soil type, and the potential ET, part or all of the crop ET may be met through upward flux. If all ET is not met by upward flux, the remainder is taken from the capillary water. As the gravitational water is depleted, and if there is no supply of water to the soil profile either by precipitation or irrigation, the water table will continue to drop. The water table can be further lowered by drainage and seepage. In arid regions, if irrigation is limited, crops depend on the upward flux of groundwater to meet ET demands. However, in regions of deep groundwater, the upward flux is very small, lower than crop ET, and the plants begin to wilt. They thus exhibit signs of drought stress.

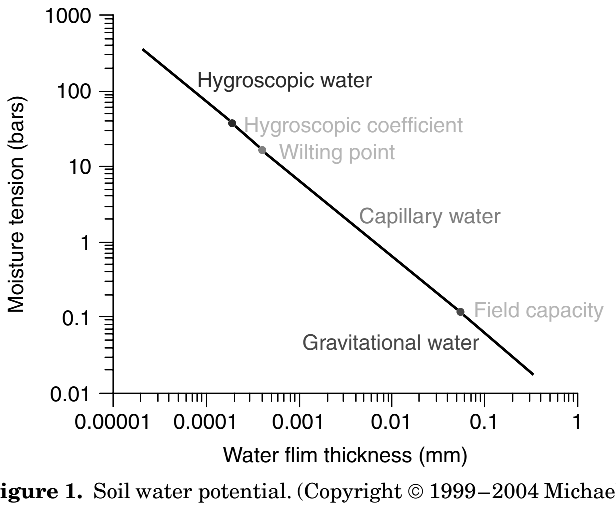

Figure 1. Soil water potential. (Copyright © 1999–2004 Michael Pidwirny).

The basic capillary rise equation ($h = 2\gamma \cos\alpha/\rho g R$) governs the height of the capillary rise (h) and is a function of the pore size distribution of the soil particles. Gardner (1) proposed the following equation to estimate the steady upward flux from a static water table:

$$q_{\max} \approx Aad^{-n} \qquad (1)$$

where $q_{\max}$ is the maximum evapotranspiration rate; A, a, and n are constants (n is a function of soil texture and is higher for coarser textured soils); and d is the depth to the water table.

Equation 1 shows that the ET rate decreases with water table height and will decrease more strongly for coarse textured soils. When the water table is close to the soil surface (low values of d), the maximum ET will be limited by the prevailing climatic conditions. At lower water table depths (high values of d), the ET will be limited by the transmissivity of the soil. Obreza and Pitts (2) developed relationships between upward flux and water table depth for four locations in Florida (Fig. 2).

The ability to meet crop ET from shallow water tables is used in a process known as subsurface irrigation (subirrigation). By making use of perforated plastic pipes installed below the soil surface (primarily for drainage), drainage outflows can either be restricted or water can be pumped back into the plastic pipes during the growing season, thus maintaining a shallow water table. Upward flux from the water table helps to meet the crop ET demands, which is a high energy and water efficient method of irrigation. Water application efficiency can be as high as 95%. It is also a low-cost irrigation system, because there is no need for additional investments in aboveground hardware. The only additional cost is a structure on the tile drain outlet.

The height at which the water table ought to be maintained depends on the crop. Shallow-rooted vegetable crops will need a water table of 30–50 cm below the soil surface. For deeper rooted crops, e.g., corn and soybeans, a water table of 60–75 cm will meet the crop ET requirement. Close monitoring of the water table depth is advantageous, especially in the wetter humid

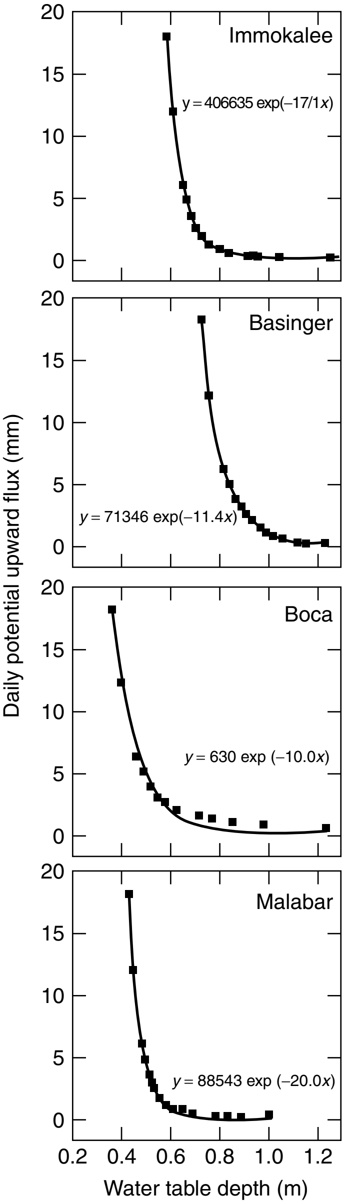

Figure 2. Upward flux vs. water table depth for 4 locations in Florida (2).

regions. Should heavy rainfalls occur, the water table may rise into the crop root zone and cause water logging. In this case, the tile outlet should be opened to lower the water table. The spacing between the tile lines also influences the height of the water table. Narrow-spaced pipe laterals will ensure a more uniform water table distribution. In just the same way that soil type influences upward flux, so too does it influence the lateral pipe spacing. Therefore, the ET rate and the soil type must be taken into account when designing a subirrigation system.

Soils affected by salinization and water logging pose a severe management problem. Salts tend to move upward by capillary action and enter the root zone, thus restricting crop growth and leading to an accumulation of salt in the root zone. Under these conditions, upward groundwater movement is harmful and subsurface drainage is required to lower the water table.

In forested regions, and in tree plantations, there could be large amounts of ET by the tree canopy, thus lowering the water table. This phenomenon is used in some parts of the world affected by salinity and water logging. Salt-tolerant trees and shrubs are planted to control water logging and salinity, which is known as biodrainage.

Modern irrigation practices are being promoted to make better use of the soil as a reservoir to store precipitation and irrigation water. By encouraging field practices that enhance infiltration and improving soil tilth, there is less surface runoff, and more water is stored at shallow depths that can be extracted by the plants' roots to meet the ET demands. This process is also known as rainwater harvesting in rainfed agriculture. The overall effect is that water is conserved in the soil rather than in large open reservoirs, thus reducing irrigation infrastructure costs, operation and maintenance costs, and water distribution losses. Higher irrigation efficiencies are thus obtained.

Valenzano, Bari, Italy

Crop evapotranspiration is a physical process in which water passes from the liquid to the gaseous state while moving from the soil to the atmosphere. It refers to both evaporation from soil and vegetative surfaces and transpiration from plants. These two processes are considered together because they occur simultaneously in nature, and it is difficult to separate them when measured or estimated.

Crop evapotranspiration refers to the water losses from a cropped field, and this term is frequently used in irrigation scheduling and irrigation water management.

Crop evapotranspiration is affected by weather factors (radiation, air temperature, humidity, and wind speed), crop parameters (crop type, variety, and development stage), and local environmental and management conditions (soil salinity, application of fertilizers, tillage practices, planting density, presence of diseases and pests, windbreaks, irrigation practices, presence of groundwater and impermeable soil horizons, etc.). Accordingly, it is possible to distinguish between crop evapotranspiration under standard (optimal) conditions and crop evapotranspiration under nonstandard conditions. Standard conditions refer to disease-free, well-fertilized crops, grown in large fields, under optimal water supply, and achieving full production for the given climatic conditions. Nonstandard conditions are defined as those that differ from standard conditions. *Crop evapotranspiration under standard conditions* is usually denoted as $\mathrm{ET_c}$, and *crop evapotranspiration under nonstandard conditions* is marked as $\mathrm{ET_{c\_adj}}$ or $\mathrm{ET_{c\_corr}}$, where the suffixes "*adj*" and "*corr*" refer to "adjusted" and "corrected," respectively. Standard conditions concur with the optimal conditions of well-managed irrigation fields, so, crop evapotranspiration under nonstandard conditions is always lower than or equal to crop evapotranspiration under standard conditions. Therefore,

$$\mathrm{ET_{c\_adj}} = K_s\mathrm{ET_c} \qquad (1)$$

where K_s is the reduction coefficient ($K_s < 1$) that accounts for the difference between standard and nonstandard conditions.

MEASUREMENTS OF CROP EVAPOTRANSPIRATION

Crop evapotranspiration can be determined by measurements and estimates. In general, measurements are carried out at agrometeorological stations and experimental sites to evaluate estimating procedures and to calibrate and derive parameters of estimation methods. Different types of lysimeters and methods based on a water and energy balance are used to measure crop evapotranspiration.

Lysimeters are tanks located in the fields and filled with soil of the same type as the surroundings. In lysimeters and their surroundings of at least 100 m around (to allow the establishment of an equilibrium sublayer), crops are grown under homogeneous management practices (standard or nonstandard) to measure the amount of water lost by evapotranspiration. The lysimeters provide direct measurements of crop evapotranspiration and can be grouped in three categories: weighing, where evapotranspiration is measured by weighing the changes in soil water content in the tank; nonweighing of a constant water table where the water table level is maintained at the same level inside as outside the lysimeter, and nonweighing of the percolation type, where water stored in the soil is determined by sampling or neutron methods and rainfall and percolation are measured. Weighing lysimeters give the most accurate estimates for short time periods (e.g., 1 hour), and they are recommended for arid and semiarid areas; nonweighing lysimeters of the constant water table type are particularly suggested for areas where a shallow groundwater table exists, nonweighing lysimeters of the percolation type are frequently used in areas of high precipitation.

The *water balance method* is a direct measurement technique based on the principles of conservation of mass which state that the difference in flow into and out of a controlled volume of soil during a specified time interval corresponds to the changes in soil moisture. This method requires monitoring many parameters such as irrigation water supply, precipitation, surface and subsurface lateral flow, and deep percolation. The accuracy of crop evapotranspiration estimates by this method is usually low due to difficulties in measuring and controlling one or more terms of the water balance equation.

Energy balance methods are based on the energy balance equation which states that the net flux density of radiation is balanced by losses of latent heat, sensible heat, and by soil heat flux. The Bowen ratio approach is the commonly used energy balance method. It relies on the flux gradient theory and expresses the latent heat flux of evapotranspiration through the measured values of net radiation, ground heat flux, the difference in air temperature between two heights above the canopy, and the corresponding difference in vapor pressure between the same two heights. This method can be used for crop evapotranspiration estimates in hourly and shorter time intervals.

ESTIMATES OF CROP EVAPOTRANSPIRATION

The estimate of crop evapotranspiration relies on the so-called two-step approach where in the first step, a reference evapotranspiration is determined and then, in the second, the crop evapotranspiration ($\mathrm{ET_c}$)is calculated as a product of reference evapotranspiration ($\mathrm{ET_o}$) and crop coefficient K_c;

$$\mathrm{ET_c} = K_c\mathrm{ET_o} \qquad (2)$$

In Eq. 2, the reference evapotranspiration term refers primarily to the climatic demand, and the crop coefficient accounts mainly for the specific crop characteristics and partially for the management practices (e.g., frequency of soil wetness, etc.).

The concepts of reference surface and reference evapotranspiration ($\mathrm{ET_o}$) estimates have been evaluated significantly during the second half of the twentieth century when they have passed from free water surface and empirical and semi empirical formulas to a hypothetical crop of fixed characteristics and more mechanistic equations.

Numerous equations for estimating reference crop evapotranspiration have been developed and successively modified to account for specific climatic conditions and availability of input information. Some of them in widespread use are presented in Table 1 along with the required input weather data and recommended timescale of applications.

In general, the methods for $\mathrm{ET_o}$ estimates do not have global validity and require local validation and calibration when applied in different environments. The accuracy of an $\mathrm{ET_o}$ estimate has a strong relation with the number and quality of required input information, local climatic conditions, timescale of applications, etc. For example, the Hargreaves method (1) could be the most appropriate for monthly $\mathrm{ET_o}$ estimates, provided that only temperature data are available. Nevertheless, it should not be used for daily $\mathrm{ET_o}$ estimates, especially when days are hot and dry and wind speed is relevant. The same can be stated for the radiation method which shows good results in humid climates and tends to underestimate $\mathrm{ET_o}$ in

Table 1. Some Methods for Reference Evapotranspiration Estimates, Weather Variables Needed, and Suggested Timescale of Application[a]

Method	Temperature	Humidity	Wind Speed	Sunshine or Radiation	Evaporation	Timescale			
						Hour	Day	Week	Month
Blaney–Criddle	+	–	–	*	–				X
Hargreaves	+	–	–	*	–				X
Pan evaporation	–	–	–	–	+			X	X
Radiation	+	–	–	+	–			X	X
Penman	+	+	+	+	–		X	X	X
Penman–Monteith	+	+	+	+	–	X	X	X	X

[a] + must be measured; – is not necessary; * estimate required; X recommended timescale of application

arid climates. The pan evaporation method integrates the effects of different weather variables on evaporation from a specific free water surface and requires calibration to account for the local environment. None of these methods should be used for daily $\mathrm{ET_o}$ estimates due to limited input information and approximations introduced in the equations. For $\mathrm{ET_o}$ estimates on daily and shorter timescales, more mechanistic methods are needed that rely on the full set of input weather variables and combine both aerodynamic and energy balance principles.

The first physically based combination equation was derived by Howard L. Penman in 1948 to describe the evaporation from a free water surface, and until now, this equation has remained the basis of numerous successive modifications and approaches. The main drawback of the Penman approach (2,3) is in the assumption that the evaporation process originates on the outer surface of the leaves rather than within their substomatal cavities. This lack of generality was satisfactorily overcome by John L. Monteith (4,5), who combined energy balance, aerodynamic, and surface parameters in an evapotranspiration equation formally valid for uniform vegetation of any type, fully covering the ground, and in any state of water status.

During the last decades of the twentieth century, many tests around the world have proved the robustness and consistency of the Penman–Monteith approach (6–9) and suggested it as the standard method for reference evapotranspiration estimates. Consequently, it was recommended to introduce a new concept of reference evapotranspiration surface necessary to standardize computational procedures for estimating reference evapotranspiration. These procedures should be used in different regions and climates of the world and thus, avoid ambiguities when the values of reference evapotranspiration have to be estimated and compared.

New reference surfaces and corresponding methodologies for evapotranspiration estimates represent the results of investigation by two groups of scientists:

- the FAO (Food and Agricultural Organization) Expert Group on the Revision of FAO Methodologies for Crop Water Requirements, which published the FAO Irrigation and Drainage paper 56 and also made it available on the Internet at www.fao.org/docrep/X0490E/x0490e00.htm, and
- the ASCE-EWRI (American Society of Civil Engineers—Environmental Water Resources Institute) Task Committee on Standardization of Reference Evapotranspiration, which released the first draft of Technical Report in July 2002.

The FAO Expert Group defined the reference surface as “a hypothetical reference crop with an assumed crop height of 0.12 m, a fixed average surface resistance of 70 s/m (over 24 hours), and an albedo (reflectance of evaporating surface) of 0.23”.

The ASCE-EWRI Task Committee distinguishes between two reference surfaces: the first is a short crop with an approximate height of 0.12 m, (similar to clipped grass and corresponding to most of the reference locations in the world), and the second is a tall crop with an approximate height of 0.50 m (similar to full-cover alfalfa and resembling many reference locations across the United States).

Then, provided that a standard set of measured input data is available (including air temperature and humidity, wind speed and incoming solar radiation), the reference evapotranspiration ($\mathrm{ET_o}$) can be calculated by the standardized form of the Penman–Monteith equation:

$$\mathrm{ET_o} = \frac{0.408\Delta(R_n - G) + \gamma \dfrac{C_n}{T + 273} U_2(e_s - e_a)}{\Delta + \gamma(1 + C_d U_2)} \tag{3}$$

where $\mathrm{ET_o}$ is the reference evapotranspiration (mm $\mathrm{day^{-1}}$ for a daily time step or mm $\mathrm{hour^{-1}}$ for an hourly time step), R_n is the net radiation, (MJ $\mathrm{m^{-2}}$ $\mathrm{day^{-1}}$ for a daily time step or MJ $\mathrm{m^{-2}}$ $\mathrm{hour^{-1}}$ for an hourly time step), G is the soil heat flux density (MJ $\mathrm{m^{-2}}$ $\mathrm{day^{-1}}$ for a daily time step or MJ $\mathrm{m^{-2}}$ $\mathrm{hour^{-1}}$ for an hourly time step), T is the mean daily or hourly air temperature at 1.5 to 2.5 m height (°C), Δ is the slope of the saturation vapor pressure vs. temperature curve (kPa $^{\circ}\mathrm{C}^{-1}$), γ is the psychrometric constant (=0.066 kPa $^{\circ}\mathrm{C}^{-1}$), e_s is the saturated vapor pressure at air temperature (kPa), e_a is the prevailing actual vapor pressure (kPa), U_2 is the mean wind speed measured at 2 m height (m $\mathrm{s^{-1}}$), and C_n and C_d are numerator and denominator constants, respectively, that change with the type of reference surface and calculation time step.

Equation 3 represents the simplest way to estimate the reference evapotranspiration from both reference surfaces (short and tall vegetation) and for different (hourly and daily) time steps. The values for C_n and C_d are derived by simplifying several terms within the Penman–Monteith

Table 2. The Values for C_n and C_d to be Used in Equation 3 (after Ref. 11)

Calculation Time Step	Short Reference Surface (Grass-Like)		Tall Reference Surface (Alfalfa-Like)	
	C_n	C_d	C_n	C_d
Daily	900	0.34	1600	0.38
Hourly during daytime	37	0.24	66	0.25
Hourly during nighttime	37	0.96	66	1.7

equation. They are presented for different reference surfaces and various time steps in Table 2.

The calculation procedures for the reference evapotranspiration and intermediate meteorological parameters ($R_n, G, e_s, e_a, \Delta, \gamma$, etc.) are reported in many books and publications: ASCE Manual 70 (6), FAO 56 (10), the ASCE-EWRI Task Committee report (11), etc. Moreover, free software (REF-ET) for standardized calculations of reference evapotranspiration and intermediate parameters is available at www.kimberly.uidaho.edu/ref-et. An example of a reference evapotranspiration estimate using the standardized form of the Penman–Monteith equation is given here for both grass-like and alfalfa-like surfaces.

Example of a Calculation daily (for a location in southern Italy on June 10, 2002)

Given:

Net radiation $R_n = 14$ MJ m^{-2} day^{-1}; soil heat flux $G = 0$ (can be neglected especially for daily ET$_o$ estimates); minimum air temperature $T_{\min} = 14\,^\circ$C; maximum air temperature $T_{\max} = 28\,^\circ$C; wind speed at 2 m height $U_2 = 1.2$ m s^{-1}; minimum relative humidity (at $T_{\max}$) RH$_{\min} = 50\%$; maximum relative humidity (at $T_{\min}$) RH$_{\max} = 80\%$.

Calculation. The slope of the saturation vapor pressure curve Δ is calculated for mean air temperature $T = 21\,^\circ$C as

$$\Delta = \frac{4098\left[0.6108\exp\left(\dfrac{17.27T}{T+237.3}\right)\right]}{(T+237.3)^2}$$

$$= \frac{4098\left[0.6108\exp\left(\dfrac{17.27*21}{21+237.3}\right)\right]}{(21+237.3)^2}$$

$$= 0.1528\ \text{kPa}/^\circ\text{C}$$

The saturation vapor pressure is calculated as the average value of the saturated vapor pressures at $T_{\min}$ and $T_{\max}$:

$$e_{s\_T\min} = 0.6108\exp\left[\frac{17.28T_{\min}}{T_{\min}+237.3}\right]$$

$$= 0.6108\exp\left[\frac{17.28*14}{14+237.3}\right] = 1.60\ \text{kPa}$$

$$e_{s\_T\max} = 0.6108\exp\left[\frac{17.28T_{\max}}{T_{\max}+237.3}\right]$$

$$= 0.6108\exp\left[\frac{17.28*28}{28+237.3}\right] = 3.78\ \text{kPa}$$

$$e_s = \frac{e_{s\_T\min} + e_{s\_T\max}}{2}$$

$$= \frac{1.60+3.78}{2} = 2.69\ \text{kPa}$$

The actual vapor pressure is calculated as the average value of the vapor pressures at $T_{\min}$ and $T_{\max}$:

$$e_{a\_T\min} = \frac{\text{RH}_{\max}}{100}e_{s\_T\min} = \frac{80}{100}1.60 = 1.28\ \text{kPa}$$

$$e_{a\_T\max} = \frac{\text{RH}_{\min}}{100}e_{s\_T\max} = \frac{50}{100}3.78 = 1.89\ \text{kPa}$$

$$e_a = \frac{e_{a\_T\min} + e_{a\_T\max}}{2} = \frac{1.28+1.89}{2} = 1.58\ \text{kPa}$$

Then, for a short (grass-like) reference surface and daily ET$_o$ estimate, the constants C_n and C_d can be obtained from Table 2 ($C_n = 900$ and $C_d = 0.34$), and the reference evapotranspiration can be estimated from Equation 3 as

$$\text{ET}_o = \frac{0.408\Delta(R_n - G) + \gamma\dfrac{C_n}{T+273}U_2(e_S - e_a)}{\Delta + \gamma(1 + C_dU_2)}$$

$$= \frac{\begin{array}{c}0.408*0.1528*(14-0)\\ +0.066*\dfrac{900}{21+273}*1.2*(2.69-1.58)\end{array}}{0.1528+0.066*(1+0.34*1.2)}$$

$$= 4.65\ \text{mm/day}$$

Similarly, assuming that the input data remain the same, for a tall (alfalfa-like) reference surface, the constants C_n and C_d can be obtained from Table 2 ($C_n = 1600$ and $C_d = 0.38$), and ET$_o$ can be estimated as

$$\text{ET}_o = \frac{0.408\Delta(R_n - G) + \gamma\dfrac{C_n}{T+273}U_2(e_S - e_a)}{\Delta + \gamma(1 + C_dU_2)}$$

$$= \frac{\begin{array}{c}0.408*0.1528*(14-0)\\ +0.066*\dfrac{1600}{21+273}*1.2*(2.69-1.58)\end{array}}{0.1528+0.066*(1+0.38*1.2)}$$

$$= 5.43\ \text{mm/day}$$

The example shows that the reference evapotranspiration is greater from a tall alfalfa-like surface than from a short grass-like surface. This is due to the fact that both the aerodynamic and surface resistance are lower for the tall alfalfa-like surface than for the short grass-like surface.

The estimate of the reference evapotranspiration on an hourly basis can be done by using the same equation and appropriate values for C_n and C_d from Table 2. Moreover, the net radiation R_n should be expressed in MJ m^{-1} hour^{-1}, and the soil heat flux G should be taken into consideration as a portion of the energy term.

The Hargreaves equation represents an alternative solution for the estimate of reference evapotranspiration when input data are limited only to the values of minimum and maximum air temperature (the data widely available and published in hydrometeorological bulletins worldwide). This simple empirical equation has shown good performance when applied on a monthly scale and also on shorter timescales (e.g., weekly), when the wind speed is not strong and the climate is humid rather than dry.

Besides the minimum and maximum air temperatures ($T_{\min}$ and $T_{\max}$, respectively), the Hargreaves method (1) employs in the estimate the extraterrestrial radiation (R_a) which is a function of the latitude of the location and the day of the year (Julian day) under consideration that can be easily obtained from agrometeorological tables or calculated by using the following set of formulas:

$$R_a = 37.586\, d_r(\omega_s \sin\varphi \sin\delta + \cos\varphi \cos\delta \sin\omega_s) \quad (4)$$

where

d_r: relative distance Earth–Sun (rad)

$$d_r = 1 + 0.033\cos\left(\frac{2\pi}{365}J\right) \quad (5)$$

J: day of the year (Julian day) number (nondimensional),

$$J = \text{integer}\ (30.42M - 15.23) \quad (6)$$

M: month number (1–12) (nondimensional),

ω_s: sunset hour angle (rad),

$$\omega_s = \arccos(-\tan\varphi\tan\delta) \quad (7)$$

φ: latitude of location (rad),

δ: solar declination (rad),

$$\delta = 0.4093\sin\left(\frac{2\pi}{365}J - 1.405\right) \quad (8)$$

Then, the widely accepted form of the Hargreaves equation for an $\mathrm{ET_o}$ estimate (mm day^{-1}) for a reference grass surface is

$$\mathrm{ET} = 0.0023\frac{R_a}{\lambda}(T + 17.8)(T_{\max} - T_{\min})^{0.5} \quad (9)$$

where R_a is the extraterrestrial radiation (MJ m^{-2} day^{-1}), λ is the latent heat of vaporization (MJ kg^{-1})

$$\lambda = 2.501 - (2.361 * 10^{-3})T \quad (10)$$

T is the average temperature (°C)

$$T = \frac{T_{\min} + T_{\max}}{2} \quad (11)$$

and multiplier (0.0023), exponent (0.5), and the value of 17.8 in the second multiplier of the equation are the parameters which should be validated and eventually calibrated for different locations.

Example of a Calculation monthly (for a location in southern Italy in June 2002)

Given:

Minimum and maximum air temperature $T_{\min} = 14\,^\circ\mathrm{C}$ and $T_{\max} = 28\,^\circ\mathrm{C}$; latitude of location is $\varphi = 40^\circ = 40 * 3.14/180 = 0.697778$ rad; the month is June which means $M = 6$.

Calculation. Using the following sequence of Equations (6–5–8–7–4), the extraterrestrial radiation (MJ m^{-2} day^{-1}) is calculated as

$$\begin{aligned} J &= \text{integer}\ (30.42M - 15.23) \\ &= \text{integer}\ (30.42 * 6 - 15.23) = 167 \\ d_r &= 1 + 0.033\cos\left(\frac{2\pi}{365}J\right) \\ &= 1 + 0.033\cos\left(\frac{2 * 3.14}{365}167\right) = 0.96818 \\ \delta &= 0.4093\sin\left(\frac{2\pi}{365}J - 1.405\right) \\ &= 0.4093\sin\left(\frac{2 * 3.14}{365}167 - 1.405\right) = 0.40715256 \\ \omega_s &= \arccos(-\tan\varphi\tan\delta) \\ &= \arccos[(-\tan 0.697778)(\tan 0.40715256)] \\ &= 0.935331 \\ R_a &= 37.586 d_r(\omega_s \sin\varphi\sin\delta + \cos\varphi\cos\delta\sin\omega_s) \\ R_a &= 37.586 * 0.96818[0.935331(\sin 0.697778) \\ &\quad \times (\sin 0.40715256) + (\cos 0.697778)(\cos 0.40715256) \\ &\quad \times (\sin 0.935331)] = 29.267 \end{aligned}$$

Then, the average temperature and the latent heat of vaporization are calculated as

$$\begin{aligned} T &= \frac{T_{\min} + T_{\max}}{2} = \frac{14 + 28}{2} = 21\,^\circ\mathrm{C} \\ \lambda &= 2.501 - (2.361 * 10^{-3})T = 2.501 - 0.049581 \\ &= 2.45142\ \mathrm{MJkg}^{-1} \end{aligned}$$

Finally, the grass reference crop evapotranspiration is

$$\begin{aligned} \mathrm{ET} &= 0.0023\frac{R_a}{\lambda}(T + 17.8)(T_{\max} - T_{\min})^{0.5} \\ \mathrm{ET} &= 0.0023\frac{29.267}{2.45142}(21 + 17.8)(28 - 14)^{0.5} \\ &= 3.99\ \text{mm/day} \end{aligned}$$

This means that the grass reference evapotranspiration on a monthly basis for June 2002 was $3.99 * 30 =$ **119.7 mm month^{-1}**.

The average daily value of the $\mathrm{ET_o}$ estimate using the Hargreaves method (3.99 mm day^{-1}) is significantly lower than the value (4.65 mm day^{-1}) obtained from the estimate using the Penman–Monteith equation. This is due to the fact that the impact of wind speed and humidity are not taken into consideration in the Hargreaves equation. However, this equation can be used on a monthly basis to estimate an average reference evapotranspiration. Moreover, the estimates of $\mathrm{ET_o}$ using the Hargreaves equation can be improved by adapting the parameters to the local conditions.

The second step in the crop evapotranspiration estimate is the determination of crop coefficient K_c and the calculation of $\mathrm{ET_c}$ by Equation (2). The crop coefficient is a nondimensional factor that represents the ratio between the crop and reference evapotranspiration. The crop coefficient integrates the features of a typical field crop that change during its growing season and differ from the characteristics of a reference surface, which has a constant appearance and is a complete ground cover. These features comprise the crop height and crop aerodynamic properties (roughness), albedo (reflectance), canopy resistance, and soil evaporation from a cropped field.

K_c values vary from crop to crop during the growing season and depend also on weather conditions and irrigation practices (Fig. 1). It is possible to distinguish between the single crop coefficient K_c and the dual crop coefficient where the K_c is split into the basal crop coefficient (K_{cb}) accounting for crop transpiration and the evaporation coefficient (K_e) referring to soil evaporation. The use of a single K_c approach is recommended in regular applications for management purposes and the development of irrigation scheduling; the dual K_c approach should be applied only for specific purposes (e.g., research) and on a daily basis.

K_c values for different crops are given in many technical materials (FAO 24, FAO 33, FAO 56, etc.) referring to short grass as the reference surface. Nevertheless, it is important to emphasize that most K_c values reported in the literature are obtained with the modified Penman equation (FAO 24) and they should be revised and updated when used with the FAO Penman–Monteith method or some other equation for a reference evapotranspiration estimate. In fact, when crop evapotranspiration has to be calculated, the K_c values should be applied in conjunction with the equations with which they were obtained.

The planting months and the lengths of crop development stages for some widely distributed species are given in Table 3, and an indicative list of K_c values for different crop growth stages is presented in Table 4. The K_c values are given, assuming that the reference evapotranspiration is calculated for a grass-like surface. Both tables are prepared on the basis of the FAO data and some other investigations. However, these data should be used only in the absence of more reliable values.

Example of an estimate of evapotranspiration for a tomato crop growing in the Mediterranean region with the planting date of April 15th.

Calculation Procedure. The lengths of the growing stages are taken from Table 3 and K_c values from Table 4. Then, the growing cycle of tomato can be presented graphically as in Fig. 2.

The K_c values can be determined daily by using a simple linear interpolation. For example, on June 10th, the K_c value is 0.92. Then, assuming that the reference evapotranspiration is 4.65 mm day^{-1} (as calculated in the example here before for the grass-like reference surface using the Penman–Monteith equation), the tomato evapotranspiration for June 10th is estimated by using Eq. 2 as

$$\mathrm{ET_c} = K_c \mathrm{ET_o} = 0.92 * 4.65 = 4.28 \text{ mm/day}$$

Finally, if the tomato crop is not growing under standard (optimal) conditions, the crop evapotranspiration can be adjusted to the real conditions by applying Eq. 1. The values of reduction coefficient K_s are always lower than one and depend on the specific site conditions to which the crop is exposed during its growing cycle. In any case, in real management, checking the results of $\mathrm{ET_c}$

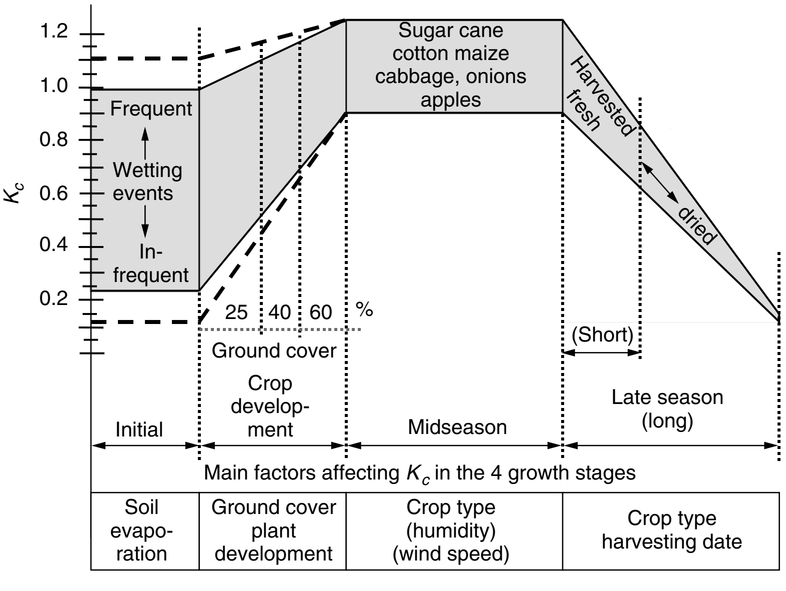

Figure 1. Main factors affecting the crop coefficient (K_c) during the four growing stages (adapted from FAO 56).

Table 3. Planting Months and Lengths of Crop Development Stages for Some Important Crops in Different Regions of the World (Adapted from FAO 56)

WATER POLLUTION FROM FISH FARMS

WASTE OUTPUT

Wastes from aquaculture plants include all materials used in the process that are not removed from the system during harvest. The principle wastes from aquaculture are uneaten feed, excreta, chemicals, and therapeutics. In addition, the term "waste" can also refer to pathogens and dead or escaped fish.

Generally, the quantity of waste is closely connected to the culture system used. *Intensive* farm systems, typically monoculture of carnivorous finfish in the temperate zone reliant on artificial feed, may cause serious local pollution. So-called semi-intensive farm systems are supplied natural feed sources, such as vegetation, oil cakes, cereal bran, and organic-chemical fertilizers. The latter systems dominate the tropical/subtropical production of herbivorous or omnivorous fish, e.g., the major production of carps and tilapia, and the waste output to the surrounding waters is much lower than from intensive fish farms. This is illustrated in Fig. 1, where the nutrient budget is estimated for intensive farms (cage or flow-through raceway systems) and for semi-intensive farms (Nile tilapia produced in static pond water). In highly intensive farms, as much as 74–84% of the nutrient inputs are released into surrounding waters, whereas only 2–6% of the nutrients are released from semi-intensive farms. Semi-intensive production of carps takes place mostly in static ponds only drained during harvest, where supplied nutrients not assimilated in fish are mainly trapped in the pond sediments. The Chinese production of carps and tilapia in freshwater constitutes more than one third of the global aquaculture production (China: 12 million MT in 1997, 1). Thus, the retained fraction of nutrients in the pond sediments is vital to avoid serious water pollution.

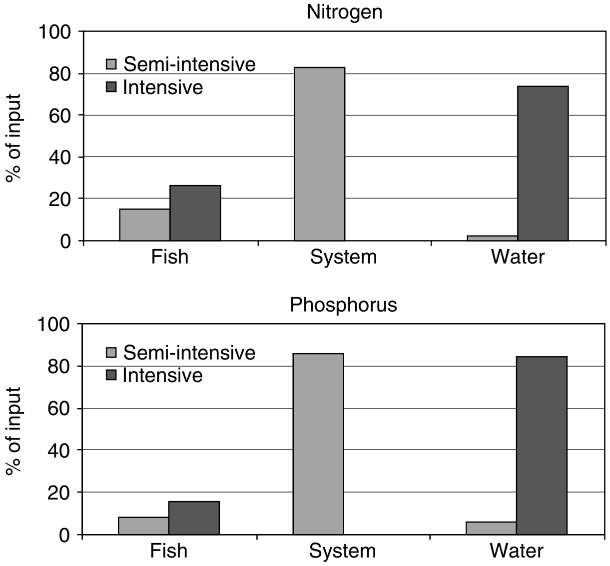

Figure 1. A comparison of the nutrient budget of a semi-intensive and an intensive aquaculture system (see text). After Edwards (2).

In distinct regions, fish farms represent a dominating water pollution source. Along the western and northern coast of Norway, cage farming of salmon and trout contributed about 55% of P and 17% of N of the total input in 1998 (see Fig. 2). Since then, the annual production has increased from c. 400,000 MT to c. 600,000 MT. The total nutrient input to this part of the coastline has strongly increased over the last 20 years because of the growing aquaculture industry. The average specific loading was 10.8 kg P and 52.0 kg N per ton of produced fish. For population equivalents (p.e.):6000 p.e. as Total P and 4000 p.e. as Total N per MT produced fish. Besides, uneaten feed and feces from cage farms load the recipient with biodegradable organic matter that may lead to significant oxygen depletion [corresponds to 300–500 kg as BOD_7 per MT produced fish, (4)].

A wide range of chemicals are used in the aquaculture industry, including disinfectants, chemotherapeutants (antibacterial, antifungal, and antiparasitic compounds), pigments incorporated into feeds, and compounds employed in and applied to construction materials (e.g., antifoulants) (5). Of particular interest is the use of chemotherapeutants because of the quantities discharged into the aquatic environment. In Norway, the only country that has kept records, around 50 MT of antibacterials were introduced into the coastal environment by the aquaculture industry in 1987. The use has, however, fallen to below 1 MT annually because of development of efficient vaccines against bacterial diseases. In semi-intensive, tropical freshwater farms, antibacterials are sparsely applied.

ENVIRONMENTAL IMPACTS

Most reported studies of environmental effects are related to intensive aquaculture. The quality of wastes from fish farms and its temporal variability are important

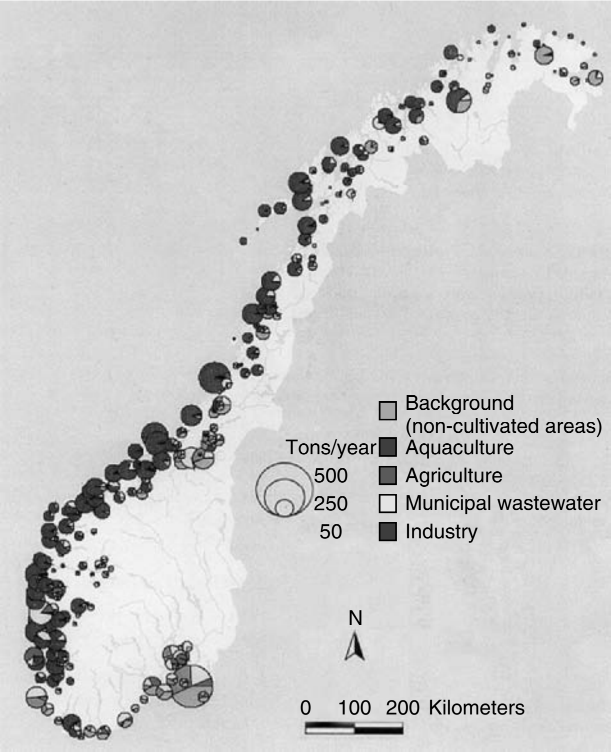

Figure 2. Estimated phosphorus inputs to the Norwegian coastal waters from the main sources in 1998 (3).

determinants of environmental impacts (6). Aquaculture wastes are rich in P with a TP/TN ratio of around 5. Thus, fish farms have been expected to be a potential source for eutrophication in freshwater sources as P is the limiting nutrient. Generally, the eutrophication rates in lakes and reservoirs influenced by fish farming seem to be lower than those predicted by lake models. Håkanson et al. (7) observed very little, if any, increased concentrations of TP in two Swedish lakes influenced by cage farm emissions. The main causes seemed to be linked to (1) direct uptake of feces and waste feed from farmed fish by wild fish, and (2) a significant amount of P from the cages that are eliminated from the lake water by different processes, e.g., sedimentation.

Nutrients emitted from cage farms are found to be highly biologically available for marine algae (8): The bioavailability of P in effluent from aquaculture, agriculture, and municipal sewage was 50/60%, 30%, and 65/70%, respectively, whereas more than 80% of N in all effluent types was available for algal growth. Despite that aquaculture is the dominating nutrient source along the western-northern coast of Norway, the cage farms are located in a zone with huge water exchange (The Gulf Stream) and large recipient capacity.

Deposition of solids from cage farms may strongly effect the benthic ecosystems beneath the cages (6). Such materials have shown to increase the extent of anaerobic sediment layers with dramatic consequences for the original biological communities. Under intensive cage farms, the bacterial activity in anaerobic sediments often causes out-gassing of methane and hydrogen sulphide. In addition, sedimentary phosphorus might be released at oxygen depletion in deeper water. Studies of benthic communities all indicate that detrimental impacts are limited to the immediate vicinity of the intensive cage (or mussel) operation.

Among other consequences of modern aquaculture are environmental effects caused by antibiotic use, e.g., drug residues in water, sediments and organisms, and introduction of exotic species for aquaculture purposes. Welcomme (9) reported that 98 species of fish had been introduced internationally involving inland waters. Also, accidentally or deliberately released farmed fish can affect their local wild forms by behavior and genetic impacts.

ENVIRONMENTAL REGULATIONS

A wide range of regulations and standards control fish farming and the discharge of effluent in parts of the world, such as North America and Europe. Aquaculture relies on precious water resources, and; as populations increase, access to good quality water and the ability to discharge effluents will become more restrictive. In many countries, aquaculture legislation is poorly developed. During the last few years, however, interest has grown to develop a comprehensive regulatory framework for aquaculture whose goals should be to protect the industry,

WORLD'S MAJOR IRRIGATION AREAS

JACOB W. KIJNE
Herts, United Kingdom

EXTENT OF IRRIGATION

Irrigation is the artificial watering of land by technical means, such as canals, pumps, sprinklers, or drip systems, to supply moisture to crops. Surface irrigation, such as basin and furrow irrigation, in which water is led to the fields through canals and ditches, has been practiced for over two millennia.

About 20% of the world's agricultural land is irrigated, but some 40% of the food and fiber production worldwide takes place on irrigated land. For cereal production, it is close to 60% (1). FAO expects this share to increase further in the next three decades. Much of this expansion will take place in developing countries, increasing their irrigated land perhaps by as much as 20% before 2030. This is a net expansion, which implies that agricultural land lost to urban growth and soil salinization will be compensated.

At present, more than 60% of the world's irrigated land is in Asia. Table 1 shows the ten top countries and river basins in terms of irrigated land area. About two thirds of the irrigated land in Asia is devoted to rice and wheat production.

Worldwide, about 70% of water withdrawals is supplied to agriculture. Table 2 shows for the ten top irrigation countries the total water withdrawal (for agriculture, industrial, and domestic use) as a percentage of the renewable water resource in the country and the percentage of this total withdrawal used in agriculture.

Although food production to 2020 is expected to increase faster in developing countries than in developed countries, experts suggest that food production will not keep pace with demand. In 1999/2000, developing countries produced 55% of the world grain production and accounted for 61% of world grain consumption. They also imported 231 million tons of grain, equivalent to 72% of worldwide imports, which suggests that developing countries although playing a major role in irrigated agriculture production still depend on international agricultural trade for their food security.

DIFFERENT METHODS OF IRRIGATION

The three main types of irrigation are canal (or surface) irrigation, sprinkler irrigation, and trickle or drip irrigation. In canal irrigation, water is distributed through a network of canals, consisting of one or more main canals conveying water from the source (e.g., a reservoir or a barrage in a river), distributary (secondary) canals from the outlets in the main canal, tertiary canals (called watercourses in the Indian subcontinent) from the outlets in the distributary canals to the farm gate, and field canals. Canal irrigation systems have lower construction and operating costs, simpler maintenance, and lower skilled labor demands than do pressurized delivery systems. A disadvantage of canal irrigation over piped systems is that the soil must convey and infiltrate the water over the fields. Because soil properties are highly variable, both spatially and temporally, designing water-efficient surface irrigation at the farm level is complicated. Much research has been done on determining the optimum flow rate for a given length of furrow and vice versa. It is now claimed that in furrow irrigation design, it is possible to attain an application efficiency (i.e., the ratio of the average depth of water applied to the root zone, and the average depth of water applied to the field) of about 70% (2). However, the reality in the field is probably different. Application efficiency refers to the average depths of application, but the uniformity of distribution is also important. It expresses the often large differences in the depths of water stored in the root zone along the length of the fields resulting from local differences in soil structure and texture and variable infiltration amounts in low and high spots in the field. Precision land leveling and automatic devices (e.g., for the release of surge flows) have

Table 1. Top Ten Countries and River Basins for Irrigated Land

improved attainable application efficiency and uniformity of distribution, while reducing the labor requirements of surface irrigation (3).

Sprinkler irrigation and drip (trickle) irrigation eliminate the need for land leveling and allow more frequent water application without alternating saturation and desiccation of the upper soil layers. But most importantly, these newer methods have improved attainable application efficiencies and, hence, lose less water. Nowadays, commercial crops that were traditionally furrow irrigated are increasingly irrigated by drip irrigation methods. For example, a subsurface drip irrigation system was chosen to replace furrow and sprinkler irrigation systems on a commercial sugarcane estate in Swaziland. A postinvestment evaluation indicated that sucrose content increased by 15% and that 22% less water was used in the drip system than in the sprinkler irrigation system it replaced (4). Similar yield increases and water savings were noted in drip irrigated corn (maize) in a project in arid southeast Anatolia, Turkey (5).

CHANGES IN IRRIGATION OBJECTIVES OVER TIME

In the colonial period, the dominant reason for installing irrigation was to prevent famines during drought years. An additional concern was flood control in the deltas of the big rivers in Asia and Africa. Famine prevention necessitated an irrigation system that would provide some water to many farmers to assure the main harvest and revenue collection for the colonial power with a minimum of control and regulation. In the Asian subcontinent, this was achieved through a form of timed rotation of a continuous flow to different watercourses, in which a shortfall in supplies is shared equally by all users. The system was not expected to provide enough water for maximum yields.

From the 1950s, irrigation rapidly expanded, especially in Asia. The peak in funding by the international development banks for construction of irrigation occurred in the 1970s and 1980s. Internal rates of return on irrigation projects between 1965 and 1985 were in the range of 12–25% (6). This period coincided with the green revolution in Asia when cereal production increased many fold as a result of the introduction of high yielding varieties of rice and wheat, enhanced fertilizer use, and improved irrigation systems. During this period, irrigation's main objectives were to obtain maximum yields per unit land through high water and fertilizer inputs. Concurrently, extensive research was done to determine and predict water requirements and evapotranspiration rates, i.e., evaporation from the soil and transpiration from the growing crop. This topic was central to the efforts to match irrigation supplies as closely as possible with the evaporative demand of the environment to maximize crop production.

After about 1985, irrigation investments dropped sharply because of lower grain prices (from which the urban population benefited more than the farmers), rising construction costs, and hence lower returns on investments. Growing opposition to further large-scale irrigation projects, such as the Namada in India and the Three Gorges Dam in China, contributed to this reduced interest in irrigation investments. Although investments slowed, irrigation development in Asia nevertheless continued unabated. Experience and research have shown that supportive policies and laws have at least as much effect on irrigation development as does the availability of international investments. Specifically, national priorities, strength in the rule of law, a free market economy, local and user participation in planning and management, as well as encouragement of the private sector have been shown to stimulate irrigation development (7).

Pumped groundwater is increasingly used for irrigation. This increase has been at such an extent that many groundwater resources are now overexploited. Recycled drainage water and wastewater have also been added as possible sources of irrigation water. Generally, some treatment of wastewater has been deemed necessary before it can safely be used in crop production. But many developing countries do not have or enforce regulations covering the use of wastewater, or lack the resources to treat wastewater adequately. From the 1990s, the irrigation strategy focused on the control and integrated management of all water resources for agricultural and nonagricultural uses, which made irrigation managers realize that low irrigation efficiencies on the farm do not imply that water is wasted. If the drainage flow is fed back into the canal and reused downstream, and seepage to the groundwater is recycled by pumping, the relevant parameter is no longer application efficiency at the farm level but at the subsystem or system level, or even at the river basin level. For example, the Nile valley in Egypt with its notoriously inefficient irrigation at the farm level has a basin level application efficiency of about 95% because of its extensive reuse of drainage water (8). Hence very little water, and of no further use because of its low quality, is discharged into the Mediterranean Sea. These examples from Third World countries follow earlier developments of a similar nature in the United States and Australia (e.g., respectively, the Imperial Irrigation District with the Colorado River, and the Murray-Darling Basin).

IRRIGATION PERFORMANCE ASSESSMENT

Performance parameters express the degree to which the objectives of irrigation are met. The chosen parameters are usually limited to those pertaining to performance of the irrigation infrastructure and the system management. Because of its large data requirement, the variability in performance among farmers and for different crops is rarely studied. In one instance, where available information allowed quantification of the way farmers managed their irrigation supplies, it was found that around half the cotton farmers irrigated either excessively or deficiently although the average performance was close to the optimum for maximum yield per unit land (9). Excessive irrigation was also found in the Gezira irrigation system in Sudan. Here the variation was attributed to unattended furrow irrigation, aging infrastructure causing siltation, and weed growth in the canals (10). Large variabilities among farmers obviously indicate a significant potential for improvement.

In protective irrigation systems (implying proportional sharing of a limited resource among the widest number of people), performance is evaluated by measuring the flow rates that reach the tail ends of watercourses. This measurement assesses the equity of distribution of the available water to as many farmers as possible. Head-tail differences in water supplies continue to be the case in many large-scale irrigation systems. Failure to recognize and address equity considerations (i.e., fairness as understood by the farmers) in performance assessment has been a major cause of problems in operation and maintenance of irrigation system.

When the irrigation objective in the second half of the twentieth century shifted from protective to productive irrigation (involving the right to maximum economic return for a limited number of farmers), the performance parameter of choice became the yield per unit of land. Toward the end of the century, water for all uses became a major concern, and irrigation management came to be seen as one element of integrated water resource management. At the same time, performance assessment of irrigation systems was no longer based only on profitability and revenue collection, but it came to include the social objectives of food security, poverty alleviation, and environmental protection.

Because of increasing pressure on available water resources, irrigation managers worldwide are now compelled to improve the performance of their systems. The list of performance parameters has consequently grown and includes all aspects of maintenance and operation of the infrastructure, output per unit irrigation water and per unit of land, financial aspects (e.g., cost recovery), and environmental performance (e.g., quality and quantity of drainage flows). Benchmarking, using a standard against which performance can be assessed, has now been applied to irrigation management. By comparing with the norm, it attempts to identify deficiencies in a system's infrastructure and organizational structures. Benchmarking thus intends to make continuous improvements, especially in the quality and reliability of the services provided to the farmers. It also intends to stimulate an institutional culture that supports innovation and reliability in service providers (11).

IRRIGATION MANAGEMENT

Three main types of irrigation management can be distinguished: commercial estates producing usually one crop (e.g., sugarcane, cotton, tobacco, pineapples, etc.), canal irrigation systems with many small farmers, and individual farmers managing their source of irrigation water, usually a tubewell or small reservoir. Of these, large-scale canal irrigation systems cover the largest area, especially in Asia, and provide employment to millions of people. Improvements in the management of these systems could have a major beneficial impact on food production. This type of management, usually done by state organizations such as irrigation departments, has therefore received the most attention. Common institutional deficiencies in water resource management are described elsewhere (12).

Along field channels, and often significantly above the field channels, farmers control the actual operation of the system. In that part of the system that is controlled by management, including reservoirs and the main and secondary (or distributary) canals, considerable discrepancy often exists between the nominal rules and procedures incorporated in the design and the actual operation of the system.

Because of widespread dissatisfaction with state management of irrigation systems, financial institutions who invested in irrigation development have stimulated state agencies since the 1990s to hand over all or part of irrigation management to the private sector. Greater participation of the farmers in system management and user-operated and managed irrigation systems as found in developed countries are examples to be followed in the Third World. Privatization was expected to lower the cost of service provision to the farmers while increasing its quality. Conditions for success of privatization include:

- A legal framework either existing or tailor-made to provide the legal background for enforceable contracts
- Quality control and other regulations
- Active participation of the farmers in the implementation of the changes
- Institutions that control and enforce the rules and regulations
- Rights to water and use of the infrastructure
- Impartial adjudication of disputes
- Sound arrangements about the financial responsibilities regarding maintenance of the irrigation infrastructure (13)

An alternative to complete privatization was introduced in Pakistan where irrigation system management was decentralized and the participation of farmers in system management was promoted. Management at some secondary canal level was handed over to the farmers' organizations. A recent evaluation of one of these sites indicates that the water distribution and allocation has become more equitable as a result of the handover, which is particularly beneficial to tail-end farmers (14). Additional benefits were that illegal tampering of outlets had almost ceased, and that cost recovery had improved significantly. However, experience with irrigation management transfer elsewhere in developing countries has not been uniformly positive. Different performance parameters show improvement in some systems but decline in others. In some systems, an increase in farmers' fees for operation and maintenance and in fee collection has occurred, but nevertheless major maintenance is deferred. The effect of management transfer on agricultural production and farm income is equally uncertain.

In recent years, many countries have gained experience with institutional reform of their water sectors, including Australia, India, Philippines, Malaysia, Turkey, Mexico, Argentina, and Chili. Institutional changes will continue to shift toward user-management and water markets, with a more regulatory role for the state. Although the long-term impact of these various efforts has not yet been assessed, the Australian experience clearly demonstrates that if farmers are to pay for the full cost of irrigation services, the irrigation agencies have to become accountable to them.

SUSTAINABILITY AND FUTURE OF IRRIGATED AGRICULTURE

Irrigated agriculture competes for water with other uses and often contributes to degradation of land and water resources. The net social benefit of irrigated agriculture is the difference between returns to the farmer and society as a whole, and the cost to society associated with its negative aspects (e.g., the cost of disposal of saline and polluted drainage water). Because no general agreement exists on the real benefits and costs of irrigated agriculture, whether irrigated agriculture is sustainable in the long run has become controversial. Many definitions of sustainability exist. A strict definition is that sustainability is achieved when irrigation and drainage are conducted on-farm and within irrigation districts, in a manner that does not degrade the quality of land, water, and other resources (15). Others define sustainability of irrigated agriculture as the ability to continue extracting net positive returns from water and land for an indefinite period of time (16). In contrast to the first definition, the latter one is not inconsistent with some degree of environmental degradation, which implies that it is not necessarily true for all ecosystems that the optimal rate of degradation is zero.

Linked with this issue of sustainability is the question of whether there is enough irrigable land and water for future needs. FAO studies (17) suggest there is still scope for expanding irrigation to satisfy future needs. Their estimates suggest that in developing countries, only half of the potential irrigated land (about 400 million ha) is in use. Moreover, only 20% of this presently unused potential area will be in production by 2030. This assessment takes into account the limitations imposed by the availability of water. In the developing countries as a whole, only about 7% of renewable water resources were withdrawn (18) for irrigation. And the projection is a 14% increase in water withdrawals for irrigation by 2030. Water availability is considered critical when at least 40% of the renewable resource is used for irrigation. Of the countries listed in Table 2, the situation is critical only in Pakistan and Iran. FAO expects this to be the case for all of South Asia and West Asia/North Africa by 2030. Although a 14% increase in water withdrawn for irrigation over a period of 30 years may not appear to be much, the development of additional resources will be increasingly difficult. For example, monsoonal river discharges are part of the unutilized resource, but they are extremely expensive to capture.

In another study (19), the potential demand (i.e., without water supply constraints) and actual consumption (realized demand given the limitations in supply, and calculated for consumption rather than withdrawal) of irrigation water were assessed. This study expects the potential demand in developing countries to grow by 12%, but the actual consumption should grow less because of water scarcity and improvements in yields per unit water. The difference in growth of the potential and realized demands leads over time to lower values of the proportion of the potential demand realized in actual consumption of irrigation water, as shown in Table 3. The expected improvements in water productivity (kg/m^3) in irrigated cereal production range from about one third in sub-Saharan Africa to two thirds in South Asia.

With respect to the potential for irrigation expansion in the industrial countries, most studies agree that there

Table 3. Proportion of Potential Demand Realized in Actual Consumption

	1995	2025
Asia	0.81	0.76
Latin America	0.83	0.75
Sub-Saharan Africa	0.73	0.72

Source: Rosegrant et al. (19).

is less scope and need for expansion in America and Europe. At present some irrigated land in California goes out of production as the water rights are sold to cities for their domestic water supply. In both the United States and Europe, some rainfed agricultural land is now left idle as there is no need for more production. If the need developed, agricultural productivity could probably be enhanced on rainfed land at a lower cost than would be involved in expanding irrigated land. Moreover, future production increases in developed countries are expected to come from higher yields per unit of land and per unit of water.

It has been argued that water pricing might reduce the demand for irrigation water. However, water used for irrigation is not simply an economic resource but also a social good. A change in the price of water would affect the urban price of food, which in turn could have major political consequences. It would be more appropriate to charge for the water actually consumed than for what is supplied in irrigation, but that is practically impossible. Another practical difficulty with water pricing as an instrument for affecting its use is that for the price to have an effect on water demand, it must be significantly increased, most likely more than politically feasible. A case in point is China, where according to the World Bank, water for agriculture is heavily subsidized. A better option for improving water use efficiency in irrigation appears to be rationing water where the demand exceeds supply (20).

A contentious issue is how to improve water productivity (e.g., kg/m^3 or $\$/m^3$) when water resources are scarce and higher water rates are not appropriate. One option is through deficit irrigation: applying less water than the crop would need for maximum production per unit of land. Another option is to design a responsive irrigation system in which all farmers have access to water as and when needed, which is expected to lead to less wastage. The latter, however, is difficult and expensive to realize in large-scale irrigation systems with many fragmented small holdings. Providing farmers in deficit irrigation with less water than they would freely demand is expected to encourage farmers to grow more water-efficient and high-value crops. The downside of deficit irrigation, though, could be the possible salt buildup in the root zone in the absence of sufficient leaching of salts from the soil profile. Model studies have shown that on-demand irrigation is profitable where water is relatively abundant or high-value crops are grown that would benefit from extreme reliability and accuracy in irrigation supplies. Yet, deliberately restricting irrigation deliveries at no less than 80% of the potential full demand, crops can still produce well without salinization of the root zone. The productivity of water (kg/m^3) could then be almost 50% higher with deficit irrigation than when water is supplied to meet full crop demand (21).

The first challenge for the future, then, is to improve crop production on irrigated land by managing water better to achieve optimal production per unit of water, which is more easily realized in developed countries than in developing ones, but because of the population growth, the latter have a greater need for more food production. Present thinking is that more food export from industrial countries is not the solution. Imports have to be paid for in hard currency and staple crops should be grown where the people live. However, this could change as a result of globalization and reductions of tariffs in agricultural trade. Hence, for now and the foreseeable future, irrigated agriculture is essential for worldwide food security. The second challenge thus becomes to enhance irrigated agriculture while minimizing the adverse environmental impacts.

IRRIGATION IN THE UNITED STATES

FREDERIC LASSERRE
Laval University
Quebec City, Canada

CONTRASTED TRENDS

The total amount of farmland, comprising both cropland and pastureland, is slowly decreasing in the United States at 71.2 million hectares (M ha) (176 million acres) in 1998, but irrigated lands kept increasing from 16.7 Mha in 1974, 19.8 Mha in 1982, 19.9 Mha in 1992, and 25 Mha in 2000. The geography of the increase in irrigated lands is contrasted. The national yearly increase for the period 1974–2000 is 1.57%, but east central and Atlantic states witnessed much stronger growth, well above 4%, on average, whereas Arizona, Montana, Nevada, Texas, Oklahoma, and Wyoming saw their irrigated lands shrink overall (Fig. 1) (1).

But this 26-year period masks a three-period evolution. From 1974 to 1982, irrigated surfaces grew on average by 2.18% yearly; sharp increases occurred in states such as South Carolina (+29%/year), Georgia (+22.7%/year), and Minnesota (+19.1%/year); other western states such as Texas and New Mexico already displayed a downward trend in their irrigated surfaces, and eastern States as well such as New Jersey and West Virginia. From 1982 to 1992, the growth is much more moderate: 0.08% per

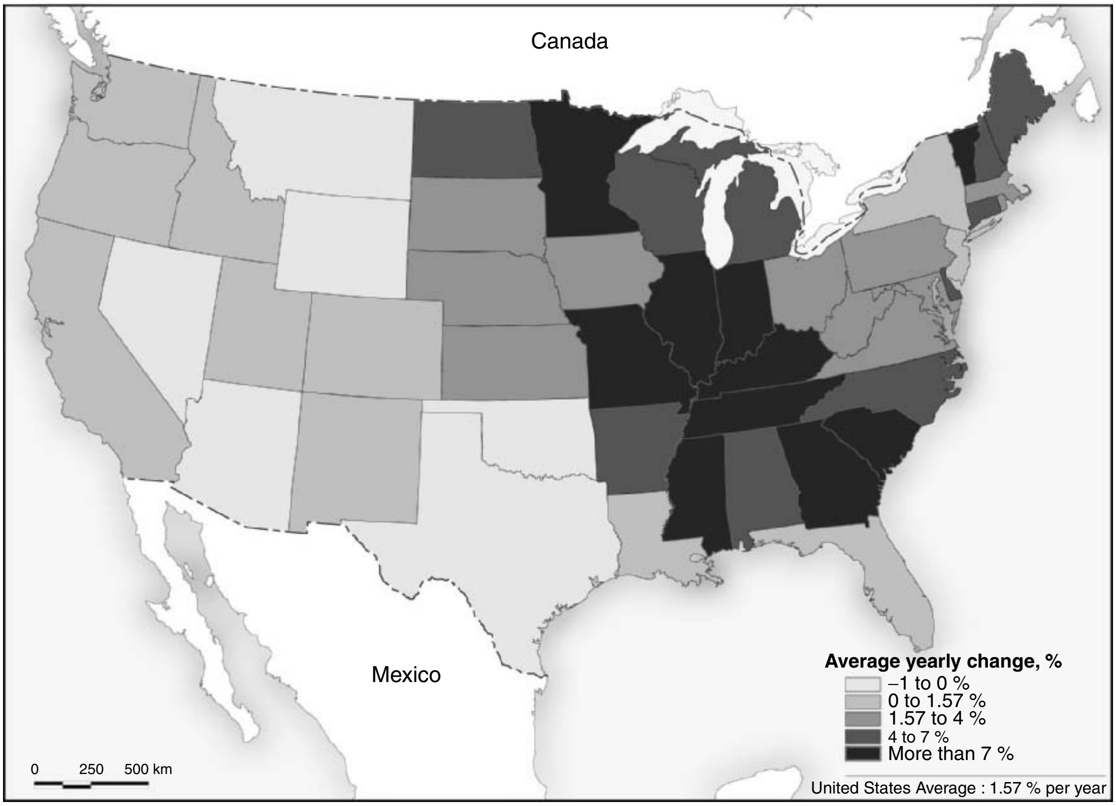

Figure 1. Irrigated surfaces evolution, 1974–2000.

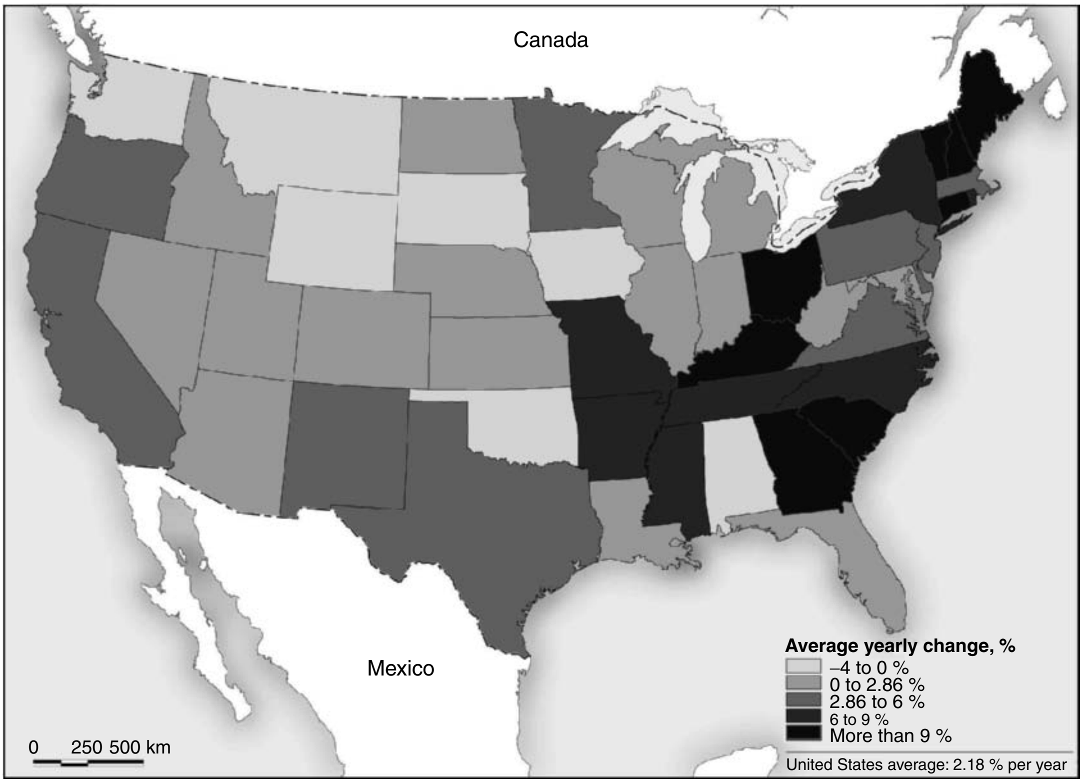

Figure 2. Irrigated surfaces evolution, 1992–2000.

year in the nation, with most states located in the western part of the country witnessed a decrease. Then growth picked up from 1992 to 2000 at a national yearly average of 2.86%. Some western states (Fig. 2) (Oregon, Montana, Wyoming, Oklahoma, South Dakota) still experienced a decline, but others grew appreciably (California: +3.7%/yr; Texas: +3.5%). The strongest growth was experienced in the Atlantic and east central regions, growth rates exceeded 9% in Georgia, South Carolina, Ohio, Kentucky, and several New England states (Tables 1 and 2).

This spectacular growth of irrigated surfaces in the eastern United States can be explained by two factors: a production objective, the desire of farmers to increase yields or switching to more water-demanding crops, such as corn, sugar, vegetables; a financial factor as well; many farmers in this wetter part of the country irrigate their cropland to avoid any risk of yield decrease. Tight markets, strong pressures from banks, and rising debt have made some farmers risk averse.

THE IRRIGATION COUNTRY: WATER IN THE DRY WEST

However strong the irrigation growth might have been in the eastern part of the country and even though a slight decline has begun to take place in a few western states, absolute irrigated surfaces still show that irrigation is concentrated mainly in the western and central United States. In 1974 as well as in 1992 (Figs. 3 and 4), the picture depicted by the maps underlines the dominant share in irrigated surfaces in states west of the 100th meridian: in 1974, irrigated land in California, Idaho, Colorado, Nebraska, and Texas accounted for 58.3% of all irrigated land. In 2000, irrigated land in the same five states still made up 51% of irrigated land countrywide.

Of course, natural conditions largely explain this spatial pattern: rainfall becomes much scarcer west of the 100th meridian and becomes more abundant again only in the northwestern part in the country, on the Pacific coast (Fig. 5). Most of the west gets less than 20 inches of rain a year; patches of California, Nevada, Arizona, Idaho, Utah, Wyoming, and even Washington receive less than 10 inches. Water is present, however, in the region: aquifers do contain large amounts of water (for instance, the Ogallala aquifer underneath Texas, Oklahoma, and Nebraska). And mountain ranges generate rivers; the Colorado drains a large basin in the area. Tapping this resource became a political objective during the conquest of the West during the second half of the nineteenth century to tame nature and embody the conquest of the land, even though it implied transferring agricultural techniques that belonged to the wetter eastern part of the country. Water schemes were designed to develop the resource, rivers were dammed, and canals built to divert rivers, paid for by the federal budget and delivering water that was and still is largely subsidized. Agriculture is flourishing in the arid west, but it is only thanks to the development of what Donald Worster (3) calls a "hydraulic society," where water is the main resource and cements the very fabric of the economy and society. This explains why, today, it is still a very political and emotional issue fiercely debated, although the age of large-scale dams and developments seems to be gone.

WATER WITHDRAWALS

The geography of water withdrawals for irrigation (Fig. 6) confirms the dominant role of irrigation in agriculture in the West: large withdrawals take place in this part of the country in every state but a few of them and reaches levels as high as 70.1 billion m^3/year in California (see Table 3).

But the geography of water withdrawals also shows that eastern states withdraw appreciable volumes of water for irrigation: Florida, of course (9.1 billion m^3/year), largely because of the fruit and sugar industries; but also Georgia (2.2 Bm^3/year); North and South Carolina (cotton, peanuts, corn, tobacco); New Jersey; Massachusetts (0.33 Bm^3/year); and Michigan. In the three latter states, large water withdrawals are largely accounted for by the redevelopment of fruit and vegetable cultures for nearby urban markets. Central States in the Missouri/Mississippi basin also use significant water for irrigation: Nebraska (14.4 Bm^3/year), Arkansas (13.3 Bm^3/year), Kansas (5.7 Bm^3/year), Mississippi (2.1 Bm^3/year), Missouri (2.1 Bm^3/year), Louisiana (1.8 Bm^3/year), and Oklahoma (1.2 Bm^3/year).

Some states rely heavily on groundwater for irrigation. In the lower 48 states, 19 states rely on groundwater for more than 40% of irrigation withdrawals; levels are as high as 49.7% for Montana and 49.1% for Kentucky. On the other hand, 17 states pump less than 30% of their irrigation water from aquifers. Reliance on groundwater is not connected to the size of the withdrawals; states along the lower Mississippi and Missouri basins and around the Great Lakes tend to pump a larger proportion of their irrigation water from surface water.

As a result of the huge withdrawals taking place in the West for irrigation, shares of irrigation water in total freshwater withdrawals (Fig. 7) are nearly always above 60%, except for Kansas (56.3%), Oklahoma (40.7%), Texas (34.8%), and North Dakota (12.7%) (Table 4).

In the eastern United States, the share of irrigation is consistently below 15%, except for Arkansas, Florida, Mississippi, Georgia (17.8%) and Missouri (17.4%), and is less than 1% in 12 states (Indiana, Vermont, Kentucky, Iowa, Virginia, New York, Alabama, Ohio, Tennessee, Pennsylvania, West Virginia, and the District of Columbia). Thus, although it is developing fast in the eastern part of the country and may at times in specific places, represent a problem for water supply in the summertime, irrigation remains by far the major demand sector only in the West. This explains the pressure exerted on ground or surface waterbodies by environmental problems such as the overexploitation (Colorado River)

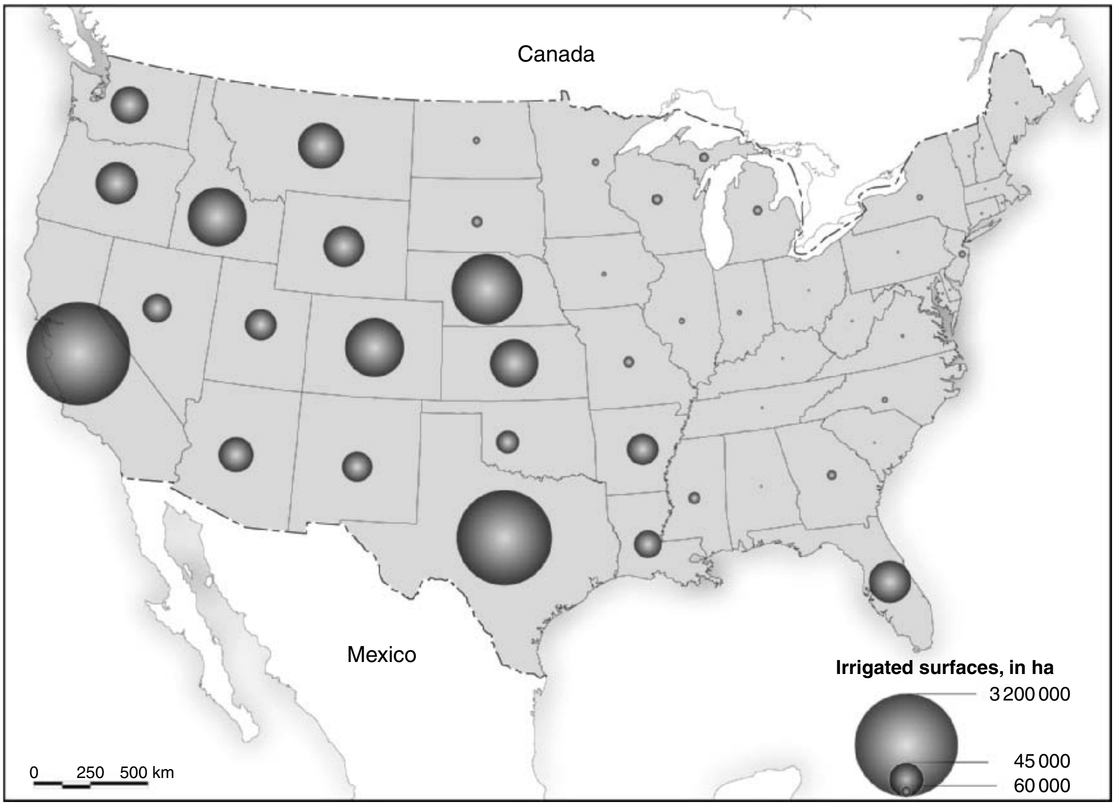

Figure 3. Irrigated surface per state, 1974.

or the salinization of rivers (such as the Gila River). It also entails a developing political debate as to whether the sharing of the resource should leave so much subsidized water to the agriculture sector, as thirsty cities and industries have begun buying up expensive water rights from farmers to satisfy their fast growing needs.

FARMING AND IRRIGATION TECHNIQUES

The agricultural sector displays a contrasting picture, as can be seen in Fig. 8. If absolute water withdrawals for irrigation are very large in the West and if agriculture there remains by far the largest demand sector, the share of irrigated land in total farmland is not necessarily dominant (Table 5).

California, Arkansas, and Mississippi are the only states whose share of irrigated land represents more than half of the total exploited land. The extent of fruit and vegetables crops in California, as well as cotton growing in the Mississippi valley, accounts for such high shares. Strong fruit and vegetable cropping (Washington, New Jersey, Michigan, Florida, Delaware), sugar (Florida), potato (Idaho), tobacco and peanuts (Georgia) are, in their respective states, dominant cultures where irrigation is extensively practiced, to enable cropping (as for most cultures in the West) or to reduce, even eliminate, the financial risk that could stem from poor rains in an otherwise pluvial agriculture.

Table 3. Top Twenty States for Irrigation Water Withdrawals, 2000 (in Billion Cubic Meters per Year)

Arkansas	65.17
California	65.90

These risk-averse farming sectors partly explain why the water application rate per surface unit can be so high in the more humid East (Fig. 9). The low cost of water is certainly a factor, but it rather accounts for profligate rates in the West, as water remains heavily subsidized in this part of the country, whereas farmers in the East, who produce high-value crops such as fruits and vegetables, reason that the extra water spread in their fields is worth the guarantee that they will not suffer from a few percent loss in their crops because of poor rains (Table 6). This is a consequence of the increasing role of financial institutions in agribusiness, as banks have stepped up their pressure on farmers who, in turn, tend to be willing to spend more on water to avoid potential losses from natural factors.

The cost factor is certainly better reflected in the irrigation technique employed. Irrigation in the East is dominated by the sprinkler technique, an easy-to-implement technology with a higher water productivity than gravity or surface watering. Drip irrigation is also

Table 6. Top Fifteen States for Water Application Rate in Thousand m^3/ha, 2000

State	Rate, 000 m^3/ha

used in Florida (34.1% of volume of water spread), Pennsylvania (20%), Virginia (17.9%), New Jersey (12.3%), New York (10.8%), and Massachusetts (8.3%). But west of the Mississippi or in its lower course, surface irrigation is either dominant or holds a significant share of total water used in fields (see Table 7).

Whereas it is well-documented that its water productivity is low (<40%), in water-scarce areas, the extent of surface irrigation definitely implies improvement potential but points to a major political problem, the very low cost farmers still pay for water carried by expensive water-development projects paid for by all taxpayers in the United States. Fees collected by irrigation districts often do not even pay for the direct costs of moving the water from the dams to the fields, let alone refund the investment.

Table 7. States Where the Share of Surface Irrigation is Greater Than 30%, 2000

State	Share, % of Total Water Used for Irrigation
Louisiana	88.30
Arkansas	86.03
Wyoming	83.10
Arizona	79.82
Montana	70.93
Nevada	70.48
Mississippi	68.03
Colorado	65.29

Oregon	46.08
Florida	40.73
Texas	36.83
Idaho	34.67
West Virginia	33.33

The low share of sprinkler and drip irrigation in water-scarce areas creates a large productivity improvement potential. Converting a fraction of surface-irrigated fields into sprinkler-irrigated fields could vastly reduce the water application rate. There is a significant relation in the West between a large share of surface irrigation and high application rates. Turning to a more sprinkler-intensive agriculture could reduce water withdrawals and consumption and help relieve the region from the ongoing, bitter, water-sharing debate. But this cannot be done by mere campaigns in favor of more effective watering techniques; farmers are well-aware of them. The issue again boils down to the pricing of water, which is definitely a question that most politicians would not want to tackle directly.

Broadening the topic, these observations underline the structure of water use that agriculture has developed in the United States as of 2000. In the East, a burgeoning and fast-growing irrigation sector relies on water-saving techniques but can use water generously. This water use does not stem from climate constraints, but from financial reasoning, avoiding risk and increasing surface productivity. In the West, water use in irrigation was the only way to develop intensive agriculture, with crops imported from Europe or the more humid East. But, because of the history of agricultural development, water prices still prevent the adoption of more efficient irrigation techniques. In the context of a slow erosion of irrigation in the West due to rising competition for water from cities and the industry and also due to unsustainable water withdrawal rates in several river basins and/or aquifers, it is important to take into account the improvement potential that agriculture displays in its water use. Massive water diversions are probably not necessary because agriculture, by far the main water user in the West, can reduce its consumption by turning to more efficient irrigation systems. But this comes at a cost.

IRRIGATION WELLS

Muhammad Nadeem Asghar
International Water
Management Institute (IWMI)
Lahore, Pakistan

In arid and semiarid areas, rainfall is markedly variable in magnitude, time of occurrence, and spatial distribution. Irrigation is required to meet the demand of agriculture, but surface water supplies are also characterized as scarce and unreliable. Consequently, farmers consider it necessary to create a dependable water supply, which is adequate and in a desired location. This management option has spurred farmers to develop the technology of irrigation wells.

History started with the development of irrigation wells to be used for lifting water from rivers (surface water), surface storage (rainfall), and subsurface dug holes (underground water). The discharge rates of such irrigation wells depend on the capacity of the lifting devices.

As pumps were introduced, a boom in another kind of irrigation well occurred to exploit underground water for irrigated agriculture. Promising technologies of irrigation wells include tube wells, skimming wells, dug wells, and radial wells. The discharge rates of these irrigation wells depend on the capacity of the lifting devices and also on the hydrogeologic characteristics of the aquifer.

A tube well has a single strainer that penetrates vertically into the aquifer and operates under suction to extract groundwater at a discharge rate usually greater than 28 L/s. In unconfined aquifers that have fresh groundwater lenses underlain by saline groundwater layers, these wells are prone to extract groundwater of deteriorated quality due to upward movement of saline groundwater that enters the well screen. The thickness of these fresh groundwater lenses varies from a few meters to more than 30 meters, depending on the recharge source. In the surroundings of canals and rivers, this thickness can be more than 30 meters. The diameter of tube-well strainers is usually greater than 10 cm. The greater the thickness of the fresh groundwater lens, the higher the possibility of extracting greater discharge, which requires a larger diameter pipe for the strainer. This type of irrigation well, however, can extract groundwater without the problem of deteriorated quality provided that the well penetrates at less than 60% of the depth of the fresh groundwater lens and its operating time does not exceed 6 hours in any day (1).

For unconfined aquifers where the thickness of the fresh groundwater lens is less than 25 meters, skimming wells are introduced. This type of irrigation well is multistrainer, spread at some horizontal distance from the suction point, and these strainers are joined to a common pump. Like tube wells, the strainers in skimming wells penetrate vertically into the aquifer. However, designing a skimming well to include four to six strainers of 5 cm diameter that spread at a 1.5-m horizontal distance from the suction point makes the design cost-effective and minimizes operation and maintenance requirements. These strainers should be installed at less than 60% of the depth of the fresh groundwater lens of the aquifer. To reduce the risk of quality decline, its operating time should also not exceed 6 hours in any day. This type of irrigation well also works under suction and can usually extract groundwater at discharge rates less than 28 L/s (2).

Dug wells can be used to extract fresh groundwater from aquifers when thickness of fresh groundwater lenses is less than fifteen meters. Depending on the well diameter, there are two kinds of dug wells found in various parts of the world; small dug wells and large dug wells. In both dug wells, groundwater gathers under gravity, and pumps are used to extract this groundwater. Dug wells are mostly suitable for smallholder irrigated agriculture.

A large dug well has a diameter large enough for workers to enter it for construction and maintenance. This type of irrigation well can be dug as deep as 90% of the depth of the fresh groundwater lens of the aquifer and can still avoid the risk of entering the underlying saline groundwater at the bottom of the dug well (3).

A small dug well, on the other hand, has a diameter too small to enter and is constructed from the ground surface using special tools. The treadle pump, which is a human-powered pump, also uses this type of irrigation well as a source of groundwater. For small-scale irrigation, these pumps were first introduced into Bangladesh in the early 1980s, and they are now making their mark in Africa (4).

Radial wells are also multistrainer wells. Unlike tube wells and skimming wells that have vertically installed strainers, radial wells have horizontal strainers. These strainers facilitate skimming a very thin (even less than 3 meters) fresh groundwater lens as they provide large discharges per unit of drawdown—a desirable feature to avoid upward movement of saline groundwater (5). These strainers (usually of 5 cm diameter) can be joined directly to the sump—a collection dug hole, or they are first connected to collector pipes (usually of 10 cm diameter), and then these pipes are joined to the sump. Groundwater comes under gravity to these horizontal strainers, and pumps are used to extract it from the sump. This type of irrigation well, which is an innovative and modern type of dug well, can also be used to support smallholder irrigated agriculture.

Washington, District of Columbia

INTRODUCTION

Many owners of agricultural lands, particularly those at the urban fringe, face strong pressures to convert their lands to residential or commercial uses. If these forces of change occurred in an environment of perfectly functioning markets, then there would be no economic problem or failure and no economic justification for public policy in the form of planning. We would simply observe the optimal rate of land conversion to reflect societal preferences and changes in income and population over time. However, the forces contributing to agricultural land conversion are rife with informational and policy- driven distortions in both agricultural and nonagricultural land markets, among them, zoning and other local policies that encourage development and inflate land values beyond the reach of agriculture, high-risk and low-economic returns to commodity production, higher incomes and the provision of health insurance in off-farm occupations, unintended consequences of state and federal farm and nonfarm policies, and improvements in telecommunications and in other infrastructure that mute the cost advantages of urban living. Moreover, agricultural lands provide many types of value to landowners, private citizens, communities, and society at large that are not reflected in the market value of agricultural products or in the capitalized value of those products in establishing land lease and sale prices. As a result of both supply- and demand-side dynamics, the market for agricultural land usually fails to reflect social values. Therefore, public policy in the form of some sort of land-use planning is justified.

The American public values agricultural land for many reasons (1,2), beyond its ability to produce food, fiber, and timber. These include curbing negative impacts of ill-managed growth; providing flood control; improving water quality; maintaining groundwater rechargeability; mitigating air pollution, ozone, and greenhouse gas emissions; providing community buffers or greenways; reducing traffic congestion; and easing the fiscal burden of public services. Such values can be reflected within a community by the relative intensity of alternative development; the opportunity for public goods and services, such as parks and trails; wildlife habitats, scenic views, and recreational opportunities; and proximity to urban dwellers (see, for a variety of sources, Ref. 3).

Public values for agricultural land preservation have translated into public support for establishing agricultural land preservation programs at the local, state, and federal levels. A mixture of both regulatory (4,5) and incentive-based approaches (4,6) have resulted in the permanent protection of nearly 1.5 million acres of agricultural land from conversion to nonagricultural uses (7) and the concentration of millions of more acres in agricultural production through zoning. Agricultural land protection through the various tools of land-use planning is a complex issue and process. This article provides only a glimpse of fundamental approaches and resources available for agricultural land-use planning and preservation.

AGRICULTURAL LAND USE PLANNING ISSUES

What land should be preserved and for what purposes? What level of private and public resources should be made available for fee simple land or development rights purchases? How should priorities be set to protect critical and sensitive areas with limited private and public funds to achieve the best results? Both private and public institutions must address these questions and concerns.

Agricultural land-use planning and preservation constitutes sensible resource management for sustainable agriculture and more broadly for sustainable development. It also stands on its own as a local, state, or national policy goal to mitigate land fragmentation and haphazard development. Various tools, resources, and model programs are available to facilitate agricultural land-use planning and preservation. Each person and community has unique goals, challenges, and collective knowledge that will determine the appropriate mixture of tools to guide its private and public actions in crafting effective local land-use management and policy (8).

Flexibility and knowledge in local conditions are the most pervasive features of successful programs to preserve lands for multiple functions meeting agricultural operations, managing land use, and achieving environmental, social, and economic vitality objectives (4). Scientists and educators at the land-grant universities provide research-based information, analyses, and educational programs that will help facilitate this process at the local and state levels.

Public programs for agricultural land-use planning and preservation may benefit both landowners and the general public. Agricultural land-use planning and preservation programs may be motivated to preserve production agriculture for national food security or for local food choice reasons. In this case, the following are many of the key characteristics typically considered to prioritize land parcels chosen for preservation:

1. Soil quality and productivity
2. Agricultural infrastructure
3. Farming methods, including conservation practices
4. Unique or critical land quality
5. Imminent threat of conversion
6. Critical size of a parcel for a viable agricultural operation
7. Proximity to other protected land for a critical mass to achieve effectiveness
8. Importance to local agricultural and economic vitality (9,2).

Alternatively, the public may be more concerned with issues related to urban growth pressure or preservation of ecological integrity and cultural resources (10). They may perceive preserving agricultural land as a way to sustain community values, lifestyle, or its natural and cultural heritage. In this case, land preservation programs may rank land parcels by the ability to provide direct environmental or economic benefits of open space and scenic beauty, economic opportunity, such as agro-tourism, wildlife habitats, community buffers or greenways, source water or watershed protection, clean air or carbon sequestration, historical or cultural significance, recreational opportunities, such as hunting, curbing current and anticipated development pressure, and/or complementary community practices, such as agricultural zoning and growth management (1,11).

NATIONAL, STATE, AND LOCAL AGRICULTURAL LAND PLANNING AND PRESERVATION PROGRAMS

U.S. Department of Agriculture (USDA)

Public interest in agricultural land protection, especially against fragmentation and haphazard development, has increased steadily since the 1950s. As this interest has grown, the preservation toolbox has expanded from local and state to the federal level. USDA programs designed to preserve working agricultural landscapes include the Farm and Ranch Lands Protection Program (FRPP), the Forest Legacy Program (FLP), and the Grassland Reserve Program.

The FRPP (www.nrcs.usda.gov/programs/FRPP) leverages federal funds with state and local funds to purchase conservation easements on prime and locally important or unique land by limiting conversion to nonagricultural uses. The FLP (www.fs.fed.us/spf/coop/programs/loa/flp.shtml) establishes partnerships between the Forest Service (USFS) and state forestry agencies to protect environmentally important private forestlands from conversion to nonforest uses. Through conservation easements or rental agreements, the GRP (www.nrcs.usda.gov/programs/GRP) protects and restores grasslands from conversion to cropland and other nonagricultural uses and enables viable ranching operations to restore plant and animal biodiversity.

Many state and local ranking systems are based on variations of the federal Land Evaluation and Site Assessment (LESA) system (www.nrcs.usda.gov/PROGRAMS/lesa/index.html). LESA encompasses a portfolio of land attributes to estimate the relative value of agricultural land. LESA provides a framework to measure the merits of keeping individual parcels in agricultural operation based on local preservation objectives. LESA recently has been tied to GIS technology to facilitate mapping and planning scenarios.

State and Local Programs

Over the past 50 years, public organizations at the state and local levels have used a variety of tools to preserve agricultural land. Examples of these tools include differential tax assessment programs, agricultural district programs, right-to-farm or nuisance protection laws, transfer of development rights (TDR) programs, purchase of agricultural conservation easements—also known as development rights (PACE or PDR) programs—growth management or urban boundaries and agricultural zoning, among a variety of other tools. Private organizations such as land trusts also have gotten involved, typically by accepting donated conservation easements or facilitating the process for landowners to sell easements to a public program.

Beginning in 1956 with the inception of Maryland's differential property tax assessment program, today every state except Michigan has a differential property tax assessment program that assesses agricultural land based on its use value, instead of its fair market value. The program either reduces property taxes on agricultural lands or defers taxes for as long as the land remains in agriculture. Michigan, Wisconsin, and New York also have programs to allow farmers to claim income tax credits to offset their local property tax bills.

California enacted the first agricultural districts law in 1965, commonly known as the Williamson Act. Landowners are allowed to create "agricultural preserves" areas. New York was the first state to create a comprehensive agricultural district program to protect farmland and support the farming business. Agricultural district programs are authorized in 16 states (7) to create legally recognized geographic entities where agricultural activities and their land bases are encouraged and protected. In addition, all 50 states have nuisance protection statutes (also known as "right-to-farm" laws) for agricultural operations.

In 1967, Boulder County in Colorado (www.co.boulder.co.us/lu) established a TDR program to protect agricultural lands and open space. This program enables landowners to transfer the development rights on one parcel of land to another parcel of land, such as from an agricultural zone to designated higher density development areas. Besides maintaining working agricultural landscapes, TDR programs may be designed for multiple purposes, such as to conserve environmentally sensitive areas or preserve historic landmarks. As of 2000, Montgomery County in Maryland had more than 40,000 acres, which accounted for 60% of the national total, enrolled in the TDR program (7).

In 1974, Suffolk County in New York enacted the first PACE (also known as purchase of development rights, PDR) program. King County in Washington and the states of Maryland, Massachusetts, and Connecticut quickly followed suit. PACE programs are voluntary on the landowner's part and permanently protect agricultural land by removing the development rights. As of 2004, PACE programs operate in 23 states, including 19 statewide and more than 45 local programs (7). Five additional statewide programs have been authorized to acquire easements but have not purchased any to date. In particular, local PACE programs are expanding probably because of incentives from the federal FRPP, which provides matching funds to support local, state, and private easement acquisitions, as well as from landowner and community interest in saving land for agriculture. From 2000 to 2004, the number of local PACE programs increased 32% (7).

Programs at the local and state levels take a variety of forms. Communities need to use a combination of tools and techniques as part of a comprehensive effort to plan for appropriate land use and protect agricultural land. Examples of other common tools that communities use include comprehensive planning; agricultural zoning; limitations on infrastructure, regional tax sharing; urban growth boundaries and growth management; and agricultural viability and economic development programs. Information on conservation easements, private conservation and donation, and local land trusts can be found at the Land Trust Alliance (LTA) (www.lta.org). Information on farmland protection and stewardship can be found on the Farmland Information Center (FIC) (www.farmlandinfo.org), which has a series of fact sheets on farmland protection tools and an extensive collection of local and state land-use and land preservation laws, statistics, and literature.

Examples of statewide PACE programs include California (www.consrv.ca.gov/DLRP/index.htm), Maryland (www.malpf.info), Michigan (www.michigan.gov/mda/0,1607,7-125-1567_1599—, 00.html), Pennsylvania (www.agriculture.state.pa.us/farmland/cwp/view.asp?a=3&q=122454&agricultureNav= |4451|), and Vermont (www.vhcb.org/conservation.html). Prominent local PACE programs can be found in Boulder County, Colorado (www.co.boulder.co.us/openspace); Montgomery County, Maryland (www.mc-mncppc.org/legacy_open_space/index.shtm); and Lancaster County, Pennsylvania (http://www.co.lancaster.pa.us/planning/site/default.asp).

Land-Grant Colleges and Universities (LGUs)

Many programs related to agricultural land preservation may be found in the Land-Grant University System, including general national level programs in applied research and outreach education, specific endowed chairs in land-use and planning, and regional or state level programs addressing land-use policy and planning.

Each U.S. state and territory has at least one land-grant university (LGU) (www.csrees.usda.gov/qlinks/partners/state_partners.html), including state agricultural experiment station(s) and a state cooperative extension service. Both the agricultural experiment stations and the nationwide Cooperative Extension Service (www.csrees.usda.gov/Extension/index.html) have a long history of engagement in research, teaching, education, extension, and outreach on issues surrounding land use and policy. Information on land-use management and policy (www.csrees.usda.gov/nea/nre/in_focus/ere_if_nercrd.html) can be found on the CSREES website. Researchers at the USDA's Economic Research Service (ERS) (www.ers.usda.gov/Topics/view.asp?T=103610) also conduct economic research on land-use policy issues.

The increasing importance and complexity of land-use issues have led to the establishment of two endowed chairs at LGUs: (1) the C. William Swank Rural-Urban Policy Chair at the Ohio State University (aede.osu.edu/programs/Swank); and (2) the John Hannah Distinguished Professor in Land Policy at Michigan State University (www.landpolicy.msu.edu). Both land-use endowed chairs provide substantial leadership at the state and national levels to address these complex issues through research, education, extension, and outreach (12).

Examples of land-use programs at LGUs include the University of California at Davis (aic.ucdavis.edu/research1/land.html), Colorado State University (dare.agsci.colostate.edu/csuagecon/extension/pubstools.htm#LandUse) (13), Michigan State University (ntweb11a.ais.msu.edu/luaoe/index.asp), the Ohio State University (landuse.osu.edu/), Pennsylvania State University (www.cas.nercrd.psu.edu/Land_use.htm), Purdue University (www.ces.purdue.edu/anr/landuse/), University of Wisconsin (www.uwsp.edu/cnr/landcenter), and University of Wyoming (www.uwyo.edu/openspace).

Nongovernmental Organizations

For landowners, one of the most common ways to permanently preserve their agricultural land is to donate a conservation easement to a qualified conservation organization or public entity. If donating the entire easement value is not feasible, landowners can make a partial donation. According to the LTA (www.lta.org/aboutlt/census.shtml), more than 1260 local and regional land trusts were operating in the United States in 2000 and had collectively preserved more than 6.2 million acres of land and other natural and cultural resources. Information about local and state growth management, land-use planning, and agricultural land preservation in general can be found at the American Farmland Trust (AFT) (www.farmland.org), the American Planning Association (www.planning.org), the Smart Growth Network (www.smartgrowth.org), the Sprawl Resource Guide (www.plannersweb.com/sprawl.html), and the Lincoln Institute of Land Policy (www.lincolninst.edu/indexhigh.asp).

Increasingly, in partnership with local, state, or federal programs, many nongovernmental organizations (NGOs), especially land trusts, work to preserve agricultural lands and open space. Until recently, except in California, most NGOs accepted donated conservation easements. As the 2002 Farm Bill made qualified NGOs eligible to receive federal funds, land trusts have since increased in purchasing agricultural conservation easements. Most land trust activities take place at the local and state levels, such as the Colorado Coalition of Land Trusts (www.cclt.org/) and Sonoran Institute (www.sonoran.org/index.html). However, prominent national organizations working on land preservation include the AFT (www.farmland.org/), the LTA (www.lta.org/), and the Trust for Public Land (www.tpl.org).

CONCLUDING REMARKS

Agricultural land policy and protection is a pressing issue of public concern. The failure of land markets to reflect the social value of extensive land uses relative to intensive uses and the irreversibility of land-use intensification decisions create a particularly fluid and pressing policy environment for lay people, land-use practitioners, and researchers alike. Federal, state, and local governmental agencies and nongovernmental organizations of various scales are engaged in land-use planning as are researchers and outreach educators at many Land Grant Universities throughout the United States. In this article, we have provided a brief overview of the issues and resources and ongoing programs directly influencing agricultural land protection and land-use policy. We have taken pains to point to many of the resources currently available on the Internet, recognizing that this is an area of inquiry characterized by rapid change and development. As such, traditional print resources, although valuable, cannot be expected to keep pace with the inchoate informational environment found within the agricultural land-use planning and protection arena. Interested readers are encouraged to consult the prominent individual practitioners, program managers, and researchers in the field to benefit from the most up-to-date information available.

WATERLOGGING

Suresh K. Gupta
CSSRI
Karnal, Haryana, India

According to Clayton, land is waterlogged if the water table is within ± 150 cm of the natural surface. A modification to account for the yield of the crop was made and decided to term a land waterlogged if the yield is reduced to 25% of the optimum value due to a rise in the subsoil water. A committee constituted by the Central Water and Power Commission (India) defined waterlogging on the basis of a definition proposed by Kuntze. According to this definition, an area is said to be waterlogged when water stagnates on the land surface or the water table rises to an extent such that soil pores in the root zone of crop become saturated, resulting in restrictions in the normal circulation of air, a decline in the level of oxygen, and an increase in the level of carbon dioxide. Due to its simplicity, the definition proposed by Clayton has been adopted in many countries, and apparently it accounts for both surface and subsurface waterlogging. Thus, the word waterlogging is used to designate stress due to water stagnation or a shallow water table because similar conditions could occur as a result of any of the two causative factors. However, to designate the problem of water stagnation on the land surface, besides waterlogging, surface stagnation and flooding have also been used synonymously. Deep submergence depths caused by floods are generally excluded from waterlogging because the causative factors as well as the solutions to such a problem could be different.

VISUAL OBSERVATIONS FOR PROBLEM IDENTIFICATION

The assessment of the degree and extent of waterlogging can usually be made through simple observations, interviews with local officers of the agricultural and irrigation departments, discussions with agricultural technicians and farmers, through communication, and possibly some field measurements. Field reconnaissance is necessary to find out if the problem exists. Look for the following to arrive at a reasonable conclusion.

- Standing water or wet spots in parts of the field where the crop stand is poor. Standing water in low spots after a prolonged dry period is a useful indicator of the problem.
- Observe wells, gravel pits, and deep channels, which show the depth to groundwater. In India, the water table in open wells is commonly measured and reported. If there are few wells, then install pits or auger small observation wells into the soil to depths of 1–2 m below the soil surface. If soil horizons are reached which are gley, wet, and may contain black or red mottles, one can assume that soils are poorly drained at this level (1).
- Vegetative cover is a good index to the depth to the water table in many areas. Certain grasses/crops and trees are more common in waterlogged lands. It is a useful practice to look for these features while surveying. Trees such as willows, cottonwood, and poplar often thrive in high water table areas. Reed grass and sedges are also common.
- A general yellowing of the crop is noticed in areas that are affected by surface stagnation or have a high water table.
- Salts in the form of a white crust on the soil surface reveal the problem of waterlogging. Since the problem could occur even when the crust is not present, so its absence does not mean that there is no problem of waterlogging.
- Absence of surface drains or their condition (full of vegetation or plugged up) could also indicate a problem of waterlogging/drainage.

FIELD MEASUREMENTS TO ASSESS THE PROBLEM

In the field, waterlogging is measured/assessed through physical measurement of the depth to the water table using open wells, tube wells, or observation wells. The depth to the water table in the range of 0–1.5 m would usually indicate a problem of waterlogging, although it would depend upon the soil and crop characteristics. A relatively shallow water table may not be a problem in a coarse-textured soil, but even a relatively deeper water table could cause a problem in a fine-textured soil.

In the field, the oxygen diffusion rate (ODR) is a good measure of oxygen deficiency. ODR is measured with an oxygen diffusion rate meter. Measurements are usually made at a 10-cm depth replicated at 5–10 locations. Stolzy and Letey (2), in a review on plant response to measured ODR, concluded that the roots of many plants do not grow in soils with ODR values of $20 \times 10^{-8}\ \mathrm{g\,cm^{-2}\,min^{-1}}$. For germination and emergence of seeds, minimum ODR values of the order of $40\text{–}80 \times 10^{-8}\ \mathrm{g\,cm^{-2}\,min^{-1}}$ are mentioned. The values of ODR that indicate adequate aeration are in the range of $20\text{–}35 \times 10^{-8}\ \mathrm{g\,cm^{-2}\,min^{-1}}$ (2).

The oxidation–reduction potential (redox potential, RP) of the soil is also used as an indicator of the problem of waterlogging. In practice, the RP of the soil is measured with an oxygen meter using an Ag–AgCl reference electrode. The readings can be converted relative to the standard hydrogen electrode by adding 222 mV. As long as O_2 is present in a significant amount, the RP remains high (800–900 mV). The oxidation–reduction potential for reduction of NO_3^- to NO_2^- is 420 mV at pH 7 and 530 mV at pH 5. Nitrate is readily reduced to N_2O or N_2 at these oxidation–reduction potentials.

CAUSES OF WATERLOGGING

A large number of factors combine to create the problem or affect the degree of the problem of waterlogging. Geomorphic features like palaeochannels, local depressions, lower elements of slopes, and flat flood plains are invariably subject to varying degrees of waterlogging. Unfavorable topography of the terrain has a profound effect on the magnitude of the problem. Climatic conditions such as heavy rainstorms, a characteristic of monsoon climatic regions, coupled with poor natural drainage and/or poor upkeep of the drainage system result in surface stagnation of water. Development activities such as construction of roads, bridges, railway lines, and buildings result in choking of natural drainage thus aiding surface stagnation and a rise in the water table. Soil texture and structure having direct bearing on water storage and transmission could cause surface stagnation of water. Formation of a hard layer at plow depth in rice–wheat rotation prolongs the surface stagnation of water, especially in areas of poor on-farm water management. Prolonged heavy precipitation and a high water table resulting in reduced absorption of rainwater is a sure prescription for surface water stagnation. Increasing encroachment of wetlands for developmental activities compounds the situation.

Many factors that result in surface stagnation aid the buildup of the water table in a region. However, a rise in the water table is an inevitable consequence of introducing surface irrigation through the interbasin transfer of water. Several factors together determine the rate at which the water table would rise in a given setting. Sources of excess soil water that result in high water tables include high precipitation in humid regions, surplus irrigation water and canal seepage in irrigated lands, and artesian pressure. The geomorphologic setting of an area and the presence of impervious substrata/hard pan such as clay pan, calcic layer, duripan, or fragipan could obstruct the downward movement of water and cause short-term waterlogging. If such conditions persist for long, the land might develop a perched water table.

EFFECTS OF WATERLOGGING

Both air and water in appropriate proportions are essential for plant growth. Disturbance of the delicate balance between these two components as a result of waterlogging results in poor aeration. Except for winter conditions, an air-filled porosity of less than 10% is considered to indicate inadequate aeration. Because gases in general, diffuse about 1000 times more slowly in water than in air (3), this causes an imbalance in the proportion of oxygen and carbon dioxide in the root zone. This imbalance manifests its effect on the physiological processes of the plants and on the nutrient status of the soils. The chemistry and microbiology of submerged lands is quite different from the chemistry and microbiology of nonsubmerged lands (4). This can affect the availability of many nutrients. For example, nitrogen can undergo denitrification more readily and be lost to the atmosphere as a gas. Leaching of plant nutrients could also result in their nonavailability to plants. The anaerobic (reducing) environment results in changes that can result in deficiencies (reduced uptake) or toxicities (excess). For example, the increased availability of silicon apparently decreases the uptake of iron, whereas sulfide, ferrous, and manganese ions accumulate in waterlogged soils. The important inorganic and organic compounds that are produced in submerged soils are iron, sulfides, and organic acids. Ponnamperuma (4) reported that the level of ferrous iron in submerged soils often exceeds 3000 ppm. Such levels could be toxic to rice plants, although the degree of toxicity may depend upon the pH and the presence of hydrogen and ferrous sulfide. Soil sulfate under highly reduced conditions as might occur in submerged land is reduced to H_2S. Some of the organic acids such as acetic, propionic, and butyric are found in submerged soils; acetic acid is the most abundantly available carboxylic acid. These acids are toxic to rice seedlings.

All biological processes are strongly influenced by soil temperature. Waterlogged soils have a large heat capacity and therefore, are relatively colder than dry soils. Crop growth in waterlogged soils, therefore starts later and is slower than in dry soils.

The unconfined compressive strength of a soil is exponentially related to the moisture content. Water content is the chief factor determining the strength and also the deformation characteristics of cohesive soils. As a result, dry soils can support heavy loads because of the rigidity of the individual soil particles and the high internal friction of the soil mass. At high moisture content, the soil is susceptible to plastic deformation and consolidation. With increasing soil moisture, it loses its load-bearing capacity altogether. As a result, heavy machinery cannot be employed on waterlogged lands. A direct consequence of this would be delays in the sowing/harvesting operations of crops. To manipulate the soil without compaction or puddling, the moisture content of the soil must be below some critical level, depending upon the soil type. Compared with sand, clays have a narrow range of water content in which tillage will readily break the soil. The timeliness of the operation significantly affects the yield of crops in humid regions and in soils that have high clay content. Even the quality of the crop is affected because of the delay in harvesting.

Besides what has been stated before, excess water and the resulting continuously wet root zone can lead to some serious and fatal diseases of the root and stem (5).

It is now apparent that the adverse effect of temporary waterlogging depends not only on plant species but also on the physiological stage of growth, the time and duration of waterlogging, the light intensity, the temperature, and the fertility of the soil. Injury to crops is particularly severe when crops are flooded on hot days. The ill effects are generally greater if the waterlogging conditions are accompanied by salinity/sodicity. It is now known that no single factor affects crop yield in waterlogged soils. Generally, it is a combination of poor aeration, reduced uptake of plant nutrients, imbalance between the uptake of various ions, and the toxic effects of various elements/cations.

The ill-effects of surface stagnation of water and a high water table extend beyond the agricultural sector. The anticipated adverse effects of waterlogging are listed in Table 1.

SURFACE STAGNATION AND CROP YIELDS

Excess water in the crop root zone is injurious to plant growth. Crop yields are drastically reduced on poorly drained soils, and in cases of prolonged waterlogging,

Table 1. Anticipated Losses due to Waterlogging

Agriculture	Landscape and Infrastructure	Socioeconomic
Decline in agricultural production	Damage to infrastructure	Increased socioeconomic disparity
Restriction on crops	Landscape degradation	Increased expenditure on health related services
Decline in product quality	Decline in ecosystem health	Migration from rural to urban areas
	Damage to soil health	Increased gender disparity

plants eventually die. Crops vary in their tolerance to surface stagnation. Considerable variation in waterlogging tolerance exists between and within species (6,7). Some crops thrive if water stagnates on cropped land. Lowland rice is one such fine example. However, most dry foot crops are adversely affected, and their yields are reduced. The late Arthur Hodgson, considered a world leader on the topic, extensively and intensively studied the effect of surface stagnation of water on cotton yield. Williamson and Kriz (8) reviewed experiments on flooding and waterlogging. Their conclusion is that when plants are actively growing, the severity of injury depends on the growth stage and the time of the year at which flooding takes place. The influence of the latter is closely related to soil and air temperatures. The Indian experience, however has been that in semireclaimed alkaline lands, surface stagnation at an early growth stage is relatively more harmful than at later growth stages. It might be due to the fact that most crops are sensitive to salts at early growth stages.

Considerable work has been reported on the flooding tolerance of rice (9–11). The extent of damage or yield reduction as a result of water stagnation depends on the crop tolerance, crop growth stage at which water stagnation occurs (12–15), duration of water stagnation/flooding (16–18), soil type, air and soil temperature, and other agroclimatic conditions. Studies have also been conducted on the imbalance between the uptake of various ions to identify the causes of yield reduction (19–22) and amelioration of adverse effects through additional doses of nutrients (21,23,24).

Because crop conditions vary over time, it would be essential and useful to integrate the degree of surface stagnation and duration to assess adverse effects. Some limited attempts in this direction have been made. In spite of their limitations, these concepts could serve as starting point for more elaborate investigations.

To integrate the effect of excess water and time on crop yield, tomato yields were related to the number of days that the soil is >10 mm wetter than field capacity. It has been shown that, on average, the yield declined by 0.26% for every day that the soil is >10 mm wetter than field capacity (5,25).

Gupta and Pandey (26), following Sieben (27), integrated the effect of depth of surface stagnation on the yield of rice. According to their hypothesis, rice yield might not suffer due to occasional high depths of water stagnation. However, at some time, the yield might start decreasing. According to this hypothesis, the stress due to excess water depth, Ewd, could be expressed as follows:

$$\mathrm{Ewd} = \sum_{i=1}^{n} \sum_{j=1}^{m} (D_{ij} - d) P_{ij} F_j \qquad \text{for } D_{ij} \geq d \qquad (1)$$

in which Ewd is the depth day index, cm days; D_{ij} is the depth of stored water at the ith depth interval and jth crop stage, cm; d is the optimum depth of ponding, cm; P_{ij} are the number of days for which submergence occurs in the jth growth stage, days; m is the number of growth stages; n is the number of days in a given growth stage; and F_j is a constant depending on the stage of growth of a given variety. Using the data reported by Gupta and Pandey (28), it was observed that the crop yield decreases only to the extent of 6.4% at a depth day index of 250 (26). The yield is not reduced until the depth day index is 150. This technique is a powerful tool to work out the severity of waterlogging as well as the actual time to carry out drainage.

Gupta et al. (29), while reviewing the Indian experience in crop yield influenced by the duration of water stagnation, attempted to develop a crop production function as affected by duration of water stagnation. It was found that a piecewise linear model of the same nature reported by Maas and Hoffman (30) fit the studied data sets well. Crops have a threshold duration up to which there is no yield decline till the threshold is reached; beyond that, there is a linear decrease in the crop yield till the duration at which the crop yield is likely to be zero. Gupta et al. (31) confirmed the validity of the model while comparing the production functions for three winter crops. The duration of water stagnation at which decline in yield would be 50%, is 7.2 days for wheat, and it is 7.9 and 12.2 for mustard and barley.

GROUNDWATER DEPTH AND TOLERANCE OF CROPS

Per se, a shallow depth of groundwater is not harmful to plants. Indirectly, it determines the prevailing moisture conditions and therefore has an influence on water supply, aeration, and the heat properties of soils. As such, the yields of most crops are affected when groundwater is shallow. As with surface stagnation, crops also vary in their tolerance to a high water table (Table 2). Lowland rice can thrive on soils that have a shallow water table.

Studies on the Ill-Effects of a High Water Table

Numerous laboratory and lysimeter/field experiments on the effect of water table depth on crop yields have been conducted at various locations. Lewis and Wor (32) reported that orchards in Oregon require, ideally, a water table depth of 180–250 cm, but a higher water table persisting for 3 to 4 days following rain or irrigation does no harm to the plants. Deep-rooting fruit trees tend to suffer most when the water table is close to the surface such that it helps establish a shallow rooting system. Roe

Table 2. Tolerance Levels of Crops to High Groundwater Table (Groundwater at 50 cm)

Tolerance Level	Crops
High tolerance	Sugarcane, potatoes, rice, willow, plum, broad beans, strawberries, some grasses
Medium tolerance	Sugar beet, wheat, oats, citrus, bananas, apple, barley, peas, cotton, pears, blackberries, onion
Sensitive	Maize, tobacco, peaches, cherries, olives, peas, beans, date palm

(33) reviewed the work on yields of vegetables related to water table depth in the eastern United States. The general finding is that a water table from 30–60 cm from the surface is required for most vegetable crops. Penman (34) observed that citrus trees in Australia, remained in healthy condition for the first 8–10 years where a water table was within 120 cm from the surface. Adverse effects appeared thereafter.

Williamson and Kriz (8) provide a good account of the tolerance of crops to a constant water table. The data given agree fairly well with values mentioned by Williamson and van Schilfgaarde (35), Williamson and Carrekar (36), and Feddes (37). In these papers, required water table depths of 60 to 90 cm for sandy soils and 100 to 150 cm for clay soils are mentioned; the depth within these ranges depends on soil type, crop, and climatologic conditions. The relative tolerance of crops to waterlogging has also been listed according to the cause of damage (8). It is now known that the responses of agricultural crops vary genetically and physiologically to the water regime and therefore, crops that are not adapted to a high water table receive a severe setback when roots encounter a high water table. The extent of damage depends upon the crop, the crop growth stage at which high water table conditions occur, the duration of the high water table, the soil type and agroclimatic conditions.

Visser (38) described an intensive survey of prevailing groundwater table depths in The Netherlands. A general crop production function was described as (1) an increasing yield as depth increases at shallow depths, (2) a certain optimum range, and (3) a yield decline at greater groundwater depths. At shallow depths, the crop suffers from lack of aeration, but at greater depths, water deficiency is the cause of yield depression. This kind of crop production function is expected when more or less the same amounts of irrigation are given to crops.

Though accepting this logic, it is now known that the contribution of the water table to meet a part of the crop water requirement should not be overlooked (39,40). By properly scheduling irrigation, the shape of the crop production function could be altered significantly. The actual experience and field results substantiate the observation that using careful management, crop production can be increased even when the water table is shallow. For an equivalent yield of a wheat crop under a different water table, the amount of irrigation needs to be decreased as water table depth decreases. For example, Pandey and Sinha (41) observed that an equivalent yield of wheat could be obtained when the number of irrigation were varied from 0 to 4 as the water table was lowered from <75 cm to 150 cm. No hard and fast rule can decide the optimum depth to the water table for a given crop. The information given in the literature should be treated only as a guideline. To take advantage of the shallow water table contribution to the crop water requirement, controlled drainage has been perfected. It has been shown that controlled drainage helps to reduce water stress at least in low rainfall years and more N use by plants (42,43).

Under field conditions, soil–plant systems vary continuously; evaluating the effect of water table on plant growth would require integration of water table depth over time during the entire growing season.

Sieben (27), when reviewing the results of experimental drainage fields in the Dutch Ysselmeer polders, drew special attention to the influence of high fluctuating winter water tables. He took 30 cm below surface as a critical level and computed so-called SEW_{30} values from

$$\mathrm{SEW}_{30} = \sum_{i=1}^{n}(30 - x_i) \tag{2}$$

where x_i are daily water table depths below the surface. For this computation only x_i values smaller than 30 are taken into account, so that the sum is a measure of the excess over the 30-cm level. Large SEW values generally indicate poor drainage conditions. It seems that at SEW values of 100 to 200, there is a decrease in yield. The analysis also revealed that the tolerance of four crops is in the order of winter wheat > peas > oats > winter barley. The yield of wheat is not adversely affected till this index passes the 200 mark, whereas barley is tolerant to waterlogging only up to an index of 120.

Questions of the validity of this concept have been raised mainly on the basis that identical SEW values do not necessarily imply identical conditions. It is also argued that the concept does not account for the stage of growth at which shallow depths to the water table occur (44). Although, it should be possible to modify the Sieben Eq. 2 to avoid such criticism, yet the nonavailability of data on crop growth stage dependent factors would usually make such modification an academic exercise. A recent attempt to determine crop susceptibility factors for five growth stages for corn and soybean could provide answers to such a criticism (45). These authors also concluded that normalized crop susceptibility factors for wet stress might be roughly approximated for some crops from existing data on yield response to dry stress.

Comparative Assessment of Stress Due to Surface Stagnation and a High Water Table

Several experimental results exist in the literature where adverse effects on crop performance at the same site due to surface stagnation as well as a high water table have been studied (19,46). However, in many studies, it has not been possible to compare the results, as the stress levels cannot be compared. Ahmad et al. (46) however, imposed equivalent stress levels based on Equation 2, as proposed by Sieben (24). At the same stress level due to submergence and depth to the water table of 15 cm, crop vegetative growth and shoot uptake of N, P, and K were significantly less for submergence than due to shallow depth to the water table.

MANAGEMENT AND RECLAMATION OF WATERLOGGED LANDS

Waterlogging is a widespread problem under different agroclimatic conditions, so several options have been field tested to minimize the adverse effects of waterlogging. Among them are land forming (bed plantation, raised and sunken beds); crop selection in favor of tolerant crops; skipping or delaying irrigation so that crops can draw a part of their water requirement from the shallow water table; applying less water per irrigation; cultural practices such as hoeing and weeding, including chemical control of weeds; application of additional doses of nutrients through soil or foliar application, and mulching to minimize secondary salinization. However, note that these are short-term measures and might or might not be useful in each and every case. Therefore, improvement in drainage seems to be essential, as it would be the only permanent solution to the problem.

The lack of drainage or the inadequacy of it is rapidly becoming a major constraint on agricultural production. The productivity of agricultural lands can be sustained only if drainage improvements are undertaken on cropland currently affected by submergence or high water tables. Very often, the natural drainage in an area along with good water management is sufficient to eliminate excess water and to preclude the need for drainage systems. However, there are many situations where surface drainage would be required. In humid regions as well as in monsoon climatic conditions where rain storms of 100 mm or more in one day can be anticipated, even in arid and semiarid regions, surface drainage is an essential prerequisite to avoid water stagnation. Farmers who have heavy textured soils, soils with a plow layer that develops in lowland rice-wheat systems, alkaline lands with poor water absorption characteristics, or those who rely mainly on surface irrigation should have adequate surface drainage facilities to remove excess water. A uniform slope of about 1:1500 is desirable to drain irrigation water or rainfall off a field.

If recharge to the groundwater is more than the discharge and is natural drainage is unable to take care of this recharge, such a situation calls for subsurface drainage. Subsurface drainage may be accomplished either through the construction of open trenches or through buried clay or concrete tiles or perforated pipes. It must, however, be realized that most crops have an optimum depth to the water table for optimum crop yields. If the water table were lowered beyond this depth, there would not be any significant effect on the yield of the crops, and additional investment in intensive drainage would not be beneficial.

WATER QUALITY MANAGEMENT IN AN AGRICULTURAL LANDSCAPE

Marianne McHugh
Michelle Clarke
Julia Duzant
Cranfield University
North Wyke, Devon, United Kingdom

INTRODUCTION

Water quality is important for a wide range of reasons including human health, food production, recreation, and biodiversity. Globally, agriculture exerts big demands and impacts on water supplies. In arid areas where groundwater may be the significant or sole source of water, agriculture can have profound effects on the rate and composition of groundwater recharge (1), while in tropical areas, high annual rainfall levels and the demands of tropical crops mean that water quality concerns are dominated by agrochemicals, untreated wastewater, and eroded sediment (2). In temperate zones, moderate rainfall throughout the year means there are few periods when agricultural activities can take place without some risk to water quality and, consequently, temperate water resources are also at constant risk of contamination from agriculture.

The range of agriculturally derived pollutants that may compromise water quality is listed in Table 1. Delivery of these contaminants to water may be associated with surface water runoff or with the movement of eroded soil particles. Contamination of water in agricultural landscapes also occurs directly, such as when grazing animals enter watercourses for access, drinking water, or shade. The contamination of water has widespread implications for human and animal health, for plant and animal biodiversity, and for safe and economical water industries, including water abstraction, fish farming, and water sports. Because of these implications, the protection and maintenance of water quality is legislated both nationally and internationally. In the following sections, the sources, mechanisms, and mitigation of agriculturally derived threats to water quality are described.

NITROGEN (N)

Nitrogen, as nitrate, is soluble, is retained inefficiently in soils, and is only weakly adsorbed by eroded sediment.

Table 1. Pollutants of Concern Within Agricultural Landscapes (5)

Category	Main Pollutants	Example Sources	Example Environmental Impacts
Soil	Silt, phosphorus, pesticides	Soil cultivation and drainage, overgrazing, outdoor pig systems; diary and beef herds	Silting of river bed gravels damaging fish spawning, invertebrate and plant habitats; excessive turbidity affecting plant growth and fish behavior; excessive sedimentation affecting rooted plants; economic costs to water abstractors; acts as carrier of other pollutants such as P and pesticides
Slurry, manure, dirty water	Organic matter, nutrients, pathogens, ammonia, metals	Slurry and manure storage and application to land; excretion directly to land; runoff from farm yards and buildings; irrigation	Deoxygenation and eutrophication, affecting all aquatic life; blooms of toxic blue-green algae; carrier of pathogens and pollutants
Fertilisers	Nitrate, phosphate	Inorganic fertilizers; slurry and manure	Eutrophication causing ecological degradation; increased water treatment costs
Veterinary medicines	Antibiotics, hormones, growth regulators, parasite control	Slurry and manure application to land; sheep dip application and disposal	Toxicity to aquatic species; contamination of potable supplies
Disinfectants	Halogens, organic chemicals, phosphorus	Use in diaries, pig and poultry housing	Toxicity to aquatic species; contamination of potable supplies; eutrophication causing ecological degradation

Runoff from agricultural farms is therefore a major source of N entering rivers, lakes, and coastal waters, particularly in areas of intensive livestock farming where stocking rates are high and feed is imported. Nitrogen levels in waters draining arable land are also high because of fertilizer inputs (surplus N not absorbed by the crops is discharged into groundwater, fresh water, and coastal waters), and because ploughing encourages organic N mineralization [the process by which organic N is converted to plant-available inorganic N (ammonium) by microorganisms]. Subsurface movement and loss of N also increases with sward age and drainage.

Nitrogen pollution of waters has significant detrimental effects. Apart from acidification due to nitrification of ammonium and the toxicity of various forms of N, the most significant impact is that of eutrophication, described as the most important environmental problem facing aquatic ecosystems in Europe (3). The process of eutrophication in surface waters can lead to a decrease in species diversity, oxygen depletion, increased sedimentation, and increases in toxic blue-green algae. Nitrogen also represents a hazard to human, particularly baby, health when present in drinking water supplies.

Preventing N pollution would require shifting from intensive arable and horticultural land use to extensive unfertilized grassland, which is socially and economically untenable. Therefore, the most effective ways to minimize excessive N leaching from agriculture include switching to organic farming (which would reduce N inputs), using minimum cultivation (which would reduce runoff generation), and planting a cover crop (such as rye or mustard) after harvest and before the next crop (which would reduce runoff generation and increase N uptake). Additional beneficial management practices include choosing high yielding crops to maximize uptake of N, calculating fertilizer requirements making allowance for existing soil N and organic amendments, avoiding unnecessary fertilizer applications, applying fertilizers away from watercourses, maintaining disease-free crops (as these cannot use N efficiently), and practising careful irrigation to avoid runoff. Alternatively, a curative approach of blending water with low N supplies or biological or chemical treatment to encourage denitrification may be employed (4), although this approach is more costly and less effective than preventing N pollution in the first instance.

PHOSPHORUS (P)

In the United Kingdom more than 50% of P entering surface waters is now thought to be derived from agriculture (5). There are three sources of P available in the landscape for mobilization and transfer to water bodies:

1. Soils contain different background levels of P and, therefore, different levels of P sensitivity to natural transfers in both soluble and sediment-laden forms through runoff and subsurface water flows. Transfer rates depend on the parent material, rainfall, and vegetation cover.
2. Their high specific surface area means soil particles detached during soil erosion have high adsorption capacity for nutrients such as P, which results in an enrichment of P in eroded sediments. The rates of detachment and transfer are accelerated by human impacts such as arable farming and livestock grazing.
3. Transfers can occur where P is added to the land in manures and fertilizers, although best management

practices are available to farmers to minimize these effects.

The relative proportions of P loss in sediment-bound and dissolved forms are highly site specific. Sediment-associated P constitutes the majority of P transported in surface runoff from agricultural land (5). However, dissolved P has a greater impact on water quality than sediment-bound P because it is more readily biologically available (6).

Phosphorus can negatively affect the quality of soils, groundwater, and surface water through eutrophication. In fresh waters, where P is considered the main limiting plant nutrient, elevated P loads tend to favor a few species and promote excessive algal growth. Submerged plants are lost and there are consequential impacts on invertebrate and fish species. As well as the diminished conservation status of eutrophic waterbodies, elevated P concentrations have been associated with impaired human and animal health.

To prevent these impacts, mitigation approaches address P sources or transfer mechanisms of both sediment-associated and runoff-dissolved P. Source approaches try to limit soil P content or its susceptibility to transfer, and include applying P based purely on the needs of the crop and the existing amount of residual soil P, or using chemical amendments to alter soil chemistry and hence reduce the solubility of soil P. Adding alum, for example, encourages P to precipitate with Fe (iron) and has been successfully applied to reduce runoff P concentrations (7). The alternative approach to controlling P is to limit transfer by reducing the occurrence and magnitude of transfer agents, especially runoff and sediment production. Measures to do this include increasing ground cover, contour cultivation, and minimum tillage. Uncultivated buffer strips at field edges, constructed wetlands, and ponds are also efficient at retaining P in agricultural runoff, but edge of field P transport can still occur in soils experiencing significant amounts of lateral subsurface flow (such as sandy soils). Also, while buffer strips can contain P bound on sediment, over time P storage within the buffer strip may create an active source of P flushed out in runoff during storm events.

ORGANIC MATTER

Organic matter as a pollutant concerns animal feces and urine (1) derived directly from grazing (unhoused) livestock, (2) deposited within housing or yards and stored, often with soiled bedding, as slurry or manure, or (3) combined with dairy parlor washings, silage effluent, and runoff from livestock yards and housing as dirty water.

Runoff of slurry, manure, or dirty water after application to land can occur with excess application, when heavy rain follows spreading, or where the terrain is too steep or insufficiently vegetated to ensure plant uptake of such applications. Contamination is also more likely where applications of organic material are close to drains and watercourses, where livestock have uncontrolled access to watercourses, and from farms with inadequate or poorly managed dirty water management systems.

Field or farmyard runoff containing organic matter may result in chronic organic enrichment of streams, ponds, lakes, and ditches. The organic material is broken down by bacteria causing deoxygenation of the water, because the biochemical oxygen demand of these materials can be one to two orders of magnitude higher than that of untreated domestic sewage. This loss of oxygen leads, in turn, to loss of invertebrate and fish life. In addition, organic matter from diffuse agricultural sources, especially from slurry and manure, may contain fecal bacteria, including *Escherichia, Cryptosporidium*, and *Giardia* species, which, in sufficient quantities, may be harmful or even fatal to human health.

Measures to minimize the risk of organic matter contamination of watercourses can be applied at the source, or during application or transfer stages. Manure can be treated to reduce pollution potential before land spreading, using chemical, biological, physical, or thermal processes. These processes may have additional benefits such as the recovery of nutrients including P (8). Alternatively, diet manipulation can be used to reduce the nutrient content of excreta without compromising animal performance (9). Within the farm area, runoff from animal enclosures and yards requires collection or diversion to storage or treatment areas to prevent runoff to watercourses. This is easier if clean water from roofs is diverted before coming into contact with organic material. Stored dirty water may then be applied to land, so that nutrients can be taken up by the crop. In storage systems for organic material, overflow or seepage can be prevented through careful siting of stores to avoid permeable soils and rock, effective sealing of the storage unit, regular checking and emptying to minimize overflow, and the diversion of surface water or rainwater (10).

Reducing organic matter contamination of water can be achieved by maintaining adequate storage facilities and land for application, maximizing knowledge of manure nutrient content and crop nutrient requirements, and employing best management practices, such as avoiding spreading when the soil is saturated or frozen, and minimizing application to steeply sloping land near watercourses. Applying soil erosion and runoff control measures is also effective in reducing organic pollutant transfer. The longer manure is in or on the soil before crops can use its nutrients, the greater the risk and opportunity for loss of nutrients and contaminants to surface waters. Spreading organic matter in spring or summer ensures maximum use of nutrient content and avoids the risk of spreading on frozen ground or before rainfall. Spreading should be at a rate appropriate to the crop and variable within the field according to slope, morphology, and proximity to watercourses. The pollution potential of grazing animals can be minimized by restricting access to streams. Once applied to land, transport of organic pollutants in runoff and sediment may be hindered by contour cultivation and the use of buffer strips.

SEDIMENT

The detachment and transport of soil particles from the land is known as soil erosion. Eroded soil particles enter rivers during periods of high rainfall and consequently high surface runoff. Sediment loads depend on land use, cultivation techniques, stocking densities, drainage, soils, slopes, geology, and rainfall. Heavy sediment loads can occur as a result of soil compaction (which may be associated with loss of organic matter, heavy machinery, multiple cultivations, or excessive livestock densities), soil capping, cultivation of inappropriate land (e.g., steep land), concentrated flow pathways along farm tracks and drainage systems, and the removal of natural runoff interceptors (such as hedges and uncropped land).

Sediment is considered a pollutant in its own right and as a carrier of adsorbed pollutants. Sediment itself increases water turbidity and smothers the bed of rivers and lakes when deposited in watercourses. Fine sediment particles clog river gravels, reducing water flow and aeration of the river bed and hence reducing the survival of fish eggs, invertebrates, and plants. Also, through their adsorption onto soil particles and aggregates, the transfer of sediment carries P, pesticides, pathogenic fecal bacteria, heavy metals, and other contaminants into surface waters.

Mitigation of the impacts of sedimentation may be focused at the source, although interception of sediment during transfer is also effective. Full consideration of site soil conditions is vital before any access or agricultural work is undertaken, as is avoiding unnecessary or ill-timed cultivations and access when the soil is wet and most susceptible to degradation. Positive measures to prevent soil erosion include contour cultivation and drainage, minimum or no tillage cultivation, establishing terraces or strip-cropping, maintaining vegetation cover through restricted grazing and the planting of cover crops, and maintaining and promoting soil organic matter content through mulching and incorporation of crop residues. Measures to minimize transport and delivery of eroded sediments to watercourses include employment of uncultivated buffer strips, grassed waterways, and sediment traps to filter suspended sediment from runoff. Sedimentation ponds or constructed wetlands can reduce runoff velocity and encourage sedimentation outside the watercourse system (11).

PESTICIDES AND OTHER CHEMICALS

A pesticide is defined as any substance prepared and used for the destruction of any pest. Pesticides therefore include herbicides, insecticides, fungicides, antifoulants, sheep dips, masonry and timber preservatives, and veterinary medicines. Agriculture and horticulture account for over 80% of pesticide sales, and applications in crop production are the main source of pesticides that may leach (move in water through the soil profile) to groundwater or run off to surface water in dissolved or particulate form. Pesticide characteristics, soil type, cultivation, and drainage all affect pesticide transport to water. Heavy rain after spraying increases the chance of pesticide movement in runoff. Loss may also occur through spray drift and volatilization, and research has shown that a high proportion of pesticides in surface waters may come from very small farmyard spills and drips from handling and sprayers: these often fall onto hard surfaces, from which they are readily washed into drains, ditches, and watercourses. The use and disposal of sheep dip is a particular risk to fresh waters: water is contaminated by dips located near watercourses and by inappropriate disposal of spent dip. Veterinary medicines and disinfectants used on dairy herds also pose a risk to the aquatic environment.

Pesticides are likely to have toxic effects on aquatic organisms either directly through toxicity or indirectly through changes in the environment. The impacts of pesticides range from rapid destruction of the tissues in contact with the pesticide to slow deterioration in a physiological process. Exposure to sublethal concentrations may cause genetic, physiological, or behavioral changes, including reproduction impairment, inhibition of brain activities, and growth reductions (12).

Pesticides applied to cropland are degraded by microbial and chemical reaction in the soil, temporarily immobilized by adsorption onto soil particles and organic matter, taken up by plants or pests, removed when the crop is harvested, or lost to the environment through runoff in surface water, volatilization into the atmosphere, and leaching to groundwater. For weakly to moderately adsorbed pesticides, the major carrier is runoff, and therefore controlling the loss of pesticides and persistent organic pollutants to watercourses involves reducing runoff. The most important factor affecting the amount of pesticide transported is the amount of pesticide present at the soil surface at the time of precipitation or irrigation. Reducing pesticide pollution can be promoted through the use of natural predators, crop rotations, integrating pesticide control with soil conservation, and using mechanical procedures, such as conservation tillage and vegetative strips (buffers), to reduce runoff and soil erosion and hence the loss of organic chemicals. The way in which the pesticide is applied may also affect pesticide loss. For example, tillage may incorporate the pesticide into the soil, so reducing the risk of pesticide loss by runoff.

HEAVY METALS

Heavy metals (high density elements naturally present in very low abundance in nature) of concern in agricultural landscapes include arsenic, cadmium, boron, selenium, nickel, lead, and mercury. Agricultural use of mineral fertilizers, feed concentrates, and medicines all contribute to farm inputs of heavy metals, although atmospheric deposition may also play a role, as in the deposition of lead and cadmium (13). Heavy metal transfer to water occurs through leaching and through adsorption onto eroded soil particles (preferentially onto clay particles) subsequently deposited within waterbodies (14).

When leached to surface waters, heavy metals are toxic to aquatic organisms (of particular concern is the impact of mercury on fish) and can impact negatively on drinking water quality. Several heavy metals, including mercury and lead, are known to bioaccumulate in the aquatic food chain.

Mitigating heavy metal contamination of water requires amending the source, plant uptake, and transfer of heavy metals. The choice of soil amendments (e.g., manure, compost, sludge, or mineral fertilizers) impacts on the heavy metal content of agricultural soils and hence on availability for transfer to waterbodies. Reducing manure use will reduce inputs of copper and zinc, for example, but the corresponding increase in mineral fertilizer required to maintain productivity may increase soil cadmium. Alternatively, changing farm management, for example, from arable to mixed farming, may reduce heavy metals at the source because of the overall reduction in fertilizers and manures used.

Minimizing the availability of heavy metals for transfer from the field can be achieved by increasing the ratio of grass to arable crop species or choosing particular arable crops to maximize plant uptake (e.g., metal removal from soil is much higher for sugar beet than for potatoes or wheat) (13). Alternatively, soil can be managed to minimize heavy metal transfer, through liming to raise pH levels and hence minimize leaching, or the application of soil conservation measures (such as minimum tillage and contour cultivation) to minimize heavy metal losses associated with soil erosion.

CONCLUSION

Water for food production, drinking, recreation, and ecology is an important but increasingly threatened global resource. The impacts of agricultural land use on the quality of water resources are numerous and include serious economic, health, and environmental implications from a wide range of specific pollutant threats. There are, however, a wide variety of measures available to minimize the sources, movement, and impacts of these agriculturally derived pollutants, most of which help to control pollution from more than one source. Control of water pollution within agricultural landscapes is, therefore, both necessary and achievable.

CLASSIFICATION AND MAPPING OF AGRICULTURAL LAND FOR NATIONAL WATER-QUALITY ASSESSMENT

Robert J. Gilliom
Gail P. Thelin
U.S. Geological Survey

INTRODUCTION

The U.S. Geological Survey's (USGS) National Water-Quality Assessment (NAWQA) Program is designed to describe the status and trends in the quality of the nation's ground- and surface-water resources and to link the status and trends with an understanding of the natural and human factors that affect the quality of water. The program integrates information about water quality at a wide range of spatial scales, from local to national, and focuses on water-quality conditions that affect large areas of the nation or occur frequently within small areas.

The building blocks of the NAWQA Program are Study-Unit investigations, which will be conducted in 60 major hydrologic basins (Study Units) of the nation (Fig. 1). The Study-Unit investigations consist of intensive assessment activity for 3 years, followed by 6 years of less intensive monitoring, with the cycle repeated perennially (Leahy and others, 1990). Twenty Study Units will be in an intensive data-collection and analysis phase during each particular year, and the first complete cycle of intensive investigations of all 60 Study Units will be completed in 2002. The 60 NAWQA Study Units cover about one-half of the conterminous United States, encompass 60–70 percent of national water use and of the population

---

89K

served by public water supplies, and include diverse hydrologic systems that differ widely in the natural and human factors that affect water quality.

The distribution of Study Units ensures that the most important regional and national water-quality issues can be addressed by comparative studies among Study Units. NAWQA National Synthesis projects combine results of Study Unit Investigations with existing information from other programs and studies of the USGS and other agencies and researchers to produce regional and national-scale assessments for priority water-quality issues. The first water-quality issues to be focused on for National Synthesis are nutrients and pesticides.

Comparative studies among study units and national or regional aggregations of data for National Synthesis require consistent data on factors that affect the sources, behavior, and effects of contaminants and other factors that determine water-quality conditions. Natural features, such as geology, and factors related to human activities, such as land-use distribution, provide an environmental framework for assessing influences on water quality in different hydrologic systems. The emphasis of NAWQA on large-scale water-quality issues affected by human activities makes land-use characterization one of the most important aspects in study design and in the analysis of causes of water-quality conditions. Land-use characterization based on a nationally consistent classification system provides a basis for comparing the influences of human activities among Study Units. It also serves as a framework upon which to add many other types of county-based data on human activities, such as waste discharge or chemical use, that are associated with land use.

The purpose of this paper is to describe a system for classifying agricultural land for national water-quality assessment. The system focuses on classification of agricultural land within the 48 contiguous states. Alaska and Hawaii were included in basic data analysis but omitted from classification results because of their unique characteristics. Agricultural land use is one of the most important influences on water quality at national and regional scales, particularly in relation to the first NAWQA National Synthesis topics, nutrients and pesticides. Considered nationwide, agricultural land has large areal extent, a high degree of land disturbance, and high use of agricultural chemicals and water. Individual areas of agricultural land, however, can vary widely in their characteristics. There is a great diversity of agricultural activities in the nation, which follow distinct regional patterns influenced by environmental setting and economics. Different mixes of agricultural activities characteristic of particular regions can have widely varying influences on water quality because of differences in management practices and natural environmental setting.

METAL TOLERANCE IN PLANTS: THE ROLES OF THIOL-CONTAINING PEPTIDES

Weihua Zhang
Yong Cai
Florida International University
Miami, Florida

Chelation and compartmentalization are important mechanisms for metal tolerance in plants. Thiol-containing peptides, i.e., *glutathione* (GSH), *phytochelatins* (PCs), and *metallothioneins* (MTs), are metal ligands and play important roles in *metal tolerance* in plants. This article summarizes the present knowledge about the functions of these thiol-containing *peptides* in plant heavy metal tolerance, especially for Cd, As, and Cu. GSH participates in the amelioration of metal-induced oxidative stress. Metal-GSH complexes are the substrate for PC synthesis. Thus, enhanced GSH synthesis can increase metal tolerance in plants. PCs, a set of thiol-rich peptides with the general structure $(\gamma\text{-GluCys})_n\text{-Gly}$, play an essential role in constitutive Cd and tolerance, whereas PCs are not involved in adaptive Cd tolerance. In contrast, PCs are required for both constitutive and adaptive As tolerance in plants. PCs may play a role in constitutive Cu tolerance in some plants, but they are not involved in Ni or Zn tolerance. MTs may play an important role in constitutive Cu tolerance, and may be involved, to some extent, in Cd tolerance in plants.

INTRODUCTION

Heavy metals are those elements that have densities in excess of 5 g/cm^3 (1). About 40 elements fit this definition (in this paper, we consider metalloid arsenic (As) to be a heavy metal, because its properties are similar to those of other heavy metals). Heavy metals are often toxic to plants, although some heavy metals, i.e., Cu and Zn, are essential nutrients for plants and other organisms at low concentrations. Prolonged exposure to elevated concentrations can cause toxicity symptoms for both essential and nonessential heavy metals (e.g., Cd, Pb, Hg, As, etc.). The toxicity may result from deactivation of proteins via the binding of metals to sulfhydryl groups, competition for the active site between the heavy metal and an essential element resulting in deficiency effects (2,3), or production of free radicals and reactive species induced by heavy metals (3,4). Terrestrial plants are immobile organisms, and metal ion uptake mechanisms are not very selective. As a consequence, plants will take up substantial amounts of toxic heavy metals from metalliferous soils. Plants must have developed strategies that enable them to tolerate the presence of toxic heavy metals. Possible mechanisms for metal tolerance in plant cells are: (a) metal binding to cell wall; (b) reduced transport across the cell membrane; (c) active efflux; (d) compartmentalization; and (e) chelation (5). Chelation and subsequent compartmentalization play important roles in metal tolerance in plants. A variety of compounds, such as organic acids, amino acids, glutathione (GSH), phytochelatins (PCs), and metallothioneins (MTs), have been identified as the chelators of heavy metals. Therefore, these ligands may be involved in metal tolerance in plants.

Metal tolerance mechanisms in plants are categorized as constitutive tolerance mechanisms that exist in normal plants and adaptive tolerance mechanisms that are present in metal-tolerant plants including hyperaccumulators (6). Constitutive metal tolerance mechanisms are complex and are controlled by multiple genes. Adaptive metal tolerance mechanisms, however, seem to involve relatively simple control mechanisms (7). Thiol-containing peptides glutathione (GSH), phytochelatins (PCs), and metallothioneins (MTs) are thought to play important roles in metal tolerance in plants (3,8–10). This article summarizes the present knowledge about the functions of these thiol-containing peptides in plant heavy metal tolerance, especially for Cd, As, and Cu.

GLUTATHIONE

Glutathione (GSH), the tripeptide γ-gultamylcysteinylglycine, is the major source of nonprotein thiols in most plant cells. GSH is synthesized from γ-glutamic acid, cystein (Cys), and glycine (Gly) by a two-step ATP-dependent reaction. The first reaction synthesizes γ-glutamyl cystein (γ-EC) from γ-glutamic acid and Cys by γ-glutamylcysteine synthetase (γ-EC synthase); the second step forms GSH from γ-EC and Gly catalyzing by GSH synthase. GSH plays an important role in protecting plants from oxidative stress induced by xenobiotics and some heavy metals, thus increasing metal resistance in plants (11). A substantial number of reports about oxidative stress induced by a variety of metals exist, e.g., Cd (12–14), Cu (4,15,16), Ni (17), Hg (18), and As (19). GSH is involved in the amelioration of metal-induced oxidative stress in plants. For example, a wild type of *Arabidopsis thaliana* exposed to Cu showed changes in GSH and glutathione disulfide (GSSG) levels, suggesting their participation in the amelioration of metal-induced oxidative stress (15). A decrease in GSH synthesis leads the hypersensitivity of plants to metals, which has been shown in *Arabidopsis* exposed to Cd (12), *Holcus lanatus* exposed to As (19), and *Silene cucubalus* exposed to Cu (4).

As metal-GSH complexes are the substrate of phytochelatin synthase (PCS) (9), synthesis of PCs may lead the depletion in the GSH pool. In the presence of metals, GSH-metal complex may limit the rate of PC synthesis (20). Therefore, an increase in GSH levels facilitates the increase in PC synthesis and the sequestration of metals (13). It has been demonstrated that increases in GSH synthesis can improve metal tolerance in plants. For example, engineered Indian mustard, which overexpresses GSH, shows an increase in Cd tolerance and accumulation (20,21); elevated GSH concentrations are also involved in conferring tolerance to Ni-induced oxidative stress in *Thlaspi* Ni hyperaccumulators (17).

Vacuolar compartmentalization is an important mechanism for heavy metal tolerance in bacteria and plants. Some metals, i.e., Cd and As, need PCs to mediate the vacuolar compartmentalization in bacteria and plants (22–25). Recent studies indicate that GSH can also mediate vacuolar compartmentalization of metals, e.g., Cd, As, and Hg, in bacteria (26–28). In yeast *Saccharomyces cerevisiae*, which lacks PCS, a Cd-GSH complex can be directly transported to vacuoles by YCF1, one of ATP-binding cassette (ABC) transporter proteins located in tonoplasm (26,29–31). YCF1 was also found to transport As-GSH and Hg-GSH complexes to vacuoles in bacteria (27,28). Recently, BPT1, another ABC transporter in vacuoles, was found in yeast. Similar to YCF1, BPT1 also transports GSH conjugates including the Cd-GSH complex (32). However, this mechanism of metal tolerance involving active sequestration of the metal-GSH complexes into vacuoles by ABC transporters has not yet been reported in plants.

PHYTOCHELATINS

Structures

PCs are a set of thiol-rich peptides with the general structure (γ-GluCys)$_n$-Gly ($n = 2$ to 11), which are synthesized from GSH catalyzed by PCS (33–36). They were first identified in the yeast *Schizosaccharomyces pombe* and termed Cadystins (37,38), and isolated and characterized by Grill et al. (39). PCs have been found in all plants studied to date and some microorganisms (40). They are also found in animals, i.e., nematode *Caenorhabditis elegans* (41). Interestingly, some iso-phytochelatins (iso-PCs) are identified in some plants under heavy metal exposure (1). Grill et al. found that a few members of the *Fabales* produced homoPCs under Cd exposure (42). HomoPCs are synthesized from homoglutathione, in which β-Ala replaces Gly as a terminal amino acid (42). Klapheck et al. found that hydroxymethyl-PCs [(γ-GluCys)$_n$-Ser] were induced by Cd in several species of the family Poaceae (43). They are thought to be formed from hydroxymethyl-glutathione [(γ-GluCys)$_n$-Ser]. Meuwly et al. discovered γ-Glu-Cys-Glu, another homologue of GSH. It is not surprising that another iso-PC, (γ-GluCys)$_n$-Glu ($n = 2 - 3$), was induced by Cd in maize seedlings (44). Recently, iso-PCs (γ-GluCys)$_n$-Gln ($n = 3 - 4$) were isolated from the hairy roots of horseradish exposed to Cd (45). In addition, some PC-related compounds, i.e., desglycine PCs [(γ-GluCys)$_n$] (46,47), Cys-(γ-GluCys)$_n$-Gly ($n = 1$–5), and Cys-(γ-GluCys)$_n$ (47), were identified in maize.

Biosynthesis

PCs are not primary gene products. They are synthesized from GSH by a specific γ-glutamylcysteine dipeptidyl transpeptidase (EC 2.3.2.15)—PCS in the presence of metal ions (48). This enzyme transfers γ-Glu-Cys from GSH or PC to an acceptor molecule (i.e., GSH and PC) (49). PC synthesis reaction can be rapidly induced *in vivo* by exposure to a variety of metal cations (Cd^{2+}, Pb^{2+}, Zn^{2+}, Sb^{3+}, Ag^{+}, Hg^{2+}, Cu^{+}, Sn^{2+}, Au^{3+}, Bi^{3+}) and metalloid anions [arsenate (As^{V}) and arsenite(As^{III})] (1,3,10,37,50,51). The reaction is self-regulated. Once the free metal ions are chelated by the reaction products PCs, the reaction terminates (48,49,52). PCS activity was identified for the first time in cell-free extracts from suspension cultures of *Silene cucubalis* by Grill et al. (48), and similar PCS activities have been detected in pea (52), tomato (49), and *Arabidopsis* (53). In 1999, genes encoding PCS were first cloned and characterized in *Arabidopsis* (*AtPCS1*), *S. pombe* (*SpPCS*), and wheat (*TaPCS1*) (54–56). Homologous genes encoding PCS have been identified in other species, i.e., *C. elegans* (*CePCS*) (57), *Arabidopsis* (*AtPCS2*) (55,58), soybean Glycine max (*GmhPCS1*) (59), and *Brassica juncea* (Indian mustard) (*BjPCS1*) (60).

PCS is expressed constitutively, and the levels of this enzyme in cell cultures or intact plants are generally unaffected by exposure to metal ions (61). Analysis of the expression of *AtPCS1* indicated that levels of mRNA were not affected by exposure of plants to Cd (54,55). However, RT-PCR analysis of *TaPCS1* expression in wheat roots indicated induction of mRNA under Cd exposure (56). In addition, a recent study showed *AtPCS1* of *Arabidopsis thaliana* was regulated at transcriptional level during the early stages of plant development (62). Therefore, in some species or specific stages of plant development, PCS activity may be regulated both at transcriptional and posttranslational levels.

Earlier studies have shown that PCS activity requires the binding of free metal ions to the enzyme (48,49,52,63,64). However, a recent study has shown that metal binding per se is not responsible for the activation of PCS, but glutathion-like peptides containing blocked thiol groups are required for the enzyme activity (9). A similar conclusion was reached by Oven et al. (59). Therefore, the real substrates of PCS are metal-thiolate complexes.

Roles of PCs in Metal Tolerance

PCs are suggested to play a role in metal detoxification and homeostasis (1,37). However, no direct evidence that PCs are involved in homeostasis currently exists (51). It has been demonstrated that PCs play an essential role in constitutive Cd and As tolerance in plants. In addition, PCs may be required for adaptive enhanced As tolerance. Some indications exist that PCs may play a role in Ag, Cu, and Hg tolerance (55,56). However, the role of PCs in Cu tolerance in plants has been debated (54–56,65). A paucity of information exists about the roles of PCs for Ag and Hg tolerance in plants. Zn and Pb are weak activators for PC synthesis (48,50), and genetic and biochemical evidence has shown that PCs are not involved in Zn tolerance in plants (53–55,65–68). No evidence exists that PCs are involved in Pb tolerance in plants. Ni cannot induce PC synthesis (48,50), thus PCs are not involved in Ni tolerance in plants.

Cadmium. Cd is a strong activator for PC synthesis, and PCs and Cd can form detectable complexes *in vivo* (48,50). PCs play an essential role in normal constitutive Cd tolerance in plants (3,10,37,51,64,69,70). This conclusion is supported by a variety of biochemical and genetic evidence. *In vitro*, PCs have been shown to substantially decrease the toxicity of Cd to metal-sensitive plant enzymes, such as alcohol dehydrogenase, glyceraldehyde 3-phosphate dehydrogenase, nitrate reductase, ribulose 1,5-diphosphate carboxylase, and urase (71). In normal *S. vulgaris*, treatment with buthionine sulfoximine (BSO), which inhibits the synthesis of the PC precursor γ-EC, resulted in hypersensitivity to Cd (72). The most convincing evidence comes from genetic studies. Cd-sensitive *cad1* mutants of *Arabidopsis* are deficient in PCS activity and do not form Cd-PC complexes. Consequently, these mutants are sensitive to Cd (67,68). Expression of cDNA clones of *AtPCS1* from *Arabidopsis* and a similar gene *TaPCS1* from wheat in *S. cerevisiae* resulted in a dramatic increase in Cd tolerance (55,56). The mutants of *Arabidopsis* and *S. pombe* that lack PCS genes exhibited hypersensitivity to Cd and were unable to synthesize PCs (54,56). Azuki bean cells lacking PCS activity were also hypersensitive to Cd (73). All of this evidence strongly suggests that PCs play an essential role in constitutive Cd tolerance.

In addition to formation of Cd-PC complexes in cytoplasm, sequestration of Cd-PC complexes to vacuoles is also required for Cd tolerance (22,74). In vacuoles, the complexes are stabilized by incorporation of acid-labile sulfide (75). In yeast *S. pombe*, vacuolar sequestration process is mediated by HMT1 (22). HMT1, a member of ABC-type transport proteins located in tonoplasm, can transport PCs and Cd-PC complexes to vacuoles (76). Vacuolar compartmentalization of Cd-PC complexes has also been observed in plants, such as tobacco (75,77), and oat roots (23). However, plant genes encoding Cd-complex transporter have not been characterized yet (40).

Although PCs are essential for normal constitutive Cd tolerance, PCs are not involved in adaptive enhanced Cd tolerance in Cd-tolerant plants. In studies that compared Cd-tolerant plants with normal *Silene vulgaris*, De Knecht et al. found that Cd-tolerant plants exhibited a much lower PC synthesis and a lower rate of longer PC synthesis under Cd exposure than normal plants, and their Cd tolerance was not reduced by BSO treatment (72,78). These observations suggest that the enhanced Cd tolerance in Cd-tolerant *S. vulgaris* is not because of differential production of PCs and synthesis of longer chain PCs, although PCs are essential for constitutive Cd tolerance in normal *S. vulgaris* (72,78). Similar results were obtained in other studies of *S. vulgaris* (65,79). In Zn/Cd hyperaccumulator *Thlaspi caerulescens*, PC synthesis under Cd exposure was lower than in nonhyperaccumulators *Thlaspi arvense* (80), and BSO treatment did not increase sensitivity to Cd (65). These results suggest that PCs are not involved in adaptive enhanced Cd tolerance in this plant. The possible mechanism for the adaptive enhanced Cd tolerance in these Cd-tolerant plants is PC-independent vacuolar sequestration (65). However, this process remains to be elucidated.

Arsenic. Similar to Cd, As^{III} can induce high levels of PC synthesis in plants (50,81). However, it is difficult to detect As-PC complexes *in vivo*, although formation of As^{III}-tris-thiolate complexes is predicted on a theoretical basis (50). With improved experimental conditions, Schmoger et al. demonstrated the formation of As^{III}-PC complexes in plants by size exclusion chromatography and electrospray ionization-mass spectrometry (24). Constitutive As tolerance in plants requires the involvement of PCs. This process may include reduction of As^{V} to As^{III}, formation of As^{III}-PC complexes, and sequestration of the complexes into vacuoles (65,81,82). Results from various studies support the role of PCs in constitutive As detoxification in normal plants. For example, BSO-treated cell cultures of tobacco (83,84) and *Rauvolfia serpentina* (83,84), *Holcus lanatus* (6,82,85), and *Cytisus Striatus* (6,82,85) were found to be hypersensitive to As. The strongest evidence for the role of PCs in As detoxification comes from genetic studies of *Arabidopsis* and *S. pombe* (54,55). PCS-deficient mutants of *Arabidopsis* and *S. pombe* are highly sensitive to Cd and As (54). Conversely, the expression of *AtPCS1* from *Arabidopsis* in yeast *S. cerevisiae* resulted in enhanced resistance to As (55). This evidence strongly supports the argument that PCs are essential for constitutive As tolerance in plants.

Unlike enhanced Cd tolerance in Cd-tolerant plants, enhanced As tolerance in As-tolerant nonhyperaccumulator plants may require PCs. In As-tolerant *H. lanatus* and *C. Striatus*, suppression of phosphate/As^{V} uptake via an altered high-affinity phosphate/As^{V} uptake system is the adapted As tolerance mechanism that is mainly responsible for the enhanced As tolerance (6,19,82,86). However, PCs are also involved in the enhanced As tolerance in these As-tolerant plants via synthesis of higher levels and/or longer chain of PCs, because BSO treatment can cause these As-tolerant plants to be more sensitive to As (6,82,85). These observations suggest that constitutive production of PCs may be involved in the adaptive As tolerance in these plants. In As hyperaccumulator *Pteris vittata*, the major mechanism responsible for As hypertolerance is not related to restriction of As uptake, but may be related to enhanced vacuolar compartmentation of As (87). PCs were suggested to play no role in As hypertolerance in *P. vittata* (88). However, considering that PCs are required for enhanced As tolerance in the As-tolerant nonhyperaccumulators, PCs may play, to some extent, a role in As hypertolerance in this hyperaccumulator, which is supplementary to the adaptive As tolerance mechanisms (87).

Copper. Cu is an essential micronutrient for plants. The mechanisms for plant Cu tolerance have not been elucidated. Cu ion can induce PC synthesis, and formation of Cu^{+}-PC complexes are observed *in vitro* and *in vivo* (89,90). The role of PC in Cu tolerance in plants has been debated. Some indications exist that PCs may, to some extent, be involved in constitutive Cu tolerance. For instance, *S. pombe* cells, for which the PCS gene expression has been disrupted, exhibit hypersensitivity to Cd and Cu (56); PCS-deficient *Arabidopsis* mutant *cad1-3* is slightly sensitive to Cu, Hg, and Ag (54,91). However, the evidence is not conclusive. Another genetic study showed that PCS-deficient *S. pombe* was insensitive to Cu, Zn, Hg, Se, or Ni ions (54). *Arabidopsis* exposure to concentrations of Cu ion did not produce Cu-PC complexes, but a change in glutathione and glutathione disulfide contents was observed (15). In normal *S. vulgaris*, BSO treatment had no effect on the plant sensitivity to Cu, indicating that PCs are not essential for constitutive Cu tolerance (65).

PCs are not involved in adaptive enhanced Cu tolerance in Cu-tolerant plants. Differential Cu tolerance in Cu-tolerant and normal *S. vulgaris* is not because of differential PC production (92). The sensitivity to Cu is unaffected by BSO treatment both in Cu-tolerant and normal *S. vulgaris*, suggesting that PCs are not involved in adaptive Cu tolerance (65). A similar conclusion was obtained in Cu-tolerant *S. cucubalus* (4).

METALLOTHIONEINS (MTs)

MTs are a class of Cys-rich polypeptides (Mr: 6000–7000) that can bind metals via thiol groups of their Cys residues (93). MTs were first reported as Cd binding protein in horse kidney (94). MTs have been found in animals, plants, eukaryotic microorganisms, and some prokaryotes (40). MTs contain characteristic motifs: Cys-Cys, Cys-X-Cys, and Cys-X-X-Cys (5). MTs are divided into two classes (95). Mammalian MTs containing 20 highly conserved Cys residues are categorized as Class I (96), whereas MTs from plants, fungi, and invertebrate animals are grouped in Class II (97). According to the arrangement of Cys residues, plant MTs are further classified into four types (40,95). MTs are gene-encoded polypeptides, and their syntheses are transcriptionally activated by several factors such as hormones, cytotoxic agents, and metals, including Cd, Zn, Hg, Cu, Au, Ag, Co, Ni, and Bi metal ions (5). A wide variety of regulatory factors and expression in many organisms suggest that MTs have important functions (40). Although MTs have been studied for more than 40 years, their function has not been completely understood in animals (3,98). They may play a role in protection against metal toxicity, function as antioxidants, and are thought to be involved in plasma membrane repair (3). The only confirmed function of MTs in animals is detoxification of Cd and Zn (96,98).

MTs have been less studied in plants than in animals. The functions of MTs in plants also remain to be elucidated. Some indications exist that MTs may play a role in Cu and probably Cd tolerance in plants. Cu tolerance in *Arabidopsis* depends on the degree of Cu-induced expression of type 2 MT genes (99,100). When MT1a and MT2a genes from *Arabidopsis* were expressed in a yeast strain lacking one of its endogenous MT genes (*cup1*), the MT genes conferred the yeast a high level of tolerance to Cu and a moderate level of tolerance to Cd (101,102). Transgenic tobacco plant with expression of yeast MT gene can accumulate significantly higher quantities of Cu than control plants (103). When an MT2b-like gene (*SvMT2b*) from a highly Cu-tolerant *S. vulgaris* was expressed in yeast, this gene restored cadmium and copper tolerance in different hypersensitive strains (104). When an MT2-like gene (*tyMT*) from *Typha latifolia* was expressed in Cu-sensitive MT-deficient strain of yeast, it restored the yeast's metal tolerance (105). Transgenic *Arabidopsis*, with expression of the *tyMT* gene, showed an increased tolerance to heavy metals Cu and Cd (105). Results from these studies suggest that MTs play an essential role in constitutive Cu tolerance in these plants.

However, other studies do not support this conclusion. For instance, In Indian mustard, Cu treatment caused a strong increase in γ-ECS mRNA, GSH, and PCs in roots and shoots, whereas MT2 mRNA was decreased in response to the $CuSO_4$ treatments (106,107); In *Vicia faba*, MT1 and MT2 transcript levels are not significantly affected by treatment with Cu, Zn, or Cd (108,109). The observed decrease or no change in MT expression under Cu exposure may be caused by increased levels of PC synthesis, suggesting that Cu quenched by PCs may be favored over sequestration by MTs in Indian mustard and *Vicia faba* (106,109). As mentioned above, genetic evidence has shown that PCs may play a role in constitutive Cu tolerance in some plants (55,56), and constitutive metal tolerance mechanisms are complicated and controlled by multiple genes (7). Therefore, both PCs and MTs may be involved in constitutive Cu tolerance in plants. For some reasons, the PC-dependent mechanism appears to dominate in some plants, whereas the MT-dependent mechanism is favored in others

MTs may also be involved in adaptive enhanced Cu tolerance in plants. Cu-tolerant *S. vulgaris* was found to have significantly higher transcript levels of type 2b MT gene than normal *S. vulgaris* (104). The increase in the MT gene expression suggests that constitutive production of MTs also contribute to the enhanced Cu tolerance, although an adaptive mechanism is mainly responsible for the enhanced Cu tolerance in *S. vulgaris* (104). Restriction of Cu uptake may be the adaptive mechanism for the enhanced Cu tolerance in plants. By comparison of normal to Cu-tolerant *Silene cucubalus*, De Vos et al. suggested that the adaptive Cu tolerance in this plant does not depend on the production of PCs but is related to the plant's ability to prevent GSH depletion resulting from Cu-induced PC synthesis, e.g., by restriction Cu uptake (4). A recent study has shown that efflux of Cu across the root plasma membrane plays a role in the Cu tolerance in Cu-tolerant *S. vulgaris* (110).

In animals, MTs play an essential role in Cd detoxification. In plants, this role is mainly occupied by PCs (40). However, MT expression can enhance Cd tolerance in plants. For instance, expression of mouse MT1 gene and *Nicotiana glutinosa* MT gene confers Cd resistance in transgenic tobacco plants (111,112), suggesting that MT may play a role, to some extent, for Cd tolerance in plants. An increase in Cd tolerance was also found in transgenic *Arabidopsis* with expression of an MT gene (105). The roles of MTs in Cd tolerance in plants need further investigation and confirmation.

CONCLUSIONS

GSH, PCs, and MTs play important roles in metal tolerance in plants. GSH participates in the amelioration of metal-induced oxidative stress, and metal-GSH complexes are the substrate for PC synthesis. Thus, enhanced GSH synthesis can increase metal tolerance in plants. PCs play an essential role in constitutive Cd tolerance, whereas PCs are not involved in adaptive Cd tolerance. In contrast, PCs are required for both constitutive and adaptive As tolerance in plants. PCs may play a role in constitutive Cu tolerance in some plants, but they are not involved in Ni or Zn tolerance. MTs may play an important role in constitutive Cu tolerance, and may be involved, to some extent, in Cd tolerance in plants.

MICROIRRIGATION

Dorota Z. Haman
University of Florida
Gainesville, Florida

Microirrigation has been defined in the Standards of the American Society of Agricultural Engineers (ASAE) as "frequent application of small quantities of water on or below the soil surface in form of drops, tiny streams or miniature spray." In microirrigation systems, water is applied through emitters or applicators placed along a water delivery line (lateral line) adjacent to the plant row (1). Microirrigation includes all methods of frequent water application, in small flow rates, on or below the soil surface. The terms drip, trickle, and spray irrigation, common since the 1960s, have been supplanted by the term "microirrigation," which is now commonly used throughout the industry. Microirrigation is sometimes called "localized irrigation" to emphasize that only a targeted part of the soil volume is wetted during water application. The other name that is frequently and incorrectly used is "low volume irrigation." In reality, a microirrigation system is characterized by low flow rates that are expressed in terms of water volume per time (L/h, m^3/h), but the total volume (liters or cubic meters) delivered can be large.

Microirrigation systems are designed to transport water from a source through a delivery network of pipes and various types of emitters to a crop. The general goal of a microirrigation system is to provide irrigation water uniformly and efficiently to a crop to help meet the water needs of plants and to maintain a favorable root zone water balance. Ideally, the volume of water is applied directly to the root zone in quantities that approach the consumptive use of the plants. Additional goals of microirrigation can be to increase fruit or fiber production, to maintain crop visual quality, to protect plants and/or fruits and flowers from extreme temperature conditions (hot or cold), to apply crop or soil chemicals (fertilizers, pesticides, etc.), or to dispose of wastewater, which can be an important water and nutrient resource.

Microirrigation is usually characterized by the following features: (1) low water application rates, (2) high frequency of water application, (3) water applied near or into the root zone, (4) low pressure delivery system, and (5) delivery of fertilizers and other agricultural chemicals with irrigation water (fertigation and chemigation).

In microirrigation systems, water is distributed using an extensive hydraulic pipe network (Fig. 1) that conveys water from its source to the plant. Outflow from the irrigation system occurs through emitters placed along the water delivery (lateral) pipes in the form of droplets, tiny streams, or miniature sprays. The emitters can be placed either on or below the soil surface. Microirrigation systems are classified by the type of emitters used in the system. These are drip, bubbler, spray jet (or microspray), and microsprinkler. The system can also be subdivided into the point source emitters and line source emitters (Fig. 1). Point source emitters are spaced sufficiently far apart to create individual discrete water patterns and they are used for trees or widely spaced shrubs. Line source emitters are used for row crop production. The emitters are placed along the line closely enough to create a continuous wetted band along the crop row. In addition, line source (drip) systems can apply water above the ground or below the ground. Subsurface drip irrigation (SDI) systems are becoming more popular due to potentially high efficiency.

A typical flow rate of a point source emitter is less than 12 L/h. The flow rate of a line source emitter is given per length of lateral and is also less than 12 L/h per meter. Bubblers emit much larger volumes of water, but usually less than 225 L/h, where the microsprinklers and jet sprays are limited to 175 L/h.

The emitter is designed to reduce the operating pressure from the supply line, and a small volume of water is discharged at the emission point at low pressure. Emitters can vary from sophisticated, constant

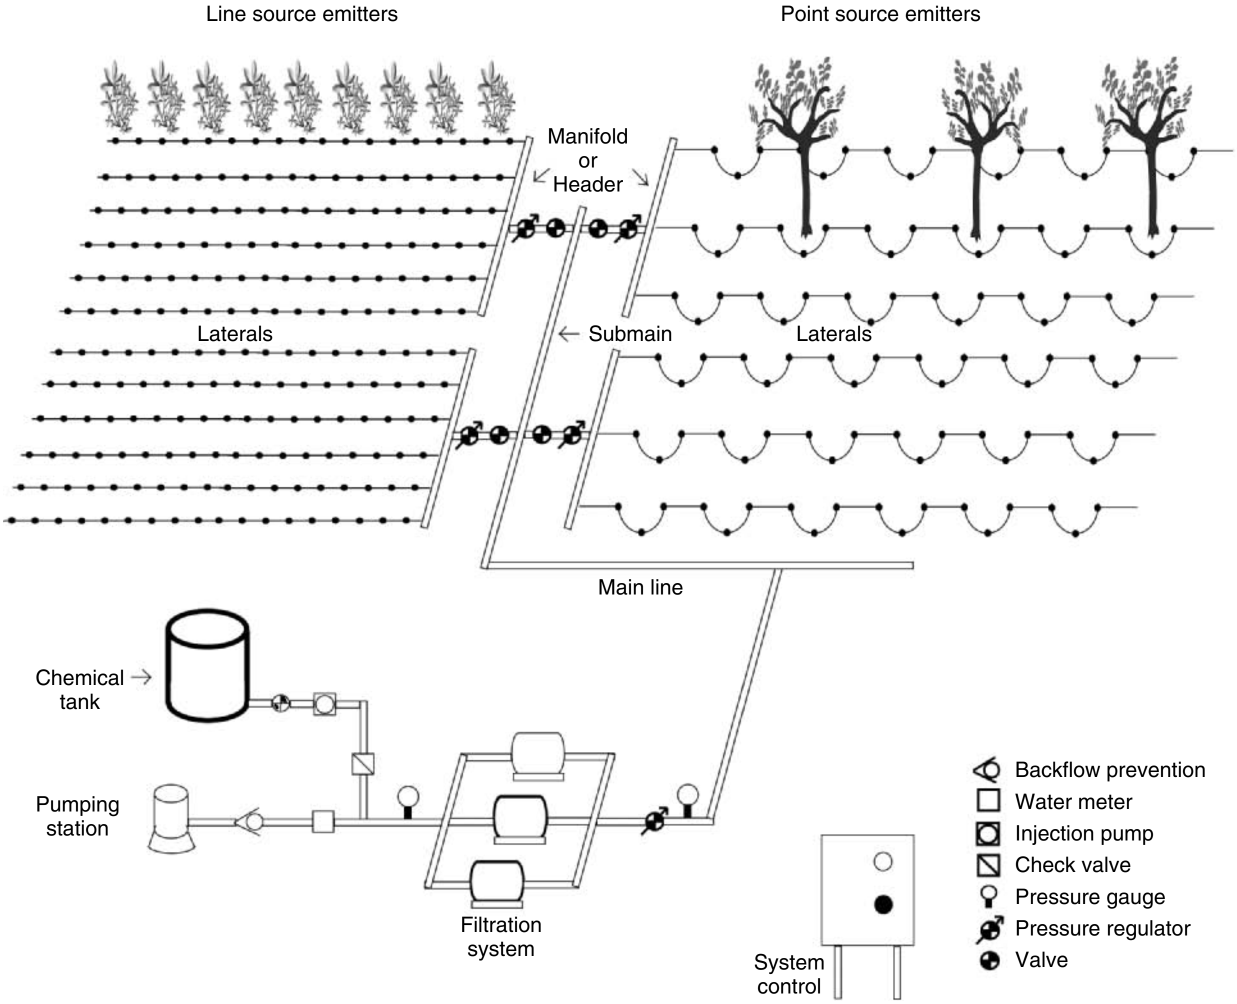

Figure 1. An example of a basic microirrigation system.

flow rate at variable pressure types of devices (pressure-compensating emitters) to very small, simple orifices. A large number of different types of emitters have been developed in attempts to find a perfect device. The main objective is to assure uniformity of water distribution. It is essential that the discharge from the emitter is uniform and that it not change significantly with small pressure variations in the system. At the same time, the emitter should be constructed in such a way that it does not clog very easily. The cost and the size are also important. The emitters presently available on the market can be classified into five distinct categories: (1) long path emitters, (2) short path orifice emitters, (3) vortex emitters, (4) pressure-compensating emitters, and (5) porous pipe or tube emitters (line source drippers).

Emitters are placed along laterals, the final water delivery lines, designed for uniform water distribution. The lateral line is generally constructed of flexible polyvinyl chloride (PVC) or polyethylene hose (PE). It is often placed above the ground, but it can be buried. For row crops, in the line source type of microirrigation system, a lateral line combines the function of the line and the emitter. These include laterals constructed from porous pipe, twin-bore PE pipe, or PE pipe provided with evenly spaced, built-in emitters. Each manufacturer of line source emitters supplies data with allowable length of laterals and recommended pressure for particular line source systems. Recommendations are based on the hydraulic characteristics of the product. The emitters, which may be connected to the lateral using a variety of connectors during installation of the irrigation system, are usually placed at predetermined positions, for example, at the base of the irrigated tree.

Lateral lines are attached to manifolds or submains. The manifolds and submains, which distribute the water to the specific parts of the field, are usually constructed from flexible smooth-walled, noncollapsible, black PE or flexible PVC pipe that can be left on the soil surface or buried. If rigid (usually white or purple) PVC pipe is used for the lateral line, it should be buried beneath the soil surface for protection against sunlight damage and prevention of algae growth in the line. The controls for adjustment of flow rate and pressure are usually located in the submain or manifold line along with valves and timing devices for the separate parts of the field. Water is delivered to the field by the main line. The main line is usually constructed from white PVC pipe that is buried beneath the soil surface for protection against harmful sunlight. Purple color is required for all PVC components in the system using reclaimed wastewater. The pipe should be properly rated for the particular application and able to withstand the design pressure in the system.

A main control station, often called the "control head," is usually located close to the water supply. A typical control station includes the pump, a backflow prevention system, a chemical injection system for fertilizers, chlorine, or other chemicals, and a combination of different filters. A main line valve and flowmeter are also included in the control head. Microirrigation systems can be controlled manually or automatically. Automatic control can be electromechanical (clock) or electronic (computer). The controller is often located next to other components of the control station. It can control the main valve, chemical injection, backflushing of filters, solenoid valves, and other controls located at remote locations in the irrigation system. Depending on the system, all or some of these components can be automated.

In microirrigation systems, only a portion of the total field area is wetted. The goal is to only wet the root zone of the crop of interest. Water flowing from the emitter is distributed in the soil by gravity and capillary forces creating the contour lines presented in Fig. 2, often referred to as "onion" patterns. The exact shape of the wetted volume and moisture distribution will depend on the soil texture, initial soil moisture, and, to some degree, the rate of water application. In the line source type of microirrigation tube that is frequently used for row crops such as vegetables, where the emitters are spaced very closely, individual "onion" patterns connect, creating a continuous moisture zone along the row.

Microirrigation systems have many potential advantages compared to other irrigation methods. Most of them are related to the low rates of the system. It can be argued that some of these benefits are not unique to a microirrigation system. However, certain combinations of these advantages are responsible for uniqueness of microirrigation in contrast to other systems.

WATER SAVINGS

Irrigation water requirements can be smaller with microirrigation when compared with other irrigation methods since a smaller portion of the soil volume is wetted, there is decreased evaporation from the soil surface, and there is reduction or elimination of the runoff. The losses due to evaporation from the soil are significantly reduced compared with other irrigation systems because only a small surface area under the plant is wetted and it is usually well shaded by the foliage. A microirrigation system allows for a high level of water control application and water can be applied only when needed in precisely controlled amounts. Deep percolation can be minimized or avoided.

SMALLER FLOW RATES

Since the rate of water application (L/S) in microirrigation systems is significantly lower than in other systems, smaller sources of water can be used for irrigation of the same acreage. The delivery pipes, the pump, and other components of the system can be smaller and therefore more economical. The systems operate under low pressure (35–200 kPa) and require less energy for pumping than high pressure irrigation systems.

APPLICATION OF CHEMICALS

Microirrigation systems allow for a high level of control of chemical applications. The plants can be supplied with the exact amount of fertilizer required at a given time. They are applied directly to the root zone and reduction in the total amount of fertilizer used is possible. There is also an advantage to the frequent application of fertilizers

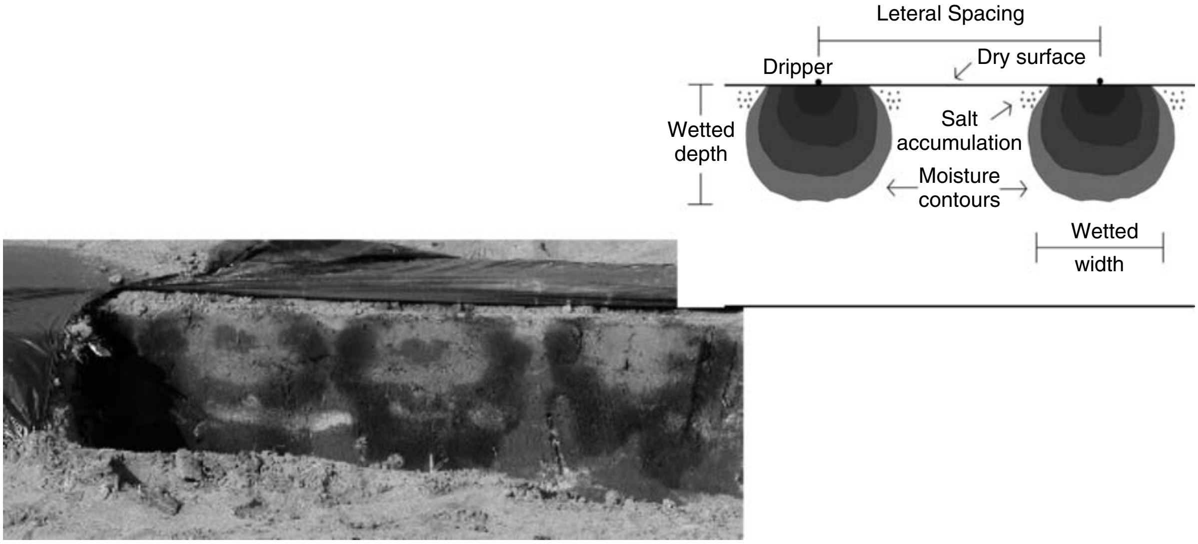

Figure 2. Wetted pattern under drip irrigation (line source type of emitter) in a sandy soil.

through the system (fertigation) in humid climates. In case of rain, only a small portion of recently applied fertilizer will be washed out and it can easily be replaced through the irrigation system, reducing the potential environmental hazard due to nutrient leaching from the production system. Fertigation is more economical, provides better distribution of nutrients throughout the season, and reduces groundwater pollution due to the high concentration of chemicals that could ordinarily move with deep percolated water. Other chemicals, such as herbicides, insecticides, fungicides, nematicides, growth regulators, and carbon dioxide can also be efficiently applied through microirrigation systems to improve crop production. This process of chemical application is called chemigation.

WATER SOURCES WITH HIGH SALT CONTENT

Water with relatively high salt content can be used in microirrigation systems. For optimum plant growth a certain range of total water potential in the root zone must be maintained. The potential defines how difficult it is for a plant to extract water from the soil. Large negative numbers are characteristic of very dry soils with low total water potentials, while potentials near zero reflect soils near saturation. The total water potential in the root zone is a sum of the matrix potential and osmotic potential. Since matrix potential is close to zero under well-managed microirrigation (high moisture content), the osmotic potential component can be a relatively large negative value, indicating high salt content, without a harmful effect on plant growth. This is not true for other irrigation systems.

IMPROVED QUALITY OF THE CROP

Microirrigated plants are supplied very frequently with small amounts of water and the stress due to the moisture fluctuation in the root zone is reduced to the minimum, often resulting in larger and better quality yield. In arid climates, or during dry seasons, proper water management can control the harvest timing.

ADAPTATION TO ANY TOPOGRAPHY

Microirrigation systems can operate efficiently on hilly terrain if appropriately designed and managed. A well-managed microirrigation system will minimize runoff even on hilly terrain.

ADDITIONAL ADVANTAGES OF MICROIRRIGATION SYSTEMS

During dry seasons or in arid climates, disease and insect damage can be reduced under the microirrigation system since the foliage of the plant is not wetted. With a small portion of soil surface being watered, field operations can be continued during irrigation. Water distribution is not affected by the wind in drip irrigation. However, wind can have some effect on spray jet patterns. Germination and water uptake by the weeds between the rows can also be significantly reduced since these areas remain dry. Microirrigation systems can also be extensively automated, decreasing labor and operating costs.

To operate satisfactorily, a microirrigation system has to be correctly designed and managed to account for the physical properties of soil, quality of irrigation water, and water requirements of the grown plants. Usually, microirrigation requires a higher management level than other irrigation systems. With all the advantages listed above, a microirrigation system is not a system without problems.

CLOGGING

One of the biggest problems encountered under microirrigation is the clogging of the emitters. The small openings can easily be clogged by soil particles, organic matter, bacterial slime, algae, or chemical precipitates. Microirrigation systems require very good filtration (most often recommended is 200 mesh screen) even with a high quality water supply.

MOISTURE DISTRIBUTION

Moisture distribution depends largely on the soil type being irrigated by the microirrigation system. In some soils, for example, deep sands, very little lateral water movement (low capillary forces) can create many problems. Under these conditions it is difficult to wet a significant portion of the root zone since most of the water moves downward due to gravity. It is also more difficult to manage the irrigation without deep percolation since only a small amount of water can be stored in the wetted volume desired. Increasing the number of emitters per plant may improve water distribution in the soil. As a result, coarse sands require much closer spacing of emitters than fine soils. In general, for any soil, the number of emitters and their spacing must be based on the geometry of wetted soil volume. It is important to realize that the microirrigation system wets only a limited portion of the potential soil root volume. Most of the plants can perform very well under these conditions. However, there is a minimum volume of roots that have to be wetted or a reduction in yield will result.

SALT BUILDUP

Microirrigation systems can use saline water. However, a problem may occur from salts accumulating at the edges of the wetted zone during prolonged dry periods. Light rain can wash these salts into the root zone and cause injury to the plants. In arid climates, where the rainfall is less than 10 in./yr, an additional irrigation system (sprinkler or surface) may be necessary to leach accumulated salts from the soil. In areas with heavy rainfall the salts will be washed out of the root zone before significant accumulation occurs.

Table 1. Extent of Microirrigation (in hectares) in Selected Countries and the World During the Period 1981–2000

Country	1981	1986	1991	2000
United States	185,300	392,000	606,000	1,050,000
India	20	0	55,000	260,000

INITIAL COST

The initial investment and maintenance cost for a microirrigation system may be higher than for some other irrigation methods. Filters, chemical injectors, and possible automation components add to the cost of a microirrigation system. Actual costs will vary considerably depending on the selection of a particular microsystem, required filtration equipment, water quality, water treatment, and selection of automation equipment.

ADDITIONAL DRAWBACKS

Rodents and insects can create additional maintenance problems by chewing holes in the plastic. In addition, some components of the system can easily be damaged by persons unaware of their locations. A microirrigation system does not provide significant frost protection when compared to sprinkler irrigation; however, it is commonly used for this purpose in citrus production where it can provide some protection.

CURRENT IRRIGATED AREA

In 1977, the Food and Agriculture Organization of the United Nations (FAO) estimated that the total global irrigated area was 223 million ha. By 1996 this estimate increased to about 262 million ha. The 2000 irrigation survey conducted by the *Irrigation Journal* (2001) listed 25.5 million ha irrigated in the United States. Approximately 12.7 million ha (49.9%) were irrigated by sprinkler irrigation, 11.5 million ha (45.1%) by gravity irrigation, and 1.3 million ha (4.9%) by microirrigation.

Results of the surveys conducted by the International Commission on Irrigation and Drainage (ICID), summarized (Table 1) by Reinders (2), indicate that microirrigation has increased from 0.4 to 3.2 million ha between 1981 and 2000. In the United States, California, Florida, Washington, Texas, Hawaii, Georgia, and Michigan account for approximately 91% of the microirrigated land area. It is a small fraction of the total irrigated area; however, many of the high value crops that require intensive production practices are grown under microirrigation and the area of marginal lands that are microirrigated is increasing.

Almost all crops can be suitable for microirrigation; however, due to the high cost, microirrigation is primarily used on high value perennial crops, tree and vine crops, fruits, vegetables, and ornamentals. There is growing interest in applying microirrigation to lower valued field crops, such as cotton and corn or sugar cane, through the use of multiyear subsurface drip irrigation (SDI). Application of microirrigation for landscaping, greenhouses, and nurseries has also increased tremendously. Large containerized nursery plants are typically irrigated with microirrigation. In addition, an increase of microirrigation in residential properties and highway roadsides often prompted by water restriction and/or high cost can be observed in many areas of the United States.

MICROIRRIGATION: AN APPROACH TO EFFICIENT IRRIGATION

Harenda Singh Chauhan
G.B. Pant University of
Agriculture and Technology
Pantnagar, India

Microirrigation, earlier known as Drip or Trickle irrigation is a highly efficient method of water application. It developed and expanded globally at a fast rate in the last two decades in more than 35 countries with maximum coverage in the United States. This is most appropriately applicable to widely spaced crops such as fruits, vegetables and field crops. Its different variations consist of surface trickle, bubbler, microsprinkler, spray, mechanical move, pulse, subsurface drip, all of which are covered under a single term microirrigation. In the present article, its advantages, components, system design, fertigation, automation and other aspects has been described. Also the extent of application to different crops, and in different countries, limitations, scope, research trends and strategies of promotion has been discussed.

INTRODUCTION

The world is facing a serious shortage of fresh water due to dwindling resources. There is growing competition for clean water making less water available for agriculture, the largest consumer of water which accounts for more than 70% of total withdrawals for the world at large. The average irrigation efficiency of the world is fairly low. As per Gittinger (1), if this efficiency can be raised by 10%, the total conserved water will equal the water required in the world for all other uses. According to Smith (2), sustainable food production will depend on the judicious use of water resources to meet future food demands. Water productivity in terms of output per unit of food per cubic meter of water needs to be increased both in irrigated and rain-fed agriculture. In short, there is need for more crop per drop.

As urbanization, industrialization, and other uses increase, the availability of water for agriculture is likely to be reduced. By 2030, it is estimated (3) that irrigated areas will have expanded by 23%. However, decreasing water availability will allow an increase of only 12% more water for agriculture. This would necessitate an increase in water productivity by increasing water use efficiency and would require improving irrigation efficiency from the present 43% to 50% by 2030. This would in consequence require reducing irrigation water losses by introducing appropriate technologies and improved water management and cultural practices.

Water management involves various important aspects, in which there is the necessity and large scope for improvement. One of the important aspects is the field application of irrigation water. In surface application, common efficiencies range from 50–60%, whereas in drip irrigation it ranges around 90%. Although a microirrigation system appears initially costly and not necessarily applicable to similar land conditions as surface irrigation, it is definitely water saving and improves the yield and quality of crops. This article discusses microirrigation and its nature, extent, and future scope.

Historical Development

Earlier experiments on drip irrigation were done in Germany around 1860 using clay pipes having open joints, for both irrigation and drainage. In the United States, some work was done at Colorado State University in 1913. With the introduction of perforated plastic pipes in Germany, Canada, and the United States for subirrigation, this concept received quite an impetus. In these efforts, the work of Symcha Blass, an Israeli engineer is worth mentioning; he observed in 1940 that a big tree near a leaking pipe showed more vigorous growth than other trees in the area. From this observation, he arrived at the concept of irrigation, wherein water was applied in small quantity, virtually drop by drop. The earlier drip irrigation system consisted of plastic capillary tubes attached to large pipes. The experiments around 1960 at Arava in Israel showed very good results. With the development of new plastic components after World War II, great headway was made in manufacturing plastic pipes and other accessories. Drip system components were gradually properly established and sold in different countries. Per one survey, this system has been adopted in 35 countries and is installed in an area of 1,784,846 ha.

Considering the rapid growth of microirrigation, six International Congresses have been organized so far: the first in Israel in 1971, the second in California in 1974, the third in California in 1985, the fourth in Australia in 1988, the fifth in Florida in 1995, and the sixth in South Africa in 2000.

MICROIRRIGATION: DEFINITION AND TYPES

According to Nakayama and Bucks (4), trickle irrigation is the slow application of water on, above, or beneath the soil by surface trickle, subsurface trickle, bubbler, mechanical move spray, or pulse systems.

In this method, water is applied by low pressure pipes at a low rate near the root zone, in small quantities at frequent intervals. The water is applied as discrete or continuous drops, small streams or sprays, through emitters placed near the plants. It is also known as localized irrigation, drip irrigation, trickle irrigation, daily flow irrigation, and microirrigation.

Microirrigation is presently the most accepted name that includes all variations such as surface trickle, subsurface trickle, bubbler, mechanical move spray, and pulse, which are briefly described below.

Surface Trickle. In this system, the emitters and laterals are placed on the soil surface. It is the most common type and is also called drip irrigation. It is used for widely spaced as well as row crops. Discharge rates are lower than 12 L/h for single outlet, point source emitters, and less than 12 L/h/m for line source emitters.

Bubbler. In this method, water is applied to the soil surface in a small stream or fountain with a point source discharge much higher than surface or subsurface trickle but less than 225 L/h. A small basin is required for proper water distribution.

Spray. In this system, water is applied as a small spray, fog, or mist Discharge is less than 175 L/h, and it is used to irrigate trees or other widely spaced crops.

Mechanical Move. In this system, the concept of the bubbler is extended to large spaced row crops. including travelling trickle and drag or hose reel systems.

Pulse. It has high discharge rate emitters, and thus short application times. The discharge ranges are 4–10 times larger than surface trickle emitters. This system has less clogging problems but needs inexpensive pulse emitters and automatic controllers.

Subsurface Drip Irrigation. This is another variation of drip irrigation, also covered under the term microirrigation. Its only difference from surface drip irrigation is that it is installed below the soil surface.

In this system, water is applied slowly below the surface through emitters whose discharges have the same range as surface trickle emitters. This is useful for small fruit or vegetable crops. Historically, it is the oldest modern irrigation method used in the United States. House (5) successfully used it for irrigating apples, alfalfa, and cereal crops with porous subsurface laid pipes. He, however, found it extremely costly and thus not economically feasible for field crops. The advancement in plastic materials, however has made it economically feasible for several crops. Blass (6) applied drip irrigation using laterals with buried drippers, but the practice was discontinued because of emitter clogging and root penetration. However, the practice was revived for the following reasons: (1) The same system could be used for several consecutive crops with minimum tillage. (2) The labor requirement in removing and installing the tubing with each crop was reduced. (3) There was less interference with weeding, spraying, or harvesting of the crop with buried laterals.

CROPS SUITED AND ADVANTAGES

Crop Suited

There are many crops for which drip irrigation has been used. The major fruit crops for which it has been used are citrus, deciduous, strawberry, grape, mango, pomegranate, banana, peach, pear, apricot, papaya, and coconut. Some of the important vegetables, cash crops, and plantation crops, to which it has been applied are tomato, potato, sugarcane, cotton, olive, coconut, watermelons, cardamom, and ornamental trees.

Advantages

These are the main reasons that drip irrigation is used:

1. It provides a high degree of control for water application. Using such control, it is possible to attain much higher efficiencies of the order of 90% compared to sprinkler irrigation (60–80%) and surface irrigation (50–60%). Thus, it provides high water saving and high water use efficiency compared to other methods of water application.
2. It supplies water at a rate sufficient to satisfy evaporative demand by maintaining high matric and osmotic soil water potentials, which minimize water and osmotic stresses. In conventional systems of water application such as flood or sprinkler methods, the fluctuations in soil matric and solute potentials are comparatively large. The lesser fluctuation and thus less stresses result in better plant growth, an increase in yield, and better quality of fruits.
3. There is partial wetting of soil with drip irrigation. Because of this, less water is lost through evaporation. However, on a seasonal basis, there may not be more water saving for this reason than in conventional methods. But this helps in reducing weeds, resulting in a lower cost of weed control. It is helpful in carrying out further cultivation operations, such as spraying and harvesting, without damaging soil structure.
4. The foliage remains dry, so there is less growth and incidence of plants diseases, reducing the use of pesticides and fungicides.
5. It permits using saline water. The increase in salt concentration because of soil drying between two irrigations is less in drip than in other irrigation methods. Salts from the wetted portion are frequently leached from the active root zone. Leaf burn is avoided because there is no foliar application in this method.
6. It can be well adapted to marginal soils, such as soils with high permeability and low water holding capacity, sands, leached tropical soils, and also for steep land and slowly permeable soils.
7. It requires less agricultural chemicals such as fertilizers, herbicides, and pesticides. Because their application is according to precise plant needs, the quantity required is less, leaching losses are less, and use is more efficient. It is thus cost as well as labor saving, and causes less nitrogen pollution in groundwater.
8. It uses less energy compared to high head sprinklers.
9. It is very well adapted to greenhouses in water and nutrient application without foliage wetting, such as needed for flowers and potted plants. It is also useful for water and fertilizer application in mulched crops and with wind tunnels.

Table 1. Yield Increase, Water Saving, and Payback Period

Sl.No.	Crop	Investment, \$/(Rs.)[a]	Payback, Years	Water Saving, %	Yield Increase, %
1.	Pomegranate	625/(30,000)	1	45	45
2.	Grape	917/(44,000)	>1 year	48	23
3.	Sugarcane	989/(47,500)	1	56	33
4.	Banana	979/(47,000)	1	49	52
5.	Tomato	625/30,000	NA	39	50
6.	Chili pepper		NA	62	44
7	Sweet lime			61	50
8	Watermelon			40	88
9	Okra			40	16
10	Cabbage			60	2
11	Cotton			53	26

[a] Rs. refers to Indian currency; 1\$ = Rs48 (variable with time).

Advantages of Subsurface Drip

Although another variation of microirrigation, its advantages need special mention. According to Phene et al. (7), it has the following advantages compared to surface drip: (1) There is a substantial increase in water use efficiency(WUE). (2) It enables precise fertilization with high frequency irrigation. There is negligible evaporation and almost total elimination of deep percolation and nitrate–nitrogen leaching. (3) There is long-term sustainability of the system.

WATER SAVING AND YIELD INCREASE

The most important aspects of microirrigation are water saving and increased yield compared to conventional irrigation. The experience for a few crops grown in India, as reported by Uriel (8) (slightly modified), are given in Table 1.

Table 1 shows that there is a 40 to 60% saving of water with drip irrigation over conventional irrigation. This water can be diverted to increase the area under irrigation or to other uses. Similarly, the yield increases from 23 to 88%. For vegetables and closely spaced crops, the investment is about \$979 (Rs.47000)/ha, whereas for trees, it is around \$625 (Rs.30000)/ha. For bananas, the payback is less than 1 year, whereas for fruits like pomegranate, the payback is 1 year.

COMPONENTS AND SYSTEM DESIGN

Components

Emission Devices. This is the most important component, for which sometimes the method of irrigation itself is named. This component acts as energy dissipater, reducing the inlet pressure head (0.5–1 atmosphere) to zero atmospheres at the outlet. It is generally made of polypropylene. Some types may be called orifice emitters, orifice-vortex emitters, long path emitters, compensating long path emitters, long path multiple outlet emitters, grove and flap short path emitters, grove and disc short path emitters, and twin wall emitters. The discharge rate of an emitter is characterized by its mean at normal operating pressure and the coefficient of manufacturing variation. Its operation varies in the range of 1–2 atmosphere. In orifice type emitters, the pressure is dissipated through a small hole 0.4–0.6 mm. They are highly prone to clogging. In long path emitters, the pressure is dissipated by flow through a long narrow path. The simplest type is the microtube. The diameters of microtubes vary from 0.6–1 mm. The energy loss in long path emitters can be increased by creating a tortuous long path in the form of a spiral or labyrinth. Sometimes, the energy can be dissipated through perforations or small holes. Biwall or twin bore are such systems. In these systems, there is a small tube or a supply chamber operating at a high pressure and fitted with large, widely placed orifices. For each inner orifice, there are many outer orifices in the emission chamber. There are several in-line systems with different designs conceived by different manufacturers.

In-Line Drippers. In-line drippers are based on the long path principle. They are molded plastic accessories, in which the thread is a long narrow passage governing the slow discharge of water. Some emitters are attached to the lateral tubing and in others, the lateral tubing forms the outer wall of the tubing fixed along with the line. They may have discharges of 2–8 L/h at 1 atmosphere.

On-Line Drippers. These drippers are fixed on the lateral by punching suitable holes in the pipe. They may be classified as nonpressure compensating type or pressure compensating type.

Simple Type with Laminar Flow. In this type, the discharge is directly proportional to pressure. It has a simple thread, labyrinth, zigzag path, or other arrangement to dissipate energy.

Turbo Key Type. This is a blockage resistant and pressure compensating type, made of stabilized polymers, available in 2,4, and 8 L/h discharge.

Pressure Compensating Type. This type, provides uniform discharge between pressures of 0.3–3.5 atm. This type dripper is provided with a high quality rubber diaphragm to control pressure. It gives 2,3,4, and 8 L/h discharge at varying pressures and is suitable for sloping topography.

Built-in Dripper Tube. In this type, the drippers are welded to the inside of the tube during extrusion of polyethylene pipes. They are provided with an independent pressure compensating discharge mechanism and wide water passage to prevent clogging.

Other Components

Lateral Pipes. These are pipes with diameters of 12–33 mm and wall thicknesses sufficient to withstand pressures of 4–6 atmospheres, to which the emitters are connected.

These pipes should be flexible, noncorrosive, resistant to solar radiation, and able to withstand temperature fluctuation. Normally, pipes are made of diameters 10,12,16, and 20 mm, 1–3 mm thick, and generally laid above the ground. They are commonly manufactured from low density polyethylene (LDPE) or linear low density polyethylene (LLDPE). LLDPE provides better protection from the ultraviolet rays of the sun.

Main and Submain Pipes. They are placed below the ground and supply water to the laterals. They are made from rigid PVC or high density polyethylene. The pipes may be 65 mm or more in diameter and can withstand pressures of 6 kg/cm^2. These pipes are laid underground for long life. For submains, rigid PVC, HDPE, or LDPE pipes are generally used; diameters are 32–75 mm and can withstand pressures of 2.5 kg/cm^2. They are commonly laid above ground.

Filters. This is an important component used to reduce or minimize blocking or clogging of emitters. They are of three types.

Media Filter. Required to remove organic matter such as algae. It is made up of a circular tank filled with layers of coarse sand and different sizes of gravel and valves for flushing the assembly in case of clogging. It is available in different sizes and capacities as required by the system.

Hydrocyclone Filter. Also known as a vortex sand separator. When the irrigation water has more sand, it is used as a prefilter to remove the sand before it enters the drip system. It is generally followed by a screen filter.

Screen Filter. It is fitted in series with a gravel filter to further remove impurities like fine sands, dust, etc. from the water. It consists of a single or double perforated cylinder placed in a plastic or metal container. Generally, 100–200 mesh screens are used in these filters. Screens are specified by the diameter of the pipe, recommended flow rate, total surface area of the filter, or by the cleaning method. The head loss needs to be periodically measured, and if it exceeds the permissible specified limits, it needs to be cleaned.

Fertigation and Chemigation

The process of adding the fertilizer with irrigation water is also known as fertigation. When other agrochemicals for control of insects and pests are used along with fertilizers, instead of fertigation it may be termed chemigation. Fertilizer application through microirrigation not only helps in providing fertilizer economy, it also minimizes health concerns. However, the potential to apply other chemicals is considered a great risk. Microirrigation cannot be used for chemigation with chemicals such as fungicides, herbicides, and growth regulators, that need to be applied to plant foliage. Three methods commonly used for fertigation consist of a bypass pressure tank, a venturi, or direct injection system.

In a bypass system with the closing of the main valve, a certain fractional quantity of flow is made to pass through the fertilizer tank. This bypassed water, dissolving the fertilizer, goes to the drip system. In the venturi type, a suction head is created at the constriction which sucks the fertilizer through the system. In the direct injection type, pumps of piston or diaphragm type, operated by system pressure inject fixed quantities of fertilizers into the system.

Automation

This refers to operation of the system with minimum manual intervention and is useful in large areas. This may be done in three ways. The first method is time-based. In this method, the time of operation is estimated according to the volume of water required and the average flow rate of water. The duration of irrigation required has to be determined for each section. The duration for each valve is fed into the controller along with system start time, and the controller clock is set with the current day and time. The clock actuates the starting time of the first valve and simultaneously the pump. After the duration of the first valve is over, the first valve is closed, or the controller switches to the next valve. The second method is volume-based. In this system, the preset amount of water can be applied in the field by using automatic control metering valves. Automation using a volume-based system is of two types. In one type, the valve with pulse output provides one pulse after completing one dial of the valve. The controller accepts the pulse input and counts the volume per pulse. The volume required in a segment, can be programmed in the controller. In the second type, the valves are placed near each segment, and no controller is required. The valves are interconnected in series through a control tube. During sequential operation, only one valve remains open. The third system is real-time feedback based on the demand of the plant. The plant itself determines the degree of irrigation required. Sensors such as tensiometers, relative humidity sensors, rain sensors, and temperature sensors control irrigation scheduling. Conventional scheduling is based on refill and full point. A real-time system controls and holds soil moisture near a constant value.

System Design

Collection of General Information. This requires collection of basic data including information about water source; topography; crops to be grown; general nature of soil and its characteristics such as texture, depth, infiltration etc.; climate; and rainfall. Such information is necessary for irrigation scheduling.

Field Layout. Depending on the type and location of the source, size, geometric layout, and topographical features, the planning is done. A contour map is helpful, but if the highest point, lowest points, ridge line, and drainage lines can be located, the layout of the system and the lengths of mains and laterals are decided.

Crop Water Requirement. The peak irrigation requirement (PIR) expressed in L/day/plant, may be estimated from the following relationship:

$$\text{PIR} = E^{*}{}_{\text{pan}} \times A \times K_{\text{p}} \times K_{\text{c}} \times K_{\text{r}} \times E_{\text{a}} + L_{\text{r}} - R$$

where

$E^{*}{}_{\text{pan}}$ = (mm/day) is the average maximum pan evaporation;

A = total area allocated to each plant, m^2;

K_{p} = the pan factor (Eto = $K_{\text{p}}.E_{\text{pan}}$ is reference crop evapotranspiration; K_{p} is less than 1 and may be taken as 0.8);

K_{c} = crop coefficient, selected for a given crop, growth stage and climatic conditions and has to be experimentally determined or adopted from available information;

K_{r} = a reduction factor, based on crop ground coverage, also known as the canopy factor varies from 0–1, and for a canopy occupying full K_{r}, is equal to 1;

E_{a} = overall application efficiency ($E_{\text{a}} = k_{\text{s}}.k_{\text{u}}$, k_{s} is a coefficient, whose value is less than 1 and takes care of deep percolation and other losses, k_{u} takes care of application uniformity smaller than 1),

L_{r} = extra amount of water needed for leaching, taken as 0, where there is no salinity and no leaching problem;

R = rainfall taken as 0, where in an arid region, a crop is to be grown only with irrigation.

For many maturing crops with good water holding capacity, different factors may be taken as 1, and a rapid estimate may be made using the relationship,

$$\text{PIR} = 0.8E_{\text{pan}} \times A \times E_{\text{a}}$$

Monthly Water Requirement. As per INCID (9), a simplified estimate may be obtained as

$$V = E_{\text{p}} \times K_{\text{c}} \times K_{\text{p}} \times A \times N(\text{liters})$$

where E_{p} is the mean monthly pan evaporation (mm/day), A is the area to be irrigated m^2, and N is the number of days in a month.

Net volume to be applied may be written as

$$V_{\text{n}} = V - R_{\text{e}}$$

where R_{e} is the effective rainfall (mm).

The operating hours of a system for a month may be obtained as

$$T = \frac{V_{\text{n}} \times W_{\text{p}}}{\begin{array}{c}(\text{Drippers/plant}) \times \text{plant numbers}\\ \times\text{dripper discharge}\end{array}}$$

where W_{p} is the wetted area.

Operating hours per application may be written as

$$T_{\text{a}} = T/N_{\text{m}}(N_{\text{m}} \text{ is number of application/month})$$

System Design

Laterals may be designed by considering the flow of each lateral (de) obtained by multiplying the discharge of each dripper by the number of drippers per lateral. The diameter of submains may be designed by considering the flow of each submain line (ds), obtained by multiplying by the number of laterals.

The design of a main line may be done by considering the total flow of all the submains (dm), obtained by multiplying (ds) by the number of laterals.

The design of diameters of laterals, submains, and mains may be done by considering the pressure drop due to the friction of each lateral, submain, and main using the head loss relationship of Blassius or the William and Hazen equation.

The pump horsepower may be determined from the friction head losses of mains, submains, and laterals (H_{f}), the static head for the pump-well system (H_{s}), and the operating pressure head of the emitter (H_{e}):

$$\text{Total head } H = H_{\text{f}} + H_{\text{s}} + H_{\text{e}}$$

Thus,

$$\text{HP} = \frac{H \times \text{d}_{\text{m}}}{75 \times M_{\text{p}} \times M_{\text{m}}}$$

where M_{p} and M_{m} are the efficiencies of the motor and the pump, and d_{m} is the discharge of the main in liters per second.

EXTENT OF MICROIRRIGATION

There has been a very fast rate of adopting and extending microirrigation in different countries in the last 20 years, and several surveys have been carried out to find its coverage.

From the third international survey by ICID, reported by Bucks (10), it was found that from an area of 412,760 ha in 1981, it increased to 1,082,631 ha in 1986, and 1,768,987 ha in 1991. This was a 63% increase in 5 years and a 329% increase in 10 years. The major users of microirrigation in decreasing order, according to a survey in 1991, were the United States, Spain, Australia, South Africa, and Israel. Other countries having sizable microirrigation were Thailand, Columbia, Jordan, Brazil, China, Cyprus, Portugal, Chinese Taipei, and Morocco.

The fourth survey has been in process through the endeavor of Kulkarni of ICID. Preliminary feedback has been reported from 1981–2000, 19 years, by Reinders (11)

Table 2. Microirrigation Area in a Few Countries Over 19 Years[a]

Country	1981, ha	1986, ha	1991, ha	2000, ha
USA	185,000	392,000	606,000	1,050,000
India	20	0	55,000	260,000
Australia	20,050	58,738	147,011	258,000[b]
Spain	0	112,500	160,000	230,000
South Africa	44,000	102,250	144,000	220,000
Israel	81,700	126,810	104,302	161,000
France	22,000	0	50,953	140,000
Mexico	2,000	12,684	60,000	105,000*
Egypt	0	68,450	68,450	104,000
Japan	0	1,400	57,098	100,000[b]
Italy	10,300	21,700	78,600	80,000
Others	70,770	434,036	294,873	523,300
World	436,590	1,030,578	1,826,287	3,201,300

[a] Reference 11.

[b] Hectarage adjusted from 1991 figures according to the average percentage increase of other countries, as per data obtained by Dr. Kulkarni of ICID.

and is given in Table 2. From 1981–1986, a 136% increase took place and from 1986–1991, a 77% increase took place. From 1981–2000, 19 years, usage increased 633%.

Although there has been a tremendous increase in the use of microirrigation, the total area under microirrigation continues to remain only 0.8% of the total irrigated area of the world (10).

Besides the ICID surveys, according to Uriel (8), there have been several other assessments of the extent of microirrigation in different countries which are briefly given below.

According to a survey, it was estimated that in the Mediterranean coastal plains in Palestine, about 70.5% of vegetables was irrigated by drip irrigation, 28% by sprinklers, and a negligible area by traditional methods. It was found that 87% of farmers in the Jordan Rift Valley can grow two crops with modern methods in comparison with 83% in the coastal region. In Jordan, mainly in the Jordan Rift Valley, 64% of farmers use drip irrigation.

In the mountainous area around Lake Titicaca between Peru and Bolivia, a combination has been made between simple rural greenhouse and drip irrigation for growing potatoes and vegetables. Potatoes grown in greenhouses produced 350 kg/50 square meters an increase of 500% in yield in comparison to traditional methods. In Mauritius, about 33,000 small farmers cultivate about 25,000 ha of sugarcane. In several other countries like Nicaragua, southern Argentina, Thailand, Turkey, Peru, Mozambique, and China, drip irrigation is being tried for vegetables and orchard crops.

According to Smajstrla et al. (12), about 20% of the U.S. microirrigated fruit crops consist of Florida fruit crops which are primarily citrus. About 358,000 ha area in Florida is occupied by fruit crops most of which is citrus. Microirrigation provides better freeze protection and faster growth of citrus trees. Over 11% of 1.9 mha of commercial agricultural crops is microirrigated, of which 94% is in fruit crops, primarily citrus.

Among field crops, microirrigation has been extended to sugarcane and tobacco; 90% of Florida sugarcane is grown in muck soils, where subirrigation is practiced. Only 10% of sugarcane is in sandy soil which has the potential for microirrigation.

Vegetable Crops

Vegetable crops are grown in over 140000 ha in Florida, most of which is irrigated. About 2100 ha of strawberries grown in Florida are drip irrigated because of production benefits.

Per Chieng and Gulik (13), of 940,000 ha of land under irrigation in Canada, about 4700 ha were under microirrigation, and the trend is increasing. Most of the large scale microirrigation systems were in the province of British Columbia. In most of these areas, chemigation was being practiced, and the systems were used for tree fruit, field vegetables, greenhouse, flowers, and vines

Drip Irrigation in some indigenous form has been practiced in India for a long time. Perforated earthenware pipes have been used for quite some time in different parts of the country such as Maharashtra and Rajasthan. Similarly, perforated bamboo pipes and pitchers have been in use. In Meghalaya, they have used bamboo drip irrigation systems for betel pepper and areca nut crops by using low flows from hill streams. Drip irrigation in modern form was introduced in the early 1970s in India. Significant development has taken place in the 1980s. Per some estimates, from a small coverage of 1500 ha in 1985, the area increased to 6000 ha in 1988, 66,000 ha in 1993, and 260,000 in 2000.

The adoption of drip irrigation has been maximum in acute water scarce areas of Maharashtra state for commercial and horticultural crops such as coconut, grapes, banana, fruit trees, sugarcane, and plantation crops. About 85% of the installed drip systems in India has taken place in Maharashtra. The states of Karnataka, Tamil Nadu, Gujarat, and Andhra Pradesh have been gradually picking up.

According to Jain (14) there were 0.38 mha of land under microirrigation, making India the second largest in the world next only to the United States which has 1.055 mha.

Extent of Application to Different Crops and Trends

Per the survey, microirrigation has been applied differently to different crops, according to Bucks (10). It has been applied most to tree crops, covering 41.5%. Among fruits, deciduous types constitute the second largest coverage having a share of 16.7%. Citrus fruits constitute the third next highest, having a coverage of 13% of all the area covered. Olives/nuts are another crop having a share of 5.1%. Among vines, it has been applied most to grapes having a share of 11.1%.

The other tree crops under major application of microirrigation consist of avocado, mango, olive, nut tree, and coconut. There has been quite an increase of microirrigation in vines and vegetables which constitute 26% of the area under microirrigation. Application of microirrigation was done for cash crops like sugarcane in Hawaii on a large scale on about 42,000 ha in 1991. Coconut occupied an area of 37,000 ha. Among vegetables, it has a maximum coverage under field vegetables.

Greenhouses are expensive, so it is understandable that the area covered under such a system would be less than that of field crops. Microirrigation has been applied to a large number of unspecified crops. The area under this category in the 1991 survey was 21.5% of the total area of 1.8 mha.

In the trend of component use, it was observed that bubblers and microsprinklers were being installed more for tree crops than individual drippers. Line source applications were being used more than individual drippers. Pressure compensating drippers were increasing in use in some countries but were generally creating problems after 2 to 5 years. Fertigation was increasing in many countries such as the United States, Spain, Australia, Israel, South Africa, and Mexico. In other countries, it was still in the initial stages. Emitter clogging was generally caused by sediments, precipitated salts, or bacterial slimes. These problems were gradually solved with bubblers and microsprinklers as well as by better fabrication. To control clogging, generally, acids and chlorine were applied. The application efficiencies ranged from 60–90%.

The costs of installation in the third survey ranged from US $ 2000 to US $ 7000 per ha. It was generally found that line sources (drip tapes, etc.) used in vegetable and field crops were more expensive than drippers or microsprinklers used for tree crops. Systems with average costs from $ 2000 to $ 4000 were economically and efficiently operated for trees, vegetables, and field crops.

Extent of Subsurface Drip Irrigation

Although economical and highly efficient, the design and laying of subsurface drip is more sophisticated and complex, and its installation fairly soil and crop specific. Thus, in spite of its being promising, its application is still in its infancy. Per the ICID third survey, it had a coverage of 54,000 ha in the United States, 2500 ha in China, 150 ha in Israel, and 2184 ha in other countries, a global coverage of 58,834 ha. According to Phene et al. (15) reporting figures from the Irrigation Journal's 1992, irrigation survey out of a total of 690.2 kha of microirrigation coverage in the United States about 76.6 kha or 11.1% was under SDI. In California SDI had grown to 61.3 kha in 1992. This constituted about 80% of all SDI in the United States. The different crops to which it has been applied were potato, tomato, strawberry, cantaloupe, lettuce, cotton, grape, hops, apples, peach, almond, walnut, turf, and ornamentals.

LIMITATIONS, RESEARCH TRENDS, SCOPE, AND PROMOTION

Limitations

Emitter Clogging. This is one of the most important problems in the use of microirrigation. This may occur due to sand, rust, microorganisms or other impurities carried by irrigation water or because of chemicals precipitating in the flow system. Root penetration also reportedly causes clogging, which occurs mostly in buried systems. Proper filtration may remove suspended particles. Suspended organic matter and algae, etc. can be removed by media filters, whereas larger suspended materials can be removed by centrifugal separators. Appropriate chemicals can eliminate clogging due to precipitation of salts in the system.

Mechanical Damage. This may be caused by rodents, birds, animals, or careless use of implements. Chemicals are now available, which if mixed with plastics, discourage or prevent damage by rodents. With subsurface drip, there is minimum cultivation, and damage due to handling or implements can be avoided.

Salinity Hazard. With the use of brackish water for irrigation, salts tend to accumulate at the wetting front. The problems are caused in arid regions if irrigation methods other than drip are used and salts cannot be leached. The problem can be reduced by using sprinkler or flood methods of irrigation to leach the salts wherever feasible.

Lack of Microclimatic Control. This method cannot commonly provide frost protection as done by sprinklers, but a variation of microirrigation, known as microsprinklering, also provides quite effective frost protection.

Higher Costs. Compared to surface and sprinkler irrigation systems, installation costs are higher. Thus, it is feasible only for appropriate field crops and fruits, where returns are cost-effective. In some developing countries, to promote economy in using irrigation water, subsidies have been given for its installation; that has given good results in extending its adoption.

Lack of Awareness. This is a system requiring high skill in design, installation, operation, and management; it requires proper demonstration and training to extend its use to farmers in developing countries.

Research Trends

The issues and type of research in different countries vary according to need. However in the United States, which has the largest area in microirrigation, per Phene (16), research trends center around four areas: (1) determination of water requirements and irrigation scheduling, (2) nutrient management/fertigation methods and water quality, (3) system design and uniformity, and (4) expert systems and simulation models. The area of water requirement is considered important in view of the difficulty of accurate determination of water requirements and irrigation scheduling. The efforts related to this area were directed toward use of personal computers for data acquisition and control systems and electronic sensors for automation. Efforts were also directed to using plant measurements for scheduling irrigation and regional and local automatic scheduling, measuring, and calculating crop evapotranspiration as well as use of simulation models. Nutrient management was considered important in view of high nitrate-nitrogen pollution because of surface application and the scope of its reduction through fertigation. Because of improvements in materials hardware availability, quality, and manufacturing uniformity, there is a good potential for improvement in designing microirrigation systems and developing microcomputer programs. Expert systems have the ability of facilitating the transfer of knowledge from researchers to users. The soil water–plant relationship is a complex phenomenon, in which, expert systems can play a useful role in irrigation selection, scheduling, and management

Future Scope

It may be observed that the world food requirement is likely to increase as population increases. On the other hand, water availability for food production is gradually shrinking. Water scarcity has become the single biggest threat to food security, human health, and natural ecosystems. The only way to match higher food production with declining water resources seems to be optimization of available water resources through efficient water management Application of microirrigation has demonstrated great savings in water and fertilizer and also increased crop yield and improvement of the quality of produce. Due to this, there has been a fast growth of this technology, and the area has increased to more than double in 5 years since 1981 and to more than 4 times in the next 5 years. Such a trend shows the great possibility of further increase in the future. According to future projections, by the year 2000, the area will increase to more than eight times its coverage in 1981.

During its period of progress, its applicability has been tried for several other fruit and field crops with encouraging results. It has shown tremendous scope for flowers and vegetables and use in greenhouses and nurseries. Lots of good work has been done in landscaping, and there is a good prospect for further expansion in this area.

Success in the use of sewage as well as saline water and poor and degraded soils has further enlarged its scope. The experiments in Abu Dhabi of growing eucalyptus and casuarinas through drip irrigation using waters of salinity of 2000 mg/L and 12,000 mg/L, respectively, for stabilising sand dunes, offers great hope of greening the world's deserts.

Subsurface drip has emerged as a new promising technology, useful in further economizing water use and reducting labor, and is likely to become commercialized in the near future.

According to Uriel (8), good prospect has been observed for further expansion of microirrigation in several developing countries. In China, there is a plan for water conservation in five provinces. There is also a plan for improvement of on-farm irrigation in an area of 2,50,000 ha with sprinkler, drip, and flood irrigation. In the desert region of Nuberia in Egypt, drip irrigation is expected to cover an area of 100,000 ha of vegetables and fruits. In Nicaragua, a world relief organization has established 100 model farms to introduce drip irrigation for vegetables. In Argentina, 20 model farms for drip irrigation have been developed for vegetables, flowers, and orchards. In Peru, small areas were laid for drip irrigation to grow asparagus and vine yards on 900 hectares. In Turkey, a large scale project is in the process of improving community irrigation of which 1200 ha is for drip irrigation. In Mozambique, citrus orchards next to a dam are planned to irrigate 210 ha. In India, microirrigation has been applied in a number of states such as Maharashtra, Gujarat, Karnataka, and Tamil Nadu. But there is still a large scope for its application in other states. In the state of Andhra Pradesh, a large project of microirrigation is on the anvil.

In developing countries, however, there may be a necessity of providing subsidies in the initial stages and carrying out training and demonstrations to improve the awareness of technical staff and farmers in the interest of economizing on water use and environmental health. Besides increasing awareness, there is a great need to increase the technical competence and skill of technical people involved in installation and maintenance. Development of a strong database and providing optimum design, installation, and maintenance are great needs in developing countries and would boost microirrigation expansion a long way.

In the developed world, microirrigation offers hope to economize, reduce, and alleviate the use of excess fertilizer and the pesticide leaching hazard in surface irrigation and subirrigation and pollution of groundwater. This would help improve water quality and environmental health.

Strategies for Promotion

The future global shortage of water is very well recognized. The agricultural sector continues to be the major user of water. As the future share of water for other uses increases, the share available for the agricultural sector is likely to be further reduced. It is, therefore, essential to stress the economic and efficient use of water through microirrigation and other improved technologies of efficient water application. The developed countries have already adopted this technology to quite a large extent, though there is still scope for further adoption and extension of the more sophisticated systems such as use of automation, SDI, etc. But it is more important for the developing countries faced with increasing population and the need for more food production. Some possible approaches to meet such objectives are identified:

1. Coordinated efforts of scientists, engineers, research institutions, and industry are needed to develop appropriate technologies for field adoption of microirrigation.
2. There is a necessity to create a database on different aspects of microirrigation for specific crops/cropping pattern in different agroclimatic zones of a region. It is specially important to match the water requirement of a crop/cropping pattern to the economic viability of a system.
3. The manufacturing industry should establish a research and development base for continued improvement of the equipment to attain better performance and economy.
4. Besides working on larger systems, the industry and researchers should also develop technologies

for smaller systems suited to farmers. Small landholders have successfully used and managed drip systems for small plots.

5. It is necessary to carry out large scale demonstrations by industry, government, and nongovernment institutions on different crops in different regions to establish economic viability and promote awareness among farmers/users.
6. For the application of fertilizers and pesticides along with microirrigation, there is a necessity of generating a database on the feasibility and compatibility of such practices with a given soil water/crop condition which is duly approved by a recognized scientific body.
7. Before a microirrigation system is made available, it is necessary to ensure that the different components are manufactured according to established or adopted standards of a country, so that the materials and manufactured products give the desired performance and life for the system.
8. Microirrigation, though providing efficient and economic use of water and improving the yield of crops, is comparatively an expensive irrigation system specially suited to fruit plantation and vegetables. Besides the technical feasibility of production for a profitable return, it is also necessary to look into infrastructural aspects, such as postharvest technology, transport, and marketing as well as pricing policy. Unless the infrastructural aspect is taken care of and transport and marketing are streamlined, fruits and vegetables, being perishable products, cannot be profitably disposed of, and this expensive system cannot be sustained.
9. In many developing countries, liquid fertilizers are not indigenous and are imported; they are not affordable. Policy decisions may be necessary to enable in-country manufacture.
10. The present cost of installation may prove high for small and marginal farmers in developing countries. It needs to be examined as a policy that keeping in mind the global shortage of water, it may be worthwhile to partly subsidize the installation cost in the initial stages. Easy disbursement of subsidies that avoid delays may be desirable.

PLANT AND MICROORGANISM SELECTION FOR PHYTOREMEDIATION OF HYDROCARBONS AND METALS

T.C. McIntyre
(from *Phytoremediation: Transformation and Control of Contaminants*, Wiley 2003)

SUMMARY OF PRACTICAL IMPLICATIONS

Information on plants and other organisms that have the potential for phytoremediation of contaminants aids in the planning and establishment of removal and restoration projects for contaminated sites. Environment Canada is compiling databases on plants, bacteria, fungi, and other organisms that remediate petroleum hydrocarbons and accumulate metals and metalloids. The databases PHYTOPET (for PHYTOremediation of

PETroleum hydrocarbon contaminants) and PHYTOREM (for PHYTOREmediation of Metals) are user-friendly, searchable, and summarize all the known literature. Environment Canada has also drafted a Protocol, "Environmental Technology Verification (ETV) Protocol for Metal Contaminants." The program provides suppliers of specified environmental technologies and services that meet the required criteria, with the right to use the licensed ETV verification mark.

PHYTOREMEDIATION APPLICATIONS

Phytoremediation has good potential as a flexible and cost-effective means to clean up contaminated sites. Two of the most important applications are the use of plants and other organisms to degrade petroleum hydrocarbons and accumulate metals and metalloids (hereafter the term metals covers both). Plants and other organisms extract and degrade contaminants using a variety of processes such as:

1. Phytoextraction—the capability of terrestrial plants, algae, and plant tissues to sequester toxic elements, especially metals, by uptake or biosorption. Contaminated organisms can be harvested for disposal or extraction (biomining when at commercial levels) (1–6).
2. Rhizofiltration—the use of plant roots to absorb and sometimes precipitate contaminants from polluted waters (e.g., 7).
3. Phytostabilization—the use tolerant plants to stabilize contaminants by reducing bioavailability.
4. Phytodegradation—the use of plants and associated microorganisms to degrade organic pollutants.
5. Phytovolatilization—the use of plants to volatilize pollutants.

Information on useful phytoremediation species is limited and scattered in the literature. Environment Canada has organized information into two databases called PHYTOPET and PHYTOREM. The PHYTOPET database is a compilation and global inventory of organisms, with a focus on plants, for phytoremediation of petroleum hydrocarbons. PHYTOREM is a similar database for metals and metalloids.

Plants and other organisms have a remarkable capacity to accumulate contaminants, e.g., the common sunflower (*Helianthus annuus*) (8), Indian mustard (*Brassica juncea*) (9), alpine pennycress (*Thlaspi caerulescens*) (10,11), and brake fern (*Pteris vittata*) (12). Some of the highest accumulation of metals occurs in the New Caledonia tree (*Sebertia acuminata*) (13) and the Australian shrub (*Hybanthus floribundus*) [reported by Streit and Stumm in 1993 (14) as first reported by Harborne in 1988 (15)]. The purpose of this chapter is to describe the compilation of data for plants and other organisms that degrade hydrocarbons, or accumulate, hyperaccumulate, or tolerate metals.

PLANTS THAT TOLERATE AND SPUR DEGRADATION OF TOTAL PETROLEUM HYDROCARBONS

The database PHYTOPET specializes in plant species that spur the rhizodegradation of petroleum hydrocarbons in terrestrial and aquatic environments, including wetlands. The plants (both monocots and dicots), bacteria, protozoa, and fungi covered by the database show potential for phytoremediation of a wide range of hydrocarbons—from crude oil to polyaromatic hydrocarbons, such as chrysene and benzo(*a*)pyrene (Hutchinson et al. this book, Olson et al. this book). In the database, special attention has been paid to the Canadian plants from the oil-producing regions in the Western Prairie and Boreal ecozones for reclamation of oil-contaminated sites. The relationships between plants, microorganisms, and other species that can phytoremediate similar chemicals or mixtures of contaminants (metals, pesticides, and hydrocarbons) have also been considered.

The database uses many of the same fields as the PHYTOREM database for plants (exchanging information on the metal elements for information on the hydrocarbons). In addition, the database compiles information on plant-associated microorganisms. The information includes concentrations of the contaminant before and after treatment, length of treatment period, soil characteristics, age of the plant when exposed to the contaminant, and requirements for phytoremediation. Data in PHYTOPET also include tolerance to salinity and Western Canadian occurrence.

Many native grasses show promise to phytoremediate hydrocarbons [e.g., *Agropyron* spp., gramas (*Bouteloua* spp.), and buffalo grasses (*Buchloe* spp.)]. Poplar (*Populus* spp.) trees also are potentially useful. Cultivated plants with phytoremediation potential include carrot (*Daucus carota*), red fescue (*Festuca rubra*), alfalfa (*Medicago sativa*), and ryegrass (*Lolium* spp.).

PLANTS THAT ACCUMULATE METALS

Scope and Organization of the PHYTOREM Database

The global inventory of PHYTOREM covers both terrestrial and aquatic plants and other organisms (such as bryophytes, lichen, fungi, algae, and bacteria) that have potential value for phytoremediation of metals. Species included in the database have an ability or potential to tolerate, accumulate, or hyperaccumulate specific metals, or be useful as sorbents for metals.

An intensive literature search was conducted for the database, for accumulation of or tolerance to the 19 selected elements listed in Table 1. Reviews on metal accumulation provided global data (16–23). Although a large number of species are known to grow over serpentine substrates, only those specifically shown to be hyperaccumulators or to accumulate substantial levels of heavy metals are included in the database.

The database contains information on organisms that are both hyperaccumulators and accumulators (Table 2). The term hyperaccumulator was originally coined for

Table 1. Metals and Metalloids Scanned for the Development of the PHYTOREM Database

Aluminum (Al)	Cobalt (Co)	Mercury (Hg)	Radium (Ra)
Arsenic (As)	Copper (Cu)	Molybdenum (Mo)	Strontium (Sr)
Beryllium (Be)	Chromium (Cr)	Nickel (Ni)	Uranium (U)
Cadmium (Cd)	Lead (Pb)	Palladium (Pd)	Zinc (Zn)
Cesium (Cs)	Manganese (Mn)	Platinum (Pt)	

plants with greater than 1000 milligrams per kilogram (0.1 percent) nickel in dried aboveground tissues (34,35). This definition has been broadened to other elements and all parts of plants. Values for accumulation were based on either literature, or a value of 100 or 200 milligrams per kilogram of dry weight was assigned where none has been specified.

Information in the database includes geographical origin of the organisms and habitat characteristics; taxonomy; environmental effects, health effects, and uses of the species; cultivation practices; sources of material or species studied; weedy or other significant relatives; and mode of action (i.e., tolerance and accumulation). See Table 3 for details of criteria and fields. The database is worldwide in scope, but focuses on species from Canada, the U.S., and high-altitude species from warmer regions.

The database, compiled using *Microsoft Access 97®* software, allows for easy access by many database formats and programs and can be updated as needed. The database consists of three organism and two reference tables (Fig. 1a). The organism tables are (1) vascular plants; (2) algae, lichens, fungi, and mosses; and (3) bacteria. The main table of reference includes all citations that relate to concentration levels of elements accumulated or tolerated, and the second is a table of general botanical and reference works consulted. The database as designed can be searched by queries (Fig. 1b) and includes three data entry forms (botany, metal, and plant) and reporting formats for organisms and reference records.

Data sets can be quickly retrieved by applying appropriate search criteria, and viewed in tabular format. An example of a data screen for a species retrieved through the filtering process is given in Fig. 2.

The database has specific search criteria, some of which are as follows:

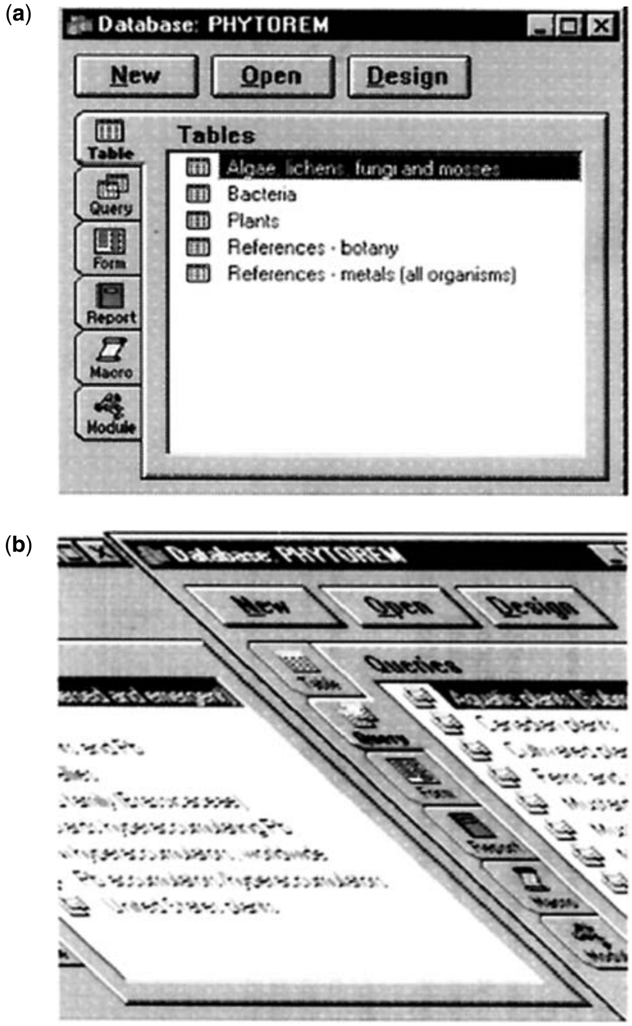

Figure 1. PHYTOREM database windows showing contents from the tables (**a**) and query (**b**) menus.

1. To access the elements radium and uranium, use the codes Rd and Ur respectively. Searches for accumulators or hyperaccumulators, however, use commonly used short forms for these elements. For example, the character code RaA will bring up accumulation data for radium.
2. To retrieve all records of species accumulating (A), hyperaccumulating (H), tolerating (T), or precipitating (P) an element, use the symbol for the element surrounded by asterisk in the elem_action field, e.g., "*Pb*" as the query or filter criterion. To retrieve species accumulating or hyperaccumulating a particular element, the search criterion should be a combination of the element and the desired accumulation code, e.g., "*PbH*" for lead hyperaccumulators.
3. There is no separate field to distinguish coniferous species; however, species can be retrieved by using the family Pinaceae or by retrieving all records with a growth form of TR for tree.
4. Species are reported as rhizofiltration agents for heavy metals. Studies dealing with nutrient culture experiments, although not aimed at identifying such agents, have been recorded with a Y for "yes" in the field biofiltr_use, because of the potential for such use.

Table 2. Values and Sources for Hyperaccumulation and Accumulation Criteria for Inclusion in the PHYTOREM Database

Element	Hyperaccumulation Criteria (Milligrams per Kilogram of Dry Weight)	Plants, Where Appropriate, Which Were the Basis of Criteria	References for Data	Accumulation criteria (Milligrams per Kilogram of Dry Weight)	Number of Records in the Database	Species with Highest Recorded Value {origin} [Value (Milligrams Per Kilogram of Dry Weight)]

Zn	10,000		17	500	48	Alpine pennycrest (*Thlaspi caerulescens*) {Europe} [52,000]

? indicates that criteria have not been defined for hyperaccumulation or accumulation of these elements.

Note: No reports were found for accumulation of beryllium, palladium, platinum, and radium.

Table 3. Fields, Description, and Access for PHYTOREM Database

Name	Description [and explanatory comments]	Plants	Bacteria	Algae	Access
Entry_seq	Automatic counter field to record sequence of data entry [allows multiple records taken from a single summary document to be grouped together for purposes of review and data management]	√	√	√	
Type_org	Vascular plant = VP, bacteria = BA, algae = AG, lichens = LI, fungi = FU, and bryophytes = BR [field allows tables of different organisms to be combined and provides the ability to distinguish records by type of organism]	√	√	√	
Growth_form	For plants only: fern = FE, graminoid = GR, herb = HE, shrub = SH, succulent = SU, vine = V, and tree = T	√			
Sci_name	Complete scientific name with authorities	√	√	√	√
Synonym	Common synonym	√		√	
Com_name	Common English name(s)	√	√	√	
Cv_strain	Cultivar or strain name, or code; also transgenic variants	√	√	√	
Family	Taxonomic category: family	√		√	√
Order	Taxonomic category: order	√		√	√
Subclass	Taxonomic category: subclass	√		√	√
Class	Taxonomic category: class	√		√	√
Duration	For plants only: A(nnual), B(iennial), A/B, P(erennial), A/P, and B/P	√			
Origin	Country or region of origin of plants on which report(s) is based [Canadian and U.S. species or those of other continents or countries can be sorted]	√	√	√	√
World_range	World range of the species	√			
Primary_habitat	T = terrestrial, A = aquatic, T/A = terrestrial and aquatic [provides the ability to distinguish between terrestrial, aquatic, marsh, and wetland species (T/A)]	√		√	√
Hab_descr	Habitat description [allows for sorting to distinguish plants from serpentine soils and to distinguish cultivated species (crop plants)]	√			
Namer_occ	North American occurrence: N(ative); E(xotic); X (not present); ? (status unknown) [allows North American species to be categorized]	√			
Namer_spp	Indication of whether other species in the genus are present in North America	√			
Sig_relatives	Other species of significance in the genus	√			
Cult_wild	For plants: crop plant = C, horticultural species = H, wild = W. For algae and other: cultured = C or wild = W	√		√	√
Cult_info	Propagation and/or test studies, or experimental conditions	√		√	
Cult_source	Source of cultivated material as indicated in publication	√	√	√	
Impact_attributes	UN = unknown, WD = weed, NX = noxious properties, HY = hybridizes, and PH = disease and insect pest host	√			
Impact_description	Documentation of potential impact [information on invasive potential of an exotic weed]	√			
Uses	General uses of plant and citations [medicinal or edible]	√			
Bio_notes	For plants: notes on such topics as pollination and dispersal mechanism. For bacteria: notes on important and interesting aspects of biology.	√	√		
Gen_notes	For plants and others: toxicity of metal to the plant or other organisms and other pertinent information and citations. For bacteria: general notes on procedures of the study or results and citations.	√	√	√	
Elem_conc_ref	Citation and concentration of elements with organ of storage	√	√	√	√
Elem_form_ref	Element form if specifically indicated [e.g., Cu(II)]	√	√	√	
Elem_chel_ref	Element, chelate used and citation	√	√	√

Figure 2. Example of a plant report form from a search of the PHYTOREM database.

Summary of the Database Contents

The database provides an extensive, though preliminary, collection of records on phytoremediation potential. At present, the database contains records of 775 species spread over 76 families, 39 orders, 9 subclasses, and 2 classes (dicots and monocots). Data come from 39 countries of origin (based on names used in the publications).

The greatest proportion (465) of species recorded in the plant table accumulate, hyperaccumulate, or tolerate a single metal of the 19 elements surveyed. Some species take up two elements (66) or three (25), with a balance of 15 species capable of accumulating four or more elements. Table 4 summarizes the species in the latter category with elements and degree of accumulation.

The highest number of records (260) was found for nickel followed by lead and copper (Fig. 3). No records were found of species accumulating beryllium, palladium, platinum, or radium. Species with the highest concentration of the elements recorded in the database (listed in the right-hand column of Table 2) provide some interesting possibilities for phytoremediation, including several commonly cultivated species such as sunflower (*Helianthus annuus*) and alfalfa (*Medicago sativa*).

Data Update Recommendations

Updates that could be considered include (1) information from a more extensive literature search, (2) fields for data on storage sites (e.g., roots), (3) mechanisms of tolerance or accumulation of metals by plants, (4) species that remediate radionuclides, (5) plants that remediate organic and other inorganic compounds and stabilize contaminated sites, and (6) expansion of data for algae, in particular those with a high absorptive capacity. In addition, the database could also provide pictures of plants and sites.

INORGANIC PHYTOREMEDIATION VERIFICATION PROTOCOL

Environment Canada is formulating a protocol to establish the limits of applicability for the phytoremediation of metals and metalloids in contaminated soil and water that will aid economic adoption and sustainable use. The pollutants (no organic contaminants to this point) are arsenic (As), cadmium (Cd), chromium (Cr), copper (Cu), lead (Pb), mercury (Hg), nickel (Ni), selenium (Se), silver (Ag), and zinc (Zn). Use of the verification protocol will allow the use of a Canadian Environmental Technology Verification symbol in remediation products. The applicant will be required to establish that a particular application has been tested (and under what conditions) (e.g., proof of principle at the bench, greenhouse, plot, or full-scale testing). Only applications that involve phytoextraction, rhizofiltration, phytovolatilization, phytostabilization, and combinations of these physiological processes will be certified initially. All phytoremediation applications (or technologies) will be evaluated based on the following criteria and information:

1. Total amount, concentration, and speciation of elements in contaminated soil, rhizosphere soil water,

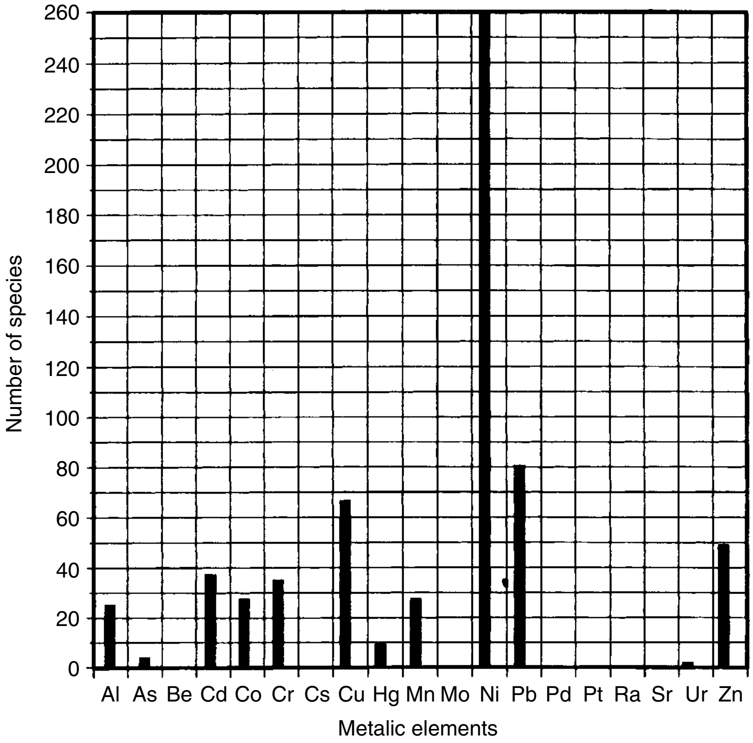

Figure 3. Number of species records for the 19 elements scanned.

Table 4. Plants Capable of Accumulating Four or More Metals

Scientific Name	Common Name	Origin and Characteristics	Elements and Degree of Accumulation[a]
Azolla filiculoides	Water fern	Africa, floating	CuA, NiA, PbA, and MnA
Bacopa monnieri	Water hyssop	India, emergent species	HgA, CuH, CrH, PbA, and CdH
Eichhornia crassipes	Water hyacinth	Pantropical/subtropical, troublesome weed	CdH, CrA, ZnA, HgH, PbH, and CuA
Hydrilla verticillata	Hydrilla	Southern Asia but introduced and spreading as a troublesome weed in the warmer states of the USA	CdH, CrA, HgH, and PbH
Lemna minor	Duckweed	Native to North America and widespread	PbH, CdH, CuH, and ZnA
Pistia stratiotes	Water lettuce	Pantropical and native to southern U.S. but an aquatic weed	CuT, CdT, HgH, and CrH
Salvinia molesta	Water fern	India	CrH, NiH, PbH, and ZnA
Spirodela polyrhiza	Giant duckweed	Native to North America	CdH, NiH, CrH, PbH, and ZnA
Vallisneria americana	Tape grass	Native to Europe and North Africa but widely cultivated in the aquarium trade	CuH, CdH, CrA, and PbH
Brassica juncea	Indian mustard	Cultivated	PbH, PbP, ZnH, NiH, CuH, CrA, CdA, and UrA
Helianthus annuus	Sunflower	Cultivated	PbH, UrH, SrH, CsH, CrA, CdA, CuA, MnA, NiA, and ZnA
Agrostis castellana	Bent grass	Portugal	AsH, PbA, ZnA, MnA, and AlA
Thlaspi caerulescens	Alpine pennycress	Europe	ZnH, CdH, CoH, CuH, NiH, PbH, and CrA
Athyrium yokoscense	Fern	Japan	CuH, CdA, ZnH, and PbH

[a] H: hyperaccumulator; A: accumulator; P: precipitator; and T: tolerant.

water below the root zone, groundwater, wastewater, roots, shoots, and air (where phytovolatilization is a factor) during and after treatment

2. Amount and timing of supplements added to treated soils and waters as related to mobilization or immobilization of contaminants, including co-contaminants, and expected effects
3. Seepage or infiltration volumes from treatment wetlands or soil plots and concentrations of contaminants and by-products for the range of expected moisture conditions
4. Range of meteorological conditions for effective phytoremediation application including, but not limited to, seasonal precipitation, air temperatures, humidity, wind speed and direction, and solar radiation
5. Time required to achieve cleanup or risk-reduction standards for various levels of initial contamination in soil or water, plants selected, soil or sediment conditions, and weather
6. Soil, sediment, or water quality during and after the treatment, including texture, mineralogy, moisture content, cation-exchange capacity for soils, organic carbon and nutrient content, pH, and redox potential for all media
7. List of plants and description of communities and any rooting depth, growing habits, and foliage requirements for effective cleanup
8. Unusual ecological conditions to avoid including endangered and threatened plants and wildlife, weeds, invasive species, bioaccumulation (in the absence of netting, fencing, motion detectors, or alarms), and wetland changes (e.g., drying up of seepage wetlands)
9. Risk-reduction or cleanup levels achieved in soil, groundwater, and air for different land uses
10. Residual management options (e.g., land filling in hazardous waste landfills, composting, and pyrolysis) and any risks during handling, transport, and disposal of residuals
11. Closure plans and options for vegetative cover

These criteria will be focused on specific issues for terrestrial and aquatic remediation. Criteria and information requirements will be weighted, depending on the application. This protocol is different from that used in the U.S. (36,37); however, the differences are expected to diminish over time with continued collaborative projects between Environment Canada and the U.S. Environmental Protection Agency.

CURRENT AND FUTURE EXPECTATIONS

Plant-based remediation and restoration applications are expected to receive increasing attention in Canada and elsewhere as options for removal of the more recalcitrant inorganic and organic constituents at contaminated sites. These Environment Canada databases and protocol could provide valuable assistance in the pre-selection of organisms, help clarify the regulatory responsibilities of proponents in securing necessary approvals prior to the use of specific organisms, and provide valuable insight into genetic materials to adapt or modify representative Canadian plant species to the climatic circumstances unique to specific sites. Future initiatives include (1) database expansion to include one for radioactive materials (PHYTORAD); (2) a Canadian network to identify, store, protect, propagate, and possibly distribute germplasm of candidate plant cultivars; (3) protocols that outline responsible provisions; (4) methods to recover inorganic contaminants from contaminated biomass; (5) a complete overview of the regulatory issues inherent in the use of plants as remediation and restoration agents; (6) definition of bioavailability and the role of plants in natural attenuation; and (7) establishment of mechanisms to limit phytoremediation site access by herbivores and omnivores.

Acknowledgments and Disclaimer. The author is extremely grateful for the opportunity to realize the conceptual development of PHYTOREM and PHYTOPET databases through the funding of the Canadian Biotechnology Strategy and the Panel on Energy Research and Development. Data were compiled and provided by Dr. Erich Haber of National Botanical Services in Canada for PHYTOREM and by Dr. J.J. Germida, Dr. R.E. Farrell, and Dr. C.M. Frick of the University of Saskatchewan for PHYTOPET. Environment Canada headquarter's library staff, Jean-François Belanger and Marie Jetten and the Canadian Museum of Nature librarian Mireille Boudreau were invaluable. Finally the author extends an incredible debt of gratitude to Dr. Marcos Alvarez of Environment Canada for his editorial support. Copies of the PHYTOREM and PHYTOPET databases are available on CD-ROM from the author at terry.mcintyre@ec.gc.ca.

Disclaimer. Environment Canada does not endorse the use of, nor does it attempt to determine the merits of any specific technology or technology provider through publication in this document, nor does Environment Canada assume any liabilities with respect to the use of any information, apparatus, method, or process discussed in this document. Mention of trade names or commercial products does not constitute endorsement or recommendation for use. Further, the views expressed in the document remain solely those of the authors.

NITRATE POLLUTION PREVENTION

Brane Maticic
Ljubljana, Slovenia

Groundwater and springwater are sources used for water supply in many countries. Pollution of surface and groundwater is caused mostly by the chemicals used in industry, urban wastes, and agriculture. The pollution of **ground water** by **nitrates,** as well as pollution of **crops** that we consume, is one of the most serious environmental concerns in most countries. A primary characteristic of most agriculturally related groundwater pollution is that it is often widely distributed (nonpoint source), whereas localized animal farms, agrochemical and crop waste disposal and storage, industry, and urban wastes may lead to point pollution.

Using high amounts of nitrogen in fertilizers leads to an increase of nitrate in plants, where a part of the nitrate, not absorbed by plants, is washed away by rain and pollutes groundwater. Drinking water and eating vegetables with high amounts of nitrate and nitrite are toxice specially for children and babies because it may cause methemoglobinemia.

Acceptable daily intake (ADI) of nitrates is 0–5 mg/kg of body weight and of nitrites is 0–0.2 mg/kg of body weight. Children younger than 6 months are not allowed to consume food that contains nitrites. (Standards are set by common Committee FAO/SZO for nutrient additives—JECFA.) The limit values, that are supposed to ensure safe amounts of toxic elements for the majority of people have only relative value. The well-known statement by Paracelsus (1493–1541) is, “dosis sola facit venenum” (dose determines if a substance is toxic or not). All these concepts fail for substances with irreversible, especially carcinogenic or mutagenic effects. For carcinogenic and mutagenic substances, it is evident from the viewpoint of toxicology that prohibiting consumption is needed; any amount of such substances consumed are supposed to be a risk for human health.

According to the EU Nitrate Directive, the maximum standard for nitrate in drinking water (according to the value adopted by WHO) is 50 mg NO_3/L of water.

Bottled water is not supposed to contain any NO_2, whereas regular drinking water can contain up to 0.005 mg/L of NO_2-N under normal conditions and not more than 0.05 mg/L of NO_2-N in extraordinary circumstances.

When considering the possibility of pollution of groundwater by nitrates due to surpluses of nitrogen in the soil, it is essential to touch on the reasons for nitrate surpluses. The quantity of nitrate in vegetables (freshly edible crops) depends on the relative speed of two physiological processes: absorption of nitrates by the roots of plants and protein synthesis with consumption of nitrate and its reduction to nitrite and to ammonium. If the speed of absorption of nitrate is higher than the rate of protein synthesis, nitrate automatically accumulates in plants. On the other hand, if nitrate is transformed into protein in step with its absorption, nitrate is present only in small amounts. A disproportion between nitrogen absorption and protein synthesis may be caused for two reasons which sometimes are synergistic: (1) excessive quantities of nitrogen in the soil and (2) slowing down of protein synthesis.

The nitrate level in plants depends on the type of soil, climate conditions (water in the soil), soil cultivation practices, age of plants, and type of vegetable (cultivar and variety). The nitrate level is always higher in young plants. An excess of nitrate in the soil results above all from chemical nitrogenous fertilizers particularly in the form of nitrates, which are easily available to vegetables. Several factors affect the intensity of protein synthesis;the most important are the following: light, the state of the foliage, the lack of minerals, particularly of trace elements, and the use of certain pesticides. The feebler the light, the richer plants are in nitrate (crops under glass, particularly out of season, shady locations or overcrowding, short days, and weak sunshine). If leaves are insufficiently developed or damaged by parasitic attack, the nitrate content in the roots of plants is raised. Lack of minerals slows down protein synthesis which affects the accumulation of nitrates. All factors that obstruct normal biochemical processes in the soil or in plants can slow down protein synthesis and therefore accelerate the accumulation of nitrates for example, lack of water in the soil, excessive water in the soil due to inadequate drainage, inadequately cultivated soil, and use of herbicides.

It is not nitrate that is toxic but the compounds derived from it, nitrites and nitrosamines. There are two reasons that nitrate derived compounds are toxic:

1. Nitrates oxidize the ferrous ion of hemoglobin into ferric, methemoglobin is formed, and transport of oxygen is hindered (methemoglobinemia).
2. Nitrosamines are carcinogenic.

Nitrites and nitrosamines are formed during the microbiological process that takes place immediately after harvest whenever vegetables—medium rich in nitrate—are stored under anaerobic conditions at ambient temperature (sawerkrout, etc.). The very same processes take place in cooked vegetable stored at ambient temperature.

Many years of experiments have been conducted at the Agrohydrologic Research Station in Ljubljana, Slovenia (B. Maticic), on the impact of different water application levels in the soil and different levels of mineral nitrogen in the soil on the content of nitrate, nitrite, and ammonium on crop yield for many different vegetables. To prove the importance of sustainable nitrogen fertilization of crops and optimal treatment of crops with water (irrigation), we present some results of the interaction between nitrogen application and water application for three different vegetable crops: cabbage, red beet, and celery. The results of "water–nitrogen fertilizer–yield" production functions as well as "water–nitrogen fertilizer–nitrate" functions for these three crops are presented in Figs. 1–3.

The increase of water application levels caused a decrease in NO_3 content in vegetables until the water application reached a certain optimal level; a further increase of water application also increased NO_3 content. The influence of water application (irrigation) on NO_3 content is greater than the influence of fertilization with nitrogen. Extreme amounts of water (minimal, when plants are suffering from drought and maximal, when plants have too much water for normal growth) increase the level of NO_3 in vegetables.

It is obvious that fertilization with nitrogen increases the nitrate level in vegetables. For red beet, the maximal increase in nitrate level, caused by fertilization with nitrogen, was 450%; for cabbage only 60%. The increase

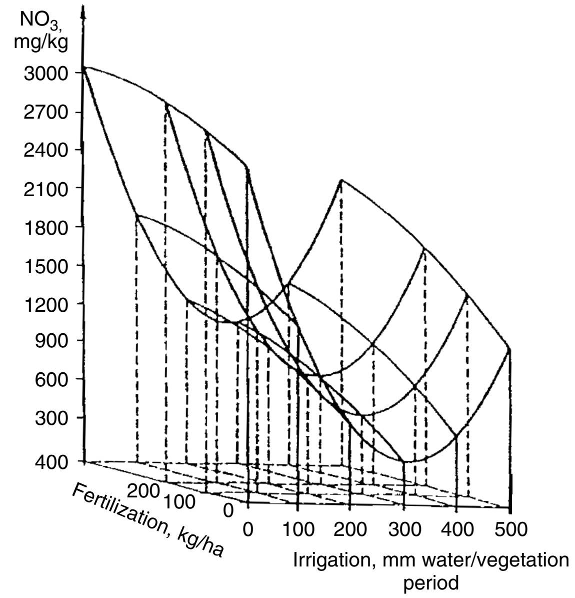

Figure 2. Nitrate content in red beet due to different water and different nitrogen treatments.

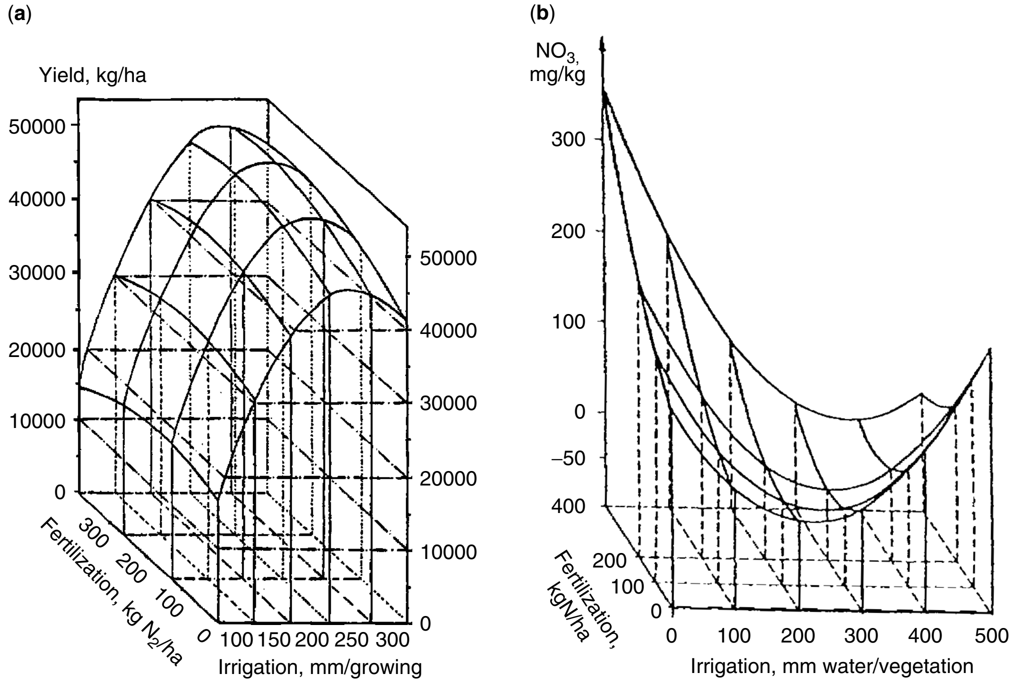

Figure 1. The impact of interaction between water application (irrigation) and nitrogen fertilization on crop yield (cabbage) and content of nitrate in the crop: (**a**) yield of cabbage due to different water and nitrogen treatments; (**b**) nitrate in cabbage due to different water and nitrogen treatments.

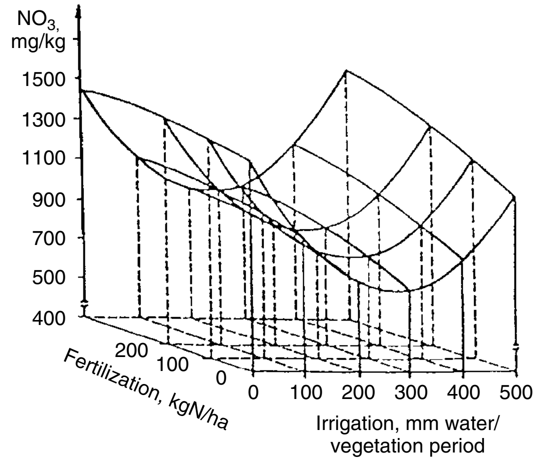

Figure 3. Nitrate content in celery due to different water and different nitrogen treatments.

in nitrogen doses from 0 to 400 kg N/ha caused an NO_3 content more than fifteen times higher in celery leaves and more than ten times higher in celery bulbs.

A significant reduction of nitrate and nitrite levels in vegetables was observed with optimal water supply and with small to medium doses of nitrogen fertilizers. According to the results, the recommended allowable water depletion from the soil for vegetable growers would be to maintain soil water conditions within the range of 20–30% of available water in the soil, and nitrogen fertilizer should be applied in several small doses.

To identify nitrogen surpluses (that may influence the pollution of groundwater and surface waters) due to agricultural technology used in different countries, it is advisable to demonstrate a "**mineral (nitrogen) balance**" on regional and farm levels using a **normative approach**. This method takes into account nitrogen input from mineral fertilizers, animal wastes, and the deposition from the atmosphere reduced by nitrogen uptake by harvested crops and ammonia losses to the atmosphere (30%).

It is also recommended to do thorough surface and groundwater quality **monitoring** according to the methodology recommended by international organizations with as many sampling points as possible for basic physical, chemical, and bacteriological analyses.

A mineral (nitrogen) balance provides information closer to the nitrate problem. Ammonia losses during storage do not directly affect groundwater. However, deposition from the atmosphere must be taken into account because it has an impact on nitrate concentration in groundwater. The average nitrogen deposition from the atmosphere is 20 kg nitrogen/ha (or 15.5 kg N/ha according to RIVM, The Netherlands). The nitrogen balance at the farm level is based on the so-called surface balance approach. The input factors include minerals provided by purchase of fertilizers and manure, minerals from production of animal manure, and deposition from the atmosphere. The output factor includes nitrogen from harvested crops. The assessments are based on elaborations by the Federal Agricultural Research Center, Braunschweig, Germany.

To reduce mineral (nitrogen) surpluses in agriculture and to meet the standards of nitrate and nitrite in drinking water and crops, it is necessary to control water and food quality in connection with nitrates and nitrites and to exact certain regulations regarding change in agriculture, especially animal excrement management. These regulations should give different norms for sustainable behavior in agricultural technology according to "Nitrate Directives" and "Code of Good Agricultural Practice." The most important norms should be as follows:

1. The highest quantity of manure allowed on agricultural land as well as limitations for the use of the manure in specific soil conditions:
   - The maximal allowed intensity of raising animals should be 3 LU/ha for cattle or 2 LU/ha for pigs and poultry.
   - Application of organic manure should not be allowed during winter on frozen soil.
   - Application of organic fertilizers should not be allowed on soil saturated with water.
   - Application of organic fertilizers should not be allowed in temporarily flooded areas.
   - Application of organic fertilizers should not be allowed near streams (10 m away from the stream) and in depressions where there is no runoff of water.
   - Applying liquid manure on bare soil should not be allowed in the period from Nov. 15 till Feb. 15.
   - Application of organic fertilizers on water aquifer protected areas should be very restricted and done only in agreement with local authorities and regulations valid for those areas.
   - In the vicinity of springwater and in underground water pumping areas, wastewater should not be drained to springwater or underground water in any case.
2. The highest quantity of N, P_2O_5, and K_2O allowed per hectare should be 170 kg N, 120 kg P_2O_5 and 300 kg K_2O.
3. Animal wastes should be stored in suitably arranged dung yards and cesspools so that there is no danger of leaking through and pouring over underground water.
4. The adjustment of farms to these regulations should be done as follows:
   - the adjustment of the number of animals (LU) according to the area of land available on the farm,
   - possible rent of additional land according to the contract, the construction of necessary dung yards and cesspools for hard and liquid manure, according to the restrictions.

Implementation of these regulations should be controlled by strict agricultural inspection in each country.

In countries where groundwater is relatively deep and drainage systems are supposed to drain "perched" water tables and to consider the hydraulics of water flow in the soil profile, drainage can prevent groundwater from pollution by minerals and pesticides that contaminate the upper layer of the soil. Polluted water flows to open canals (collectors) and further to rivers. In order not to pollute water in the rivers, it is an idea (B.Maticic) to install phytoremediation lagoons at the end of open canals (collectors) before water is discharged into surface water streams (rivers). This action would undoubtedly protect the quality of groundwater and water in rivers, and therefore act as an environmental measure.

When the world is going through many changes regarding exploitation of its natural resources and environmental protection, a new idea for efficient and sustainable draining of soil is of great importance. It provides the opportunity to obtain a common goal a “sustainable development.”

For many countries, where agriculture is a very important part of the economy, efficient and sustainable water management of agricultural land is very important. In the process of the transition of our society, there is strong emphasis on sustainable development, and it is believed that the field of agriculture is especially sensitive in this regard. That is why a big effort to overcome the mistakes of past development is being put forward to establish a whole new approach to agricultural planning and production with emphasis on the rational use of natural resources and modernized use of drainage and irrigation.

A determination exists to change old attitudes toward agricultural areas as underdeveloped areas, used only for mass food production, regardless of impacts on the environment. We believe that by careful planning and protection of the fertile soil in agricultural areas and forests as well as water resources, it is possible to achieve living conditions which would be attractive to people to remain on their land and continue farming traditions, as well as to the others to enjoy the environment of the countryside.

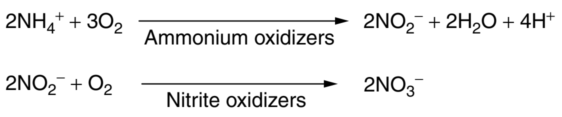
NITRIFICATION

David D. Tarkalson
University of Nebraska-Lincoln
North Platte, Nebraska

Nitrification is the biologically facilitated oxidation of ammonium ($NH_4{}^+$) to nitrate ($NO_3{}^-$). The process of nitrification is performed by ammonium and nitrite ($NO_2{}^-$) oxidizing bacteria found in soil and waters (Table 1). In soil and water, ammonium is supplied through decomposition of organic matter by microbes and/or anthropogenic or natural additions of inorganic nitrogen sources containing ammonia (NH_3), urea, or ammonium. Nitrification consists of two independent microbially facilitated reactions. In the first reaction, *ammonium* oxidizers oxidize ammonium to nitrite, and in the second reaction, *nitrite* oxidizers oxidize nitrite to nitrate.

The purpose of nitrification (microbial facilitated conversion of ammonium to nitrate) is to provide nitrifying bacteria the energy they require for metabolism. The nitrification reactions are represented in Fig. 1, and the bacteria involved are listed in Table 1. There are two different microbially mediated nitrification reactions.



$$2NH_4{}^+ + 3O_2 \xrightarrow[\text{Ammonium oxidizers}]{} 2NO_2{}^- + 2H_2O + 4H^+$$

$$2NO_2{}^- + O_2 \xrightarrow[\text{Nitrite oxidizers}]{} 2NO_3{}^-$$

Figure 1. Nitrification reactions.

Table 1. Common Species of Nitrifiers and their Habitats[a]

Bacterial Species	Habitat
Ammonium oxidizers	
Nitrosomonas europea	Soil, water, sewage
Nitrosospira briensis	Soil
Nitrosococcus oceanus	Marine
Nitrosococcus mobilis	Marine
Nitrosococcus nitrosus	Marine
Nitrosolobus multiformis	Soil
Nitrosovibrio tenuis	Soil
Nitrite oxidizers	
Nitrococcus mobilis	Marine
Nitrobacter gracilis	Marine
Nitrobacter winogradski	Soil
Nitrobacter agilis	Soil, water

[a] Ref. 1.

Chemoautotrophic nitrification is the use of carbon dioxide and carbonates as a carbon source for cell construction and oxidation of inorganic molecules such as NO_3^- or NO_2^- as an energy source. Chemoautotrophic nitrification is carried out only by a select group of bacteria. Heterotrophic nitrification is the use of organic compounds for both a carbon and energy source. Heterotrophic nitrification is executed by a wide variety of heterotrophic bacteria and fungi (2). Chemoautotrophic nitrification is believed to be up to 1000 times faster and is better understood than heterotrophic nitrification. Chemoautotrophic nitrification dominates in neutral to alkaline agricultural soils, whereas heterotrophic nitrification dominates in acid forest soils (2).

RELATIONSHIP BETWEEN SOILS AND WATERS

Nitrification is a key component of the nitrogen cycle (Fig. 2). The nitrogen cycle represents the fundamental transformations of nitrogen in the environment. In agricultural soil systems, we strive to manage this cycle better to increase crop production and minimize the negative impacts of nitrogen on the environment. Implementing management practices that will help manage nitrogen in agricultural systems to protect surface and groundwaters is an example. Nitrate, the end product of the nitrification process, is highly soluble in water and is not readily adsorbed to soil particles; therefore, if nitrate is not used by plants or microbes as a nutrient, it can move vertically through soils to groundwater and in runoff to surface waters resulting in problems from nutrient enrichment. Because nitrification is a microbially mediated process, many management practices aimed at reducing nitrate leaching focus on the nitrification process.

FACTORS INFLUENCING NITRIFICATION

Assuming an adequate supply of ammonium and a sufficient population of nitrifying bacteria, there are several factors that affect nitrification in natural systems. These factors include pH, moisture, temperature, and oxygen concentration.

pH

Soil and water pH influence the availability of many essential nutrients such as calcium and phosphorus (3). Microbes require these nutrients for growth and development; therefore, pH ranges that promote adequate availability of these nutrients are required for nitrification. Nitrification in soils is optimized at pH 8.5 but can proceed in a pH range of 4.5 to 10 (3). Figure 3 illustrates the relationship between soil pH and nitrification. At low pH levels, many essential nutrients are less available for use by plants and microbes.

Moisture

Nitrifying bacteria require water to live and function. In soils, the optimum water content for nitrification is at field capacity (water remaining in soil after gravity has removed excess water after a period of saturation). Research shows

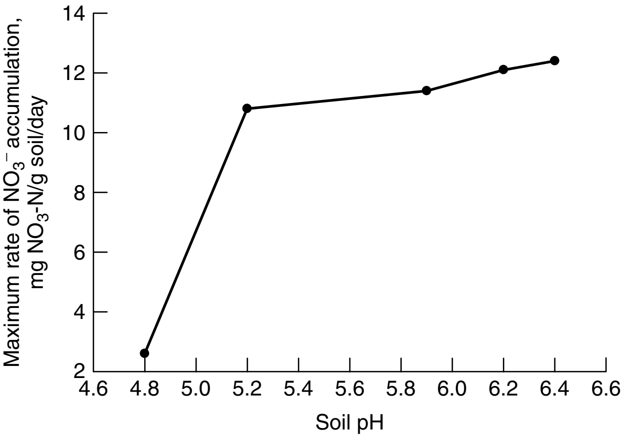


Figure 3. Effect of soil pH prior to incubation on nitrate accumulation in soil treated with 169 kg N as NH_4NO_3/ha and incubated at 23 °C for 30 days (4).

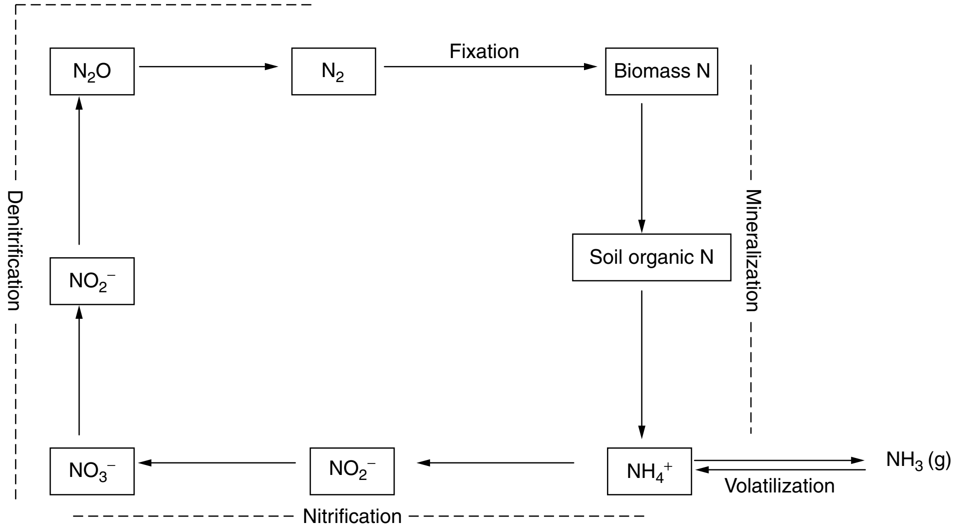

Figure 2. Nitrogen cycle.

Next Page

that, as water content increases in soil from dry to an optimum content, nitrification rates increase (Fig. 4). However, waterlogged conditions drastically decrease oxygen content and thus decrease the rate of nitrification. The water content at field capacity varies, depending on the soil physical properties such as texture and organic matter content.

Temperature

Generally, as temperature increases to a point so does the rate of nitrification (Fig. 5). Studies have shown that ammonium is converted to nitrite at temperatures from 0 °C to 65 °C and nitrite is converted to nitrate from 0 °C to 40 °C. Rates of nitrification dramatically decrease above and below these ranges. Optimum temperatures for nitrification are between 30 °C and 35 °C.

Oxygen Concentration

Figure 1 illustrates the need for oxygen in the nitrification process. Diffusion rates and concentrations of oxygen in soils and water will directly influence the rates of nitrification.

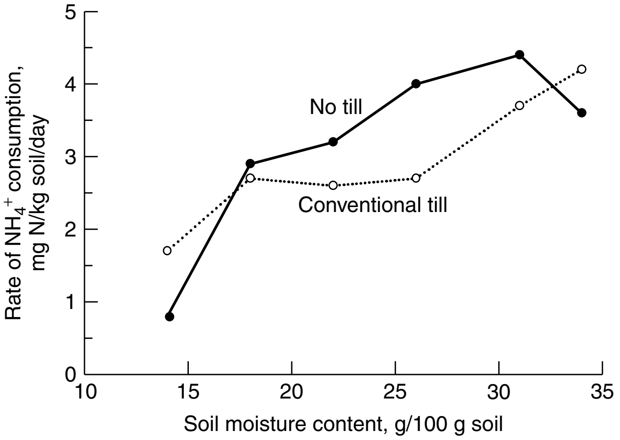

Figure 4. Nitrification rate of two tillage systems of a Maury silt loam soil column related to soil moisture content (5).

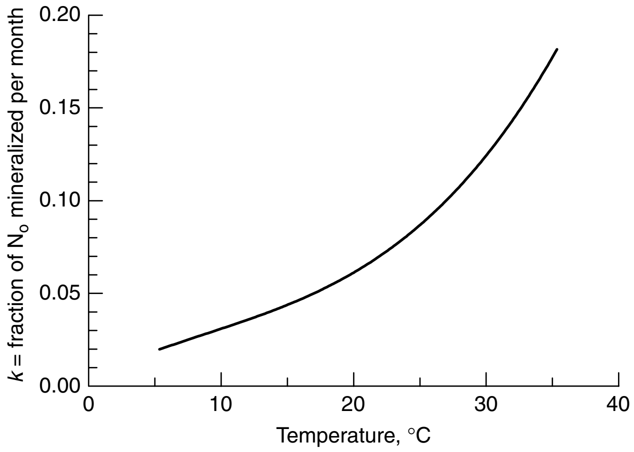

Figure 5. Fraction of N mineralized per month, k, in relation to temperature (k was estimated graphically for observed average monthly air temperatures) (6).

MANAGEMENT OF NITRIFICATION IN SOIL TO REDUCE NITRATE LOSSES TO SURFACE AND GROUNDWATER

Reducing nitrate losses in agricultural soils that receive large nitrogen (ammonia and ammonium) input from fertilizers is important to maintain high quality water resources. Chemicals called nitrification inhibitors have been developed that inhibit the nitrogen oxidative processes of nitrifying bacteria when added to agricultural soils concurrently with ammonium based fertilizers. In other words, nitrogen in the form of ammonium persists in the soil for longer periods of time that allow for increased plant use of the ammonium. Ammonium is adsorbed to soil particles; therefore, it does not readily move with water like nitrate. Nitrification inhibitors have a finite effective functionality in soil because soil microbes degrade them over time. Studies have shown that nitrification suppression by the inhibitor dicyandiamide can last 3 months, depending on the amount added with fertilizer (3).

Management practices that use knowledge of the factors that influence nitrifiers are common. For example, most farmers apply their ammonium based nitrogen fertilizers late in the fall when soil temperatures have declined to a point where nitrification is inhibited. If the farmer applies the fertilizer when soil temperatures are sufficiently high, then the ammonium is nitrified to nitrate and rainfall and/or snowmelt can leach the nitrate out of the root zone to the groundwater before the next crop can use the nitrogen.

Nitrification is a natural biological process involved in the transformation and fate of nitrogen in the environment. However, anthropogenic influences can either accentuate or reduce nitrification rates and can have a large impact on water quality.

INTRODUCTION

The role of agrochemicals in modern agriculture is continuously evolving, and their contribution to crop protection continues to increase. At a global level, the use of pest control agents (i.e., pesticides) has proved to assist the solving of many problems facing human health and food production. Organochlorine pesticides (OCPs) are a class of compounds of particular concern in the environment because of their recalcitrance in natural solids, global transport, distribution, and toxicity, which leads to include them into the group of persistent organic pollutants (1). This group had been widely used since early 1940, with an intensified usage during the Second World War. At that time, crops were duplicated and malaria incidents were reduced in India from 75 millions to less than 5 millions persons affected in 10 years as the result of DDT usage. However, such usage has occasionally been accompanied with hazards to man and the environment. Target species became resistant, leading to the application of higher doses of pesticides. For these reasons, most developed countries banned or restricted their usage since 1970. However, in the poorer countries, OCP restrictions or prohibitions date from the later 1990s. In addition, many of the banned or withdrawn pesticides from the developed market are still produced and sold in developing country market (2). Pesticides such as DDT are still in use in India and Brazil with public sanity purposes (3–5).

When pesticide are agriculturally applied, roughly 85–90% of pesticides never reach the target organism, but disperse through the air, soil, and water (6,7). Pesticides that are bound in soils or taken up by plants and animals are drawn into rivers and lakes and move into the aquatic food chains inducing severe damage to aquatic life (8,9). The environmental behavior of OCPs is largely related to their physical and chemical characteristics. Some of them are volatile enough to evaporate, reaching the upper atmosphere and being carried hundreds or thousands of kilometers by a process known as “Global Distillation” (1,10,11). Thus, the capability of these pollutants for long-distance transfer, precipitation, and accumulation in environmental materials results in the formation of background concentrations in remote regions from the emission sources (12). Therefore, OCPs can be found in many places where they had never been applied. They have been linked to carcinogenicity and endocrine disruption in mammals, and concerns over toxicity are exacerbated by their hydrophobicity, which results in bioaccumulation in fatty tissues and biomagnification through food chains (13).

The general population can be exposed to low levels of pesticides in three general ways:

1. vector control for public health and other nonagricultural purposes
2. environmental residues
3. food residues

Regarding food residues, consumption of plants or plant products, such as vegetables, fruits, and grains, form a major part of the food consumption of human beings and cattle (14). Moreover, vegetables are an essential component of our diet because of their nutritional value (15).

The impact of soil contaminants on human health and accumulation of pesticides in food crops is a great concern because of increased dietary exposure of consumers (16).

Considering that vegetation is the link among the atmosphere, soil, and human food supply, contamination of plants will have a great influence on the total daily intake of a substance (14). Thus, it is important to understand those processes by which pollutants enter into this environmental compartment.

ABSORPTION AND ACCUMULATION OF OCPs IN PLANTS

Plants may accumulate OCPs via different pathways:

1. adsorption to the root surface
2. root uptake and transport to the upper plant tissues
3. uptake of airborne vapors by aerial plant parts (stem, leaves, and fruits)

The relative significance of each route by which OCPs can be taken up into fruits and vegetables is likely to be influenced by a wide range of factors (i.e., physicochemical characteristic of the pesticide, environmental conditions, and specie-specific characteristics) (17,18) (Fig. 1).

Air to Plant Route

OCPs are emitted to the atmosphere via various routes: by transfer to the airflow during the treatment of agricultural crops, evaporation from treated surfaces of plants and soils, and finally by wind erosion (12).

Simonich and Hites (19) presented a simplified mechanism of pollutants absorption by plants from air. Air to vegetation transfer of gaseous pollutants will be on the partition coefficient of the pollutant in the octanol

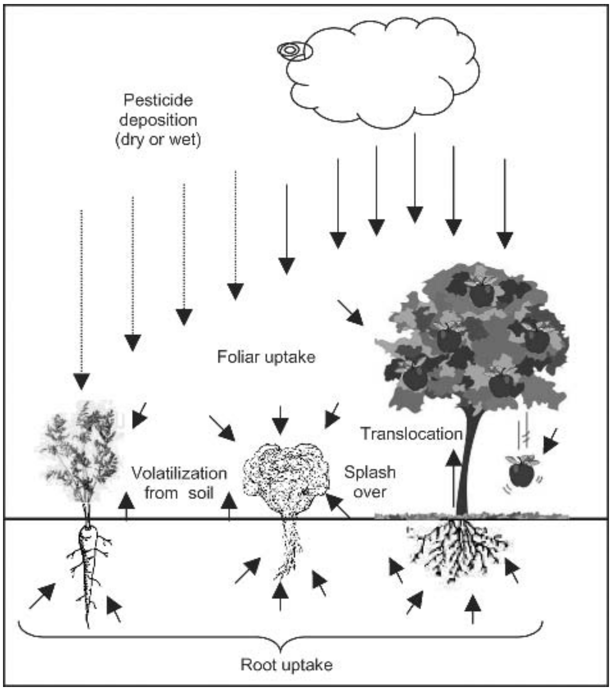

Figure 1. Pathways for accumulation of Organochlorine Pesticides by plants. Modified of Lovett et al. (18).

air system, the surface area, and lipid concentration in plant tissues.

Plant cuticles are the first barrier in the absorption of airborne and fall out OCPs in all aboveground organs and parts of higher terrestrial plants (fruit, flowers, stems, and leaves). Moreover, gaseous contaminants can directly reach the intercellular aerial medium through the open stomata (20–22). It was found that OCP residues in plant tissues decrease very slowly because of their low solubility in water and high solubility in oils. Thus, sorption of pesticides by plant surfaces depends significantly on the morphological features of the leaf, velocity, waxing, etc. (12,23). Moreover, vapor transfers of OCPs from soil to the aboveground parts of plants would be expected to occur to varying extents for all crops. For vegetables such as lettuce, courggetes, or zucchinis, which develop in contact with or in close proximity to the ground, it is possible that uptake of OCPs could also occur by direct adsorption from the soil and by splash-over of soil particles during heavy rain (12,23,24).

Soil to Plant Route

The transition of OCPs from soils into plants (35–70%) will be, in general, higher than into adjacent environments: water (2–18%) and atmosphere (18%) (12).

The uptake of OCPs by plant roots is affected by the bioavailability of the pesticide in the soil, leading to a competition between the organic fraction of the soil and the root material. Higher soil adsorption will result in a lower plant bioavailability (25).

After root uptake, plants can translocate pesticides via xylem to the aboveground plant parts. The extent of such mobilization will be on pesticide solubility and plant characteristics, such as root exudates (26). Thus, pesticides whose kow are higher than 4 will not be able to translocate from root to aerial tissues in most plant species (17). However, an exception has been reported for vegetables from the cucumis and cucurbitacea genera, which are able to translocate highly hydrophobic compounds, such as the insecticide DDT, PCBs, and dioxinas, from roots to fruits (26–29).

OCPs OCCURRENCE IN VEGETABLES

As was previously mentioned, vegetables are essential components of the human diets. As pesticide residues remain on fruits and vegetables, it is important to know the magnitude of such contamination from the point of view of safety to consumers. Thus, a growing concern for safer foods has led research into increased pesticides residues monitoring.

In order to regulate and control such residues, the concept of maximum residues levels (MRL) was established. This level represents the maximum concentration of the residue (expressed in mg/Kg) that is legally permitted in specific food items and animal feeds (31).

OCP residues in vegetables are included in the Food and Drug Administration (FDA) monitoring program because they are still present in the environment (32). A residual content of these compounds in foods today is still quantifiable, and their avoidance in farming is largely impossible (33).

Regular surveys and monitoring programs of OCP residues have been carried out for decades in developed countries, such as the United States (32,34), the United Kingdom (35), and Spain (36). Although in some developing countries, such as India (37), Tunisia (38), Nigeria (39), Rumania (40), Brazil, the Philippines (41), Egypt (42–44), Honduras (45), and Argentina (46), reports about OCP levels in vegetables were made, they were not made as a part of governmental monitoring programs. Most of the reports showed that OCPs, such as HCHs, DDTs, Aldrins, Chlordane, and Heptachlor, were present in all analyzed samples. In the United States, about 1% of the samples violated the established MRL (32), but in developing countries, such as Brazil, this value can increase up to 3.7% (41). The presence of OCPs in vegetable samples is the consequence of either recent and current use in developing countries and/or the result of their persistent residues 30 years after their prohibition.

One alternative to synthetic pesticide use is organic farming. Thus, two decades ago, growing environmental awareness and concerns about safer foods have lead people to question modern agricultural practices, which has been reflected in an increasing demand for organic production, which is perceived as less damaging to the environment and to be healthier than conventionally grown foods (47,48).

ORGANIC AGRICULTURE: WORLD WIDE SITUATION

Organic agriculture has developed rapidly during the last decade, and governments have encouraged the development of this tillage practice, mainly in developed countries. Chemophobia is the commonest reason for the public to choose organic food on the assumption that such food is free of synthetic pesticides (49).

Organic farms distinguish from all other forms of farming, namely conventional, by a rejection of soluble minerals as fertilizer and synthetic pesticides in favor of natural ones (49). However, organic food contains pesticide traces, although the amounts are lower than in conventional produce (50,51). Although it is likely that organically grown foods are lower in pesticide residues, very little documentation of residues levels exists (52). Moore et al. (33) studied the residue of eight OCPs in two matrices (carrots and winter squash) used to elaborate conventional and organic baby food brands. They found no detectable residues among all types of food. These results were the consequence of processing fruits and vegetables (washing, peeling, and cooking) that largely eliminates residues, as was largely demonstrated (53–55).

Today, developing countries represent a source of a wide range of organic produce, especially tea, coffee, cocoa, herbs, and spices, as well as tropical and subtropical fruits and vegetables for Europe and the United States (56).

Vegetable diversity produced in Argentina reaches 115 species with field crops covering a surface area of some 600,000 hectares (57), and about 160,000 hectares are destined to organic production. The European Union, EE.UU, and Switzerland are the main markets of destiny for these products (58). Therefore, the study of the factors that may impact in this kind of production is relevant. Most organic farms are supposed to remain small and self-sufficient, whereas conventional farms are increasing in size as the result of economic pressures.

The environmental fate of OCPs in agricultural environments of Argentina have been studied, including the impact of these pollutants in watersheds characterized by rural and small-case farming land use (59–62). OCPs were found in vegetables from organic and conventional farming (46,52,63,64). The presence of these contaminants in the organic farm was an interesting finding.

OCPs IN VEGETABLES ORGANICALLY CULTIVATED

Previous to the settlement of the organic farm, the area was characterized by natural vegetation. The farm is surrounded by important hedgerows and trees, and neighboring fields on both sides are conventionally farmed since its establishment about 30 years ago. Agrochemical use was a common practice in surroundings fields, and unsprayed field margins were not established.

From the organic farm, several vegetable species were studied in order to estimate the OCPs levels in their tissues. The produces include leafy vegetables (lettuce and chard), tomato, and leek. Most of the studied crops showed similar OCP levels between root and aboveground plan parts (stem or leaves). This observation was not consistent with previously published data where plants were cultivated in treated soils (28,30,65). Thus, in the organically treated soils, the air to plant route would be as important as the soil to plant route in all species.

The main OCPs found in vegetables were the same that were previously reported for conventional produce: HCHs, DDTs, and Chlordane being these pesticides forbidden for agricultural purposes. Moreover, high levels of endosulfans (α- and β-isomers and sulfate metabolite) were also found as a consequence of their current usage. All species accumulated OCPs efficiently from soil in their roots, leading to high root bioconcentration factors. Common practices in organic tillage constitute the enrichment of soil with vegetal rests. In this farm, pine needles collected form surrounding forests are usually added to the soil at the beginning of the growing periods. Pine needles, rich in waxes, are known to accumulate highly lipophilic pollutants from the atmosphere (66,67). Therefore, those soils enriched with this amendment showed the highest level of OCPs. Moreover, plants growing in such soils showed enrichment in the more lipophilic compounds in their roots.

Aerial tissues showed a great variation in accumulation regarding species and tissues. In lettuce, differences between inner and outer leaves were found, with the lowest concentrations in the outer leaves despite the higher lipid content, maybe by the growth dilution effect or weathering. Moreover, plant morphology could be an important factor affecting OCPs uptake and distribution (23,24). Thus, lettuce with outer leaves enlarging inner leaves had higher OCP levels in stem and inner leaves, probably as a consequence of the accumulation of pollutants between outer and inner leaves. On the other hand, chard plants with an inverse wide-high relation and longer stem showed higher OCP levels in outer leaves (51).

Tomato fruits contained OCPs not only in their peel but also in the inner flesh tissues, which indicate absorption rather than adsorption (63). Total OCPs in flesh were 3-fold greater than in peel, probably as a consequence of either continuous uptake by aerial tissues (fruit peel, leaves, and stem) of airborne OCPs, followed by translocation via phloem throughout the plant and accumulation in fruit flesh or removal of pesticides from peel by weather influences as photodegradation, volatilization, and so on (17).

Acaricide Dicofol is still in use in this country and has been reported to contain a significant amount of DDT as manufacturing impurity. Thus, it represents a potential continuous source of DDT in the studied area. DDT breaks down to DDE and DDD in soil and generally with time the parent/metabolite ratio decrease (68). DDT/DDE ratios found > 1 suggest that besides Dicofol use, new DDT can be continuously transported to the atmosphere of the organic farm. The presence of this new DDT can be attributed to illegal use or to atmospheric transport from those countries, mostly tropical, where DDT is still in use (61). Moreover, data suggest that long-range transport could be the predominant source of chlordane in the farm. The α-/γ-HCH ratio can be used as diagnostic of HCH sources, inputs of γ-HCH (lindane) decrease the ratio found in air and vegetation containing a background of technical HCH (α-/γ- = 4–6) (68). The low α-/γ-HCH ratio found in all samples reflect recent inputs of lindane to the atmosphere of the studied area.

Endosulfan is one of the few organochlorine insecticides still in use; it is primarily used on summer crops such as tomatoes in the agricultural belt on the northwest area of the studied watershed. Occurrence of endosulfan in aerial tissues of tomato agrees with their summer usage in the surrounding farms, showing the relevance of drift pesticide during application events. Research has reported that drift of endosulfans from aerial agricultural spraying can produce lethal concentration to fish in shallow exposed water bodies 200 m away from the target spray area (8). In this watershed, it is also common during summer months that a massive "fish kill" can occur. One possible explanation could be that lethal concentration inputs of endosulfans applied in the surrounding area that reach the waterbody. Moreover, surface runoff from the organic farm may constitute a source of endosulfans to the waterbody.

As a whole, it was demonstrated that plants bioaccumulated OCPs efficiently from both routes, air and soil. In organic tillage, it is common that crop residues are reincorporated into soil after harvest. Thus, soil OCP values may reflect contributions from decomposed plant material rather than changes either within soil or via the atmospheric deposition. Therefore, plant residues constitute a way of entry of atmospheric pollutants into of the organic farm, leading to the subsequent availability for root uptake. This fact will be relevant for plants whose edible parts grow below ground (i.e., carrots, potatoes) or those that are able to translocate them. Despite OCPs being detected in all edible tissue (leaves, stem, and fruit in the studied vegetables), the levels were below the maximum residue limits (MRL) considered by both Código Alimentario Argentino (CAA) (69) and the Codex Alimentarius (CA) (31).

Despite the practice of organic farming management, OCPs were present in the soil environment and vegetable tissues confirming the importance of contamination from adjacent conventional farms. Therefore, the occurrence of OCP residues in the organic samples may be attributed to ecosystem factors such as pesticide runoff, drift from pesticide used by neighboring farming, volatilization, leaching, and washout. Thus, when organically grown vegetables are subject to such potential sources of contamination, the meaning of the term "organic" becomes obscure and is difficult to interpret especially from the perspectives of the public consumers.

INTRODUCTION

Pesticides have greatly enhanced the production and quality of food, feed, and fiber, as well as the control of disease vectors and pests adversely affecting the health and welfare of the world. Specifically, pesticides have been used in: (a) agriculture to increase productivity and quality and quantity of food, feed, and fiber; (b) forestry for pest control in silviculture; (c) the industrial, commercial, municipal, and military sector for rodent and weed/brush control around plant sites and in right-of-ways; (d) medical vector control; and (e) urban environment for termite control around structures and pest control in gardens (1). As a consequence, of all the environmental contaminants, pesticides have probably been the most widely criticized because of their direct use in natural systems. The nature of pesticide usage often requires broadcast distribution over large areas of crops. This wide treatment of the crop environment often results in treatment of adjacent areas as well. The use of pesticides is indispensable for conventional labor and extensive farming systems. Although the use of pesticides has resulted in increased crop production and other benefits, it has raised concerns about potential adverse effects on the environment and human health.

ENVIRONMENTAL BEHAVIOR OF PESTICIDES

The proportion of applied pesticide reaching the target pest has been found to be less than 0.3%, thus leaving over 99% elsewhere in the environment (2). Environmental entry and transport processes can occur either between or during rainfall events, including wet and dry deposition, foliar washoff, and spray drift. Moreover, pesticide dissolved in atmospheric water vapor may be deposited either on the soil surface directly or indirectly to the foliar surface, with subsequent removal during rainfall events via the process of foliar washoff. Once in the soil, pesticides may volatilize into the air, enter the surface and groundwater by runoff or leaching, be taken up by plants and soil organisms, or stay in the soil (3–13).

As the use of pesticides in agriculture inevitably leads to exposure of nontarget organisms (including humans), undesirable side effects may occur on some species, communities, or on ecosystems as a whole. Therefore, the knowledge of pesticide environmental behavior, like adsorption to soil, leaching to groundwater, and volatility in the atmosphere, is of primary concern for an accurate assessment of the risk to the environment and humans (14).

SORPTION TO SOIL COMPONENTS (ORGANIC AND INORGANIC)

The soil is a complex medium whose physical, chemical, and biological properties are highly heterogeneous. The horizontal and vertical distribution of textural and structural elements in soil, and the differences in physicochemical properties, lead to variations in sorption, desorption, transport, and permeability of soil. The soil serves as a temporary or permanent sink for any chemical substance that hits its surface (12).

The sorption of pesticide on soil reduces its mobility; it is dependent on the physical and chemical properties of the soil as well as the molecular characteristics of the pesticide. Soil organic matter is the main soil constituent responsible for sorption of nonionic pesticides. In order to assess pesticide mobility, a sorption constant, based on the soil organic carbon (K_{oc}, $dm^3\ kg^{-1}$), can be used. Thus, $K_{oc} = K_d/oc$, where K_d is a measure of the extent of pesticide sorption by the soil and oc is the fraction of the organic carbon presents in the soil (15).

A significant proportion, typically ranging from 20% to 70%, of a pesticide or its metabolites may remain in the soil as “persistent residue,” sequestered in soil colloids (16).

The sequestration results in a diminution in the rate and extent of biodegradation by microorganisms in the field. The decline in toxicity and bioavailability as a result of the accompanying sequestration may represent a natural remediation process (17,18).

BIOLOGICAL AND CHEMICAL DEGRADATION

Losses of pesticide in the soil via microbiological and chemical pathways are collectively termed degradation. The rates of degradation can be characterized by a half-life (DT50). In soil, this rate increases with temperature and water content (19). The products of pesticide degradation, named metabolites, may have environmentally undesirable characteristics. Therefore, when the evaluation of the environmental fate of a pesticide is carried out, it is recommended to take the fate of metabolites into consideration.

VOLATILIZATION

Volatilization is a major cause of pesticide loss from target areas, particularly when pesticides are applied to the surfaces of soils or plants. Atmospheric transport and deposition are the major processes for distributing many pesticides around the world (20). The most appropriate criterion of the volatilization rate of a pesticide is Henry's law constant (K_h, dimensionless), the ratio of the vapor pressure to the water solubility (21,22). Compounds with K_h much greater than 2.5×10^{-5} are volatile, with volatility decreasing with time, whereas compounds with K_h much smaller than 2.5×10^{-5} are much less volatile, with volatility increasing with time (21–23).

RUNOFF AND LEACHING

Water may disperse pesticides into the environment via foliar washoff, surface runoff, and leaching. Runoff may contribute to pollution of surface water and leaching to contamination of groundwater.

Runoff is defined as the water and any dissolved or suspended matter it contains that leaves a plot, field, or small single-cover watershed in surface drainage (15). Runoff may include dissolved, suspended particulate, and sediment-adsorbed pesticides. Pesticides that remain at the soil surface for longer periods of time because they are strongly adsorbed and resistant to degradation and volatilization will be more susceptible to runoff, whereas incorporation into the soil will reduce runoff risk (24). Soluble pesticides may be more readily leached into the soil during the initial rainfall.

Pesticide leaching may cause groundwater pollution. The extent to which groundwater contamination occurs will depend on pesticides properties, soil characteristics, drainage rate, and water table depth. A combination of mobility and persistence determines whether a compound will be degraded during its residence time in the zone above the groundwater (21,25). Gustafson et al. (25) propose a single numerical index for predicting the water contamination potential of pesticides, the groundwater ubiquity score (GUS). It is defined as $GUS = \log(DT_{50}) \times (4 - \log(K_{oc}))$.

Pesticides detected in groundwater generally have GUS values exceeding 2.8, whereas compounds with GUS values below 1.8 were not detected in groundwater.

Rate of pesticide leaching in soil decreases with increasing organic matter content and depth of the surface zone with high biological activity. Moreover, the presence of macropores (cracks, worm holes, root channels) in soils enhances the hazard of pesticide leaching to the groundwater. Via these macropores, water and solutes can be transported rapidly to the subsoil and groundwater, bypassing much of the soil matrix (26).

PESTICIDES GROUPS

Over the last 20–25 years, a drastic change in the general characteristics of pesticides has occurred. They have changed from those with extremely low water solubility, strongly sorbed with long half-life to those that are more water soluble, only slightly sorbed, and less persistent. According to the chemical structure, pesticides can be classified as organochlorines, extremely hydrophobic with very high partition coefficient, and as organophosphates, carbamates, and pyretroids, which are more hydrophilic with lower partition coefficient value (27). Moreover, pesticides can be conveniently divided into classes, depending on which particular pest they are directed toward. Thus, the main groups are the herbicides, insecticides, and fungicides.

Pesticide properties, combined with the amount applied, determine how many pesticides can be transported along each route into the environment.

As was mentioned above, the low water solubility and the high partition coefficient of the organochlorine pesticides (OCP) confer to these pollutants a high environmental persistence. For this reason, the monitoring of these compounds is highly recommended.

WHAT ARE "ORGANOCHLORINE PESTICIDES"?

Organochlorine pesticides are important classes of environmental contaminants. Owing to their environmental persistence, toxic properties, and potential for bioaccumulation, they can be classified as "persistent organic pollutants" (POPs). Of additional concern is the ability of many POP compounds to undergo long-range atmospheric transport, developing from their semivolatile nature, which has resulted in their distribution in nearly all environmental compartments on a global scale, often far removed from their places of production and application (28–30).

OCP have been widely used throughout the world since the 1950s, although the use of many of these chemicals has been subjected to restriction and/or banned in many countries in recent years. However, the use of OCP in tropical and subtropical countries has been increasing in recent years in agricultural and public health programs (31). In addition to current usage, significant environmental burdens remain for many of these chemicals, which can act as secondary sources from which releases to the environment can occur, even decades after initial use (32).

OCP enter the soil by deposition from air, drift, or by washing off from plant surfaces during rainfall or irrigation. As a result of their strong hydrophobic (lipophilic) character, these compounds are mainly found associated with organic matter in soil and lipid tissues of organisms.

Organochlorine Pesticide Distribution in Relation to Land Uses: A Study Case

Knowledge of pesticide concentration and spatial distribution is necessary in order to asses the environmental impact of these compounds. A field study was carried out as part of an integral research about the dynamics of OCPs in a shallow lake watershed, Argentina, in relation to surrounding land uses (12).

The primary objective of this study was to assess the effect of land uses, such as agricultural, recreational (used for hiking, camping, and campfires), and natural (forested area that have never been cultivated) on the occurrence and distribution of organochlorine pesticides in soils from Argentina.

The organochlorine compounds analyzed included α-, β-, γ-, and δ-HCH; p,p′-DDT and its degradation products; p,p′-DDE and p,p′-DDD; heptachlor and its metabolite (heptachlor epoxide); aldrin; dieldrin; α- and γ-chlordane; and α- and β-endosulfan. Three depths were selected from each land use (0–15 cm, 15–30 cm, and 45–55 cm).

The results showed that, as was expected, the soil total organic carbon (TOC) decreased with depth for all three land uses. For the natural soils, total OCP concentrations were well correlated with the levels of TOC through the soil profile, whereas in agricultural and recreational soils, this correlation was not observed. These results imply that although TOC is known to be the most important OCP sorbent in soil surface horizons, additional factors exist, such as particle size characteristics and organic matter composition, and physicochemical characteristics of OCPs involved in pesticide retention.

Natural soil accumulated OCP to a greater extent than the other soils, even though it has never received direct OCP application. It is located on a hill that is clothed with trees and grass cover, which would act as an OCP trap, avoiding the OCP to leach up through soil profile, volatilization, and minimizing the risk of soil erosion. The highest concentrations were found in the surface layer, decreasing gradually with depth as a result of an undisturbed soil profile. DDT (472.5 ng/g dry wt), DDE (99.98 ng/g dry wt), and HCHs (25.44 ng/g dry wt) were the main pesticides found. Moreover, the levels of OCP in soils from an organic farm near to these natural soils ranged between 4–12 ng/g dry wt depending on the enrichment with pine needles collected from the surrounding natural areas (33,34). It is known that the waxy surfaces of pine needles has the ability to bioaccumulate airborne lipophilic pollutants (35). The soils from the organic farm could be considered as "natural soil," because it has never received direct pesticides application, either the lack of permanent vegetal cover and the soil disturbation by tillage practice lead to lower OCP levels. However, in both soils (natural and organic farm), a similar OCP pattern was found, as a consequence of the exposure to the same agricultural environment.

The values of natural soils are similar to those found by Dimond and Owen (36), (in Maine) for forest soils in sprayed areas during 1958 to 1967.

DDT was heavily used in Argentina, but it was totally banned in 1990. Commercial acaricide (Dicofol), still in use in Argentina, has been reported to contain a significant amount of DDT as manufacturing impurity and might represent a continuous source of DDT in the studied area. However, the high values of DDT found in these soils suggest that "new" DDT continues to be atmospherically transported from other countries, mostly tropical, where DDT is still in use (37–40).

High levels of heptachlor epoxide, a metabolite of heptachlor, were also found possibly because of physicochemical processes, such as photolysis and photodechlorination, and because of the abundance of microorganisms and edaphic biota in the surface layer of these natural soils, biotransformation processes are also assigned.

Chlordane residues were found in all the samples with the highest values being those from the surface layer of natural soil. The ratios γ-/α-chlordane found in these soils suggest direct application of technical chlordane in this zone.

Regarding to HCH group, the surface layer of the three studied soils showed higher concentration of lindane than the deeper depth, although there were not marked differences among depths. Lindane is one of the few OCPs analyzed in this work that is currently being used in Argentina.

Those soils dedicated to recreational activities showed the highest OCP values in the middle depth. During flooding periods, weathering of the surface layer occurs; as a result, a clearance of OCPs and predominance of HCHs are observed. The contribution of these compounds would come from the lagoon water; significant evidence exists that HCHs are the main pesticide group found in the aquatic biota of this waterbody (41).

In the agricultural soil during the last 25 years, a traditional tillage has been carried out in which a moldboard plough was used at a depth of 25–30 cm and in which straw was burned. This kind of tillage practice enhances organic carbon and fine particles (clay and silt) loss (30% in relation to natural soils), jointly OCP loss by volatilization or surface runoff. In addition to this management practice, the topography enhanced by slopes, wind, and water erosion during rain and irrigation periods justify these losses. Despite this, high values of OCPs in the surface layer were detected, with DDT being the main pesticide found, supporting the assumption that, because these pesticides (except lindane and endosulfan) are forbidden in Argentina, they would reach these soils via atmospheric transport.

Finally, soil characteristics, topographic position, and land uses justify the differences in OCP accumulation among the studied soils. The accumulation pattern represent a dynamic balance between deposition and erosion in association with wind-induced circulation, tillage management practices, and effects by natural processes, such as rainfall and flooding periods, according to different soils.

The results of this study suggest that natural areas should not be overlooked when assessing the sources and monitoring the occurrence of OCPs.

RELATION TO SURFACE WATER

The use of pesticides on agricultural land may have a negative effect on nearby aquatic ecosystems (12,13,42,43). This effect is determined by the specific chemicals used, the place and methods of application of the chemicals, and the various mechanisms available for transporting compounds to the waterbodies, with soil erosion being a major pathway (44). The extent to which pesticides move from treated soils depends on the physicochemical properties of the different active ingredients, the soil management practices, and the combination of environmental variables, such as frequency, intensity, and duration of precipitation (45).

Hydrophobicity and persistence are the main properties of pesticides that control their accumulation in sediment and aquatic biota. Thus, this fact confirms the current necessity of OCP monitoring.

CONCLUDING REMARKS

It is known that pesticides are released into the environment as formulated products that are designed to deliver the active ingredient to the target organisms. During the last forty years, a transition in the type of used pesticides has taken place. Thus, the highly persistent and bioaccumulatives organochlorine pesticides were replaced by organophosphates, carbamates, and pyretroids, currently used, with faster degradation in the environment.

However, despite pesticides undoubtedly contributing to increase farm productivity and human health, they also create several problems including widespread accumulation of residues with damage to wildlife, fisheries, beneficial insects, and even humans as a result of their dispersion toward nontarget areas. Today, the concern is the impact of those “environmental healthy pesticides,” because they are being linked to a high fish, wildlife, and bees toxicity, and some of them, because of their high water solubility, are potential groundwater contaminants. For these reasons, the monitoring of pesticide applications is necessary because it can be helpful in modifying the application techniques or use of particular chemicals to avoid adverse effects. Concern over possible impacts of pesticides on the environment and humans is not confined just to the highly industrialized nations. Developing countries are also experiencing the same concern exacerbated by lack of infrastructure and resources to deal with them.

REMEDIATION OF PESTICIDE-CONTAMINATED SOIL AT AGRICHEMICAL FACILITIES

William R. Roy
Illinois State Geological Survey
Champaign, Illinois

AGRICHEMICAL FACILITIES

An agrichemical or crop production facility is a commercial agricultural application business. These facilities store, sell, mix, load, and apply pesticides and fertilizers to fields for farmers and livestock producers. There are about 9,250 of these relatively small businesses in the United States and about 850 registered agrichemical businesses in Illinois. Pesticide mixing, loading, and handling sites are diverse and vary in the types of products handled at the site, the size of the facility, and the construction and type of containment (1).

Sources of Water and Soil Contamination

Bulk liquid and dry pesticides and fertilizers are typically mixed, repackaged, or transferred from one container to another. Accidental and incidental chemical releases such as spills, tank leaks, hose breaks, and transport accidents can result in contaminated water and soil at agrichemical facilities. Moreover, catastrophic events such as fires and floods can also result in soil, sediment, and water contamination.

Extent of Water and Soil Contamination

About 25% of the groundwater samples collected from 52 agrichemical facilities in Illinois contained 11 pesticides (2). The four most frequently occurring pesticides were bentazon, atrazine, trifluralin, and metolachlor. Nitrate was detected in 16 samples at concentrations ranging from 0.17 to 59 mg N/L. In additional sampling at four agrichemical facilities, 17 contaminants (nitrate, pesticides, and pesticide degradates) were detected. Atrazine, for example, detected in 15 of 22 samples, ranged from 0.54 to 61 μg/L. Environmental property audits conducted at 49 randomly selected agrichemical facilities in Illinois revealed that pesticides were detected in at least one soil sample collected at every site and at all sampling depths (3). The most frequently detected pesticides were alachlor, atrazine, metolachlor, trifluralin, pendimethaline, cyanazine, metibuzin, metribuzin DA, butylate, and α-BHC. Pesticides were detected to depths of 4.5 m. About 50% of all pesticide detections, however, were found in the gravel layer that serves as the parking lot/road base for each facility. In an extreme case, the gravel layer at an abandoned agrichemcial facility in Illinois contained 4.4% trifluralin by weight (4). Pesticide-contaminated soil and groundwater at retail agrichemical facilities have also been documented in Minnesota, California, Florida, Michigan, Wisconsin (1), and Arkansas (5).

Movement of Pesticides and Fertilizers

A portion of the pesticides and fertilizers in soil may leach into groundwater. Many of the commonly used pesticides and fertilizers are fairly mobile and can be leached as surface water infiltrates into the ground. The contaminated gravel, in which the bulk of pesticides may occur, poses a risk to groundwater quality (4). Hence, contaminated soil and gravel can adversely impact groundwater and possibly drinking water in rural communities. Because of this potential, it may be necessary to remediate contaminated soil to minimize its impact on water quality.

CLEANUP OBJECTIVES

Groundwater Cleanup Objectives

The values for groundwater-cleanup objectives depend on the specific chemical and the type of groundwater at the site. For example, in Illinois, Class I groundwater is called Potable Resource Groundwater, and Class II groundwater is General Resource Groundwater (6). A major distinction between the two types of groundwater is the hydraulic conductivity of water-bearing geologic materials: groundwater in an aquifer that has hydraulic conductivity equal to or greater than 1×10^{-4} cm/s is classified as Class I Groundwater. Therefore, Class II groundwater would be expected in less permeable materials. The groundwater quality standards for Class II groundwater are less stringent than those for Class I groundwater. Class II groundwater cleanup objectives are five times greater than those given for Class I groundwater. For example, the objective for atrazine in Class I groundwater is 3 μg/L, whereas it is 15 μg/L for Class II groundwater (6).

Soil Cleanup Objectives

The remediation of contaminated soil also requires establishing some type of cleanup goals or objectives. Such objectives are used to determine whether the soil is "contaminated" in a regulatory context. Depending on the specific type, agrichemicals are subject to various physicochemical and biological processes that can reduce their concentrations in soil and groundwater. Unlike other common contaminants such as chlorinated hydrocarbons, agrichemicals are *intentionally* released into the environment to promote plant growth and to limit the spread of weeds. A mixture of application-rate equivalents and risk-based processes to derive soil cleanup objectives have been promulgated in the Midwest. For example, the Illinois Department of Agriculture provides a default soil-cleanup objective (SCO) for surface soil (0 to 12 inches) and subsurface soil (12 to 60 inches) for each major pesticide used in Illinois. A facility also has the option of developing site-specific SCOs. These SCOs were derived from the application of soil screening levels (SSLs) developed by the U.S. Environmental Protection Agency (7,8). The resulting SCOs take into account the movement and chemical fate of a given chemical in soil–water systems. In the application of the SSL concepts, three physicochemical-fate mechanisms are considered: dilution in groundwater, adsorption by soil organic matter, and volatilization. Degradation by biotic or abiotic mechanisms is not considered. The SSL model provides a dynamic link between groundwater concentrations and soil concentrations. The default subsurface (12 to 60 inches depth) SCOs were calculated using Class I groundwater quality standards. The default surface SCOs were also based on Class I groundwater standards with the exception of acetochlor, alachlor, aldicarb, atrazine, cyanazine, dimethoate, disulfoton, phorate, simazine, and terbufos. For these pesticides, application-rate equivalents are used as SCOs. As given in (9), each SCO was based on pesticide label rates to the upper foot of soil or of a soil/gravel mixture.

EXCAVATION OF CONTAMINATED SOIL

Once the SCOs have been established, the areas and depths of contamination by agrichemicals at an agrichemical facility can be estimated. The delineation of the area and depth of material to be removed is not an exact science. In practice, the boundaries for excavation are subjectively interpolated between the locations where soil cores were collected. The boundaries for excavation may also, in part, be determined by any physical constraints such as facility buildings, railroad tracks, or other permanent structures. Once the contaminated materials have been excavated from the dealership, they must be disposed in an environmentally acceptable manner. There are three options available: land application or spreading, landfilling, and above-ground treatment.

OPTIONS FOR REMEDIATION

Land Application

Land application for the disposal of soils contaminated with agrichemicals is a common approach in the Midwest and may be the least expensive and most readily available disposal technique (10). It is based on the premise that if contaminated soil is spread in a thin layer on an agricultural field, the pesticides and/or fertilizers will dissipate to smaller and harmless concentrations. In practice, the pesticides in the contaminated material are applied at the application-rate equivalent that would be appropriate for that field and would be expected to biodegrade with time. If more than one pesticide or fertilizer is present, the application rate is based on the most limiting rate for the chemical detected in the contaminated soil sediment, or fill.

When pesticide-containing soil is land applied, it may be necessary to minimize the amount of coarse material in the soil before application. Attempting to spread soil that contains a significant amount of coarse material such as gravel can damage most spreading equipment and be objectionable to the landowner or farmer. A practical technique to remove the coarse material is to use field-scale screeners. The excavated, unsorted material is fed into some type of mechanical screener to separate the coarse debris from the finer soil. Depending on the size of the equipment and the mesh size of the screen, a screener can process between 50 to 150 tons per hour. The coarse material may be used as a road base, field roads, or placed back in the original excavation. The fine material is then land applied using spreading equipment. There is a relatively narrow window of opportunity in which site remediation and landspreading can occur: postharvest to preplanting. During the planting season, agrichemical facilities are in their busiest periods and are reluctant to allow any site excavation because it can hinder the operation of the facility and service to their customers. During the winter, it is advisable to avoid freezing conditions because the soil cannot be handled effectively if frozen.

Often, there is not enough room at an agrichemical facility for soil screening. In actual practice, the excavated soil is transported from the facility to an area where the soil can be screened and land applied. Compensation to local farmers or land owners for the use of land to establish a staging area for the screening process and for the agricultural fields can add to the costs of remediation.

Landfilling

Historically, pesticide-contaminated soil excavated at agrichemical facilities has been placed in landfills. When land application is not possible, using contaminated soil as a refuse cover or backfill may be an option. However, it may be more expensive to place the soil in a landfill. For example, if transportation costs are ignored, the average cost of landfilling pesticide-contaminated soil in the Midwest is about $25 per cubic yard compared with an average of $10 per cubic yard for land spreading. Moreover, limitations in landfill capacity may be a barrier to the disposal of contaminated soil in some areas.

Soil Washing

Although land application and landfilling are commonly used approaches for pesticide-contaminated soil at agrichemical facilities, other options are under study. It has been suggested that soil washing could be applied for a relatively wide range of pesticides (11). Soil washing is a treatment process in which contaminants are extracted from the excavated material using a solution containing chemical surfactants. For example, under laboratory conditions, a 3% solution of the nonionic surfactant polyoxethylene-4-lauryl ether was efficacious for removing atrazine from contaminated fill samples that were collected at an agrichemical facility (12). After 1 hour of mixing the fill–liquid suspensions, about 85% of the atrazine was extracted, compared with 26% removal by deionized water.

Bioremediation

Bioremediation is another option for remediating contaminated soil. Biodegradation is a process in which microorganisms transform or alter the structure and properties of chemical compounds by enzymatic biochemical reactions. Biochemical transformations can break down toxic, anthropogenic compounds into less toxic metabolites, and/or into inorganic compounds. Bioremediation is the application of biodegradation to reduce the concentrations of contaminants in soil by enhancing the physicochemical conditions for degradation, the creation of optimum conditions for remediating contaminated sites. For example, the biodegradation of trifluralin, metolachlor, and pendimethaline in gravel fill samples was promoted by mixing them with yard-waste compost under laboratory conditions (13). The initial concentration of trifluralin (2200 μg/kg) was reduced to about 505 μg/kg in a 1:1 fill:compost mixture after 40 days.

The basis for enhanced biodegradation is creating an environment where microbes are more numerous thereby increasing the probability of significant degradation. There are several critical environmental conditions that affect microbial activity: moisture content, oxygen, redox potential, pH, nutrients, temperature, and especially the supply of nitrogen and phosphorous. If the contaminated soil contains a large amount of carbon but little nitrogen and phosphorous, biodegradation will cease when available N and P are depleted. Therefore, fertilization of the contaminated fill materials may be required as a management technique to enhance biodegradation. For example, the addition of cornmeal can enhance the extent of biodegradation of pesticide-contaminated soil from an agrichemical facility when the material is land applied (14).

The addition of a mixture of cornmeal, surfactant, fertilizer, and clean soil, under laboratory conditions, increased the rate of biodegradation of atrazine, alachlor, and metalochor in gravel fill samples that were collected at three different agrichemical facilities (15). The fill samples were then either moistened with sterilized deionized water to 25% moisture content, or amended with the surfactant-fertilizer solution containing 0.1% oleic acid, urea, polyoxyethylene-12-octyl phosphate (modified from the oleophilic fertilizer Inipol EAP 22). After 8 weeks of incubation, the amount of atrazine recovered decreased by 55 to 74% in fill–soil samples amended with cornmeal and the surfactant-fertilizer mixture. Similar reductions of alachlor and metolachlor were also observed in those samples (Fig. 1). No significant degradation of atrazine, alachlor, and metolachlor was observed in the unamended and sterilized fill samples. During the same incubation period, however, the rate of reduction of atrazine, alachlor, and metolachlor was slower in samples amended with cornmeal alone. The biodegradation half-lives of atrazine in the fill samples amended with corncob and the surfactant-fertilizer mixture ranged from 3.9 to 6.8 weeks.

Phytoremediation

Phytoremediation is a technique in which plants, primarily hybrid poplar trees, legumes, and grasses, are planted in contaminated soil. The plants have the potential to take up and incorporate contaminants into plant tissues, enhance biodegradation in the root zone, and reduce the volume of groundwater available to transport contaminants off-site. There are few, however, published examples of field-scale applications of phytoremediation at agrichemical facilities. Poplar trees were planted at an agrichemical facility in Illinois to remove nitrogen and herbicides from shallow surface groundwater (Eric Aitchison, Ecolotree, Inc., personal communication). A total of 440 trees planted grew to a height of 15 feet in 17 months, and a significant volume of groundwater was apparently used by the trees. Phytoremediation may have a future,

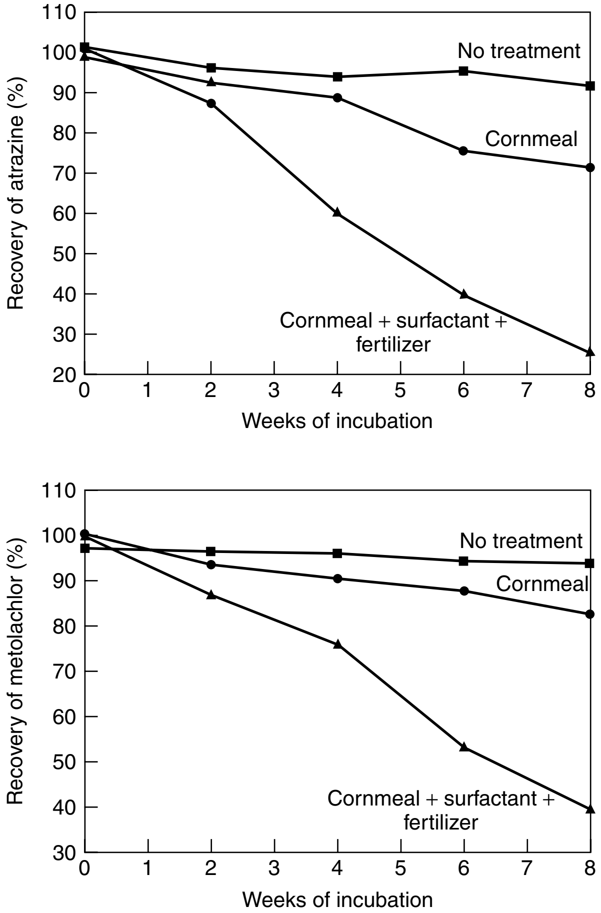

Figure 1. Amount of atrazine (top) and metolachlor (bottom) in soil–fill samples and the control sample (no treatment) in the presence of ground cornmeal and the cornmeal–soil–surfactant–fertilizer combination as a function of incubation time (15).

but additional research and development are needed. Phytoremediation, like bioremediation, may be too slow when rapid remediation is required. Phytoremediation may be suitable for inactive or abandoned agrichemical facilities. Moreover, relatively large concentrations of phytotoxic chemicals in soil and groundwater can limit plant growth (16).

OTHER APPROACHES

Other approaches for remediating pesticide-contaminated soil have been proposed such as incineration, solidification/stabilization, thermal desorption, radio-frequency heating, supercritical carbon dioxide extraction, and dechlorination by zero-valent iron (10,11,17,18). However, these approaches may not be cost-effective for a typical agrichemical facility. For example, incineration of soil may cost from $800 to $3,000 per cubic yard (17). However, if the contaminated soil also contains chemicals that are defined as hazardous under the Resource Conservation and Recovery Act, the soil may have to be incinerated (1).

THE SELECTION OF THE REMEDIAL APPROACH

Past handling practices have resulted in pesticide-contaminated soil and groundwater at retail agrichemical facilities. During about the last ten years, however, new containment regulations have been implemented in the Midwest which will hopefully reduce incidental releases of pesticides and fertilizers. For example, the Secondary Containment, Operational Area Containment, and Containment Management and Operations in Illinois (19) require the use of a containment system designed to intercept, retain, and recover operational and accidental spillage, leakage, wash water, and agrichemical residues. When contaminated soil, fill, or sediment is detected at an agrichemical facility during a site assessment, however, remediation may be required to minimize the adverse impact of the material on surface and groundwater. Techniques for remediating pesticide-contaminated soil is a current area of research, and new techniques and technologies are currently under study. However, land application and landfilling may be the most cost-effective, routine, and available technique to remediate contaminated soil at retail agrichemical facilities. Experience gained in the Midwest may be very useful for other domestic and international facilities.

PESTICIDE OCCURRENCE AND DISTRIBUTION IN RELATION TO USE

Xuefeng Chu
Grand Valley State University
Muskegon, Michigan

GENERAL RELATIONSHIP BETWEEN PESTICIDE OCCURRENCE AND USE

In the United States, about 1 billion pounds of pesticides are used each year to control weeds, insects, and other organisms and about 80% of them are used in agriculture (1). Widespread use of pesticides over the past several decades has led to their occurrence in groundwater, surface water, aquatic biota and sediment, and the atmosphere (2). In 8200 sample analyses conducted by the National Water Quality Assessment (NAWQA) program during 1992–1996, 58 pesticides were detected at least once at or above 0.01 μg/L in both surface and groundwaters in 20 of the nation's major hydrologic basins (3). The NAWQA studies also revealed that more than 90% of water and fish samples from all streams contained one or, more often, several pesticides and about 50% of the sampled wells contained one or more pesticides; the highest detection frequencies were in shallow groundwater. In particular, the top 15 pesticide compounds found in water are among those with the highest current use, although some organochlorine compounds (e.g., DDT) heavily used in the 1960s were found most often in fish and sediments. The most frequently used pesticides occurred in geographic and seasonal patterns that mainly correspond to distributions of land use and associated pesticide use (4). Clearly, a significant relation can be expected between the use of pesticides and their occurrence in both surface and groundwaters. However, the extent of their occurrence and spatial and temporal distributions in surface and groundwater (how, when, and where the pesticides occur) may vary significantly.

ENVIRONMENTAL PATHWAYS OF PESTICIDES VERSES THEIR OCCURRENCE AND DISTRIBUTION

The environmental pathways of pesticides determine their occurrence and distribution. Following release into the environment, pesticides can be washed off the target application fields into adjacent surface waterbodies (e.g., streams, rivers, lakes) by runoff and erosion, leached by percolating water down through the vadose zone into the underlying aquifers, volatized into the atmosphere, taken up by plants, and accumulated in aquatic organisms through the food chain and even in human bodies. Thus, pesticides follow complex pathways and patterns of occurrence and distribution in the environment (Fig. 1).

TRANSPORT AND TRANSFORMATION PROCESSES OF PESTICIDES VERSES THEIR OCCURRENCE AND DISTRIBUTION

Pesticides, existing in three phases (dissolved, adsorbed, and vapor phases) in the environment, undergo a series of physical, chemical, and biological transport and transformation processes such as advection, dispersion, degradation, sorption, volatilization, and partitioning between dissolved and vapor phases in surface and groundwater (Fig. 1). These essential transport and transformation processes dominate pesticide occurrence and distribution in the environment. Due to the complexity of these processes, the occurrence and distribution of pesticides in surface and groundwater can be extremely variable and are affected by numerous factors such as pesticide use, pesticide properties, land use, soil types, topographic features, agricultural practices, climatic conditions, hydrology, and hydrogeologic settings. Whether or not pesticides occur in a certain part of the environment (a specific river reach, soil layer, or aquifer) depends on three essential elements: (1) availability of pesticide, (2) availability of flowing water, and (3) accessibility/pathways.

VARIABILITY IN THE RELATIONSHIP BETWEEN PESTICIDE OCCURRENCE AND USE

The relationship between pesticide occurrence and use varies for different pesticides and geographic regions.

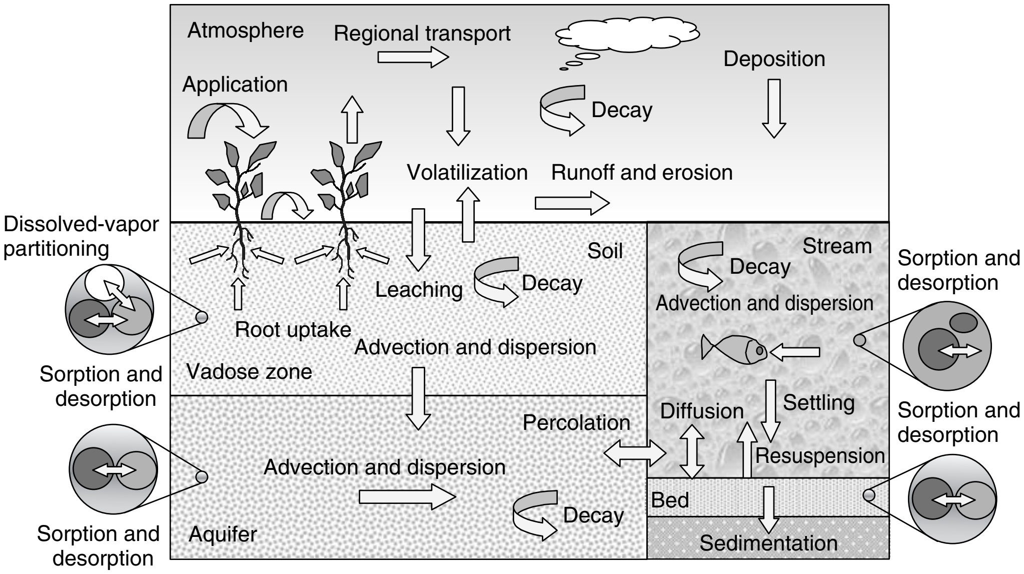

Figure 1. Fate and transport of pesticides and their occurrence in the environment.

Even for a specific pesticide at one site, the relationship changes with time due to the variability and complexity of hydrology. In addition, the relationship for surface water is different from that for groundwater due to their distinct hydrologic characteristics and pesticide fate and transport processes. Surface and groundwater systems have dissimilar timing of pesticide occurrence, temporal and spatial distributions, and magnitude of pesticide exposure levels. A pesticide application may result in a peak concentration in streams and shallow soils in hours, whereas it may take days, even months, to reach a peak exposure level in a groundwater system. The peak concentrations in groundwater can also be much smaller than those in surface water and shallow soils. A time shift of arrival of peaks can often be observed in the transport direction in both surface and subsurface water systems.

FIVE KEY PESTICIDE-USE ISSUES RELATED TO OCCURRENCE AND DISTRIBUTION

In terms of pesticide use, five key issues that affect pesticide occurrence and distribution need to be addressed: (1) which pesticide is applied (type and properties of pesticide), (2) how much and how often the pesticide is applied (amount and frequency of application), (3) when the pesticide is applied (timing of application), (4) how the pesticide is applied (method of application), and (5) where the pesticide is applied (domain of application). The types of pesticides that possess specific physical, chemical, and biological properties affect their occurrence and distribution directly by altering their environmental persistence, mobility, and other fundamental transport processes. The amount of applied pesticides determines the overall level of pesticides potentially available for occurrence in surface and groundwater, and the application frequency may determine the possibility and extent of pesticide buildup. The timing and method of application of pesticides affect occurrence primarily by changing their environmental pathways and thus spatial and temporal distributions and exposure levels. Additionally, the overall patterns of pesticide occurrence and distribution vary with pesticide-treated crops (application domain) that have different growing periods and canopy characteristics and require different soil–water–pesticide management practices.

EFFECTS OF USE OF PESTICIDES ON THEIR OCCURRENCE AND DISTRIBUTION

Effects of Pesticide Properties on its Occurrence and Distribution

The capabilities of sorption and volatilization of pesticides, characterized by distribution coefficient and Henry's law constant, determine their existing forms (dissolved, adsorbed, or vapor phases) and thus their mobility. These two processes and the degradation of pesticides are critical to their occurrence and distribution. Pesticides of lower sorptive capability tend to move quickly with flowing water. The spread of this type of pesticide throughout the environment is, to a great extent, determined by water movement. In contrast, long-lived pesticides of strong sorption, such as DDT, may last decades in the environment (4).

Effects of Application Quantity and Frequency on Pesticide Occurrence and Distribution

Frequent applications of pesticides increase the total amount of pesticides released into the environment and hence endanger the vulnerable hydrologic system. In particular, the accumulative effect of long-lived and strongly sorbed pesticides is often of great concern.

Effects of Application Timing on Pesticide Occurrence and Distribution

The combined timing of pesticide application and rainfall/irrigation can dominate exposure levels of some organophosphate insecticides in both surface and subsurface environments (5). A pesticide application, immediately followed by rainfall or overcanopy irrigation, provides an extremely high potential for the pesticide to transport from target fields to nearby surface waterbodies with runoff and erosion and to leach into soils and the underlying groundwater.

Effects of Application Methods on Pesticide Occurrence and Distribution

Pesticides can be applied by different methods, such as over-canopy spray, under-canopy ground surface spray, and soil-incorporated application. Application methods of pesticides affect their occurrence in the environment by changing their initial distribution and hence altering their following transport–transformation pathways and environmental fate. In addition, irrigation methods (e.g., over-canopy and under-canopy irrigation) and their combination with various pesticide application methods can be critical to pesticide occurrence and distribution. High variability of concentrations of some pesticides during irrigation periods can be attributed to differences in irrigation frequency and water management (6).

SUMMARY

The occurrence and distribution of pesticides in the environment are closely related to their use and are determined by a series of pesticide transport and transformation processes. The occurrence and use of pesticides follow extremely complex and dynamic patterns that are affected by numerous factors related to pesticide use, hydrology, and agricultural activities. Different ways of pesticide use (application quantity, frequency, timing, and method) can lead to distinct environmental fates of pesticides in terms of their occurrence, extent, as well as spatial and temporal distributions.

ASSESSMENT OF POLLUTION OUTFLOW FROM LARGE AGRICULTURAL AREAS

Ramakar Jha
K.K.S. Bhatia
National Institute of Hydrology
Roorkee, Uttaranchal, India

C.S.P. Ojha
Indian Institute of Technology
Uttaranchal, India

The pollution from large agricultural areas in general is discussed. The potential of remote sensing and geographical information system as input for NPS pollution assessment is emphasized. Mathematical models commonly used for assessing of nonpoint source (NPS) pollution are also described. Assessment of nutrient pollution from three agricultural watersheds of a typical Indian river basin ranging from 2–5 km^2 is considered as an illustrative example.

INTRODUCTION

The sources of surface water pollution typically fall into one of two categories: point-source pollution and nonpoint-source pollution. The term point-source pollution refers to pollutants discharged from one discrete location or point, such as an industry or municipal wastewater treatment plant, to surface water resources. The term nonpoint-source pollution refers to the discharge of pollutants, which cannot be identified as coming from one discrete location or point. The pollution outflow from agricultural areas is known as nonpoint source (NPS) pollution or diffuse pollution. NPS pollution occurs when rainfall, snowmelt, or irrigation water runs over land or through the ground, picks up pollutants, and deposits them in rivers, lakes, and coastal waters or introduces them into the groundwater. Sediment, nutrients, and pesticides are common agricultural pollutants, which cause surface water and groundwater quality problems (1–3).

Estimation of NPS pollution from cropland runoff is an important feature of regional water quality planning. The primary objective of NPS pollution estimation is to protect or restore the designated use of a water resource by reducing pollutant delivery to the water resource. All nonpoint sources of pollution are not equal. Many nonpoint sources of pollution are insignificant, whereas other sources contribute substantially to water resource impairment. Topographic, hydrologic, and agronomic factors often combine to make some nonpoint sources more detrimental to the beneficial use of water resources than others. Therefore, a method or strategy to identify and prioritize for treatment NPS areas, which are more detrimental than others, is desirable. A land treatment strategy should be developed to guide the selection and implementation of best management practices (BMPs). The BMP approach involves identifying and implementing land use practices in agricultural areas that prevent or reduce nonpoint pollution. In the case of erosion-sedimentation, many such practices are well known for agricultural activities. However, for some other types of pollutants, the BMP may not be known. In such instances, research that relates land use to water quality is needed.

ROLE OF GEOGRAPHICAL INFORMATION SYSTEM (GIS) AND REMOTE SENSING FOR NPS POLLUTION ASSESSMENT

Like any environmental phenomena, there is a spatial dimension to the management of water quality and the control of nonpoint-source pollution in agricultural watersheds. Understanding the spatial relationships among the various pollution sources in a watershed is critical to the successful implementation of the best agricultural management practices. A geographical information system (GIS) enables the effective integration, management, and analysis of disparate data sets related to chemicals, soils, climate, topography, land cover, and land use. These data sets are important driving variables for a nonpoint pollution model (4).

Several strategies for integrating distributed water quality models and GIS have emerged during the past few years (5–7). In most applications, the GIS was used primarily to generate model input data and to display output data from the model—an approach usually referred to as loose coupling of a model and the GIS (8–10). In loose coupling, there are two options: (1) loose coupling through interchange of data files in ASCII format between the model and the GIS and (2) loose coupling using a common binary file (10). An interface program (e.g., pre- and postprocessor) is normally used to convert and organize the GIS data in the form that the model requires. The loose coupling can often be time-consuming and problematic, particularly, for large watersheds. The loose coupling also, depends on the data structure of the GIS and the data file format specified by the water quality model (11,12).

The second strategy of coupling the GIS and water quality models involves close coupling in which the control programs in the GIS software are slightly modified to provide an enhanced environment for data transfer between the model and the GIS database (8–10). The options for loose and close coupling have significant overlap, depending on the characteristics of the water quality model. However, in close coupling, information is passed between the model and the GIS via memory-resident data models rather than external files. This improves the interactive capabilities and performance of closely coupled modeling environments.

The third strategy of coupling water quality models and the GIS is tight coupling or full integration (8–10). This strategy is based on incorporating the functional components of one system (e.g., the model) within the other, thereby eliminating the use of interface programs. The most widely used option of tight coupling involves developing tightly coupled seamless interfaces between the model and the GIS. The major benefits, of tight coupling strategy include improved performance, enhanced user interface, and increased problem-solving capabilities through efficient analysis of "what if?" scenarios. There is also little or no redundancy in the development process because the systems can leverage off each other.

Data acquired from remote sensors on aircraft and satellites offer great promise in providing numerous model inputs. Water quality models used to determine nonpoint source pollution vary in type and extent of land use for which these are best suited. Water bodies, urban areas, forests, cropland, and bare soils or rock can generally be differentiated very well. Individual species of vegetation often can be separated, surface soil properties can be delineated, and the percentage of vegetation or residue cover on the land can sometimes be estimated. The spectral, spatial, and temporal characteristics of remotely sensed data make those data useful for models that require knowledge of land use, cover, and conditions when calculating nonpoint-source pollutant loads. The relevant studies are available in many textbooks and the literature.

MATHEMATICAL MODELS FOR ESTIMATING POLLUTANTS FROM AGRICULTURAL AREAS

Mathematical models have been used extensively since the late 1960s to estimate pollutant outflows from agricultural areas. The term mathematical model may be new, but all of us have used mathematical models since we took algebra in school. Such models are mathematical representations of physical, chemical, biological, social, economic, and related processes. The advancement in computers, has made it possible now to evolve different mathematical approaches (from simple linear regression to complex differential equations) for obtaining favorable outcomes. Some of the mathematical models used for NPS pollution estimation are as follows: (1) SWMM (13), (2) HSPF (14), (3) ANSWERS (15), (4) CREAMS (16), (5) SWAM (17), (6) NTRM (18), (7) SWRRB (19), (8) SHE (20), (9) AGNPS (21), (10) SWAT (22), and (11) ANSWER-2000 (23).

Most of the mathematical models cited before simulate hydrologic, chemical, and physical processes involved in the transport of sediment, nutrients, and pesticides. In general, mathematical models for estimating NPS are divided into two classes: (1) a temporal class that includes event simulation and continuous simulation and (2) a spatial class that includes lumped parameters and distributed parameters.

In the temporal class, the continuous simulation models are preferred because they simulate all NPS pollution producing events and can be used to estimate total maximum daily loads and seasonal variations in NPS loading. However, in the spatial class, distributed parameter models are preferred. The principal advantage of distributed parameter models over lumped parameter models is that distributed parameter models represent the spatial variability of watershed features (soil, topography, land use etc.) more accurately. Moreover, the distributed parameter models can also estimate pollutant losses at different locations within the agricultural area. Some of the most commonly used distributed parameter

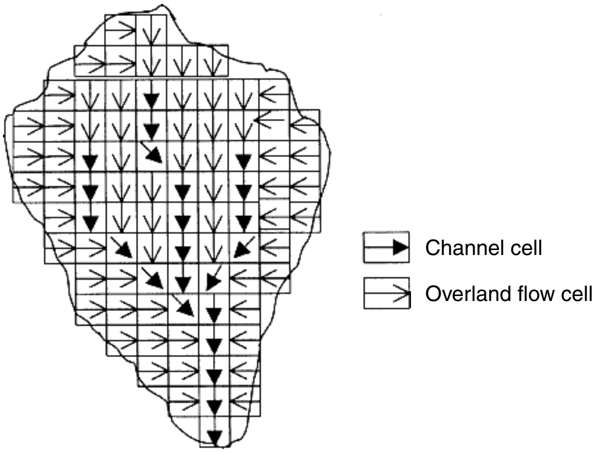

Figure 1. Mixed cell and routing process in overland and channel flow.

continuous simulation models are AGNPS and ANSWER-2000. The processes involved in these models are explained next.

In the beginning of the modeling process, a large agricultural area is divided into smaller grids or cells. A typical arrangement of such cells is shown in Fig. 1. The flow, sediments, and nutrients available at the beginning of the cell, coupled with those generated within the cell, are used to assess these values at the outlet of the cell. Subsequent routing of these values can lead to the estimation of flow as well as the NPS pollution load at the outlet of the agricultural watershed.

In a hydrological process, the rainfall added to an agricultural area in the beginning is intercepted by the canopy cover, evapotranspirated or infiltrated. Infiltration capacity is very high initially because of movement of water to the unsaturated zone, and water within this layer percolates downward. Water is discharged to the channel drainage system, when infiltration capacity is exceeded by the water supply and the depression storage has been satisfied. The total inflow to the channel drainage system is a combination of surface runoff, interflow, and base flow, which is calculated by using a water depletion function to gradually diminish it. A few specific relevant equations for the computation of different flow components are shown in Appendix 1. However, many more equations can be obtained from the literature.

The sediment transport capacity and potential sediment are important variables of nonpoint source pollution from a large agricultural area. As seen from Appendix 1, the sediment transport capacity is based on a sediment concentration ratio, c, estimated with a shear–stress relationship between the dominant flow shear on the soil and the critical stress based on the Shields criteria (24). The potential sediment supply due to rainfall can be calculated from an empirical relationship for rainfall energy rate adapted from the Universal Soil Loss Equation (USLE) method. The method accounts for the effects of canopy cover by introducing cover factors into the calculations of soil detachment due to rainfall and runoff. Similar models available in the literature can also be applied for estimating the sediment transport capacity and potential sediment.

The mathematical approaches used for the NPS water quality component in this chapter are widely used NPS models (Appendix 2). These were developed for the CREAMS model (25). Young et al. (20) modified the algorithms applied in the CREAMS model and created the AGNPS model, suitable on watershed scale. The nutrient simulation is normally divided into two parts to handle the soluble nutrient in the runoff and in the sediment separately (21). For the soluble part, the general assumption is that the rate of change in concentration of soluble nutrients at the surface is proportional to the difference between existing concentrations and concentration in rainfall. The available nutrient content at the surface is a result of combining the residual nutrient at the surface with the amount from fertilizer application. The available nutrient due to rainfall is estimated from the nutrient concentration in rainfall and given as input data. The movement rates are evaluated using nutrient leaching and runoff extraction coefficients given as input data for the model.

The mathematical equations are used separately for each grid or cell where the total runoff, sediment, and nutrient quantities are calculated by adding the surface runoff contributions from various grids or cells to the base flow. The routing through the channel system is achieved using a storage-routing technique based on continuity. Deposition of sediment and decay of nutrients are estimated using fractions of the transported mass. Mixing cell models, like other transport models, is subject to numerical dispersion affected in part by cell size and the assumption of complete mixing. Appendix 2 summarizes some of the commonly used equations.

ASSESSMENT OF NUTRIENTS FROM A TYPICAL INDIAN RIVER BASIN

To calibrate and test the mathematical equation shown in Appendixes 1 and 2, the nonpoint-source pollutants from three agricultural watersheds, ranging from 2–5 km^2, of Kali Basin, western Uttar Pradesh, India have been analyzed. River Kali in western Uttar Pradesh, India, has a significant socioeconomic value for nearby areas. It receives many point and nonpoint sources of pollution (26–29). The study area (Fig. 2) is part of the Yamuna basin in the Indo-gangetic Plains, composed of Pleistocene and subrecent alluvium, and lies between 29° 13′ to 30°N latitude and 77° 35′ to 77° 45′ E longitude. The mean rainfall across the basin is 1000 mm, which occurs mainly during the monsoon period. The basin area lies between elevations from 276 m above mean sea level to 221 m above mean sea level, and the major land use is agriculture. The soils of the area are loam to silty loam and are normally free from carbonates. Agricultural waste is also an important factor contributing to the pollution of the river water.

The basin boundary, drainage pattern, contour maps, spot heights and built-up area maps for River Kali, were digitized using ILWIS—GIS. For the analysis, the spatial data set available in grids or cells has been transformed

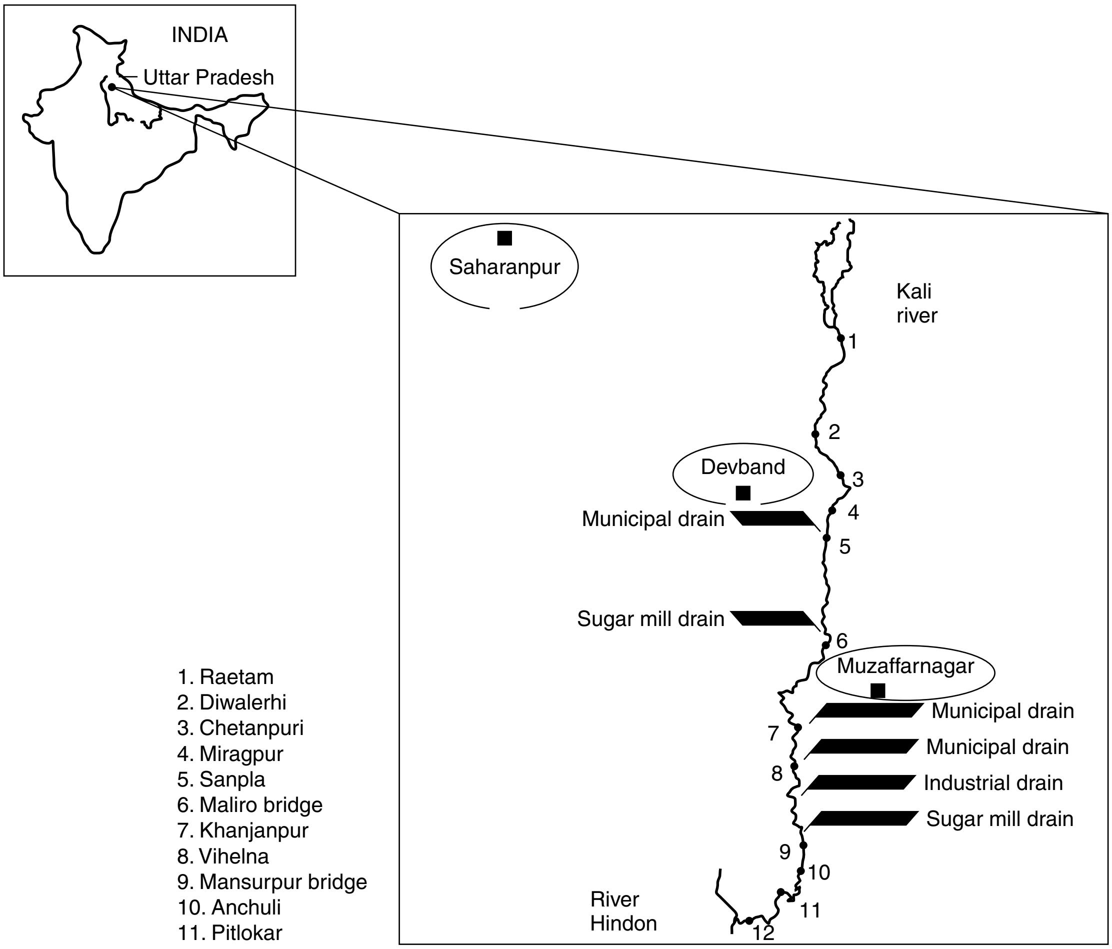

Figure 2. Location of River Kali in India.

to a digital elevation model (DEM), followed by filtering to arrive at a slope map, or a flow path map. For delineating land use/land cover maps, classification and quantification of different crops, and its temporal variation, IRS LISS III multispectral imageries and IRS-PAN data for the study period have been used. Ground truth verification was done to verify the results obtained using remote sensing data.

Further, extensive sampling from different sampling points giving a total of 576 data sets for nitrate (NO_3) and orthophosphate (o-PO_4) was done from March 1999 to February 2000. The nutrients were analyzed following a standard method (30). The NPS nutrient (NO_3 and o-PO_4) values obtained using mathematical equation based on the mixing cell concept, given in Appendixes 1 and 2, were compared with the observed nutrient values for all four agricultural watersheds (Fig. 3). It was found that the coefficient of determination, r^2, between observed and computed values of nutrients was greater than 0.85 in all four agricultural watersheds. It was also found that the error estimate viz., standard error, was less than 2 for all cases.

SUMMARY

To estimate pollution from a large agricultural area, distributed parameter and continuous simulation models are preferred because they simulate pollution producing events, total maximum daily pollution load, its seasonal variations, and represent the pollutant losses at different locations within the agricultural area. Remote sensing and GIS are important tools coupled with the mathematical models to estimate pollution from a large agricultural area. An illustrative case study from India demonstrates that NPS pollution can be computed well using the mixing cell concept with remote sensing and GIS support.

DEEP-WELL TURBINE PUMPS

Blaine Hanson
LAWR
Davis, California

Deep-well turbine pumps are used to pump groundwater to the surface, and in some cases, they may be used to pump water out of sumps and supply pressure. Deep-well turbines consist of a housing or bowl, impellers, and a shaft, all of which are installed in the well [Figs. 1(a) and 1(b)]. The housing or bowl contains both the impeller and the diffuser vanes. The shaft connects the impeller to the electric motor or engine, whereas the impeller transfers the energy developed by the motor or engine to the water. Diffuser vanes guide the flow of water from the impeller to the discharge point of the bowl.

Impellers transfer energy from the motor or engine to the water either by centrifugal force or by lifting action. They may be enclosed or semi-open. Enclosed impellers have a disk or shroud on both sides of the vanes (Fig. 2). These impellers require a close clearance between a wearing ring, located at the inlet of the impeller, and the impeller skirt of the bottom extension of the impeller. In semi-open impellers, the shroud is only at the top of the impeller. Semi-open impellers have a shroud only on the top (Fig. 2). A close clearance (0.076 mm–0.177 mm) between the bottom of the vanes and the pump housing is necessary for good performance. Semi-open impellers are less susceptible to wear from sand because they can be raised slightly to reduce abrasion. This process, however, will decrease pump output and efficiency.

Mixed flow impellers are often used in deep-well turbine pumps. Mixed flow impellers use both centrifugal and lifting forces to pump water. When the impeller rotates, centrifugal forces develop in the water inside the impeller and cause water to flow toward the impeller's outer edge. This flow, in turn, results in water flowing into the center or eye of the impeller. Rotating a mixed flow impeller also transfers energy to the water by a lifting force. Impellers that pump water only through centrifugal force are classified as radial flow impellers. Impellers that pump water only through lifting forces are classified as axial or propeller impellers.

Some deep-well turbines use a line-shaft to connect the impellers to an electric motor or engine. Line shafts are supported by bearings—either oil-lubricated or water-lubricated—spaced at intervals along the shaft length. Oil-lubricated bearings are housed within a tubing inside the column pipe (the pipe that carries the water to the surface). An oil reservoir located on the pump head drips oil down the shaft.

Submersible pumps are deep-well turbines with a waterproof electric motor installed in the well below the pumping level. The motor is attached directly beneath the bowl assembly, and water intake is between the motor and the pump. A specially designed motor, slimmer and more compact than a line-shaft motor, is installed in the well. As both motor and pump are situated inside the well, submersible pumps do not require a line shaft.

In submersible pumps, it is crucial that enough water circulate around the motor to keep it cool. As water in the well should flow past the motor casing into the pump intake, submersible motors should be located above the level at which most of the flow enters the well. A shroud can be installed over the pump intake to force water to flow past the motor.

As the impellers and bowls must be submerged inside the well, the diameters of the impeller and bowl are limited by the diameter of the well, which in turn limits the output (capacity and pressure) developed by each impeller. This limitation can be overcome if the bowls are installed in stages, with each stage adding to the output developed by the preceding stages. A five-stage pump will, therefore, have five bowl assemblies, each containing an impeller, with the water guided from stage to stage by diffuser vanes built into the bowl assembly. Figure 1 shows a two-stage pump.

Because deep-well turbine pumps are installed in the well, pump size is limited by the diameter of the well casing. If the pump is too large for the casing, rocks from the gravel pack can become lodged between the casing, which makes it difficult to remove the pump and—particularly if the well is crooked—the pump may be difficult to install. The clearance between the bowls and the well casing should be at least 25 mm. Narrower clearances may complicate installation or, in crooked wells or where gravel becomes lodged between the pump and casing, may make it difficult for the bowls to be removed for repair.

The output of the pump must be sufficient to lift the water to the ground surface and provide the desired pressure at the desired flow rate or pump capacity. However, in some cases, deep-well turbines lift the water only and a centrifugal pump located at the discharge point of the well, commonly called a booster pump, is placed in line with the deep-well turbine pump to supply pressure.

The output of a pump is described by its performance characteristic curves, developed by pump manufacturers. These curves show the amount of total dynamic head developed by a single stage at a particular capacity, the pump efficiency at that capacity, and the horsepower requirements of the pump. Performance curves show which pump will provide the desired total head and capacity and determine what size electric motor or engine the pump will require.

Figure 3(a) shows the total head and capacity performance curve for a typical pump. In a no-flow condition (shut-off), the total head is maximum, or 22 m for this

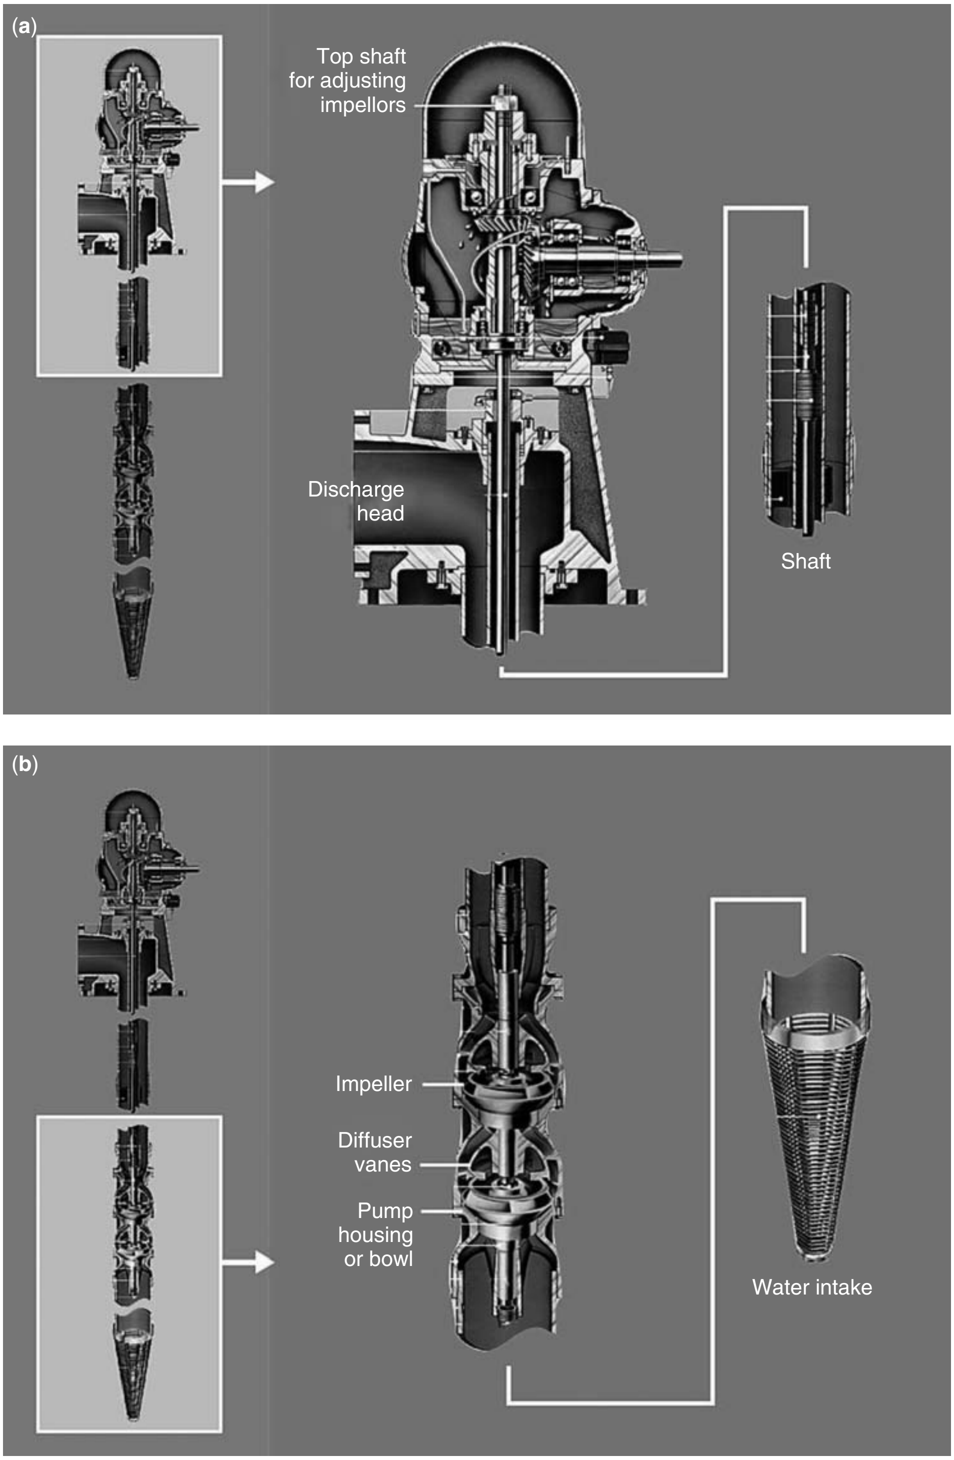

Figure 1. Cutaway of a deep-well turbine pump that shows (**a**) the pump head, gear head, and shaft; and (**b**) pump housing, impellers, and shaft. [*Source*: Hanson (1)].

pump. As the pump capacity increases, the total head decreases. At low capacities, most of the pump output consists of total head (normally measured as the sum of the pumping lift and the discharge pressure head), whereas at high capacities, most of the pump output is in capacity.

Pump efficiency increases as pump capacity increases until a maximum efficiency is reached [Fig. 3(b)]. Thereafter, pump efficiency decreases as capacity continues to increase.

Metric horsepower (mhp) increases slightly as capacity increases to a maximum, and then it may decrease slightly [Fig. 3(c)].

The performance curves are only for one-stage, but they can develop performance curves for multiple-stage pumps. For example, Fig. 3(a) shows that in a one-stage pump, 14.6 m of head is developed at 3028 L/min. The mhp is 14.2. In a three-stage pump, the head developed at 3,028 L/min will be three times that of a single stage, or 43.8 m. The mhp will also be tripled, to 42.6 mhp, and the pump efficiency may change slightly. Usually the manufacturer's curve will show the efficiency adjustments. The performance curve for a multiple-stage pump can therefore be estimated by multiplying the head and bhp of the performance curve by the number of stages for each capacity.

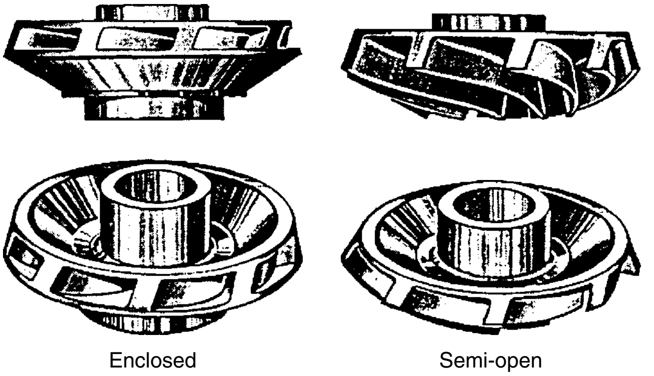
Pump performance curves have a variety of shapes. Some head/capacity curves are steep (large decreases in head occur as capacity increases), whereas others are flat (small decreases in head occur as capacity increases). The best curve will depend on changes in pumping conditions. Where pumping levels fluctuate significantly, a steep curve may allow for significant changes in pumping lift with only slight changes in pump capacity. A flat curve may help to maintain a relatively constant pressure over a wide range of flow rates.

An initially efficient pump with the necessary head and capacity can become inefficient. Inefficiency is frequently caused by wear because of sand in the well water, but it can also be caused by a mismatch between the pump and water system characteristics because of long-term changes in groundwater levels or changes to the water supply system. A mismatched pump is one that is operating properly but at an efficiency much less than the potential maximum efficiency. "Repairing" a mismatched pump will not improve efficiency.

The pump's performance can be evaluated by first testing the pump and then comparing that information with the manufacturer's performance curves. The pump test consists of measuring the pumping lift, discharge pressure, capacity, and input power to the pump and then calculating overall pumping plant efficiency—that is, the combined efficiency of the pump and motor or engine. The overall efficiency will be less than the pump efficiency reflected in the manufacturer's performance curve because of the inefficiency of the motor or engine.

Pump tests are conducted by utility companies, pump dealers, and consultants. In defining the current status of the pump, the test may provide any or all of the following information:

- Pumping lift or level—elevation difference between the discharge pipe at the pump head and the water level in the pumping well



Enclosed Semi-open

Figure 2. Enclosed and semi-open impellers. [*Source*: Hanson (2)].

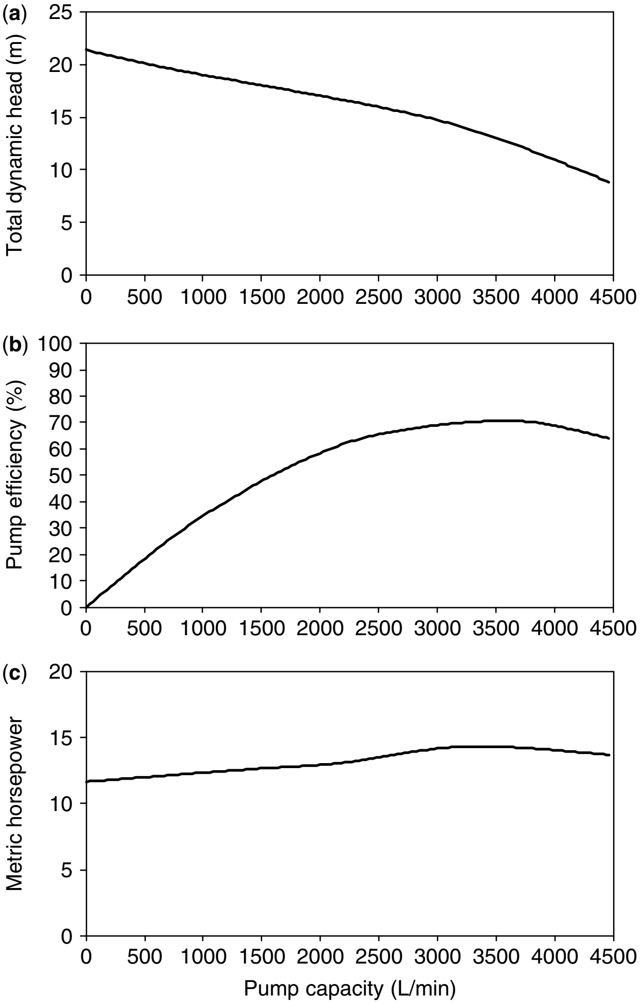


Figure 3. Pump performance curves that show the relationships between (**a**) total head and capacity, (**b**) pump efficiency and capacity, and (**c**) metric horsepower and capacity.

- Static or standing water level—elevation difference between discharge pipe and water level in the well before pumping
- Drawdown—difference between the pumping level and the static water level
- Discharge pressure—pressure at the discharge point of the pumping plant measured with a pressure gauge
- Discharge pressure head—the height of the column of water needed to provide the pressure at its base—calculated by multiplying the pressure by a conversion constant (0.704, 0.1021, or 10.21 for discharge pressure in psi, kPa, or bars, respectively)
- Total head—sum of the pumping lift and the discharge pressure head (note that if the pump is situated deep in the well, pressure losses caused by friction in the column pipe may have to be added to the total head)
- Pump capacity—water flow rate of the pumping plant.

- Well yield—flow rate or capacity divided by the drawdown (a well yield decreasing over time may indicate plugging in the well)
- Input horsepower to electric motor
- Percent motor overload
- Input kilowatts to motor
- Kilowatt-hours per acre-foot of pumped water
- Overall pumping plant efficiency

The pumping lift is measured by lowering an electric water level indicator (two electrodes attached to a wire connected to an ampere meter) or some other measuring device into the space between the well casing and the column pipe. In some cases, an air line is permanently installed to measure the pumping lift. This measurement requires access to the inside of the well casing; without such access, the pump test cannot be performed.

The pump capacity is measured with a flow meter installed in the discharge pipe. To operate properly, a flow meter requires a straight section of pipe eight to ten pipe diameters long immediately upstream from the meter to prevent or reduce turbulence in the water. Too much turbulence from valves, bends, or elbows will prevent accurate flow measurements. It is also recommended that a straight section of pipe two pipe diameters long be installed immediately downstream from the flow meter.

The input power of an electric motor or engine must be determined to calculate the overall pumping plant efficiency. Input horsepower of electric motors can be easily calculated. In some cases, the power meter will provide this information. Determining the input horsepower of engines is much more complicated and will require measuring the fuel flow rate to the engine.

The overall pumping plant efficiency can be calculated by the following equation:

$$E_o = (Q \times H)/(4634 \times \text{mhp})$$

where E_o is the overall pumping plant efficiency, Q is the capacity (L/min), H is the total head (m), and mhp is the metric input horsepower.

The pump test data should be compared with the manufacturer's performance curves to determine how the pump's actual performance compares with the manufacturer's recommended performance. This comparison step is important because it is possible to have a pumping plant measuring low efficiency but nonetheless operating properly. Repairing such a pump would be of no benefit. If the operating point is close to the head/capacity performance curve, the pump is operating properly, regardless of the overall efficiency calculated from the test data. If a significant difference exists between the performance curve and the operating point, the pump may be worn and should be repaired or replaced.

The pump test data shown in Fig. 4 illustrate the evaluation process. Two pump tests were conducted—the first when the pump was worn, with an overall efficiency of 39% and the second after the pump was repaired, with an overall efficiency of 50%. The worn pump showed a significant difference between the manufacturer's curve and the operating point, whereas the repaired pump showed only a slight difference. However, the efficiency of the repaired pump suggests that the pump is mismatched to its operating conditions and probably should be replaced by a matched pump.

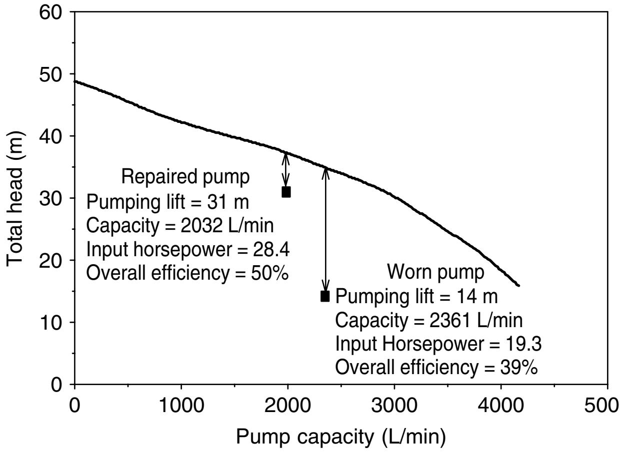

Figure 4. Comparison of pump test data with manufacturer's total head-capacity curve.

Adjusting the impellers can partially restore the capacity and total head of deep-well turbine pumps using semi-open impellers that are slightly or moderately worn. The adjustment consists of slightly lowering the pump shaft to which the impellers are connected by turning the nut at the top of the motor or gear head. The adjustment must also account for line shaft elongation that occurs when the pump is operating.

MICROBIAL QUALITY OF RECLAIMED IRRIGATION: INTERNATIONAL PERSPECTIVE

Absar Alum
Arizona State University
Tempe, Arizona

Wastewater reuse has been practiced in different forms throughout the history of human civilization. Previously, sewage had been dumped in rivers and lakes or used locally to irrigate crops. Explosive population growth and diminishing fresh water resources around the globe have now made wastewater a valuable resource, especially in arid and semiarid areas of the world. The introduction of modern wastewater treatment processes has given new dimensions to water reuse. Reclaimed waters are commonly used for landscape or recreational irrigation (parks, golf courses, athletic fields, school yards, highway medians, and public and private lands) and agricultural crop irrigation (field crops, vegetables, orchids, and tree plantations).

Human feces, which may have microbial constituents as high as 10–30%, are one of the major sources of infectious and noninfectious agents found in municipal wastewater. Thus, wastewater can contain high concentrations of excreta-related microorganisms. The principal microorganisms (infectious agents) that may be present in raw sewage can be classified into three broad groups: bacteria, parasites (protozoa and helminths), and viruses. During an outbreak, pathogen numbers in local sewage go up. More than 30 excreta-related diseases of public health importance have been documented, and many of these are of specific importance in wastewater reuse schemes. Table 1 summarizes the major infectious agents potentially present in raw domestic wastewater and their respective diseases.

TYPES OF MICROORGANISMS

Bacteria

Bacteria are microscopic organisms, ranging from approximately 1 to 6 μm in length. Human and animal intestinal tracts are colonized by different types of bacteria, which are routinely shed in the feces. The number of bacteria in feces can be in the range of 10^8–10^{11} per gram of fecal material, and these bacteria end up in municipal wastewater (1). Coliforms, such as *Escherichia coli,* and *Enterobacter* constitute a small group of intestinal bacteria, which has historically been used as an indication that an environment is contaminated by human excreta. In addition to coliforms, some pathogenic bacteria, such as *Salmonella, Shigella, Vibrio, Mycobacterium, Clostridium, Leptospira*, and *Yersinia*, can also colonize part of a gastrointestinal tract, resulting in gastroenteritis.

A number of opportunistic bacterial pathogens can also be found in waste and reclaimed water. These opportunistic pathogens include *Pseudomonas, Streptococcus, Flavobacterium*, and *Aeromonas* species (2).

Parasites

Parasites are a very diverse group of microorganisms; they can be further categorized as protozoan, metazoan, or helminth. Parasites often have a complex life cycle sometime requiring a stage in intermediate hosts. The environmental stage of parasites found in wastewater is normally called cyst/oocyst (protozoans) or egg (helminth). In general, parasite cysts or eggs are larger than bacteria. Parasites are present in the feces of infected persons; however, healthy carriers may also excrete them. Cysts do not reproduce in the environment but can survive in soil for months or even years, depending on environmental conditions.

Entamoeba histolytica, the most dangerous protozoan parasite, occurs worldwide, although the incidence in the

United States is not very well documented. *Cryptosporidium parvum* oocysts are the most important biological water contaminants in the United States (3).

Several helminthic parasites may be found in wastewater. *Ascaris lumbricoides* (roundworm) is one of the most important human parasites. It is estimated that approximately 25% of the world's population is infected by this nematode (4).

Viruses

Viruses are smaller than bacterial disease agents and range in size from approximately 20 to 200 nm. They are obligate intracellular parasites that can multiply only within a host cell. Viruses that can replicate in the gastrointestinal tract of humans or animals are referred to as enteric viruses. The presence of enteric viruses in sewage is a matter of concern because they can be transmitted through the fecal–oral route. Morethan 120 different human enteric viruses have been reported to date. An infected person can excrete as many as 10^6-10^{10} plaque-forming units (pfu) of enteric viruses per gram of fecal material.

The most important human enteric viruses are enteroviruses (polio, echo, and Coxsackie), caliciviruses, rotaviruses, reoviruses, parvoviruses, and adenoviruses. Caliciviruses are the most frequently reported and documented that are transmitted by contaminated water. Even though the etiologic agent cannot be successfully cultivated in the laboratory, there is epidemiological evidence that caliciviruses are the most common cause of viral gastroenteritis. Hepatitis A, the virus that causes infectious hepatitis, is one of the most resistant to environmental stresses (5). Rotaviruses are the most infectious of all enteric viruses (6) and thus can be considered a high risk to health if present in wastewater.

MECHANISM OF DISEASE TRANSMISSION

There are several ways in which an individual can acquire disease from wastewater use, and those can be broadly categorized into two modes; direct ingestion and indirect ingestion. Humans can acquire an etiologic agent either directly by contact, ingestion, or inhalation of reclaimed irrigation water or indirectly by contact with the objects previously contaminated by the reclaimed water. Following are some of the conditions for a successful infection or disease from exposure to reclaimed wastewater.

- *Etiologic Agent*: The disease-causing agent (bacteria, virus or a parasite) must be present in wastewater and hence, in the wastewater from that community.
- *Survival of Etiologic Agent*: The disease-causing agent must survive all wastewater treatment processes to which it is exposed.
- *Exposure*: The disease competent person must come in contact, directly or indirectly, with reclaimed water carrying the disease agent.
- *Infectivity and Infective Dose*: The etiologic agent must be infectious, moreover, the disease-causing agent must be sufficiently numerous at the time of contact to cause illness.

The exposure to an etiologic agent does not always result in disease. Disease results from a series of complex interactions between the host and the infectious agent, which can be defined in terms of the pathogenicity and virulence of the disease-causing agent and the relative susceptibility of the host. The susceptibility of the host depends on the general health of the subject and the specific pathogen. Age and the nutritional and immunological status of subjects are some of the other factors that determine the outcome of an infection.

MONITORING MICROORGANISMS

The detection, isolation, and identification of all microorganisms in a wastewater sample are very difficult, time-consuming, and cumbersome. The detection efficacy and sensitivity are influenced by various physicochemical parameters of the water sample, which further undermine the significance of such a strategy. To avoid the necessity of undertaking such a huge task, which has no equivalent value, indicator microorganisms are used to estimate the presence of fecal pathogens in water samples. An indicator should be present in equal or higher numbers and be more resistant than pathogens. Historically, fecal coliforms, in particular, *E. coli*, have been used as indicators of fecal contamination (7).

REMOVAL OF MICROORGANISMS BY WASTEWATER TREATMENT PROCESSES

The purpose of most advanced treatment processes is to remove either inorganic or organic constituents. Therefore, the removal of biological contaminants by these processes is only incidental in many cases and, generally is not too great. Microbial removal efficiencies of some treatment processes are given Table 2. Conventional biological treatment processes (trickling filters, activated sludge, and oxidation ponds) reduce the quantities of biological organisms in raw or settled sewage but do not eliminate them.

The most important treatment process for pathogen destruction is disinfection. In the United States, the most common disinfectant for both water and wastewater is chlorine. The efficiency of disinfection with chlorine depends on the water temperature, pH, length of contact, degree of mixing, presence of interfering substances, concentration and form of the chlorinated species, and nature and concentration of the organisms to be destroyed.

TYPES OF RECLAIMED IRRIGATION PRACTICES

Reclaimed irrigation can be practiced in the following five different ways:

- Flood irrigation, which wets almost all the land surface;

Table 2. Concentration of Various Microorganisms in Raw and Treated Wastewater[a]

Microorganisms	Number per 100 Raw Sewage	Reduction in Number of Microbes ($\log_{10}$) Primary Effluent	Secondary Effluent	Tertiary Effluent
Fecal coliform (MPN)	10^9	2	1	6
Salmonella (MPN)	8×10^3	1	2	1
Enteric viruses (PFU)	5×10^4	0.5	1	5
Helminth ova	8×10^2	1	2	1
Giardia cyst	10^4	0.5	0.5	3

[a] Reference 8.

- Furrow irrigation, which wets only part of the ground surface;
- Sprinkler irrigation, in which the soil is wetted in much the same way as by rain;
- Surface drip irrigation, in which water is applied at each individual plant at an adjustable rate;
- Subsurface drip irrigation, in which the topsoil remains relatively dry but the subsoil is saturated.

CONTROL OF HUMAN EXPOSURE

Four groups of people are at potential risk from reclaimed irrigation:

- agricultural field workers and their families;
- crop handlers;
- consumers (of crops, meat, and milk);
- population living near the affected fields; and
- recreational area visitors, players, etc.

GUIDELINES AND TREATMENT PRACTICES FOR WASTEWATER REUSE IN AGRICULTURE

All reuse guidelines or criteria have a single basic objective, to ensure the safety of public health. Wastewater is known to harbor a variety of different microorganisms, influenced by various environmental factors, so it is possible to address different aspects of this issue. Reuse guidelines can be based on the level of indicator microorganisms, epidemiological and/or risk models, and treatment practices.

Early guidelines for wastewater reuse in agriculture were concerned only with the pathogen content of wastewater. A World Health Organization (WHO) meeting of experts on the reuse of effluents in 1971 reviewed the information concerning health risks and concluded that only a limited health risk would result from unrestricted crop irrigation with wastewater containing no more than 100 coliforms per 100 mL. Following the recommendation of the WHO meeting in 1971, new epidemiological evidence was accumulated, and earlier studies were reevaluated. A meeting in Engelberg in 1985 of public health experts, environmental scientists, and epidemiologists reviewed the work that had been done and concluded that the risk of infection was lower than previously thought, particularly, from bacterial and viral pathogens (9).

The WHO guidelines for wastewater reuse, which were proposed by the Engelberg meeting in 1985 and reaffirmed in 1989, were aimed at providing a high degree of health safety to workers and consumers, but at the same time to be realistic in the light of resource constraints and limited technology in many countries.

In the United States the State of California has a long history of reclaimed water regulation. The relatively stringent California standards are not economically or technologically feasible for developing countries.

INTERNATIONAL STANDARDS

The WHO water reuse guidelines (Table 3) have served as a baseline for the development of reclaimed irrigation standards throughout the world generally and in developing countries particularly. On the other hand, California criteria, which represent the higher end, are extensively followed by developed countries. Different countries have adapted both standards to develop their regional microbial standards for reclaimed irrigation (Table 4).

Italy became the first European country to regulate reclaimed irrigation when it adopted wastewater reuse guidelines in 1977 under its 1976 national Water Law. Although the Italian guidelines were published 1 year earlier than California guidelines, both essentially follow the same approach. The region of Sicily has adopted different regulations, which are much closer to the WHO approach. As an added precaution, this regulation forbids irrigating vegetables that are eaten raw with any type of reclaimed wastewater.

Cyprus produces approximately 25 Mm^3 of urban effluent every year. Government has planned to expand irrigated agriculture by introducing reclaimed irrigation. Provisional standards for reclaimed water irrigation were introduced to regulate reclaimed irrigation, which take into account the special ecological and environmental conditions of Cyprus. These standards, which are stricter than the WHO guidelines, ensure the best possible application of the effluent for irrigation.

In France, reclaimed irrigation of crops is practiced mostly around big cities as the easiest way to treat and dispose of wastewater. In the early 1990s, the growing demand for irrigation water along with periodic droughts resulted in increased interest in water reuse. French health authorities [the Conseil Supérieur díHygiène Publique de France (CSHPF)] issued the “health guidelines for reuse, after treatment, of wastewater for crop

Table 3. Microbiological Quality Guidelines for Wastewater Use in Agriculture[a] by WHO

Category	Reuse Conditions	Exposed Group	Intestinal Nematodes (Mean Arithmetic Number of Viable Eggs per liter)	Faecal Coliforms (Geometric Mean, Number per 100 mL)	Wastewater Treatment Expected to Achieve the Required Microbiological Quality
A	Irrigation of crops likely to be eaten uncooked, sports fields, public parks	Workers, consumers, public	1	1000	A series of stabilization ponds designed to achieve the microbiological quality indicated, or equivalent treatment
B	Irrigation of cereal crops, industrial crops, fodder crops, pasture and trees	Workers	1	No standard recommended	Retention in stabilization ponds for 8–10 days or equivalent helminth and fecal coliform removal
C	Localized irrigation of crops in category B if exposure of workers and the public does not occur	None	Not applicable	Not applicable	Pretreatment as required by irrigation technology, but not less than primary sedimentation

[a] Reference 10.

Table 4. Guidelines and Criteria for Wastewater Reuse in Irrigation in Various Countries[a]

Country	Crop Type	Treatment Required	Microbial Criteria (max.)
Australia	Residential use, municipal irrigation, unrestricted crop irrigation	Secondary, tertiary, filtration and disinfection	<10 thermotolerant coliforms/100 mL
	Ornamental ponds with public access, restricted crop irrigation, irrigation of pasture and fodder crops for dairy animals, fire fighting	Secondary and disinfection	<100 thermotolerant coliforms/100 mL
	Municipal irrigation with restricted crop irrigation, irrigation of pasture and fodder crops for grazing animals	Primary sedimentation and lagooning or secondary plus disinfection (if required)	<1000 thermotolerant coliforms/100 mL
	Irrigation for turf production, silviculture, nonfood chain aquaculture	Primary sedimentation and lagooning or secondary	$<10,000$ thermotolerant coliforms/100 mL
Israel	Cotton, sugar beet, dry fodder seeds, forest irrigation	None	None
	Green fodder, nuts, citrus, olives, peanuts, bananas, almonds, etc.	None	None
	Deciduous fruits, conserved vegetables, cooked and peeled vegetables	Disinfection with chlorination (60 minutes contact time)	250 coliforms/100 mL
	Unrestricted crops, including vegetables eaten raw, parks, and lawns	Sand filtration and disinfection with chlorination (60 minutes contact time)	12 coliforms/100 mL (80%)
			2.2 coliforms/100 mL (50%)
Japan	Landscape irrigation	Disinfection (>0.4 mg/L residual chlorine)	0.0 *E. coli*/100 mL
Kuwait	Fodder, food crops not eaten raw, forest land	Advanced water treatment (1 mg/L residual chlorine after 12 h@20 °C)	10,000 coliforms/100 mL
	Food crops eaten raw	Advanced water treatment (1 mg/L residual chlorine after 12 h@20 °C)	100 coliforms/100 mL
Saudi Arabia	All irrigation purposes (unrestricted)	Advanced water treatment	2.2 coliforms/100 mL
	All irrigation purposes	Treatment plants and waste settling ponds	<1 intestinal nematode egg/100 mL
South Africa	Irrigation of dry fodder crops, seed crops, trees, non-recreational parks, nurseries (restricted access)	Primary and secondary	<1000 fecal coliforms/100 mL
	Food crops not eaten raw, cut flowers, orchards and vineyards, pastures, parks	Primary, secondary, and tertiary; oxidation pond system	<1000 fecal coliforms/100 mL
	Pasture for milking animals	Primary, secondary, and tertiary	0.0 fecal coliforms/100 mL
	Food crops eaten raw, lawns, nurseries (unrestricted access)	Advanced (general) drinking water standards	Drinking water standards

[a] Reference 11.

and green spaces irrigation"(12). The guidelines stipulate maintaining of extensive water quality data. Wastewater reuse authorizations are granted on a case-by-case basis after review of a highly detailed dossier of French reclaimed irrigation regulations based on WHO guidelines but complement them with strict rules of application such as a minimum distance required between irrigation sites and residential areas or roadways.

In Mexico, wastewater is extensively used to irrigate crops. Because a very significant part of Mexican farm produce is sold in U.S. markets, Mexico has developed very comprehensive reclaimed irrigation regulations that are stricter than WHO suggested standards (Tables 5 and 6).

Israel has developed very comprehensive reclaimed water usage regulations because reclaimed water constitutes a significant part of its national water budget. About 92% of the total wastewater is collected, and 72% is reclaimed for various purposes. Almost 42% of total wastewater is reused for irrigation (13). The Israel Ministry of Health has established criteria for reclaimed irrigation and water reuse that are stricter than WHO standards. According to Israeli standards, settled effluent can be used on industrial and fodder crops, pastures and hay, vegetables eaten cooked, fruit trees, ornamental plants, or seed plants. Irrigation should be stopped 1 month before the harvest of apples, pears, and plums; broccoli and cauliflower when furrows are irrigated, and tomatoes used for canning if furrows are irrigated.

WHO guidelines have been debated for their effectiveness to protect public health. A large part of the answer probably lies in the treatment requirements of limit values. In spite of their safety, the stringency of the California standards is acting as a barrier to their widespread adoption worldwide. The WHO point of view is often criticized as being too lax, but the California approach is too technologically intensive and expensive for developing countries. One must realize that where raw wastewater is directly reused, a widespread practice in many developing countries, the WHO guidelines are already a major step forward.

However, other requirements also seem to be necessary to complement WHO guidelines. Based on an extensive analysis of existing guidelines worldwide, the need for developing health-related chemical criteria for land application of reclaimed wastewater has also been reported by the WHO (14). This, added to the fact that the controversy between the 'WHO camp' and the 'California camp' has now been raging for a number of years means that the time has come to update the existing guidelines on an international basis. The door is therefore now open worldwide for a 'third approach' integrating the epidemiological knowledge base generated since 1989 and the latest technological developments in wastewater treatment.

Table 6. Crops Regulated by 1991 Mexican Reuse Guidelines

Salad Vegetables	Vegetables	Herbs	Fruits
Beet root	Beet	Coriander	Blackberries
Celery	Broccoli	Epazote	Melon
Cucumber	Cabbage	Mint	Strawberries
Lettuce	Carrot	Parsley	Sweet turnip
Radish	Cauliflower		Watermelon
Red tomato	Courgette		
Watercress	Garlic		
	Green tomato		
	Mushrooms		
	Onion		
	Papalo		
	Spinach		
	Wild greens		

Table 5. Conditions for Irrigation of Restricted Crops Under 1991 Mexican Guidelines

Type of Irrigation	Type of Wastewater[a]	Minimum Time Between the Last Irrigation and the Harvest (days)	Crops/Banned Crops
Flood	1	20	All crops listed in Table 6, except garlic, cucumber, sweet turnip, melon, and watermelon
	2	20	All crops listed in Table 6, except melon and watermelon
	3	20	All crops listed in Table 6
	4	20	All salad crops, vegetables, and fruits in general
Furrow	1	15	All crops listed in Table 6, except garlic, cucumber, sweet turnip, melon, watermelon, and green tomato
		20	No restrictions
	2	20	All crops listed in Table 6, except garlic, cucumber, sweet turnip, melon, watermelon, and green tomato
	3	20	All crops listed in Table 6, except melon and watermelon
	4	20	All salad crops, vegetables, and fruits in general
Spray	1	20	All crops listed in Table 6, except garlic, cucumber, sweet turnip, melon and watermelon
	2,3,4	20	All salad crops, vegetables and fruits in general

[a] Wastewater Type 1: <1000 total coliforms/100 mL and 0 helminth eggs/liter;
Wastewater Type 2: 1–1000 fecal coliforms/100 mL and ≤1 helminth eggs/liter;
Wastewater Type 3: 1001–100,000 fecal coliforms/100 mL, and no restriction on helminth eggs;
Wastewater Type 4: >100,000 fecal coliforms/100 mL and no restriction on helminth eggs.

SOIL SALINITY

Dennis L. Corwin
Salinity Laboratory
Riverside, California

DEFINITION, SOURCES, EFFECTS, AND GLOBAL IMPACTS

Soil salinity refers to the presence of major dissolved inorganic solutes in the soil solution (i.e., aqueous liquid phase of the soil and its solutes), which consist of soluble and readily dissolvable salts, including charged species (e.g., Na^+, K^+, Mg^{2+}, Ca^{2+}, Cl^-, $HCO_3{}^-$, $NO_3{}^-$, $SO_4{}^{2-}$, and $CO_3{}^{2-}$), nonionic solutes, and ions that combine to form ion pairs. The primary source of salts in soil and water is the geochemical weathering of rocks from the earth's upper strata, with atmospheric deposition and anthropogenic activities serving as secondary sources. The predominant mechanism causing the accumulation of salt in the root zone of agricultural soils is loss of water through evapotranspiration (i.e., combined processes of evaporation from the soil surface and plant transpiration), which selectively removes water, leaving salts behind.

The accumulation of soil salinity can result in reduced plant growth, reduced yields, and, in severe cases, crop failure. Salinity limits plant water uptake by reducing the osmotic potential, making it more difficult for the plant to extract water. Salinity may also cause specific ion toxicity or upset the nutritional balance of plants. In addition, the salt composition of the soil solution influences the composition of cations on the exchange complex of soil particles, which influences soil permeability and tilth.

Irrigated agriculture, which accounts for 35–40% of the world's total food and fiber, is adversely affected by soil salinity on roughly half of all irrigated soils (totaling about 250 million ha), with over 20 million ha severely effected by salinity worldwide (1). As a result of the potential detrimental impacts of soil salinity accumulation, it is a crucial soil chemical property that is routinely measured and monitored.

LABORATORY METHODS OF SOIL SALINITY MEASUREMENT

Although a variety of instrumentation has been developed for the measurement of soil salinity in the field, the most common technique is still laboratory analysis of aqueous extracts of soil samples. In the laboratory, soil salinity is commonly determined from the measurement of the electrical conductivity (EC) of soil solution extracts. The current-carrying capacity of soil solution is proportional to the concentration of ions in the solution. Soil salinity is quantified in terms of the total concentration of the soluble salts as measured by the EC of the soil solution in $dS\,m^{-1}$ (2).

To determine EC, measurements are made in a cell containing two electrodes of constant geometry and distance of separation (3). The soil solution is placed between the two electrodes. An electrical potential is imposed across the electrodes, and the resistance of the solution between the electrodes is measured. The measured conductance is a consequence of the solution's salt concentration and the electrode geometry whose effects are embodied in a cell constant. At constant potential, the current is inversely proportional to the solution's resistance:

$$\mathrm{EC}_T = k/R_T \tag{1}$$

where EC_T is the electrical conductivity of the solution in $\mathrm{dS\,m^{-1}}$ at temperature T (°C), k is the cell constant, and R_T is the measured resistance at temperature T. One $\mathrm{dS\,m^{-1}}$ is equivalent to one $\mathrm{mS\,cm^{-1}}$ and one $\mathrm{mmho\,cm^{-1}}$, where $\mathrm{mmho\,cm^{-1}}$ are the obsolete units of EC.

Partitioning of solutes over the three soil phases (i.e., gas, liquid, solid) is influenced by the soil/water ratio at which the extract is made, so the ratio must be standardized to obtain results that can be applied and interpreted universally. Customarily, soil salinity has been defined in terms of laboratory measurements of the EC of the saturation extract ($\mathrm{EC_e}$) because it is impractical for routine purposes to extract soil water from samples at typical field water contents. One widely used technique is to obtain an extract by vacuum filtration of a saturated soil paste made with distilled water (4). Commonly used extract ratios other than a saturated soil paste are 1:1, 1:2, and 1:5 soil/water mixtures. However, extracts at these ratios only provide relative salinity because the soils are adjusted to unnaturally high water contents not found in the field. Soil salinity can also be determined from the measurement of the EC of the soil solution at some defined field water content ($\mathrm{EC_w}$). An example would be the EC at field capacity, which represents the water content of soil 2–3 days after irrigation when free drainage is negligible. Theoretically, $\mathrm{EC_w}$ is the best index of soil salinity because it is the salinity actually experienced by the plant root. Nevertheless, $\mathrm{EC_w}$ has not been widely used for two reasons: (a) it varies over the irrigation cycle as the soil water content changes and (b) methods for obtaining soil solution samples are too labor and cost intensive to be practical for field-scale applications (5).

Soil solution extracts can be obtained by various means. For disturbed samples, soil solution can be obtained in the laboratory by displacement, compaction, centrifugation, molecular adsorption, and vacuum- or pressure-extraction methods. For undisturbed samples, $\mathrm{EC_w}$ can be determined either in the laboratory on a soil solution sample collected with a soil-solution extractor (see Fig. 1) or directly in the field using *in situ*, imbibing-type porous-matrix salinity sensors (see Fig. 2).

Electrolytic conductivity increases at a rate of approximately 1.9% per degree centigrade increase in temperature in the range of 15–35 °C. Customarily, EC is expressed at a reference temperature of 25 °C for purposes of comparison. The EC (i.e., $\mathrm{EC_e}$ or $\mathrm{EC_w}$) measured at a particular temperature T (°C), EC_T ($\mathrm{dS\,m^{-1}}$), can be adjusted to a reference EC at 25 °C, $\mathrm{EC_{25}}$ (8):

$$\mathrm{EC}_{25} = f_t \cdot \mathrm{EC}_T \tag{2}$$

$$f_T = 0.4470 + 1.4034\exp(-T/26.815) \tag{3}$$

where f_T is a temperature conversion factor.

Theoretical and empirical approaches are available to predict the EC of a solution from its solute composition (3).

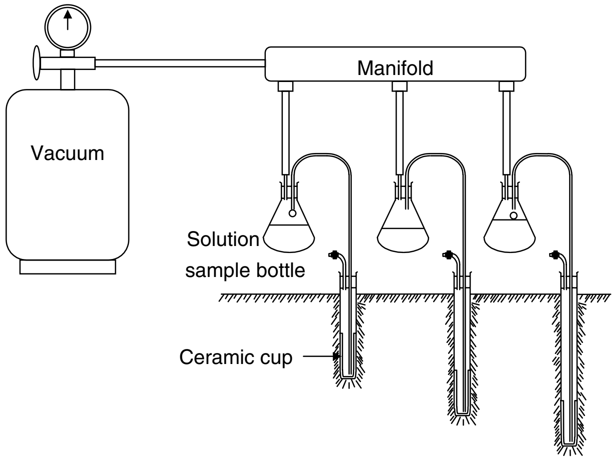

Figure 1. Diagram of a basic suction cup extractor setup for sampling the soil solution. Courtesy of Corwin (6).

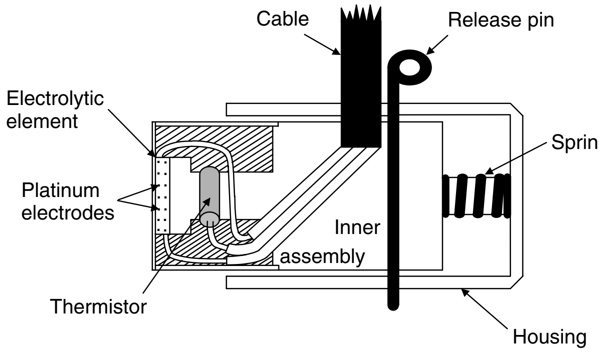

Figure 2. Schematic of a porous-matrix salinity sensor. Courtesy of Corwin (7).

Equation 4 is an example of a theoretical approach based on Kohlrauch's Law of independent migration of ions, where each ion contributes to the current-carrying ability of an electrolyte solution:

$$\mathrm{EC} = \sum_i \mathrm{EC}_i = \sum_i \frac{c_i(\lambda_0^i - \beta\sqrt{c_i}}{1000} \tag{4}$$

where EC is the specific conductance ($\mathrm{dS\,m^{-1}}$), EC_i is the ionic specific conductance ($\mathrm{dS\,m^{-1}}$), c_i is the concentration of the *ith* ion ($\mathrm{mmol_c\,L^{-1}}$), $\lambda^{i}{}_{0}$ is the ionic equivalent conductance at infinite dilution ($\mathrm{cm^2\,S\,mol_c{}^{-1}}$), and β is an empirical interactive parameter (9). Equation 5 shows an empirical equation developed by Marion and Babcock (10):

$$\log \mathrm{TSS} = 0.990 + 1.055 \log \mathrm{EC} \quad (\mathrm{r}^2 = 0.993) \tag{5}$$

where TSS is the total soluble salt concentration ($\mathrm{mmol_c\,L^{-1}}$).

FIELD METHODS OF SOIL SALINITY MEASUREMENT

Serious doubts exist about the ability of soil core samples, soil solution extractors, and porous-matrix salinity sensors (also known as soil salinity sensors) to provide representative soil water samples. Small soil core samples, extractors, and salt sensors do not adequately integrate spatial variability because of their small sphere of measurement; consequently, Biggar and Nielsen (11) suggested that these are "point samples" that can provide qualitative measurement of soil solutions, but not quantitative measurements unless their field-scale variability is established.

As salinity is a highly spatially variable soil property, the use of EC_e to measure salinity at field scales is generally impractical because of the need for hundreds and even thousands of soil samples. The use of EC_e to measure salinity at field scales is only practical when soil sampling is directed using correlated spatial information. Two potential sources of correlated spatial information used to direct where soil samples should be taken to measure EC_e are: (a) visual crop observations and (b) geospatial measurements of apparent soil electrical conductivity (EC_a) using electrical resistivity (ER), electromagnetic induction (EMI), or time-domain reflectometry (TDR). These sources of spatial information are used to direct soil sampling to characterize field-scale soil salinity variation.

Visual Crop Observation

Visual crop observation is a quick and economical method, but salinity development is detected after crop damage has occurred. For this reason, visual observations are unrealistic because crop yields are reduced to obtain soil salinity information. However, remote imagery potentially represents a quantitative approach to visual observation. Remote imagery may offer a potential for early detection of the onset of salinity damage to plants.

Apparent Soil Electrical Conductivity

As a result of the time and cost of obtaining soil solution extracts, developments in the measurement of soil EC have shifted to the measurement of electrical conductivity of the bulk soil, referred to as the apparent soil electrical conductance (EC_a). Apparent soil electrical conductivity measures the conductance through not only the soil solution but through the solid soil particles and via exchangeable cations that exist at the solid-liquid interface of clay minerals. The techniques of ER, EMI, and TDR measure EC_a.

The interpretation of EC_a measurements is not trivial because of the complexity of current flow in the bulk soil. Three pathways of current flow contribute to the EC_a measurement: (a) a liquid phase pathway via salts contained in the soil water occupying the large pores, (b) a solid-liquid phase pathway primarily via exchangeable cations associated with clay minerals, and (c) a solid pathway via soil particles that are in direct and continuous contact with one another (5). As a result of the three pathways of conductance, the EC_a measurement is influenced by several soil physical and chemical properties: (a) soil salinity, (b) saturation percentage, (c) water content, and (d) bulk density. The saturation percentage and bulk density are both closely associated with the clay content. Measurements of EC_a as a measure of soil salinity must be interpreted with these influencing factors in mind. Traditionally, EC_e has been the standard measure of salinity used in all salt-tolerance plant studies. As a result, a relation between EC_a and EC_e is needed to relate EC_a back to EC_e, which in turn is related to crop yield. In spite of these complicating factors, EC_a is the only viable means of spatially characterizing soil salinity at field scales.

As a result of the ease and quickness of measuring EC_a and the ability to mobilize EC_a-measurement equipment, geospatial measurements of EC_a are the most reliable means of characterizing the spatial variability of soil salinity at field scales. Geospatial measurements of EC_a are not used to directly measure soil salinity but rather to direct soil sampling from which EC_e measurements are subsequently made. From the geospatial EC_a measurements and a site-specific relation between EC_a and EC_e, a map of soil salinity distribution across the landscape and through the soil profile can be created. Detailed procedures and protocols for conducting an EC_a survey to characterize the spatial variability of soil salinity with EC_a-directed soil sampling are provided by Corwin and Lesch (12).

ER methods introduce an electrical current into the soil through current electrodes at the soil surface. The difference in current flow potential is measured at potential electrodes that are placed in the vicinity of the current flow (Fig. 3). The electrode configuration is referred to as a Wenner array when four electrodes are equidistantly spaced in a straight line at the soil surface. The two outer electrodes serve as the current or transmission electrodes, and the two inner electrodes serve as the potential or receiving electrodes. The depth of penetration of the electrical current and the volume of measurement increase as the interelectrode spacing, a, increases. For a homogeneous soil, the soil volume measured is roughly πa^3, and the depth of penetration is roughly equal to a. Additional electrode configurations are discussed by Burger (14).

By mounting the electrodes to "fix" their spacing, considerable time for a measurement is saved. Veris Technologies[1] has developed a commercial mobile system for measuring and mapping EC_a using the principles of ER coupled to a global positioning system (GPS). The Veris Model 3100 consists of a pair of transmission coulter electrodes and a pair of potential coulter electrodes to measure the voltage drop. Two sets of arrays permit the measurement of EC_a to depths of 0–30 cm and 0–90 cm.

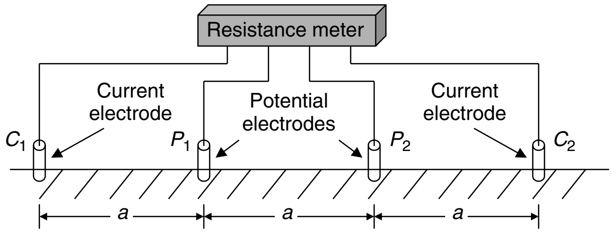

Figure 3. Schematic of electrical resistivity four electrodes, where C_1 and C_2 represent the current electrodes, P_1 and P_2 represent the potential electrodes, and a represents the interelectrode spacing. Courtesy of Corwin and Hendrickx (13).

EMI instrumentation consists of a transmitter coil and a receiver coil (Fig. 4). The transmitter coil located at one end of the instrument induces circular eddy-current loops in the soil. The magnitude of these loops is directly proportional to the EC in the vicinity of that loop. Each current loop generates a secondary electromagnetic field that is proportional to the value of the current flowing within the loop. A fraction of the secondary induced electromagnetic field from each loop is intercepted by the receiver coil at the opposite end of the instrument, and the sum of these signals is amplified and formed into an output voltage, which is related to a depth-weighted EC_a. The amplitude and phase of the secondary field will differ from those of the primary field as a result of soil properties (e.g., clay content, water content, salinity), spacing and orientation of the coils, frequency, and distance from the soil surface (15).

The two most commonly used EMI conductivity meters in soil science are the Geonics[2] EM-31 and EM-38. The EM-38 has had considerably greater application for agricultural purposes because the depth of measurement corresponds roughly to the root zone (i.e., 1.5 m), when the instrument is placed in the vertical coil configuration. In the horizontal coil configuration, the depth of the measurement is 0.75–1.0 m. The operation of the EM-38 equipment is discussed in Hendrickx and Kachanoski (15).

Mobile EM equipment developed at the USDA-ARS Salinity Laboratory (16) is available for appraisal of soil salinity and other soil properties (e.g., water content and clay content) using an EM-38 or a dual-dipole EM-38 unit. The dual-dipole EM-38 conductivity meter simultaneously records data in both dipole orientations (horizontal and vertical). The mobile EM equipment is suited for the detailed mapping of EC_a and correlated soil properties at specified depth intervals through the root zone. The advantage of the mobile EM equipment is that it is noninvasive, so it can be used in dry, frozen, or stony soils that are not easily measured with the invasive “fixed-array” approach, which requires good electrode-soil contact. The disadvantage of the EM approach would be that the EC_a is a depth-weighted value, which is nonlinear with depth (17).

ER and EM are both well suited for field-scale applications because their volumes of measurement are large, which reduces the influence of local-scale variability. However, ER is an invasive technique that requires good contact between the soil and four electrodes inserted into the soil; consequently, it produces less reliable measurements in dry, frozen, or stony soils than the noninvasive EM measurement. Nevertheless, ER has a flexibility that has proven advantageous for field application, i.e., the depth and volume of measurement can be easily changed by altering the spacing between the electrodes.

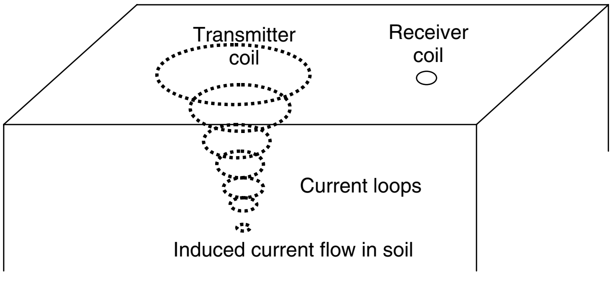

Figure 4. Transmitter coil, receiver coil, and induced current flow for EMI.

Time-domain reflectometry (TDR) was initially adapted for use in measuring water content. Later, Dalton et al. (18) demonstrated the utility of TDR to also measure EC_a, based on the attenuation of the applied signal voltage as it traverses the medium of interest. Although TDR has been demonstrated to compare closely with other accepted methods of EC_a measurement, it is still not sufficiently simple, robust, or fast enough for the general needs of field-scale soil salinity assessment (5). Only electrical resistivity and EM have been adapted for the geo-referenced measurement of EC_a at field scales and larger.

PLANT TOLERANCE TO SOIL SALINITY

The primary effect of soil salinity is on plant growth. Virtually all plant salt-tolerance studies conducted in the past have related plant yield response to EC_e, which is another reason why EC_e continues to be used as the primary measure of soil salinity. A salt-affected soil is one that contains enough soluble salts to hamper the growth of the crop. The proportions of dissolved ions (primarily Na^+, Ca^{2+}, Mg^{2+}, Cl^-, $SO_4{}^{2-}$, and HCO^{3-}) can vary, and the effects on plants can vary. Generally, however, plants respond similarly to salinity over a fairly wide range of combinations of salt. To quantify yield response to soil salinity, Maas and Hoffman (19) proposed a two-piece linear response function with a tolerance plateau of slope zero and a concentration-dependent line whose slope indicates the yield reduction per unit increase in salinity:

$$Y_r = 100 - b\,(EC_e - a) \tag{6}$$

where a is the salinity threshold ($dS\,m^{-1}$), b is the slope expressed in percent per $dS\,m^{-1}$, and EC_e is the mean EC_e taken from the root zone. Values for a and b can be found in Maas (20).

MAINTAINING SALT BALANCE ON IRRIGATED LAND

Jacob W. Kijne
Herts, United Kingdom

DEFINITION

The salt balance of an area is described by an equation that compares the movement of salt into and out of an area. The salt fluxes are in balance when inflow and outflow of salt are equal. Salt moves in solution, and the water and salt balances are therefore linked as in Eq. 1, which describes the salt balance of an irrigated area:

$$IC_{\mathrm{i}} + RC_{\mathrm{r}} + GC_{\mathrm{g}} = PC_{\mathrm{p}} + \Delta S \tag{1}$$

where: I = irrigation water infiltrating the root zone
R = rainfall entering the root zone
G = capillary flow from the groundwater into the root zone
P = deep percolation from the root zone
C = salt concentration, and the subscripts referring to irrigation, rainfall, capillary flow, and percolation
ΔS = the change in salt content of the soil solution in the root zone

The water flows can be expressed in m^3/ha/day or any other convenient set of units, such as mm/month, in which the unit of time indicates the period over which the salt balance is measured. The unit of salt concentration, C, is usually mg/L or part per million (ppm). Apart from areas close to the sea, it is reasonable to assume that C_{r} is zero. It is also often assumed that C_{g} equals C_{p}, which is reasonable for annual periods but not necessarily true for shorter periods.

For steady-state conditions, the salt concentration in the soil solution remains the same, and hence, ΔS equals zero. The ratio of the amounts of drainage water (percolating from the root zone) and the amount of water entering the root zone as irrigation and rainfall is called the leaching fraction, LF. Hence:

$$\mathrm{LF} = P\Delta t/(I+R)\Delta t = P/(I+R) \tag{2}$$

where Δt equals the time period under consideration.

The ratio of the electrical conductivity (EC) of the drainage water to that of the applied water ($A = I + R$) can be written as $\mathrm{EC_p/EC_a}$. For steady-state conditions, this ratio is proportional to the inverse of the leaching fraction (1/LF). For solutions consisting mainly of chloride salts, the proportionality constant is 1. For concentrated solutions, the proportionality constant is less than 1. Often irrigation water also has a proportionality constant of less than 1, and its value depends on the LF. For example, the proportionality constant of Colorado River water dropped to below 1 when LF became less than about 20% (1). The lower the value of LF, the lower the proportionality constant. Leaching fractions of less than 20% are common in irrigation practice. The relationship between $\mathrm{EC_p/EC_a}$ and 1/L is also influenced by the solubility of soil lime, which is a function of the partial pressure of $\mathrm{CO_2}$.

PRESENCE OF SALTS

The salts carried in irrigation water come from salts that are continuously released from rocks and soils by mineral weathering and dissolution. Because of their low rainfall, most arid and semiarid lands are rich in these primary salts. The salts were deposited over time in sedimentary rock layers and are dissolved in the waters of aquifers. Unfavorable salt balances are common in arid lands: The global extent of salt-affected lands is considerable. It has been estimated that worldwide 100 million ha of irrigated land suffer from salinity, 20% of which is severely affected (2). Annually some 2 to 3 million ha of potentially productive agricultural land are taken out of production because of salinization. How much of this land is reclaimed (to various degrees) and then cultivated again is unknown. Wide divergence in the salinity figures is reported by different institutions, probably because of incomplete data and different definitions of salinity-affected lands; e.g., estimates for salt-affected land in India, according to different sources, range from 7 to 26 million ha, or between 17% and 60% of the irrigated land. For Pakistan, the most likely figure is some 40%, Israel 13%, Australia 20%, China 15%, Iraq 50%, and Egypt 35% of the irrigated land (3).

In many coastal regions, salt water intrusion has a strong negative effect on the regional salt balance. The problem is associated with groundwater extraction from deep fractured aquifers in the coastal region, often for drinking water in a coastal city. Sea water intrusion into the delta of rivers also upsets the regional salt balance. Here the cause is usually a much diminished outflow from the river because of upstream extractions for agricultural and industrial use. Examples include the Colorado River in the United States, the Murray in South Australia, and the Rhine in the Netherlands.

SALT BALANCE OF THE ROOT ZONE

Soluble salts added with the irrigation water must be removed by leaching to maintain the salt balance in the root zone of irrigated land. If not, crop yields will drop and—in case of predominantly sodium salts—soil crusting is likely to occur with an adverse effect on infiltration and hydraulic conductivity of the soil. The less soluble salts gradually precipitate when solutions become more concentrated and are again mobilized when the solutions become diluted by mixing with freshwater. Depending on whether precipitation or dissolution of salts (e.g., of lime or gypsum) occurs in the soil, the amount of salt leached from the root zone must be less than or more than that applied by irrigation. Generally, again depending on the occurrence of precipitation and dissolution reactions, when too much irrigation water is applied to the soil, more salts are added with the water, and in consequence, the drainage water also contains more salts than necessary. If the drainage water is returned to the river downstream, water quality becomes worse. Salt concentrations in the root zone must therefore be controlled to sustain irrigated agriculture over the long term.

When the quality of irrigation water deteriorates, for example, by extensive use of (slightly) saline groundwater when canal water became scarce, nonsteady conditions occur and cation reactions will change the salt load of drainage water. Because of exchange of sodium and magnesium for calcium on the clay particles, mineral precipitation could double in a soil profile that was initially high in exchangeable calcium. These nonsteady conditions could last for many years before a new steady state evolves. Irrigation thus interferes with the geohydrological and geochemical regimes of the area. When irrigation was introduced in areas with low groundwater tables, excessive irrigation often occurred and deep percolation was the agent of interference. The main consequences of this increased groundwater recharge are a high watertable and the mobilization of natural salt residues of the semiarid lands. The latter is referred to as salt pickup.

The relationship among the salinity of the applied water, the leaching fraction, and the resulting soil salinity is an important one. Crop yields and the salinity of drainage water could be more accurately predicted if one could unambiguously calculate the soil salinity resulting from irrigation applications of known salinity and at a specified leaching fraction. Table 1 presents various relationships among leaching fraction (LF), the dimensionless ratio of the average weighted root-zone salinity (Cs), and the average salinity of applied water (Ca).

The values in the table are based on steady-state conditions. Because of differences between the underlying assumptions, considerable variation exists in the calculated ratios of root zone salinity to irrigation water salinity. For the four methods of Table 1, the salinity-tolerance data are from threshold salinity-response functions, and the leaching equations ignore the effect of sodium salts on the soil structure. The relation between soil and water salinity as governed by leaching is a dynamic one and hard to predict, subject as it is to site-specific feedback mechanisms among growth of the crop (hence, their water use through evapotranspiration), weather conditions (5), and the leaching of salts (6). A contributing factor is the variability in measured values of the EC of saturated-soil extracts. The coefficient of variation of the EC of soil moisture at saturation is about 50% (7).

Below a leaching fraction of 0.1, a small change in the leaching amount can make a large difference in root zone salinity. The ratio of root zone salinity to irrigation water salinity is less sensitive to changes in the leaching amount at LF values between 0.1 and 0.4, which are most common. In this range of LF values, root-zone salinity increases about linearly with the salinity of the applied water. With the introduction of precision irrigation to reduce water losses and reduce drainage flows, leaching fractions tend

Table 1. Relationships Between Leaching Fraction and Ratio of Soil Salinity Over Applied Water Salinity

LF	Cs/Ca[1]	Cs/Ca[1]	Cs/Ca[1]	Cs/Ca[1]
0.05	3.00	7.00	4.0	10.50
0.1	2.00	5.00	2.6	5.50
0.2	1.25	3.00	1.4	3.00
0.3	1.00	2.50	1.3	2.15
0.4	0.83	2.35	1.0	1.75

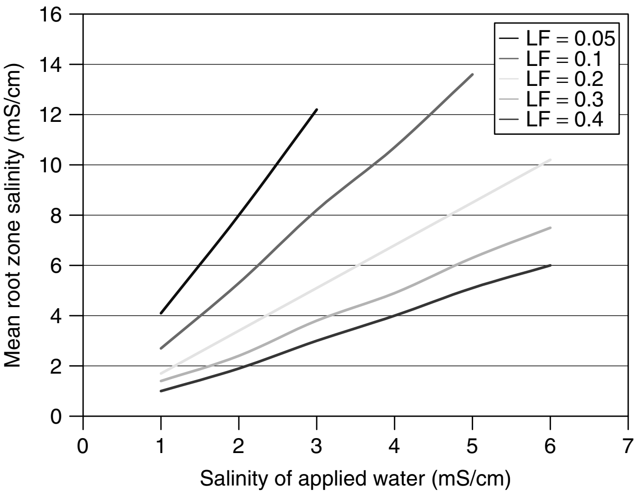

Figure 1. Root zone salinity as a function of the applied water and the leaching fraction. [*Source*: Hoffman and van Genuchten (8)].

to be lower with an enhanced risk of salt accumulation in the root zone.

The relationship of the fourth column in Table 1 uses a root water uptake function that is exponential with depth. This function is often used in modeling studies where a relationship between leaching and root-zone salinity is required. It is plotted in Fig. 1.

LEACHING OF SALT TO PREVENT YIELD REDUCTION

In irrigation practice, the leaching requirement is usually linked to the expected yield reduction. During leaching, soil salinity in the root zone increases with depth. In planning the desired leaching fraction for crop production purposes, it is commonly assumed that the EC at the lower root zone boundary corresponding to 25% to 50% yield reduction is still acceptable. The weighted average EC value for the entire root zone (weighted according to root distribution) would then be less than at the lower root zone boundary, and the resulting yield reduction is assumed to be less than 25% to 50%. This result gives some indication of the required leaching fraction based on the relation between yield and soil salinity.

The rate of downward flow is highest shortly after irrigation when the soil water content is still above or near field capacity. Thereafter leaching continues at a much-reduced rate. When the soil profile dries between irrigations, the soil solution becomes more concentrated. In many soils, the soil solution at field capacity is about twice as concentrated as when the soil is saturated. A further complication is that not all downward flow is equally effective in leaching salts from the root zone. Leaching is more effective when water moves through the soil mass, rather than through cracks between aggregates. Water moving through cracks and wormholes is called preferential flow. The efficiency of leaching depends on the fraction of irrigation water moving down the soil profile mixing with the soil solution. At the start of the leaching process as much as three-quarter of the applied water may flow through cracks in clay soils. Once the soil swells up with moisture, cracks close and the leaching process becomes more efficient.

LEACHING CONTROL

Leaching practices influence the quality and quantity of drainage water. Their control is important when rising watertables are a problem (waterlogging) or where the salt load in the drainage water needs to be brought down. In such cases, restrictions are placed on the amount of salt farmers are allowed to discharge in the drainage water. Experience in Australia and the United States indicates that strict adherence to a set of site-specific regulations on the amount and quality of drainage flows and recharge to the groundwater is necessary to maintain the salt balance in irrigated agriculture. Because of the presence of monitoring systems, farmers in those countries can make well-informed choices about the crops to be grown and the cropping intensities they adopt. Thus, agricultural choices are made within a strict set of rules and the farmers are made responsible for the consequences of their decisions. The successful introduction of regulations with respect to permissible pumping from and recharge to the groundwater, including salt loading, in developing countries will be conditional on the development of adequate monitoring systems and management institutions.

RIVER SALINITY

All arid zone rivers have natural salt profiles resulting from mobilization of salts in the catchment area and saline seeps. Also, irrigation-induced transport contributes to river salinity as drain water with fossil salts from pumped groundwater discharges into a river. Increases in the salinity of rivers and streams in many dry parts of the world pose an ecological hazard that has largely been overlooked. This lack of attention for the ecological impact of increased salinity in inland waters is unfortunate considering the vulnerability of aquatic ecosystems to increased salt levels (9).

Salinity profiles for four rivers are shown in Fig. 2, which illustrates the various degrees to which salts are returned to the river or remain in the land and the groundwater (10). The data used in Fig. 2 are averages that ignore the seasonal changes in salt load as affected by the flow regime of the rivers. Most drainage water from agricultural land in Pakistan's Punjab is being reused, either from surface drains or pumped up from shallow groundwater. In fact, in some irrigation systems, one half to two thirds of the irrigation water is pumped from the groundwater. According to one estimate, about 116 million tons of salt are added annually to the irrigated land in Pakistan (11). Because of the absence of extensive drainage, the leached salts are returned to the land rather than disposed of in the Indus River system or in evaporation ponds. The average annual salt load of the Indus River water measured at rim stations in the catchment is estimated at 33 million tons, whereas the outflow to the sea contains only 16.4 million tons. Hence about half of the annual salt influx remains in the land

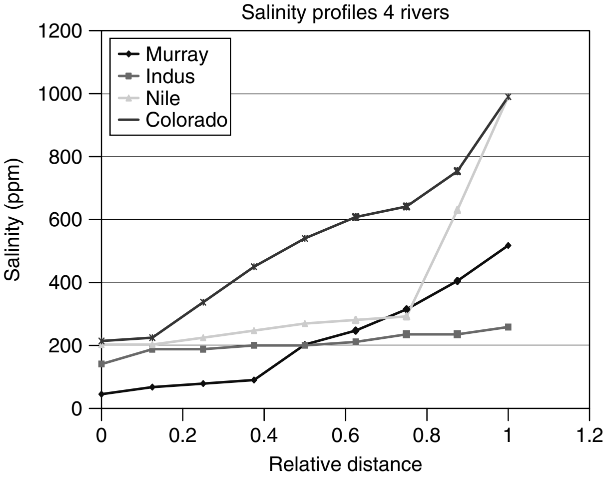

Figure 2. Salinity profiles of four rivers. [*Source*: Smedema (10)].

and in the groundwater (10). Most accumulation takes place in the Punjab, which is in sharp contrast with Egypt where a large portion of the irrigated land is underlain by subsurface drains that take the drainage water back to the Nile River. The salts do not stay in the Nile Basin but are discharged into the Mediterranean Sea. During part of the year, the salt content in the lower Indus is much lower than in the lower Nile and more salt disposal into the Indus could be accepted. However, during critically low flow periods, such disposals would not be possible as the salinity of the Indus water would exceed acceptable limits. The only option during those periods would be to store the drainage water temporarily for release during high flood periods. Extending the Left Bank Outfall Drain, now operating in Sindh, into Pakistan's Punjab may provide a more permanent, but also more expensive, solution than the present inadequate number of evaporation ponds.

The salt load of the Murray River shows considerable seasonal changes. At high flows when most of the river flow originates in the upper catchment, the salt influx is low, but at low flows of the river, when more of the river flow comes from groundwater base flow, the salt influx is higher. At low flows, salinity levels of the Murray are sometimes lowest downstream as the salinity of some tributaries is so much less than that of the main river that the water is diluted.

The salinity profile of the Colorado River is the result of large-scale irrigation development in the basin and concentration of the river water because of evaporative losses from storage reservoirs along its course. Under the salinity control projects of the Colorado River basin, several measures are undertaken to reduce further increases in river salinity. These measures include control of canal seepage by lining, restrictions on the quality of drainage flow back into the river, on-farm water savings by land leveling and changes in cropping patterns, retirement of irrigated land, and watershed management.

These examples of analyzing river salinity profiles clearly demonstrate their potential importance in understanding salt balances of irrigated lands at the scale of river basins.

MEASURING AND MODELING THE SALT BALANCE

Although the methodology for monitoring salinity at field level has been developed, using it in practice is problematic. The ability to diagnose and monitor field-scale salinity has improved considerably during the last 30 years or so. The apparent electrical conductivity of the soil can be measured by means of four-electrode sensors, either surface array or insertion probes, remote electromagnetic induction sensors (e.g., EM31 and EM38), and time-domain reflectometric sensors. Estimation of solute concentration from such measurements requires a calibration model relating soil solution EC to bulk EC. Many examples of the application and calibration of this technique illustrate the limited usefulness of manufacture-provided calibration curves and the different degrees of sophistication of the calibration models (12).

Various models have been developed to simulate transport through soils [e.g., LEACHM (13), SWAP (14)] that require soil solution EC data for their validation. These models are based on physical processes of water infiltration, redistribution, and evaporation. They enhance the understanding of water flow and chemical transport behavior and have been applied to simulate the terms of the water and salt balance (15). Widespread application of the models is restricted by the need for calibration with locally collected data and matching adjustment of some of the parameters. For example, in an Indian study with LEACHM-C, the root mean square errors (RSME) in the comparison of observed and predicted values of soil profile salinity ranged from 28% to 70%. After the water retention parameters were adjusted, the RMSE values ranged from 13% to 24% (16).

Similar problems of uncertainty in model application are associated with high watertables developing from excessive percolation in irrigated areas without adequate drainage. Plant roots take up water from shallow watertables as capillary rise meets part of the water demand of the crop. But if the shallow groundwater is saline, salt accumulation in the root zone affects crop production. Several models have been applied to this situation to ascertain the correct balance between the potentially positive and negative effects of shallow groundwater (17).

The spatial variability of soils and the temporal variability of the hydraulic parameters, especially in clay soils, as well as the largely unknown quantity of lateral groundwater flow constrain the applicability of models to larger areas. Yet, the focus of attention should be changed to the larger scale because of increased recycling of drainage water either through pumping from groundwater or by reusing water from surface drains. It is no longer sufficient to maintain a favorable salt balance at field scale; the salt balance should be maintained at system or river basin scale. As is apparent from the examples of river salinity mentioned earlier, the need for a holistic approach to the salt balance of irrigated areas is large and urgent.

SALT TOLERANCE

Suresh K. Gupta
CSSRI
Karnal, Haryana, India

Salinity has adversely affected irrigated agriculture for thousands of years, probably since the first human civilization in Mesopotamia. The fall of this ancient civilization is attributed to both waterlogging and soil salinity (4). David Shedidan in his book "Desertification of the United States" calls soil salinization of irrigated lands one of the deadliest forms of desertification (5). No other region, where irrigated agriculture is practiced, can be an exception to this kind of desertification. In recent years, soil salinity has assumed a worldwide dimension and has become a serious threat to at least one-third of irrigated lands in the arid and semiarid regions where lots of irrigation water is used without providing adequate drainage. Although a long-term solution to the problem is to carry out improvements in land drainage, differences in salt tolerance of crops provide opportunities to continue growing increasingly salt-tolerant crops on salty lands to buy time before investments are arranged for reclamation.

SALT TOLERANCE: DEFINITION

The literal meaning of tolerance is to endure, sustain, or put up with. Thus, the salt tolerance of a plant could be defined as the plant's capacity to endure the effects of excess salt in the medium of root growth (1). That plants can withstand a fair amount of salts without adverse effects is implicit in this definition. In fact, a fair proportion of salts in the growing medium is needed for good growth. There are instances where plant growth is stimulated at low concentrations of salts, and only thereafter, the yield starts declining (2). Apparently, the problem of soil salinity develops only when the salts accumulate in the root zone to an extent that it becomes harmful to the plants. The salt tolerance of a plant is also expressed in terms of the yield decrease expected for a given level of salinity compared to the yield under nonsaline conditions (3). Many times, salt tolerance and salt resistance have been used synonymously although, the two do not convey the same meaning. Salt resistance is a plant's ability to decrease or prevent the stress from penetrating into its tissues, but tolerance is the ability of the plant to eliminate, reduce, or repair the stress once it has already penetrated.

Salt or salinity in this article is used as a general term for salt stress, which could manifest itself from altogether different causes and compositions of salts under different situations. The stress could be due to bulk salinity of the soil water caused by excess soluble salts. Electrical conductivity (EC) of the saturation extract (EC_e) of a bulk soil solution has been widely used as a measure of this kind of stress (6). The adverse effects could also appear due to high exchangeable sodium, usually expressed in terms of exchangeable sodium percentage (ESP), due to excess ions such as chlorides and sodium expressed in meq L^{-1}, or due to excess toxic ions such as boron and fluorine, expressed in mg L^{-1}. A plant tolerant to one kind of stress need not necessarily be tolerant to other kinds of stresses. Therefore, a large number of relative tolerance tables are now available in the literature (1). These tables can provide a first approximation of the relative tolerance of plants to the anticipated kind and level of stress.

BIOLOGICAL RESPONSE TO SALINITY

The response of plants to salinity has been extensively studied and widely reported. For the purpose of discussions in this section, salinity effects are grouped under the heads (1) the effect of excess soluble salts, (2) the effect of high exchangeable sodium, and (3) a specific ion effect or toxicity of specific ions.

Effect of Excess Soluble Salts

Adverse effects appear to be related to the bulk soil salinity of the soil solution. As the salt concentration increases, the osmotic pressure of the soil water increases which affects the availability of water to the plants. When the osmotic pressure of the soil solution is high, the plants are unable to extract water as readily as they can from a relatively nonsaline soil. As such, even if water is present in the soil, it might not be available to the plants and results in physiological drought or osmotic desiccation. To survive, the plants must adjust osmotically and build up high internal solute concentrations, as is the case with salt accumulating halophytes. In salt sensitive plants, excess amounts of salt in the plant cells can be harmful because of damage to cell membrane, enzymes, and organelles.

The limited uptake of water hinders the uptake of ions by the plant root system. Thus, plants might encounter deficiencies of nutrients. Because the soil solution has high concentrations of certain ionic species, some of these ions, which are otherwise not harmful, might become toxic when absorbed in excess amounts. Salt-sensitive glycophytes have inadequate control over ion uptake, so such excess absorption of ions cannot be ruled out. Besides, preferential absorption of one ion may also retard the absorption of other essential plant nutrients necessary for the normal growth of plants. Evidence of potassium deficiencies and inhibition of absorption of nitrate from saline soils can be cited.

Even glycophytes, which are salt tolerant and possess the ability to adjust osmotically, exhibit growth reduction largely on account of energy expenditure for uptake and synthesis of solutes.

Exchangeable Sodium

High ESP of a soil is associated with structural deterioration of soils. As a result, the edaphic environment is adversely affected and results in restricted air and water movement in the root zone. The factors that limit the uptake of water in alkali/sodic soils are a shallow wetting zone, an impermeable layer (crust) on the surface, low unsaturated hydraulic conductivity, and low available moisture content. Besides water availability, sodium toxicity, as a result of high ESP, can also affect the yield. High ESP can also disturb the mineral nutrition of the plant because it results in nutritionally inadequate amounts of Ca, or it might retard the absorption of some ions (7).

Specific Ion Effects

Some constituents of salts, for example, chlorides, which are harmless to most crops at moderate concentrations, may be toxic to some crops at higher concentrations, for example, citrus and grapes. In addition, some elements like lithium, and boron are toxic to plants even though they may be present in only very small quantities. Under such situations, plants would be subjected to toxic effects, nutritional imbalance, and deficiencies of certain essential elements.

In all the cases discussed in this section, it is believed that the adverse effects are usually due to the cumulative effects of several factors, although one may be dominating others in many cases.

DIFFERENCES IN SALT TOLERANCE OF PLANTS

Plants differ greatly in tolerance to salts. A wide range of salt-tolerant plants that evolved over millions of years exists in the plant kingdom. Plants with natural salt tolerance can survive in water of varying degrees of saltiness, from slightly brackish in the case of barley to ocean water in some hardy species of mangrove trees. Plant species called 'halophytes' are highly salt tolerant; some of them withstand salt concentrations in excess of that of seawater. At least 1500 of them are currently known (8), many of them have potential for commercial exploitation (9). These plants contain genes that protect them from salts in a variety of ways, such as growing salt-blocking membranes, excreting salt through their leaves, or sequestering salt in microscopic compartments called vacuoles. The natural vegetation of arid regions, xerophytes, also has high salt tolerance. On the other hand, almost all crop species are glycophytes, plants that do not grow well in the presence of salts. Most fruit trees and vegetables are salt-sensitive plants. Generally, vegetable crops are more tolerant than fruit crops but are more sensitive to salt than field and forage crops. Within field and arable crops, beans, pulses, oil-seed crops, and cereal crops, in that order, show increasing sensitivity to salts. Many wild relatives of cultivated plants, however, are reportedly highly tolerant to soil salinity, alkalinity, and other associated conditions (10).

VISIBLE SYMPTOMS ON PLANTS GROWING UNDER HIGH SALINITY

Within a narrow range around a plant's salt tolerance level, no visible symptoms might appear on plants under field situations Yet, the crop yield might still be affected. At high salinity, the plants show signs of wilting, a similar symptom that appears when a plant is water stressed. The leaves of salt stressed plants may turn yellow, a condition called chlorosis. It happens because the excess sodium blocks iron uptake and the lack of iron inhibits production of chlorophyll. Stunted growth and deep bluish green foliage of plants followed by low production are other common signs in plants grown under high salinity. The toxic effects that are characteristic of the specific ion causing toxicity usually show on plant parts.

FACTORS INFLUENCING SALT TOLERANCE

Absolute tolerance to salinity cannot be expressed explicitly. It varies considerably with edaphic and environmental factors, which influence salt tolerance in plants. The most important among the edaphic factors are the physical condition of the soil, soil fertility, salt species present in the soil solution, salt distribution in the profile, salinity level, and irrigation methods. The environmental factors include temperature, humidity, radiation, and pollutants in the environment. It has been found that poor aeration as a result of inadequate drainage may adversely affect plant response to soil salinity. For several crops, sensitivity to salts is known to differ markedly according to the type of salts present and as a result, isosmotic solutions of different composition might affect the plants differently. Sorghum plants exhibited greater growth reduction with sulfate type than chloride type salinity (11). Therefore, the type of salinity might alter the order of tolerance in crops. Since salinity stress is expressed as the total sum of the matric potential and the osmotic potential, the salt tolerance of crops would be significantly different in frequently irrigated than infrequently irrigated conditions. As such, shallow and frequent irrigations are recommended for crops growing under a saline/sodic environment. Because of the same reasoning, a plant response at the same salinity is better in drip irrigation than with surface irrigation. Gupta and Dubey (12) reported that irrigation water of much higher salinity could be used for growing vegetable crops with pitcher irrigation than with conventional surface irrigation techniques, as reported by Minhas and Gupta (13). Apparently, the salt tolerance of most crops under pressurized modern irrigation techniques needs to be worked out.

Plants respond better to salt stress in cool and humid than in hot and dry weather. Studies on several crops such as alfalfa, bean, beet, carrot, cotton, onion, squash, strawberry, clover, salt grass, and tomato have shown that salinity decreased yields more when these crops were grown at high temperatures (14–16). Hoffman et al. (17) observed that alfalfa yields were highest under ozone concentrations found in many agricultural areas in California at moderate salinity levels which were otherwise found to reduce growth in the absence of ozone.

Besides the environmental and edaphic factors discussed in the foregoing section, biological factors such as the varieties and rootstock of plants and the stage of growth also cause significant differences in the response of plants to salt stress. Evidence is abounds revealing inter- and intragenic differences in plants' response to salt stress. Green alga (*Dunaliella vindis*) survives in the highly saline Dead Sea at a salinity level exceeding 35 $\mathrm{dS\,m^{-1}}$. A survey of reported data on the response of crop plants to increasing salinity levels reveals about eightfold differences among them in tolerance to salinity stress (18). An evaluation of more than 1000 wheat genotypes revealed a wide variation in the tolerance to soil sodicity (given by the pH of the soil solution). These wheat genotypes could be classified into tolerant, that grew well up to a pH of 9.6 (ESP and pH are well correlated for alluvial soils of the Indo-Gangetic plains) and sensitive, that did not grow well unless the pH was below 8.5. In between these two classes, varieties could be classified as medium tolerant and medium sensitive (19). Aswathappa et al. (20) recorded that some acacia species grew in NaCl concentrations of 1000 $\mathrm{mol\,m^{-3}}$, whereas others stopped growing at 200 $\mathrm{mol\,m^{-3}}$.

Some crops are known to be sensitive to salt stress at germination and others at emergence and early seedling growth. In cereal crops, the early productive stage has been found sensitive. Recent studies indicate that corn (21), sorghum (22), and cowpea (23) are most sensitive during the vegetative and early reproductive stages and least sensitive during the grain filling stage. It has been found that the tolerance of wheat increased with ontogeny. The soil saturation extract values at which yield would decline by 50% is 9.3 $\mathrm{dS\,m^{-1}}$ for seeding to crown root initiation stage and increases with age to 13.2 $\mathrm{dS\,m^{-1}}$ for dough stage to maturity (24). Though data sets are increasingly added to the literature to highlight such differences in response, some criticism is also appearing because of the limitations of the methods used in such evaluations. It is highlighted that presently used conventional methods of soil tests fail to reveal the true stress to which a plant is subjected at different growth stages. For example, it is difficult to say whether the young roots at the time of the emergence and initial establishment stage are really sensitive to salts or are exposed to a high salt stress particularly when the salt accumulate at the soil surface. Similarly, the salinity of the soil water that is approximately equal to that of the irrigation water at the top of the root zone is several times more than the salinity of irrigation water at the bottom. It is natural that at the later growth stages, plant roots moving deep into the profile might experience greater salt stress than that given by the average soil salinity. Thus, one would tend to agree to a general statement that in many crops and plants, increased tolerance with age has been observed, yet the data are not sufficient to draw conclusions in absolute terms about the differences in salt tolerance at different growth stages.

CHARACTERIZATION AND ASSESSMENT OF SALT TOLERANCE

A number of models have been used to appraise the relative tolerance of crop plants. In some models, survival of the plants has been used as a criterion whereas in others, vegetative growth, absolute yield, and relative yield have been used to characterize relative salt tolerance. When comparisons are made among the models, some drawbacks are apparent in a few of them. For example, survival of the plants used in many ecological works is very often at the expense of production. Thus, it seems inappropriate for agricultural situations. Similarly, vegetative growth has a limitation. It has been seen that, where vegetative growth has been affected, many plants pick up later and yield almost at the optimum level. Absolute yield is useful agriculturally, as it tells the farmer what to expect, but has little use for quantifying differences in tolerance between crops with different levels of yield, for example, sugar cane and wheat. The use of relative yield compared to a control (say, non saline environment) allows comparisons between crops and cultivars, where the yield is expressed in different units or where the components of economic yield differ between them. More and more reports are now appearing where crop production functions are plotted in terms of relative yield as a continuous function of increasing salinity or for that matter ESP or the concentration of a particular ion. At this stage, it seems to be the most appropriate criterion for evaluating the relative salt tolerance of plants, although some limitations are known.

Maas and Hoffman (3), probably for the first time, proposed a linear response model, containing three independent parameters, the non saline control yield ($Y_{\max}$), a salinity threshold ($\mathrm{EC_t}$), below which yield (Y) was unaffected, and a slope (S) representing the decrease in yield with increase in salinity above this level. $\mathrm{EC_0}$ represents the salinity at which there is no yield. Mathematically, the response function is written as

$$Y = Y_{\max} \qquad 0 \le \mathrm{EC} \le \mathrm{EC_t} \tag{1}$$

$$Y = Y_{\max} - S(\mathrm{EC} - \mathrm{EC_t}) \qquad \mathrm{EC_t} < \mathrm{EC} \le \mathrm{EC_0} \tag{2}$$

$$Y = 0 \qquad \mathrm{EC} > \mathrm{EC_0} \tag{3}$$

The relative yield of the crop as a ratio of the nonsaline control could also be used in this model. Then, Y would become RY, the relative yield and $Y_{\max}$ would be equal to 1 or 100 depending upon whether the relative yield is expressed in terms of a fraction or percentage.

The piecewise linear model has been used to produce tables of salinity response functions for a number of crops (1,3). Later studies have established that such a model can effectively describe the production function as affected by high ESP (25). A model proposed independently by Oosterbaan is also based on the same premise and uses segmented regressions defining the threshold as a breakpoint. The model proposed by Oosterbaan (26) seems to be quite flexible and could be used for many more situations besides studying the salt tolerance of crops.

Based on this model, threshold salinity, the salinity at which a 50% ($\mathrm{EC_{50}}$) reduction in yield is expected, and the salinity at which the yield is zero ($\mathrm{EC_0}$) have been used to assess the relative salt tolerance of crops. Both the threshold salinity and $\mathrm{EC_0}$ are not well defined (2), so $\mathrm{EC_{50}}$ seems to be the most appropriate parameter to assess the relative salt tolerance of crops (18,27), as it integrates both the slope and the threshold. The data derived from Maas (28) show that both $\mathrm{EC_t}$ and slope overlap between two classes (Table 1). Such overlap gets masked while calculating the $\mathrm{EC_{50}}$. van Genuchten (2) proposed a sigmoid model, defined in terms of $\mathrm{EC_{50}}$ and p where again $\mathrm{EC_{50}}$ is the salinity where the yield is reduced by 50%, and p is an empirical constant defining the shape of the curve. This model also fits well with almost all the data sets of the Maas and Hoffman model, so it attests to the fact that $\mathrm{EC_{50}}$ could be a good parameter to define relative salt tolerance.

The use of this model in field experimentation, besides other limitations, may be difficult where differences between genotypes are small. A limitation of this model is explained well in Fig. 1. Using $\mathrm{EC_{50}}$ as the criterion, it would be concluded that the tolerance of four crops is in the order crop a > crop b = crop c > crop d. On the other hand, within crops b and c, one would tend to conclude that crop b is more tolerant to salt at low and medium salinity levels and crop c is more tolerant at high levels of salinity. Another problem with this model is that it can be used to identify tolerance as distinct from yield potential in many crop cultivars. In wheat, for instance, Kharchia 65, a wheat variety from Rajasthan (India) showed the highest degree of salt tolerance though it was not one of the top yielders amongst the varieties tested at Karnal (India). Notwithstanding such minor difficulties, this approach has the potential of application in categorizing the relative salt tolerance of crops.

RELATIVE SALT TOLERANCE OF CROPS

Extensive data on this issue are part of the literature. The most comprehensive information on this aspect is compiled and reported by Maas (1). This includes information on the relative salt tolerance of herbaceous crops (fiber, grains, grasses, forage, and special crops), vegetable and fruit crops, woody crops, ornamental shrubs, trees, and ground cover crops to the bulk soil salinity of the growing media. It

Table 1. Range of Model Parameters in Describing the Relative Salt Tolerance of Agricultural Crops

Relative Salt Tolerance of Crops	$\mathrm{EC_t}$ (dS $\mathrm{m^{-1}}$)	Slope (%)
Sensitive	1–2	15–35
Moderately sensitive	1–3	6–20
Moderately tolerant	3–7	4–20
Tolerant	4–8	4–7

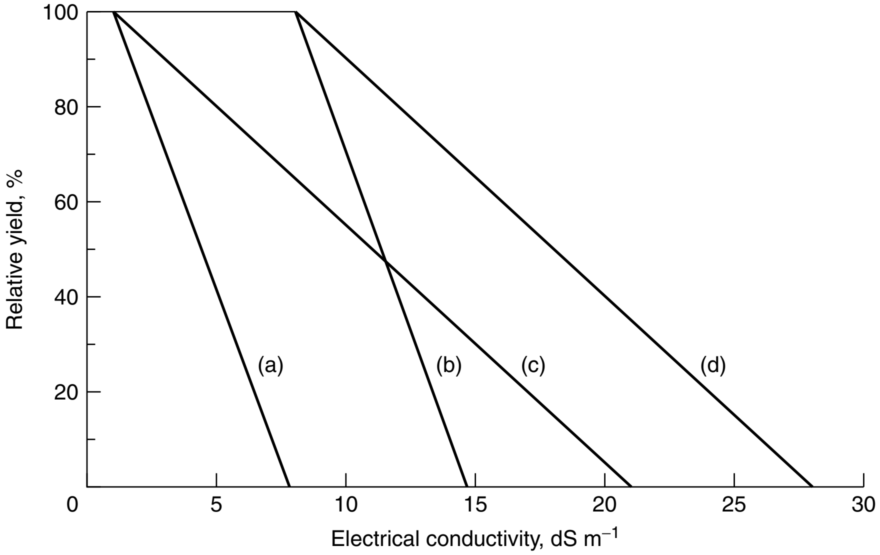

Figure 1. Crop salt tolerance as revealed by the piecewise linear model of Maas and Hoffman.

also lists the tolerance of agricultural crops and fruit-crop cultivars and rootstocks to chloride and the tolerance of agricultural crops and citrus and stone fruit rootstocks to boron. A number of tables listing the relative tolerance of crops have also appeared, but most are based on data reported by Maas and his co-workers. A table showing the relative tolerance of field, vegetable, forage, and fruit crops is given in Appendix 1. Gupta and Sharma (25) reported on the tolerance of a few agricultural crops and grasses to soil ESP. Porwal et al. (29) compiled the available data in India on tolerance of crops to saline water and presented the threshold and slope of the Maas and Hoffman function in terms of irrigation water quality. Per se, saline water might not directly affect crop yield, but once the leaching fractions under a given set of conditions are known, this data could be effectively used to assess crop tolerance to soil salinity. Later on, similar data were compiled and reported by Minhas and Gupta (13).

Although extensive literature is available on the relative tolerance to salts, considering the different agroclimatic conditions, different methods employed, varying farming conditions, and varieties used, the results obtained do not always agree. As an example, the alkali tolerance of rice in the literature has been rated as medium, but in the Indian context, it has been rated as highly tolerant. This difference arises because of the fact that the earlier rating was for direct seeded rice and the India rating is based upon transplanted rice where 35–40 day seedlings have been used for transplanting.

SALT TOLERANCE AND MANAGEMENT OF POOR QUALITY LAND AND WATER RESOURCES

Several treatments and management practices can reduce the salt level in soil. However, there are some situations where it is either not possible or not economically practical to attain desirably low soil salinity levels. In such cases, proper plant selection is one way to moderate yield reductions caused by excessive soil salinity. The ability of a plant to grow on salty lands or to remove salt from such soil makes salt-tolerant plants potentially useful for restoring salt-damaged soils. Salt-tolerant plants can also provide farmers with greater flexibility in crop selection besides reducing the leaching requirement. The difference in the salt tolerance of plants is now being exploited both on experimental and field scales to use salty water resources for crop production and to dispose of them in an ecofriendly manner with reduced investments. It is achieved through sequential concentration of water. In such a system, following each cycle of use, the volume of water decreases, but its salinity increases. Thus, after each cycle, a more salt tolerant crop is chosen before finally disposing of the water in an evaporation tank or by some other means (Fig. 2). This kind of practice has also been referred as a multiple water use system in the literature. The quantity of water to be disposed of at this stage is much less, so the investment in an evaporation tank is significantly reduced.

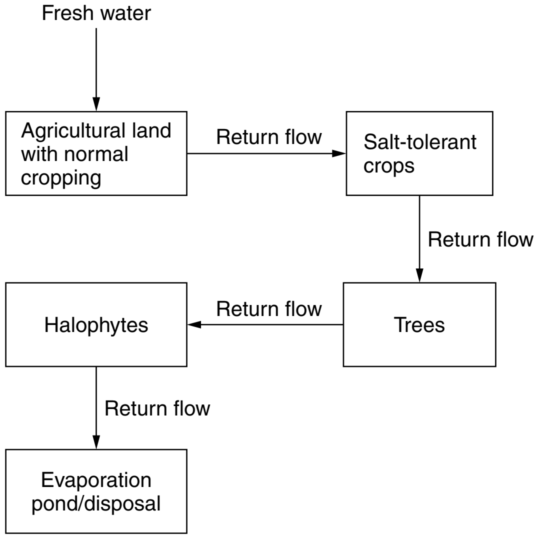

Figure 2. A schematic representation of sequential concentration for managing water resources.

RECENT DEVELOPMENTS IN SALT TOLERANT CROPS

Conventional breeding for developing salt-tolerant plants has been attempted for a long time, and the subject of breeding for salt tolerance has been reviewed by many workers (30). The lack of success in generating tolerant varieties [given the low number of varieties released and their limited salt tolerance (31)] would suggest that conventional breeding practices are not enough. Plant breeding from the existing gene pools could help to achieve small increases in salinity tolerance. Advances in molecular biology as well do not appear to have helped greatly in the development of salt-tolerant genotypes. There is good evidence that salt tolerance in truly tolerant species (halophytes) is a multifaceted trait. In halophytes, tolerance depends upon ion exclusion or compartmentation, synthesis of compatible solutes, regulation of transpiration, control of ion leakage through the apoplast, membrane characteristics, and the ability to tolerate low K:Na in the cytoplasm. It has been demonstrated that a range of traits is also important in crops. This suggests that the overall trait of salt tolerance is determined by a number of genes.

Twenty years ago, Epstein (32) argued for development of crops in which the consumable portion is botanically a fruit, such as grain, berries, or pomes, and that have a truly halophytic response to salinity. In these plants, Na^+ ions would accumulate mainly in leaves, and because water transport to fruits and seeds is primarily through the phloem pathway (i.e., the intercellular connections), much of the salt from these organs would be screened. Initially, this hypothesis looked beyond realization. But in the last few years, scientists have reported increasing success in using genetic engineering to unravel the secrets of the genes and proteins that govern salt tolerance. A genetically engineered tomato that thrives in brackish water was produced in mid-2001 by a team of plant biologists at UC Davis (33). In late 2001, Purdue University scientists discovered a protein that guides salt into plants (34). Biotechnology specialist Alan McHughen at UC Riverside plans to begin research into producing salt-tolerant avocado trees. We also have other transgenic plants, for example, canola. Up to 10% of the dry weight of the leaves in this plant is sodium chloride. Schroeder and his colleagues have also discovered a gene that helps protect plants from salt damage by keeping salt in the roots. These results clearly support Epstein's argument.

With some success coming our way, it must not be forgotten that much more basic research is yet to be conducted. To develop genetically modified plants that have the triple characteristics of high yield, good quality, and tolerance to salts will not be an easy task in the foreseeable future. Besides, the genetically modified plants must be stable, so their descendants can be reliably grown with the added traits, and the plants must be tested for safety. This might take years of testing. Moreover, recent criticism and experience with genetically modified plants might hamper the progress of work. For example, some environmental groups say that large agricultural companies are rushing too quickly to introduce genetically modified crops without regard for potential dangers. Genetically engineered corn to produce a natural insecticide has been opposed on the grounds that it could kill insects that are not pests, such as the monarch butterfly. Even more worrisome, early genetically modified plants weren't very useful to consumers. An earlier genetically engineered tomato called the Flav-Savr, also produced from research at UC Davis, flopped in the mid-1990s. To resolve such issues would require much more effort. Till then, an integrated approach based on conventional plant breeding, molecular biology, and genetic engineering should continue.

APPENDIX A

Relative Tolerance of Crop/Plants to Soil Salinity (EC_e)[a]

Tolerant	Moderately Tolerant	Sensitive
	Field Crops	
Barley	Rye	Black gram
Sugar beet	Wheat	Bengal gram
Rape	Oat	Green gram
Cotton	Rice	Lentil
	Sorghum	
	Corn	
	Sunflower	
	Castor	
	Safflower	
	Soybean	
	Pearl millet	
	Linseed	
	Cluster bean	
	Pigeon pea	
	Cowpea	
	Sesame	
	Groundnut	
	Vegetable Crops	
Garden beets	Bitter gourd	Radish
Asparagus	Bottle gourd	Carrot
Spinach	Brinjal	Celery
Amaranths	Tomato	Green beans
	Cabbage	Coriander
	Pea	Cumin
	Lady's finger	Mint
	Onion	
	Potato	
	Carrot	
	Turnip	
	Sweet potato	
	Dolichos	
	Sponge gourd	
	Watermelon	
	Muskmelon

GROUNDWATER ASSESSMENT USING SOIL SAMPLING TECHNIQUES

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

Groundwater assessment for environmental projects involves significant soil sampling to evaluate hydrologic and lithologic conditions. Soil samples in environmental investigations are typically collected at a minimum of every one to two meters and at changes of lithology or obvious signs of contamination, based on soil staining or discoloration of the soil or in the case of volatile organic compounds, organic vapor readings. Continuous coring is recommended for a minimum of at least one soil boring per site to characterize the subsurface adequately.

VADOSE ZONE

Soil samples collected in the vadose zone above the water table are in the unsaturated zone. Groundwater is moving generally vertically, and some horizontal movement is caused by rootlets, faults, impermeable layers, or other conduits. Soil samples collected within the capillary fringe or below the groundwater table are in the saturated zone.

The capillary fringe moves up and down with seasonal variations of the groundwater table. Petroleum hydrocarbons move vertically from the source, such as an underground storage tank, through the vadose zone. As the hydrocarbons move vertically through the lithologic section, in general, the finer grained the soil, the greater the lateral spreading of the contaminant (Fig. 1).

K_p = Conc soil/conc gas Soil zone	Unsaturated zone
K_p = Conc soil/conc gas Intermediate zone	
K_h = Conc gas/conc water Capillary fringe Water table	Saturated zone
K_d = Conc soil/conc water Groundwater	

Figure 1. Equilibrium expressions for partioning volatile organic compounds among aqueous, vapor, and sorbed phases.

CAPILLARY FRINGE ZONE

The capillary fringe, within the saturated zone, is the zone immediately above the water table, where water is drawn upward by capillary attraction. Due to irregularities in pore sizes among the grains of sediment, the capillary water does not rise to an even height above the water table but rather forms an irregular capillary fringe. The capillary fringe is higher in fine-grained soils such as a fine silt than in coarse grained soil such as a gravel due to greater tensions created by the smaller pore openings. The capillary fringe can be the zone of direct evaporation of groundwater if the water table is close enough to the surface (1).

The vertical movement during a complete hydrologic cycle can be a few centimeters, in other cases, it can be tens of meters, depending on the recharge of the water, the proximity of pumping wells, and other factors. This movement greatly affects the zone above the water table, which includes the capillary fringe zone, especially when it is impacted by light nonaqueous phase liquids (LNAPL), also called floating product or free-product.

When the free-product of a hydrocarbon fuel, such as gasoline, moves up and down through the hydrologic cycle, a smear zone develops in the zone above the water table. Some of this highly impacted soil zone (HISZ) is above the current capillary fringe zone and may exist below the top of the current groundwater table. Therefore, a HISZ equals the cumulative thicknesses of the migrating capillary fringe zones and frequently exists in areas where free-product or high concentrations of dissolved hydrocarbons have existed for a long period (Fig. 2).

For hydrocarbon fuels, which are lighter than water, the soil sample just above the water table is typically collected and analyzed. This sample may contain the highest concentration of contaminants within a soil boring. Sometimes, buried or submerged contaminants are trapped beneath the water table when water levels rise, leaving a former free-product zone below the water table (2). In these cases, soil samples collected within the groundwater zone would be appropriate (Fig. 3).

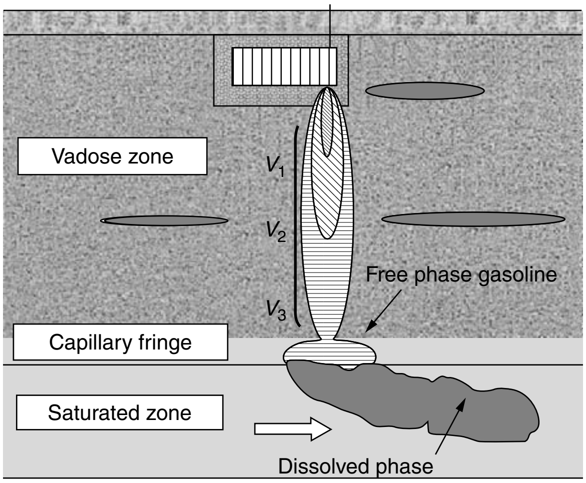

Figure 2. Gasoline movement from source (underground storage tank) to saturated zone (2).

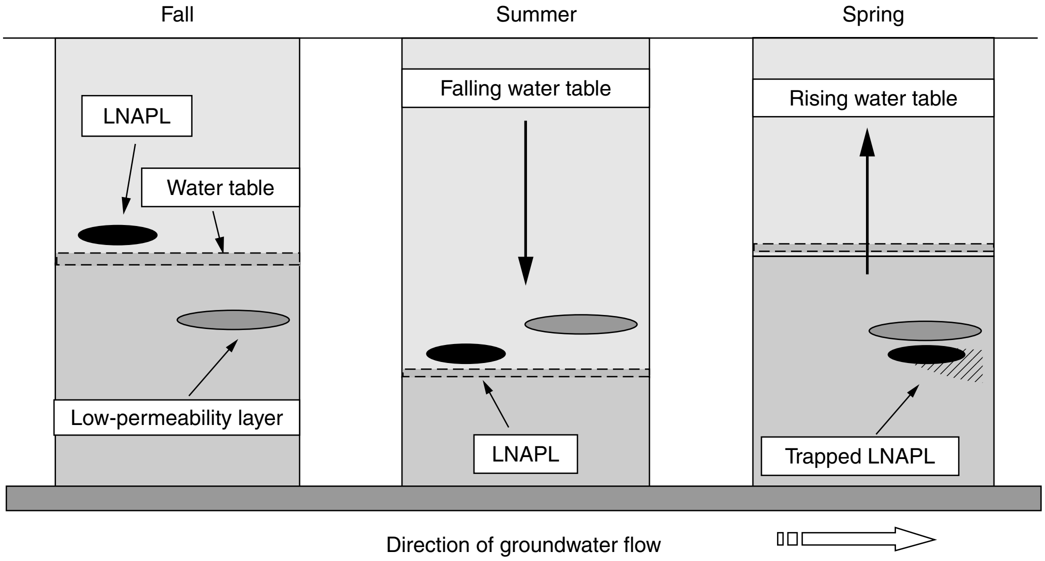

Figure 3. Trapping gasoline contaminants below the water table by fluctuating groundwater elevations (2).

For dense nonaqueous phase liquids (DNAPLs) such as chlorinated solvents, which have a specific gravity greater than water, soil samples are collected throughout the aquifer for hydrogeologic characterization. The highest concentrations of these dense liquids may be at the base of the aquifer, above the top of the next underlying aquitard.

SATURATED ZONE

Soil samples collected in the saturated or phreatic zone below the water table are used to evaluate the aquifer's characteristics. Soil samples collected below the groundwater table are generally not analyzed at a chemical laboratory, in favor of the more representative groundwater sample. Nonetheless, these saturated soil samples can provide a wealth of information about aquifer characteristics, total organic carbon, solid oxygen demand, porosity and permeability, as well as free-product distribution. Continuous soil coring of aquifer sediments allows complete lithologic analysis for potential groundwater remedial designs. These soil samples help scientists and engineers understand groundwater dynamics and the vertical and lateral movement of contaminants in the subsurface. Although groundwater sampling is imperative for groundwater assessments, data from soil samples used in conjunction with groundwater data provide a more complete understanding of subsurface conditions.

More detailed soil sampling information can be obtained from Testa (3), Jacobs (4), American Society for Testing Materials (5), California Regional Water Quality Control Board (6), and Morrison et al. (2). There are numerous minor differences in soil sampling and record keeping techniques and methods among field samplers, regional variations, and specific regulatory requirements that vary from state to state. A generalized summary of selected environmental soil sampling techniques follows.

SOIL SAMPLING METHODS

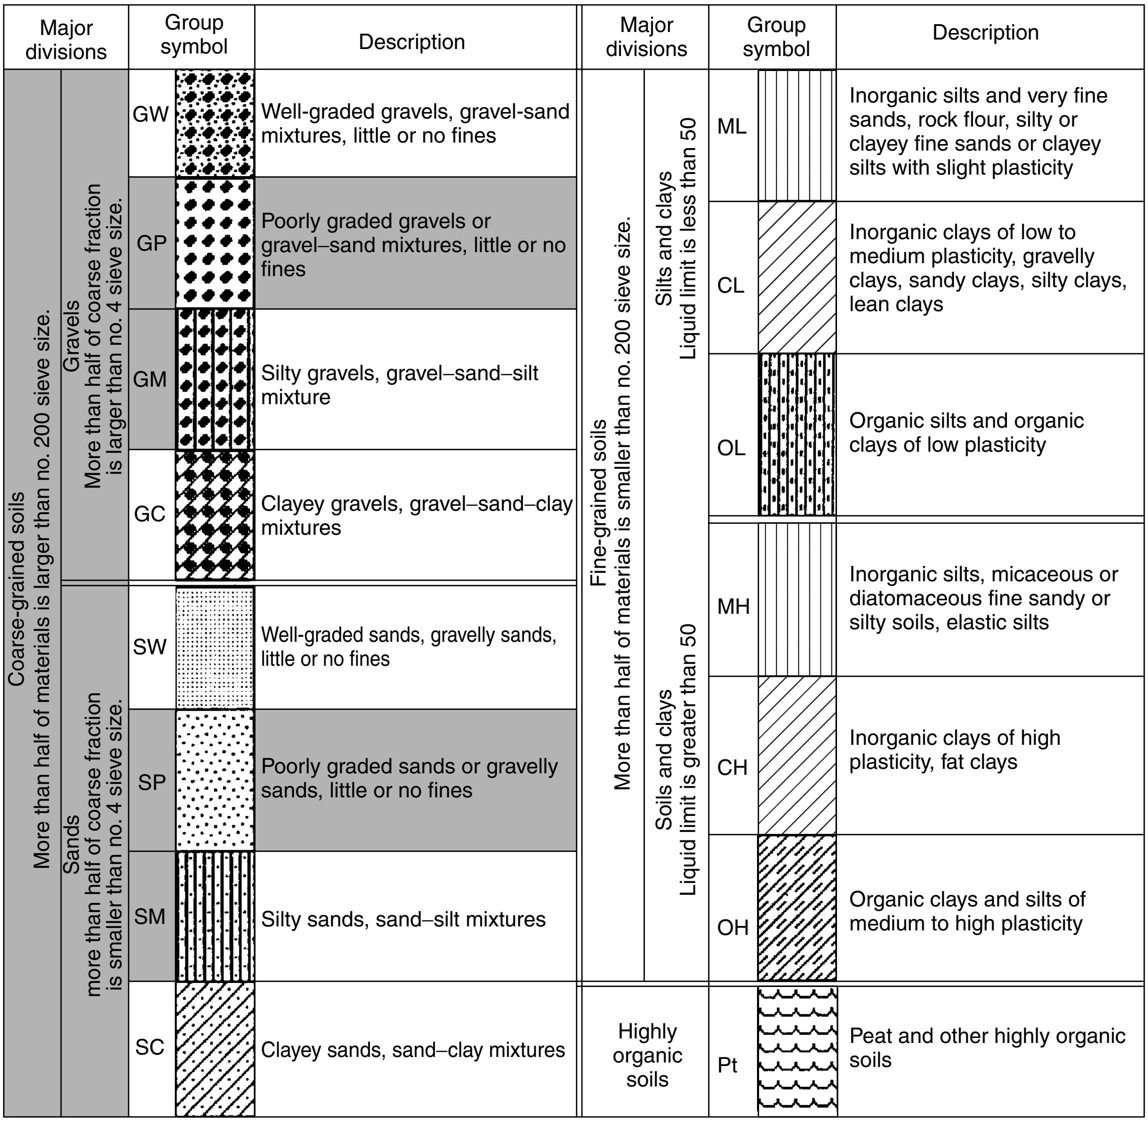
Undisturbed or minimally disturbed samples are obtained by driving a sampler into the soil, either manually, or using a drilling rig. The soil sampler is retrieved and opened, and the sample liner containing the soil sample is extracted. Samples are collected during subsurface investigations in vertical borings using rigs. Split-spoon samplers and direct push core samplers are used frequently for shallow soil sampling. The inner sample liners are typically composed of polyethylene, brass, or stainless steel. Samples may also be collected from tank pits and soil piles by driving a sampling tube into the soil by hand or using a drive-hammer.

Some analyses or guidelines allow collecting disturbed samples using a trowel, and then placing them in glass jars. Photoionization detectors (PID) are used in the field to measure organic vapors in soil samples. Soil samples should be collected in accordance with regulatory guidelines, which may vary among states and locales. The sample liners, containing soil, are typically sealed with Teflon tape and plastic caps at both ends. The samples are then labeled and stored in a refrigerated environment.

Small variations in soil lithology within several inches can lead to large differences in the results of chemical analysis. Duplicate soil samples, if taken, are collected as near as possible to the actual initial soil sample. Typically, these duplicate samples are collected in the same lithologic zone as the original sample. Duplicate samples should be a minimum of 5% of the samples. To maintain sample integrity, soil samples are delivered to certified laboratories using chain-of-custody procedures.

Lithologic Description

Soils and unconsolidated deposits for environmental projects are commonly described according to American Society for Testing Materials (ASTM) Method D 2488-84 (5) and the United Soil Classification System (USCS)



Major divisions		Group symbol	Description
Coarse-grained soils More than half of materials is larger than no. 200 sieve size.	Gravels More than half of coarse fraction is larger than no. 4 sieve size.	GW	Well-graded gravels, gravel-sand mixtures, little or no fines
		GP	Poorly graded gravels or gravel–sand mixtures, little or no fines
		GM	Silty gravels, gravel–sand–silt mixture
		GC	Clayey gravels, gravel–sand–clay mixtures
	Sands more than half of coarse fraction is smaller than no. 4 sieve size.	SW	Well-graded sands, gravelly sands, little or no fines
		SP	Poorly graded sands or gravelly sands, little or no fines
		SM	Silty sands, sand–silt mixtures
		SC	Clayey sands, sand–clay mixtures
Fine-grained soils More than half of materials is smaller than no. 200 sieve size.	Silts and clays Liquid limit is less than 50	ML	Inorganic silts and very fine sands, rock flour, silty or clayey fine sands or clayey silts with slight plasticity
		CL	Inorganic clays of low to medium plasticity, gravelly clays, sandy clays, silty clays, lean clays
		OL	Organic silts and organic clays of low plasticity
	Soils and clays Liquid limit is greater than 50	MH	Inorganic silts, micaceous or diatomaceous fine sandy or silty soils, elastic silts
		CH	Inorganic clays of high plasticity, fat clays
		OH	Organic clays and silts of medium to high plasticity
Highly organic soils		Pt	Peat and other highly organic soils

Figure 4. Unified soil classification system (USCS).

for physical description and identification of soils. The USCS was first used in the geotechnical engineering field and is now commonly used in the environmental field. Unfortunately, the USCS is not very useful for describing lithologic characteristics, geologic properties, or the origin or depositional environment of the soil or sediments (Fig. 4).

Other soil identification systems include the Burmister Soil Identification System (BS) for unconsolidated deposits, which is commonly used with the USCS. The other soil description system is the Comprehensive Soil Classification System (CSCS) developed by the U.S. Department of Agriculture. The CSCS describes soils as to agricultural productivity potential and best agricultural land use.

The ASTM Soil Classification Flow Chart and the USCS are generally accepted soil description methods used in the engineering and environmental fields. Descriptions of moisture, density, strength, plasticity, etc. are made using ASTM guidelines. Stratigraphic, genetic, and other data and interpretations are usually also recorded in the boring log. For consolidated deposits, including igneous, metamorphic, and sedimentary rocks, the USCS is combined with other geologic characteristics such as weathering, sorting, sphericity, and separation.

Color is commonly described by comparing the soil sample with a Munsell Rock Color Chart (7). Each layer of soil is identified by the geologist or engineer using the following items: color, soil type (USCS), classification symbol, color, consistency or relative density, moisture, structure (if any), and modifying information such as grain sizes, particle shape, cementation, plasticity, stratification, and other notes.

LITHOLOGIC INTERPRETATION

Once the lithology has been determined, geologists and engineers compare the data to develop a geologic model for the depositional environment. Knowing the type and origin of the soil, sediments and rocks provides a better understanding of groundwater and contaminant movement and allows predictive modeling of an aquifer. Once the geochemical data have been evaluated, a site conceptual model can be developed, and a corrective action plan and remedial design can begin if the site requires environmental cleanup.

SKIMMED GROUNDWATER

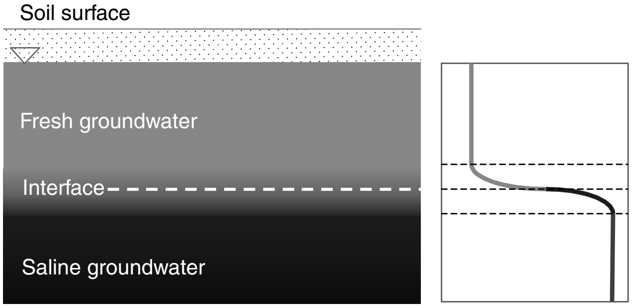
Muhammad Nadeem Asghar
International Water
Management Institute (IWMI)
Lahore, Pakistan

In several unconfined aquifers under irrigated agricultural areas, the groundwater system consists of a saturated porous medium containing miscible fluids (fresh groundwater and saline groundwater). The native groundwater is deep and saline because of the marine origin of the hydrogeologic formation. However, fresh groundwater lenses from deep percolation of the extensive water conveyance and distribution system, as well as from irrigation and rainfall, overlie this native saline groundwater.

According to Sufi et al. (1), over 20 BCM of fresh groundwater is being recharged annually in the Indus Basin of Pakistan.

The thickness of these fresh groundwater lenses varies from a few meters to more than 100 meters. For instance, in the Indus Basin of Pakistan, this is around 30 m thick in the lower or central parts of the *doabs* (area between two rivers), 60 m or more along the margins of the *doabs*, and approximately 150 m near the rivers and canals (2). When groundwater is extracted from these fresh groundwater lenses, it is called skimmed groundwater. Different types of irrigation wells are available for extracting this skimmed groundwater (3).

Under natural conditions, the saline groundwater tends to remain separate from the overlying fresh groundwater. However, when waterbodies of variable solute concentrations are in contact, molecular diffusion causes mixing across the line of contact. Due to groundwater and saline water movement, a zone of dispersion, which is also known as the interface, forms between these two fluids. This interface, which varies in thickness, is not static but responsive to recharge and discharge mechanisms. Thus, the processes of diffusion and dispersion result in a transition zone where the salinity gradually changes from completely fresh to fully saline.



Therefore, the use of irrigation wells for skimming fresh groundwater may cause mixing of the ‘interface’ either within the well or in the aquifer. As a result, the irrigation well starts supplying skimmed groundwater of marginal quality. Therefore, the decision regarding the use of skimmed groundwater must consider the quality of groundwater with depth, the local hydrogeologic conditions of the aquifer, the socioeconomics of skimming well installation and operation, the discharge rate, the duration of pumping, and above all, the tolerable limits of skimmed groundwater quality for its intended uses (4).

Farmers are using this skimmed groundwater to fill the gap between the supply and demand of surface water in the conjunctive water use environment of the Indus Basin of Pakistan (5). This irrigation water resource has emerged as a formidable poverty reduction tool. Potentially, skimmed groundwater is a huge resource of irrigation water. In the Indus Basin of Pakistan alone, it has been estimated that nearly 200 billion cubic meter (BCM) of fresh groundwater is lying above salty groundwater (6), and covers about 30% of the irrigated area of Pakistan.

SOIL MOISTURE MEASUREMENT—NEUTRON

Mukand Singh Babel
Asian Institute of Technology
Pathumthani, Thailand

The water (liquid and/or vapor phase) contained in the soil above the water table is called soil moisture. Soil moisture is a function of precipitation, soil texture, porosity, the rate of soil moisture uptake by plants, and the rate of evapotranspiration. Measurements of soil moisture are needed for several purposes, including irrigation planning and scheduling, agronomic studies, flow and transport processes in the unsaturated zone, and geotechnical investigations.

Soil moisture can be measured by direct and indirect methods. Direct methods are those wherein water is removed from a soil sample by evaporation, leaching, or chemical reaction, and the amount removed is determined. Indirect methods involve measuring some property of the soil that is affected by soil moisture content or measuring a property of some object placed in the soil, which comes to water equilibrium with the soil. The indirect methods generally require calibration. They are suitable for quick and repetitive measurements and do not require destructive sampling as needed in direct gravimetric methods (1).

Although a variety of indirect techniques are available for measuring soil moisture content, they are neither equivalent nor applicable in all situations. Thus, choosing a suitable method and following a well-defined procedure are important for obtaining reproducible and reliable information. Various *in situ* recording sensors, water budget models, and experimental approaches are used for soil moisture measurement, including neutron probe, time domain reflectometry, electromagnetic induction, electron resistivity tomography, tensiometers, heat dissipation sensors, and thermocouple psychrometers. Modern methods of soil moisture measurement such as airborne radar and satellite imagery are still at the research and development stage.

The neutron probe also called the "neutron moisture meter" is a nondestructive, indirect method commonly used for repetitive field measurement of soil water content volumetrically.

PRINCIPLE

The neutron probe is based on the principle of neutron thermalization. Hydrogen nuclei are nearly the same size and mass as neutrons and therefore, can scatter and slow neutrons. High-energy (0.1–10 Mev.), fast (1600 km/s) neutrons emitted from a radioactive source, such as americium–beryllium or radium–beryllium are slowed and changed in direction by elastic collisions with atomic nuclei of hydrogen atoms in soil. This process is called "thermalization," and the low-energy (about 0.03 eV) neutrons, after collision, are called "thermal/thermalized neutrons." The density of the thermal neutrons (thermal cloud of neutrons) depends on the soil–water content; the vast majority of hydrogen in soil is associated with water. Higher water content in soil leads to increased thermalization and, thus, a denser thermal cloud. A "slow neutron" detector is installed adjacent to the source (emitter) to measure the cloud density. The measurement is usually in the form of a "count ratio"; a higher count ratio denotes higher water content and vice versa. Thus, the density of thermal neutrons can be calibrated against the water content volumetric. (2).

THE EQUIPMENT

Figure 1 shows a typical neutron moisture meter. The equipment consists of

1. a neutron moisture depth probe containing a radioactive source that emits high-energy neutrons, and a detector of thermalized neutrons.
2. protective shielding (for gamma rays) of lead and polyethylene or paraffin for neutron absorption. The depth probe is stored within the shield when not in use.
3. a meter assembly that includes a pulse counter to register the counts generated by the thermal neutron detector, a built-in computer, a display screen, and a keyboard.
4. a thin-walled aluminum or plastic access tube. The tube diameter is recommended by manufacturers for optimized equipment performance.
5. a radioisotope license, radioisotope leak test kit, and radiation monitoring equipment, as required by the license.
6. calibration curves and parametric data for calibrating the computer of the equipment, if needed.

CALIBRATION OF EQUIPMENT

The sources of hydrogen other than water (the primary source of hydrogen) in a given soil are assumed constant and are accounted for during calibration. Similarly,

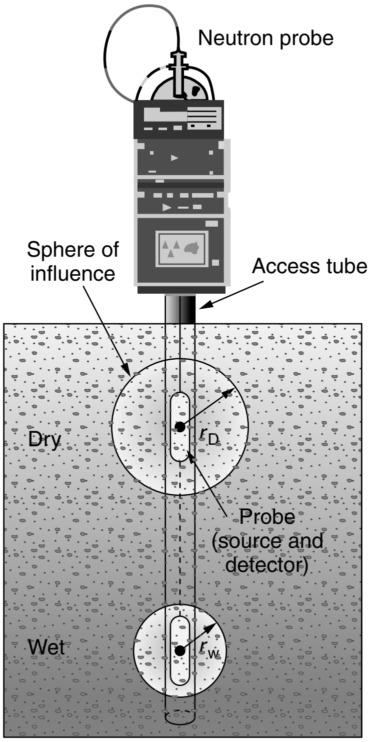

Figure 1. Neutron probe device. r_D and r_W are the radii of measurements in dry and wet soils (*Source*: Reference 3).

several nonhydrogen substances including C, Cd, B, Cl, and Li may be present in some soils and may also thermalize fast neutrons. However, their effect is compensated for through soil specific calibration. The neutron probe is calibrated by paired measurements of soil moisture content and neutron probe counts. Usually, the volumetric moisture content, θ_v is linearly related to the slow neutron count ratio (CR) as follows:

$$\theta_v = a + b(\mathrm{CR})$$

where CR is the ratio of slow neutron counts at a specific location in the soil and a standard count obtained with the probe in its shield. A calibration curve can be obtained with a sufficient number of measurements. This calibration curve is approximately the same for many soils. Figure 2 depicts a typical calibration curve.

The sphere of influence of neutrons around the radiation source varies with water content from about 0.15 m for wet soil (almost saturated) to more than 0.60 m for very dry soil, depending on how far fast neutrons must travel to collide with a requisite number of hydrogen nuclei. An approximate relationship for the radius of influence, r (in cm), as a function of soil water content is given by

$$r = 15(\theta_v)^{-1/3}$$

PROCEDURE

1. Use the soil auger to form a hole for installing the access tube. The access tube is left so as to protrude about 10 cm above the soil surface and is covered with an empty can or a stopper to keep water and debris from entering.
2. Place the probe unit over the access tube to make a measurement. Select an appropriate counting time, and make several standard counts while the probe is in the shield. This will correct for any electronic changes in the counting circuits.
3. Make one or more counts at each selected measurement depth.
4. Use the calibration curve to convert the count ratios to volumetric moisture content, or read the moisture content directly if the equipment has a built-in computer.

COMMENTS AND PRECAUTIONS

1. In regard to the radiation hazard of devices with radioactive sources, it is strongly recommended that the equipment be used according to the manufacturer's instructions, which must comply with safe procedures dictated by the radioactive source license.
2. Site-specific calibration may be required for a soil of unusual neutron-absorption properties or if the diameter or material of the access tube is different from the manufacturer's recommendations.
3. As the zone of measurement is spherical and at least greater than 0.15 m in radius, the probe depth increment in the access tube should not be less than

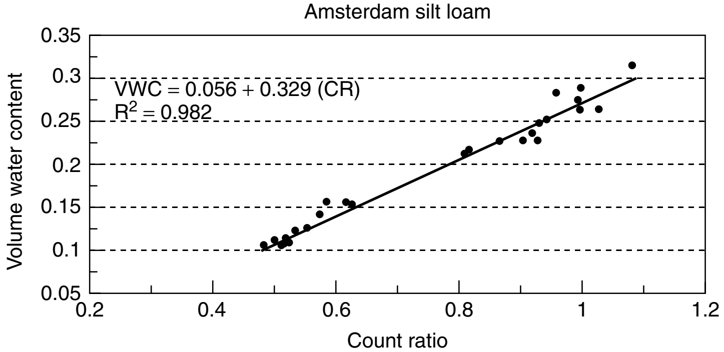

Figure 2. A neutron probe calibration relationship (*Source*: Reference 3).

0.15 m. The approach to the soil surface should be no closer than 0.15 m because a portion of the neutrons may escape from the soil.

ADVANTAGES AND DISADVANTAGES

The neutron probe moisture meter has several advantages:

1. It is a widely accepted method of soil moisture measurement with highly reproducible results.
2. After initial tube installation, no further monitoring is required.
3. Both horizontal and vertical installation are possible.
4. It can measure soil water content at multiple depths and locations.
5. It is possible to couple the equipment with other devices.
6. The equipment produces reliable results for a long period.

Following are the disadvantages of the equipment:

1. It contains a source of radioactivity and, therefore, cannot be automated. It may also pose a health risk if adequate precautions are not taken.
2. The equipment is expensive and requires calibration.
3. It has relatively limited spatial resolution of measurement.

SOIL N MANAGEMENT IMPACT ON THE QUALITY OF SURFACE AND SUBSURFACE WATER

Dibyendu Sarkar
Vandana Vandanapu
Rupali Datta
University of Texas at San Antonio
San Antonio, Texas

Nitrogen (N) in the forms of nitrate or ammonium is a nutrient needed for plant growth. When the amount of soil-supplied N is considered deficient for satisfactory crop yields, N fertilizer is added to supplement the soil-supplied N. If N is supplied in excess of crop needs, a surplus is created that can cause significant water quality problems. Until recently, the main reason for investigations into the forms of N in soil systems below the rooting depth of plants was to evaluate the loss of nitrate to crops and to estimate the loss of production. In recent years, much attention has been focused on forms of N as potential pollutant sources of both groundwater and surface water. Nitrate concentrations above a certain level in drinking water may have critical health effects on animals and human infants. Alternately, N can also contribute to surface water contamination via surface water runoff and erosion. Excessive nitrate concentrations in surface water bodies, such as streams or lakes, can accelerate algae and plant growth, resulting in oxygen depletion. Nitrogen must be managed properly to protect water quality. Best management practices (BMPs) are methods that are the most effective, practical means of preventing or reducing nutrient pollution from nonpoint sources. Nitrogen BMPs primarily involve a change in fertilizer management practices, such as changing the timing, placement method, and/or the amount of fertilizer applied to reduce the possibilities of contaminating water resources. In addition, conservation tillage practices, cover crops, and crop rotation all help reduce surface runoff, erosion, and leaching of soil N. It is imperative to continue the development and implementation of new and effective management practices that increase N recovery and reduce potential N losses to the environment.

INTRODUCTION

Nitrogen is one of the most abundant elements on earth. It exhibits a number of oxidation states and combines with a number of other elements to form organic and inorganic compounds (1). Nitrogen accounts for 78% of the earth's atmosphere as elemental nitrogen (N_2) gas (2). However, the majority of the earth's N (98%) is in rock, sediment, and soils. The amount of N in rocks is about fifty times more than that in the atmosphere (3). For mineral soils in the United States, the approximate range of total N content in the surface six inches is 0.02% to 0.50% (4). Growing plants, animals, and microbial populations need a continual source of N. It is an essential component of the proteins that build cell material and plant tissue. In addition, it is necessary for the function of other biochemical agents, including chlorophyll (which makes photosynthesis possible), enzymes (which help organisms carry out biochemical processes and assimilate nutrients, and nucleic acids such as DNA and RNA which are involved in reproduction) (5). Of all the major plant nutrients, N is often the most important determinant of plant growth and crop yield. Without adequate N, plant growth is restricted. Characteristic symptoms of N deficiency in plants include yellowing and death of leaves and stunted growth. Just as too little N can cause problems, too much N can also cause problems. These problems can extend to plants, humans, animals, and the environment. The problems posed to the environment occur when excess N in soils is carried away with surface runoff to lakes, rivers, groundwater, and other aquatic ecosystems. Excess N in rivers, lakes, and groundwater can be toxic to humans and causes water quality problems in natural water systems (6). Nitrogen, particularly as nitrate, is the most common contaminant in aquifer systems (7). Hallberg (8) points to agriculture as the most substantial anthropogenic source of nitrate, and Keeney (9) suggests that this is caused by intensive and extensive land use for crop and animal production. The United States Environmental Protection Agency (USEPA) has identified eutrophication as the main problem in U.S. surface waters that have impaired water quality (10). Excessive amounts of nutrients, especially N and phosphorus (P), speed up eutrophication (11). Excess N in the estuaries of the oceans enhances the growth of aquatic organisms to the point that they affect water quality and lower dissolved oxygen levels (12–14). This affects the metabolism and growth of oxygen requiring species, causing hypoxia (12,13). Implementation of N-BMPs (best management practices) allows efficient, profitable production and minimizes N movement to surface water and groundwater. This article addresses the concept of N movement in soils and the impacts of N management on surface and subsurface water quality.

SOURCES OF NITROGEN IN THE ENVIRONMENT

Atmosphere

The earth's atmosphere is made up of 78% N as a colorless, odorless, nontoxic gas. The same N_2 gas found in the atmosphere can be found in spaces between soil particles. However, plants cannot use this form of N (15). A group of microbes (*Rhizobium* bacteria) that naturally exists in the soil converts N to ammonium. In *biological fixation*, nodule-forming *Rhizobium* bacteria inhabit the roots of leguminous plants and through a symbiotic relationship, convert atmospheric N_2 to a form the plant can use (16).

Atmospheric fixation occurs during lightning storms. The enormous energy of lightning breaks down N_2 molecules and enables their atoms to combine with oxygen in the air to form nitrogen oxides. These dissolve in rain forming nitrates that are carried to the earth. Atmospheric N fixation probably contributes some 5–8% of the total N fixed (5).

The large amount of fossil fuels used to produce electricity and in manufacturing industries oxidizes N because the intense heat given off by their combustion causes the molecules to react with each other, thereby adding N to the air as nitrates. These nitrates fall to the earth during precipitation, adding more N to the soil (17).

Animal Manure

Animal manures are important sources of N in the terrestrial environment. Manure usually contains both organic and inorganic N forms. The amount of N in manure depends on the animal's species, age, diet, and bedding materials. Ammonium N is the primary inorganic form in manure and is readily available to crops. Organic N becomes available to plants as manure decomposes; 20 to 50% of organic N is available to the first crop after application. Much of the remaining organic N becomes available in subsequent years as mineralization continues (18).

Legumes

Leguminous crops, such as alfalfa, beans, and peas, generally do not require N fertilization because the *Rhizobium* bacteria living on their roots take N from the air and convert it to forms that plants can use. Legumes provide some of the N for their own growth and often build up a supply that can be used by crops that follow (19).

Commercial Fertilizers

Commercial fertilizers are derived from the atmospheric N pool. Industrial processes used to manufacture commercial fertilizers usually combine atmospheric N with hydrogen and/or oxygen and/or carbon and then convert the products to various N fertilizers such as ammonium nitrate, anhydrous ammonia, and urea (4). These fertilizers are generally applied directly to soils.

Crop Residues

Crop residues returned to the soil are important sources of N for succeeding crops if they are properly managed (20). Nitrogen exists in crop residues in complex organic forms; the residues are decayed by soil microbes, thereby converting N and other nutrients to inorganic forms, which then become available for plant uptake (16).

Organic Soil Matter

Organic soil matter is a major source of N in terrestrial ecosystems. Organic matter is composed primarily of a relatively stable material called humus. Even though the soil has a large pool of N stored in soil humus, this N is mostly insoluble and is not available for plant uptake. Organic N must be mineralized to inorganic forms by soil microbes before plant uptake can occur.

FORMS OF NITROGEN IN SOILS

Nitrogen in soils is found in organic and inorganic forms, both of which are important sources of N for plant and microbial uptake. Organic N occurs in crop residues and organic matter as protein compounds, amino acids, amino sugars, and complex, largely unidentified substances (4). More than 90% of all soil N exists as organic N, and for the most part, is not available for plant uptake. Natural biological processes carried out by microorganisms in soil convert organic N to inorganic forms, which plants can use (15). Inorganic N exists in soil primarily in three forms: elemental N, ammonium N (NH_4^+) and nitrate N (NO_3^-). Ammonium N and nitrate N are two forms of soil N that can be readily used by plants, whereas elemental N cannot be used directly by plants. However, some N-fixing bacteria, particularly *Rhizobium* that coexists with leguminous plants, use N in the air (elemental N) and converts it in to a form of N that can be used by plants.

NITROGEN LOSSES FROM SOILS

Nitrogen is lost from soil in several ways: leaching, denitrification, volatilization, soil erosion and runoff, and crop removal.

Leaching

Leaching is the loss of soluble N. The NO_3^- ion is negatively charged and is not attracted to soil's clay and humus, which are also negatively charged. So it stays in the water between soil particles. As water moves through soil, the nitrate in the soil solution moves along with the water (21). This loss most frequently occurs in areas of heavy rainfall, under excessive irrigation, and in coarsely textured soils.

Denitrification

Denitrification is the conversion of NO_3^- molecules to gaseous forms that are lost to the environment. When there is a deficit of oxygen in the soil (i.e., under anaerobic conditions), certain bacteria meet their energy needs by reducing NO_3^- to dinitrogen gas or to nitrogen oxide (N_2O). These gases are released to the atmosphere, resulting in a loss of N from soil (22). Denitrification can be significant when soils are saturated with water.

Volatilization

Volatilization is the loss of N from the soil as ammonia (NH_3) gas. NH_3 volatilization commonly takes place when N is in an organic form called urea. Urea may originate from animal manure, fertilizers and, to a lesser degree, from the decay of plant materials. Urea is converted to ammonium carbonate by urease, an enzyme found in soils. Ammonium carbonate easily dissociates to ammonium and carbonate ions. The carbonate ions result in a relatively short-lived increase in soil pH. Ammonium ions convert at high pH to NH_3 gas, which may escape to the air (23). This results in a net loss of N from the soil system.

Surface Runoff and Soil Erosion:

Surface runoff and soil erosion can also cause significant losses of soil N. Runoff and erosion losses include both inorganic and organic N. Erosion leads to the removal of organic N in the upper soil profile (24) and NH_4^+ N, which is adsorbed to soil particles (25). Nitrate N is water soluble and is generally not adsorbed to soil particles; hence, it quickly moves off the soil surface as runoff with increased rainfall.

Crop Removal/Harvest

Substantial amounts of N are lost from soil through crop removal (16). When crops are harvested, the N source is removed. Crop removal accounts for a major portion of the N that leaves the soil system.

HUMAN HEALTH AND WATER QUALITY CONCERNS RELATED TO LOADINGS OF N INTO SURFACE AND GROUNDWATER

Nitrogen is the one element of most concern as it relates to water quality. Although N can be found in many forms in the soil, the nitrate form primarily affects water quality (15). The contamination of surface water or groundwater by NO_3^- N presents a potential health threat to human population. High NO_3^- N levels in water are a concern because the ingestion of such water can reduce the oxygen carrying capacity of the blood. Nitrate is reduced to NO_2^-, which oxidizes the Fe of the hemoglobin in the blood, and methemoglobin, which cannot carry oxygen, is formed (9). Infants have greater potential than adults to suffer these ill effects. In the United States, the maximum NO_3^- N level for potable water has been set at 10 mg/L (26). Secondary and related deleterious effects of exposure to NO_3^- include increased respiratory infections, inhibition of iodine uptake by the thyroid, and possible reproductive problems (27).

Another area of concern is the toxic effect of ammonia (NH_3) on freshwater aquatic life (28). It has been known since the early 1900s that NH_3 is toxic to fish and that this effect varies with water pH and temperature. A concentration of 0.02 mg/L as unionized NH_3 is the current limit in freshwater in the United States (29).

The most significant water quality concern with respect to N is the overenrichment or eutrophication of surface waters. Nitrates stimulate the growth of algae and other plankton, which provide food for higher organisms; however, excess NO_3^- N can cause over production of plankton. As these planktons die and decompose, they use up the oxygen dissolved in water, which causes an oxygen shortage for other aquatic organisms. Elevated N concentrations have altered natural aquatic floral and faunal population dynamics, exacerbated occurrences of hypoxia and anoxia, and sped eutrophication in the Gulf of Mexico (12,30).

NITROGEN BEST MANAGEMENT PRACTICES: IMPACT ON SURFACE AND GROUNDWATER QUALITY

Nitrogen from fertilizers as well as from other sources (e.g., biosolids, animal manures) has a direct impact on water quality. The primary goal of N best management practices (N-BMPs) is to manage N inputs to crop production to prevent degradation of water resources while maintaining profitability. Typically, BMPs are farming methods that assure optimum plant growth and minimize adverse environmental effects (31). By putting N-BMPs into practice, N losses from agricultural soils can be controlled. There are many BMPs currently in use; some of the more popular soil N management practices and their potential effects on surface and subsurface water quality have been categorized by Owens (32) as follows.

Crop Management

Cover Crops. The use of cover crops in cropping systems provides several benefits. However, only in recent years has much of the attention been focused on their potential to reduce NO_3^- leaching losses (32). The key to reducing NO_3^- N losses is to keep soil nitrate concentrations low during periods of high leaching potential. Nitrate can leach to groundwater when the soil contains significant NO_3^- N and when water percolates below the root zone. These conditions often exist during the winter months, when percolation of winter rainfall can be high and uptake of water and nitrate by plants is minimal (33).

Cover crops influence nitrate leaching in two ways: water budget effects and N uptake effects. Cover crops can influence the water budget by reducing the water content of the soil during their active growth stage (33,34). In humid climates, this water usage can reduce nitrate leaching significantly. Cover crops function by accumulating the inorganic soil N between main crop seasons and by holding it in an organic form, thus preventing it from leaching. Nonleguminous cover crops can immobile as much as 70% of the available NO_3^- N in the upper soil profile (35). Generally, nonlegumes are about three times more efficient than legumes in reducing nitrate leaching (36). Meisinger et al. (33) reported that cover crops reduced both the mass of N leached and the NO_3^--N concentration of leachate by 20–80% compared to no cover crop control. They also determined that grasses and *Brassicas* were two to three times more effective than legumes in reducing NO_3^--N leaching. Because, grasses and grains become quickly established in the fall and develop an extensive root system, they are more efficient than legumes in capturing soil nitrate and preventing late fall and winter leaching to groundwater (35,37). In a western Oregon study of nitrate movement in the soil profile following harvest of a broccoli crop fertilized with 250 lb N/acre, Hemphill and Hart (38) demonstrated the effectiveness of a fall-planted rye cover crop in reducing the movement of soil nitrate to the soil profile. Areas with cover crop contained 0.18 mg/kg nitrate at 30–40 inches of soil depth compared to 5.38 mg/kg nitrate at the same depth where no cover crop was grown.

Controlling erosion is an important component of surface water quality protection. Cover crops protect against soil erosion (39,40). Cover crops can be effective in reducing runoff and erosion, especially during the winter when there is little crop residue (32). Farmland is most susceptible to erosion when there is no vegetative ground cover or plant residue on the soil surface. Cover crops provide vegetative cover when a crop is not present to cushion the force of falling raindrops, which otherwise would detach soil particles and make them more prone to erosion. The rate of runoff is also slowed, thus improving moisture infiltration into the soil (41). When legumes are used as the winter cover crop, fixed N in the legumes can be supplied to the subsequent crop so that less fertilizer N has to be applied. This reduces the amount of inorganic N, which is readily available for removal in surface runoff (32).

Crop Rotations. Understanding the relationship between N and crop rotation is very important in N management decisions (42). Although there are several benefits to crop rotations (e.g., lower fertilizer N input because of residual N from legumes, erosion reduction, minimization of crop diseases, reduction in insect problems), relatively little attention has been given to impacts of NO_3^- N leaching by most crop sequences (32). Proper crop sequencing can sometimes be used to improve fertilizer-N efficiency and reduce nitrate leaching. Johnson et al. (43) showed that unfertilized soybeans scavenge large quantities of residual N fertilizer from a previous corn crop. Monocultures of crops, such as corn, winter wheat, and sorghum, require high N input. It is possible to reduce N use in a farming system by rotating these crops with small grains, which require less N, or with legumes, which may require no added N. This type of crop diversification should result in less N in the soil profile and, in general, less leaching.

The combination of crops grown in a rotation also affects the potential for groundwater contamination by N. For example, less N moves beyond the rooting zone with a corn–soybean rotation compared to continuous corn (44). Including perennial legumes or non leguminous crops in rotations also decreases NO_3^--N losses. Baker and Melvin (45) found much lower NO_3^--N concentrations beneath alfalfa than for corn or soybean.

The key to successful erosion control with crop rotations is soil cover. Fallow land has the highest erosion potential in any cropping system. Crop rotations that include small grains or other cover crops create a vegetative cover, which protects the soil surface from erosion (46). Grasses and legumes or small grains provide more protection against water erosion than row crops (47). Cropping systems with a higher frequency of sod reduce soil erosion. Growing cover crops with low residue crops and rotating high residue crops with low residue crops are also effective erosion control practices. Some crop rotations do not reduce erosion unless other practices, such as cover crops and residue management are followed (48). Crop rotations that use the land more intensively, such as corn, wheat, and soybeans grown in 2 years, produce larger amounts of biomass during the rotation and are more effective in reducing erosion than a continuous cropping sequence (49).

Tillage Practices. Soil erosion and runoff contribute to the degradation of surface water quality. Tillage management is an important factor to be considered when attempting to reduce soil erosion and subsequent sedimentation (50). Tillage practices that leave the soil surface unprotected greatly increase the potential for runoff, erosion, and nutrient losses from fields (44). Conventional tillage buries the protective crop residue cover and disturbs the soil structure; increased rainfall may then lead to amplified runoff and erosion (51). Conservation tillage practices, which reduce runoff and erosion, reduce N losses (52–54). Such practices leave greater amounts of crop residue and cause less soil disturbance. Both factors help reduce runoff and erosion, reduce transport of soluble and sediment-attached chemicals, and promote infiltration (55). Baker and Laflen (56) concluded that conservation tillage should reduce soil erosion by 75–90% (depending on the amount of surface residue) compared to conventional tillage. Conservation tillage also increases infiltration and reduces average annual runoff volumes by about 25% compared to conventional tillage (57). The majority of the N in surface runoff is associated with sediments, so conservation tillage usually results in a net decrease in N losses.

Several of the factors that reduce surface runoff promote an increase in subsurface flow (32). Conventional tillage disrupts surface soil structures, destroying macropores in the tilled layer. It also enhances the mineralization of organic N from crop residues and soils and increases the accumulation of residual NO_3^- N. In recent years, technological innovations have led to reduced levels of tillage in many areas. This trend seems to protect groundwater in some areas because of reduced N mineralization and increased N immobilization (44). The effect of tillage on macropores and the flow of water and chemicals through macropores are important (58–60). However, using conservation tillage, macropores remain intact from the soil surface to their full depth in the soil profile (61–63). Macropores potentially increase the amount of water entering the soil; this increase in infiltration leads to more leaching. Tillage has both advantages and disadvantages with respect to groundwater; information from studies on local soils should be used to determine if conservation tillage would have positive or negative impacts on subsurface water quality.

Fertilizer Management

Nitrogen Rate. The one most important practice affecting the N contribution to groundwater is the rate of N application (64). Excessive application of N fertilizer increases the likelihood that N is leached into surface water and groundwater (47). The amount of N from other sources should be given appropriate credit to avoid excess fertilizer N. The soil can supply N to plants as mineral N, usually NO_3^- N, and as N mineralized from organic matter. There can be substantial overwinter carryover of residual NO_3^- (65), which would allow reducing of subsequent N fertilizer applications.

Nitrogen rate recommendations also include credits for N fixed by legumes. Winter leguminous cover crops and legumes in rotation can provide a significant amount of N for a subsequent nonleguminous crop (66–68). Some legumes can provide as much as 120 kg N/ha, which shows strongly that credit needs to be given for legume N to reduce excessive N fertilizer applications (32). Similarly, N application rates can be significantly adjusted to account for manure application. By failing to account for these sources of N in determining the correct application rate, a surplus of N may be created; this surplus may leach to groundwater (69).

Similarly, N credits need to be given for manure applications. Recent reports of long-term manure applications indicate that high rates of application can pose a hazard for NO_3^--N contamination in groundwater (32).

Fertilizer Placement. Correct fertilizer placement is a BMP that can help protect both surface and groundwater quality from nutrient pollution. The two most often used fertilizer placement strategies are banding and broadcast placement (70).

The efficiency of N fertilizer is generally increased by band placement that provides many agronomic and environmental advantages over broadcast applications (71). Banding causes an increase in plant N use efficiency. High crop-use efficiency leaves less N in the soil to leach into groundwater (70). Banding of N below or with the seed is by far the best N-BMP to protect surface water quality because no N is left on the soil surface for erosional loss. A broadcast-incorporated application leaves a portion of the N fertilizer on or near the soil (70). A study in Montana found that spring wheat yields are approximately 6% higher when urea was banded 1 inch below the seed and between rows compared to broadcast (72).

Fertilizer Timing. The timing of N fertilizer application is an important factor that affects the efficiency of fertilizer N because the interval between application and crop uptake determines the length of exposure of fertilizer N to loss processes, such as leaching and denitrification. Timing N applications to reduce the chance of N losses through these processes can increase the efficiency of fertilizer N use (21).

Fertilizer applied in the fall causes groundwater degradation. Fertilizer-N applications should be managed very carefully on sandy or gravelly soils due to the high potential for leaching. Fall applications are not recommended on these types of soils (44). Fall applications of anhydrous NH_3 or urea on finer textured soils should be delayed until soil temperature reaches 45 °F or less when conversion to NO_3^- is slow, hence, the potential for NO_3^--N leaching losses is reduced. Split application of N fertilizers as opposed to a single application can reduce potential N losses by up to 30% and thereby reduce groundwater contamination (73).

Organic Wastes. Animal manure is a good source of N. It benefits plant growth, improves soil structure, and provides nutrients. However, manure can become an environmental problem when it pollutes groundwater and surface water as a result of improper handling, storage, and application on erosion-prone soils (74). This is primarily due to the particulate nature of the material compared to the more soluble forms of N in inorganic fertilizers (44).

The other major concern with manure is the movement of NO_3^- N to groundwater. Manure contains mostly organic and NH_4^+ N. These forms of N do not move through soils. However, soil microorganisms can convert these compounds to soluble NO_3^- N that may leach to groundwater. Nitrogen not mineralized in the first year after application of manure generally becomes part of the soil organic matter and releases N relatively slowly. Constant annual manure applications that supply N to meet the entire crop demand ultimately cause excessive fertilization. Potential pollution problems resulted when manure was applied on a long-term basis at recommended rates (475 kg/N ha) in Alberta, Canada (75).

To use manures efficiently as a nutrient source for crop production, the spread pattern must be uniform throughout the field (76). Nonuniform applications of manure result in improper nutrient crediting and can increase the possibility of overfertilization, which threatens groundwater and surface water quality (77). Manure should be applied when crops have the highest need for nutrients. The quicker the nutrients are used, the less the chances of pollution due to runoff into surface watercourses or leaching into groundwater sources.

Manure should be stored in properly designed facilities that are protected from excessive runoff, flooding, or overflow that would allow contamination of surface water. Injecting manure is especially important in preventing contamination of surface water supplies. Injection methods place liquid manure below the soil surface, thus eliminating surface runoff on sloping soils and volatilization of ammonia from the manure on all soils (76).

FUTURE DIRECTIONS

As Owens (32) points out, much is known about using N for efficient crop production and minimizing its adverse impacts on surface and subsurface water quality. Nevertheless, there are areas where further knowledge is needed to fill in the gaps and to improve upon what is already known. Following Owens (32), the areas mentioned here demand particular attention in research:

- *Subsurface water quality*: Much of the reported research in this area has been conducted with soil columns and lysimeters. There is need for more groundwater quality research on a field or watershed scale. A systems approach, in which existing knowledge is harnessed into quantitative, explanatory models, is more attractive and acceptable.
- *Urban use*: Fertilization of lawns and turf areas and the subsequent impacts on groundwater quality need more regulatory attention. In many states, there is no environmental law protecting water resources from overfertilization of privately owned lawn or gardens, although according to a Gallup poll, 22 million U.S. homeowners spent more than $14.6 billion on professional landscape/lawn care/tree care services in 1997. Research on this aspect of N management has been limited and needs to be revisited as a potential major source of N pollution.
- *Soil N Availability Tests*: Crops are probably more deficient in N than in any other element, and yet there are no widely accepted methods of testing soils other than testing for residual NO_3^- N and NH_4^+ N (78). Considerable attention needs to be directed toward developing soil tests that provide an accurate in-season assessment of N need for a crop, yet take into account variation in soil types and kinds of crop while recommending fertilizer N needs.
- *Education*: Knowledge about N fertilizer efficiency and techniques for minimizing nitrate leaching are available but are not consistently used. The real value of continued research will be the adaptation and implementation of these technologies, which require a major educational/outreach effort.

SOIL PHOSPHORUS AVAILABILITY AND ITS IMPACT ON SURFACE WATER QUALITY

Dibyendu Sarkar
University of Texas at San Antonio
San Antonio, Texas

Phosphorus (P) is ubiquitous in soils and is an essential element for plant and animal growth. Without enough soil P, crop yields will be low. However, excess soil P may become a part of surface runoff and can accelerate eutrophication of receiving fresh waters. Eutrophication has been identified as the main problem in U.S. surface waters that has impaired water quality. Although P and nitrogen (N) both influence eutrophication, P is generally the limiting nutrient in freshwater bodies. The degree of P input in surface waters depends on the soil availability of P and the degree of transport of dissolved and particulate P, especially in agricultural lands that have been fertilized for a long period of time. The availability of P in soils is controlled by various factors, such as soil pH, clay content, soil organic matter, amorphous Fe/Al oxide and carbonate content, soil moisture content, and degree of soil compaction. The amount of available P is generally estimated by a variety of soil-test methods, including both chemical extractants and nondestructive techniques simulating plant root action. Phosphorus transport from the source to surface waters is controlled by the rate of erosion and surface runoff. Hence, reducing P loss in agricultural runoff may be brought about by implementing proper source and transport control strategies. Popular source control techniques include soil P management, estimating thresholds for environmental risk assessment, manure management, and refining feed rations, common transport management techniques include conservation practices such as reduced tillage, cover crops, and buffer strips in critical areas of P export from a watershed.

Phosphorus makes up about 0.12% of the earth's crust. It forms complex compounds with a wide variety of elements—about 150 minerals are known that contain at least 0.44% P (1). Phosphorus is ubiquitous in soils. It is found naturally in all soils (1) and ranges between less than 0.04% in the sandy soils of the Atlantic and Gulf coastal plains to more than 0.3% in the soils of the northwestern United States (2). Phosphorus is an essential element for plant and animal growth. Its input has long been recognized as necessary to maintain profitable crop and livestock production (3). Without enough soil phosphorus, crop yields will be low (4). However, many soils in the United States reportedly contain P well in excess of crop needs, which may enter lakes and streams in runoff from landscapes that drain to surface water bodies. Sources of P contamination of surface waters are numerous and include both nonpoint and point sources, such as agriculture, municipal sewage treatment plants, individual septic treatment systems, decaying plant material, runoff from urban areas and construction sites, stream bank erosion, and wildlife (5). Drainage of P-rich runoff to surface water bodies may increase their biological productivity by accelerating eutrophication, the natural aging of lakes or streams brought on by nutrient enrichment. The United States Environmental Protection Agency (USEPA) has identified eutrophication as the main problem in U.S. surface waters that have impaired water quality (6). Because it causes increased growth of undesirable algae and aquatic weeds, as well as oxygen shortages, eutrophication restricts water use for fisheries, recreation, industry, and drinking (7). In addition, associated periodic surface blooms of cyanobacteria (blue-green algae) occur in eutrophic drinking water supplies and may pose a serious health hazard to livestock and humans. Although eutrophication is a natural process, it can be hastened by changes in the land use of a watershed that increase the amount of nutrients added to an aquatic system (7). Recent outbreaks of the dinoflagellate *Pfiesteria piscicida* in the eastern United States, most notably in the Chesapeake Bay, have been linked to high nutrient levels in affected waters (3). Nitrogen (N) and P both influence eutrophication, but P is the critical element in most freshwaters (7). Due to low natural levels of P, biological productivity in surface waters is usually limited by P availability (5). The identification of P as a major cause of eutrophication in surface waters led to early emphasis on point sources delivering P to surface waters, for example, sewage systems delivering P-enriched wastewater. According to the National Research Council (8), overall trends show about equal numbers of U.S. rivers that have increasing and decreasing P loads. In general, the decreases are linked to point-source reductions, and the increases are linked to nonpoint source increases that result from increased agricultural land use (9). This review will address the concept of soil availability of P in agricultural lands and the relationship between P availability, P transport, and surface water eutrophication. Popular practices for P management will also be discussed.

PHOSPHORUS IN SOILS

The total P content of most surface soils is low, averaging only 0.6%. This compares to an average soil content of 0.14% N and 0.83% potassium (K) (2). In most soils, the P content of surface horizons is greater than that of the subsoil. Except in special situations, added P tends to be fixed by the soils where it is applied and allows little movement down through the soil profile (7). In addition, P is cycled from roots to aboveground parts of the plant and redeposited in crop residues on the soil surface. This builds up organic material and stimulates biological activity in surface layers. In reduced tillage systems, fertilizers and manures are incorporated only to shallow depths, thereby exacerbating P buildup in the top 5 inches of soil (7).

Many factors influence the P content of soil. Among these are (1) the type of parent material from which the soil is derived, (2) the degree of weathering, and (3) climatic conditions. Among other factors influencing soil P levels are the rates of crop removal, erosion, and P fertilization (2).

There are two primary forms of P in soil systems—organic and inorganic. The organic form of P in many soils represents more than half of the total P. Organic P has three different sink/sources (10), namely nucleic acids (e.g., guanine, adenine, thymine, uracil), phosphate esters of inositate (e.g., phytin), and phospholipids (e.g., lecithin). Biological processes in the soil, such as microbial activity, tend to control the mineralization of organic P. Mineralization is the breakdown or conversion of organic P to inorganic solution P (7). The inorganic form of P in soils (orthophosphates) exist in various forms: (1) oxide–phosphate complexes, such as clay mineral edge-P complexes, and (2) minerals of apatite (Ca phosphates), Mn phosphates, Fe phosphates, Al phosphates, and to a lesser degree, pyrophosphate (10).

AVAILABILITY OF SOIL PHOSPHORUS

Loosely defined, P availability refers to the amount of soil P that is readily available for uptake by plants. If the amount of available P exceeds plant needs, the excess P may become available for drainage to surface water bodies as part of the surface runoff, thereby degrading surface water quality. As a rule of thumb, soluble P is considered the most available. However, the solubility of many inorganic P compounds, as well as organic P, is generally low, and only small amounts of soil P are in solution at any one time. In fact, most soils contain less than a 1 lb acre^{-1} of soluble P (2). Soluble P in soils, either from fertilizer or natural weathering, reacts with clay, iron, and aluminum compounds in the soil and is converted to less mobile (hence, less “available”) forms by the process of P fixation. Because of the fixation processes (e.g., sorption and precipitation), P moves very little in most soils, stays close to its place of application, and crops seldom absorb more than 20% of fertilizer P during the first cropping system after application. This fixed, residual P remains in the rooting zone and becomes slowly available to succeeding crops (2).

Factors Controlling Availability of Soil Phosphorus

Soil P availability is influenced by the following factors (2):

- *Soil pH*: Soil pH affects both adsorption and precipitation of phosphorus. Precipitation of P as slightly soluble Ca phosphates occurs in calcareous soils whose pH values are around 8.0. Under acidic conditions, P is precipitated as Fe or Al phosphates that have low solubility. From a precipitation standpoint, the maximum availability of P generally occurs in the pH range of 6.0 to 7.0 (2). As a typical oxyanion, phosphate tends to be adsorbed more at lower pH than at higher pH. Hence, P generally tends to be more available in high pH soils, unless precipitated as low-solubility basic salts. Amorphous Fe and Al oxides that have high specific surface strongly adsorb P in soil systems (11).

- *Soil Organic Matter*: High amounts of organic matter in soils promote mineralization of organic P, thereby providing available P for plant growth. Organic matter also acts as a chelating agent, thereby preventing the formation of insoluble iron phosphates. Application of organic materials such as manure, plant residues, or green manure to soils that have high pH values increases the availability potential of mineral forms of P in the soil (2).
- *Clay Content*: Fine-textured soils such as clay and clay loams have greater P-fixing capacity than coarse-textured sandy soils. Among soils of similar clay mineralogy, P fixation increases as clay content increases and crystallinity decreases (12). Among clay minerals, 1:1 type clays (kaolinite) have greater P-fixing capacity than 2:1 type clays (e.g., montmorillonite, illite). Soils formed under high rainfall and high temperatures generally contain large amounts of kaolinitic clays and therefore have relatively lower soil P availability.
- *Soil Aging*: Fixation of soil P increases with time of contact between soluble P and soil particles. Consequently, more efficient use of fertilizer P is generally obtained by applying the fertilizer shortly before planting the crop (2). As soil ages, the possibility that P binds to soil particles increases, thereby decreasing its potential availability.
- *Soil Compaction and Soil Moisture*: Soil compaction reduces the soils oxygen supply and decreases the ability of plant roots to absorb soil P. Compaction reduces aeration and pore space in the root zone. This reduces P uptake and plant growth. Compaction also decreases the soil volume that plant roots penetrate and limits their access to soil P. Many studies have been conducted on the effect of soil moisture on P availability and response to applied P (13). Power et al. (14) reported that 53% of the variation in the fertilizer response of spring wheat on medium P soils resulted from variation in soil moisture. MacKay and Barber (15) showed that P availability decreased at soil moisture contents above and below field capacity because of the effects on both P diffusion and root growth rates. Uptake of P by corn dropped more than total plant weight when soil moisture was decreased below field capacity, indicating that the decrease in uptake was not likely due only to decreased demand.

In addition to the factors discussed before, several other factors define soil P availability (13). These factors include, but are not limited to soil solution P concentration, the amount of solid phase P that can enter the soil solution, the dissolution/desorption rate, the diffusion rate, Fe content, carbonate content, carbonate specific surface area, and organic P content (16–19).

Phosphorus Availability Indices

To evaluate P availability in soils, numerous soil tests have been developed that extract varying amounts of P, depending on the types of extractants used. The extractants can be generally classified into several categories (20):

- Water or unbuffered salt solutions (e.g., $CaCl_2$).
- Dilute concentrations of weak acids (e.g., lactate, acetate) with or without a complexing agent (e.g., F^-, EDTA).
- Dilute concentrations of strong acids (e.g., HCl, H_2SO_4) with or without a complexing agent (e.g., F^-, lactate, EDTA).
- Buffered alkaline solutions (e.g., $NaHCO_3$, NH_4HCO_3) with or without a complexing agent (e.g., EDTA).
- Anion exchange resin or iron oxide impregnated filter paper strips.
- Isotopic exchange with ^{32}P.

Water derives readily soluble P; unbuffered/neutral salt solutions derive easily exchangeable P (21). Dilute strong acid solutions solublilize Ca-P, Al-P, and to a lesser extent, Fe-P (22). Complexing agents are generally introduced to prevent readsorption of P by Fe oxides (20). Anion exchange resins and iron oxide impregnated filter papers (nondestructive to soil components in contrast to chemical extractants) function as sinks that simulate the action of plant roots by continuously removing dissolved P from the soil solution. The quantity of P that is isotopically exchangeable within a specified time interval gives an estimate of labile (hence, available) soil P (20).

Criteria for a suitable soil test have been detailed in several reports (13). Thomas and Peaslee (23) felt that the extract should (1) remove a reproducible and consistent proportion of the soil's available P and (2) reflect the extent and nature of reactions between soil and added P. Barrow (24) also felt that a soil test was an integration of several factors affecting soil P status (e.g., soil P buffering capacity, P quantity, soil P reaction time) into one numerical value. Kamprath and Watson (25) noted that (1) the extractant should extract a proportionate fraction of available P from soils that differ in other properties, (2) the procedure should work with reasonable accuracy and speed, and (3) the soil test P value determined should be correlatable with P uptake. On the basis of the major soil types and their properties, various states in the United States have adopted different soil test methods to predict available P. A field rating system, the "P index," has been developed to assess the potential for soil P to contribute to surface water pollution (26).

TRANSPORT OF SOIL PHOSPHORUS

Phosphorus enters lakes and streams in runoff from landscapes that drain to those surface water bodies (5).

The eutrophication process is clearly accelerated by the addition of P to surface waters. All forms of P (soluble, adsorbed, precipitated, and organic) are susceptible to transport from source soils to water bodies. Transport of soil P occurs primarily through surface flow, although the background levels of P entering streams and lakes via subsurface flow certainly reflect the impacts of land use. For example, in soils that have considerable slope, surface or overland flow can infiltrate into the soil during movement down the slope, move laterally through a conduit in the soil, and reappear as surface flow (7). However, in most cases, the concentration of P in subsurface flow, it has been found is quite low and well below the eutrophication threshold. In overland flow (surface runoff), P may be dissolved in runoff water (soluble/dissolved P or DP). The small quantity of soluble or readily desorbable P in most soil environments is due to the low solubility of phosphate minerals and the considerable adsorption capacities of clays and Fe/Al oxides for P. These factors result in the majority of total P transport that occurs as particulate P (PP). Particulate P enters streams and other surface waters, first undergoing a solubilization reaction (e.g., desorption) before becoming available for aquatic biota. The mechanisms involved in soluble P transport include initial desorption or dissolution of P bound by soil particles, followed by water movement from the source soil to a stream or a lake that later intercepts a sensitive water body (27).

Factors Controlling Surface Transport of Soil Phosphorus

Two major factors influence P losses from the landscape and movement to surface water bodies (5):

- *Erosion*: Particulate P is the primary form of P contributing to degradation of surface water quality. Erosion largely determines PP movement in the landscape. Sources of PP in surface waters include eroding surface soil, stream banks, channel beds, and plant materials. The contribution of eroded soil material to P enrichment of surface waters is rather complex (5). First, part of the sediment eroded from the landscape deposits at the toe slope in depressional areas, along field boundaries, or in grassy riparian zones. Thus, sediment yield from the field to a water body is only a portion of that eroded from the slope. Second, during the movement of sediment, the finer fractions are preferentially transported, whereas larger particles tend to settle out. Therefore, the P concentration and reactivity of eroded particulate material is usually greater than that of the source soil. The enrichment of P may increase as much as six-fold as the relative movement of fine to coarser particles increases. For this reason, fine-textured soils (clay loam, silty clay loam, silty clay, or clay) have a higher potential of supplying P to surface waters if erosion occurs (5).
- *Runoff*: As discussed earlier, runoff water across the soil surface can contain significant concentrations of DP. In addition to the readily available P loss from surface soils via desorption/dissolution during rainfall, DP can also be lost from standing vegetation via spring snowmelt because P contained in the tissue is released due to breakdown of plant cells by freezing and thawing. The removal of P from plant residue by overland drainage may account for differences among watersheds and seasonal fluctuations in P movement (5). Concentrations of DP in subsurface flow are low because the P-deficient subsoils sorb much of soluble P contained in the water percolating through the soil profile. Exceptions may occur in organic, highly permeable, peaty, or waterlogged soils, which tend to fix less P (7).

There is a well-defined relationship between the DP and PP fractions of total P in runoff as a function of soil erosion. As erosion increases, the PP fraction of total P increases, whereas the DP fraction decreases significantly (5). Irrigation, especially furrow irrigation, can significantly increase the potential for soil and water contact and therefore, can increase P loss by both surface runoff and erosion in return flows. Furrow irrigation exposes unprotected surface soil to the erosive effect of water movement. The process of irrigation also has the potential to increase greatly the land area that can serve as a possible source for P movement, a fact that is especially important in the western United States (3) where the surface water bodies suffer from an increased threat of eutrophication.

ENVIRONMENTAL MANAGEMENT OF SOIL PHOSPHORUS

When looking at management and/or remedial practices to minimize the environmental impact of P, several important factors must be considered. To cause an environmental problem, there must be a source of P (i.e., high soil P levels, manure or fertilizer applications, etc.), and it must be transported to a sensitive location (i.e., by runoff, erosion, or to a lesser extent, leaching). Hence, reducing P loss in surface runoff (thereby lowering the eutrophication potential of surface waters) may be brought about by source and transport control strategies (3).

Source Management

Source management attempts to minimize soil P buildup by controlling the amount of P applied to a given area. One of the most highly recommended avenues for source management is by measuring (and monitoring) soil test P in agricultural lands and estimating threshold levels for environmental risk assessment.

Decades of fertilization at rates exceeding those of crop removal have resulted in widespread increases in the P status of many agricultural soils, even to levels considered “excessive.” Environmental concern has forced many states to consider developing recommendations for P applications and watershed management based on the potential for P loss in agricultural runoff (3). As a result, well-defined “agronomic” and “environmental” thresholds for soil test P have been developed for many states. The environmental threshold levels range from two times in Michigan (40 ppm P-agronomic and 75 ppm P-environmental) to four times in Texas (44 ppm vs. 200 ppm). However, one still cannot accurately project that a soil test level above an expected crop response level exceeds crop needs and therefore is potentially polluting. What will be crucial in terms of managing source P based in part on soil test levels will be the interval between the critical soil P value for crop yield and runoff P (3).

Among the other popular source management techniques currently being implemented in farmlands are manure management (e.g., composting, lime or alum amendment, separation of solids from liquids); reduction of off-farm inputs of P in animal feeds (3); and controlling the rate, method and time of P application (5).

Transport Management

Phosphorus loss via erosion and runoff may be reduced by increasing residue cover on the soil surface through conservation tillage (5). Results from a flat, tiled, clay loam site in Michigan show significantly lower losses of sediment, total P, and soluble P for chisel tillage compared to moldboard plow tillage. However, sediment reductions were much greater than the reductions in total or soluble P. In other research, DP concentration in the runoff from no-till practices has often been greater than that from conventional practices (5).

Strategically placed and properly designed filter strips, it has been shown, effectively reduce erosion and P movement, especially PP (5). However, the strips have had little consistent effect on reducing DP concentrations.

Other common practices for reducing potential P transport include terracing, contour tillage, riparian zones, cover crops, and impoundments (settling basins). Basically, all these methods reduce the impact of rainfall on the soil surface, reduce runoff volume and velocity, and increase soil resistance to erosion. Most of these practices are more efficient in reducing PP than DP, and none of them should be relied on as the primary or sole practice to reduce P losses in surface runoff (3). Several researchers report little decrease in lake productivity (i.e., eutrophic plant growth) with reduced P inputs, following implementation of conservation measures (28,29). Thus, the effect of remedial measures in the contributing watershed will be slow for many cases of poor water quality (7).

SOIL WATER ISSUES

Eliot C. Roberts
Rosehall Associates
Sparta, Tennessee

Landscape plants and *turfgrass* can eliminate erosion and conserve water most effectively by considering many variables in the makeup of the landscape. These variables include the sizes of mineral components of soil, the components of the root zone, *soil moisture capacity*, soil texture, soil pH, the soil's *biodegradable capacity*, and its mulching capacity. All these factors are explained in this entry.

Because water and soil are the lifeblood of the planet, any policy that governs water use or proposes water conservation must incorporate the dynamic relationship that takes place between plants, the soil and water. The soil on which all plants grow is a highly valuable natural resource. We have a responsibility to protect it from erosion and to conserve and enrich it for future generations, just as we have a responsibility to use our supplies of water judiciously and maintain or improve its quality. *Landscape* plants generally and turf-grasses specifically can help achieve both of these goals.

To realize these benefits, it's helpful to look at what scientists have learned about the characteristics of soil such as texture, size of soil particles, the presence of organisms, capacity to hold moisture, acidity–alkalinity, and the presence of pollutants.

Soils are not homogenous, inert materials. They are composed of mineral particles that include sand, silt, and clay, as well as living and dead *micro/macroflora* and fauna, chemicals, air, and water in various percentages.

SIZES OF THE MINERAL COMPONENTS OF SOIL

From largest to smallest, mineral components of soil consist of the following:

- Stones = 10 to 100 millimeters in diameter (25 per inch).
- Gravel = 2 to 10 millimeters
- Coarse sand = 0.2 to 2 millimeters
- Fine sand = 0.02 to 0.2 millimeter
- Silt = 0.002 to 0.02 millimeters
- Clay = smaller than 0.002 millimeter. Clay particles are so small that they are measured in microns (0.002 millimeter is equivalent to 2 microns)

In terms of comparative size, if we enlarge a clay particle to the size of an apple, then a silt particle on the same scale would be the size of a limousine and a medium sand particle would be the size of the White House in Washington D.C. Because soil particles have relative sizes this small, there are many of them. For example, a pound of medium sand contains about 2.5 million particles, a pound of silt contains more than 2.5 billion particles, and a pound of clay contains more than 40 trillion particles. On the basis of total particle surface, one pound of sand would account for 20 square feet; silt would present 220 square feet of surface, and clay would have 5500 square feet of particle surface (Fig. 1).

THE MULTIPLE COMPONENTS IN A LANDSCAPE ROOT ZONE

Also present in most soils are high microbe counts within the root zone. Often there are more than 900 billion for each pound of soil. In each 1000-square-foot surface to a 6-inch root-zone depth, there will be a total of about 45 quadrillion organisms. As these organisms complete their life cycle and die, they deposit into the soil some 10 pounds of nitrogen, 5 pounds of phosphorus, 2 pounds of potassium, a half-pound of calcium, a half-pound of manganese, and one-third of a pound of sulfur for each 100 pounds of dead organisms on a dry-weight basis.

Soil microbiological processes also convert organic matter into humus. This is an ongoing reaction of great importance. Humus helps to form and stabilize soil aggregates that are essential for deep and extensive root growth. Humus also contributes to the process within the soil that holds and releases nutrients for plant growth.

In addition, many small animals known as soil fauna occupy the root zones of plants and contribute to the living nature of the soil. Depending upon soil conditions that are favorable for these macroorganisms, from 1 million to 2 million may be present for each 1000 square feet of root zone. The live weight of these organisms would range from 15 pounds to 30 pounds per 1000 square feet.

Of course, the water molecule associated with the soil is exceptionally small. One fluid ounce of water contains approximately 1,000,000,000,000,000,000,000,000 (24 zeros, or one trillion trillion) molecules.

GRASS PLANTS HAVE A TREMENDOUS POTENTIAL FOR ROOT GROWTH

Grasses fit right in with the sizes and numbers of soil particles found within this fascinating system. For example, there may be as many as 35 million individual grass plants per acre, or about 800,000 per 1000 square feet. No other type of plant culture involves such crowding. Roots grow down into the soil, and it is there that grass plants have a tremendous potential for root growth—up to 375 miles of roots from one plant and as many as 14 million

Figure 1. In terms of comparative size, if we enlarge a clay particle to the size of an apple, then a silt particle on the same scale would be the size of a limousine, and a medium sand particle would be the size of the White House in Washington, DC.

individual roots that may have a total surface area of 2500 square feet. Thus, root numbers and surfaces fit well within the very small spaces surrounding aggregated soil particles.

It is important to understand soil properties so we can appreciate how turfgrass needs moisture to grow and enhance the environment (Fig. 2).

SOIL'S CAPACITY TO HOLD MOISTURE

Soils differ in their capacity to hold moisture. Heavier clay and silt soils hold more moisture. Sandy soils can lose moisture through leaching as it runs through the root zone and down into the subsoil. Grasses with well-developed, deep root systems add sufficient organic matter to help hold moisture in the soil and thus prevent leaching.

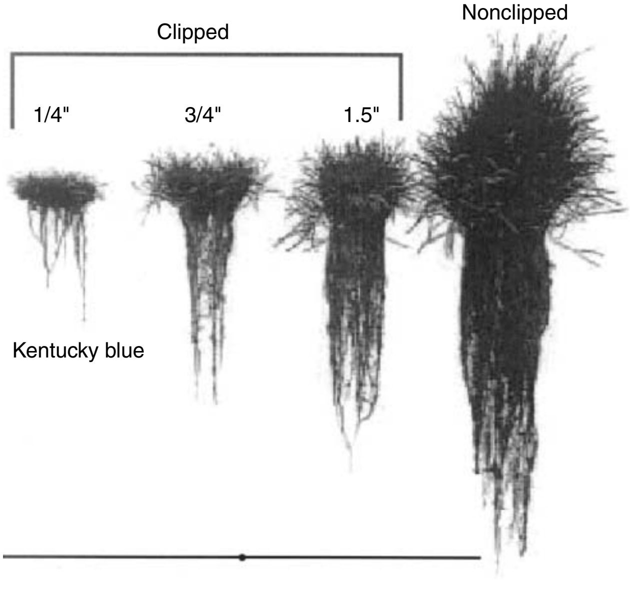

Figure 2. Higher mowing of turfgrass promotes a good root system. For Kentucky bluegrass, 1.5 inches is about right.

THE INFLUENCE OF SOIL TEXTURE ON WATER PENETRATION

The texture of the soil (as determined by the amount of sand, silt and clay) and the amount of thatch (organic deposit between green leaves and roots) influence the speed of water penetration into the soil. In general, heavy soils have many smaller pore spaces and take water in slowly. Sandy soils with fewer but larger pore spaces take moisture more rapidly, unless they are inherently hydrophobic or hard to wet. Soils and thatch that are hard to wet must be watered slowly with small amounts of water applied over longer periods of time to prevent runoff. Sandy soils require less water to penetrate to a given depth. Loam soils need intermediate amounts of water, and clay soils require more water to reach the same depth. As solid particles in the soil decrease on a percentage basis, moisture-holding capacity increases, and soil aeration decreases.

THE DEGREE OF ACIDITY AND ALKALINITY IN SOILS

Soil may either be acid, neutral, or alkaline. Soil pH (the measurement of the degree of acidity and alkalinity) is influenced by soil properties, biological influences, and climatic influences. Under acidic soil conditions, silt and clay particles tend to exist as individual units. Under more alkaline soil conditions, where calcium and magnesium are more plentiful, clay and silt particles group together to form granules. These provide improved soil structure, which results in more favorable balances of air and water in the soil. Where soils are acid and have poor structure, water penetration is much slower.

Soils become acid as carbon dioxide changes to carbonic acid in the soil, acid-reacting fertilizers are used on a continuing basis, or acid rainfall lowers soil pH values. Often a combination of all three of these causes occurs.

In addition to the effect of acidity on physical soil properties, nutrient fixation and availability also are modified, depending on the degree of acidity or alkalinity. For example, phosphates are most available from pH 5.5 to 7.5. Above and below these levels, phosphates are tied up with other minerals, and their availability is reduced. Regular soil tests can determine the need for lime or sulfur or for fertilizer mineral nutrients for specific plant types.

SOIL AS A BIODEGRADABLE AGENT

Biologically healthy soil is the best known medium for decomposing of all sorts of organic compounds, including pesticides and pollutants transported by air and water. These chemicals are known to be biodegradable. This is an ongoing process, which changes these substances into harmless compounds plus carbon dioxide and water. Limited prescribed use of pesticides is not harmful to beneficial soil organisms and should continue to be an important, well-accepted part of plant culture.

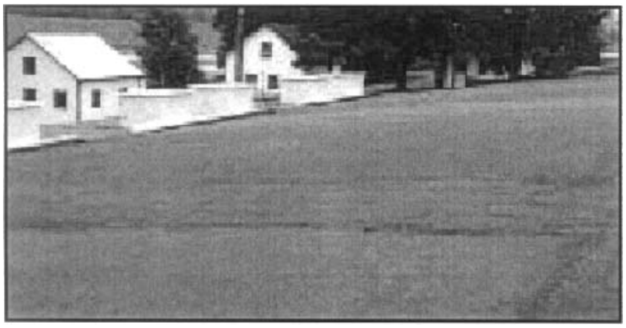

Figure 3. Dr. Thomas Watschke, Pennsylvania State University, created this highly controlled watershed site documenting that established turfgrass has a dramatic, positive effect on reducing nutrient and pesticide pollutants from water runoff.

Water and any pollutants associated with it infiltrate into the ground more quickly on grass-covered soils than on any other surface. Thus, runoff is diminished. Infiltration rates may be as high as 7 inches an hour on sandy soils and as low as 0.10 inch per hour on clay soils. Thus, recharge of purified groundwater is an important benefit. An acre left in open space provides an average of 600,000 gallons of recharge each year in humid regions. Grasses may use up to 10% of the water infiltrated, leaving 90% to recharge the local aquifer (Fig. 3).

GRASS GROUNDCOVER PROVIDES A LIVING MULCH

Good horticultural practice involves using mulches to conserve soil moisture and increase soil productivity. Unlike many landscape plants that are either widely spaced or simply annual in their growth habits, grass groundcover provides a living mulch over the soil surface. This is essentially perennial and provides long lasting soil and water conservation benefits.

Instead of viewing green-lawn groundcovers as static liabilities, these areas can be seen as dynamic, ever-changing populations of plants and animals living within and above the soil. All grasses are natural soil builders. Particularly in residential areas, lawns and landscapes help sustain the soil. Within the soil are large populations of micro- and macroorganisms that are highly competitive. These create a living, moist soil environment best suited to sustaining productive landscape soils, while at the same time purifying our water supply.

WATER SPREADING

Peyman Daneshkar Arasteh
Soil Conservation and
Watershed Management
Research Institute (SCWMRI)
Tehran, Iran

INTRODUCTION

In arid and semiarid regions, irrigation water shortage forces farmers to use floodwater for crop production. Water spreading is a form of runoff farming. It is a form of flood irrigation accomplished by diverting and spreading runoff from sloping areas over adjacent flood plains (1). Water spreading involves the construction of basins, pits, or barriers in or near natural stream channels to impound water and cause it to infiltrate the ground surface rather than leave the basin as surface runoff (2,3).

In other words, diverting or collecting runoff from natural channels, gullies, or streams with a system of dams, dikes, ditches, or other means, and spreading it over relatively flat areas is called water or floodwater spreading (1,4,5).

In a large part of the world, runoff water harvesting is best known and practiced in the semiarid areas (6,7). Runoff farming, which is identical with water harvesting for irrigation purposes, was already used for more than 2000 years. For example, runoff irrigation facilities in the Negev Desert in Israel were built 1300 to 2900 years ago (8). Flood irrigation also has been practiced in other parts of the world, such as Iran, for many years. Traditional flood irrigated farms, called band-sar, can be observed in 400,000 ha of Khorasan, the northeast province of Iran. Band-sar controls about one-fiftieth of 200–250 mm annual precipitation and one-fourteenth of 14,000 MCM annual surface runoff of Khorasan Province, Iran (9). Many sources exist addressing the floodwater spreading affects on soil, groundwater, wild habitats, etc. Baghernejad (10) studied physicochemical and micromorphological changes in topsoil because of flood spreading in Damghan Playa, Iran. Kowsar and Yazdian (11) investigated the fate of the dissolved nitrogen in floodwater that reached the watertable in Bisheh Zard Basin, Iran, because of flood spread over the land. The floodwater was from a geological formation containing NO_3 and NH_4. They found that the NO_3 exceeded the N required by plants of the region (rangelands and forest area), and purification of water must be in order to prevent the groundwater pollution. Nejabat (12) reported that a 2500 ha floodwater spreading system affected about 7500 ha of adjacent area in Gareh Bygon, Iran. He used a technique on the base satellite imagery to determine the increase in cultivated and rangeland areas and the decrease in wind erosion in water spread area.

Floodwater spreading has several advantages that are summarized by FAO (13) as follows:

a. Controlling floodwater damage
b. Reducing erosion and sedimentation
c. Increasing groundwater recharge
d. Improving plant cover and vegetation of the land
e. Increasing economic return for people
f. Increasing rangeland productivity
g. Increasing animal and agricultural production
h. Increasing soil fertility
i. Reclamation of renewable resources
j. Land use change by providing an optimized model for use of flow efficiency land and farming
k. Job creation by fruit trees plantation and increasing the income of local people

l. Improving the ecological balance of the environment
m. Reclamation of the pasture and vegetation cover
n. Providing ground for public participation
o. Providing ground for sustainable development

Floodwater spreading also has some disadvantages (14), listed as follows:

a. Affected by water shortage and climatic risks
b. Affected by farmers' experiences rather than on the scientifically well-established techniques
c. The possible conflicts between upstream and downstream users
d. Possible harm to fauna and flora adapted to running waters and wetlands
e. Requirement of relatively large labor inputs
f. Need to a relatively large natural watershed area
g. Need to appropriate investment and policy reforms to enhance the contribution of rainfed agriculture

In this article, water spreading as an irrigation technique will be introduced.

FLOODWATER SPREADING

Water harvesting refers to methods used to collect water from sources where the water is widely dispersed and quickly changes location or form and becomes unavailable or that is occurring in quantities and at a location where it is unusable unless some intervention is practiced to gather the water to locations where it can provide benefits (15). A number of water harvesting techniques exist that are practiced in many of the water scarce areas of the world, including (15,16):

a. Roof rainwater collection
b. Terracing
c. Small dams
d. Runoff enhancement
e. Runoff collection
f. Water holes and ponds
g. Tanks
h. Floodwater spreading

Floodwater spreading or spate irrigation is one of the common methods of runoff farming in arid and semiarid areas with rainfall intensity more than the infiltration rate of the catchment. USDA emphasized that a major difference between the water spreading system and other surface irrigation techniques, such as border and basin systems, is that the water spreading system is designed to meet precipitation and runoff conditions of the area and apply runoff to cropped fields, whereas other systems are designed to deliver water in accordance with plant needs (17).

Floodwater spreading has at least an inlet to divert flow from natural channels to the system, a delivery channel, and some contour spreader channels to spread water on the ground as overland flow. Figure 1 shows a schematic layout of a floodwater spreading system. Figures 2, 3, 4, 5 show a diversion dam and intake system with sediment control facility, a delivery channel, and the spreaders of flood spreading system, respectively.

the spreading area provides sufficient time to infiltrate more and more water to the soil and completes water holding capacity of the plant root zone. Excess water will be drained to a downstream contour spreader from one or more spillways. Figure 6 shows a schematic flood spreading system with some spillway, and Figs. 7, 8, 9 show three types of spillways, a cemented sandbag, a gabion type, and a cemented rockwork spillway, respectively.

GOVERNING EQUATIONS

Overland flow because of floodwater spreading is on the base of shallow water hydraulics. The general characteristic of shallow water flow (SWF) is that the vertical scale is much smaller than typical horizontal scale, which is true in many situations. SWF surface is nearly horizontal, which allows a considerable simplification in the mathematical formulation and numerical solution by assuming the pressure distribution to be hydrostatic. However, they may not exactly be two-dimensional (2D). The flow exhibits a 3D structure, because of bed friction, just as in boundary layers. Moreover, density stratification, because of a difference in temperature or salinity, causes variations in the third direction. In many SWFs, these 3D effects are negligible, and it is sufficient to consider the depth averaged form, which is 2D in the horizontal plane (18). This restricted form is commonly indicated by the term shallow water equations (SWEs).

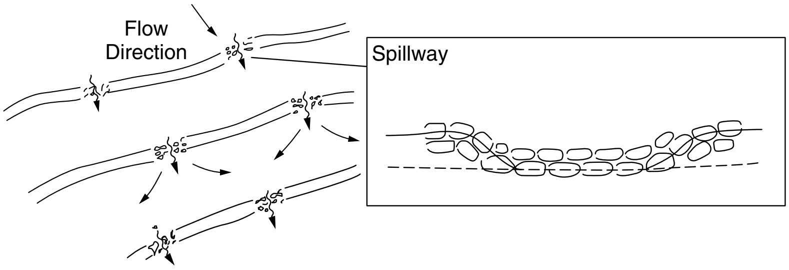

Figure 6. Schematic spillway (16).

Photo by: R. Hasanzadeh

Figure 9. A cemented rock work spillway of Chikhab flood spreading, Dehloran, Iran.

In this article, we limit our attention to incompressible fluid (water) and constant temperature and salinity. By assuming hydrostatic pressure, and with no Coriolis and wind effects and negligible effective stresses, the 2D depth averaged equations of motion are written as (19,20):

Continuity equation:

$$\frac{\partial h}{\partial t} + \frac{\partial (uh)}{\partial x} + \frac{\partial (vh)}{\partial y} = -I \tag{1}$$

x-momentum equation:

$$\frac{\partial (uh)}{\partial t} + \frac{\partial (u^2 h)}{\partial x} + \frac{\partial (uvh)}{\partial y} + g\frac{\partial}{\partial x}\left(\frac{h^2}{2}\right) = gh(S_{0x} - S_{fx}) + \frac{uI}{2} \tag{2}$$

y-momentum equation:

$$\frac{\partial (vh)}{\partial t} + \frac{\partial (v^2 h)}{\partial y} + \frac{\partial (uvh)}{\partial x} + g\frac{\partial}{\partial y}\left(\frac{h^2}{2}\right) = gh(S_{0y} - S_{fy}) + \frac{vI}{2} \tag{3}$$

where h is flow depth; u and v are flow velocities in x and y directions, respectively; I is the infiltration rate; t is time; g is gravitational acceleration; S_{0x} and S_{0y} are ground surface slopes because of x and y directions, respectively; and S_{fx} and S_{fy} are friction slopes in the direction of x and y axes, respectively.

Numerical solutions of SWEs with full or simple forms were described in several articles. Menendez (19), Akanbi and Katapodes (20), and Vreugdenhil (18) introduced numerical methods of solution of 2D SWEs. Arasteh and Vahhadj (21) developed a quasi2D finite difference semianalytical model of kinematic waveform of SWEs for Bisheh Zard flood spreading system, Iran. Arasteh (22) used an implicit finite difference scheme for the mentioned quasi2D model. Arasteh and Banihashemi (23–25) developed a solution method for implicit four points finite difference method to solve 1D kinematic wave SWE, called growing coefficient matrix, and used it for a typical floodwater spreading plot in advance phase of flow to the end of the spreading area.

DESIGN

NRCS (4) introduced the main conditions for applying the floodwater spreading as:

a. Soils have suitable intake rates and adequate water holding capacities for the crop to grow
b. Soils are suitable for production of feed, forage, or grain crops
c. The topography is suitable for the diversion or collection and spreading of water to achieve the desired results
d. Runoff or stream flow is available at the time of the year and in a volume sufficient to increase plant growth
e. Flows can be collected or delivered and spread and exceed water returned without causing excessive erosion
f. Fish and wildlife will not be significantly adversely affected
g. Grazing of the spreading area can be controlled

NRCS (4) also described the water quantity and quality requirement of flood spreading. FAO pointed out that water spreading can be used under 100 to 350 mm annually with a slope of less than 1% and even topography (16). USDA divided floodwater spreading systems into flow-type and detention-type systems (17). The flow-type systems incorporate free drainage from the irrigated area and are divided into spreader-ditch, syrup-pan, and dike-bleeder types. Detention-type systems retain the applied water on the irrigated area until it has infiltrated and are divided into manual and automatic inlet control subsystems. Apart from the type of system, two parameters must be determined as design criteria of the system, design application depth (DAD) and divertible volume of flow rate (DV or DQ). USDA stated that DAD could be determined by a relationship between intake rate, flow duration, or time of concentration, and DV or DQ could be determined as a ratio of volume of storm or peak discharge of upstream catchment.

SPRINKLER IRRIGATION

Muhammad Nadeem Asghar
International Water
Management Institute (IWMI)
Lahore, Pakistan

In arid and semiarid environments, supplemental irrigation has become a prerequisite to minimize risks of crop failures in both rain-fed and irrigated agricultural areas. Usually, surface irrigation, in which the entire or most crop area is flooded, is used for irrigating these croplands (Fig. 1). More often, however, water management skills on the farm are lacking, water supplies may be uncertain, and so irrigation efficiency tends to below.

Because of the present scarce global water resources, improving irrigation efficiency—getting more crop per drop—and making the best use of water for agriculture are prerequisites for the future (1). Shifting from surface irrigation to sprinkler irrigation, which is a method of irrigation under pressure in which water is sprinkled

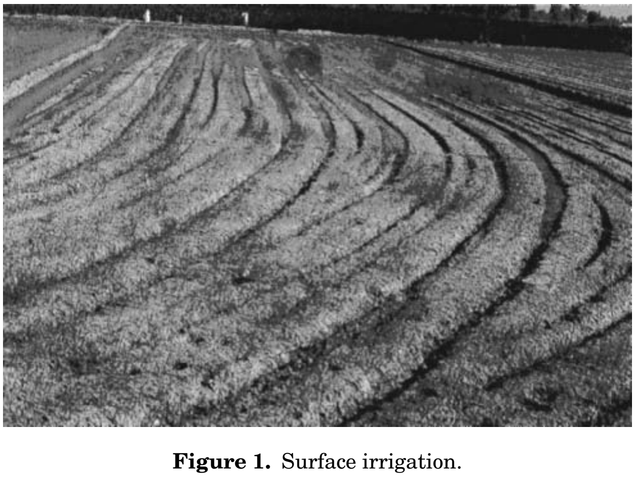

Figure 1. Surface irrigation.

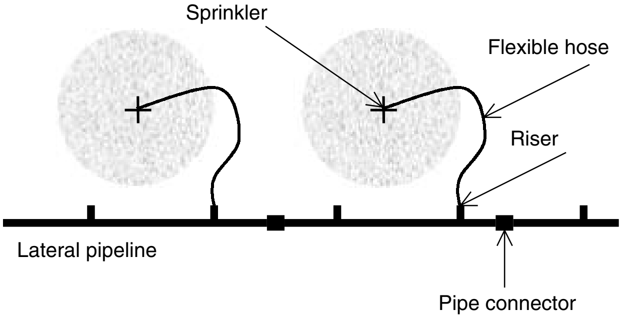

Figure 2. Lateral pipeline.

Figure 4. Hose-move sprinkler irrigation.

to imitate rainfall, will contribute substantially to these goals. In contrast to surface irrigation, sprinkler irrigation can help to irrigate frequently with just the right amount of water to avoid crop distress and to avoid overirrigation (Figs. 2 and 3).

In recent decades, various sprinkler irrigation methods and installations have been developed to meet the needs of farmers, particularly smallholders. Hand-move sprinkler irrigation is the most widely adopted and least expensive system operated with pressure ranges from 2.0–3.5 bars. The sprinklers are mounted on lateral pipelines temporarily laid across a field. To reduce labor requirements, this system was modified to hose-move sprinkler irrigation (Fig. 4). In this modified system, lateral pipelines are placed permanently, and the sprinklers, mounted on tripod stands, are not fitted directly to the lateral pipelines but are connected to them via flexible hoses. The hoses and sprinklers can be moved laterally on either side to cover a number of lateral positions (2).

Generally, in sprinkler irrigation, the uniformity of distribution is more sensitive to wind. However, this irrigation provides 'air-conditioning' effects on the crops if used in anti frost sprinkling and can also reduce pesticide applications if used as a spray. It is also fairly well established that a plan of heavy sprinkling at infrequent intervals will ordinarily produce a deeper root structure and thus better crop growth and yields than frequent, light sprinkling. However, light irrigation may be beneficial when there is a minimum crop water requirement. Under shallow water table conditions, when groundwater contributes significantly to meet the crop water requirement, light irrigation is also required to dilute the salinity in the effective root zone. Sprinkler irrigation may be used to germinate and establish salt-sensitive crops by keeping the seedbed adequately moist and salt-free by uniformly applying small depths of irrigation water.

Figure 3. Hand-move sprinkler irrigation.

When sprinkler irrigation is done with saline water, it brings water into contact with foliage, and salt deposits on leaves may adversely affect some crops. However, the susceptibility of plants to leaf injury from saline sprinkled water depends on leaf characteristics that affect the rate of absorption and is not generally correlated with tolerance to soil salinity. The degree of spray injury varies with weather conditions, especially the water deficit of the atmosphere. Visible symptoms may appear suddenly following irrigation when the weather is hot and dry. Increased frequency of sprinkling, in addition to increased temperature and evaporation, increases the salt concentration in the leaves due to adsorption and results in leaf damage. However, irrigation at night (or any other low evaporation period) minimizes the salt concentration in the leaves due to adsorption (3). Furthermore, evaporation losses during sprinkling can also be minimized by avoiding midday irrigation.

High capital costs, nonavailability of needed equipment in the local market, energy dependence, and lack of local expertise to operate and maintain sophisticated hydraulic equipment are the main constraints that hinder the acceptability of the system by the farmers, particularly smallholders. For the same reasons, surface irrigation is still likely to be dominant in the future, even though it wastes water and is a major cause of waterlogging and salinization.

However, the integration of surface irrigation and sprinkler irrigation could help in controlling salinity in the root zone with minimum application of irrigation water by improving leaching efficiency. In this practice, sprinkler irrigation helps in uniform distribution of groundwater, and surface wetness due to sprinkling that helps in minimizing the application of surface water still can meet the crop water requirement. This surface wetness also allows salts to dissolve in the root zone, which improves the leaching efficiency of surface irrigation. Therefore, the value of sprinkler irrigation can still be promised by promoting it together with surface irrigation (4).

STOMATES

R. Andrés Ferreyra
Ag Connections, Inc.
Murray, Kentucky

Stomates or stomata (singular: stomate or stoma) are structures on the surfaces of plant leaves that allow gas exchange (transpiration, i.e., loss of water vapor, uptake of CO_2, and emission or uptake of O_2) between the interior of a leaf and the atmosphere.

Plant leaves are covered by a waxy layer, the cuticle, that prevents water loss from the cells on the leaf surface, or epidermis. The cuticle does not completely cover the leaves, however; it is interrupted by microscopic pores, surrounded by pairs of specialized guard cells (Fig. 1a). A stoma is a unit composed of a pore and its guard cells. Guard cells, unlike regular epidermal cells, usually contain chloroplasts (photosynthesizing organelles containing chlorophyll). In some plants, there are also additional, specialized subsidiary cells that differ in shape from regular epidermal cells and participate in the osmotic changes that drive guard cell movement.

Stomata can be found in all aboveground parts of plants but are more frequent in leaves. They usually appear on one (the lower) side of leaves but may appear on both. When stomata occur on the lower (abaxial) leaf surface, the plant is said to be hypostomatous; hyperstomatous plants have stomata only on the upper (adaxial) leaf surface, and plants with stomata on both surfaces are called amphistomatous. In this latter case, abaxial stomata are generally more numerous. The number of stomata per unit area is called the stomatal density. This figure may vary when plants are grown under different environmental conditions such as atmospheric CO_2 concentration.

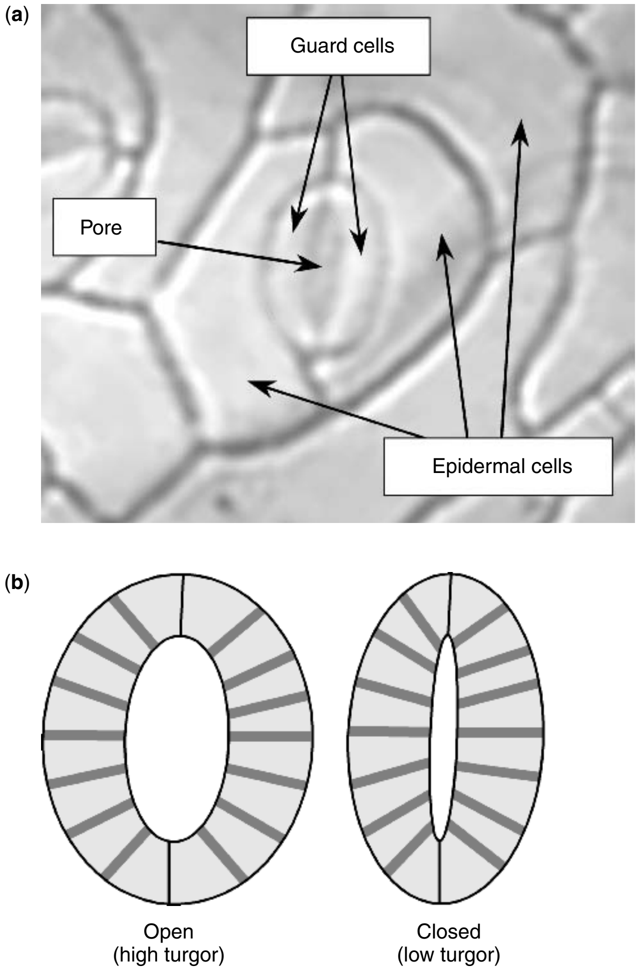

Figure 1. (**a**) Micrograph of a peanut (*Arachis hypogaea* L.) epidermis, showing the guard cells, the stomatal pore, and epidermal cells: (**b**) Diagram of open and closed stomata, showing cellulose microfibrils.

The size and density of stomata vary widely among species (Table 1). When fully open, stomatal pores are 3–12 μm wide and from 10 to more than 30 μm long. Species with smaller stomata tend to have a higher density that can range from 60–80 per mm^2 in corn to 150 in legumes such as alfalfa and clover, 300 in apple, and more than 1000 in scarlet oak (1). Dicotyledon leaves with a netted venation pattern generally have a scattered arrangement of stomata, whereas monocotyledons and conifers tend to have their stomata arranged parallel to the main axis of leaves.

Some plants locate their stomata at the bottom of recessed hollows and sometimes grow hair-like structures above them, apparently to limit water loss by creating a high-humidity environment above the pore. Most plant leaves have small open spaces under the pore, called substomatal cavities (Fig. 2).

STOMATAL CONDUCTANCE MODEL

Transpiration and its dependence on stomatal control have been traditionally described by using an electric analog model based on conductances or their reciprocal, resistances. The basic assumption of the conductance

Table 1. Occurrence and Dimensions of Stomata for Several Representative Species[a]

[a] Adapted from Reference 1.

model is that the diffusion of gases within plant tissues and in the atmospheric boundary layer is restricted by resistances and that the resulting system of gas fluxes into and out of leaves can be described by the equations developed for analyzing electrical circuits (Fig. 3).

Nobel (2) described the diffusion of gases along stomatal pores by applying Fick's law and a stomatal conductance (which we will denote as $g_{\mathrm{w}}^{\mathrm{st}}$). This is a widely used parameter in modeling applications; stomatal conductance, the rate of flow per unit area of the leaf, is considerably easier to measure than the flux density within a stomatal pore. Stomatal conductance is closely related to stomatal aperture; Jones (3) showed how to estimate conductance from observed stomatal dimensions. Given the dynamic behavior of stomatal aperture, however, conductance is highly variable, especially in natural conditions. Time-averaged values are typically used in calculations.

The cuticular conductance, $g_{\mathrm{w}}^{\mathrm{cut}}$, is probably the most uncertain of all conductances in this model. Traditionally it has been assumed to be negligible, but experimental data show that cuticular transpiration varies greatly among species. Larcher (4) generalized that it constitutes 10–33% of total transpiration, but some researchers presented even higher values (5).

Nobel proposed calculating $g_{\mathrm{w}}^{\mathrm{ias}}$, the conductance of intercellular air spaces, based on the average distance between mesophyll cell surfaces within a leaf and the inner surface of stomatal pores. Consistent application of the conductance model would thus require measurements on leaf cross-sectional images. Parkhurst (6) postulated that intercellular air space is a very important, usually ignored, component of the leaf gas exchange pathway, although it is more relevant for photosynthesis than for transpiration.

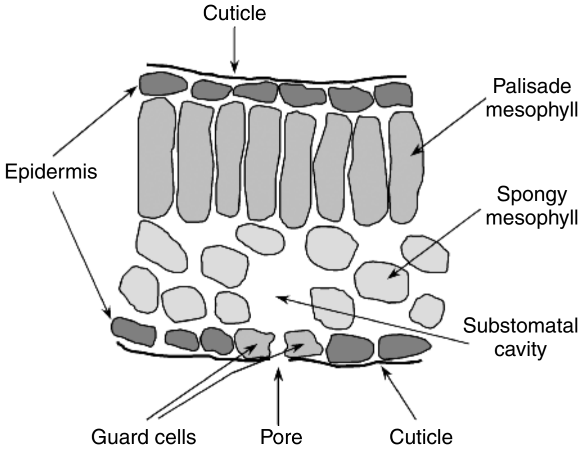

Figure 2. Diagram of a (hypostomatous) leaf cross section, showing different tissues and cell types.

Calculations with the electric analogy are simplified by replacing all conductances with resistances, taking $r_{\mathrm{w}}^{\mathrm{i}} = \left(g_{\mathrm{w}}^{\mathrm{i}}\right)^{-1}$, where the superscript "i" stands for "bl," "st," "cut," or "ias" (boundary layer, stomata, cuticle, and intercellular air space, respectively). Figure 3 presents the corresponding equivalent electrical circuit. The cuticular resistance acts as a resistance in parallel with the series sum of the stomatal and intercellular space resistances. According to this scheme, the total leaf resistance to water movement can be described as

$$r_{\mathrm{w}}^{\ell} = \frac{\left(r_{\mathrm{w}}^{\mathrm{ias}} + r_{\mathrm{w}}^{\mathrm{st}}\right) \cdot r_{\mathrm{w}}^{\mathrm{cut}}}{r_{\mathrm{w}}^{\mathrm{ias}} + r_{\mathrm{w}}^{\mathrm{st}} + r_{\mathrm{w}}^{\mathrm{cut}}} + r_{\mathrm{w}}^{\mathrm{bl}}$$

and the total leaf conductance is

$$g_{\mathrm{w}}^{\ell} = \left(r_{\mathrm{w}}^{\ell}\right)^{-1}$$

Nobel (2) provided some representative conductance values: for crop plants such as beet, spinach, tomato, and pea, $g_{\mathrm{w}}^{\mathrm{ias}}$ ranges from 800 to 4000 mmol/m^2/s (20 to 100 mm/s); for open stomata, $g_{\mathrm{w}}^{\mathrm{st}}$ ranges from 200 to 800 mmol/m^2/s (5 to 20 mm/s). These values are somewhat lower for other agricultural crops.

THE STUDY OF STOMATA

Malpighi saw pores on leaf surfaces in 1674. Grew showed them in his anatomical work of 1682. The term "stomata"

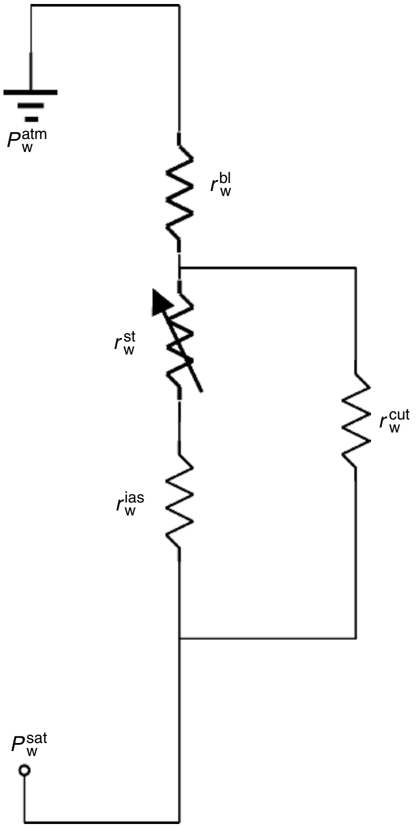

Figure 3. Conductance model of leaf water vapor movement, expressed in resistance form using electrical symbols. P_w^{atm} and P_w^{sat} are the water vapor pressure in the atmosphere and on the surface of mesophyll cells, respectively. The r_w^i are the resistances to water vapor movement in the boundary layer (i = "bl"), in stomata ("st"), through the cuticule ("cut"), and in the intercellular air spaces ("ias").

may have been first used by A. de Candolle in 1827, and research on stomatal behavior began earnestly in the mid-1900s (1). Gas exchange through small pores such as stomata was explained formally in physical terms by Brown and Escombe (7). Later, Stålfelt (8) and Bange (9) showed how, in moving air (when boundary resistance is low), transpiration and stomatal aperture are closely correlated. More recently, Zeiger (10) reviewed the multiple environmental influences on stomatal behavior; the review by Outlaw (11) shows the current state of the art.

The crucial role of stomata in controlling plant CO_2 uptake and water loss has motivated the search for methods of measuring stomatal aperture and conductance. Weyers and Meidner (12) extensively reviewed these techniques. A few salient methods are discussed briefly below.

Microscopy

In some plants, pieces of epidermis can be peeled off the leaf and observed on the microscope after fixing in alcohol. However, it is very difficult to peel the epidermis from some plants, and the process can also affect stomatal aperture. An alternative is to make impressions of the epidermis while the leaves are still on the plant, using substances such as collodion, silicone rubber, dental paste, or nail polish. These impressions are later peeled off and examined on the microscope (1).

The above mentioned methods involving epidermal manipulation may not be fully representative of *in vivo* conditions because the material used to make the impression may invade the pore or stomatal aperture may change during the process. There is evidence that ultrafast freezing can prevent aperture changes (13). This, coupled with scanning electron microscopy, can capture stomatal characteristics in great detail (e.g., 14).

Anatomically Explicit Models

Most implementations of conductance models assume that diffusion paths for both CO_2 and water vapor are identical, thus making transpiration and photosynthesis proportional to each other as stomatal aperture changes. This assumption ignores the intracellular, liquid-phase components of the CO_2 pathway, although Nobel (2) postulated that liquid-phase conductance values are significant.

Parkhurst (6) criticized conductance models "in part because they are usually one-dimensional representations, but also because they treat continuously interacting processes as if they were sequential." The lumped-parameter conductance approach, as opposed to using spatially distributed parameters and processes, may introduce error even in the apparently simple simulation of diffusion within intercellular spaces, especially when estimating photosynthesis: assimilation really occurs throughout the tortuous intercellular space concurrently with a gradual fall in CO_2 concentration, rather than lumped at the end of the flow path as in typical conductance models.

However, lumping the properties of the leaf interior was unavoidable until recent developments in numerical methods made it possible to solve diffusion equations in very complex domains. Parkhurst (6) proposed a complex distributed electrical analog model, and Pachepsky and Acock (15) created a very sophisticated finite-element model, 2DLEAF, that explicitly represents leaf tissues in a two-dimensional domain based on measurements made on micrographs of epidermal peels and leaf cross sections. Driven by environmental variables such as photon flux density, air and leaf temperature, gas concentrations in the atmosphere, and a novel form of parameterizing the leaf boundary layer (16), the model then simulates the fluxes of water vapor, CO_2, and O_2. Calculations with 2DLEAF have shown that distributions of water vapor and CO_2 concentrations in the leaf interior differ from each other, that photosynthesis and transpiration rates are not proportional to each other, and that stomatal aperture affects transpiration more than it affects photosynthesis (15); this confirms the statement by Parkhurst (6) that low stomatal conductance reduces water loss more than it reduces CO_2 uptake.

Infiltration

Another experimental technique for estimating stomatal aperture involves infiltrating graded solutions of different viscosity into leaves. The viscosity of the most viscous solution that can infiltrate the pores serves as a measure of aperture (17). However, this method does not allow calculating stomatal resistances, and, due to the differences in stomatal anatomy among species, it is better suited to relative measurements of stomatal aperture within the same species (3).

Mass or Viscous-Flow Porometers

The combined resistance of the stomata and the intercellular air spaces of the mesophyll can be estimated for an amphistomatous leaf by forcing pressurized air through the leaf from one surface to the other and then measuring the airflow rate (or the time needed for a specified drop in pressure). The flow rate is inversely proportional to the viscous-flow resistance.

Many such mass- or viscous-flow measuring devices, or porometers, have been described in the literature (18–20). However, absolute calibration is difficult because the flow path inside the leaf is complex and the series circuit measured by the instrument (air flows in through one leaf surface, the mesophyll, and out the other surface) is not representative of the actual water vapor diffusion paths, where the stomata of the two leaf surfaces are in parallel (3). Additionally, mass flow porometer designs have been cumbersome (albeit ingenious), and contemporary interest in separating the adaxial, abaxial, and mesophyll resistance components has decreased interest in mass flow instruments in favor of the diffusion porometer.

Diffusion Porometers

More advanced porometers generally include small cuvettes or chambers that can be attached to leaves and either measure the time necessary for a specified change in the humidity in the chamber (transit-time diffusion porometers; 21) or measure the water vapor concentration differential between the air leaving the chamber and the air entering it (continuous-flow diffusion porometers; 22). They can work with one or both leaf surfaces.

Diffusion porometers are powerful, albeit expensive. They are portable, operate rapidly (seconds to a few minutes), and store data in an onboard memory for subsequent downloading to a personal computer. Although they can work with individual leaf surfaces (unlike mass-flow porometers), they must still average over a relatively large leaf area and thus cannot describe the behavior of individual stomata. They are also affected by any factor that influences water loss (e.g., cuticle conductance), not just stomatal conductance.

Jones (3) suggested the following equation to estimate leaf conductance from a continuous-flow porometer:

$$g_{\mathrm{w}} = (r_{\ell\mathrm{w}} + r_{\mathrm{aw}})^{-1} = \frac{u_{\mathrm{e}}(x_{\mathrm{w0}} - x_{\mathrm{we}})[1 - (x_{\mathrm{ws}} + x_{\mathrm{w0}})/2]}{A(1 - x_{\mathrm{w0}})(x_{\mathrm{ws}} - x_{\mathrm{w0}})}$$

where g_{w} is the total conductance to water vapor (mol/m^2/s); $r_{\ell\mathrm{w}}$ is the leaf (combined stomata, cuticle, intercellular air space, and cell wall) resistance to water vapor (m^2 s/mol); r_{aw} is the boundary layer resistance to water vapor, typically specified by the porometer manufacturer; u_{e} is the flow rate entering the chamber (mol/s); x_{we} is the mole fraction of water vapor in the air entering the chamber (mol/mol); x_{w0} is the mole fraction of water vapor in the air leaving the chamber (mol/mol); x_{ws} is the saturation mole fraction of water vapor at the chamber temperature (mol/mol), where the relative humidity of the outlet air is equal to $x_{\mathrm{w0}}/x_{\mathrm{ws}}$; and A is the surface area of the leaf exposed in the chamber (m^2).

STOMATAL FUNCTION

Stomata open and close due to changes in the shape of guard cells. Changes in the concentration of ions inside guard cells make water move into or out of the cells osmotically. The corresponding changes in hydrostatic pressure (turgor pressure, the pressure exerted by the fluid in the cell that presses the plasma membrane against the cell wall) in turn make the cells swell or shrink. Two additional factors influence the change in shape; first, guard cell walls have a set of cellulose microfibrils arranged radially around the cell (radial micellation). When the cell volume tends to increase with turgor pressure, the microfibrils force a lengthening of the cells rather than an increase in diameter. Additionally, the inner walls of guard cells, those adjacent to the pore, are more rigid than the outer walls. Thus, a lengthening of the cell translates into an increase in its curvature, and consequently into an opening of the stoma (Fig. 1b).

The intake of ions for stomatal opening occurs through the guard cell membrane. A special form of enzyme called proton ATPase removes protons from the inside of the cell. This creates an electrical gradient across the membrane; potassium ions can move into the cell (through specialized ion channel proteins embedded in the membrane) driven by this gradient. Chlorine and calcium ions, as well as starch, play additional roles in this process. For further reading, Nicholls and Ferguson (23) presented an excellent introduction to ATPases and active transport through membranes; Mansfield et al. (24) discussed the role of calcium.

Stomatal aperture responds to numerous environmental factors such as light, temperature, relative humidity, CO$_2$ concentration, and pollutants. It also depends on internal variables such as water stress, periodic metabolic oscillations (circadian rhythms), and the concentration of signaling substances such as abscisic acid (ABA) and cytokinins. Outlaw (11) and Zeiger (10) explained all of this in detail; a brief outline is given below.

In general, stomata tend to open in the light, when there is energy available for photosynthesis. An interesting exception is that of desert succulent plants of the crassulacean acid metabolism (CAM) type. They open their stomata at night (when atmospheric water demand is low), store CO$_2$ as malic acid, and then convert that into sugars via photosynthesis during the day with their stomata closed and the plant safe from water loss.

Stomatal aperture is generally inversely proportional to CO$_2$ concentration. Some researchers believe that plants sense the concentration of CO$_2$ in the leaf interior and respond to that; others believe that the plant responds to the ratio of internal to external CO$_2$ concentrations.

Stomata tend to close at midday, suggesting that plants can either sense atmospheric humidity, or sense transpiration rate and react to limit water loss. Temperature also affects stomatal aperture differently for different species; in general, temperature extremes close the stomata. However, it is difficult to separate the high temperature effect from that of a high vapor pressure deficit (i.e., high water demand). Wind effects are complex. On one hand, wind reduces boundary layer resistance and thus tends to increase transpiration. On the other, there are reports of plants closing their stomata in response to wind or vibration.

ABA is a plant hormone believed to be the main signaling mechanism for stomatal control. Roots subjected to dry soil (or hypoxia due to flooded soil) produce ABA, which moves upward to the leaves through plant vascular tissues. ABA interacts with guard cells, allowing the membranes to leak potassium ions out of the cell, reducing its concentration gradient, which is accompanied by a loss of water and turgor pressure and subsequently, stomatal closure. Tal and Imber (25) presented an interesting experimental confirmation of the central role of ABA in stomatal control. They showed that mutants that cannot synthesize ABA show permanent wilting because they cannot close their stomata to stop water loss. When ABA is applied to these plants from an external source, however, the stomata close, turgor pressure is restored, and wilting stops.

STOMATAL REGULATION

Stomatal aperture provides plants with a control mechanism with which they can balance the entry of the CO_2 used for photosynthesis and the water lost by diffusion through the pore from evaporation from the surfaces of cells inside the leaf (2). Transpiration is usually considered an inevitable, undesirable side effect of CO_2 uptake. However, transpiration does have important roles: transpiration provides energy to transport water (and hence, nutrients and signaling substances) in the plant, and it also dissipates the heat of direct sunlight (by evaporative cooling).

Many ideas have been proposed to explain stomatal behavior in terms of optimization of cost (transpiration) and benefits (photosynthesis). Optimally, stomatal aperture would vary throughout the day such that there is maximum photosynthesis and minimum transpiration. This implies a complex control system that monitors several input variables (several of which were mentioned in the previous section). Jones (3) and Nobel (2) provided interesting conceptual discussions in terms of feedback and feedforward systems. The latter explains the popular hypothesis that stomata behave so that the sensitivity of photosynthesis and transpiration to stomatal aperture (i.e., the corresponding partial derivatives with respect to stomatal aperture) are a constant multiple of each other. Cowan (26) and Farquhar and Sharkey (27) discussed this and other optimization strategies in greater detail.

Remote sensing in the optical spectrum has potential to detect plant manifestations of both transient and chronic crop water stress. Crop water status and evaporation rate have been directly related to thermal indexes, such as the crop water stress index (CWSI), the water deficit index (WDI), and the thermal kinetic window (TKW) index. Measurements of surface reflectance in narrow visible and near-infrared wavelengths have potential for monitoring crop photosynthesis and fluorescence. Surface reflectances in wide bands of the visible, near-IR, and short-wave IR spectrum have been used to detect plant manifestations of chronic crop water stress, such as phenological adaptations and leaf expansion and loss. To apply these approaches with satellite-based sensors for farm-scale irrigation scheduling and crop management, there are still needs for improved sensor design, timely image delivery, and reduced image cost.

INTRODUCTION

Numerous studies have shown that crop water stress has a direct effect on crop growth, development, yield, and ultimately, on farmers' profits. New management techniques in arid and semiarid regions are designed for controlled deficit irrigation to ensure low water loss without yield reduction. To achieve this delicate balance between water use and crop yield, farm managers need an operational means to quantify plant water deficit and evaluate the effects of stress on a given crop species at any stage of development. The following sections present the plant manifestations of water stress that can be detected using passive remote sensing methods with sensors that acquire data in the visible (VIS), near-infrared (NIR), short-wave infrared (SWIR), and thermal infrared (TIR).

CROP ADAPTATIONS TO WATER STRESS

Turner (1) provided a good synthesis of the effects of water deficit on crop plants and physiological adaptations to transient stress. He identified crop physiological adaptations associated with three types of drought resistance—drought escape, drought tolerance at high water potential, and drought tolerance at low water potential—where "drought" was defined as a period without significant rainfall. The following discussion focuses on the physiological adaptations that might have the greatest effect on the reflective and thermal spectral regions and on the optical properties of plants that would allow stress detection by remote sensing.

Drought escape is the ability of the plant to complete its life cycle before serious soil and plant water deficits develop. For example, studies have shown that wheat can hasten maturity in response to mild water deficits at the critical time between flowering and maturity. When stress occurred between floral initiation and wheat ear emergence, the number of wheat tillers that produced ears was less than that under well-watered conditions.

Drought tolerance at high tissue water potential is sometimes referred to as drought avoidance; it allows plants to endure drought periods while maintaining high plant water status. One such crop adaptation is the reduction of water loss through increased stomatal and cuticular resistance. This is expressed in increased epidermal waxes of leaves and a reduction in general plant productivity. Another adaptation is to reduce the radiation absorbed by the plant through leaf movement (e.g., leaf cupping, paraheliotropism, or wilting) or increased leaf pubescence and waxiness. Drought tolerance is also achieved by reduction of leaf area through decreased leaf expansion, reduced tillering and branching, and leaf shedding.

Water stress is often expressed by the inability of some crop species to maintain cell turgor at low water potentials. The capability of crops to control cell turgor varies widely by species (1). These variations in cell turgor under drought conditions can influence the closure of stomatal apertures and the rates of photosynthesis, evaporation, and leaf expansion.

Optical Properties of Plant Leaves

A great deal has been written on the optical properties of crop leaves in the VIS, NIR, SWIR, and TIR domains (2). In the visible domain, leaf reflectance is affected mainly by leaf pigments such as chlorophyll, xanthophyll, carotenoids, and anthocyanins, as well as by the leaf structure and the dry matter content. In the NIR, reflectance depends on the anatomic structure of the leaves and increases with the number of cell layers and the size of the cells. In the SWIR, reflectance is mainly affected by the leaf water content; strong water absorption bands are at 1.45, 1.95, and 2.5 μm. It is generally reported that leaves under water stress show a decrease in reflectance in the NIR spectrum, a reduced red absorption in the chlorophyll active band (0.68 μm), and a consequent blue shift of the red edge (3). In the TIR, there is a direct link between the process of plant water evaporation and the plant thermal response (i.e., water evaporates and cools the leaves).

The theory to explain these leaf optical properties and the effect of leaf constituents on leaf reflectance and transmittance was developed into a leaf model by Allen and Richardson (4). The PROSPECT model (5), based on a plate model for multiple layers, is widely used to simulate leaf optical properties as function of leaf chlorophyll concentration (C_{ab}), equivalent water thickness, dry matter content, and leaf internal structure; it enables simulation of leaf reflectance and transmittance as a function of different stresses.

Optical Properties of Plant Canopies

Though knowledge of the optical properties of individual leaves contributes to our understanding of the processes involved, field studies have shown that leaf optical properties alone are not sufficient to understand canopy-level reflectance. Canopy reflectance is a function of the leaf optical properties previously described, plus viewing and illumination geometry, canopy structure, and soil reflectance. For example, Guyot et al. (6) reported that the most important factor that influences the reflectance of a plant canopy is its geometric structure, not its leaf reflectance. Jackson and Ezra (7) concluded that water stress-induced changes in visible, NIR, and SWIR reflectance of a cotton canopy were due largely to canopy geometry changes rather than leaf physiological/anatomic changes in all but the red spectral band.

Furthermore, Myers et al. (8) identified seven parameters (in addition to leaf reflectance) that determined crop canopy reflectance, of which only the first three could be directly related to crop stress: (1) transmittance of leaves, (2) amount and arrangement of leaves, (3) characteristics of other components of the vegetation canopy, (4) characteristics of the background, (5) solar zenith angle, (6) look angle, and (7) solar azimuth angle. Canopy reflectance models enable the simulation of these canopy structural characteristics and viewing geometry on canopy-level reflectance. Closed agricultural canopies can easily be assumed to be horizontally homogeneous, plane-parallel turbid mediums, and therefore the plate model theory can be applied successfully. On the other hand, open crop canopies, showing heterogeneous structure with different shapes, need the development of models that specifically treat the effects of openings, shadows, and canopy geometry on the modeled reflectance. A detailed discussion of the different canopy reflectance model approaches by turbid-medium, geometric, hybrid, and ray-tracing methods is provided by Goel (9).

Similarly, the TIR emittance of a plant canopy is a function of the temperatures of both the plant components and the soil. T_c is the canopy temperature, defined by Norman et al. (10) as the TIR temperature in which the "vegetation dominates the [measurement] field of view minimizing the effect of soil." T_o is the temperature of the soil surface. T_s is the surface composite temperature, defined by Norman et al.(10) as the "aggregate temperature of all objects comprising the surface," which was shown by Kustas et al. (11) to be a linear function of T_c and T_o.

REMOTE SENSING FOR DETECTING CROP WATER STRESS

During the past 30 years, progress has been made in using remotely sensed data to retrieve information useful for irrigation scheduling and management. The basic approaches have focused on parameters directly related to crop water status (e.g., crop water loss, evaporation, metabolism, photosynthesis, and fluorescence) and plant manifestations of chronic crop water stress (e.g., phenology and leaf expansion and loss).

Crop Evaporation

An important breakthrough in using remote sensing for water stress detection was the development of the Idso–Jackson crop water stress index (CWSI) (12,13). Jackson et al. (12) derived the theoretical CWSI ($\mathrm{CWSI_t}$) by relating the canopy–air temperature difference ($T_c - T_a$) to net radiation (R_n), vapor pressure deficit (VPD), soil heat flux (G), volumetric heat capacity of air (ρC_p), psychrometric parameters (γ and Δ), and canopy and aerodynamic resistances (r_c and r_a), where

$$(T_c - T_a) = [r_a(R_n - G)/\rho C_p]\{\gamma(1 + r_c/r_a)/[\Delta + \gamma(1 + r_c/r_a)]\} - \{\mathrm{VPD}/[\Delta + \gamma(1 + r_c/r_a)]\} \quad (1)$$

Taking the ratio of actual (E for any r_c) to potential (E_p for $r_c = r_{cp}$) crop evaporation rates gives

$$E/E_p = [\Delta + \gamma^*]/[\Delta + \gamma(1 + r_c/r_a)] \quad (2)$$

where r_{cp} is the canopy resistance at potential evaporation. Jackson et al. (12) defined the $\mathrm{CWSI_t}$, ranging from 0 (ample water) to 1 (maximum stress), as

$$\mathrm{CWSI_t} = 1 - E/E_p = [\gamma(1 + r_c/r_a) - \gamma^*]/[\Delta + \gamma(1 + r_c/r_a)] \quad (3)$$

Though Jackson et al. (12) provided a thorough theoretical approach for computing CWSI, the concept is more universally applied using a semiempirical variation proposed by Idso et al. (13) based on the "non-water-stressed baseline." This baseline is defined by the relation between ($T_c - T_a$) and VPD under nonlimiting soil moisture conditions, example, when the plant water is evaporating at the potential rate (Fig. 1). Such non-water-stressed baselines have been determined for many different crops, including aquatic plants and both preheading and postheading growth periods for small grains (14).

Application of CWSI with satellite- or aircraft-based measurements of surface temperature is generally restricted to almost full-canopy conditions, so that the surface temperature sensed is equal to the canopy temperature (15). To deal with partial plant cover

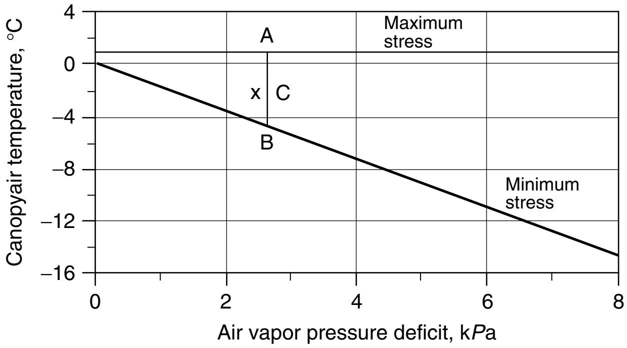

Figure 1. Canopy minus air temperature ($T_c - T_a$) versus vapor pressure deficit (VPD) for well-watered (line labeled minimum stress) and maximally stressed alfalfa based on measurements at various sites across the United States. The CWSI for a measured alfalfa canopy is computed as the ratio of the distances CB and AB (13).

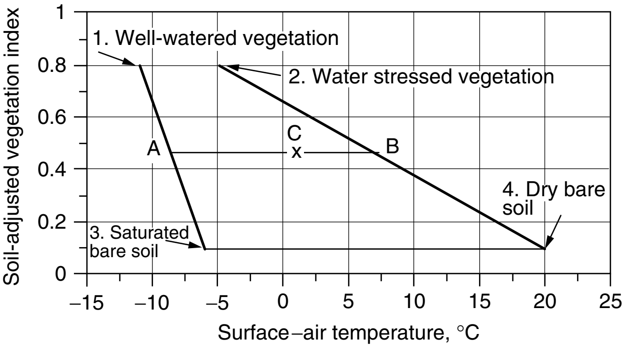

Figure 2. The trapezoidal shape that would result from the relation between surface temperature minus air temperature ($T_s - T_a$) and the soil-adjusted vegetation index (SAVI). Using a measurement of $T_s - T_a$ at point C, the ratio of actual to potential evaporation (which is equivalent to the Water Deficit Index or WDI) is equal to the ratio of the distances CB and AB (16).

conditions, Moran et al. (16) developed a Water Deficit Index (WDI) which combined measurements of reflectance with surface temperature measurements (a composite of both the soil and plant temperatures), as expressed by

$$\mathrm{WDI} = 1 - E/E_\mathrm{p} = [(T_\mathrm{s} - T_\mathrm{a})_\mathrm{m} - (T_\mathrm{s} - T_\mathrm{a})_\mathrm{r}]/[(T_\mathrm{s} - T_\mathrm{a})_\mathrm{m} - (T_\mathrm{s} - T_\mathrm{a})_\mathrm{x}] \qquad (4)$$

where subscripts m, x, and r refer to minimum, maximum, and actual, respectively. The WDI is operationally equivalent to the CWSI for full-cover canopies, where $T_s = T_c$. Graphically, WDI is equal to the ratio of distances AC/AB in the trapezoidal shape presented in Fig. 2, where WDI = 0.0 for well-watered conditions and WDI = 1.0 for maximum stress conditions. The left edge of the Vegetation Index/Temperature (VIT) trapezoid corresponds to $T_s - T_a$ values for surfaces evaporating at the potential rate; the right edge corresponds to $T_s - T_a$ values for surfaces in which no evaporation is occurring. In practice, WDI uses the Penman–Monteith energy balance equation to define the four vertices of the VIT Trapezoid that encompasses all possible combinations of a spectral vegetation index (e.g., Normalized Difference Vegetation Index or NDVI) and $T_s - T_a$ for one crop type on one day (Fig. 2).

Another promising approach for operational application is the use of remotely sensed crop coefficients (the ratio of actual crop evaporation to that of a reference crop) for estimating an actual, site-specific crop evaporation rate from readily available meteorologic information (17,18). This approach requires only a measure of NDVI and is simply an improvement of an approach already accepted and used by farmers to manage crops, where such improvements include increases in the accuracy of evaporation estimates and, by using images, the ability to map within-field and between-field variations.

Crop Metabolism

Quite distinct from the CWSI and WDI, Burke et al. (19) developed a concept of thermal stress in plants that linked the biochemical characteristics of a plant with its optimal leaf temperature range. The thermal kinetic window (TKW) is the range of temperatures within which the plant maintains optimal metabolism. For example, the TKW for cotton growth is 23.5 to 32 °C; the optimum temperature is 28 °C, and biomass production is directly related to the amount of time that canopy temperatures are within the TKW (Fig. 3), provided that insolation, soil moisture, and nutrients are nonlimiting. TKWs have been identified for several crop species, including cotton, wheat, soybean, potato, cucumber, and bell pepper. In practice, the TKW provides a biological indicator of plant health that is being used for irrigation management.

Crop Photosynthesis

Measurements of leaf chlorosis, which causes diminished leaf photosynthetic capacity, may be particularly suitable for early water stress detection. Differences in remote sensing reflectance due to changes in chlorophyll concentration levels have been detected in the green peak and along the red edge spectral region (690 to 750 nm) (20). The red edge occurs between the wavelengths of 0.69 and 0.76 μm due to the change in reflectance caused by chlorophyll absorption in the red spectrum and multiple scattering from leaves in the NIR spectrum (21) (Fig. 4). Several hyperspectral

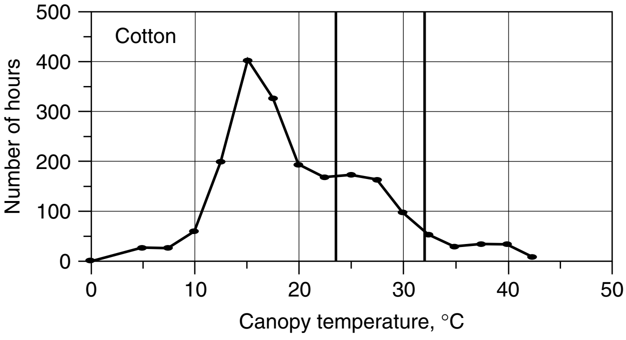

Figure 3. A frequency distribution of seasonal canopy temperatures of cotton, where the vertical lines represent the temperature range that comprises the species-specific thermal kinetic window (TKW) as determined from the changes in the apparent K_m with temperature (19).

indexes proposed in the literature track and quantify chlorophyll concentration for both leaf and canopy-level studies (22,23), allowing remote sensing detection methods to identify vegetation stress through the influence of chlorophyll content variation. These narrow-band vegetation indexes are, among others, the Simple Ratio Pigment Index, SRPI (ρ_{430}/ρ_{680}); Normalized Phaeophytinization Index, NPQI ($\rho_{415} - \rho_{435})/(\rho_{415} + \rho_{435}$); Photochemical Reflectance Index, PRI ($\rho_{531} - \rho_{570})/(\rho_{531} + \rho_{570}$); Normalized Pigment Chlorophyll Index, NPCI ($\rho_{680} - \rho_{430})/(\rho_{680} + \rho_{430}$); Greenness Index, G ($\rho_{554}/\rho_{677}$); Structure Intensive Pigment Index, SIPI ($\rho_{800} - \rho_{450})/(\rho_{800} + \rho_{650}$); and red edge reflectance-ratio indexes such as (ρ_{740}/ρ_{720}), ($\rho_{734} - \rho_{747})/(\rho_{715} + \rho_{726}$), ($\rho_{750}/\rho_{700}$), and ($\rho_{750}/\rho_{710}$). See a review by Zarco-Tejeda et al. (23) for more detail.

In agricultural canopies that have large spectral contributions from the soil background and LAI variation in different growth stages, combined indexes are proposed to minimize background soil effects while maximizing the sensitivity to chlorophyll concentration. CARI (chlorophyll absorption in reflectance index) (24) and MCARI (modified chlorophyll absorption in reflectance index) (25) have been proposed for combination with SAVI (soil-adjusted vegetation index) (26) and OSAVI (optimized soil-adjusted vegetation index) (27) to reduce background reflectance contributions. Successful chlorophyll estimation for corn canopies at different growth stages was achieved using the TCARI/OSAVI combined index (28) and with MCARI/OSAVI on open-tree crop canopies (29).

New developments related to vegetation stress, that have potential application to water stress detection, focus on monitoring chlorophyll fluorescence (CF). Red and far-red light is emitted from photosynthetic green plant tissues in response to photosynthetically active radiation. Several reviews offer details on theory, measurement methods, and interpretation, as well as the relationship to photosynthesis, plant physiological status, and photosynthetic functioning (30–32). In particular, relationships between steady-state and dark-adapted chlorophyll fluorescence features with water stress status have been investigated for both active and passive sensors (33–37). This suggests the potential for stress detection using far-distance remote sensing instruments.

Steady-state CF and photosynthetic rates are inversely related, such that CF is low when photosynthesis is high, although it can be reversed because of an intensified protective quenching action on CF production. The total amount of CF emitted by Photosystems I (PS-I) and II (PS-II) is typically less than 5% of total light absorbed. Thus, accurate remote detection of natural CF would enable the measurement of canopy-level CF without direct contact with the vegetation canopy. Zarco-Tejeda et al. (38) demonstrated that CF could be detected at both leaf and canopy levels using multiple approaches, including observing its effects on the red edge spectral region.

Crop Phenology

There is evidence that chronic crop water stress can either hasten (1) or delay (39) crop development, depending on the species involved and the timing of water stress. The timing and duration of stress is also of critical importance to ultimate yield; example, if intense water stress occurs during anthesis of a wheat crop, the impact on final grain yield is usually much greater than if this same stress occurs earlier or later in crop development. Tucker et al. (40) showed that crop phenological stage could be determined using a combination of spectral data and accumulated temperature units (growing degree day). Idso et al. (39) equated the slope of the spectral vegetation index (VI) over time with the rate of senescence and correlated this slope with final grain yield for wheat and barley under stressed and nonstressed conditions (Fig. 5). In a similar study, Fernández et al. (41) found that the hydric stress on wheat could be determined by the slope of the NDVI with time.

Chronic crop water stress can also manifest itself in reduced leaf expansion and leaf loss. There have been several studies that have monitored stress-induced reductions in biomass and GLAI using remote sensing techniques (42–44). Though these results are encouraging, this approach is limited by the fact that the VI–GLAI relation is exponential, leading to saturation of the NIR response at GLAI values of five to six (2). A better measure of the effects of water stress on leaf expansion and biomass production might be the amount of solar radiation intercepted, which is related directly to plant growth. Kumar and Monteith (45) showed that the fraction of absorbed photosynthetically active radiation (fAPAR) is related linearly to NIR/red reflectance. More recent work

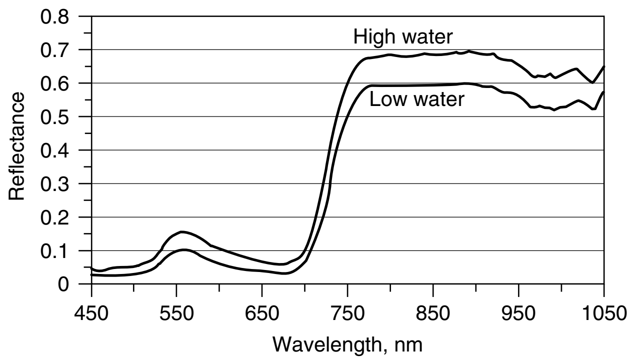

Figure 4. The expected trends of spectral reflectance of a crop canopy with high and low water treatments (21).

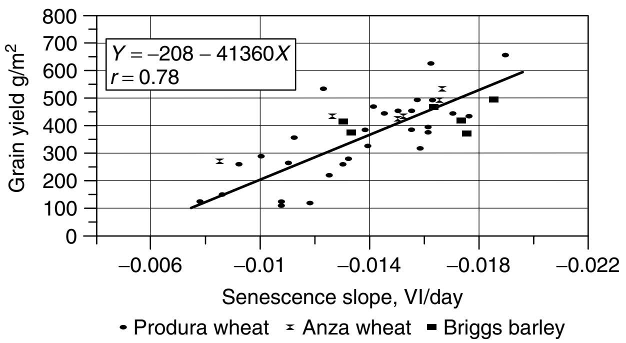

Figure 5. Final grain yield of Produra wheat, Anza wheat, and Briggs barley versus the slope of the transformed vegetation index (TVI6) during the senescence period (39).

by Pinter (46) has shown that this relation between VI and fAPAR is independent of variations in the solar zenith angle, thus increasing the usefulness of this remote sensing approach.

CONCLUDING REMARKS

The CWSI, WDI, and TKW are good examples of remote sensing indexes that link surface temperature measurements to crop and soil evaporation rates. Quantification of leaf chlorosis based on surface reflectance in narrow wavelength bands also has potential for detecting transient water stress. Season-long measurements of surface reflectance in wide wavelength bands have been used to detect the effects of chronic plant stress, such as delayed (or hastened) crop phenology and leaf expansion or loss. These are only some examples of the many approaches available for detecting crop water stress using remote sensors. However, to realize the full potential of satellite-based estimation of crop water stress, it will be necessary to continue sensor development, improve image availability and timely delivery, and reduce image cost.

VACUUM GAUGE TENSIOMETER

Mahbub Alam
Kansas State University
Garden City, Kansas

Soil water plays an important role in providing water for plant growth. The vacuum gauge tensiometer is a soil water measuring device that is sensitive to soil water change. The quantity of soil water that adheres around soil particles determines the energy level at which it is being retained or pulled. In other words, the plant root has to exert energy to pull water out of a soil matrix. This energy is also expressed as tension the roots experience in removing the water. Tensiometer is like a mechanical root but shows the tension in the vacuum gauge attached to it. It is an indirect method to determine soil water status. Direct measure of water content is time-consuming and labor-intensive, and the result lags behind the current time. Hence, irrigators depend on indirect methods. Vacuum gauge tensiometer is inexpensive, easy to use, and a preferred measurement method, especially for course-textured soils.

A vacuum gauge tensiometer with its components is shown in Fig. 1. Variations from this design exist on the market. A tensiometer is a sealed, water-filled tube equipped with a vacuum gauge on the upper end and a porous ceramic tip on the lower end. The basic components include: a cap, body tube, vacuum gauge with dial, and a porous ceramic tip (Fig. 1).

The Cap: The cap must seal the tensiometer body tube airtight or the device will not work. Some models have a reservoir, like the one shown in Fig. 1, which serves as a water supply source for the body tube. In these models, the cap assembly has an extended stem to hold a neoprene stopper that seals the body tube from outside atmosphere.

Body Tube: The body tube provides support and a liquid connection between a porous tip and the vacuum gauge. Tensiometers come in various lengths. Standard lengths are 6, 12, 18, 24, 36, 48, and 60 inches.

Vacuum Gauge: A hermetically sealed vacuum gauge (Bourdon[1] vacuum gauge) with a round dial is attached

---

[1] A thin-walled flattened tube used in a gauge to read pressure or vacuum developed by Bourdon, an inventor in France some 150

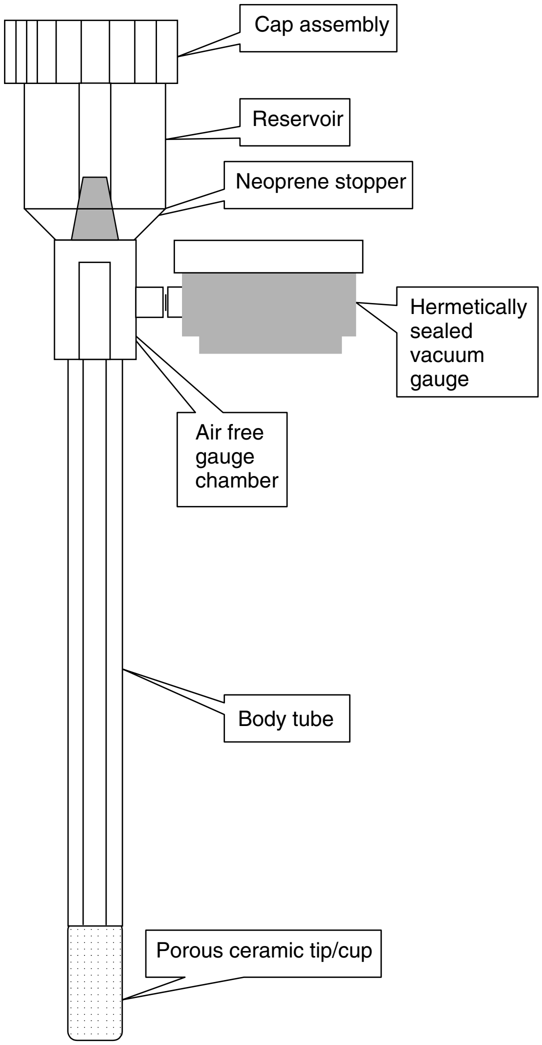

Figure 1. Sketched view of a vacuum gauge tensiometer showing its components.

at the air-free gauge chamber of the body tube. The round dial in the gauge is marked with a scale in centibars to indicate the gauge reading. The scale is calibrated to read in centibar, or hundredths of one "bar." A bar is the unit of pressure, either positive or negative, that has been adopted for the expression of soil water tension. The bar is an international unit of pressure in the metric system and equivalent to 14.5 lb/sq. inch, or 0.987 atmospheres. One centibar is equal to 1 kPa (kilopascal).

Ceramic Tip/Cup: The ceramic tip is built like a tubular cup, and it is porous. The openings of the pores are so small that when saturated with water, air cannot pass through within the range of soil water tensions to be measured. As soil water content outside the porous cup in the soil matrix declines from saturation, water inside the tube starts moving out through the porous tubular tip, which causes a partial vacuum inside the tensiometer that can be read on the vacuum gauge. The needle in the gauge starts moving above the face of the dial. The dial reading, indicated by the needle, shows the suction or tension at which the water is being pulled by the surrounding soil.

A reading of zero corresponds to a completely saturated condition, regardless of the type of soil. A reading of 80 kPa (centibar) indicates a dry condition for sandy soils and would hurt sensitive crops. This number is also the functional upper limit for tensiometer readings. A tension higher than 85 kPa (centibar) will cause the water inside the tube to vaporize, restricting its use to suctions less than about 85 kPa.

The cup conductance and the gauge sensitivity determine the response time of the tensiometer. Ceramic tensiometer tips/cups for field use generally have a conductance in the order of 3×10^{-5} cm^2/s, which, in a vacuum gauge system, would have a response time of five seconds. A response time of 1 minute is adequate for most field applications.

The tensiometer is sensitive to very small changes in soil water, making it useful for irrigation scheduling. Irrigation scheduling is a process to determine when to irrigate and how much water to apply. Applying water in an untimely manner with too little or too much water can result in yield reductions. Overirrigation wastes water, costs dollars to pump, and may leach nutrients beyond the root zone. Tensiometers are particularly accurate at low tensions, which is the wettest part of the soil water range. Tensiometers are popular with growers of high-value crops, such as vegetables and fruits, on sandy soils.

A depth label is usually placed on the vacuum gauge or on the side of the tube to indicate the depth at which the ceramic tip will be set when installed, which is important for identification purposes. The soil suction reading on the vacuum gauge dial is an indication of soil water availability for plant use and does not need to be calibrated for salinity or temperature. The readings, however, have different meanings in terms of their use for irrigation scheduling depending on soil type. Table 1 and Fig. 2 provide some interpretation of tensiometer readings in relation to soil texture.

TENSIOMETERS WITH ELECTRONIC READER

The vacuum gauge tensiometer is not suitable for automated continuous data collection or for controlling irrigation system operation by switching it on or off. However, some models have electronic technology added to the tensiometer that allow them to be remotely read or automatically switch irrigation on or off.

The switching tensiometer models employ the standard vacuum gauge, to which a circular magnet is affixed to the hub of the indicator needle. This magnet is rotated by the action of the indicator needle as it moves according to drying/wetting cycle of the soil. The switch is affixed to the outside of the gauge face and can be adjusted for various readings where the switch will turn "on" The switch contains a reed switch that is held open by a small biasing magnet installed inside the switch. This magnet is of lesser power than the one mounted on the hub of the gauge indicator needle. As the indicator needle of

---

years ago. It was brought to the United States by Ashcroft Gauge Company 100+ years ago and still is the standard gauge used practically worldwide.

Table 1. Interpretations of Tensiometer Readings

Reading (Centibars)	Status	Explanation/Action
0	Saturated	Soil is saturated regardless of soil type. If readings persist, there is possible danger of waterlogged soils, a high water table, poor drainage and soil aeration, or the continuity of the water column in the tube may have broken.
5–10	Surplus water	Indicate a surplus of water for plant growth. Drainage continues, and persistent readings indicate poor drainage.
10–20	Field Capacity	Field capacity for all types of soils. Additional water will drain as deep percolation carrying nutrients without opportunity for plant use. Sandy soils, however, have very little storage capacity, and suction values increase rapidly as plants remove water past 15 to 20 centibars. For sensitive crops, like potato, rapid irrigation may be required before damaging stress can develop.
20–40	Irrigation range	Available water and aeration good for plant growth in fine- and medium-textured soils. Irrigation is not required for these soils at this range. Coarse-textured soils may require irrigation in the 20 to 30 centibar range and the finer sandy soils at 30 to 40 centibar ranges.
40–60		Usual range for starting irrigation. At 40 to 50 centibar, irrigation may need to be started for loamy soils. On clay soils (silty clay loams, silty clays, etc.), irrigation usually starts from 50 to 60 centibars. Heavy clay soils still have some available water. Irrigation, however, ensures maintaining readily available soil water. The stage of growth and type of crop will influence the decision.
70	Dry	Stress range. However, crop is not necessarily damaged. Some soil water is available in clay soils, but may be low for maximum production.
80		Top range of tensiometer accuracy; higher readings are possible, but tension within the water column inside tensiometer will break between 80 to 85 centibar, which has relationship to elevation of the area compared with mean sea level. At higher elevation, the continuity of water column inside the tube may break at a lower reading because of change in vapor pressure according to change in atmospheric pressure.

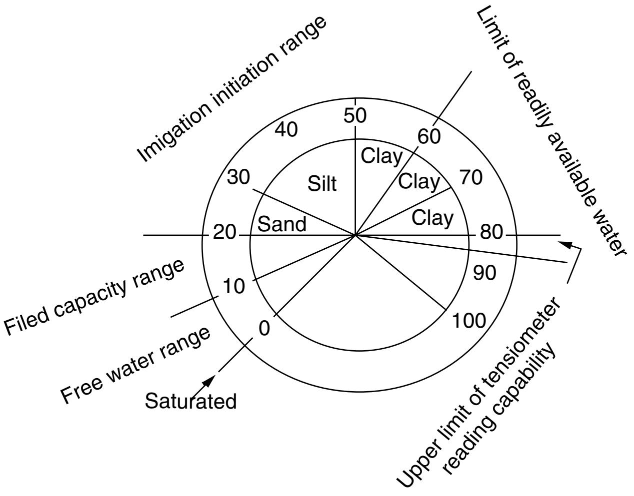

Figure 2. Schematic of the tensiometer vacuum gauge dial to show interpretation of readings in relation to soil type.

the tensiometer rises with the drying of soil to the point where the switch has been set, the magnet on the gauge overrides the small biasing magnet inside the switch, which causes the reed switch to close. The switch is wired into a low-voltage current loop from the control device to the solenoid valve. The switch closure completes the circuit and allows the solenoid valve to open and irrigation to start. When the soil rewets, the indicator needle drops down and the switch opens interrupting current loop from the control device that causes the solenoid valve to close, terminating irrigation.

For automated data collection, the standard vacuum gauge is replaced by a pressure transducer, where the partial vacuum reading is converted as current flow signal. The partial vacuum, caused by water moving out of tensiometer, causes a deflection in the face of the transducer, which excites the electronic elements of the device to generate the signal in a certain milliampere range equivalent to centibar or kPa linear scale. These changing signals coming from the transducer may be recorded by data logger or computer. The reading is continuous. The data acquisition computer may be programmed to start an irrigation system at a certain value. The automated versions of tensiometers enable remote operation of the irrigation system.

WORKING PRINCIPLE OF A TENSIOMETER

Soil water exists primarily as thin films around and between soil particles and is bound to soil particles by strong molecular forces. As the soil dries, the water films become thinner and become more tightly bound to soil matrix. This increase in tension within the films now in contact with the tensiometer causes water to be drawn from the ceramic tip. The withdrawal of water from the ceramic tip creates a partial vacuum within the tensiometer. Water continues to be drawn until the vacuum created inside the tensiometer equals the tension of the water films outside. At this point, equilibrium is reached and water ceases to flow. The vacuum gauge reading indicates the amount of suction or tension.

As water is added to the soil from rainfall or irrigation, the soil suction is reduced. The higher vacuum in the tensiometer causes soil water to be drawn into the tensiometer, and the vacuum will be reduced until a balance in tension is reached. The tensiometer continuously responds and maintains a balance with the soil water suction or tension, and the vacuum gauge indicates the amount of tension, hence the name tensiometer.

PREPARING THE TENSIOMETER FOR FIELD USE

Preparing a tensiometer for use starts with filling the reservoir and body tube with distilled water, taking care that the ceramic tip is wetted from one direction to avoid air entrapment in the finer pores of the ceramic tip. Allow the tensiometer to stand upright, and soon the tip will wet-up and free water will appear like sweat on the outer surface of the ceramic tip. Refill as necessary to dispel all the air from the tensiometer. A hand-operated vacuum pump may be used to help remove air from the tensiometer. Operating the pump when the tensiometer is filled with water and the tip is submerged in water helps remove gases from the pores of the ceramic tip and solution. After each pumping, refill the tensiometer completely with water and repeat until no more bubbles are observed. The tensiometer is then sealed by screwing the reservoir cap down securely.

After letting it stand in water in a bucket overnight, the tensiometer may be set outside upright in the air. The air will start drying the tip. The gauge should read 70 when the tip is air-dried. Repeat the wetting and drying cycle with the tensiometers that do not respond correctly the first time.

Tensiometers require checking prior to installation. As with any measurement device, proper care and maintenance are required. If the tensiometer was used previously, begin by washing and rinsing it inside and out. Residues on the porous ceramic tip that were not removed by washing may be removed by sanding lightly. Distilled water treated with three to five drops of chlorine bleach per gallon of water can be used to inhibit algae growth. Manufacturers also provide solutions for water treatment, which may be used according to direction. Distilled water available in a grocery store has been found to be adequate. If an excessive amount of air bubbles are noticed, then boiling may be helpful, but the remaining water must be stored in an airtight container.

If tensiometers are not to be installed immediately, cover the tips with a plastic bag to prevent evaporation or let them stand in a bucket of water until installed.

TENSIOMETER INSTALLATION

Site Selection

The number of tensiometer installation sites required will depend on the crops grown and field conditions. Fewer stations of tensiometers are needed when a single crop is grown in large blocks of uniform soil. If the soils are variable, different crops are to be grown and more stations are necessary. Stations need to be selected to represent an area, and care should be taken not to cause excessive compaction or destruction of plants during the installation process.

Except for very shallow-rooted crops, tensiometers are normally installed in groups of two or more to characterize the soil in the top half to three-quarters of the root zone. If the potential root zone is less than 12 inches, a single tensiometer may be installed in the center of the zone at 6 inches deep. With deeper-rooted crops, one tensiometer should be placed at the upper one-quarter of the rooting depth and another at the lower quarter point or three-quarters of the depth (see Fig. 3).

In deeply rooted crops, or situations where a distinct break in soil textures exists, three or more tensiometers may be needed. An example might be 18 inches of sand overlying a silty soil on which corn is grown and 3 to 4 feet of the root zone is to be managed. One tensiometer might be placed at 6 inches, a second at 18 inches, and a third at 2 to 3 feet. The differences in tension readings would make it possible to better assess the soil water conditions. Almost 70% of crop water is supplied by the top half and only 10% from lower one-fourth of the rooting depth. Irrigators, therefore, often manage only the top half or three-fourths of the root zone. Tensiometers should be long enough to reach the desired depth, and the diaphragm of the vacuum gauge must not touch the ground. The tensiometer should never be set in a hole or a depression.

Tensiometers may be installed using a soil auger or a probe. Manufacturers also provide simple coring tubes. Placement should be in a crop row to avoid traffic. Where furrow irrigation is used, the tensiometers may be angled slightly to place the tip under the furrow. The electronic tensiometers may require a cover to safeguard the electric connections from sprinkler or rainwater. If a valve cover box is used, the tensiometer tips need to be slanted out to be in the crop area. The hole should be small enough to create resistance to insertion of the tensiometer and the bottom shaped to form a close soil contact at the tip, which may be accomplished by returning a little loosened

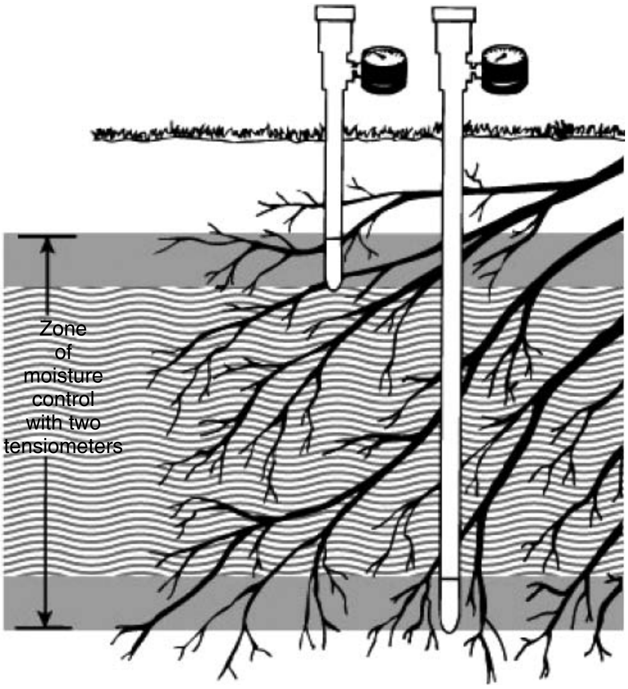

Figure 3. Sketch showing root zone moisture evaluation and control by two tensiometers.

portion of the soil from the depth of placement back into the hole and adding a little water. When the tensiometer is pushed for placement, the soft soil will move around the tip to conform to the rounded shape of the tip and make a good contact. A good contact is absolutely essential for the tensiometer to perform.

Tensiometers must be handled with care, because the tips may break if handled roughly. The depth label on the tensiometer will identify the root zone being monitored. Tensiometer locations need to be marked both in the row and at the edge of the field. A wooden stake painted bright or a metal rod with a colored flag attached are good markers. Locating tensiometers in tall crops can be a problem. A written log of the station locations is also recommended.

Servicing

Tensiometers are weatherproof, except for freezing, and generally require very little service. When first installed, there may be tiny air bubbles clinging to the sides of the body tube. However, after one cycle of soil water use, which creates a high vacuum, the bubbles will rise to the top and can be eliminated by refilling. The amount of bubbles will depend on the gas originally present in the vacuum gauge and the amount dissolved in the water. Servicing is best done soon after irrigation. Tensions are low, and air that may have been drawn into the cup at high tensions can be eliminated by refilling. Tensiometers return to equilibrium rapidly at low tensions. They also respond quickly to a very minute withdrawal of water from the system. If much air is drawn into a tensiometer at low tensions, the porous cup may be defective, and the tensiometer may need to be replaced. Some air entry is unavoidable. When using a number of tensiometers, watch for tensiometers that accumulate abnormal amounts of air. The colored fluid concentrate, supplied by the manufacturer for control of algae, helps to spot air bubbles in the tensiometer more easily.

Tensiometers should be removed from the field before freezing. The water can freeze and break the ceramic tip or the body, or damage the vacuum gauge. Tensiometers need to be emptied before long-term storage, which prevents salt deposition in the porous material with evaporation or rusting of the gauge.

Troubleshooting

A tensiometer that is out of water or leaking will remain at zero on the gauge, or the reading will fluctuate in the low suction range. Two or more successive zero readings may be a sign of a malfunction and should be investigated. If the gauge remains at zero, refill with water and use a hand pump, if available, to remove air. The tensiometer may have been empty because of dry soil. If the tip was dry, fine air bubbles will rise rapidly for several minutes and then cease. If larger bubbles rise and continue, a leak is indicated and the source should be determined. If the bubbles rise from the bottom, remove the tensiometer and replace the tip. If the bubbles enter from the side, the body tube may be cracked and should be fixed. If bubbles rise from the gauge, the leak may be in the gauge or the threaded connection. A leaky gauge needs to be replaced, but a threaded connection can be resealed. If no large bubbles rise and yet the reading remains at zero then the reservoir cap may be cracked or the seal may be defective. Inspect for 'O' ring if there needs to be one for a proper seal. In most cases, the trouble is easily corrected.

A damaged vacuum gauge may stick in one position or may not respond smoothly with changes in soil water. Check a suspect gauge against one known to be in good working order or replace the suspect gauge with a new one. Readings that are higher than expected, especially after irrigation, generally do not indicate a tensiometer failure. The irrigation water may not have penetrated to the depth of the tensiometer tip.

General Guidelines

- Place two or more tensiometers of different lengths near one another (a station), usually in the crop row. Two stations may be enough in a field with uniform soil and slope. One station should be near the start of an irrigation set and the other at the end of that irrigation set. The location of stations will depend on the type of irrigation system. With furrow irrigation, this location may be at the upper and lower quarter points of the first set in the field. For a center pivot, it may be in the outer and middle spans. If desired, one set may be established at the starting point of the pivot and another set at the endpoint.
- Tensiometer stations should be located in representative areas of the field. Do not position tensiometers in low spots or on knobs, and place them where the plant population is representative of the field.
- Tensiometer installation depth is determined by the active root zone of the crop. For example, for a corn crop on a deep soil, three tensiometers, installed at depths of 12, 24, and 36 inches, are recommended at each station.
- One should wait 24 hours after installing the tensiometer to obtain reliable readings. If the soil was dry at installation, irrigation or rainfall may be needed before obtaining satisfactory readings.
- Tensiometers should be installed as early as possible during the growing season and left in the field for the duration of the growing season. The roots of the crop must grow around the porous tip for reliable readings. Moving of the tensiometer during the growing season is not recommended.

LIMITATIONS OF TENSIOMETER

The major criticism of the tensiometer is that it functions reliably only in the wet range of soil water at readings of about 80 centibar or less. At higher readings, the porous tip may leak air and the gases will be drawn out of the water, and at low pressure, the water will vaporize causing discontinuation of the tension column or vacuum. The gauge reading will fall to zero, which is not as serious as it may seem, because most of the available water in coarse-textured soils, and about 50 percent or more in fine-textured soils, have already been used up at this range.

Another criticism is the price, which ranges from $35 to $60. When used in large quantities, the cost may seem prohibitive. Irrigation scheduling, however, has been shown to easily pay off through increased yields or reduced pumping cost. Proper handling may extend the useful life, and the cost may be spread over many seasons, making it cost effective.

Finally, the ceramic tip may gradually fill with precipitates because of soil water movement through the pores, which slows water transfer through the tip and increases the time required for the tensiometer to respond to a change in soil-water conditions. Some slowing does no harm, but if the response time becomes too slow, a new tip should be installed. The response time may be improved by rubbing the exterior of the tip with fine sand paper or soaking the tip in a mild acid solution. The amount of plugging depends on the soil-water chemistry and the manner of use.

Where tensiometers can be left in the ground, the tip porosity remains satisfactory for several years in most soils. However, each time the tensiometer is removed from the soil, tip life is reduced, which is particularly true if the soil is calcareous or saline. In extreme cases, where the tensiometer is installed and removed several times per season, the tip may need to be replaced after one year of use. To minimize this damage, a tip that is removed from the soil should be protected from drying until the tensiometer has been emptied, cleaned, and dried.

TILE DRAINAGE

Tara Reed
University of Wisconsin-Green Bay
Green Bay, Wisconsin

Tile (or relief) drains are porous pipes buried approximately 1 m beneath the surface of the soil. These pipes drain excess water from the land into nearby water bodies, most typically cisterns, open ditches, or streams. The most common use of tile drainage is to improve agricultural production by draining excess moisture from the plant root zone and allowing cultivation normally saturated soils. Subsurface tile drainage also lowers the water table and reduces soil salinity. Many of the world's productive agricultural areas, including 25% of the cropland in the United States, require artificial drainage (1). The area drained by subsurface drainage systems in the United States has increased since 1900 from less than 5 to almost 30 million hectares (2).

TILE DRAINS AND SURFACE WATER QUALITY

The impact of tile drainage on receiving water bodies varies (3). Site-specific variables such as soil characteristics, topography, climate, and precipitation patterns as well as the configuration of the drainage network and other land management practices determine the proportion of precipitation resulting in surface runoff and subsurface drainage and the overall impact on receiving water bodies. Because rainfall can penetrate further into the soil, surface water drainage is reduced in tile-drained fields compared to saturated soils (4). Depending on local conditions, subsurface drainage can reduce surface runoff (4,5).

Increased infiltration prolongs the time that water is in contact with the soil, thereby often reducing the transport of pollutants that are likely to adsorb to soil particles and increasing leaching of pollutants that are easily released (6). The difference between surface and subsurface water drainage may be minimized when there are direct surface water inlets into the subsurface drainage network or during particularly heavy rains, although Schwab et al. (5) found that good subsurface drainage decreased storm peak discharge by as much as 30%. On the other hand, management practices such as riparian buffer strips that are designed to reduce surface runoff usually do not target subsurface drainage. In these cases, tile drains may result in increased pollutant loading during storms (7).

Pesticides and Herbicides

Agricultural pesticides and herbicides enter surface waters by both surface runoff and subsurface drainage. Whether subsurface drainage decreases the amount of pollutant entering the waters depends on the hydrologic characteristics of the site and the particular chemical used. The two pollutant characteristics important to this discussion are persistence (the time it takes to degrade to a nonpollutant form) and soil sorption (the degree to which the pollutant adsorbs to soil particles). Persistent pesticide/herbicides are most likely to drain (either by surface runoff or subsurface drainage) into nearby receiving waters. Subsurface drainage is most likely to reduce the transport of pesticides and herbicides with high soil sorption qualities. Soil characteristics can influence sorption, which is greatest in strongly organic soils and those that have high clay content.

Pesticides are most commonly detected in subsurface flow during the first heavy rain following application. Other peak periods include soil thawing and tillage. However, the most important factors determining pesticide transport are precipitation volume and timing and soil type. Pesticide loss through tile drainage is usually substantially lower than loss through surface runoff. For an excellent review of tile drainage and pesticide transport, see Kladivko et al. (6).

Nutrient Pollution

Nitrogen. Much of the fertilizer applied to a field can be lost through tile drains. This is particularly true for nitrogen, which is more mobile than phosphorus in soil. Different species of nitrogen react differently. Tile drainage usually decreases losses of organic nitrogen and increases loss of nitrates and ammonium (3).

Depending on the form of fertilizer applied, in wet years, up to 70% of the nitrate applied as fertilizer can flow off fields through drainage systems (8). Manure application leads to significantly less nitrate loss to tile drains than commercial fertilizer application (9). Drain placement may also be important for reducing nitrogen losses through drain tiles. For example, shallow drains reduce nitrate leaching (10), and more frequent drain tile spacing reduces ammonium losses (11). Placement of tile drains in areas of preferential flow for manure or fertilizer applications can elevate effluent nutrient concentrations (12).

Phosphorus. Even though phosphorus (P) adsorbs strongly to soil particles, artificial drainage is an important contributor to nonpoint-source phosphorus pollution (13). Burke (14) reported phosphorus losses through drainage of approximately 33% of the amount applied in fertilizer. Other estimates range from 2% (15) to 17% of the applied phosphorus lost in drain tile effluent (16).

The greatest P loss from agricultural systems occurs during intensive rains (17). At these times, both surface flow and tile drain effluent P concentrations are highest (18). Tile drain discharge may be nonlinearly related to rainfall intensity. For example, in a small drainage system in Sweden, Ulen and Persson (19) found that half the yearly P export through drain tiles occurred during an average of 140 hours of episodic rain.

The ability of soils to retain P depends on soil P concentrations. As soils become P saturated, leaching becomes more prevalent. The point at which this happens varies in different soils ranging from 10–119 mg Olsen P kg^{-1} soil (20). The mass of phosphorus lost from agricultural systems via tile drains is small compared to nitrogen (21), but the impact on phosphorus-limited aquatic systems may be substantial.

TILE DRAINAGE AND MANAGEMENT

Agriculture in many areas would be difficult, if not impossible, without subsurface drainage. Research is ongoing into strategies for managing pollutants in drain tile effluent. Examples include controlled drainage where subsurface drainage systems are fitted with barriers to restrict drainage (3), subirrigation systems that both control drainage and provide increased irrigation to crops during nonsaturated periods (22), constructed treatment wetlands (23), and land retirement (24). Finding solutions that are both environmentally and agriculturally acceptable is critical to the survival of the world's waterways.

TILE DRAINAGE: IMPACTS, PLANT GROWTH, AND WATER TABLE LEVELS

Chandra Madramootoo
Macdonald Campus of McGill University
Ste-Anne de Bellevue, Quebec, Canada

Tile drainage is a method of artificial drainage, which lowers the water table and reduces water logging on productive agricultural lands. Improved drainage is an agricultural, rather than a land conversion, practice. The objective is to increase production efficiency, crop yields, and profitability on poorly drained agricultural lands. In the wetter, humid regions, precipitation will cause the water table to rise at, or near, the soil surface. If high amounts of precipitation occur during the growing season, the water table could rise within the crop root zone. The same situation occurs in the drier, arid, and semi-arid regions where irrigation is extensively practiced. Continual irrigation and canal seepage over the years lead to an accretion of the water table, and this could also be injurious to plant growth.

Every soil has some degree of natural drainage. However, if the rates of precipitation or irrigation exceed the natural drainage rate of the soil, the high water table conditions will impair crop growth, because of a lack of oxygen in the root zone. Artificial, or tile drainage, is therefore required to remove excess soil water and to lower the water table, to maintain an optimum soil–air environment within the crop root zone. Most of the world's highly productive agricultural soils require either surface drainage or tile drainage, or a combination of both, to maintain stable crop yields. It is estimated that there are about 200 million hectares of cropland worldwide with improved drainage. The benefits of drainage are given in Fig. 1.

- Ability to better manage and control the water table for enhanced crop productivity
- Reduced flooding
- Better soil water conditions for seedbed preparation and planting
- Earlier and more uniform seed germination
- Improved field machine trafficability
- More favorable air and salt balances in the crop root zone
- Higher crop yields and reduced yield variability
- Ability to plant higher value crops
- Higher farm incomes
- Increased land values
- Less soil erosion
- Better uptake of nutrients
- Improved soil structure
- Enhanced soil microbiological activity
- More timely field machine operations
- Ability to effectively lengthen the growing season, and make better use of lower heat units in northern regions
- Potential to improve water quality

Figure 1. Benefits of tile drainage.

Tile drainage (also known as subsurface pipe drainage) is the installation of horizontal, corrugated, perforated plastic pipes below the soil surface to enable water table drawdown. Parallel lateral pipes are normally of 75 to 100 mm in diameter and are installed on grades varying from 0.1% to 3%. The downstream ends of the laterals are connected to a buried collector pipe. The diameter of the collector increases with the area drained. The spacing between the lateral pipes depends on the soil type and the amount of water to be removed. The lateral pipes can be installed in a parallel layout, herringbone layout, or at random. Depending on topography, land formation, and proximity of a water receiving body, the collector may outlet by gravity to a watercourse, or into a sump. In the case of the latter, the discharge is then pumped to a lake or stream. Before the advent of plastic pipe in the late 1970s, clay tile pipes were used. However, plastic pipes are lighter and easier and faster to install. The drainage coefficient (or volume of water to be removed by the drainage system) in humid regions is about 10–15 mm/day.

One adaptation of tile drainage is the use of surface inlets to remove water ponded in surface depressions, or as conservation structures to reduce surface runoff and erosion on sloping lands. The drainage coefficient for these systems ranges from 15 to 20 mm/day.

In the irrigated regions, tile drainage not only controls the rise of the water table, but also reclaims salinized soils. The salinity of irrigated soils could increase with time, and this also reduces crop yields. Water in excess of the plant evapotranspiration requirement is applied during irrigation. This additional quantity of water is known as the leaching fraction. Salt is then leached from the root zone and removed from the field via the tile drains. Deeper drain installation ensures that salts do not rise to the root zone because of capillary action, which also prevents waterlogging of the root zone. The amount of surplus irrigation water to be removed by the tile drainage system is less than in humid regions. Consequently, lateral pipe drainage spacings are wider than in the humid regions. The drainage coefficient in irrigated regions varies from 2 to 5 mm/day.

Horizontal pipe drainage systems are usually installed with either a trenchless plow or a chain or wheel type trencher. The trenchless plow is widely used in Europe and North America and results in faster installation rates. The depth and grade of the pipe installation equipment is achieved with a horizontal laser grade control system. In cases in which installations are conducted in fine sand and silty soils, the pipes are wrapped with a synthetic geotextile, to minimize blockage of the drainage system by the soil particles.

Another form of subsurface drainage is known as vertical drainage or tubewell drainage. It primarily controls waterlogging and salinity in the irrigated regions. The primary purpose of tubewells is to abstract groundwater for irrigation, and consequently, the water table is lowered, and salinization caused by capillarity is minimized. This situation is ideal where the groundwater is not very brackish, or saline, and therefore suitable for irrigation. In areas where the groundwater is saline, then the pumped irrigation water must first be mixed with fresher, or sweeter, water in irrigation canals.

When subsurface pipe drainage reclaims salinized and waterlogged lands, it is viewed as an environmentally beneficial practice, because degraded lands that were once intensively irrigated and cropped are returned to their full productive potential.

Drainage installations result in both hydrologic and land use changes. On poorly drained lands, surplus water is either ponded on fields or moves as surface runoff to nearby open water bodies. On tile drained lands, water percolates below the root zone, which reduces surface ponding and runoff. Infiltrated water is stored in the soil profile and will eventually percolate to the deeper groundwater table.

Some of the most significant technological developments in tile drainage occurred in the period 1965–1975. Beginning in the 1980s, environmental concerns about drainage water quality emerged. High concentrations of nitrates were being measured at the outlet of tile systems. Drainage practitioners responded to these concerns with new technologies such as watertable management, controlled drainage, and subirrigation. Tile drainage is now regarded as a multifunctional water management practice, with systems being designed to not only serve crop needs, but also minimize environmental impacts.

Controlled drainage and subirrigation make use of the existing tile drainage system to raise the water table during certain periods of the year. By either restricting the outflow of water from the tile outlet or by pumping water back into the drainage system, particularly during the growing season, the crop can obtain water from the water table to meet its evapotranspiration requirement. This process helps to reduce the effects of drought stress during the growing season, thus increasing crop yields. An additional important benefit is that the amount of nitrates leaving the tile outlet is reduced, because of a process known as denitrification.

The benefits of tile drainage go beyond the control of excess soil water and salts in the crop root zone. Environmental and socioeconomic benefits are associated with vector control and public health. For example, drainage of stagnant water eliminates malaria, foot-rot in large animals, yellow fever, the liver fluke snail, and other waterborne diseases. The overall benefit is a healthier human population. Drainage also reduces or eliminates mildew infections and various root rots of plants.

MEASURING AND MODELING TREE AND STAND LEVEL TRANSPIRATION

J.M. Vose
G.J. Harvey
K.J. Elliott
B.D. Clinton

(from *Phytoremediation: Transformation and Control of Contaminants*, Wiley 2003)

SUMMARY OF PRACTICAL IMPLICATIONS

Transpiration is a key process in the application of phytoremediation to soil or groundwater pollutants. To be successful, vegetation must transpire enough water from the soil or groundwater to control or take up the contaminant. Transpiration is driven by a combination of abiotic (climate, soil water availability, and groundwater depth) and biotic (leaf area, stomatal functions, root amount and distribution, and hydraulic characteristics) that need to be evaluated when considering appropriate site and species combinations. The protocols are not trivial, but transpiration can be measured at a variety of scales using techniques such as direct measurements of sap flow on individual trees, eddy flux gradient analyses, or gauged watersheds. Alternatively, models can be used to estimate transpiration, but these usually require on-site calibration or parameterization to produce accurate predictions. Case study analyses across a range of site conditions and species indicate a maximum transpiration capacity of approximately 7.5×10^6 liters of water per hectare per year (8×10^5 gallons of water per acre per year), with a range of 1.5×10^6 to 7.5×10^6 liters per hectare per year (1.6×10^5 to 8×10^5 gallons per acre per year). Variation among sites is related to species, tree size, and stocking (i.e., vegetation density) differences. Application of a physiologically based and site-specific parameterized model suggests reasonable agreement between measured and predicted transpiration estimates for the Air Force Plant 4 site in central Texas.

IMPORTANCE OF ACCURATE MEASUREMENTS OF TRANSPIRATION

Transpiration—the amount of water used by a tree or stand of trees—is one of the key processes in the application of phytoremediation of soil water or groundwater pollutants. To be successful, native or planted vegetation must transpire enough water from the soil or groundwater layer containing the pollutant to control the transport or decrease the mass of contaminant. Hence, quantifying current and future transpiration and determining the principal location of water uptake by native and planted vegetation on the site must be the evaluation criteria for applying phytoremediation. Quantifying transpiration requires a thorough and accurate assessment of water use patterns such as, transpiration rates, depth of soil water uptake, interactions with climate, and soil water availability. Measuring current transpiration or predicting future transpiration is not trivial. Because transpiration is an integrated response of the atmosphere–plant–soil continuum, measurements and predictions of transpiration capacity must account for (1) variation in climatic driving variables (i.e., solar radiation, water vapor saturation deficit, precipitation, wind speed, and temperature), (2) structural and physiological (leaf stomatal function) characteristics of the vegetation (leaf surface area, and root area and extent), and (3) soil water dynamics (water-holding capacity, and permeability).

Evapotranspiration and transpiration are often used interchangeably, but these processes are different. Evapotranspiration includes the amount of water transpired by the vegetation, and losses due to evaporation of intercepted precipitation and soil surface evaporation. In forests, interception evaporation is a function of rainfall intensity and leaf and branch surface area, ranging from about 10 to 50 percent (1–3). In closed canopied forests, soil evaporation is a minor component of the overall water budget (3), but may become increasingly important in open stands. From a phytoremediation perspective, transpiration is the key factor to consider because interception evaporation does not involve soil water or groundwater.

The process of transpiration involves water movement through the soil, roots, stems, and leaves into the atmosphere in response to water potential gradients—always moving in the direction of smaller potential or negative gradients. Water potential is near zero when water is freely available and decreases to negative values when water becomes more limiting. The movement of water from the leaf interior to the atmosphere occurs through small openings in the leaf called stomata, which open and close in response to external (e.g., climatic factors) and internal (e.g., water potentials of leaves) driving variables. Species vary considerably in stomatal responses to these driving variables and provide opportunities for selecting species to optimize transpiration in different climatic environments.

Five methods are used to quantify transpiration: (1) precipitation minus runoff on gaged watersheds, (2) energy balance (e.g., Penman-Monteith equation), (3) eddy covariance, (4) hydrologic models, and (5) direct sap-flow measurements. The first three methods are integrated estimates for the entire vegetation–soil complex and provide estimates of evapotranspiration not transpiration. Hence, those methods do not directly partition water losses based on transpiration *versus* evaporation and provide no information on the source of water (i.e., shallow *versus* deep soil layers) for transpiration. Estimating transpiration with methods 1, 2, and 3 requires an independent analysis of the contribution of interception and soil surface evaporation. Hydrologic models vary considerably in complexity, ranging from very simple models [e.g., Thornthwaite (4) indices of potential evapotranspiration] to detailed physiologically based models that link vegetation, soils, and the atmosphere (3). In contrast, sap-flow measurements provide a direct measure of transpiration (after correcting for time lags) under field conditions at the individual tree level (5–7). However, modeling or other scaling approaches are required to extrapolate tree-level measurements to the stand.

In summary, there are numerous approaches to quantifying transpiration in native or plantation-derived vegetative ecosystems. However, these methods vary considerably in accuracy, in data and measurement requirements, and in the capability to predict future transpiration rates as stands develop. In this chapter, we review approaches to quantifying forest transpiration from the leaf level to the stand and discuss the pros and cons of different approaches. We then provide applications of a subset of these approaches from phytoremediation case studies in Texas, Colorado, and Florida.

OVERVIEW OF CONTROLS ON TRANSPIRATION

Transpiration rates vary considerably among species and geographic regions (Fig. 1). Which factors contribute to this variation? At large scales (i.e., regions), climate is an overriding control. The strong relationship between evapotranspiration and precipitation (Fig. 1) suggests that transpiration is principally limited by soil water supply. However, other climatic factors such as temperature, atmospheric vapor pressure deficit, and solar radiation also play important roles and interact with soil water availability and physiological status of the plants (Fig. 2). For example, one of the key effects of temperature is through the influence on the length of growing season, in which longer periods with temperatures above freezing promote longer leaf area duration and hence, surface area available for transpiration. Frozen or cold soils also restrict transpiration (9) by limiting the permeability of cell membranes (10,11). Solar radiation provides the

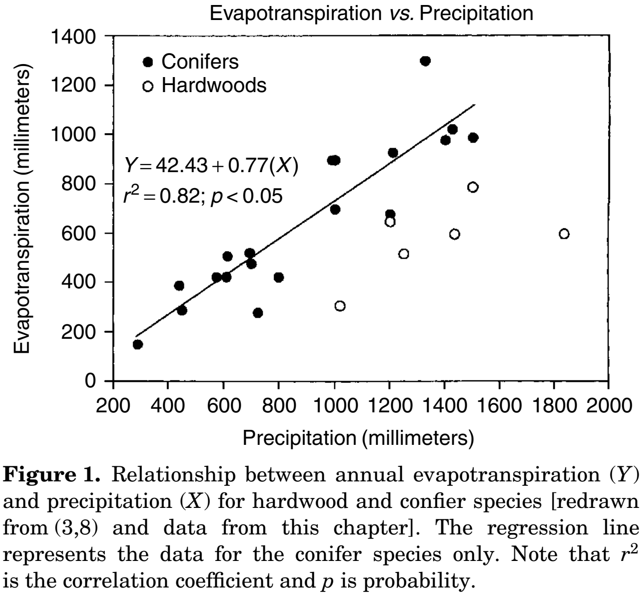

Figure 1. Relationship between annual evapotranspiration (Y) and precipitation (X) for hardwood and confier species [redrawn from (3,8) and data from this chapter]. The regression line represents the data for the conifer species only. Note that r^2 is the correlation coefficient and p is probability.

energy for transpiration and regulates stomatal opening. As a result, a strong relationship generally occurs between solar radiation and transpiration, estimated as sap flow in Fig. 2. Atmospheric vapor pressure deficit provides the gradient to which leaf-water vapor responds through the leaf stomata (Fig. 2), and wind speed has a direct influence on the leaf boundary layer (12). Optimal climatic conditions for transpiration include high soil water availability, high solar radiation, high vapor pressure deficits, warm temperatures for extended periods, and high wind speed. In most cases, these conditions do not occur simultaneously because increased soil water availability is usually a result of high rainfall that decreases solar radiation (due to increased cloud cover) and vapor pressure deficit (due to higher humidity). Species that have the ability to utilize deeper sources of soil or groundwater [i.e., phreatophytic vegetation such as poplar (*Populus* spp.) and willow (*Salix* spp.)] are an especially attractive option in hot, dry, and windy environments in the southwestern U.S., because transpired water can be derived from groundwater (13,14). Several studies have evaluated the influence of phreatophytes on surface and groundwater [e.g., (15–17)] from the perspective of negative impacts on streamflow and groundwater recharge. From a phytoremediation standpoint however, the high water consumption of phreatophytes has a positive effect to decrease aquifer recharge and influence the movement of contaminated shallow groundwater.

The structure, morphology, and physiological characteristics of the vegetation are also important regulators of transpiration. For example, at equal precipitation inputs, there are large differences in transpiration between conifer and hardwood species (Fig. 1), with hardwoods generally lower than conifers. Causes for these coarse scale differences are generally well known. The single greatest controlling factor is the quantity of leaves, expressed as leaf area index (in square meters per square meter). Site water availability and leaf area are related in that, sites with the

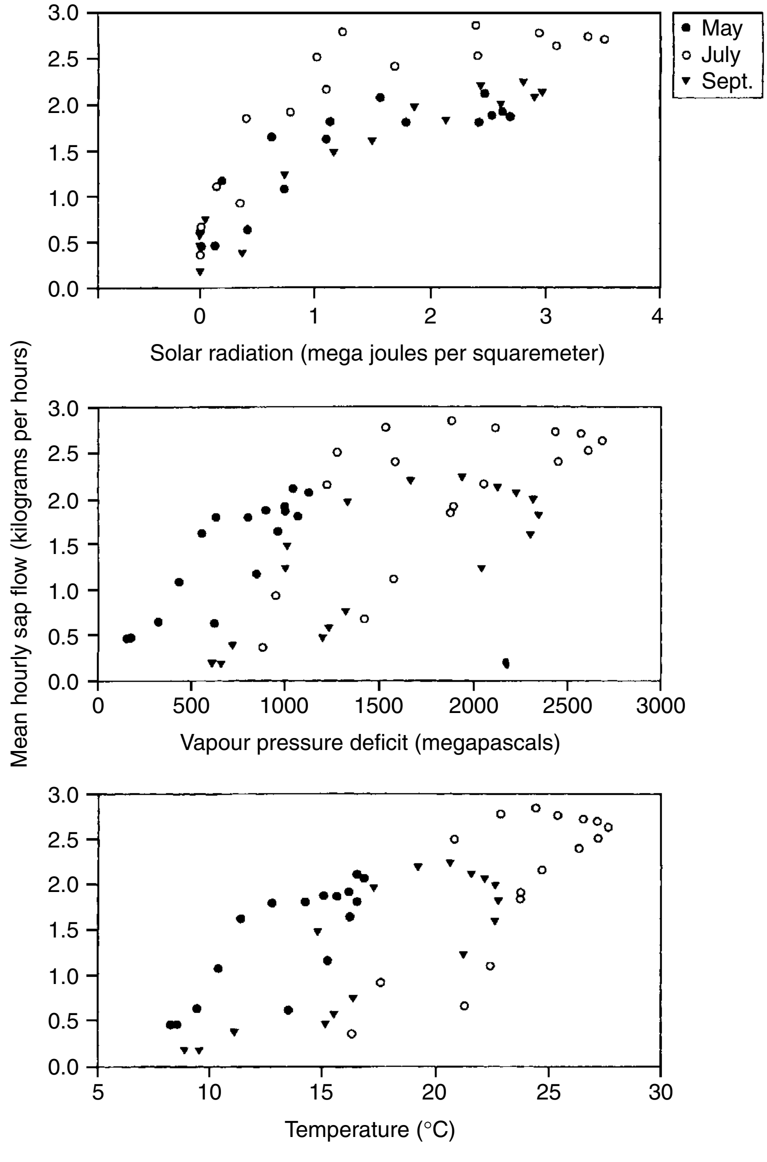

Figure 2. Mean hourly sap flows *versus* climatic driving variables for three seasonal measurement (May, July, and September) periods in central Colorado.

greatest water availability typically have the highest leaf area index (18,19), although nutrient availability (20,21) and temperature also play a role (22,23) in determining the maximum leaf area index. Watershed studies have documented strong relationships between leaf area and streamflow, with streamflow increasing exponentially as leaf area decreases (24,25). Because precipitation minus streamflow is an estimate of evapotranspiration at watershed scales, the implication is a direct control of stand-level transpiration by leaf area. Other structural and physiological factors regulating transpiration include the amount and permeability of sapwood and stomatal characteristics such as conductance and responsiveness to climatic variation and overall plant water status (i.e., water potential of leaves). Differences among species in leaf area, the rate of attainment of maximum leaf area, and physiological characteristics regulating the rate of water movement through the plant (sapwood amount and permeability, and stomatal conductance) provide opportunities for manipulating vegetation composition and structure to optimize transpiration. Optimal structural and physiological conditions for high transpiration amounts include rapid development of high leaf area, high stomatal conductance and sapwood permeability, and physiological characteristics that facilitate rapid responses to climatic conditions promoting transpiration.

Because transpiration is a function of root uptake from the soil and groundwater, soil characteristics are an important factor determining transpiration. Root growth and volume of soil occupied by roots are also important because water movement is slow when soils are drier than field capacity. Several factors determine soil water availability. First, the amount of precipitation entering the soil is a function of infiltration rate. Soils with low infiltration rates due to factors such as compaction or fine texture will have lower soil water availability because some precipitation may move across the soil surface in overland flow. Once in the soil, soil water availability is a function of water holding capacity and unsaturated hydraulic conductivity, both of which are determined by soil texture. Texture impacts water availability in different ways. Heavy clay soils (e.g., pore size less than 0.2 micrometer) have limited soil water availability because of very low rates of movement in the soil (i.e., conductivity) due to the fine pore space. In contrast, coarse textured sandy soils (e.g., pore size greater than 50 micrometers) have low water availability because of rapid drainage. Rooting volume and the presence or absence of restrictive layers are also important soil factors determining transpiration. For example, compacted soils provide a physical barrier to root growth, limiting root extension (26).

QUANTIFYING TRANSPIRATION

Leaf Level

Because water exits the plant primarily through leaf stomata (a small amount of cuticular transpiration may also occur in stems of some species), leaf–water relations are a key factor determining whole-plant transpiration (27). The concentration gradient of water vapor between the interior of the leaf and the atmosphere at the leaf boundary layer defines the maximum transpiration rate. Vapor exchange is also determined by the opening size of the stomata. When stomata are wide open, transpiration occurs at about 20 percent to 40 percent of the rate of evaporation of open water (28), whereas closed stomata limit transpiration to less than 1 percent of open water. Stomatal opening is controlled by guard cell turgor, which responds to light, temperature, vapor pressure, and water potential of the leaves. The rate of movement of water through the stomata is the stomatal conductance. The rate of stomatal response to climatic conditions varies by species, but generally reflects responses to current conditions, whereas stomatal responses to water potential in leaves may reflect previous climatic and environmental conditions.

Because of the tight linkage between transpiration, leaf stomatal conductance (hereafter referred to as leaf conductance), and water potential of leaves, knowledge of all three parameters is useful for evaluating transpiration capacity. For example, species that exhibit high leaf-level transpiration and conductance, and maintain high water potential in the leaves have the capacity to transpire large quantities of water. Similarly, the relationship between water potential in the leaves and conductance is often threshold dependent; i.e., species that maintain high leaf conductance at low water potential have the capacity to transpire more water under dry conditions (29). Because of the importance of factors such as leaf area index and distribution, sapwood amount and permeability, and the difficulty in extrapolating spatially and temporally from the leaf to stand level, there may be no direct correspondence between leaf-level transpiration and overall stand transpiration. Typically, leaf conductance and tree and stand-level transpiration are most highly related in young stands with simple canopy architecture (7), such as closely spaced, even-aged monocultures. However, as stands develop, the linkage between leaf conductance and tree or stand-level sap flow declines due to shifts in the importance of stomatal *versus* boundary layer conductance to total vapor phase conductance (30,31). Hence, leaf-level measurements should only be used as an indicator of transpiration capacity.

Tree Level

Transpiration at the whole-tree level represents the integrated movement of water vapor from all the leaves in the crown of the tree. As mentioned in the previous section, spatial and temporal variation severely limits extrapolation of individual leaf measurements to the tree, so more direct measurements at the tree level are required. Two approaches have typically been used. In a few instances, entire trees have been enclosed in a cuvette and the flux of water vapor calculated based on the rate of increase in humidity within the enclosure. This approach is severely limited by methodological constraints such as the size of trees, heat buildup within the cuvette, and alterations in the boundary layer and vapor pressure gradients.

Sap-flow rate and volume have also been used as an estimate of transpiration (32). Because of lags between water movement in the stem and leaf-level transpiration, sap flow is not a direct measure of transpiration, but can be corrected after accounting for lags (33,34). Typically, a 1- to 2-hour lag correction is applied to real time sap-flow data to account for this temporal difference (7,34).

Two sap-flow techniques have been utilized; heat balance and heat pulse. For the heat-balance approach, collars consisting of a heating element and thermocouples above and below the heating element are placed around the stem and the entire stem section is heated. Sap flow is calculated using the heat-balance principle based on the difference in temperature between thermocouples above and below the heated stem section, after subtracting for heat loss due to conduction by stemwood (35). An advantage of this approach is that it integrates sap flow along the entire stem and does not require an independent estimate of sapwood area. For larger trees, paired probes are inserted vertically into the sapwood (36). The upper probe is heated and both contain thermocouples. The probes measure heat dissipation, which increases with sap flow and the resultant cooling of the heat source, as the apparent thermal conductance of sapwood increases with sap velocity. To convert sap velocity to sap flow rate, the cross-sectional area of sapwood must also be determined. Typically, trees are cored and sapwood to heartwood ratios quantified. Because sap-flow probes measure sap flow velocity at only one location, multiple probes are required to adjust for the variation in sapwood thickness and permeability in the stem section. Despite this, unaccounted for variation in horizontal and vertical variation in sapwood thickness and permeability introduces some error into sap-flow estimates obtained with probes. The magnitude of error can be determined experimentally and corrected for in small trees by comparing sap flow with actual transpiration using procedures such as weighing lysimeters. In large trees, corrections are much more difficult and hence, predictions have more uncertainty. In contrast to the heat-balance method, the heat pulse method estimates sap flow based on the time lag between pulses of heat and the distance between the sensors (37).

Stand Level

While it is informative to understand transpiration at the leaf and tree level to help evaluate species and environments suitable for phytoremediation, stand-level transpiration ultimately determines how much soil water and groundwater are removed. However, unlike leaf and tree measurements, no methods directly measure stand transpiration. Instead, three indirect measurement approaches have been utilized. These approaches involve gaged watersheds, extrapolation of individual tree measurements, and eddy flux estimates. Gaged watersheds require a combination of well-defined watershed boundaries, tight bedrock, and well-constructed weirs or gages to provide accurate transpiration estimates. If these criteria are met, then evapotranspiration (ET) is estimated by the equation

$$ET = P - RO \pm \text{soil water storage} \qquad (1)$$

where P = precipitation and RO = runoff, determined from weirs or gages. Because P is a component of the equation, the accuracy of precipitation measurements will also influence evapotranspiration estimates. Changes in soil water storage are usually assumed to be negligible at annual time steps, although this is clearly not the case over shorter intervals. Hence, using this approach at time steps less than a year requires determining changes in soil water storage. Because evapotranspiration is estimated, interception evaporation must be determined and subtracted to estimate transpiration.

Extrapolating individual tree measurements to the stand can be done in a number of ways. For example, instruments that measure sap flow can be installed on trees representing the averaged sized tree and mean sap flow multiplied times the number of trees in the stand (i.e., a “mean-tree” approach). Considerable uncertainty in stand-level estimates can accompany this approach where sites are variable. Alternatively, relationships between tree diameter, sapwood area, or basal area and sap flow at the individual tree level can be applied to all trees. In both approaches, repeated sampling is required to account for seasonal variability.

The eddy flux method uses water vapor gradients at fixed intervals above and below the canopy to calculate evapotranspiration. The technique is based on the assumption that water vapor flux is proportional to the vertical gradient of water vapor between two measurement points (averaged over several minutes). Typically, measurements are conducted from towers extending through the canopy. To be useful for estimating transpiration of a particular stand, the stand must be large enough to encompass most of the footprint measured by the sensors. In many phytoremediation applications conceived as of 2003, the stands are too small for an eddy flux approach to be appropriate.

Modeling

The use of modeling provides a potentially powerful tool for predicting current transpiration of native or planted vegetation and for projecting future transpiration capacity as a function of stand development. At the coarsest level of forecasting, gross measures of plant water demand and use can be derived from empirical estimates of potential evapotranspiration (4,38). These approaches usually consider climate and soils to some extent, but do not consider vegetation effects such as leaf area index, rooting depth, or leaf-level physiological characteristics. Hence, empirical approaches are useful for gross estimates of transpiration, but have limited utility for evaluating actual effects on the groundwater. At the other extreme, detailed physiological models that link the soil–plant–atmosphere continuum provide much more accurate estimates of transpiration. Depending upon the structure, models may also provide estimates of specific uptake locations within the soil profile (3,39,40). Using detailed physiologically based models results in significantly greater data requirements. The most accurate application of these models requires site-specific estimates of soils, climate, and physiological characteristics of the major species on the site. However, large-scale application of detailed models with generalized parameters may provide estimates sufficiently accurate to be used in evaluating phytoremediation applications.

MEASURING AND MODELING TRANSPIRATION: CASE STUDY APPLICATIONS

Study Site Descriptions

Sap flow was measured at sites in Texas, Florida, and Colorado as components of larger studies evaluating the efficacy of using phytoremediation technology to clean up shallow groundwater contaminants. The north–central Texas study site was located, about 15 kilometers west of Fort Worth. The climate of this area is characterized as subhumid, with mild winters and hot, humid summers. The average annual precipitation is 80 centimeters per year with most rainfall occurring between May and October. Average annual temperature is 18.6 °C. Study plots were located on the U.S. Naval Air Station, which adjoins U.S. Air Force Plant 4. A plume containing trichloroethylene was detected in the terrace alluvial aquifer in 1985. To demonstrate phytoremediation potential, eastern cottonwood (*Populus deltoides* Marsh.) trees were planted in two plantations over the TCE plume. One plantation was planted with vegetative cuttings (whips) and the other with 1-year-old nursery grown seedlings. Each plantation was approximately 80 by 20 meters and located perpendicular to groundwater flow in the alluvial aquifer. Sap-flow measurements were conducted using the heat-balance method (collars) in the first and second year after plantation establishment.

The eastern Florida site was located in the city of Orlando. The climate of the area is humid, with mild winters and hot, humid summers. The average annual temperature is 22.6 °C and the average annual rainfall is 123 centimeters. Native vegetation of interest was located on the U.S. Naval Training Center. Trichloroethylene and tetrachloroethylene, which originated from a dry-cleaning facility that is no longer in operation, contaminate shallow groundwater. The plume extends under a 2-hectare forest and seepage wetland before reaching Lake Druid that borders the forest. A dense and diverse mix of overstory and understory species occur in the forest (density of 107 trees per hectare), with red bay [*Persea borbonia* (L.) Spreng.], camphor [*Cinnamomum camphora* (L.) Nees & Eberm.], slash pine and longleaf pine (*Pinus* spp.), sweet bay (*Magnolia virginiana* L.), and live oak and laurel oak (*Quercus* spp.) most abundant in the overstory. The most abundant understory species are skunk vine (*Paederia foetida* L.), saw palmetto [*Serenoa repens* (Bartr.) Small], cinnamon fern (*Osmunda cinnamomea* L.), and Christmas fern [*Polystichum acrostichoides* (Michx.) Schott.].

The central Colorado site is located approximately 20 kilometers southwest of Denver. The climate of the area is dry, with warm summers and cold winters. Annual precipitation averages approximately 44 centimeters, with 30 percent of this amount received in April and May. The average annual temperature is 12 °C. Study plots were located on the U.S. Air Force Plant PJKS. Trichloroethylene and dichloroethylene from a variety of sources contaminate the site. Measurements were conducted in two existing stands of natural vegetation: cottonwood–willow (*Populus* spp.–*Salix* spp.) and Gambel oak (*Quercus gambelii* Nutt.) The cottonwood–willow (*Populus* spp.–*Salix* spp.) stand is restricted to riparian areas (approximately 1 percent of the total land area of the site), while the Gambel oak (*Quercus gambelii*) stand is on more midslope locations (approximately 30 percent of the total land area of the site).

Methods

The sampling approach and methods varied among the three studies based on study objectives, species composition, and tree sizes. For the Texas study, sap flow from saplings in the plantation was estimated using sap-flow gauges (Dynamax Inc., Houston, TX) on 14 to 16 trees (divided equally among whips and 1-year-old trees) in May, June, July, August, and October over a 2-year period. During each measurement period, sap-flow measurements were taken every minute for 2 to 3 consecutive days. Data presented in this chapter represent averages of both plantations. In addition, sap flow was measured on nine larger native trees growing near the plantations using thermal dissipation probes (Dynamax, Inc., Houston, TX). Species sampled were: eastern cottonwood (*Populus deltoides* Marsh.), American elm (*Ulmus americana* L.), black willow (*Salix nigra* Marsh.), sugarberry [or large hackberry, (*Celtis laevigata* Willd.)], Eastern red cedar (*Juniperus virginiana* L.), and mesquite (*Prosopis pubescens* Benth.). At the end of sampling, increment cores were taken from the nine large trees for determining sapwood area.

For the Orlando study, sap flow was estimated using thermal dissipation probes installed on nine trees representative of major canopy species. Species sampled were: slash pine (*Pinus elliottii* Engelm.), longleaf pine (*Pinus palustris* Mill.), live oak (*Quercus virginiana* Mill.), laurel oak (*Quercus hemisphaerica* Bartram ex. Willd.), sweet bay (*Magnolia virginiana* L.), and camphor [*Cinnamomum camphora* (L.) Nees & Eberm.]. Two probe sets were installed into the sapwood on the north and south sides of sample trees, and sampling was conducted in November, March, and July for 2 to 3 consecutive days over a 1-year period. At the end of sampling, increment cores were taken and sapwood area determined.

For the Colorado study, sap flow was estimated using thermal dissipation probes on eight trees representing three species: eastern cottonwood (*Populus deltoides* Marsh.), narrow-leaf cottonwood (*Populus angustifolia* James.), and Gambel oak (*Quercus gambelii* Nutt.). Two probe sets were installed into the sapwood on the north and south side of sample trees and sampling was conducted in May, July, and September over a 1-year-period. At the end of sampling, increment cores were collected and sapwood area determined.

For all three studies, data were summarized to provide average hourly sap flow rates (kilograms per hour) or daily totals (kilograms per day). In addition, climate was measured at all three studies with climate stations located on-site. Measurements included: hourly rainfall (centimeters), wind speed (meters per second), solar radiation (Watts per square meter), temperature (°C), and relative humidity (percentage). Relative humidity and air temperature were used to calculate vapor pressure deficit (megapascals).

For the Texas plantation site, we parameterized and applied a mechanistic model of sap flow (PROSPER) and compared the results to sap flow measurements. Evapotranspiration at the Texas site was simulated because data were available to parameterize the model (7). The PROSPER model has been described in detail elsewhere (39,41), so only a general description is provided here. The PROSPER code is a phenomenological, one-dimensional model that links the atmosphere, vegetation, and soils. Plant and soil characteristics are combined into a single evapotranspiration surface that is characterized by a resistance to water vapor loss. This resistance is analogous to the relationship between stomatal resistance and water potential of the leaves and is a function of the water potential of the evapotranspiration surface. Evapotranspiration is predicted by a combined energy balance–aerodynamic method [Penman-Monteith equation modified as described in (42)] that is a function of the surface resistance to vapor loss described previously. The PROSPER model uses electrical network equations (41) to balance water allocation among vegetation and soil horizons. The flow of water within and between soil and plant is a function of soil hydraulic conductivity, soil water potential, root characteristics in each soil layer, and surface water potential. The PROSPER model predicts evapotranspiration, transpiration, and soil water distribution between soil layers daily, but monthly data are most accurate. The PROSPER model requires the following climatic data: solar radiation, precipitation, wind speed, air temperature, and vapor pressure. Initial model parameters include surface resistance to vapor loss, leaf area index, root distribution and surface area, soil moisture release, and several other parameters listed in Goldstein et al. (41).

Transpiration Estimates

Maximum transpiration rates for the study sites indicate large variation in transpiration potentials among sites (Table 1). On a per tree basis, rates ranged from 8 to 120 kilograms per tree per day. Much of this variation was related to differences in tree size that reflects differences in leaf area and sapwood area. For example, when pooling the data across the sites, a significant proportion of the variation in transpiration rates among and within sites can be explained by tree diameter (Fig. 3). Larger trees typically have greater sapwood volume resulting in more water transporting vessels (angiosperms) and tracheids (conifers) for sap-flow movement in the stems. Because leaf area is also related to sapwood area, larger trees will typically have greater leaf area index; and hence, greater surface area for transpiration.

When sap-flow rates are adjusted based on sapwood area (i.e., kilograms per day per square meter of sapwood), the variation in transpiration reflects species related differences in physiology (leaf, stem, and root), leaf area to sapwood area ratios, and site-dependent factors such as soil water availability and climate driving variables. Because species composition varies among sites and physiological and physical factors influence transpiration simultaneously, these studies

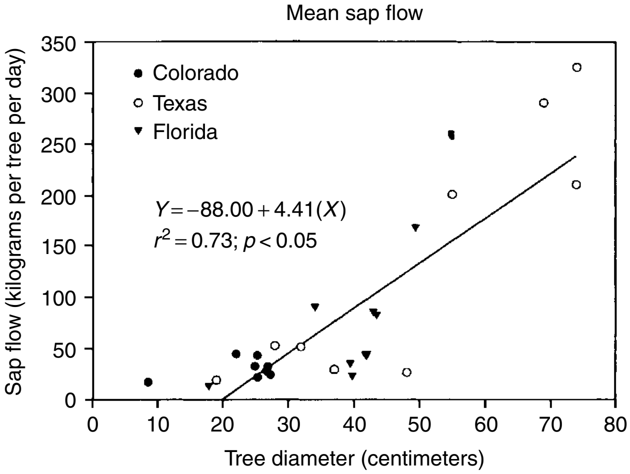

Figure 3. Total daily sap flows (Y) during peak transpiration periods (midsummer) *versus* tree diameter (X) across a range of species and site. Note that r^2 is the correlation coefficient and p is probability.

Table 1. Midsummer Peak Sap-Flow Rates Averaged Across Species and Measurement Days

		Sap-Flow Rates			
Site	Sapwood Area (Square Centimeters Per Tree)	Kilograms Per Day Per Square Meter of Sapwood	Kilograms Per Tree Per Day	Liters Per Hectare Per Year	Gallons Per Acre Per Year
Texas					
Plantation	30	2600	8	3 620 000	387 200
Native trees	820	1463	120	7 551 000	807 600
Colorado	234	1043	24	1 510 000	161 500
Florida	710	1535	109	6 859 000	733 600

cannot separate physiological and climatological effects; to do so requires an evaluation of transpiration rates of the same species and genotype in differing climatic and soil water availability conditions. For example, species sampled at the three sites represent a mixture of conifers, and ring porous and diffuse porous hardwood species, resulting in large differences in sapwood permeability and specific conductivity among sites and among species within sites (Fig. 4). In general, sap-flow velocity is lower in conifers and diffuse-porous species because sap flow moves through a number of annual rings, whereas water moves through only one or two annual rings in ring-porous species (11,43). Despite the limitations of the current approach, some notable patterns emerge when evaluating transpiration after adjusting for differences in sapwood area. For example, the cottonwood (*Populus deltoides*) plantation in Texas had the highest transpiration rate per unit of sapwood area, followed by the Florida stand, large trees in Texas, and the Colorado stand (Table 1). The high transpiration rate for cottonwood (*Populus deltoides*) in the plantation is a function of species characteristics that promote high transpiration, high leaf area per unit sapwood in the developing canopy, and access to shallow groundwater. In contrast, transpiration rates per unit of sapwood area were lowest in Colorado, even though the site contained cottonwood (*Populus deltoides*) and several of the measured trees occurred in the riparian zone. The combination of species composition and climate characteristics were not as conducive to high sap-flow rates per unit sapwood area relative to the other sites.

Using sap-flow techniques to predict actual stand transpiration requires frequent sampling to account for seasonal variation. Ideally, sap flow should be measured continuously for the entire growing season on a large number of trees. Because this approach is often impractical, an alternative is to measure sap flow at shorter frequencies and calculate bounds or maximum values as a tool to evaluate phytoremediation potentials. Because the sampling frequency varied among the case studies described here, we focused only on measurements during the highest transpiration period (midsummer). These estimates can be used as a “best-case scenario” approach—that is, if these rates occurred on the site, would transpiration be sufficient to control the plume? To estimate maximum potential transpiration at the stand level (i.e., kilograms per hectare or gallons per acre), we extrapolated the tree transpiration data (kilogram per tree per day) assuming a 180 days transpiration period and a stem density of 350 stems per hectare, except for the plantation where actual tree density was used (Table 1). We emphasize that these data provide estimates of maximum transpiration capacity under *in situ* climate conditions because the peak sap-flow rates were used in the extrapolation and previous studies have shown considerable seasonal variation in sap flow (7). The 350 stems per hectare is representative of a fully stocked stand under most forest conditions and is consistent with full canopy closure and maximum leaf area index.

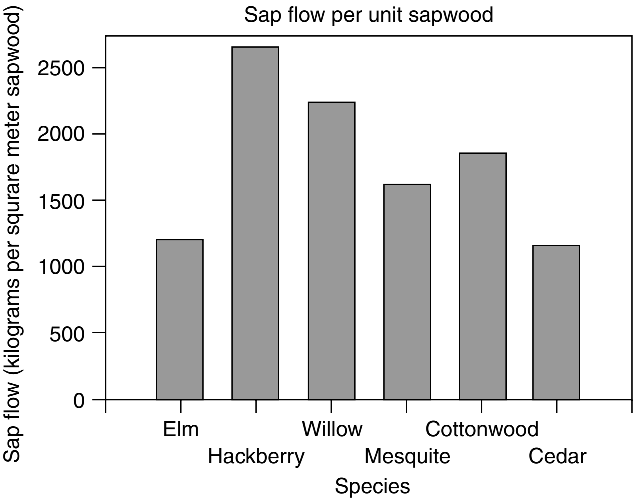

Figure 4. Mean growing season sap-flow rate per unit sapwood for six species in north–central Texas. Black willow (*Salix nigra* March.), eastern cottonwood (*Populus deltoides* Marsh.), and eastern red cedar (*Juniperus virginiana*, L.) are diffuse porous species, while American elm (*Ulmus americana* L.), hackberry (*Celtis laevigata* Willd.), and mesquite (*Prosopis pubescens* Benth.) are ring porous.

When comparing results from the sites with mature trees, the variation in maximum transpiration capacity is considerable. The Texas site has a maximum transpiration capacity of approximately 7.5×10^6 liters of water per hectare per year (8×10^5 gallons of water per acre per year) if the site was fully stocked with the sampled species. By contrast, the Colorado site has a maximum transpiration capacity of approximately 1.5×10^6 liters per hectare per year (1.6×10^5 gallons per acre per year). The plantation site in Texas currently has a maximum transpiration capacity of approximately 3.7×10^6 liters per hectare per year (4×10^5 gallons per acre per year). However, we anticipate that transpiration will equal or exceed the estimate from mature trees on the site (*versus* 7.5×10^6 liters per hectare per year or 8.0×10^5 gallons per acre per year) once the canopy develops and achieves the maximum leaf area.

Comparison of Measured versus Modeled Transpiration

A critical need for phytoremediation is the development and application of a tool to provide species and site-based estimates of transpiration. While a powerful tool for measuring transpiration from vegetation already on-site or quantifying transpiration of planted vegetation, sap-flow measurements at every phytoremediation site may not be practical. One potential tool for application across sites is the development or application of models. In most cases, however, models need to be calibrated or parameterized for specific site and species conditions. To evaluate the use of such a tool, we parameterized PROSPER for the Texas plantation using intensive site (soils, climate, and root distribution) and leaf-level measurements (stomatal characteristics and leaf area index) [see (7)]. We compared monthly transpiration estimates obtained with PROSPER to transpiration estimated from sap-flow measurements over a 2-year period (Fig. 5). Comparisons indicated generally good agreement between predicted and measured values, except during the late summer that was coincident with some of driest and hottest periods (August and September 1998) in our study. During this period, PROSPER predicted a considerable decline in transpiration, while measured values showed an increase. We attribute this discrepancy to an inability of PROSPER to adequately simulate root uptake from shallow groundwater during drought conditions, since the original formulation of PROSPER was designed to only simulate surface and soil water dynamics (39,41). The results of this comparison are consistent with other studies that have shown that PROSPER provides reasonable estimates of either evapotranspiration or transpiration (3,40). However, refinements in the subsurface water and groundwater hydrology and subsequent availability to tree roots might improve the predictive capability and usefulness as a phytoremediation evaluation tool.

CONCLUSIONS AND RECOMMENDATIONS

The importance of transpiration to the success of phytoremediation applications suggests that accurate estimates of current and potential transpiration should be a high priority when considering this approach for site management. Both measuring and modeling transpiration are important. Assessments require a substantial sampling commitment for direct measurements or parameterizing physiologically based models. This requires detailed knowledge of local site conditions and physiological parameters for the major species. For screening assessments, we recommend that published estimates be used to set the bounds for maximum transpiration capacity based on general climate and vegetation characteristics of the location. If these general transpiration rates are great enough to influence groundwater hydrology, then evaluations of current, enhanced (e.g., manipulating the structure and species composition of current vegetation), or new vegetation transpiration capacity should proceed. Technology and models exist to provide reasonable estimates and predictions of transpiration. However, the accuracy of the estimates depends on the investment in accounting for the spatial and temporal variation or in providing site and species-specific estimates for physiologically based transpiration models.

WATER LOGGING: TOPOGRAPHIC AND AGRICULTURAL IMPACTS

CHANDRA MADRAMOOTOO
Macdonald Campus of McGill University
Ste-Anne de Bellevue, Quebec, Canada

Water logging occurs on poorly drained soils. Under periods of heavy precipitation or snowmelt, water percolates very slowly, and soils become wet in short periods of time. Some soils have inherently low ability to infiltrate and hydraulic conductivity, especially heavier clay soils. Soil compaction because of heavy farm equipment further reduces bulk density, which in turn reduces the ability to infiltrate soil. The result is that the water table accretes and may eventually rise to the land surface. High-intensity rainfalls also lead to ponding of water on the soil surface. These conditions of surface ponding, a saturated soil profile, and gradual rise of the water table to the soil surface all lead to water logging. One very specific hydrogeologic condition that contributes to water logging is groundwater artesian pressure.

Land topographic features have an influence on water logging. On very flat lands, with low hydraulic gradients to rivers and watercourses, surface runoff is not easily drained. Water is also easily trapped in surface depressions on undulating lands. Low-lying coastal and riverine areas are very susceptible to flooding in the wet rainy periods. Towns, villages, and agricultural lands suffer from backwater effects. Infrastructural works sometimes exacerbates water logging. For example, during heavy rainfalls, water becomes trapped behind road and railway embankments. The situation could be extremely damaging under monsoon conditions in Asia, where widespread flooding occurs with loss of life and property.

Water logging also occurs in the arid and semiarid regions on poorly drained soils, because of excess irrigation water applications and canal seepage. It is estimated that about 25–30 million hectares of irrigated land suffer from water logging.

Globally, some areas of permanently wet or water logged regions exist, which are known ecologically as wetlands, and they serve very important environmental and hydrologic functions. Wetlands provide habitats for waterfowl, flora, fish, and animals. They also replenish groundwater, provide flood control, and filter pollutants. Organic soil deposits, or peat bogs, are also characterized by naturally high water tables.

It is estimated that over 200 million hectares of agricultural land worldwide suffer from poor drainage. Crops need an optimum soil-air environment in the root zone in which to thrive. Under high water table conditions or poor drainage, crop growth is retarded because of a lack of oxygen in the root zone. Root and shoot growth are affected by high water table conditions, as are other plant physiological conditions. For example, stem elongation is slowed, senescence and abscission of older leaves occur, rapid stomatal closure exists, and leaves begin to yellow. Crop failure is inevitable under prolonged flooding. Anaerobic conditions lead to reduced oxygen, and an accumulation of carbon dioxide, ethylene, other toxic substances, and byproducts in the soil profile, all of which are harmful to plant growth.

Some plants have the ability to withstand high water tables better than others. For example, rice is grown under flooded conditions. Some berry crops, e.g., highbush blueberries and cranberries grow under saturated soil conditions. Native vegetation and trees can be found in swamps, marshlands, and peat bogs. Crop tolerance to high water tables not only depends on crop type, but also on stage of crop growth. For example, most crops are likely to be killed by flooding during germination and early vegetative growth. As plants mature, they are slightly more tolerant to high water tables. However, vegetable crops are very sensitive to high water tables during their entire growth period. Deeper rooted crops, such as grasses, sugarcane, corn, shrubs, and trees, are somewhat hardier.

Apart from rice and some berry crops, it is impossible to undertake large-scale commercial plant and animal production without removal of excess soil water. Drainage is therefore essential for lowering the water table on poorly drained soils. The most common form of drainage is surface drainage. Open ditches are dug in fields to evacuate excess water. Lands are also shaped either by forming bedded fields or by a ridge and furrow system. In this way, crops can be grown on the raised beds or ridges. Other forms of land shaping include land leveling and smoothing, or grading the fields with a slope toward open drains. Surface depressions in fields can also be filled in by land leveling, and this will reduce ponded water on the land surface. Tile drainage, or subsurface pipe drainage, is another form of drainage for improving the productivity of poorly drained agricultural lands.

Tile drainage or tubewells are also used to lower the water table in irrigated lands. If seepage from irrigation canals is determined to be a major contributor to the water logging of adjacent lands, the canals can be lined, or buried pipe interceptor drains are installed adjacent to the canal. Relief wells are normally installed in lands affected by artesian uplift.

In the lowing coastal and riverine areas, flood control structures are built, which include levees, dykes, walls, and berms. Sluice gates or pumping stations are constructed to evacuate water from behind these structures to either the sea or rivers.

WEED CONTROL STRATEGIES

J.R. Newman
IACR-Centre for Aquatic Plant
Management
Reading Berkshire, United
Kingdom

The control of nuisance vegetation in watercourses is often necessary to ensure adequate flood defense for surrounding land, to provide facilities for recreational sporting activity, to provide better angling environments, to aid navigation, on public health grounds, for industrial uses, and to maintain adequate water supply and quality. In recent years, weed control for conservation has also become necessary to protect native habitats from invasion by alien, introduced, or nonnative species.

Aquatic weeds are different from terrestrial weeds in that they are usually a normal constituent of the aquatic ecosystem. Aquatic plants become weeds when they grow to excess and become a nuisance by blocking channels, reducing flow, or preventing other normal uses of the waterbody. Increased urbanization has resulted in an increase in the number of nonnative species now considered aquatic weeds, due primarily to escape of plants from domestic situations. The increased recreational pressure on enclosed inland waterways has also resulted in greater demands for aquatic plant management.

During the last 50 years, there has been a dramatic change in the type of aquatic weed problem. Emergent weeds, such as reeds and rushes, and floating leaved weeds, such as waterlilies, were the major problem, but eutrophication since the Second World War, as a result of intensification of agriculture, increased urbanization, and consequent sewage treatment requirements, has resulted in a shift to problems caused by filamentous and blue-green (cyanobacterial) algal blooms.

TYPES OF AQUATIC WEEDS

Although there are a large number of individual aquatic weed species, for the purposes of control, they can be divided into four major groups.

Emergent Plants

Emergent plants are rooted in the sediment at the margins of watercourses. They have stems and leaves that protrude above the water's surface. Growth is often limited by increasing water depth, making this type of weed common along the edges of water. Some common characteristics of these plants are long narrow leaves, and heights between 1 and 3 m. Species include *Phragmites communis* (common reed), *Typha latifolia* (bulrush), *Schoenoplectus lacustris* (common club rush), *Glyceria maxima* (reed sweet grass) and *Sparganium erectum* (common bur reed).

Smaller emergent and bankside plants, except grasses, tend to be broad-leaved weeds. These include *Rorippa nasturtium-aquaticum* (watercress) *Apium nodiflorum* (fool's watercress), *Berula erecta* (water parsnip), and others.

Other plants in this group are predominantly submerged but may form different types of leaves when they become emergent due to lowered water levels or grow above the water surface. These include some *Ranunculus* spp. (water crowfoots) and *Hippuris vulgaris* (mare's tail).

Plants that grow on banks at or above the water line should be included in this group. Common weeds in this class include *Lythrum salicaria* (purple loosestrife), *Epilobium hirsutum* (greater willow herb) and *Phalaris arundinacea* (reed canary grass).

A number of riparian weeds associated with watercourses can be included in this group. The dispersal of these species is furthered by flowing water. The alien invasive species *Fallopia japonica* (Japanese knotweed), *Heracleum mantegazzianum* (giant hogweed) and *Impatiens glandulifera* (Himalayan balsam) are included here.

Floating Plants

Free-Floating Plants. This group includes many of the worst types of aquatic weeds, such as *Azolla* spp. (water fern), *Eichhornia crassipes* (water hyacinth), *Lemna* spp. (duckweeds), *Pistia stratiotes* (water lettuce) and *Salvinia molesta* (giant water fern), all of which have been found in Britain. They are characterized primarily by very rapid vegetative reproduction and spread.

Floating-Leaved Plants. This type of plant is characterized by rooting in the sediment and forming floating leaves. They may be rooted at the margins and form floating mats over the surface of the water, such as *Hydrocotyle ranunculoides* (floating pennywort). This species has leaves held above the water surface. Plants rooted in deep water that have floating leaves held flat on the surface include *Potamogeton natans* (broad-leaved pondweed), *Nuphar lutea* (yellow water lily) and *Nymphaea alba* (white water lily).

Other plants in this group are predominantly submerged, but may form different types of leaves when they reach the water surface, such as the rosette type of leaf produced by *Callitriche* spp. (water starworts).

Submerged Plants

This group includes all submerged plants except algae. It can be divided into two sub-groups, those rooted in the sediment, such as *Elodea* spp. (waterweeds), *Myriophyllum spicatum* (spiked water milfoil), and *Potamogeton pectinatus* (fennel pondweed), or those free-floating below the water, such as *Ceratophyllum demersum* (rigid hornwort) and *Lemna trisulca* (ivy-leaved duckweed).

Algae

Algae can be divided into two types for the purpose of control, macrophytic types, including filamentous algae and charophytes, and unicellular types, including pea-soup algae and cyanobacteria or blue-green algae. Nuisance algae tend to grow best in nutrient-rich still or slow flowing water.

THE BIOLOGY AND ECOLOGY OF AQUATIC WEEDS

Seasonal Growth and Dispersal

Aquatic plants are usually a problem only during the summer months. Various forms of dieback or washout during autumn and winter ensure that very little aquatic vegetation is left to overwinter. However, nuisance aquatic weeds use several strategies to survive winter. These include seed production by annual riparian weeds and as an insurance policy by perennial submerged aquatic macrophytes. Others produce turions (specialized leaf buds) tolerant of anoxic conditions, for example, *P. pectinatus*, fennel pondweed. The majority of emergent macrophytes have dormant roots and rhizomes. Algae use spore production and *Azolla* and others can overwinter as intact plants, for example, *Callitriche* spp. and *Crassula helmsii*.

Aquatic weed growth usually starts when mean diel water temperature rises above 6°C; this is normally a week to a few weeks behind terrestrial plant growth. However, growth is rapid once started and stem elongation in *Ranunculus* spp. can produce 6 m of growth before flowering. Shortening day length usually initiates flowering so the majority of aquatic plants flower in or after the last week in June in the temperate Northern Hemisphere.

Stem fragmentation and vegetative reproduction is the most common form of dispersal within systems, and seed production is not considered important for maintaining weed populations. However, establishment of new weed populations is most likely to derive from establishment of seeds. Birds, animals, machinery, boats, and man can also spread viable fragments of weeds to new sites.

Characteristics of Nuisance Plants

Growth Rate. Species that have extremely fast growth rates tend to become greater problems than other species. For example, duckweed and *Azolla* can double their biomass in less than 4 days in good conditions.

Morphology. Species that produce dense masses of vegetation impede the flow of water. Others have rigid stems that may impede boat traffic, interfere with access to the water, and trap detritus, forming temporary dams that may cause flooding.

Dispersal Strategies. Plants that produce new plants by fragmentation are also very effective aquatic weeds. Often, mechanical control is responsible for increases in the distribution of these species in watercourses.

Toxicity and Taint. Some plants are toxic to animals, and others taint potable waters. Blue-green algae produce toxins that can kill fish, and other animals and also impart an unpleasant taste to drinking water.

CONTROL METHODS

Factors Affecting Choice

A number of factors influence the choice of weed management technique, including the cost of control. These factors are related to the uses of the water and the specific landscape situation of the waterbody. Often, a compromise between weed control efficacy and other considerations must be made.

Type of Control. In some cases, it is not desirable to attempt complete eradication of the weed population, and localized control is preferable. Selective control can be either by type of species or by, for example, clearing swims for anglers. Total control may be required where flood defense is an issue or where nonindigenous species are present. Temporary alleviation of a weed problem is sometimes possible by frequent mechanical control during the season.

Use of the Water. Certain weed control practices may not be compatible with the use of the water. The most obvious of these is when water is abstracted for drinking water supplies downstream of an intended herbicide application site. The limit of $0.1\,\mu g\,L^{-1}$ for individual pesticides set by the EU Drinking Water Directive imposes strict requirements on the distance between the site of application and the abstraction point. Dilution and flow rate affect this distance.

Human and Livestock Safety. This includes direct toxicity of herbicides to operators and water users, increases in turbidity due to stirring up of sediments, and unpleasant odors from rotting vegetation or herbicide residues in water. The safety of farm and other animals can be compromised by the direct toxicity of the herbicide, or, as is more likely, by increasing the palatability of treated poisonous plants.

Irrigation. The hazards to adjacent crops should be considered through irrigation with water containing pesticides or spray drift at the time of application and the spread of weeds such as *P. australis* into cropland when dredged spoil is deposited onto land adjacent to watercourses.

Industry. Weeds blocking intake sluices or the presence of pesticides in water may affect industrial processes requiring water.

Environmental Impacts. In general, the more effective a weed clearance operation, the greater the environmental impact. Deoxygenation of water, which affects fish, can occur when large volumes of cut or herbicide-treated weed are allowed to rot *in situ*. The number of invertebrates removed by mechanical control is estimated at approximately 1 million per m^3 of cut weed, and the number of vertebrates, mainly small fish, is estimated at about 40 per m^3 of weed removed. Care should be taken to avoid removing marginal vegetation during bird nesting times. Other indirect effects include destabilization of banks by removal of plant cover or by deposition of thick layers of cut vegetation on sloping banks.

MANAGEMENT OPTIONS

Mechanical Control

The following points should be considered when using mechanical weed control. Rafts of cut weed can drift downstream and block sluices, pumps, weirs, and other water control structures. Deoxygenation can occur if weed is left to rot in water, posing a risk to fish and invertebrate life. Rapid regrowth of cut weeds often necessitates a late season cut. In practice, the cost of mechanical control limits the frequency of the operation, thus a compromise between weed control and cost is usually necessary.

Cutting. Aquatic weeds can be cut manually or by using machines; the choice of technique depends on the scale of the problem to be tackled. Cutting by hand and raking cut material onto banks is not used widely now, although the majority of small drainage ditches used to be managed in this way. Now a wide range of mechanical cutting boats and weed bucket attachments for bank-based machines is available, but the principles of cutting and removing the cut weed remain unchanged. In general, the deeper the cut, the longer the weed control will last. Timing of the cut is critical. Good control can be achieved by regular cutting throughout the growing season, but this may not be possible for operational reasons. Cutting submerged weeds before the end of June will require a further cut toward the end of the season, and regrowth during summer tends to be faster than initial growth rates. The timing of cutting emergent and bankside weeds is less critical, but care should be taken to avoid bird nesting seasons.

Weed boats are used to cut submerged weeds in relatively deep and wide watercourses where large areas of weed require cutting. They usually have a front mounted reciprocating cutting bar which can cut to a depth of about 1.5 m. The work rate is estimated at approximately 1 km per day on a 10-m wide river. Cut weed must be removed from the water, either by a separate boat or by the action of a front rake on the cutting boat after cutting.

Bank-mounted equipment includes draglines, flail mowers, and dredging equipment. The work rate for cutting buckets and weed rakes is, on average, about 500 m day^{-1} on wide rivers.

Harvesting. The use of aquatic weed harvesters combines the cutting and collecting operation, therefore reducing time and increasing efficiency. They can and/or collect all types of weed, including filamentous algae and duckweeds and can deposit them at a collection point on the bank. The work rates for this type of equipment vary considerably with the density of weed and the distance traveled to offload the collected weed.

Uses for Cut Weed. There are a limited number of uses for cut weed; these include composting, reed for thatching, mulches, soil conditioners, and cattle forage. The material has low value, and processing should be done locally to minimize costs.

Chemical Control

Herbicides can be used to control a wide range of aquatic plants. They may be applied to emergent or surface-floating weeds by a foliar spray in much the same way as recommended for land plants. Submerged weeds and algae are treated by adding the herbicide to the water to build up an effective concentration in the water. This method will also control some floating and emergent species. Chemicals currently used to control aquatic plants are listed in Table 1.

Consideration should be given to the effects of herbicide treatment on the function of the waterbody. This not only involves the direct toxicity of the chemical but also indirect effects caused by decomposition of dead weeds. Retaining a proportion of the weed growth is recommended to maintain a habitat for invertebrates, fish, and other wildlife and to stabilize the ecosystem. Vegetation left *in situ* will take up nutrients and help to prevent the growth of algae. To minimize the effects of decomposing weed, herbicide labels have recommendations on treatment intervals that should be observed. It is normal to treat only 25% of an infested waterbody at one time, separated by the application interval. Consideration should be given to the irrigation interval when using herbicides in water. This is the time between application and the time when water is safe to use for irrigating of crops or watering livestock.

Application Methods

Application to Foliage. Recommendations for the correct dose are made in the form of weight of product or active ingredient per hectare. Herbicides are usually applied by knapsack or boat-mounted sprayer equipment. Using high-volume and low-pressure equipment to deliver a coarse spray with a minimum of small droplets is advisable to reduce the risk of spray drift. Localized or selective control can be achieved by the appropriate choice of herbicides and by spraying only those plants required. Water velocity and quality do not affect the treatment, but to avoid a buildup of chemical in the water, it is normal to apply herbicides in an upstream direction.

Application to Water. Recommendations usually refer to the theoretical concentration of active ingredient that would be achieved when the chemical has been evenly distributed throughout the water body but before any adsorption or degradation has occurred. This is usually expressed as parts per million (ppm or mg l^{-}1 or g m^{-3}). Some formulations may be applied on a rate per surface area basis because they sink onto the weeds or mud.

Table 1. Herbicides Suitable for Controlling Major Weed Groups

	Asulam	Copper	2,4-D amine	Dichlobenil	Diquat	Diquat Alginate	Endothall	Fluridone	Glyphosate	Maleic Hydrazide	Terbutryn
Trees and shrubs on banks									●		
Bracken and docks	●				○				●		
Broad-leaved weeds			●	○	○			○	●		
Grasses				○	○			●	●	●	
Reeds and sedges					○		●	●	●		
Floating-leaved plants				●	○	●	●	○	●		○
Free-floating plants			○		●			○	●		●
Submerged plants			○	●	●	●	●	●			●
Submerged plants (flowing water)						●	○				
Algae		●			●	●		○			●

● suitable for control; ○ short-term control or some species within groups not susceptible

The methods of application depend on the formulation. Herbicides should be spread as evenly as possible over the surface of the water. Granular formulations can be spread by hand using a suitable container, by a mechanical spreader, or by using an air-assisted blower. Liquid formulations should be diluted and applied by subsurface injection. This is usually achieved by trailing nozzles below the water as close to the top of the weed bed as possible, without disturbing the bottom sediment. Viscous gel formulations should be applied with specialized equipment.

Timing. Emergent and floating leaved plants should be treated from midsummer, when the leaves have formed fully. Annual weeds should be treated before flowers have set to prevent production of seeds.

Treatment of submerged weeds and algae is normally recommended in spring and early summer when weeds are actively growing. Treatment of floating-leaved plants is usually more successful before the floating leaves have formed. Later in the season, when large biomasses of weed have developed and particularly when the water is warm, there is a severe risk of deoxygenation of the water, after control, caused by decomposition of the dead weed. This effect is particularly acute when using terbutryn, as the mode of action blocks photosynthesis very quickly, but respiration continues.

An indirect hazard to fish may arise through possible effects on fauna that provide food for fish. These may be due to direct toxicity to invertebrates or more likely to loss of habitat after weed control operations. However, loss of habitat can lead to increased predation by fish. These effects are temporary and should be set against the disadvantages of dominant weed species reducing habitat structure for all aquatic fauna.

Biological Control

The decline in public acceptability of herbicide use in water, coupled with an increase in the costs of mechanical control has led to the development of several biological control agents for aquatic weeds.

Livestock. Horses, cows, goats, and sheep can be used to graze marginal vegetation. Care should be taken to avoid excessive poaching of the banks (although some poached banks are a valuable habitat), and fencing is required to keep animals from straying.

Chinese Grass Carp and Other Fish. Herbivorous fish are most common in Asia and South America. One species, the Chinese grass carp, *Ctenopharyngodon idella*, is available for weed control in enclosed situations. Triploid grass carp are used in the United State to ensure that the fish cannot breed. Licenses are usually required to introduce of these fish. Stocking densities vary depending on the type and severity of the weed problem, but usually a density of between 75 and 150 $\mathrm{kg\,ha^{-1}}$ will achieve adequate weed control. Bottom feeding fish stir up sediment and create turbid conditions in which submerged macrophytes cannot grow. These fish include primarily carp and bream.

Waterfowl. Waterfowl graze on some species of floating and submerged weed. When present in large numbers (e.g., swans on *Ranunculus*), they can cause significant losses of aquatic vegetation, which may not be desirable.

Pathogens and Insects. Classical biological control is not widely practiced in Europe, and not at all on aquatic and riparian weeds. Biological control agents survive only on their host species, meaning they cannot spread to ornamentals or related crop species. Most native plant species have a number of native host-specific pathogens or insect predators. There are effective biological control agents for many aquatic weed species (Table 2) established in other parts of the world, but none is used in Europe.

Biological control has been successful in about 45% of the attempts made on aquatic weeds. It is essentially a management tool designed to maintain the level of a pest

Table 2. Established Biological Control Agents for Aquatic Weeds

at a tolerable level in the community without necessarily eradicating the weed species. It is a useful tool to employ in combination with other techniques such as mechanical or chemical control.

Environmental Control

Environmental control is the technique of changing the environment, either temporarily or permanently, to reduce the suitability of the habitat for the target weed. This technique tends to shift the weed species to other plants, which may or may not be desirable depending on the ultimate use of the waterbody in question.

Flow. Aquatic plants are divided into riverine or lacustrine species. Although not mutually exclusive, plants that tend to favor slow flowing environments do not grow in faster flowing water and vice versa. Alterations to flow can have marked effects on the composition of the aquatic plant community.

Water Chemistry. Reduction of the quantity of major plant nutrients entering water tends to reduce the biomass development of weed species but not necessarily the species composition of the weed community. Diversion or further treatment of sewage effluent to remove excess P has been effective in stabilizing river communities by removing the dominance of filamentous algae. Nutrient release from sediments is a major source of supply for lakes and other slow flowing watercourses, such as canals and drainage ditches. Even if all nutrients could be prevented from entering such systems, there would be sufficient nutrient supply in the sediment to provide for continued aquatic plant growth for more than 100 years in most cases.

Shade. Shading submerged aquatic macrophytes can be an effective method of control, especially in sensitive areas where chemical control is inappropriate. Shade can be produced by planting trees or shrubs on the banks of watercourses. However, this often interferes with access to the water and may not be appropriate in all situations. Opaque floating material can be used in still waters to achieve increased shading, although it must remain in place for at least 4 months to have a lasting effect. The use of dyes that absorb light at photosynthetic wavelengths is also widely used in amenity lakes and ponds. Increased turbidity from bottom feeding fish also excludes light, as does the action of powered boats, and these techniques are most effective in sluggish water where the sediment can remain suspended for long periods.

Burning. Emergent weeds, particularly the stiffer stemmed reeds, do not always collapse in the autumn and can form large masses of dead, standing material. In dry ditches and on banks, this material can sometimes be burned. This can be a useful way of reducing the bulk of plant material which might otherwise collapse during the winter and block channels. Burning can also be used to destroy cut material after drying. This is good way of disposing of poisonous plants, some of which remain toxic after death but become palatable to livestock.

Alterations in Water Level. Exposure of part, or all, of the bed of a water body by lowering the water level has been used successfully to manage aquatic vegetation. Control is achieved either by dehydration of the vegetation or by exposure to low temperatures. The process is sometimes termed drawdown or dewatering. It can also alter the character of the sediment which may reduce weed growth. However, in deeper water bodies, drawdown can allow weeds to establish in depths below their normal limit. Once established, they can grow up toward the surface, as the level is again raised, to remain in the higher light intensity. In these situations, drawdown can spread a weed problem into areas which would normally remain weed-free.

Some indication of the relative effectiveness of treatments can be see in Table 3. This is not a definitive guide for every situation, and expert advice should be sought before applying any technique to a particular weed problem to optimize efficacy and minimize costs.

The benefits assigned to each technique are for general guidance only, and the results obtained may be modified by specific site conditions.

Other Methods of Control

Many other techniques for controlling aquatic vegetation have been tried, which do not fit closely into any of the previous categories. These include the following: (1) the use of lasers to control emergent or floating weeds and ultrasound vibrations that can disrupt cells of submerged plants; (2) floating oil films that cause floating weeds to sink, and (3) increasing wave action that submerges floating weeds and increases turbidity thus suppressing submerged vegetation. There are also several biological control agents, including crayfish, other invertebrates, and wildfowl, that have been effective against some weeds. Most of these have been tested in tropical or subtropical conditions and, at present, the grass carp is the most effective biological control agent in more temperate regions. Some of the more effective alternative treatments are outlined below.

Magnetic Treatment of Flowing Water. The use of magnetic water treatment devices, it has been shown, affects the growth of algae. This is thought to be due to interference with the uptake and storage of calcium in algal cells. This treatment is most effective in closed recirculating systems.

Ultrasound. Ultrasonic devices are used widely in Europe to disrupt cells mainly of algae and biofilm bacteria in water storage reservoirs where herbicides cannot be used.

Miscellaneous Treatments. There are a number of alternative treatments for water that affect the nutrient concentration and, therefore availability, to aquatic plants. Most of these involve precipitation of phosphate in an insoluble form.

SCREEN FILTERS FOR MICROIRRIGATION

Dorota Z. Haman
University of Florida
Gainesville, Florida

Water quality is a major concern in the management of microirrigation systems (drip, microsprinkler, microspray). Emitters plugged by physical, chemical, or biological contaminants may create significant problems in everyday maintenance. Effective and reliable filtration is required for successful operation of microirrigation systems. There are different types of filters available for the removal of physical contaminants from irrigation water. Selection of a filter depends on the type and amount of contaminants in the irrigation water, the type of emitters, the size of the irrigation system, and the desired management practices. Screen filters should be a primary choice when water is pumped from a well where the only filtration requirement is to remove mineral particulate matter (Fig. 1). They are sufficient in the absence of organic contamination and in addition they are usually inexpensive and easy to maintain. To remove both particulate matter and organic growths, media filters (also called sand filters) may also be used. They are usually recommended when large amounts of algae or other organic contaminants are present.

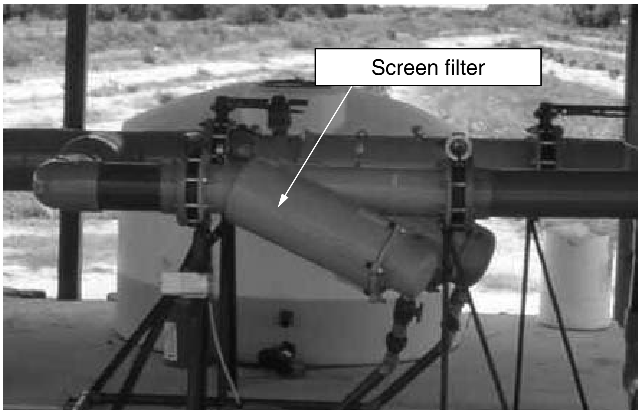

Figure 1. Screen filter installed in the main line of irrigation system.

Screen filters are simple and economical filtration devices of various shapes and sizes that are frequently used for the removal of physical contaminants. They can be made of metal, plastic, or synthetic cloth enclosed in a special housing. Screen filters are recommended for the removal of very fine sand or larger-sized inorganic debris from irrigation water. It is normally not effective to use screen filters for the removal of heavy loads of algae or other organic material typical in surface water supply, since screens clog rapidly, requiring too frequent cleaning to be practical.

When surface water is used for microirrigation, screens are often used as secondary filters, after organic matter has been removed with media (sand) filters. In this capacity they prevent washed out media from entering the irrigation system. When well water is used for irrigation, a screen filter may be used as a primary filter, or it may be secondary to a vortex sand separator, depending on the mineral particle load in the water.

Filtering screens are classified according to the number of openings per inch, with a standard wire size given for each screen size (Table 1). The minimum size of particle retained by a screen filter with a certain mesh can be determined from Table 1. A 200-mesh screen is usually recommended for drip type microirrigation where 150 mesh is often sufficient for microsprinklers and microsprays. Water filtered with a 200-mesh screen will contain only smaller particles of very fine sand, silt, and clay. These particles should freely move through the emitter openings unless flocculation, aggregation, and bridging are taking place due to unusual water chemistry. If clogging problems persist with 200-mesh filtration, chemical treatment of water may be necessary.

Generally, it is recommended to remove particles down to a size ten times smaller than the emitter's passageway so that grouping and bridging of particles will not cause clogging. The maximum particle size that can safely enter the irrigation system with a given emitting device should be provided by the manufacturer. Organic particles with a density approaching the density of water tend to group and bridge more easily. Particles heavier than water, typically mineral particles, may settle and collect in the low flow zones of the irrigation system.

The size of the filter is specified by its effective area, which is the area of the openings in the screen. It is specified in relation to cross-sectional area of the main pipe. A desirable ratio is 2 or more (area of openings much larger than the cross-sectional area of the pipe). The mesh size of the filter (opening size) will depend on the smallest particle size to be removed from the irrigation water.

Table 1. Representative Screen Mesh Numbers and the Corresponding Standard Opening Size Equivalents

Screen Filters		Removed Particles	
Screen Size, mesh	Opening Size, μm	Soil Classification	Particle Size, μm
4	4760	Very coarse sand	1000–2000
10	2000		
20	711	Coarse and medium sand	250–1000
40	420		
80	180	Fine sand	100–250
100	152		
120	125		
150	105		
180	89	Very fine sand	50–100
200	74		
270	53		
325	44	Silt	2–50
—[a]	—[a]	Clay	2 and less

[a] Screen filters are not normally used to remove this size particles.

When estimating the appropriate size of filter for a specific application, one should consider the quality of water needed, volume of water required to be passed through the filter between consecutive cleanings, filtration area of the filter screen, and allowable pressure drop through the filter. A screen filter can handle a large range of discharges. However, discharges that are large in relation to the filtering surfaces will result in greater pressure losses, shorter life of the filter, and the requirement for frequent cleaning.

If the irrigation water contains large amounts of sand or other inorganic contaminants, it is advisable to use vortex sand separators before the screen filters, which use centrifugal force to separate heavier particles away from the fine mesh cartridge. Heavy particles collect at the bottom of the filter, where they can be periodically flushed away.

Simple gravity screen filters are often used as primary filtration where an elevated water source from a canal or reservoir is available. Since the pressure loss through a gravity screen filter is very small, these filters are often used in systems where such losses must be minimized. They operate on the principle of gravity force, not water pressure. Because only atmospheric pressure is used, soft organic material is not forced through the screen. Gravity screens are easy to install and maintain. Usually, these filters are constructed as two chambers separated by a fine mesh screen, which can be cleaned manually or automatically. Most of them incorporate self-cleaning water jets.

If water is pumped from a surface source (lake, pond, stream, river, irrigation canal, or pit), aquatic plants, fish, and animals should be kept away from the intake pipe since the efficiency of pumping may be reduced by debris in the water entering the suction pipe. This can be accomplished with an intake screen. The design of the screen must allow for the separation of the debris from the water without pulling the debris against the screen. A horizontal screen placed below the water surface or an intake basket-type filter are often used for this purpose. Some of these screens are self-cleaning and require very little maintenance.

Small amounts of larger particles, such as lime rock flakes from the aquifer, can be removed using a Y-type strainer with replaceable screens and with clean-out faucets or valves. They can be flushed while in use if the required high flow for flushing is provided. Blowdown filters operate in the same way as other types of pressure screen filters. They are designed for easy cleaning, which is done by opening a valve that diverts the water flow through the screen, releasing trapped particles.

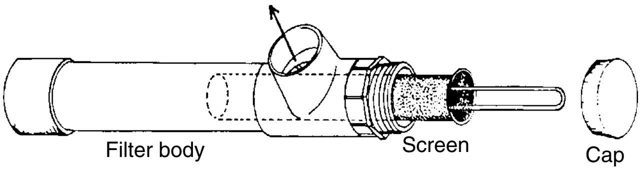

Figure 2. Schematics of a typical screen filter.

Occasionally, blowdown filters require manual cleaning to eliminate particles that have become lodged in the screen.

Screen filters can be cleaned manually by removing the screen and washing it with clean water (Fig. 2). However, dismantling is not very practical for use with waters containing high levels of contaminants, since it must be done very often. Blowdown screen filters greatly simplify the cleaning process. They are cleaned with the water diverted through the screen by opening a valve. This operation does not require disassembling. The screen does not have to be removed for routine cleaning of the filter, but it must be removed for occasional cleaning of the particles that become lodged in the screen.

The most convenient method for cleaning screen filters is automatic screen flushing triggered by critical pressure differential across the filter, which increases with buildup of debris on the screen. Automatic cleaning can also be set on a time schedule. Filtered water is always recommended for washing and backflushing. Additional safety devices such as secondary screen filters at the entrance to each irrigation system subunit are highly recommended.

XERISCAPE

Douglas F. Welsh
Texas A&M University
Collage Station, Texas

Much attention and controversy have surrounded the *xeriscape* concept of *landscaping* since its inception in 1981. The proper definition of xeriscape is "quality landscaping that conserves water and protects the environment." Above all things, it must be a quality design that balances the lawn area, shrub and flower plantings, and the hardscape (i.e., decks, patios and sidewalks). Landscapes composed of rocks or plastic flowers alone are not xeriscapes. Xeriscapes are in tune with the environment; therefore, xeriscape applies to the desert in southwestern United States as well as the semitropical southeast.

Xeriscape has seven basic principles:

- planning and design
- soil improvement
- appropriate plant selection
- practical turf areas
- efficient irrigation
- mulching
- appropriate maintenance

USE OF PRACTICAL TURF AREAS IN A XERISCAPE DESIGN

Of the seven principles, none has received more attention than practical turf areas. This principle, which concerns turfgrass in the landscape, has been shrouded in misinformation that has been touted as fact by "experts" in xeriscape, water supply, and turf culture.

The original turf-related principle established by the Denver originators of xeriscape was "limited turf use." For Denver and much of the arid West, the seemingly logical approach to reducing landscape water consumption was simply to reduce the use of turf. However, as the Xeriscape concept has matured and spread, the principle of limited turf use was increasingly scrutinized by horticulturists and turf experts. Today's xeriscape movement incorporates a more holistic approach to reducing turf irrigation, fully recognizing that the type of plant materials or irrigation in the landscape has as much of an effect on water consumption as the human factor and good landscape water management (Fig. 1).

THE NEED TO CHANGE ATTITUDES AND HABITS

Throughout the xeriscape movement, the evident truth is that plants do not waste water; people do. Another fact is that irrigation systems do not waste or save water; people do. The mission of xeriscape is clear: Change the attitudes and irrigation habits of professional and amateur landscape managers. Proper water management provides the greatest opportunity for *water conservation* in the landscape.

Xeriscape focuses on the use of turfgrass in the landscape because of the tremendous potential for irrigation water abuses in the name of maintaining green turfgrass. Within the traditional landscape, turfgrass has received the major share of total landscape irrigation because grass often makes up a large percentage of the total landscape. Through the principles of xeriscape, turf irrigation can be reduced and the many benefits of turfgrass can still be derived.

BENEFITS OF TURFGRASS IN THE LANDSCAPE

Turfgrass is an integral component of most landscapes. It is certainly the best recreational surface for children and athletes. Furthermore, it has a tremendous mitigating effect on the environment, reducing heat loads, noise and water and air pollution. A turfgrass lawn is second only to a virgin forest in the ability to harvest water and recharge groundwater resources. As a design component, turfgrass provides the landscape with unity and simplicity while inviting participation in it.

However, the fact remains that turfgrass is the highest user of irrigation water in the traditional landscape. This

Figure 1. The proper definition of xeriscape is "quality landscaping that conserves water and protects the environment." Above all things, it must be a quality design that balances the lawn area, shrub and flower plantings and the hardscape (i.e., decks, patios and sidewalks).

is significantly different from saying that turfgrass is the highest water-using plant in the landscape—which is not the case. The discrepancy between these two statements yields the most common misconception and misrepresentation in xeriscape, and it is therefore the basis of controversy and unproductive efforts. To resolve this controversy, some scientific and practical fundamentals of turfgrass are explained using actual xeriscape principles.

XERISCAPE PRINCIPLES FOR REDUCING TURFGRASS IRRIGATION

Specifically, xeriscape principles promote the following strategies to reduce turfgrass irrigation:

- Prepare soils for turf areas as carefully as any other planting area to use all the moisture available, promoting the plant's vigor and water-use efficiency.
- Place turf species in landscape zones based on water requirements.
- Select adapted turf species and varieties that have lower water demands.
- Irrigate turf in areas that provide function (i.e., recreational, aesthetic, foot traffic, dust and noise abatement, glare reduction, temperature mitigation).
- Use nonirrigated turf areas where appropriate.
- Irrigate turf based on true water needs.
- Decrease fertilization rates and properly schedule fertilization.

FINE-TUNING TURFGRASS XERISCAPE PRINCIPLES

In traditional landscape design, turfgrass makes up the major portion of landscapes. The tremendous square footage of turfgrass in a landscape accounts for the reason that turfgrass irrigation, as a percentage of total landscape irrigation, is so high. The "practical turf areas" guideline promotes the use of turf only in those areas of the landscape that provide function. In residential landscapes, a turf area is usually a necessity for recreation and entertainment. But turf should not be irrigated on narrow strips of land or other areas that are difficult to water (Fig. 2).

Good landscape water management begins with planning and design. By designing the landscape as zones based on plant water needs, turf can be appropriately placed for function, benefit and water efficiency. Zoning the landscape and irrigation system allows watering turfgrass on a more frequent schedule than shrubs. For established trees and shrubs, the irrigation strategy should use deep soil moisture and depend on natural rainfall to replenish soil moisture. When sufficient rainfall does not occur, supplemental irrigation of trees and shrubs may be required.

Another way to incorporate turf into the landscape and conserve water is simply not to irrigate. Many turfgrass species are drought-tolerant and can survive extreme drought conditions. The grass may turn brown for a while, but rainfall will green it up again. This approach may be unacceptable for many residential and commercial landscapes, but in the case of parklands, industrial sites and rights-of-way, brown turf may be acceptable.

Figure 2. In residential landscapes, turf areas are important for recreation and entertainment.

SELECTING THE PROPER TURFGRASS SPECIES AND VARIETIES

Wherever the landscape, selection of turfgrass species and varieties is of utmost importance. Extensive research has shown that there are significant differences in water requirements among turf species and even among varieties within species. The capacity of different turf species to avoid and resist drought also varies significantly. To help reduce landscape water requirements, xeriscape recommends selecting turfgrass varieties (and other landscape plants) that are both adapted to the area and have the lowest practical water requirements.

Landscape managers should be keenly aware of drought-stress indicators shown by turfgrass and other plants in the landscape, including a range of color changes, leaf curl, and wilting, and they should strive

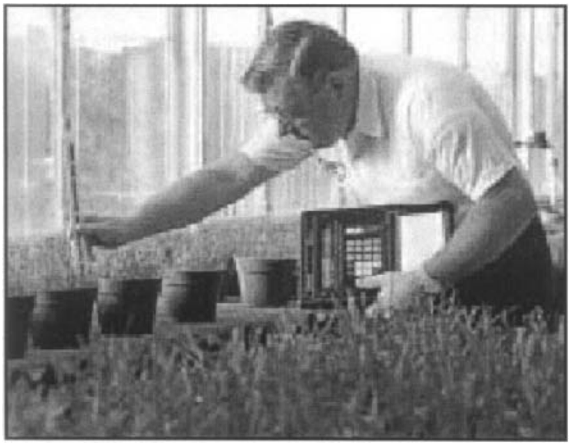

Figure 3. Wherever the landscape, selection of turfgrass species and varieties is of utmost importance. Extensive research has shown that there are significant differences in water requirements among turf species and even among varieties within species.

Figure 4. Attitudes and habits about turf are changing. For much of the arid West, the seemingly logical approach to reducing landscape water consumption was simply to reduce the use of turf. However, as the xeriscape concept has matured and spread, the principle of limited turf use was increasingly scrutinized by horticulturists and turf experts. Today's xeriscape movement incorporates a more holistic approach to reducing turf irrigation, fully recognizing that the type of plant materials or irrigation in the landscape has as much of an effect on water consumption as the human factor and good landscape water management.

to meet the water needs of each group of plants. By irrigating only when the plants require water versus by the calendar, the manager can dramatically reduce landscape water use.

The water requirements of turfgrasses can be minimized through specific horticultural practices. Decreasing fertilizer application rates and timely applications of slow-release fertilizers tend to reduce flushes of growth that can increase water requirements (Fig. 3).

THE XERISCAPE CHALLENGE

Xeriscape is a challenge and an opportunity for the "green" (landscape, turf and nursery) and "blue" (water utilities and agencies) industries. Through xeriscape, these two industries have been brought together to focus on landscape water use. Although this marriage has not always been easy, the best minds are prevailing in efforts to perfect and implement the xeriscape concept.

By embracing the xeriscape concept, including the principle of practical turf areas, the green and blue industries can continue to be recognized as good stewards of the environment (Fig. 4).

MEDIA FILTERS FOR MICROIRRIGATION

Dorota Z. Haman
University of Florida
Gainesville, Florida

To avoid plugging of microirrigation emitters, it is generally recommended to remove particles down to a size ten times smaller than the emitter's passageway so that grouping and bridging of particles will not cause clogging. The manufacturer should provide the maximum particle size that can safely enter the irrigation system with a given emitting device. Organic particles with a density approaching the density of water tend to group and bridge more easily.

Media (also called "sand") filters are well suited for removal of either organic or inorganic particles. Due to their three-dimensional nature, media filters have the ability to entrap large amounts of contaminants. They do not seal off as easily and therefore will not clog as often as filters that trap particles on their surface, such as screen filters.

Media filters used in microirrigation systems operate under pressure. They consist of fine gravel and "sand" (that actually is crushed granite or silica) of selected sizes placed in pressurized tanks (Fig. 1). The main body of the tank contains sand, which is the active filtering ingredient. The sand is placed on top of a thin layer of gravel that separates it from an outlet screen. Sharp-edged sand or crushed rocks are recommended for the filtering media since the sharp edges catch soft algal tissue. Crushed granite or silica graded into specific sizes for a particular system are commonly used porous media. It is not recommended to use natural sand as a filtering media since the particles are usually rounded and smooth. The size of media particles is very important. Too coarse particles result in poor filtration and possible clogging of the emitting devices, while too fine particles trigger unnecessary frequent backwashing of the filter.

Two factors describe the media used in the filter: uniformity coefficient and mean effective size. Uniformity coefficient reflects the range of sand sizes within the grade. It is desirable to keep sand particles as uniform in size as possible. The uniform size of filtering media assures better control of the filtration. Grading in size from fine to coarse causes premature clogging of the filter, since the nonuniform pores of the media also retain particles small enough to be tolerated by the emitters. The uniformity coefficient is represented by the ratio of the size of the screen opening that would pass 60% of the filter sand to the screen opening that will pass 10% of the same sand. For irrigation purposes a uniformity coefficient of 1.5 is considered adequate.

The mean effective sand size is the size of the screen opening that will pass 10% of the sand sample. It is a measure of the minimum sand size in the grade and therefore an indicator of the particle size that will be removed by the media. Some examples of sand media are shown in Table 1. It can also be seen that the quality

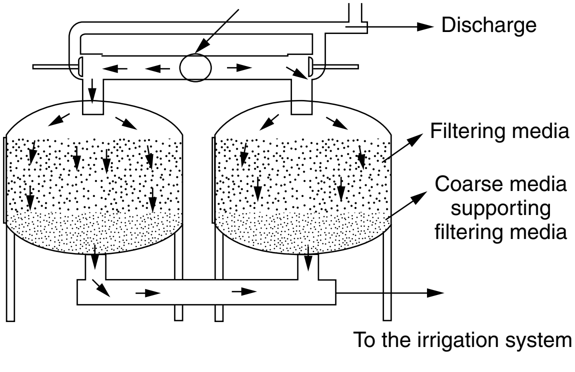

Figure 1. Schematic of media filters in filtration mode.

Table 1. Relationship Between Designated Media Numbers, Filtration Quality, and Equivalent Screen Sizes

		Removed Particles		Media Filters

325	44	Silt	2–50			
—[a]	—[a]	Clay	2 and less			

[a] Screens are not normally used to remove this size particles.

Figure 2. Media filters installed in a field.

of filtration increases with a smaller effective size of filtering media.

The design flow capacity of a media filter is expressed in liters per second of flow per square meter of surface area of the media normal to the direction of flow. The filter should be sized so it can handle the poorest water quality at a given site and provide the required flow for the functioning of the irrigation system (Fig. 2). The quality of irrigation water before filtration may vary with the seasons and weather conditions. This is especially true with regard to surface water but can also apply to well water in some cases.

The effectiveness of a filter is a measure of its ability to remove particles of a certain size. The effectiveness of filtration increases with a decreasing size of filtering media grain size (larger designation number). However, smaller media size will require more frequent cleaning.

Filtration effectiveness is also inversely proportional to the flow rate through the filter. The higher the flow rate, the lower the effectiveness of the media filters. Therefore, filter manufacturer's specifications and water quality samples should be used to select a filter for a specific application.

Media filters are cleaned by backwashing (Fig. 3). This operation consists of reversing the direction of water flow in the tank. Clean water is usually supplied from the second tank. The upward flow fluidizes the media and flushes collected contaminants. The backflush water is discharged and does not enter the irrigation system. The backwash flow must be carefully adjusted in order to provide sufficient cleaning without accidental removal of the media. If flows larger than those recommended are used to backflush the media, it is very likely that the media will be flushed from the filter by the backflow water. Only recommended flow rates for a given media should be used.

Most media filters are backflushed at prescheduled time intervals or by using automatic devices based on the pressure loss across the filter. For systems in which low quality water requires frequent backflushing, automatic cleaning is necessary to avoid problems.

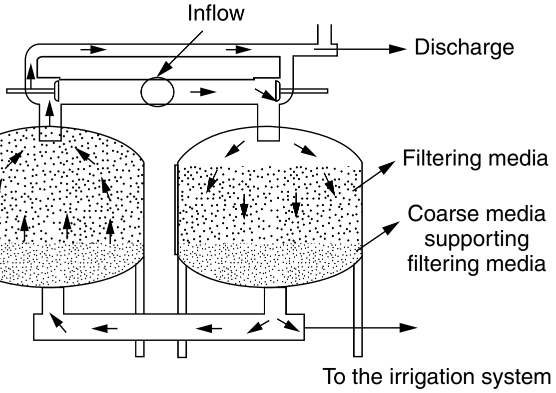

Figure 3. Schematic of the media filters in backflush mode.

As the filter is backflushed every time the pressure differential exceeds a predetermined value, large pressure drops in the irrigation system are avoided, maintaining the system's uniformity and efficiency. The pressure differential triggering backflushing depends on the pressure required for the proper functioning of the irrigation system. The irrigation system pump should be able to supply enough pressure to compensate for the pressure drop through the filter just before the filter is washed. Pump capacity must also be adequate to supply enough pressure and flow rate to flush the filter. Also, it is advisable in a large irrigation system to use a number of smaller tanks instead of a few large ones because of the higher backwash flow that large tanks require for good cleaning. Automatic backflush systems will eliminate sudden changes in water quality that can create problems if a filter is washed only at regular intervals. This is especially important in systems using surface water supplies with changing contamination levels.

AIR–SEA INTERACTION

S.A. HSU
Louisiana State University
Baton Rouge, Louisiana

INTRODUCTION

Air–sea interaction is, according to Geer (1), the interchange of energy (e.g., heat and kinetic energy) and mass (e.g., moisture and particles) that takes place across the active surface interface between the top layer of the ocean and the layer of air in contact with it and vice versa. The fluxes of momentum, heat, moisture, gas, and particulate matter at the air–water interface play important roles, for example, in environmental hydraulics and water–environment–health interactions, during low wind speeds before the onset of wave breaking, the exchange of air bubbles is limited. If this situation persists for a long time, algal blooms may develop, ultimately affecting water quality. On the other hand, during typhoon/hurricane conditions, the storm surge may affect the sewerage outflow at a greater depth than normal because of shoaling. In the area on the right-hand side of the storm track (in the Northern Hemisphere), runoff may also be blocked due to the surge, thus increasing the flood potential and saltwater intrusion.

Air–sea interaction encompasses vast scales in both spatial and temporal viewpoints, so only a few basic and applied topics are summarized here, including the parameterization of stability length, determination of friction velocity, wind–wave interaction, and the estimation of shoaling depth during storms. For more detailed laws and mechanisms in air–sea interaction, see Donelan (2) and recently Csanady (3); for air–sea exchange of gases and particles, see Liss (4) and most recently Donelan et al. (5); for the role of air–sea exchange in geochemical cycling, see Buat-Menard (6) and recently Liss (7); for larger scale air–sea interaction by La Niña and its impacts, see Glantz (8); for more physics, chemistry, and dynamics related to air–sea exchange, see Geernaert (9); and for wind–wave interaction, see Janssen (10).

PARAMETERIZATION OF THE STABILITY LENGTH

In the atmospheric boundary layer, the buoyancy length scale, L, also known as the Obukhov (or Monin–Obukhov) length, is a fundamental parameter that characterizes the "stability" of the surface layer (11). L describes the relative importance between the buoyancy effect (or thermal turbulence) and wind shear (or mechanical turbulence). According to Hsu and Blanchard (12), L can be parameterized as follows.

For unstable conditions (i.e., when $T_{\text{sea}} > T_{\text{air}}$),

$$\frac{z}{L} = -\frac{1000(T_{\text{sea}} - T_{\text{air}})(1 + \dfrac{0.07}{B})}{(T_{\text{air}} + 273.2)U_z^2} \tag{1}$$

For stable conditions ($T_{\text{air}} > T_{\text{sea}}$),

$$\frac{z}{L} = \frac{620(T_{\text{air}} - T_{\text{sea}})}{(T_{\text{air}} + 273.2)U_z^2} \tag{2}$$

According to Hsu (13,14),

$$B = 0.146(T_{\text{sea}} - T_{\text{air}})^{0.49} \tag{3}$$

where z is the height normally set to 10 m; T_{air} and T_{sea} stand for the air and sea temperatures, respectively; U_z is the wind speed at height z; and B is the Bowen ratio.

For operational and engineering applications, $z/L \leq -0.4$ is unstable, $|z/L| < 0.4$ is neutral, and $z/L \geq 0.4$ is stable.

PARAMETERIZATION OF THE ROUGHNESS LENGTH

The roughness parameter Z_0 can be computed based on the formula provided in Taylor and Yelland (15) that

$$\frac{Z_0}{H_s} = 1200\left(\frac{H_s}{L_p}\right)^{4.5} \tag{4}$$

and, for deep water waves,

$$L_p = \frac{gT_p^2}{2\pi} \tag{5}$$

where g is gravitational acceleration, H_s and L_p are the significant wave height and peak wavelength for the combined sea and swell spectrum, and T_p is its corresponding wave period. Note that H_s is defined as the average of the highest one-third of all wave heights during the 20-minute sampling period.

ESTIMATION OF THE FRICTION VELOCITY

The friction velocity (u_*) can be obtained as follows:

$$u_* = U_{10}C_d^{1/2} \tag{6}$$

where U_{10} is the wind speed at 10 m and C_d is the drag coefficient.

According to Amorocho and DeVries (16), the WAMDI Group (17), and Hsu (18), one may classify the air–sea interaction into three broad categories based on wave breaking conditions:

In light winds, $U_{10} < 7.5$ m/s, prior to the onset of wave breakers,

$$C_d = \left(\frac{u_*}{U_{10}}\right)^2 = 1.2875 * 10^{-3} \tag{7}$$

Both thermal and mechanical turbulence are important.

In moderate winds, $7.5 \leq U_{10} \leq 20$ m/s, the range after the onset but before the saturation of wave breakers,

$$C_d = (0.8 + 0.065U_{10}) * 10^{-3} \tag{8}$$

Mechanical turbulence is more important than thermal effects.

In strong winds, $U_{10} > 20$ m/s, after the saturation of wave breakers,

$$C_\mathrm{d} = 2.5 * 10^{-3} \tag{9}$$

Mechanical turbulence dominates.

ESTIMATING LATENT HEAT FLUX (OR EVAPORATION)

Using the parameter of the Bowen ratio supplied by Hsu (13,14), as shown in Eq. 3, the latent heat flux (H_latent) can be estimated as

$$H_\mathrm{latent}(\mathrm{W\,m^{-2}}) = \frac{1}{B}H_\mathrm{sensible} = \frac{1}{B}\rho_\mathrm{a}C_\mathrm{p}C_\mathrm{T}(T_\mathrm{sea} - T_\mathrm{air})U_{10} \tag{10}$$

where H_sensible is the sensible heat flux, ρ_a (=1.2 $\mathrm{kg\,m^{-3}}$) is the air density, C_p (=1004 $\mathrm{J\,kg^{-1}\,K^{-1}}$) is the specific heat at constant pressure for dry air, C_T ($=1.1 * 10^{-3}$) is the transfer coefficient for heat, ($T_\mathrm{sea} - T_\mathrm{air}$) is in K, and U_{10} in $\mathrm{m\,s^{-1}}$.

A latent heat flux of 1 $\mathrm{W\,m^{-2}}$ is equivalent to an evaporation rate of $3.56 * 10^{-3}$ $\mathrm{cm\,day^{-1}}$, so Eq. 10 can be used to estimate the evaporation rate.

ESTIMATING MAXIMUM SUSTAINED WIND SPEED DURING A HURRICANE

Under hurricane/typhoon conditions, intense air–sea interaction occurs. Beach erosion, engineering structures, storm surge, and sewerage outflow can all be affected, so this topic should deserve more attention than the deepwater environment. The very first subject related to a tropical cyclone is to estimate its maximum sustained wind speed at the standard height of 10 m (i.e., U_{10}). This is accomplished as follows.

From the cyclostrophic equation (i.e., centrifugal force = pressure gradient) (11),

$$\frac{U_\mathrm{a}^2}{\gamma} = \frac{1}{\rho_\mathrm{a}}\frac{\partial P}{\partial \gamma} = \frac{1}{\rho_\mathrm{a}}\frac{\Delta P}{\Delta \gamma} = \frac{1}{\rho_\mathrm{a}}\frac{P_\mathrm{n} - P_0}{\gamma - 0} \tag{11}$$

where U_a is the maximum sustained wind speed above the surface boundary layer, γ is the radius of the hurricane, $\partial P/\partial \gamma$ is the radial pressure gradient, P_n is the pressure outside the hurricane effect (1013 mb, the mean sea level pressure), and P_0 is the hurricane's minimum central pressure. Because $\rho_\mathrm{a} = 1.2\ \mathrm{kg\,m^{-3}}$, $\Delta P = (1013 - P_0)$ mb, and 1 mb = 100 $\mathrm{N\,m^{-2}}$ = 100 $\mathrm{kg\,m^{-1}\,s^{-2}}$, Eq. 11 becomes

$$U_\mathrm{a} = \left[\frac{100\ \mathrm{kg\,m^{-1}\,s^{-2}}}{1.2\ \mathrm{kg\,m^{-3}}}\right]^{1/2}\sqrt{\Delta P} = 9\sqrt{\Delta P} \tag{12}$$

According to Powell (19), $U_{10} = 0.7U_\mathrm{a}$; therefore

$$U_{10} = 6.3\sqrt{\Delta P} = 6.3(1013 - P_0)^{1/2} \tag{13}$$

where U_{10} is in $\mathrm{m\,s^{-1}}$ and ΔP in mb.

Equation 13 has been verified by Hsu (18). In 1985, during Hurricane Kate over the Gulf of Mexico, the U.S. National Data Buoy Center (NDBC) buoy #42003, located on the right-hand-side of the storm track near the radius of maximum wind, recorded a minimum sea-level pressure (P_0) of 957.1 mb. Therefore, $\Delta P = (1013 - 957.1) = 55.9$ mb. Substituting this value in Eq. 13, $U_{10} = 47.1\ \mathrm{m\,s^{-1}}$ which is in excellent agreement with the measured $U_{10} = 47.3\ \mathrm{m\,s^{-1}}$.

Another verification is provided in Fig. 1. According to Anthes (20, p. 22 and Fig. 2.8),

$$U_{10\gamma} = U_{10\,\mathrm{max}}\left(\frac{R}{\gamma}\right)^{0.5} \tag{14}$$

where $U_{10\gamma}$ is the sustained wind speed at a distance 10 m away from the storm center and $U_{10\,\mathrm{max}}$ is the maximum sustained wind at 10 m at the radius of maximum wind, R.

According to Hsu et al. (21), for operational applications,

$$\frac{R}{\gamma} = \ln\left(\frac{1013 - P_0}{P_\gamma - P_0}\right) \tag{15}$$

where P_γ is the pressure at a point located at a distance from the storm center and ln is the natural logarithm.

Substituting Eq. 15 in Eq. 14,

$$U_{10\gamma} = U_{10\,\mathrm{max}}\left[\ln\left(\frac{1013 - P_0}{P_\gamma - P_0}\right)\right]^{0.5} \tag{16}$$

During Hurricane Lili in 2002, the NDBC had two buoys, #42001 located near R, and #42003 located due east along 26 °N, approximately 280 km from 42001. The wind speed measurement at both buoys was 10 m. From the NDBC website (www.ndbc.noaa.gov/), at 20Z 2 October 2002 at #42001, $P_0 = 956.1$ mb. Substituting this P_0 in Equation 13, $U_{10\,\mathrm{max}} = 47.5\ \mathrm{m\,s^{-1}}$, in excellent agreement with the measured value of 47.2 $\mathrm{m\,s^{-1}}$ (=106 mph). Therefore, Eq. 13 is further verified. At the same time, $P_\gamma = 1011.1$ mb was measured at #42003. Substituting this P_γ in Eq. 16, we obtain $U_{10\gamma} = 8.8\ \mathrm{m\,s^{-1}}$. The measured $U_{10\gamma}$ at 42003 was 9.2 $\mathrm{m\,s^{-1}}$. The difference is only about 4%, so we conclude that Eqs. 13 and 16 can be used for nowcasting using the pressure measurements at P_γ and P_0 which are normally available via the official "Advisory" during a hurricane.

ESTIMATING MAXIMUM SIGNIFICANT WAVE HEIGHT DURING A HURRICANE

According to the USACE (22, p. 3–85, Eq. 3–64),

$$T_\mathrm{p} = 12.1\sqrt{\frac{H_\mathrm{s}}{g}} \tag{17}$$

$$\therefore\ \frac{H_\mathrm{s}}{gT_\mathrm{p}^2} = 0.0068 \tag{18}$$

More verification of Eq. 18 is provided in Hsu (23).

According to Hsu et al. (21), based on the evaluation of nine fetch-limited wind–wave interaction formulas, that provided by Donelan et al. (24) ranked best as follows:

$$\frac{gH_\mathrm{s}}{U_{10}^2} = 0.00958\left(\frac{gT_\mathrm{p}}{U_{10}}\right)^{1.65} \tag{19}$$

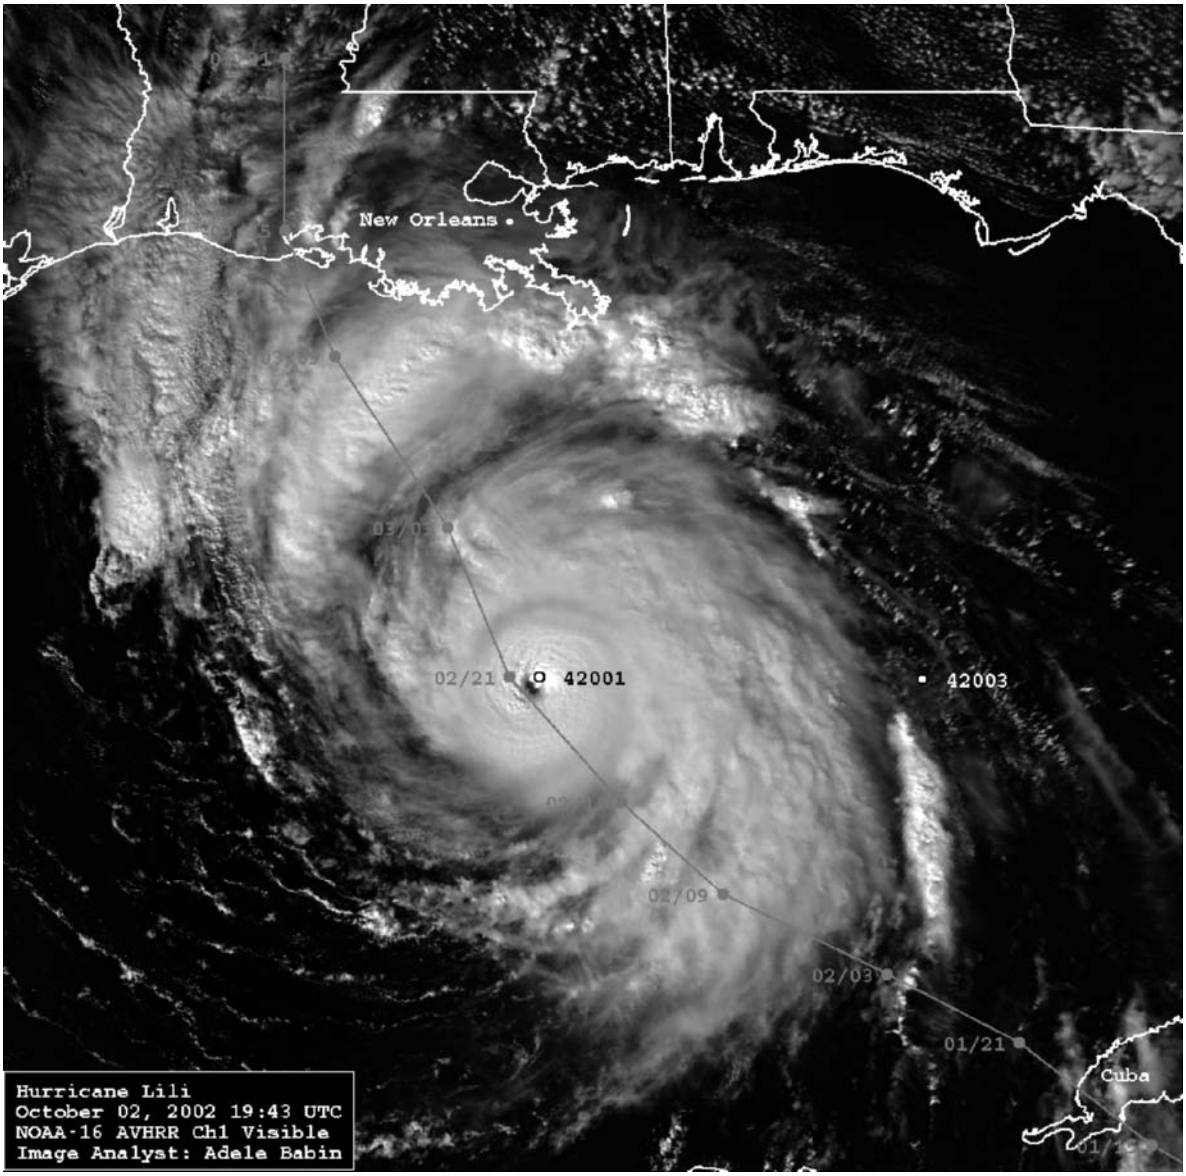

Figure 1. Satellite data (visible channel from NOAA-16) received and processed at the Earth Scan Lab, Louisiana State University, during Hurricane Lili (2002) in the Gulf of Mexico. The solid line represents the storm track. Data from NDBC buoys 42001 and 42003 are employed in this study. Note that the anemometers for both bouys were located at the standard 10 m height.

From Eqs. 18 and 19,

$$H_s = 0.00492\ U_{10}^2 \tag{20}$$

Substituting Eq. 13 in Eq. 20,

$$H_{s\ \max} = 0.20\ \Delta P \tag{21}$$

where $H_{s\ \max}$ is in meters and ΔP is in mb. Equation 21 is verified in Fig. 1. Buoy 42001, located near the radius of maximum wind, measured $P_0 = 956.1$ mb at 20Z 2 October 2002, so that $\Delta P = (1013 - 956.1) = 56.9$ mb. Substituting this value in Eq. 21, $H_{s\ \max} = 11.38$ m, which is in excellent agreement with that of 11.22 m measured at 21Z 2 October 2002 (within 1 hour after the measured minimal P_0).

ESTIMATING STORM SURGE AND SHOALING DEPTH

To estimate a typhoon/hurricane—generated storm surge (ΔS), and shoaling depth (D_{shoaling}), the following formulas are useful operationally, provided that the storm's minimum (or central) pressure near the sea surface (P_0) is known.

According to Hsu (23), for the storm surge in deep water before shoaling (i.e., when the waves feel the sea floor),

$$S_I = 0.070(1010 - P_0) \tag{22}$$

where S_I is the initial peak storm surge before shoaling. For the peak surge at the coast,

$$S_P = 0.070\,(1010 - P_0) * F_S * F_M \tag{23}$$

where F_S is a shoaling factor dependent on shelf topography and width and F_M is a correction factor for storm motion. Both F_S and F_M for certain areas are included in Hsu (23). A verification of Eq. 23 during Hurricane Georges in 1998 is also available in Hsu (23).

The shoaling depth is computed as follows:

From Taylor and Yelland (15), $D_{\text{shoaling}} = 0.2\ L_p$, and from Eq. 5,

$$D_{\text{shoaling}} = 0.2\,\frac{gT_p^2}{2\pi} = \frac{0.2\,H_s}{2\pi\left(\dfrac{H_s}{gT_p^2}\right)}$$

where $H_s/gT_p{}^2$ is called wave steepness, a useful parameter in coastal engineering.

From Hsu et al. (21) and under hurricane conditions from Eq. 18, $H_s/gT_p{}^2 = 0.0068$. Thus, from Eq. 21,

$$D_{\text{shoaling}} = 4.7\,H_s = 4.7 * 0.2(1013 - P_0)$$

$$\therefore \text{shoaling depth (meters)} \approx (1013 - P_0) \qquad (24)$$

CONCLUDING REMARKS

Although all formulas presented in this article are based on the open literature, they may need some verification before being applied to site-specific conditions. For example, Eq. 22 for the storm surge is for an open coast before shoaling. It needs to be adjusted for flooding at the coast due to different storm speeds and local bathymetry, as needed in Eq. 23.

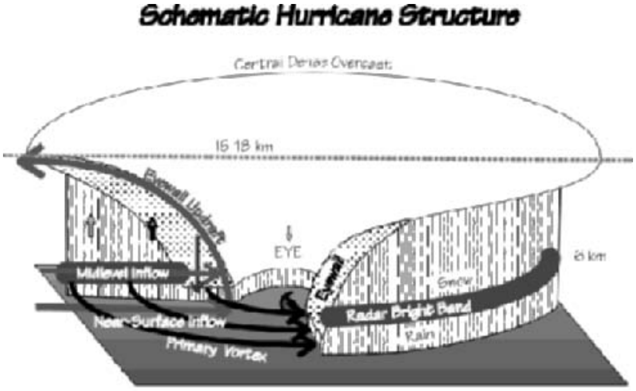
NOAA'S ATLANTIC OCEANOGRAPHIC AND METEOROLOGICAL LABORATORY

National Oceanographic and
Atmospheric Administration
(NOAA)

June 18, 1999—The Atlantic Oceanographic and Meteorological Laboratory (AOML) in Miami, Florida, is one of 12 environmental research laboratories that work on environmental issues for NOAA's Office of Oceanic and Atmospheric Research (OAR). OAR research advances NOAA's ability to predict weather, helps monitor and provides understanding of climate and global change, as well as improve coastal ocean health.

AOML's mission is to conduct a basic and applied research program in oceanography, tropical meteorology, atmospheric and oceanic chemistry, and acoustics. The programs seek to understand the physical characteristics and processes of the ocean and the atmosphere, both individually and as a coupled system.

The principal focus of these investigations is to provide knowledge that may ultimately lead to improved prediction and forecasting of severe storms, better use and management of marine resources, better understanding of the factors affecting both climate and environmental quality, and improved ocean and weather services for the nation.



The inner core of a mature hurricane, showing the clear eye surrounded by the wall cloud, which is in turn surrounded by the overhanging Central Dense Overcast (CDO). The primary circulation is the air orbiting horizontally around an axis of rotation inside the eye. Superimposed upon the primary circulation is a secondary, in-up-out, circulation. The updrafts slope outward so that rain and snow or graupel fall from them.

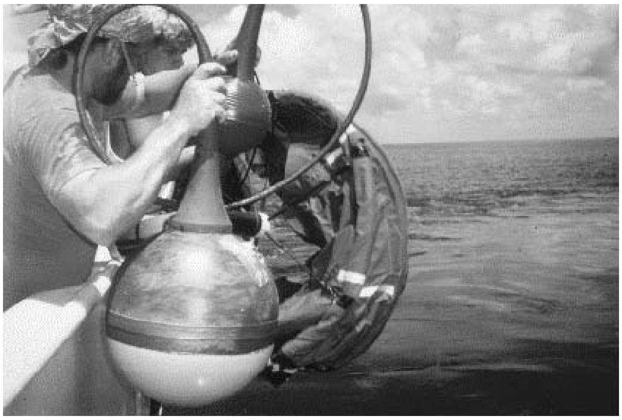
Originally under the jurisdiction of the Environmental Science Services Administration (ESSA), the forerunner of NOAA, AOML was founded in Miami, Florida, in 1967. Several months after NOAA was established in 1970, groundbreaking began on a new 12-acre federally funded research facility on Virginia Key. AOML dedicated its new location on Feb. 9, 1973. It celebrated its 25th anniversary in 1998.

AOML has four main research divisions: Hurricane Research, Ocean Acoustics, Ocean Chemistry, and Physical Oceanography.

To learn more about AOML visit: http://www.aoml.noaa.gov/

HURRICANE RESEARCH DIVISION

An AOML/OAD Oceanographer prepares a 150 kHZ upward looking Acoustic Doppler Current Profiler (ADCP) for deployment 3 miles east of the Port of Miami. The 4 red transducers are covered with a mixture of cayenne pepper and silicone grease to prevent biofouling. The ADCP is used to obtain water column current profiles and provides such information as current speed and direction, information used in this project to determine optimal conditions for disposal of dredge materials.



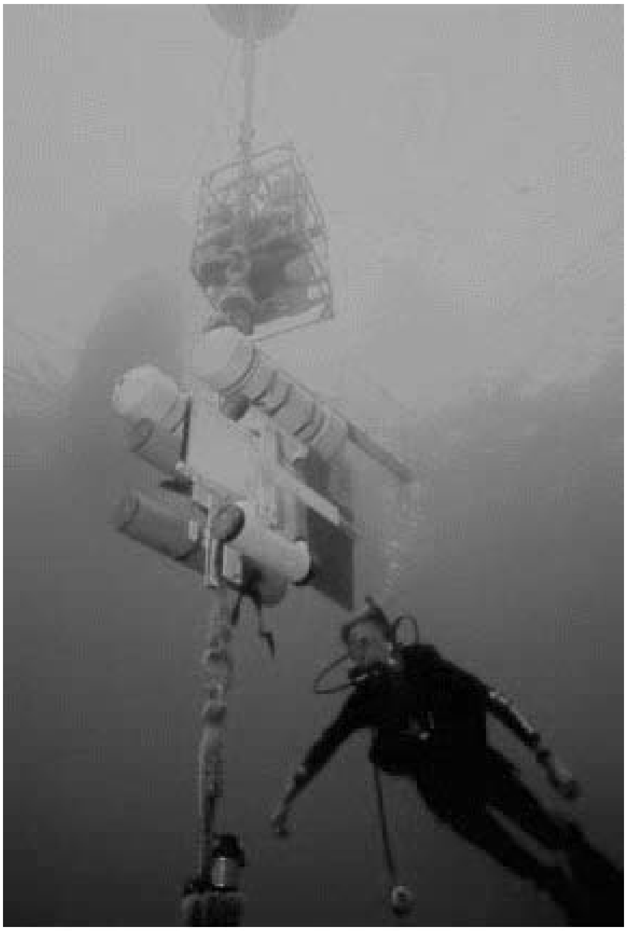
This image depicts the manual deployment of a global surface Lagrangian drifter (buoy). These devices measure sea surface temperature, surface currents, bathymetric pressure and wind. There are currently 756 of these instruments transmitting data back to AOML/PhOD from the oceanic regions all over the globe. The data re used for a variety of projects and programs.

The Hurricane Research Division (HRD) is NOAA's primary component for research on hurricanes. Its highest priority is improving the understanding and prediction of hurricane motion and intensity change. A key aspect of this work is the annual hurricane field program, supported by the NOAA Aircraft Operation's Center research/reconnaissance aircraft. Research teams analyze data from field programs, develop numerical hurricane models, conduct theoretical studies of hurricanes, prepare storm surge atlases, and study the tropical climate.

HRD works with the National Hurricane Center/Tropical Prediction Center in all phases of its research, the National Meteorological Center and the Geophysical Fluid Dynamics Laboratory—another of OAR's research labs—in research related to numerical modeling of hurricanes, and the National Severe Storms Laboratory—yet another OAR lab—in the study of landfalling hurricanes, as well as other NOAA groups, federal agencies, and universities in a variety of basic and applied research.

OCEAN ACOUSTICS DIVISION

The Ocean Acoustics Division (OAD) gathers, analyzes and reports coastal ocean data on human-related discharges and their potential environmental impacts. Additionally, OAD has an ongoing research program on the use of acoustics to measure coastal and deep ocean rainfall, an important element in calculating the global energy balance for climate monitoring and prediction. The Division works in cooperation with other federal, state, and local authorities to maximize research knowledge for use in economically and environmentally important projects in the coastal ocean.



AOML/OCD and RSMAS scientists install multi-sensor optical/acoustic moorings off the Florida Keys in support of an ERL funded Pilot Study investigating the biology, physics and chemistry of Gulf Stream topographic and frontal eddies. The moorings provide time series data within an Ocean Surface Current Radar (OSCR) field.

OCEAN CHEMISTRY DIVISION

With a diverse scientific staff of marine, atmospheric, and geological chemists, as well as chemical, biological, and geological oceanographers, the Ocean Chemistry Division (OCD) is able to use multidisciplinary approaches to solve scientific research questions. The Division's work includes projects that are important in assessing the current and future effects of human activities on our coastal to deep ocean and atmospheric environments.

PHYSICAL OCEANOGRAPHY DIVISION

The Physical Oceanography Division (PhOD) provides and interprets oceanographic data and conducts research relevant to decadal climate change and coastal ecosystems. This research includes the dynamics of the ocean, its interaction with the atmosphere, and its role in climate and climate change. Data is collected from scientific expeditions, both in the deep ocean and in coastal regions. Satellite data is processed and incorporated into the analyses. PhOD manages the Global Ocean Observing (GOOS) Center, which manages the global collection, processing, and distribution of drifting buoy data and the information collected from ocean temperature profilers. This information is crucial to understanding and predicting shifts in weather patterns and the relationship of the ocean and the atmosphere as a coupled system.

LABORATORY EXPERIMENTS ON BIVALVE EXCRETION RATES OF NUTRIENTS

Paolo Magni
IMC—International Marine Centre
Torregrande-Oristano, Italy

Shigeru Montani
Hokkaido University
Hakodate, Japan

BACKGROUND

Benthic nutrient regeneration may be referred to as a new availability to the water column of significant amounts of nitrogen, phosphorus, and other nutrients, as a consequence of the metabolism of organic matter by the benthos (1). The processes of benthic nutrient regeneration in coastal marine systems are strongly influenced by the presence of abundant macrofauna (2–5). Correct evaluation of the biogenic flux of nutrients due to the excretory activity of infaunal species is therefore an important background of information to investigate the cycling of biophilic elements (nitrogen, phosphorus, and silicon).

In field studies, major drawbacks include the difficulty to discern between nutrient upward flux due to animal excretion and a number of local effects, such as microbial mineralization (4,6–8) and uptake (9–14), animal bioturbation and irrigation currents (15–19), tidal currents and wind-generated waves (20–22). Laboratory experiments on the animal excretion rates of nutrients under more controlled conditions represent a useful tool for quantifying the actual biogenic contribution by macrofauna to the total upward flux of nutrients from sediments. Nevertheless, these experiments have often restricted their investigations to ammonium (23–28) or, in a few cases, to ammonium and phosphate (29).

CASE STUDY

This study was conducted within a multidisciplinary project on the cycling of nutrients and organic matter in a tidal estuary in the Seto Inland Sea (30–37). Laboratory experiments were carried out on the excretion rates of ammonium, phosphate, and silicate by different size classes of the bivalves, *Ruditapes philippinarum* and *Musculista senhousia*. These species were selected as they were dominant on a sandflat of the estuary under investigation. An extrapolation of these results to a field community is presented in Temporal Scaling of Benthic Nutrient Regeneration in Bivalve-Dominated Tidal Flat. Both studies will be the basis of a third companion paper on the relationship between the temporal scaling of bivalve nutrient excretion and the seasonal change of nutrient concentrations in the porewater (Seasonal Coupling Between Intertidal Macrofauna and Sediment Column Porewater Nutrient Concentrations).

In these experiments, 2.5 L aquaria with and without (control) animals were employed and run on two different occasions for 24 hours. Each experiment consisted of a 10 h day (light) and a 10 h night (dark) treatment in which the changes in nutrient concentrations were measured every 2 h. Between the two (light and dark) treatments, a low tide lasting 2 h (like that approximately on the flat where animals were collected) was created, during which the experimental animals were not removed from sediments to keep the experiment continuous. The experimental setup and procedure are detailed in our associated paper where the bivalve excretion rates of ammonium and phosphate have been presented and discussed (35). We will extend this study to silicate, a nutrient species whose regeneration through animal excretory activity has been less investigated, either *in situ* (38,39) or in the laboratory (5,40). Table 1 includes some characteristics of the experimental animals, as well as the field-relevant (33) amount of algal food (*Thalassiosira* sp.) offered in four spikes during each experiment (35). In all treatments, there was a marked increase in all three nutrient concentrations, in the control (no animals), the increase was much more limited (i.e., silicate) or not observed (i.e., ammonium) (Fig. 1).

Based on the differences in nutrient concentrations between treatments and controls, relevant linear regression lines of five to six measurements were used to calculate the nutrient excretion rates for each size class of *R. philippinarum* and *M. senhousia* (Table 2). This approach may be a more reliable way to quantify the daily bivalve excretion, whereas previous similar experiments have been based on shorter incubations and/or the sole difference between initial and final values of nutrient concentrations (4,7,22,28,29). The data sets were subjected to ANOVA in a two-factor randomized complete block design, using the day/night variable as factor A, the time (hour) variable as factor B, and the size classes of each bivalve species as replicates (35). As found for ammonium in *R. philippinarum*, but not in *M. senhousia*, silicate excretion was significantly higher (57%, $p < 0.001$, $n = 36$) during the day than during the night, suggesting a possible effect of light on the excretory activity of this bivalve species. A comparison of nutrient excretion rates (μmol g^{-1} DW h^{-1}) of bivalve species obtained through *in situ* or laboratory experiments is given in Table 3.

According to the excretion rates of silicate found in our laboratory experiments, this study points to the importance of the excretory activity of these bivalve species to the biogenic regeneration of silicate. This aspect

[b] Mean day (light) excretion significantly higher (ANOVA $p < 0.001$) than night (dark) excretion (based on Reference 35).

has been more controversial than the contribution of bivalves to the regeneration of ammonium and phosphate. The extent of silicate excretion also varies considerably, depending on the bivalve species investigated and the environmental/experimental conditions employed.

In *in situ* experiments, Prins & Small (4) found no significant excretion of silicate by *Mytilus edulis* beds on an intertidal zone of the Westerschelde (The Netherlands). The occurrence of silicate fluxes was attributed to the possible increased rate of dissolution of silicate at higher temperature. Asmus et al. (38) in the eastern Wadden Sea (Germany) and Dame et al. (39) in the Easterschelde and the western Wadden Sea (The Netherlands) found high fluxes of silicate from mussel beds of *M. edulis*. Although, in both studies, the actual excretion rate of silicate by *M. edulis* was not estimated per biomass unit (e.g., μmol g^{-1} DW h^{-1}), Dame et al. (39) suggested that silicate release from mussel beds results from phytoplankton cells breaking down as they are metabolized by the mussels. Dame et al. (39) argued that the longer turnover time for silicate, compared to phosphate and ammonium, implies a lesser role for the mussel beds in recycling this nutrient species in the two estuaries under investigation.

In contrast, Asmus et al. (38) found rapid silicate release in the Sylt-flume study and suggested that the mussels are an accelerator in recycling biogenic silica. Similarly, a study on the nutrient excretion of *R. philippinarum* in core incubation experiments found that silicate regeneration was, on average, 9.2 times faster in the site farmed with clams (5). In mesocosm experiments using large tanks, Doering et al. (40) also found that the level of flux was elevated in the presence of another clam, *Mercenaria mercenaria*, by 86% and 57% for silicate and ammonium, respectively. Our results indicate

well-balanced stoichiometric ratios among the nutrient species excreted by the bivalves (35), which can also be related to the use of the diatom *Thalassiosira* sp. as a food (35). This was aimed to approximate the actual field situation on the tidal flat, where abundant microalgal biomass, including resuspended benthic diatoms, is available to filter-feeders such as in *R. philippinarum* and *M. senhousia* (31,33). The high excretion rates of silicate of these two dominant bivalve species found in our laboratory experiments, together with those of ammonium and phosphate, suggest a major contribution of bivalve nutrient excretion to the upward flux of nutrients from sediments in our relevant study area. This will be the subject of the subsequent paper where we will apply these rates to the actual bivalve standing stock found in the field (Temporal Scaling of Benthic Nutrient Regeneration in Bivalve-Dominated Tidal Flat).

TEMPORAL SCALING OF BENTHIC NUTRIENT REGENERATION IN BIVALVE-DOMINATED TIDAL FLAT

Paolo Magni
IMC—International Marine Centre
Torregrande-Oristano, Italy

Shigeru Montani
Hokkaido University
Hakodate, Japan

Beside light and temperature (1–5), nutrients such as ammonium ($NH_4{}^+$-N), phosphate ($PO_4{}^{3-}$-P), and silicate [$Si(OH)_4$-Si] are a key factor in controlling the growth, abundance, and structure of primary producers in the ocean (6,7). Hence, it is important to investigate the availability, sources, and distribution of these nutrient species, as well as their spatial and temporal scaling. Biological processes strongly influence nutrient regeneration in different marine systems. In the open ocean, an important portion of reduced N-forms (e.g., $NH_4{}^+$-N), for instance, is made available *in situ* from waste products of plankton metabolism (8,9) and supports the so-called "regenerated" primary production (10). In coastal marine ecosystems, benthic nutrient regeneration is a major driving force in cycling biophilic elements (e.g., N, P, and Si) (11–13) and abundant macrofauna, for example, dense assemblages of bivalves, it has been shown, play a major role in these processes (14–16).

BACKGROUND

The contribution of benthic macrofauna to the total upward flux of nutrients has been investigated (mostly for ammonium and, to a lesser extent, for phosphate) in many coastal and estuarine areas using several approaches. They include laboratory and mesocosm experiments (17–19). *In situ* benthic chambers and sediment core incubations (20–22), and open flow/tunnel systems (16,23–26). Measurements of macrofauna-influenced nutrient flux, however, often have temporal limitations as they are based on one or relatively few sampling occasions, and thus seasonal patterns are in most cases not known. In this article, we evaluate the magnitude and temporal scaling of biogenic flux of nutrients from intertidal sediments densely populated by bivalves, based on extrapolating nutrient excretion rates of dominant bivalves to a field community. In particular, we show that the seasonal pattern of nutrient fluxes can be strongly influenced by the animal standing stock and its temporal distribution. This is beside the effect and importance of variation in excretion rate due to animal physiological factors, such as seasonal cycles of gametogenesis, storage and use of body reserves, and water temperature (27,28). The nutrient species considered in this study include ammonium, phosphate, and silicate, for which we quantified in associated laboratory experiments Laboratory Experiments On Bivalve Excretion Rates of Nutrients the excretion rates of different size classes of two dominant bivalve species. The relevance of macrofaunal excretion in regenerating the inorganic forms of three major bioelements such as N, P, and Si is discussed.

MACROFAUNAL COMMUNITIES

We present here the macrofaunal composition and distribution at an individual station (Stn B5) of a transect line selected in a sandflat of the Seto Inland Sea of Japan (29). At this station, the porewater nutrient concentrations (ammonium, phosphate, and silicate) in the uppermost 10 cm of sediments were also investigated in parallel from January 1995 to April 1996. They will be the subject of a subsequent associated paper focusing on the relationship between the seasonal pattern of bivalve nutrient excretion, described here, and the seasonal variation of porewater nutrient concentrations Seasonal Coupling Between Intertidal Macrofauna and Sediment Column Porewater Nutrient Concentrations. The total density and biomass of macrofauna varied from 7,400 (July 1995) to 22,050 ind.m^{-2} (October 1995), and from 70.9 (July 1995) to 244 g DW m^{-2} (September 7, 1995), respectively (Fig. 1). The bivalves *Ruditapes philippinarum* and *Musculista senhousia* and the polychaetes *Ceratonereis erithraeensis* and *Cirriformia tentaculata* were dominant; they accounted for 60.5% and 94.7% of the total density and biomass, respectively. Remarkably, *R. philippinarum* and *M. senhousia* alone accounted for up to 83.3 ± 6.7% of the total biomass when this exceeded

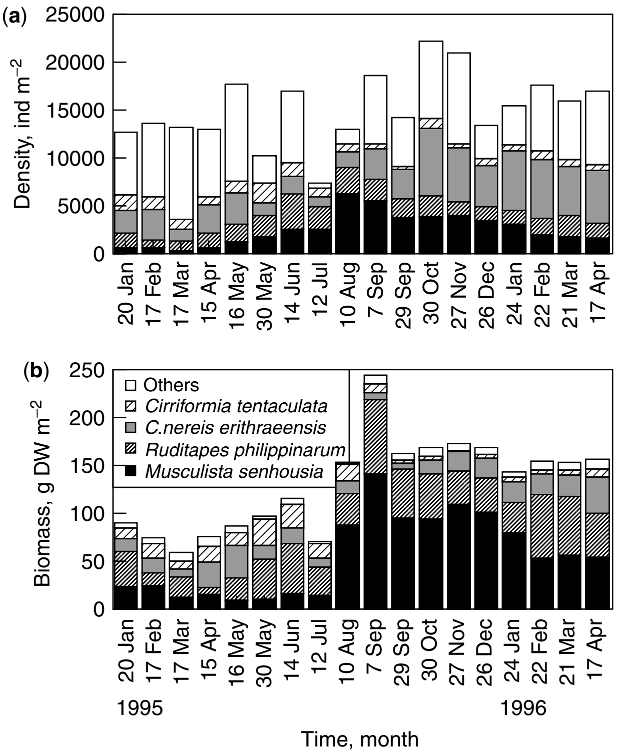

Figure 1. Seasonal variation of density (**a**) and biomass (**b**) of dominant macrozoobenthic species at Stn B5 (29). Note that in May 1995 and September 1995, sampling was carried out fortnightly.

120 g DW m^{-2}, from August 1995 till the end of the investigations. The high values of total macrofaunal and bivalve biomass may be regarded as a typical feature of many estuarine and intertidal areas, which are amongst the most productive systems in the ocean (30). In addition, biomass was markedly lower during the first half of the year (January 1995 to July 1995) than between late summer and winter; yet values progressively increased from early spring (March 1995) to early summer (June 1995). These marked temporal changes of macrofaunal communities reflect the high variability of these ecosystems. To estimate the magnitude and temporal scaling of biogenic nutrient excretion, we used an indirect approach. The mean excretion rates of ammonium, phosphate, and silicate for the two dominant bivalves *R. philippinarum* and *M. senhousia*, which were obtained in laboratory experiments Laboratory Experiments On Bivalve Excretion Rates of Nutrients, were applied to the relevant monthly biomass values found in the field. The ammonium and phosphate excretion rates of each bivalve species and their scaling to a field community have been extensively reported in Magni et al. (29). In this article, we applied these excretion rates to the bivalve biomass found at Stn B5 and extended this scaling to silicate, whose size-class dependent excretion rates are presented in Laboratory Experiments On Bivalve Excretion Rates of Nutrients. For silicate, we adopted the same temperature-dependent excretion rate factors as those used for ammonium and phosphate (Table 1).

BIVALVE NUTRIENT EXCRETION

The highest excretion rates of nutrients were estimated in September 7, 1995, up to a total of 50.2, 7.5, and 34.1 mmol m^{-2} d^{-1} for ammonium, phosphate, and silicate, respectively (Fig. 2). This corresponded to the period of highest biomass of both *R. philippinarum* and *M. senhousia*, which also accounted for the highest bivalve percentage (91.8%) of the total macrofaunal biomass. The lowest excretion rates occurred in April 1995 for *R. philippinarum* (lowest biomass on the same occasion), in March 1995 for *M. senhousia* (lowest biomass on May 16, 1995), and in February 1995 as the sum of the two bivalve species excretion rates. These latter rates were 4.1, 0.64, and 2.9 mmol m^{-2} d^{-1} for ammonium, phosphate, and silicate, respectively. The upward flux rates of nutrients obtained through this extrapolation of laboratory experiments on bivalve nutrient excretion to a field community are comparable to the highest biogenic releases reported for dense assemblages of bivalves such as oyster reefs (34) and mussel beds (16,35). This study also points to the importance of bivalve excretion to the biogenic regeneration of silicate, as previously suggested by field measurements indicating evidence of increased levels of silicate flux in the

[a] A factor (*f*) of 1 is used for the mean of the excretion rates obtained in laboratory experiments (see Laboratory Experiments On Bivalve Excretion Rates of Nutrients and based on Ref. 29).

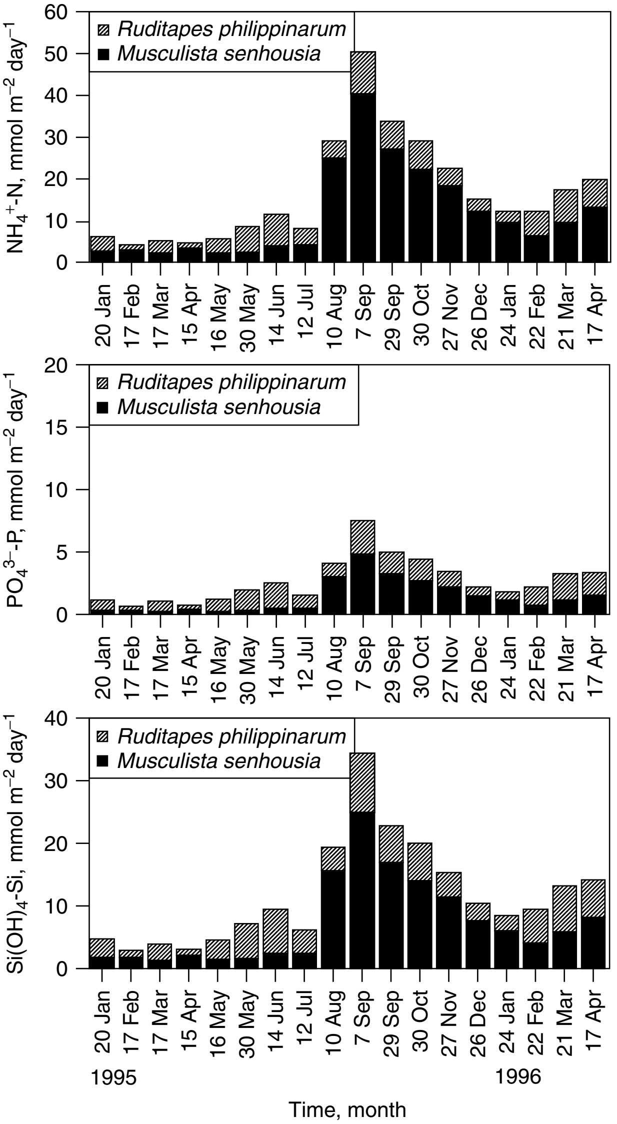

Figure 2. Magnitude and temporal scaling of ammonium (NH_4^+-N), phosphate (PO_4^{3-}-P), and silicate [$Si(OH)_4$-Si] excretion by *Ruditapes philippinarum* and *Musculista senhousia* in a field community.

presence of bivalves (17,24,36). The temporal scaling of bivalve nutrient excretion showed a marked seasonal pattern of large variations of nutrient flux, up to ca. 10-fold (*R. philppinarum*) and 20-fold (*M. senhousia*) between March–April 1995 and September 7, 1995, and a progressive decrease from late summer through winter. This approach may involve some limitations, such as the effect of differences between the bivalve performance in controlled laboratory experiments and that in the field and a relative approximation in adopting different excretion rates at temperatures other than those actually employed in the laboratory experiments (29). However, it indicates the strong influence of animal distribution on the magnitude and temporal scaling of biogenic nutrient regeneration due to bivalve excretion.

The great potential of this biogenic source of nutrients in cycling biophilic elements can also be highlighted by a comparison with the extent of benthic nutrient regeneration through diffusive flux. In particular, nutrient flux measured from nutrient concentrations in the porewater in adjacent intertidal and coastal areas was more than one order of magnitude lower; it varied from 0.2 to 1.5 mmol NH_4^+-N m^{-2} d^{-1} and from 0.01 to 0.05 mmol PO_4^{3-}-P m^{-2} d^{-1}. It can be inferred that a marked increase in biogenic nutrient regeneration is importantly controlled by the animal biomass increase (36) and has a major impact, acting as a positive feedback, on primary producers (41). These results indicate that abundant macrofauna and its excretory products play a primary role in benthic nutrient regeneration, are well balanced in their stoichiometric ratios, and thus act as a major factor to support primary production within the intertidal zone.
